Heat stress can cause considerable pre- and postharvest damages, including scorching of leaves and twigs, sunburns on leaves, branches, and stems, leaf senescence and abscission, inhibition of shoot and root growth, fruit discoloration and damage, and reduced yield [22]. High temperature-induced responses in plants may differ from one phonological stage to another. For example, long-term effects of heat stress on developing seeds may include delayed germination or loss of vigor, ultimately leading to reduced emergence and seedling establishment. Significant decrease in growth, shoot dry mass, and net assimilation rate has been observed due to prolonged heat stress in several monocotyledons. Heat stress, alone or in combination with drought, is a common constraint during anthesis and grain-filling stages in many cereal crops of temperate regions. For example, heat stress lengthened the duration of grain filling with reduction in kernel growth leading to losses in kernel density and weight by up to 7% in spring wheat [23]. In wheat, both grain weight and grain number appeared to be sensitive to heat stress, as the number of grains per ear at maturity declined with increasing temperature [24]. Reproductive processes are markedly affected by high temperatures in most plants, which ultimately affect fertilization and postfertilization

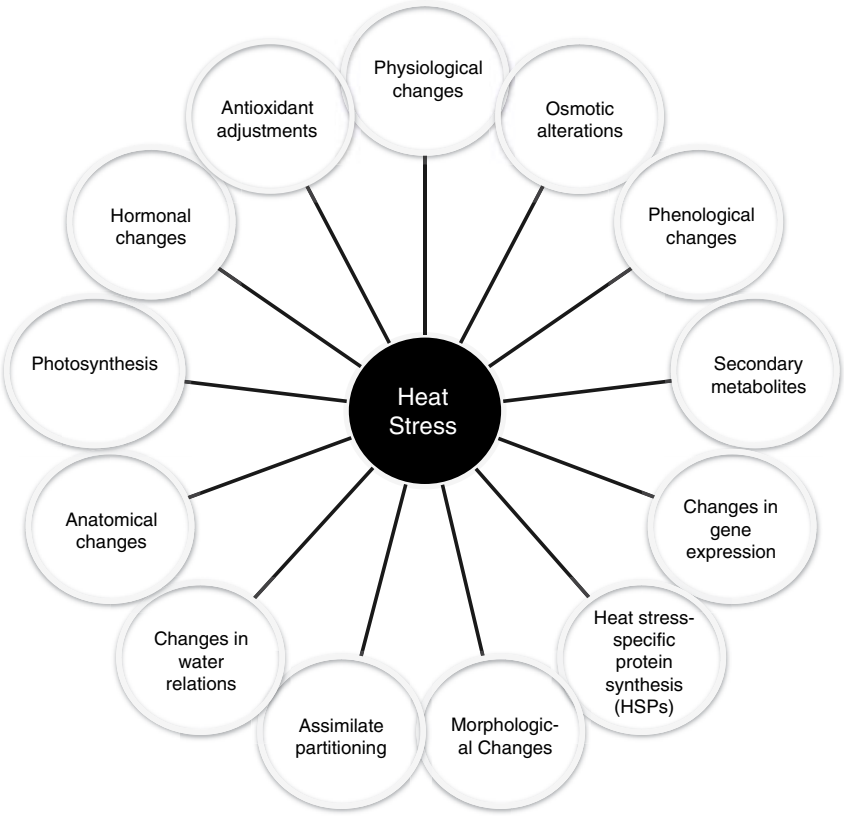

Figure 29.1 Heat stress-induced changes in plants.

processes, leading to a reduced crop yield. A study of postanthesis heat stress on grain yield and quality of Australian wheat reported a decline in individual kernel mass by 23% and alteration in the gliadin:glutenin ratio in response to high temperature treatment. They also reported a considerable genetic variability in wheat in tolerance to short periods of high temperature for both grain yield and quality [25].

29.4.2 Anatomical Responses

It is evident that high temperature considerably affects anatomical structures not only at the tissue and cellular levels but also at the subcellular level. Anatomical changes under high ambient temperatures are generally similar to those under drought stress. At the whole-plant level, there is a general tendency of reduced cell size, closure of stomata, and curtailed water loss, increased stomatal and trichomatous densities, and greater xylem vessels of both root and shoot [26]. At the subcellular level, major modifications occur in chloroplasts, leading to significant changes in

photosynthesis. For example, high temperatures reduced photosynthesis by changing the structural organization of thylakoids [27]. Specific effects of high temperatures on photosynthetic membranes result in the loss of grana stacking or its swelling. Such changes result in the formation of antenna-depleted photosystem II (PSII) and hence reduced photosynthetic and respiratory activities [28].

29.4.3 Phenological Responses

Different phonological stages differ in their sensitivity to high temperature; however, this depends on species and genotype as there are great inter and intraspecific variations. It is, however, not known whether damaging effects of heat episodes occurring at different developmental stages are cumulative. Vulnerability of plant species and cultivars to high temperatures may vary with the stage of development, but all vegetative and reproductive stages are affected by heat stress to some extent. During vegetative stage, for example, high day temperature can damage leaf gas exchange properties. During reproduction, a short period of heat stress can cause significant increases in floral bud and open-flower abortion; however, there are great variations in sensitivity within and among plant species [29, 30]. Impairment of pollen and anther development by elevated temperatures is another important factor contributing to decreased fruit set in many crops at moderate to high temperatures [31]. The staple cereal crops can tolerate only narrow temperature ranges, which if exceeded during the flowering phase can damage fertilization and seed production, resulting in reduced yield [10]. Furthermore, high temperatures during grain filling can modify flour and bread quality and other physicochemical properties of grain crops such as wheat [32], including changes in protein content of the flour [33]. High temperature is one of the major environmental constraints to wheat yield. Heat stress during grain filling is a common occurrence in wheat. High temperatures, typically above 34 °C, affect final grain weight by reducing the duration of grain filling due to suppression of photosynthesis [34] and by directly inhibiting starch biosynthesis in the endosperm [35, 36].

29.4.4 Physiological Responses

Higher temperatures affect all phases of wheat growth, accelerate floral initiation, and reduce the period of spike development, resulting in shorter spike with lower number of spikelets and adversely affecting pollen development. The duration of grain growth in the postanthesis period is considered the most significant determinant of yield in wheat. Higher temperatures further associated with limitation of water cause rapid shrinkage of grain volume. Wheat plants have four to eight leaves on the main shoot when the growing apex changes from the vegetative to the reproductive stage. Temperatures above 30 °C during floret formation cause complete sterility [37, 38]. Previous studies have reported a positive correlation between the length of the vegetative phase and the number of spikelets per spike [39].

Therefore, shortening the duration of the vegetative stage of the apex induces fewer spikelets per spike. The main effect of heat stress after/during floral initiation is observed on kernel number. The numbers of kernels per unit area decreases at a rate of 4% for each degree increase in the mean temperature during the 30 days preceding anthesis [40]. Considerable experimental effort has been devoted to examining carbohydrate availability for developing wheat florets as a major factor in the grain number [41–43]. It has been suggested in previous studies that the time of floret death corresponded with the period when the ear and stem were accumulating dry matter at their most rapid rate and that inadequate assimilate availability may be critical in the loss of florets [44]. It has been well established that wheat yield and quality response to short spells of heat could be improved by heat shock treatment during early grain-filling phase [45].

29.4.5 Water Relations

Plant water status is the most important variable under changing ambient temperatures. Plants tend to maintain stable tissue water status regardless of temperature when moisture is ample; however, high temperatures severely impair this tendency when water is limited [46]. Under field conditions, high-temperature stress is frequently associated with reduced water availability [47]. High temperatures seem to cause water loss in plants more during daytime than during nighttime. During daytime enhanced transpiration induces water deficiency in plants, causing a decrease in water potential and leading to perturbation of many physiological processes.

29.4.6 Osmotic Alterations

A key adaptive mechanism in many plants grown under various abiotic stresses, including extreme temperatures, is accumulation of certain organic compounds of low molecular mass, generally referred to as compatible osmolytes. Under stress, different plant species may accumulate a variety of osmolytes such as sugars and sugar alcohols (polyols), proline tertiary and quaternary ammonium compounds, and tertiary sulfonium compounds [48]. For example, glycine-betaine (GB), an amphoteric quaternary amine and proline, plays an important role as a compatible solute in plants under various stresses, such as salinity or high temperature [49], and has been known to occur widely in higher plants and normally accumulates in large quantities in response to environmental stresses. It is suggested that proline or GB synthesis may buffer cellular redox potential under heat and other environmental stresses. Similarly, accumulation of soluble sugars under heat stress has been reported in sugarcane, which entails great implications for heat tolerance [50]. Among other osmolytes, γ-4-aminobutyric acid (GABA), a nonprotein amino acid, is widely distributed throughout the biological world to act as a compatible solute. GABA is synthesized from the glutamic acid by a single-step reaction catalyzed by

glutamate decarboxylase (GAD). An acidic pH activates GAD, a key enzyme in the biosynthesis of GABA. Episodes of high temperature increase the cytosolic level of Ca, which leads to calmodulin-mediated activation of GAD. Rapid accumulation of GABA in stressed tissues may provide a critical link in the chain of events stemming from the perception of environmental stresses to timely physiological responses [51].

29.4.7 Photosynthesis

Inhibition of photosynthesis by heat stress is a common occurrence for plants in tropical and subtropical regions and is experienced periodically by plants in the temperate zone [52]. Photochemical reactions in thylakoid lamellae and carbon metabolism in the stroma of chloroplast have been suggested as the primary sites of injury at high temperatures [53]. Increasing leaf temperatures and photosynthetic photon flux density influence heat tolerance adjustments of PSII, indicating their potential to optimize photosynthesis under varying environmental conditions as long as the upper thermal limits do not exceed. A broad survey of the literature reveals that PSII is often considered the most heat-labile component of the photosynthetic apparatus, which may be due to the properties of thylakoid membranes where PSII is located [54]. Heat stress may lead to the dissociation of oxygen evolving complex (OEC), resulting in an imbalance between the electron flow from OEC toward the acceptor side of PSII in the direction of PSI reaction center [55]. Heat stress causes dissociation of manganese (Mn)-stabilizing 33-kDa protein at PSII reaction center complex followed by the release of Mn atoms [56]. In wheat, high temperatures and excessive light damaged different sites of PSII implying different pathways for the recovery of its functional activity [57]. Studies in controlled environments have revealed genetic variability in photosynthetic rate among wheat cultivars when exposed to high temperatures [7, 58]. Such differences in photosynthesis under heat stress have been shown to be associated with a loss of chlorophyll and a change in the a:b chlorophyll ratio due to premature leaf senescence [34, 59].

High temperature influences the photosynthetic capacity of C_3 plants more strongly than in C_4 plants. It alters the energy distribution and changes the activities of carbon metabolism enzymes, particularly the rubisco, thereby altering the rate of RuBP regeneration by the disruption of electron transport and inactivation of the oxygen evolving enzymes of PSII [60]. Heat shock reduces the amount of photosynthetic pigments [61], soluble proteins, rubisco binding proteins (RBP), and large (LS) and small subunits (SS) of rubisco in darkness, but increases them in light, indicating their roles as chaperones and HSPs [62]. Moreover, under heat stress, starch or sucrose synthesis is greatly influenced as activities of sucrose phosphate synthase [63], ADP-glucose pyrophosphorylase, and invertase [64] is significantly reduced.

In any plant species, the ability to sustain leaf gas exchange under heat stress has a direct relationship with heat tolerance. During the vegetative stage, high day temperature can cause damage to compensated leaf photosynthesis, reducing CO_2 assimilation rates. Increased temperatures curtail photosynthesis and increase CO_2

transfer conductance between intercellular spaces and carboxylation sites. Stomatal conductance (g_s) and net photosynthesis (P_n) are inhibited by moderate heat stress in many plant species due to decrease in the activation state of rubisco [65] that catalyzes the first step in two competing pathways, photosynthesis and photorespiration, whose rates are determined by the rates of the carboxylase and oxygenase activities, respectively [66]. The V_{Max} of the carboxylase activity increases with temperature, but the affinity of rubisco for CO_2 and the solubility of CO_2 decrease [67, 68]. A well-known consequence of elevated temperature in plants is the damage caused by heat-induced imbalance in photosynthesis and respiration; in general, the rate of photosynthesis decreases while dark- and photorespiration rates increase considerably under high temperatures. Rate of biochemical reactions also decreases and enzyme inactivation and denaturation take place as the temperature increases leading to severely reduced photosynthesis [69]. However, the magnitude of such alterations in response to heat stress differs with species and genotypes [54]. Furthermore, it has been determined that the photosynthetic CO_2 assimilation rate is less affected by heat stress in developing leaves than in completely developed leaves. Heat stress normally decreases the duration of developmental phases leading to smaller organs, reduced light perception, and reduced carbon assimilation processes including transpiration, photosynthesis, and respiration [70]. Nonetheless, photosynthesis is considered as the physiological process most sensitive to high temperatures, and that rising atmospheric CO_2 content will drive temperature increases in many already stressful environments.

29.4.8 Assimilate Partitioning

Under low to moderate heat stress, a reduction in source and sink activities may occur leading to severe reductions in growth, economic yield, and harvest index. Assimilate partitioning, taking place via apoplastic and symplastic pathways, under high temperatures has significant effects on transport and transfer processes in plants. However, a considerable genotypic variation exists in crop plants for assimilate partitioning, for example, among wheat genotypes [71]. In wheat, temperature effects on translocation result indirectly from temperature effects on source and sink activities. Higher temperatures further associated with limitation of water cause rapid shrinkage of grain volume. Higher temperatures at earlier stages reduce the spike length and the number of spikelets (sink capacity). Heat stress after anthesis reduces the net availability of assimilates, reducing grain number and weight. Increased mobilization efficiency of reserves from leaves, stem, or other plant parts has been suggested as a potential strategy to improving grain filling and yield in wheat under heat stress.

Carbohydrates in wheat grain are derived from postanthesis CO_2 assimilation, of which the flag leaf has a large share. Rubisco constitutes 60% of the soluble protein in the flag leaf. In limiting soil N supply, rubisco becomes the source of N for the developing grains. High turnover of rubisco 10 days after anthesis has been reported. Degradation of rubisco further enhances flag leaf senescence, contributing to

reduction in the supply of assimilates to developing grains. Specific data on the turnover of the HSPs in wheat could not be found, though their degradation and resynthesis in other organisms is known. Therefore, competition for both C and N assimilates between Rubisco, HSPs, and storage proteins in developing grains are expected during continuing heat stress.

29.4.9
Membrane Thermostability

Sustained function of cellular membranes under stress is pivotal for processes such as photosynthesis and respiration. Heat stress accelerates the kinetic energy and movement of molecules across membranes, thereby loosening chemical bonds within molecules of biological membranes. This makes the lipid bilayer of biological membranes more fluid by either denaturation of proteins or an increase in unsaturated fatty acids. The integrity and functions of biological membranes are sensitive to high temperature, as heat stress alters the tertiary and quaternary structures of membrane proteins. Such alterations enhance the permeability of membranes, as evident from increased loss of electrolytes. The increased solute leakage, as an indication of decreased cell membrane thermostability (CMT), has long been used as an indirect measure of heat stress tolerance in diverse plant species including wheat [72]. Three commonly used assays of heat tolerance in plants [73] are related to the plasmalemma ("cell membrane stability" or CMS assay), the photosynthetic membranes (chlorophyll fluorescence assay), and the mitochondrial membranes (cell viability assay based on 2,3,5-triphenyl-tetrazolium chloride (TTC) reduction). Genetic variation in membrane thermostability (MT) has been inferred using conductometric measurements in various field-grown crops including spring wheat [74]. There are reports of a significant increase in yield of spring wheat in hot locations by selecting membrane thermostable lines, as determined by measurements on flag leaves at anthesis [75].

29.4.10
Hormonal Modulations, Secondary Metabolites, and Antioxidant Adjustments

Hormones play an important role in plants for monitoring and adapting under adverse environmental conditions. Hormonal homeostasis, stability, content, biosynthesis, and compartmentalization are altered under heat stress [76]. Abscisic acid (ABA) is implicated in plant osmotic stress responses and mediates one of the intracellular dehydration signaling pathways [77]. In the field, where heat and drought stresses frequently occur simultaneously, ABA induction can be an important component of heat tolerance. ABA mediates acclimation/adaptation of plants to desiccation by modulating the up- or downregulation of numerous genes [78]. Induction of several HSPs by ABA could be one mechanism by which it confers tolerance to heat stress [79] and can cooperate with other HSPs to reactivate heat-denatured normal proteins [80]. However, the effects of gibberellins and cytokinins on high temperature tolerance are opposite to that of ABA.

A gaseous hormone, ethylene, regulates almost all growth and developmental processes in plants, ranging from seed germination to flowering and fruiting, as well as tolerance to environmental stresses. Ethylene has nearly full biological activity at 1 μl l^{-1}, corresponding to 6.5×10^{-9} M at 25 °C. Heat stress changes ethylene production differently in different plant species [81]. For example, while ethylene production in wheat leaves was inhibited slightly at 35 °C and severely at 40 °C, in soybean ethylene production in hypocotyls increased by increasing temperature up to 40 °C and it showed inhibition at 45 °C. Wheat leaves transferred to 18 °C followed by a short exposure to 40 °C showed an increase in ethylene production after 1 h lag period, possibly due to conversion of accumulated ACC to ethylene during that period [82]. Among other hormones, salicylic acid (SA) has been suggested to be involved in heat stress responses elicited by plants. SA is an important component of signaling pathways in response to systemic acquired resistance (SAR) and the hypersensitive response (HR) [83]. SA stabilizes the trimers of heat shock transcription factors (HDFs) and aids them bind heat shock elements (HSEs) to the promoter of heat shock-related genes. Long-term heat tolerance can be induced by SA, in which both Ca^{2+} homeostasis and antioxidant systems are thought to be involved [84]. Sulphosalicylic acid (SSA), a derivative of SA, treatment can effectively remove H_2O_2 and increase heat tolerance.

Heat stress causes accumulation of secondary metabolites of multifarious nature in plants. Most of the secondary metabolites are synthesized from the intermediates of primary carbon metabolism via phenylpropanoid, shikimate, mevalonate, or methyl erythritol phosphate (MEP) pathways. High-temperature stress induces production of phenolic compounds such as flavonoids and phenylpropanoids. Phenylalanine ammonia-lyase (PAL) is considered to be the principal enzyme of the phenylpropanoid pathway. Increased activity of PAL in response to thermal stress is considered as the main acclamatory response of cells to heat stress. Thermal stress induces the biosynthesis of phenolics and suppresses their oxidation, which is considered to trigger the acclimation to heat stress.

Carotenoids are widely known to protect cellular structures in various plant species irrespective of the stress type [18]. For example, the xanthophyll cycle (the reversible interconversion of two particular carotenoids, violaxanthin and zeaxanthin) has evolved to play this essential role in photoprotection. Since zeaxanthin is hydrophobic, it is found mostly at the periphery of the light harvesting complexes, where it functions to prevent peroxidative damage to the membrane lipids triggered by ROS [85]. Recent studies have revealed that carotenoids of the xanthophylls family and some other terpenoids, such as isoprene or α-tocopherol, stabilize and photoprotect the lipid phase of the thylakoid membranes. When plants are exposed to potentially harmful environmental conditions, such as strong light and/or elevated temperatures, the xanthophylls including violaxanthin, antheraxanthin, and zeaxanthin partition between the light-harvesting complexes and the lipid phase of the thylakoid membranes. The resulting interaction of the xanthophyll molecules and the membrane lipids brings about a decreased fluidity (thermostability) of membrane and a lowered susceptibility to lipid peroxidation under high temperatures.

Phenolics, including flavonoids, anthocyanins, lignins, and so on are the most important class of secondary metabolites in plants and play a variety of roles including in tolerance to abiotic stresses [18]. Studies suggest that accumulation of soluble phenolics under heat stress was accompanied by increased phenyl ammonia lyase (PAL) and decreased peroxidase and polyphenol lyase activities. Another plant secondary product, which is a low molecular weight and volatile in nature, called isoprenoid confers heat stress tolerance to photosynthesis apparatus in different plants. It is proposed that endogenous production of isoprene protects the biological membranes from damaging effects by directly reacting with oxygen singlets ($^1O_2$) by means of isoprene-conjugate double bond.

High temperature-induced oxidative stress in various higher and lower plants has been reported by many workers [86, 87]. Generation and reactions of activated oxygen species (AOS) including singlet oxygen ($^1O_2$), superoxide radical ($O^{2\cdot -}$), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH\cdot^-$) are symptoms of cellular injury caused by high temperature [88]. Active oxygen species cause lipid peroxidation and consequently membrane injury, protein degradation, enzyme inactivation, pigment bleaching, and disruption of DNA strands and thus limiting growth and yield [89]. Superoxide radical is regularly synthesized in the chloroplast and mitochondrion and some quantities are also produced in microbodies. The scavenging of O^{2-} by superoxide dismutase (SOD) results in the production of H_2O_2, which is removed by APX or CAT. However, both O^{2-} and H_2O_2 are not as toxic as the (OH^-), which is formed by the combination of O^{2-} and H_2O_2 in the presence of trace amounts of Fe^{2+} and Fe^{3+} by the Haber–Weiss reaction. Plants protect cellular and subcellular systems from cytotoxic effects of these active oxygen radicals using antioxidant enzymes such as glutathione reductase, superoxide dismutase, ascorbate peroxidase, and catalase and metabolites such as glutathione, ascorbic acid, α-tocopherol, and carotenoids [90]. Tolerance to heat stress in crop plants has been reported to be associated with an increase in antioxidant enzyme activities [91]. It has also been reported that heat stress in wheat during greening led to inactivation of PS2 vis-a-vis high turnover of both PS1 and superoxide dismutase, which allowed formation of superoxide and its dismutation product, H_2O_2, and reversible modulation of enzymatic H_2O_2-scavenging suggesting a central role of H_2O_2 metabolism in seedling response to thermal stress [92].

29.5
Heat-Induced Protein Synthesis

To cope with heat stress, plants activate a large set of genes leading to the accumulation of specific stress-associated proteins [93]. Expression of stress proteins is an important adaptation toward heat-stress tolerance by plants. Of these, expression of low and high molecular weight HSPs, widely reported in a number of plant species, is the most important one. These proteins show organelle- and tissue-specific expression with deduced function such as chaperones, folding and unfolding of cellular proteins, and protection of functional sites from the adverse effects of high

temperature. Most of the stress proteins are soluble in water and therefore contribute to stress tolerance presumably via hydration of cellular structures.

29.5.1 Heat Shock Proteins

Plants respond to high-temperature stress by synthesizing an assortment of proteins, termed heat shock proteins. Certain HSPs are expressed under certain stages of development such as embryogenesis, germination, pollen development, and fruit maturation [94]. HSP-triggered heat tolerance is attributed to the observations that (a) their induction coincides with the organism under stress, (b) their biosynthesis is extremely fast and intensive, and (c) they are induced in a wide variety of cells and organisms. Among five conserved families of Hsps (Hsp100, Hsp90, Hsp70, Hsp60 and sHsp), the small heat shock proteins (sHsps) are found to be most prevalent in plants, the expression of which can increase up to 200-fold under heat stress. sHsps vary in size from 12–40 kDa [95]. All sHSPs in plants are encoded by six nuclear gene families, with each gene family corresponding to proteins found in distinct cellular compartments such as cytosol, chloroplast, endoplasmic reticulum (ER), mitochondria, and membranes. The major chaperone activity of sHsps is to bind and hold denatured substrates in a folding-competent state for subsequent refolding by a chaperone network. However, some members of the plant sHsps can also stabilize or reactivate inactivated enzymes.

The mechanism by which HSPs contribute to heat tolerance is still enigmatic though several roles have been ascribed to them. Many studies assert that HSPs are molecular chaperones ensuring the native configuration and functionality of cell proteins under heat stress. There is considerable evidence that acquisition of heat tolerance is directly related to the synthesis and accumulation of HSPs [96]. For instance, HSPs provide for new or distorted proteins to fold into shapes essential for their normal functions. They also help shuttling proteins from one compartment to another and transporting old proteins to "garbage disposals" inside the cell. The HSPs were recognized to protect normal proteins from the direct effects of denaturation during heat stress treatment. Earlier studies also reported a similar correlation between the thermostabilization of normal proteins and the amount of HSPs synthesized [97]. Among others, HSP70 has been extensively studied and is proposed to have a variety of functions such as protein translation and translocation, proteolysis, protein folding or chaperoning, suppressing aggregation, and reactivating denatured proteins. In many plant species, heat tolerance of cells and tissues after a heat stress is pretty much dependent upon induction of HSP70, though HSP101 has also been shown to be essential [11]. HSP70 participates in ATP-dependent protein unfolding or assembly/disassembly reactions and it prevents protein denaturation during heat stress. Evidence for the general protective roles of HSPs comes from the fact that mutants unable to synthesize them or the cells in which HSP70 synthesis is blocked or inactivated are more susceptible to heat injury [98]. LMW-HSPs play structural roles in maintaining cell membrane integrity. Localization

of LMW-HSPs in chloroplast membranes further suggested that these proteins protect the PSII from adverse effects of heat stress and play a role in photosynthetic electron transport.

There is accumulating evidence that HSPs play an important role in heat tolerance of wheat. A wheat ditelosomic line lacking the long arm of chromosome 1B, DT1BS, was able to acquire heat tolerance at lower induction temperatures and was therefore better protected from heat stress damage [99]. Coincidentally, expression of HSPs in this line was induced at temperatures 4 °C lower than those required for HSP induction in the original wheat cultivar Chinese Spring. Hence, the long arm of chromosome 1B is likely to carry genes repressing both the heat shock response (HSR) at lower temperature and heat tolerance. In contrast, a ditelosomic line missing the long arm of chromosome 7D was heat sensitive and exhibited reduced expression of some HSPs; it was concluded that it carries genes necessary for induction of several HSPs and the capacity to acquire heat tolerance [100].

29.5.2
Other Heat Stress Proteins

Besides HSPs, there are a number of other plant proteins, including ubiquitin, cytosolic Cu/Zn-SOD, and Mn-POD whose expressions are stimulated upon heat stress. For example, in *Prosopis chilensis* and soybean under heat stress, ubiquitin and conjugated ubiquitin synthesis during the first 30 min of exposure emerged as an important mechanism of heat tolerance [101]. A number of osmotin-like proteins induced by heat and nitrogen stresses, collectively called Pir proteins, have also been found to be overexpressed in many plant cells under heat stress conferring them resistance.

Late-embryogenesis abundant (LEA) proteins can prevent aggregation and protect the citrate synthase (an important enzyme of TCA cycle) from desiccating conditions such as heat and drought stress (Figure 29.2). Using proteomics tool, enhanced expressions of 25 LEA proteins in hexaploid wheat during grain filling has been reported [102]. LEA-type proteins fall into a number of families, with diverse structures and functions [103]. Predictions of secondary structures suggest that most LEA proteins exist as random coiled α-helices. It was therefore proposed that most LEA and dehydrin proteins exist as largely unfolded structures in their native state, although a few members exist as dimers or tetramers. Function of these proteins is apparently related to protein degradation pathway, minimizing the adverse effects of dehydration and oxidative stress during heat stress. Hydrophilicity is a common characteristic of LEA-type and other osmotic stress-responsive proteins. Heat stability is another notable feature of LEA proteins, that is, they do not coagulate upon boiling. Another common characteristic of LEA-type proteins is that, in most cases, their related gene expression is transcriptionally regulated and responsive to ABA. It has been suggested that LEA-type proteins act as water binding molecules, both in ion sequestration and in macromolecule and membrane stabilization (i.e., chaperone-like activity).

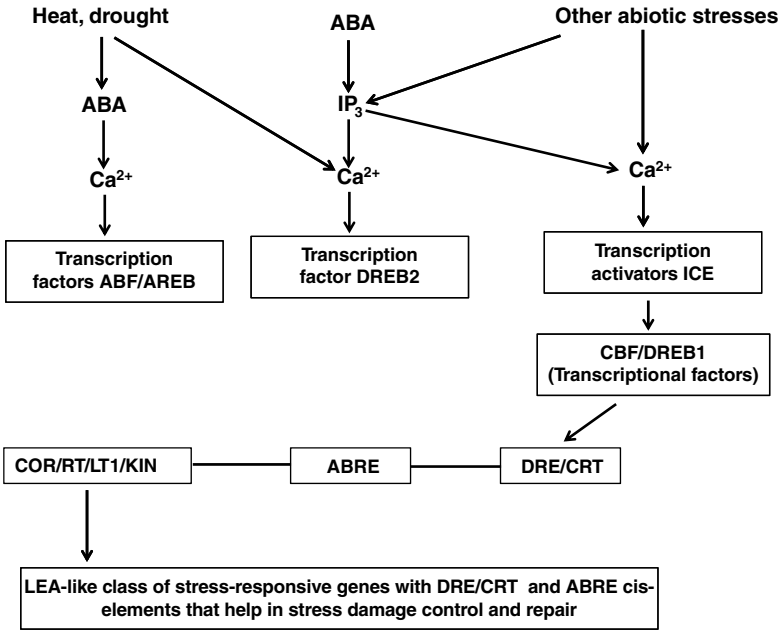

Figure 29.2 LEA proteins activation in response to abiotic stresses.

29.6 Mechanisms of Heat Tolerance

Heat tolerance includes the ability to withstand growth and developmental phase acceleration and to maintain economic yields. A major effect of heat on plants is the acceleration of plant growth and development phases by high temperatures [73]. If the acceleration is severe, economic yield can be affected. Plants adapt to heat stress through long-term evolutionary manifestation of developmental and morphological changes and short-term adaptation mechanisms such as spirational cooling and changes in composition of membrane lipids. Under heat stress, many crop plants employ early maturation as one of the surviving mechanisms that results in reduced yield. Initial effects of heat stress, which include plasma membrane disruption, osmotic changes, and ionic effects, may initiate a downstream signaling and transcriptional cascade that activate stress-responsive mechanism for the reestablishment of the homeostasis and repair of the damaged proteins and membranes. Delayed or poor responses at any step in the signaling and gene activation processes may result in irreversible damage to cellular homeostasis and destruction of functional and structural proteins and membranes, leading to cell death [104, 105]. Various types of stresses may be encountered by a plant at various developmental stages, and the mechanism of the stress response may be tissue specific. [106]; however, the effect of heat stress is not limited to just one level or organelle [107], but the initial effects are on plasma membrane whose fluidity increases under stress

triggering Ca^{2+} influx and cytoskeletal reorganization resulting in the activation of some mitogen-activated protein kinases (MAPK) and calcium-dependent kinases (CDPK). This leads to a series of changes and heat tolerance mechanisms such as ion transporters, osmoprotectants, free radical scavengers, late-embryogenesis abundant proteins, and factors involved in signaling cascades and transcriptional control are essentially significant to counteract the stress effects [108]. Generation of ROS is accompanied by membrane damage; however, these play a crucial role in signaling cascade. In wheat genotypes, increased activity of SOD and CAT and high ascorbic acid content has been well correlated with acquiring heat tolerance by overcoming the oxidative damage [48]. Induction of HSPs along with other proteins (such as LEA and dehydrins) is another mechanism of acquiring heat tolerance. In addition to their chaperone-like activity, they act as signaling molecules and interact with other stress response mechanisms such as osmolytes and antioxidants [109, 110]. The significance of HSPs in heat tolerance was first mooted on the basis of correlative evidence (for a review, see Refs [95, 111]), but the involvement of several HSPs in the acquired heat tolerance of *Arabidopsis* is now well demonstrated [106, 112, 113]. HSPs are also involved in stress signal transduction and gene activation, in protecting photosynthetic electron transport [114], and in maintaining cellular redox state [115, 116].

Heat stress is known to swiftly alter patterns of gene expression [117], stimulating the expression of HSP complements and suppressing the expression of many other genes [118], resulting in a heat shock response, which is defined as a transient reprogramming of gene expression and is a conserved biological reaction of cells and organisms to elevated temperatures [11]. The mRNAs encoding non heat stress-induced proteins are destabilized during heat stress. Heat stress may also inhibit splicing of some mRNAs. Heat stress transcription factors (HSFs) are the terminal components of signal transduction pathways mediating the activation of genes (including their own) responsive to heat stress. Heat tolerance is not controlled by a single "thermotolerant" gene in cereals. Different components of tolerance determined by different sets of genes are critical for heat tolerance at different stages of the life cycle and in various tissues. Quantitative trait loci analysis, correlation, and cosegregation approaches, and the use of genetic stocks are most applicable to the dissection of the genetic basis of heat tolerance in cereals.

Genetic diversity for heat tolerance in cultivated wheat is well established [119–122]. Genetic diversity for heat tolerance has been shown to exist in wild *Triticum* and *Aegilops* species in a study in which accessions from Afghanistan, Iran, Iraq, Israel, Jordan, Syria, Lebanon, Turkey, and the former USSR were tested [123]. It was found that all heat-tolerant accessions came from only three regions: Eastern Israel, Western Jordan, and South-western Syria. Hence, it was suggested that the bread and durum wheat landraces from these regions might provide genotypes with a high degree of heat tolerance that could be incorporated into modern wheat backgrounds.

Heat tolerance can be acquired by prior exposure to a conditioning pretreatment, which can be a short but sublethal high temperature or it may also be induced by a gradual increase in temperature to lethal highs, as would be experienced under natural conditions [95]. This protects cells and organisms from a subsequent lethal heat stress. It has been well established that quality and yield responses of wheat

genotypes to short spells of heat could be considerably improved by a heat shock treatment during the early grain-filling phase [45].

29.6.1 Signal Transduction under Heat Stress

In order to achieve heat stress tolerance, multiple stress signaling cascade pathways play key role. Some of these pathways are common to various abiotic stresses while some are stress specific [124]. Various signaling molecules such as ROS, Ca^{2+}, and hormones reprogram the genetic information via signaling cascades [125]. Various heat stress sensors are thought to be located in thylakoid membrane and are capable of detecting physical phase transition and eventually leading to conformational changes in membrane through cycles of phosphorylation and dephosphorylation due to temperature changes [126]. The presence of highly unsaturated lipids and temperature-sensitive photosystem make thylakoid membrane a crucial heat stress sensor [107].

Heat stress signaling involves various chemical molecules. As a response to heat stress, cytosolic Ca^{2+} rises sharply and activates the MAPK, which in turn activates various transcriptional factors via phosphorylation cascade, which then regulates the expression of genes involved in stress adaptation. In other pathway, Ca^{2+} binding activates the calmodulin that in turn activates CDPKs, which are found to be involved in the regulation of the expression of various HSP genes. It is well established that increasing cytosolic Ca^{2+} content under heat stress may alleviate heat injury, increase the activity of antioxidants [127], maintain turgor in the guard cells [128], and enable plant cells to better survive. However, excessive Ca^{2+} released into the cytosol and sustained high cytosolic Ca^{2+} concentration might be cytotoxic [129]. Other signaling molecules include SA, ACC, ABA, and H_2O_2, which are involved in reducing oxidative damage to the cell and hence help in providing heat tolerance to the plant. Although numerous molecules including ROS, hormones, nitrous oxide, and ethylene have been identified for the perception of heat stress cues, the role of Ca^{2+} is most important.

29.6.2 Genetic Approaches to Combat Heat Stress

When a plant is subjected to heat stress, a number of genes are turned on, resulting in increased levels of several metabolites and proteins, some of which may be responsible for conferring a certain degree of protection against these stresses. A key to progress toward breeding better crops under stress has been to understand the changes in molecular machinery that occur in response to stress. Various stress responses accommodate short-term reaction or tolerance to specific stresses. However, genome plasticity in plants, including genetic (e.g., directed mutation) and epigenetic (e.g., methylation, chromatin remodeling, and histone acetylation) changes, allows long-term adaptation to environmental changes/conditions [130], which may be necessary for long-term survival of plant genotypes/species in

particular environmental niches. The use of various biotechnological approaches provides a way to reduce the losses caused by high temperature, but it requires sound biological knowledge of particular organism and the mechanism of tolerance. With the advances in genome sequencing techniques, we have the genomic information of various cereal crops (e.g., maize, rice, and sorghum) that can be exploited to improve heat tolerance in crop species. Cultural practices such as planting time, planting methods, and soil and irrigation management have long been in use to minimize the stress effects. However, in practice, to be successful in improving agricultural productivity in stress environments, both genetic improvement and adjustment in cultural practices must be employed simultaneously the advent of recombinant DNA (rDNA) technology methods has opened avenues for tackling issues relating to complex genetic traits. In particular, the application of quantitative trait locus (QTL) mapping has contributed to a better understanding of the genetic relationship among tolerances to different stresses.

29.6.3
Conventional Breeding

Most plant breeding programs have been focused on the development of cultivars with high-yield potential in favorable (i.e., nonstress) environments. Such efforts have been very successful in improving the efficiency of crop production per unit area and have resulted in significant increases in total agricultural production [131]. The progress in breeding for stress tolerance depends upon an understanding of the physiological mechanisms and genetic bases of stress tolerance at the whole plant, cellular, and molecular levels, for which considerable information is available regarding the physiological and metabolic aspects of plant heat stress tolerance, as discussed earlier. Selection of tolerant genotypes under field conditions is not a viable approach due to the presence of various environmental factors that affects the results in the repeated trials and stage-specific responses making it difficult to correlate the results of one developmental stage with other. One of the traditional breeding methods for the selection of heat-tolerant progenies is to grow the breeding material in the heat-prone environment and to screen the lines with greater yield capacity, but the presence of other abiotic and biotic stresses make the selection process quite difficult. To overcome this problem, one effective strategy is the use of glasshouses for selecting heat-tolerant material, where the required temperature conditions can be maintained effectively throughout the experiment. But still the efficient and reliable selection method for the screening of heat-tolerant genotypes is a major challenge in traditional breeding. Several other selection methods have also been adopted such as a heat tolerance index (HTI), which is a ratio of the increase in coleoptile length after a finite exposure to heat stress (e.g., at 50 °C) to the increase in coleoptiles length in the no-stress treatment, first described in sorghum. This is a very cost-effective and easy-to-assay technique of screening for heat tolerance, but its correlation with performance under field conditions and its effectiveness in different crop species are yet unknown [132]. Pollen viability has been suggested as an additional indirect selection criterion for heat tolerance.

Wheat cultivars capable of maintaining high 1000-kernel weight under heat stress appear to possess higher tolerance to hot environments [122]. Physiological traits that are associated with wheat yield in heat-prone environments are canopy temperature depression, membrane thermostability, leaf chlorophyll content during grain filling, leaf conductance, and photosynthesis [122]. Breeding programs may measure such traits to assist in the selection of heat-tolerant parents, segregating generations, or advanced lines. In a previous study, canopy temperature depression was used to select for yield under a hot, dry, and irrigated wheat environment in Mexico [133], whereas another study reported that leaf chlorophyll content was correlated with 1000-kernel weight while screening Mexican wheat landraces [134]. Such sources of alleles coupled with some of the above traits can provide means for genetically enhanced wheat by design in heat-prone environments. Multidisciplinary research involving genetic resource enhancement and crop physiology at CIMMYT has led to a physiological trait-based approach to breeding for abiotic stress that has merit over breeding for yield per se by increasing the probability of successful crosses resulting from additive gene action. Advances have already been made in the drought breeding program [135, 136], and this strategy will be used to breed wheat for the high-temperature stress environments.

Traditional breeding strategies for heat stress tolerance have attempted to utilize genetic variation arising from varietal germplasm, interspecific or intergeneric hybridization, induced mutations, and somaclonal variation in cell and tissue cultures have met with only limited success due to several reasons, for example, lack of suitable source of genes in sexually compatible gene pools, complexity of the heat stress tolerance trait, lack of understanding of the genetic mechanisms of the high-temperature tolerance response, low genetic variance of yield components under stress conditions, and lack of efficient selection techniques. However, classical breeding prove more effective when blend with various biotechnological approaches to seek the natural sources of heat stress tolerance. Despite all the complexity of heat tolerance and difficulties encountered during transfer of tolerance, some heat-tolerant inbred lines and hybrid cultivars with commercial acceptability have been developed and released, at least in a few crop species such as tomato [137, 138].

29.6.4
Molecular Approaches

It has been well established by various traditional and transgenic approaches that plant heat stress tolerance is a multigenic trait, that is, heat tolerance components are controlled by different set of genes at different developmental stages of plant or in different tissues [105]. Thus, the use of genetic stocks with different degrees of heat tolerance, correlation and cosegregation analyses, molecular biology techniques, and molecular markers to identify tolerance QTL are promising approaches to dissect the genetic basis of heat tolerance [76]. Quantitative trait loci analysis is a powerful tool for qualitative and quantitative genetic analysis of complex traits [139, 140]. Simple sequence repeats, also called microsatellites, were interspersed ubiquitously in the DNA of hexaploid wheat [141]. The PCR-based, sequence-tagged site markers

detected a higher level of genetic variation than did RFLP and RAPD [142–145] and were useful for genetic analysis of species such as hexaploid wheat that exhibit a narrow genetic base due to their recent origin [141, 146]. The chromosome-specific feature of the SSR markers was also valuable for localizing linked alleles and detecting the QTL of interest. Wheat microsatellites were used recently for mapping genes in hexaploid wheat [147], characterizing the identity of genetic stocks [148], studying the genetic diversity of hexaploid wheat and related species [143, 149], and identifying QTL that control grain protein content [150] and preharvest sprouting [151]. High temperature-induced gene expression system is one of the best-studied model systems for analyzing induced gene expression. In recent years, detailed understanding has been gained on various components of the HSR in living organisms including features such as heat shock genes/proteins, heat shock promoters, and heat shock elements (HSEs), heat shock factors (HSFs), possible receptors of the heat shock response, signaling components, and chromatin remodeling aspects [152, 153]. It has been determined that induction of many heat-inducible genes is attributed to the conserved HSEs, which are located in the TATA box proximal 5′ flanking regions of heat shock genes [11]. A number of other sequence motifs have also been identified in plants that show quantitative effect on the expression of heat shock genes such as CCAAT box and AT-rich sequences [154].

Marker-assisted selection (MAS) and genetic engineering are two most common molecular approaches for improving stress tolerance in plants. With the advent of molecular markers, MAS has become an essential component of new discipline termed as "molecular breeding," with the help of which allelic variation among the genes underlying traits can be precisely and efficiently detected [155]. Numerous markers such as RAPDs, AFLPs, RFLPs, and SSRs have been reported for various abiotic stresses for achieving mapping of the QTL involved in stress tolerance [156]. Comparatively, however, limited research has been conducted to identify genetic markers associated with heat tolerance in different plant species. In *Arabidopsis*, for example, four genomic loci (QTL) determining its capacity to acquire heat tolerance were identified using a panel of heat-sensitive mutants [113].

29.6.5
Transgenic Approach

In contrast with traditional breeding and marker-assisted selection programs, the direct introduction of a small number of genes by genetic engineering seems to be a more attractive and rapid approach for improving stress tolerance. Present engineering strategies rely on the transfer of one or several genes that encode either biochemical pathways or endpoints of signaling pathways that are controlled by a constitutively active promoter. These gene products protect, either directly or indirectly, against environmental stresses. The need for raising high-temperature-tolerant crops using recombinant DNA methods was felt since the early days of recombinant DNA science, but not much could be achieved as the underlying physiological processes, biochemical enzymes, and molecular mechanisms that

impart high temperature tolerance were not precisely understood. But recently, many studies have shown that plants for high-temperature tolerance can be genetically engineered by altering Hsps either directly or through regulatory circuits that govern Hsp levels, levels of osmolytes, components of the cell detoxification mechanisms, and components that regulate membrane fluidity [157, 158]. Transgenic technology has emerged as a useful tool for improving genetics of crops for better survival, growth, and yield [159]. During the past one decade, major success has been achieved in producing transgenic plants with increased tolerance to different abiotic stresses [159]. However, not much progress has been made in producing transgenic wheat plants tolerant to heat stress. Table 29.2 provides comprehensive details on some plant transgenics raised for high-temperature tolerance. During the past nearly 30 years of research, Hsps have been extensively analyzed for their physiological, biochemical, cellular, and molecular properties [160, 161].

Hsp are believed to be important for the protection of cells against heat injury both in basal heat tolerance (i.e., heat tolerance achieved without prior HS) and in acquired heat tolerance responses. Over the years, a large number of *hsp* genes have been isolated, sequenced, and cloned [161, 162]. Experimental data obtained from transgenics, reverse genetics, and mutation approaches in noncereal species confirm causal involvement of HSPs in heat tolerance in plants [106]. Several groups have altered levels of sHsps in bacterial cells and plants and have shown that overexpression of sHsps has a role in conferring heat tolerance. For example, it has been shown that overexpression of *Oshsp16.9* in *Escherichia coli* confers heat tolerance to bacterial cells [163]. The involvement of Hsps in regulating heat tolerance in plants has been indicated by downregulating their levels through antisense and RNAi approach. Mutants of *Z. mays* and *A. thaliana* plants underexpressing their respective Hsp100 proteins are observed to lack both basal and induced heat tolerance [113, 164, 165]. Heat shock elements interact with positively acting regulatory HSF proteins to bring about increased transcription of *hsp* genes [166]. In recent years, *hsf* gene induction system has emerged as a powerful target for manipulating levels of Hsps in transgenic experiments.

Various osmolytes such as amino acids (e.g., proline), polyamines (e.g., putrescine), quaternary ammonium compounds (e.g., glycine-betaine), sugars (e.g., mannitol, fructans, sorbitol, and trehalose), and sugar alcohols (e.g., polyols) help plants to acclimatize largely against the osmotic stresses [167]. Many heat stress-tolerant transgenic plants have also been raised by altering osmolytes. Development of plants capable of higher production of glycine-betaine through transformation with the *BADH* gene has been suggested as a potentially effective method to enhance heat tolerance in plants [168]. Overaccumulation of glycine-betaine has been shown to improve heat tolerance in transgenic wheat line T6 due to increased osmotic adjustment and improved antioxidant defense system including antioxidative enzymes and antioxidants [169].

Altering membrane fluidity provides another means for producing heat-tolerant plants. For example, transgenic tobacco plants with altered chloroplast membranes by silencing the gene encoding chloroplast omega-3 fatty acid desaturase have been produced that produce less trienoic fatty acids and more dienoic fatty acids in their

Table 29.2 Transgenic attempts to enhance plant temperature stress tolerance.

Gene	Host	Function	Target	Phenotype	Reference
Zmeftu1	*T. aestivum*	Chloroplast protein synthesis elongation factor, Ef-Tu	Constitutive overexpression	Heat shock tolerant	[174]
Fad7	Tobacco	Fatty acid desaturation	Cosupression	Heat shock tolerant	[170]
Hsf3	*Arabidopsis*	Transcription factor	Constitutive overexpression	Heat shock tolerant	[110]
Hsp101	Maize	HSP	Knockout	Abolished acquired heat tolerance	[165]
Atshf1	*Arabidopsis*	Transcription factor	Heat shock factor	High-temperature tolerant	[175]
HvAPX1	Barley	Photoproduced H_2O_2 detoxification	Ascorbate peroxidase	Heat shock tolerant	[172]
Fad8	Oilseed rape	Oxidoreductase acting on paired donors with incorporation or reduction of molecular oxygen	Desaturase enzyme	High-temperature tolerant	[28]
Hsp17.7	Carrot	HSP	Constitutive overexpression or antisense	Mild tolerant to high temperature	[176]
Fad7	Tobacco	Fatty acid desaturation	Constitutive overexpression in chloroplast	Increased levels of 16:3 and 18:3 fatty acids, HS tolerant	[177]

chloroplasts than do the wild type. These plants exhibited greater photosynthesis and grew better than wild type plants under high temperatures [170]. Molecular manipulations focused on the component of cell detoxification mechanisms have been employed in specific experiments to alter heat tolerance response in transgenic plants. Reactive oxygen species are induced by most types of stresses [48, 171] and their production has been envisaged in stress cross-tolerance. Overexpression of barley *hvapx1* gene (encoding for peroxisomal ascorbate peroxidase) in *Arabidopsis* brought about increased heat tolerance in transgenic plants compared to wild-type plants [172]. Overexpression of Cu/Zn superoxide dismutase is also noted to protect plants from high-temperature stress [173]. Details of the transgenic events produced for improving heat tolerance in plants are presented in Table 29.2.

29.6.6
Functional Genomics of Heat Stress

Heat stress is not a single-step event. Rather, it triggers in plants a cascade of physiological, metabolic, and molecular events. The long history of breeding, genetics, and physiology of crops provides a unique resource for genomics studies in these species. Genomics, proteomics, and metabolomics, coupled with a strong bioinformatics capability, now enable a "broad" approach to be taken in the study of plant responses to abiotic stresses. Recent advances in genome-wide analyses have revealed complex regulatory networks that control global gene expression, protein modification, and metabolite composition. Genetic regulation and epigenetic regulation, including changes in nucleosome distribution, histone modification, DNA methylation, and npcRNAs (nonprotein-coding RNAs) play important roles in heat stress gene networks. Transcriptomics, metabolomics, bioinformatics, and high-throughput DNA sequencing have enabled active analyses of regulatory networks that control abiotic stress responses. Such analyses have markedly increased our understanding of global plant systems in responses and adaptation to heat stress conditions.

Functional genomics technologies provide tools for the detection and definition of cellular networks through which stress perception, signal transduction, and defensive responses are mediated. This understanding can be used for the manipulation of the responses or their transfer to important cereal crops species through either conventional, marker-assisted, or transgenic approaches (Figure 29.3). Various genes and gene products, which are involved in signal transduction and eventually gene expression involved in heat stress tolerance mechanism, have been elucidated by both forward and reverse genetics approaches [178].

Functional genomics and proteomics have emerged as a powerful tool in understanding the various mechanisms behind the heat tolerance and eventually in producing heat-tolerant genotypes. Various techniques such as TILLING, antisense RNA/RNA interference, posttranscriptional gene silencing, virus-induced gene silencing, gene knockout, and T-DNA insertional mutagenesis have revolutionized our understanding of the function of various genes involved in heat stress response [179] (Figure 29.4). Insertional mutagenesis has been widely employed to

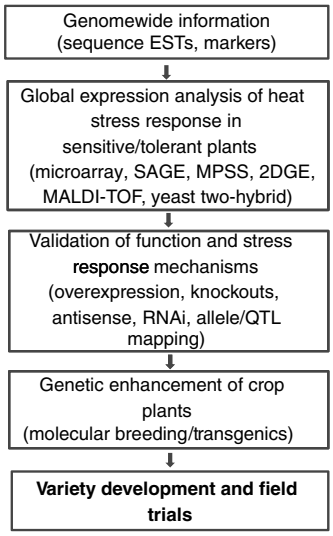

Figure 29.3 Different genomics and proteomics approaches used in understanding heat stress tolerance mechanism.

characterize abiotic stress-responsive genes, including those coding for *At HKT1, CBL1, OsRLK1, CIPK3, OSM1/SYP61,* and *HOS10.*

When expression profiling is undertaken in plant tissue, it is necessary to identify protein components to maximize the information that can be gleaned from expression profile. Analysis of proteome provides a direct link of the genome sequence to biological activity. Analysis of the proteome includes acquiring knowledge of the entire protein repertoire as well as other aspects, such as expression levels, post-

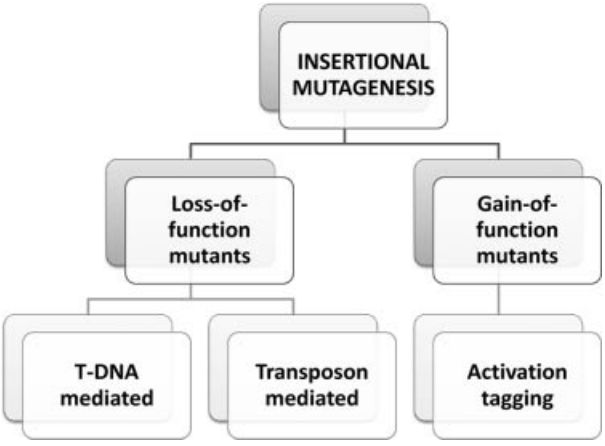

Figure 29.4 Insertional mutagenesis approaches for identifying genes responsible for heat tolerance.

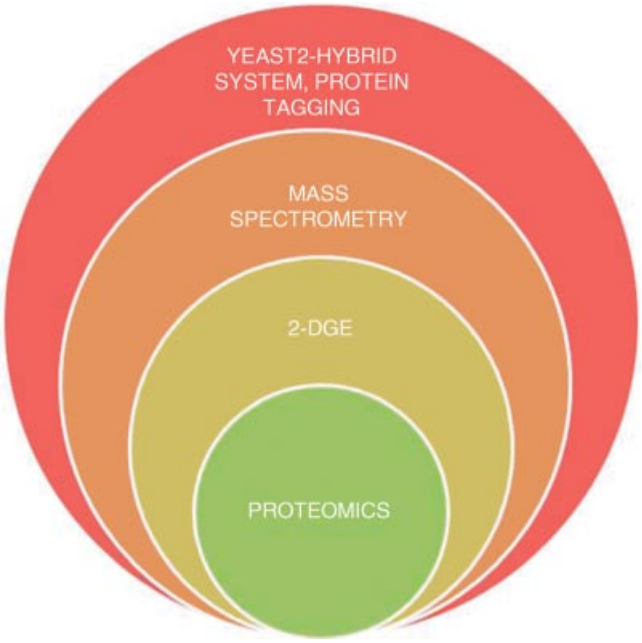

Figure 29.5 Major components involved in proteomics.

translational modifications, and interactions, to understand the cellular processes at the protein level.

Proteomics is a powerful approach to study changes in the proteome of plant system under various stresses including heat stress (see Figure 29.5). Techniques such as two-dimensional electrophoresis, Y2H (yeast two-hybrid) assay, and mass spectrometry offer opportunity to discover the various proteins involved in heat tolerance mechanism. Proteomic reference maps have been made for various crops including wheat [180] at various growth stages. Upregulation of various heat shock proteins and downregulation of several other proteins (e.g., proteins involved in starch metabolism) have been shown in wheat under heat stress during grain filling [102, 181]. Proteome approach has been successfully used to study the effect of heat shock on wheat grain quality using 2D gel electrophoresis and to identify protein markers that enable breeders to produce cultivars with desired characters under heat stress conditions [182].

Identifying novel genes and studying their expression patterns in response to heat stress will provide a molecular basis for improving heat tolerance in crops. Microarray analysis of gene expression has been used to investigate transcriptome changes in response to heat stress and combined stresses in several plant species [183, 184], including wheat [185]. Using Affymetrix Wheat Genome Array, it was found that ~11% (6560) of total probe sets were responsive to short and prolonged heat stress treatments in wheat and hence it was concluded that the differences in heat tolerance in different wheat genotypes may be associated with multiple processes and

mechanisms involving HSPs, transcription factors, and other stress-related genes [185]. Heat acclimation has little effects on gene expression under prolonged treatments, but it affects gene expression in wheat under short-term heat stress. The heat stress-responsive genes identified through micoarray will facilitate our understanding of molecular basis for heat tolerance in different wheat genotypes and future improvement of heat tolerance in wheat and other cereals.

Metabolite profiling has also been used to characterize stress responses to many abiotic stresses such as water deficit (dehydration and high salinity) and extreme temperature (cold and heat) for comprehensive analyses of the final steps of stress signal transduction pathways. A comparative metabolite analysis between *Arabidopsis* Columbia (Col-0) plants responding to heat shock and cold shock was carried out using GC-MS (gas chromatography–mass spectrometry) [186] and GC-TOF–MS (gas chromatography–time-of-flight mass spectrometry) [187]. The majority of metabolites produced in response to heat shock overlapped with those produced in response to cold shock. Moreover, these results suggested that a metabolic network of compatible solutes including proline, monosaccharides (glucose and fructose), galactinol, and raffinose has an important role in tolerance to temperature stress.

In summary, genetic engineering for improving plant heat stress tolerance is still at its infancy, and the success to date represents only a beginning. Advancements in marker technology and genetic engineering are expected to contribute significantly to the development of plants with tolerance to high temperatures in future. Future knowledge of tolerance components and the identification and cloning of responsible genes may allow transformation of plants with multiple genes and production of highly stress-tolerant transgenic plants. In addition, there is no report to date of any study testing the performance of transgenic plants under field stress conditions. Therefore, much more work is needed to gain a clearer understanding of the genetic, biochemical, and physiological basis of plant heat tolerance. To improve plant heat tolerance, alternative approaches to genetic means would include pretreatment of plants or seeds with heat stress or certain mineral or organic compounds. The success of such approaches, however, depends on plant species and genotypes and must be studied on a case-to-case basis.

29.7
Energy Crises during Heat Stress

Under heat stress, various events interfere with the energy production via photosynthesis and electron transport chain in mitochondria and hence lead to reduction in growth of plant. During light reactions, due to increase in leaf temperature, there is an increase in ATP production to meet the energy requirement of the cell. In dark reactions, rubisco activation is inhibited under heat stress, which leads to reduction in carbohydrate production due to interrupted C_3 cycle [188, 189]. Heat stress leads to oxidative stress and DNA damage, which induces the poly(ADP)-ribosylation of various nuclear proteins as their posttranslational modification. This modification is achieved by an enzyme named poly(ADP-ribose) polymerase (PARP), whose activity

is enhanced under various environmental stresses including high temperature. As NAD^+ is used as a substrate for this enzyme, an increase in the activity leads to a decrease in the pool of NAD^+. Since ATP molecules are required to resynthesize the depleted NAD^+, these reactions deplete the energy of the plant due to ATP overconsumption and enhance the production of ROS, which eventually leads to cell death [190]. Hence decreasing the poly(ADP)-ribosylation can prove an effective strategy for maintaining the plant energy homeostasis under adverse conditions such as high temperature. In short, heat tolerance in plants is a cost-intensive process and consumes considerable cellular energy to cope with adversaries such as a high temperature.

29.8 Conclusions and Outlook

Great variation exists within plant species in response to heat stress, which also varies with developmental stage. However, heat stress affects plant growth almost at every developmental stage of the plant, but for wheat, the grain-filling stage has been reported as the most susceptible. Membrane disruption, disarrangement of cell organelles, disturbance in leaf water relations, impaired photosynthesis due to changes in series of biochemical and photochemical reactions, production of ROS, and lipid peroxidation and hence generation of oxidative stress in plant cells are some of the adverse effects that are caused by heat stress. Various adaptive strategies have been reported in plants in response to heat stress. These include initiation of signaling cascade leading to profound changes in specific gene expression in which the role of Ca^{2+} is most important; enhanced expression of HSPs that act as molecular chaperones that play a role in preventing protein denaturation and removing denatured proteins and dissolving protein aggregates in poststress period to reduce toxicity. While adaptation to stress under natural conditions has some ecological advantages, the metabolic and energy costs may sometimes mask and limit its benefit to agriculture and result in yield penalty. Therefore, the improvement in abiotic stress tolerance in agricultural plants can be achieved, practically, by combining traditional and molecular breeding [191–193]. Conventional breeding strategies have shown some notable progress in the development of crop plants with improved heat tolerance, but the progress is slow due to inherent difficulties of selecting the desired genotypes. More emphasis should be given to identifying the molecular markers linked to component traits for heat tolerance so that these could be used for marker-assisted selection. A comprehensive understanding of the molecular, physiological, and biochemical basis of the mechanism of heat tolerance in some plant species has paved the way for genetically engineering the plants that will withstand the heat stress to produce better yield in heat stress environments.

Global warming is likely to increase the frequency of heat stress episodes and cause yield loss. There is need to be aware of this likelihood and take adaptive management and breeding steps to reduce the associated risks. These steps should improve further research to understand the mechanisms involved in heat stress tolerance and provide

breeders with selection tools to assist in the production of varieties that will tolerate heat stress. Among several wild species of wheat, *Aegilops speltoides* appears to have the highest level of heat tolerance. This species continues to grow without any adverse effect on pollen fertility even in the month of May in Punjab state of India, when the temperature is 40 plus. The authors' group is exploring the mechanism of heat tolerance in this species and attempting to transfer the trait to hexaploid wheat using tetraploid wheat *T. durum* as a bridging species.

Wheat and Rice Crops: "Omics" Approaches for Abiotic Stress Tolerance

Suja George, Ajay Parida, and Monkombu S. Swaminathan

Abiotic stresses are the principal causes of crop failure, reducing average yields of most major crops by more than 50%. Rice and wheat are the two most important food crops in the world, together occupying about 28% of all crop area. A considerable amount of crop biomass for which genetic potential exists in the present-day cultivars in wheat and rice is not harvested under field conditions, primarily because of the sensitivity of these crops to various stresses. To meet human needs by 2050, grain production must increase at an annual rate of 2% on an area of land over what is being produced at present. Modern biotechnology has a lot to offer in the field of crop improvement in the present scenario both in understanding the mechanisms of stress and stress tolerance in plants and in developing crop plants better equipped for harsher environmental conditions. A great deal of research has been carried out in the recent past in the field of plant abiotic stress tolerance encompassing genomics, transcriptomics, proteomics, and metabolomics. These "omic" technologies investigate different facets of a given scientific issue such as abiotic stress tolerance, but complement each other. Integration of phenotypic, genetic, transcriptomic, proteomic, and metabolomic data will enable accurate and detailed gene network reconstruction. This chapter discusses the recent "omic" studies in wheat and rice in the field of abiotic stress tolerance.

30.1
Introduction

Abiotic stresses such as drought, high salinity, low and high temperature, submergence, and so on are frequently encountered by plants in both natural and agricultural systems. In many cases, several classes of abiotic stress challenge plants in combination. For example, high temperatures and scarcity of water are commonly encountered in periods of drought and can be exacerbated by mineral toxicities that constrain root growth. Abiotic stresses are the principal causes of crop failure, reducing average yields of most major crops by more than 50% [1].

Rice (*Oryza sativa*) is one of the most important food crops in the world with almost half of the world's population depending on it as their staple food. More than 90% of

Improving Crop Resistance to Abiotic Stress, First Edition.

the world's rice is grown and consumed in Asia, which is home to 60% of the Earth's population. Rice accounts for 35–75% of the calories consumed by more than 3 billion Asians. It is grown on about 154 million hectares annually or on about 11% of the world's cultivated land. Rice is cultivated in 42 million hectares (mha) under four major ecosystems, namely, irrigated (19 mha), rain-fed lowland (14 mha), flood-prone (3 mha), and rain-fed upland (6 mha) ecosystems. A considerable amount of rice biomass for which genetic potential exists in the present-day cultivars is not harvested under field conditions, primarily because of the sensitivity of this crop to various stresses [2].

Wheat (*Triticum aestivum* L.) was the first domesticated crop and is the youngest polyploid species among the agricultural crops. Together with rice and maize, wheat provides 60% of the calories and proteins for our daily life. Unlike rice and maize, which prefer tropical environments, wheat occupies 17% of all crop area (in 2002, 210 million hectares). The trade value of wheat exceeds that of any other cereal species, including rice and maize ($31 billion of world trade in 2001 versus $13 and $19 billion for rice and maize, FAOSTAT database: http://apps.fao.org/default.jsp). Wheat cultivators lose about 25% annually due to various biotic (pests) and abiotic stresses [3].

The world population is continuing to rise, but the gains in agricultural output provided by the Green Revolution have reached a plateau by now [4]. Many explanations have been offered for this, including deteriorating irrigation infrastructure, soil degradation, stagnant technology for rain-fed farms, and the technological fatigue being reached on irrigated farms. Adverse regional climate changes caused by the combined effects of atmospheric brown clouds (ABC) and greenhouse gases (GHG) add to this crisis. To meet human needs by 2050, grain production must increase at an annual rate of 2% on an area of land over what is being produced at present [2]. Modern biotechnology has a lot to offer in the area of crop improvement in the present scenario both in understanding the mechanisms of stress and stress tolerance in plants and in developing crop plants better equipped for harsher environmental conditions.

Since 2000, plant science has moved forward into the stage of postgenomics. A great deal of research has been carried out in the recent past in the field of plant abiotic stress tolerance encompassing genomics, transcriptomics, proteomics, and metabolomics. The availability of whole genome sequences, microarrays, micro-RNA libraries, and so on has opened up research and result avenues that did not exist a decade ago. Completed in 2003, the Human Genome Project was a 13-year project. However, with the next-generation sequencing technologies from companies such as Roche, Illumina, and Applied Biosystems, sequencing of the whole genome of higher organisms is being done with unprecedented speed. Researchers all over the world have been enthusiastically exploiting the latest technologies and bioinformatics tools to provide better insights into various facets of abiotic stress tolerance.

This chapter explores the progress of research in the field of genomics, transcriptomics, proteomics, and metabolomics in wheat and rice, the most important cereal crops, in the recent past.

30.2 Genomics

Major genomics initiatives have generated valuable data for the elucidation of the expressed portion of the genomes of higher plants. The genome sequencing of *Arabidopsis thaliana* was completed in 2000 (The Arabidopsis Initiative), while the finished sequence for rice was published in 2005 (project IRGS). The relatively small genome size of these model organisms was a key element in their selection as the first plant genomes to be sequenced with extensive coverage. On the other hand, wheat is an allohexaploid having three homologous genomes. These genomes have been designated as A, B, and D, with the coding regions of the homologous genes sharing more than 90% homology. Wheat genome is one of the largest among crop species with a haploid size of 16.7 billion bp [5], which is 110 and 40 times larger than *Arabidopsis* and rice, respectively [6]. The large size, combined with the high percentage (over 80%) of repetitive noncoding DNA, presents a major challenge for comprehensive sequencing of the wheat genome. Although common wheat genetic maps with molecular markers and cytological maps with deletion mutants of the chromosome segments have been constructed, the number of mapped DNA markers for both map-based cloning and anchoring of the genome positions remains restricted [7].

In 2005, the International Wheat Genome Sequencing Consortium (IWGSC) was created with the purpose of sequencing the complete genome of bread wheat. In the mean time, a significant insight into the expressed portion of the wheat genome has been gained through large-scale generation and analysis of ESTs. cDNA libraries prepared from different tissues exposed to various stress conditions and developmental stages are valuable tools to obtain the expressed and stress-regulated portion of the genome.

To identify genes involved in cold acclimation and associated stresses, a large-scale EST sequencing approach was undertaken by the Functional Genomics of Abiotic Stress (FGAS) project [8]. As part of this project, 73 521 quality-filtered ESTs were generated from 11 cDNA libraries constructed from wheat plants exposed to various abiotic stresses and at different developmental stages. In addition, 196 041 ESTs for which trace files were available from the National Science Foundation wheat EST sequencing program and DuPont were also quality filtered and used in the analysis. Assembly of the resolved ESTs generated a 75 488 unique sequence set (31 580 contigs and 43 908 singletons/singlets). Digital expression analyses indicated that the FGAS data set is enriched in stress-regulated genes. Over 43% of the unique sequence set was annotated and classified into functional categories according to Gene Ontology.

In a similar study [7], a comprehensive collection of ESTs was prepared from various tissues that develop during the wheat life cycle and from tissues subjected to stress. The study also examined their expression profiles *in silico*. By grouping the ESTs of recombinant clones randomly selected from the full-length cDNA library, the researchers were able to sequence 6162 independent clones with high accuracy. About 10% of the clones were found to be wheat unique genes, without any counterparts within the DNA database. Wheat clones that showed high homology

to those of rice were selected and their expression patterns in various tissues throughout the wheat life cycle and in response to abiotic stress treatments were investigated. Their results showed each clone's expression in various tissues and stress treatments and its variability in wheat and rice as a result of their diversification.

Comparative genomics is a powerful tool for investigating plant evolution at the whole genome level. In a comparative analysis of wheat and rice genomes, 4485 expressed sequence tags that were physically mapped in wheat chromosome bins were compared with the public rice genome sequence data using BLAST [9]. This rice genome view of homologous wheat genome locations based on comparative sequence analysis revealed numerous chromosomal rearrangements between the two species over the course of evolution.

In the case of rice, the availability of the whole genome has made it possible to do genome-wide analysis of specific classes of genes. Most of these analyses are quite exhaustive, including identification of all the genes in a specific class, transcript profiling, phylogenetic analysis, regrouping based on the phylogenetic analysis or the presence or absence of protein domains, identification of splice variants and intronless variants, expression in transgenic systems, proposing new functions, and so on. These studies often present a comprehensive view of the specific class of genes. There are many reports of genome-wide identification and characterization of genes functioning in abiotic stress tolerance in rice.

Genome-wide analysis resulted in identification of 79 glutathione S-transferases (GSTs) genes in the rice genome [10]. A phylogenetic analysis grouped the GST proteins into seven classes. Sequence analysis together with the organization of putative motifs indicated the potential diverse functions of GST gene family members in rice. The authors proposed that tandem gene duplications have contributed a major role in expansion of this gene family. Microarray data analysis revealed tissue/organ- and developmental stage-specific expression patterns of several rice GST genes. At least 31 GST genes showed response to plant hormones auxin and cytokinin. Furthermore, expression analysis showed the differential expression of quite a large number of GST genes during various abiotic stress (20), arsenate stress (32), and biotic stress (48) conditions. Many of the GST genes were commonly regulated by developmental processes, hormones, and abiotic and biotic stresses. The transcript profiling suggested overlapping and specific role(s) of GSTs during various stages of development in rice. The study also provides evidence for the role of GSTs in mediating crosstalk between various stress and hormone response pathways [10].

A similar whole-genome analysis revealed 103 genes encoding WRKY transcription factors in rice. Among them, the majority of rice WRKY genes (77.7%) were located in duplicated regions; 45.6% of WRKY genes were fragmentally duplicated and 35% of them were tandemly duplicated. These results suggested that genome duplications might be regarded as a major mechanism for expansion of this family in the rice genome. Under abiotic (cold, drought, and salinity) stresses and various phytohormone treatments, 54 WRKY genes exhibited significant differences in their transcript abundance; among them three genes were expressed only under stressed conditions. Among the stress-inducible genes, 13 genes were regulated only by

abiotic stresses, another set of 13 genes were responsive to only phytohormone treatments, and the remaining 28 genes were regulated by both factors, suggesting an interaction between abiotic stress and hormone signaling [11].

DREB2s (dehydration-responsive element binding protein 2s) are transcription factors that interact with a *cis*-acting DRE (dehydration-responsive element)/CRT (C-repeat) sequence and activate the expression of downstream genes involved in water and heat shock stress responses and tolerance. A study analyzed all five DREB2-type genes in rice (OsDREB2s: OsDREB2A, OsDREB2B, OsDREB2C, OsDREB2E, and OsABI4) to determine which of them contribute to plant stress responses. The expression patterns of these genes under abiotic stress conditions were studied and the subcellular localization and transcriptional activation activity of their translational products in protoplasts were examined. Only OsDREB2A and OsDREB2B showed abiotic stress-inducible gene expression. In addition, OsDREB2B showed nuclear-specific localization and the highest transactivation activity. OsDREB2B has functional and nonfunctional forms of its transcript similar to its orthologues in the grass family, and the functional form of its transcript was markedly increased during stress conditions. The splicing mechanism of OsDREB2B was analyzed with transgenic rice that expressed the nonfunctional transcript, which revealed that the nonfunctional form is not a precursor of the functional form, indicating that stress-inducible alternative splicing of pre-mRNA is an important mechanism for the regulation of OsDREB2B. Transgenic *Arabidopsis* plants overexpressing OsDREB2B showed enhanced expression of DREB2A target genes and improved drought and heat- shock stress tolerance. These results pointed out the key role of OsDREB2B in stress-responsive gene expression in rice [12]. Another database search identified 29 C3HC4-type RING finger family genes in rice. A comprehensive expression analysis of these genes has been performed using microarray data obtained from 27 tissues or organs of three rice genotypes, Minghui 63, Zhenshan 97, and Shanyou 63. Expression analysis of C3HC4-type RING finger genes under abiotic stresses suggested that 12 genes are differentially regulated by hormones or stress in rice seedlings [13].

Heat shock proteins (Hsps) constitute an important component in the heat shock response of all living systems. Among the various plant Hsps (i.e., Hsp100, Hsp90, Hsp70, and Hsp20), Hsp20 or small Hsps (sHsps) are expressed in maximal amounts under high temperature stress. The characteristic feature of the sHsps is the presence of alpha-crystallin domain (ACD) at the C-terminus. sHsps cooperate with Hsp100/Hsp70 and cochaperones in ATP-dependent manner in preventing aggregation of cellular proteins and in their subsequent refolding. A database search revealed the presence of 40 alpha-crystallin domain containing genes in rice. Phylogenetic analysis showed that 23 out of these 40 genes constitute sHsps. The additional 17 genes containing ACD clustered with Acd proteins of *Arabidopsis*. A detailed scrutiny of 23 sHsp sequences resulted in categorizing these proteins in a revised scheme of classification, constituting 16 cytoplasmic/nuclear, 2 ER, 3 mitochondrial, 1 plastid, and 1 peroxisomal genes. Expression analysis based on microarray and RT-PCR showed that 19 sHsp genes were upregulated by high-temperature stress. Besides heat stress, expression of sHsp genes was up- or downregulated by other abiotic and biotic stresses [14].

Several studies have pointed out the involvement of WRKY transcription factor gene family in a range of biological processes, including abiotic stress. A whole gene family WRKYs expression study was carried out in rice. Twenty-four members of the rice WRKY gene family (22% of the total) were differentially regulated in response to at least one of the stress conditions tested. The existence of nine OsWRKY gene clusters comprising phylogenetically related and unrelated genes that were significantly coexpressed suggested that specific sets of WRKY genes might act in coregulatory networks. By identifying *Arabidopsis* orthologues of the coexpressed OsWRKY genes, it was also shown that specific coregulatory networks were conserved between the two model species. It is possible to highlight novel clusters of plant genes contributing to the same biological processes or signal transduction pathways using such data [15].

Similar studies have also been conducted in wheat, although limited by the unavailability of the whole-genome sequence. From 960 174 ESTs of *T. aestivum*, 117 putative AP2/ERF family genes were identified [16]. On the basis of the model species *A. thaliana*, the AP2/ERF transcription factors from *T. aestivum* were classified into five subfamilies with the following number of members: DREB (57), ERF (47), AP2 (9), RAV (3), and Soloist (1). Using the available EST information as a source of expression data, the putative AP2/ERF family genes from *T. aestivum* were detected in nine kinds of tissues. Transcripts of the genes were shown to be most abundant in leaves, followed by roots and seeds, and least abundant in stem.

Enzymatic methylation, which is catalyzed by the large number of *O*-methyltransferases (OMTs), is one of the important reactions in the flow of primary and secondary metabolism. The structural and expressional divergence of genes encoding *O*-methyltransferase has been studied in wheat [17]. Wheat OMT genes TaOMT3, TaOMT4, and TaOMT5 were analyzed using a bioinformatics approach for their genomic organization, tissue-specific expression, responses to abiotic stresses and hormones, and *cis*-elements.

30.3 Transcriptomics

With the ever-increasing availability of genomic sequences and the introduction of microarray technology, enabling the high-throughput analysis of gene expression, transcriptome profiling has rapidly become a favorite tool with many researchers. The study of plant transcriptomes has led to important discoveries and to an accumulation of profiling data covering a wide range of different tissues, developmental stages, perturbations, and genotypes. Querying a large number of microarray experiments can provide insights that cannot be gained by analyzing single experiments.

In an effort to elucidate genome-level responses to drought and high-salinity stress in rice, a 70-mer oligomer microarray covering 36 926 unique genes or gene models was used to profile genome expression changes in rice shoot, flag leaf, and panicle under drought or high-salinity conditions [18]. Patterns of gene expression

in response to drought or high-salinity stress within a particular organ type showed significant overlap, but comparison of expression profiles among different organs showed largely organ-specific patterns of regulation. Both stresses appeared to alter the expression patterns of a significant number of genes involved in transcription and cell signaling in a largely organ-specific manner. This study identified that promoter regions of genes induced by both stresses or induced by one stress in more than one organ type were relatively enriched in two *cis*-elements (ABRE core and DRE core) known to be associated with water stress. Further computational analysis that indicated that novel promoter motifs are present in the promoters of genes involved in rehydration after drought led the authors to propose that rice might possess a mechanism that actively detects rehydration and facilitates rapid recovery.

The rice genome encodes a total of 10 genes that contain the highly conserved MTase catalytic domains found in DNA methyltransferases (MTases). A microarray-based gene expression profile of all 10 MTases during 22 stages/tissues that included 14 stages of reproductive development and five vegetative tissues together with three stresses, cold, salt, and dehydration stress, revealed specific windows of MTase activity during panicle and seed development. One of the MTases was activated in young seedlings in response to cold and salt stress [19].

Microarray-based transcriptome profiling has been successfully used to analyze the differences in gene expression between salt-sensitive and -tolerant rice cultivars. The expression profiles of 1194 salinity-regulated cDNAs in rice salt-sensitive cultivar IR64 and Pokkali, a well-known, naturally salt-tolerant relative, were analyzed using microarrays [20]. The study revealed that salinity tolerance of Pokkali may be due to constitutive overexpression of many genes that function in salinity tolerance. Analysis of genome architecture revealed the presence of these genes on all the chromosomes with several distinct clusters. A few genes were mapped on one of the major quantitative trait loci, Saltol, on chromosome 1 and were found to be differentially regulated in the two contrasting genotypes. The study revealed that a set of known abiotic stress-inducible genes, including CaMBP, GST, LEA, V-ATPase, OSAP1 zinc finger protein, and transcription factor HBP1B, were expressed at high levels in Pokkali even in the absence of stress.

Mitochondrial responses to abiotic stresses at the early stages of wheat development after imbibition under normal and low temperature, high salinity, and high osmotic potential stress have been evaluated by transcriptome profiling [21]. Microarray analysis of the mitochondrial transcriptome revealed stress specific in transcript levels in the case of most genes, but few groups of genes were found to respond commonly to different stresses. Under continuous stresses for 3 days, 13 genes showed low-temperature-specific responses with up- or downregulation, while 14 and 23 genes showed responses specific to high salinity and high osmotic potential, respectively. On the other hand, 13 genes showed common responses. Among the nuclear-encoded mitochondrial-targeted genes, MnSOD and AOX increased their transcript amounts. These results also point out toward common and different regulatory mechanisms that can sense different abiotic stresses and modulate both nuclear and mitochondrial gene expression in wheat.

In order to reveal differences in global expression profiles of drought-tolerant and -sensitive wild emmer wheat genotypes, a shock-like dehydration process was deployed to compare transcriptomes at two time points in root and leaf tissues [22]. The comparison of transcriptomes revealed several unique genes or expression patterns such as differential usage of IP_3-dependent signal transduction pathways, ethylene- and abscisic acid (ABA)-dependent signaling, and preferential or faster induction of ABA-dependent transcription factors by the tolerant genotype that distinguish contrasting genotypes indicative of distinctive stress response pathways. This comparison of transcriptomes in the absence of and after dehydration indicates that gene networks involved in drought response especially in root tissues may have been lost in the selection processes generating modern bread wheat.

T. aestivum "Opata" is an elite hard red spring wheat that has been used as a parent of the ITMI (International *Triticeae* Mapping Initiative) mapping population and also in the production of synthetically derived hexaploid wheats, some of which (following selection) show increased drought tolerance relative to Opata. The response of Opata roots to water withholding was described using physiological variables and oligonucleotide microarrays [23]. They identified 190 transcripts whose expression increased following water limitation. In addition to previously characterized markers of abiotic stress and many genes of unknown function, they were able to identify multiple putative glucanases and class III peroxidases as being particularly responsive to stress. A comparison of these data with microarray analyses of Opata's more drought-tolerant, synthetic-derived Progeny revealed a relatively high correlation between responsive transcripts in the two genotypes, despite differing physiological responses. Some of the transcripts that were differentially expressed between Opata and the more tolerant synthetic-derived genotype under stress included a class III peroxidase, an AP2 family transcription factor, and several transcripts of unknown function.

There are a few software applications that have been developed to query large microarray gene expression databases using a Web-browser interface. GENEVESTIGATOR, a database and Web-browser data mining interface for Affymetrix GeneChip data, is an example. Users can query the database to retrieve the expression patterns of individual genes throughout chosen environmental conditions, growth stages, or organs. Reversely, mining tools allow users to identify genes specifically expressed during selected stresses, growth stages, or in particular organs. Using GENEVESTIGATOR, the gene expression profiles of more than 22 000 *Arabidopsis* genes can be obtained, including those of 10 600 currently uncharacterized genes [24]. More recently, Genevestigator rice and barley gene expression databases have been released that contain quality controlled and well-annotated microarray experiments using ontologies [25]. The databases comprise experiments from pathology, plant nutrition, abiotic stress, hormone treatment, genotype, and spatial or temporal analysis, but are expected to cover a broad range of research areas as more experimental data become available. The transcriptome meta-analysis of the model species rice is expected to deliver results that can be used for functional genomics and biotechnological applications in cereals.

In addition to the whole transcriptome profiling studies, a plethora of research reports are recently available on transcript profiling of individual genes or specific

class of genes functioning in abiotic stress tolerance in wheat and rice. These studies complement the whole transcriptome profiling studies and in many cases are more in-depth when individual gene's function is concerned. Many of them have served to reveal novel functions for already known genes and help in elucidating their interactions with other genes and pathways.

A recent review analyzed the role of APETALA 2/ethylene response element binding protein (AP2/EREBP) family transcription factors in abiotic stress tolerance. *O. sativa* subsp. *Japonica* has 163 gene loci assigned to this transcription factor. AP2/EREBP transcription factors have been implicated in hormone, sugar, and redox signaling in context of abiotic stresses such as cold and drought. It was suggested that AP2/EREBP transcription factors integrate metabolic, hormonal, and environmental signals in stress acclimation and retrograde signaling [26].

Many transcription factors involved in abiotic stress tolerance in an ABA-dependant manner have been characterized. Two group A bZIP transcription factors in rice, OsABF1 and OsABF2 (*O. sativa* ABA-responsive element binding factor), were found to be expressed in various tissues in rice and induced by different types of abiotic stress treatments, such as drought, salinity, cold, oxidative stress, and ABA [27, 28]. MYBS3 is a single DNA binding repeat MYB transcription factor previously shown to mediate sugar signaling in rice. A recent study revealed that MYBS3 also plays a critical role in cold adaptation in rice. Transgenic rice constitutively overexpressing MYBS3 tolerated 4 °C for at least 1 week and exhibited no yield penalty in normal field conditions. Transcription profiling of transgenic rice overexpressing or underexpressing MYBS3 led to the identification of many genes in the MYBS3-mediated cold signaling pathway. MYBS3 was found to repress the well-known DREB1/CBF-dependent cold signaling pathway in rice, and the analysis revealed that the repression appears to act at the transcriptional level. DREB1 responded quickly and transiently while MYBS3 responded slowly to cold stress, which suggests that distinct pathways act sequentially and complementarily for adapting short- and long-term cold stress in rice [29].

Differences in expression pattern of two abiotic stress-inducible genes in contrasting rice genotypes varying in their salt stress sensitivity were studied [30]. Expression levels of two genes, Rab16A and SamDC, and corresponding proteins, in the seeds, at the background level (dry or water-imbibed state) and ABA-imbibed conditions in rice genotypes M-1-48 (salt sensitive), Nonabokra (salt tolerant), and Gobindobhog (aromatic) were analyzed. An extremely low abundance of Rab16A or practically undetectable SamDC transcripts were observed in M-1-48 and Gobindobhog seeds under control conditions, induced only after exogenous ABA treatment, whereas they were expressed at a much higher level even in dry and water-imbibed seeds of Nonabokra and lesser induced by ABA. The RAB16A and SAMDC protein expression in the three varieties were also identical to the gene expression patterns. Thus, the expression was found to be stress inducible in M-1-48 and Gobindobhog, while constitutive in Nonabokra. Their results indicated that the difference in expression profiles of the two genes is partly responsible for increased salt tolerance in Nonabokra.

In an effort to characterize previously uncharacterized rice genes, a large population of *Arabidopsis* plants were transformed with rice full-length cDNAs to isolate the rice genes that improve the tolerance of plants to environmental stress [31]. One salt-tolerant line identified, R07047, expressed a rice gene, OsSMCP1, which encodes a small protein with a single C2 domain, a Ca^{2+}-dependent membrane targeting domain. Line R07047 showed enhanced tolerance to high salinity, osmotic, dehydrative, and oxidative stresses. Furthermore, R07047 showed improved resistance to *P. syringae*. *In vivo* localization studies revealed the plastid localization of the protein. Overexpression of OsSMCP1 was found to induce overexpression of several nuclear-encoded genes, including the stress-associated genes, in transgenic *Arabidopsis* [31].

In similar experiments, the role of a previously unknown zinc finger transcription factor called DST (drought and salt tolerance) that negatively regulates stomatal closure by direct modulation of genes related to H_2O_2 homeostasis in drought and salt tolerance was analyzed [32]. A DREB1B gene (dehydration-responsive element binding factor) from rice, differentially regulated at the transcriptional level by osmotic stress, oxidative stress, salicylic acid, ABA, and cold, was characterized by overexpression in tobacco plants and analysis of transgenic plants [33]. Another study revealed the involvement of specific MAP kinase kinase (mitogen-activated protein kinase) in different abiotic stress signaling [34]. Two rice calmodulin promoters OsCaM1 and OsCaM3 were characterized by fusion with GUS reporter gene and transformation into tobacco [35].

A study in two wheat recombinant inbred lines contrasting in their salt tolerance examined the expression levels under salt or drought stress of 10 MYB transcription factor genes [36]. Four MYB genes were found to be consistently upregulated in the seedling roots of both genotypes under short-term salt treatment. Three MYB genes were found to be upregulated in both genotypes under long-term salt stress. One MYB gene was upregulated in both genotypes under both short- and long-term salt stress. Of these salt upregulated MYB genes, one MYB gene (TaMYBsdu1) was markedly upregulated in the leaf and root of wheat under long-term drought stress. In addition, TaMYBsdu1 showed higher expression levels in the salt-tolerant genotype than in the susceptible genotype under salt stress, indicating that it is an important regulator involved in wheat adaptation to both salt and drought stresses.

A novel wheat NAC transcription factor gene (TaNAC4) was found to share high homology with rice OsNAC4 gene. TaNAC4 transcript in wheat leaves was induced by the infection of strip rust pathogen and also by exogenously applied methyl jasmonate (MeJA), ABA, and ethylene. Environmental stimuli, including high salinity, wounding, and low temperature, also induced TaNAC4 expression [37]. A pectin methylesterase inhibitor (PMEI) was found to be upregulated under hydrogen peroxide treatments in wheat [38]. Dehydration-responsive element binding factors (DBFs) belong to the AP2/ERF superfamily and play vital regulatory roles in abiotic stress responses in plants. Three novel homologues of the DBF gene family in wheat (TaAIDa-c, *T. aestivum* abiotic stress-induced DBFs) were isolated by screening a drought-induced cDNA library [39]. Overexpression of TaAIDFa activated CRT/DRE-containing genes under normal growth conditions and improved drought

and osmotic stress tolerances in transgenic *Arabidopsis* plants. Vacuolar H^+-translocating pyrophosphatase (V-PPase) is a key enzyme related to both plant growth and abiotic stress tolerance. V-PPase genes TaVP1, TaVP2, and TaVP3 were identified from wheat [40]. TaVP2 was observed to be mainly expressed in shoot tissues and downregulated in leaves under dehydration. Its expression was upregulated in roots under high salinity. TaVP1 was relatively more ubiquitously and evenly expressed than TaVP2. Its expression level in roots was highest among the tissues examined and was inducible by salinity stress. These results indicated that the V-PPase gene paralogues in wheat are differentially regulated spatially and in response to dehydration and salinity stresses.

Sucrose nonfermenting 1-related protein kinase 2 family members play essential roles in response to hyperosmotic stresses in *Arabidopsis*, rice, and maize. A study characterized the function of TaSnRK2.4, an SNF1-type serine/threonine protein kinase of wheat, in drought, salt, and freezing stresses in *Arabidopsis* [41]. Transgenic *Arabidopsis* overexpressing TaSnRK2.4 had enhanced tolerance to drought, salt, and freezing stresses, which were simultaneously supported by physiological results, including decreased rate of water loss, enhanced higher relative water content, strengthened cell membrane stability, improved photosynthesis potential, and significantly increased osmotic potential. The results indicated that TaSnRK2.4 is involved in the regulation of enhanced osmotic potential, growth, and development under both normal and stress conditions and imply that TaSnRK2.4 is a multifunctional regulatory factor in *Arabidopsis*.

A novel aquaporin gene from wheat, TaNIP (*T. asetivum* L. nodulin 26-like intrinsic protein), was characterized in a study [42]. TaNIP was identified and cloned through the GeneChip expression analysis of a salt-tolerant wheat mutant RH8706-49 under salt stress. The overexpression of TaNIP in transgenic *Arabidopsis* produced higher salt tolerance than wild-type plants. Under salt stress treatment, TaNIP overexpressing *Arabidopsis* accumulated higher K^+, Ca^{2+}, and proline contents and lower Na^+ level than the wild-type plants. The overexpression of TaNIP in transgenic *Arabidopsis* also upregulated the expression of a number of stress-associated genes. Their results suggested that TaNIP plays an important role in salt tolerance.

30.4 Evaluation of the Role of MicroRNAs in Abiotic Stress

MicroRNAs (miRNAs) are small single-stranded RNAs with a length of about 21 nt; these noncoding RNAs regulate developmental and stress responses in plants by cleaving mRNAs. Most of the physiological processes are controlled by miRNAs in several organisms including plants. A huge database exists on miRNAs identified from diverse species. However, the processes of data mining of miRs in most of the species are still incomplete. Although many miRNAs have been identified in rice and wheat, relatively little is known about their role in abiotic stress.

Cloning and identification of approximately 40 new putative miRs is reported from a basmati rice variety [43]. About 23 sequences were derived from rice exposed to salt

stress, while 18 were derived from rice infected with tungro virus. A few of these putative miRs were common to both. Their results showed that at least two of these miRs were upregulated in response to both abiotic and biotic stresses. The miR target predictions indicated that most of the putative miRs target specific metabolic processes. The upregulation of similar miRs in response to two entirely different types of stresses suggests a converging functional role of miRs in managing various stresses. Recently, 18 cold-responsive rice miRNAs were identified using microarrays [44]. The existence of hormone-responsive elements in the upstream regions of these cold-responsive miRNAs indicated the importance of hormones in this defense system mediated by miRNAs. Their findings confirm the role of miRNAs as ubiquitous regulators in rice.

Deep sequencing of small RNA libraries is an effective approach to uncover rare and lineage- and species-specific miRNAs in any organism. A study constructed three small RNA libraries from control rice seedlings and seedlings exposed to drought or salt stress and then subjected them to pyrosequencing [45]. A total of 58 781, 43 003, and 80 990 unique genome-matching small RNAs were obtained from the control, drought, and salt stress libraries, respectively. Twenty-three new miRNAs, mostly each derived from a unique locus in rice genome, were identified. Six of the new miRNAs are conserved in other monocots.

In wheat, 12 miRNAs responsive to heat stress have been identified [46]. Another study identified 2076 small RNAs in a small RNA library from leaf, root, and spike of wheat. These small RNAs mapped to noncoding regions, the CDS region of protein-coding genes, and 5′ UTR and 3′ UTR regions. The expression of small RNAs in wheat seedling leaves, roots, and spikes were analyzed by Northern blot, which indicated that some small RNAs were responsive to abiotic stress treatments, including heat, cold, salt, and dehydration [47].

30.5
Generation of Transgenic Wheat and Rice Plants Tolerant to Abiotic Stress

Transgenic rice plants overexpressing ZFP245, a cold- and drought-responsive gene that encodes a zinc finger protein, were found to display high tolerance to cold and drought stresses. The transgenic plants did not exhibit growth retardation, but showed growth sensitivity against exogenous abscisic acid, increased free proline levels, and elevated expression of rice pyrroline-5-carboxylate synthetase and praline transporter genes under stress conditions. Overproduction of ZFP245 enhanced the activities of reactive oxygen species scavenging enzymes under stress conditions and increased the tolerance of rice seedlings to oxidative stress. It was postulated that ZFP245 may contribute to the tolerance of rice plants to cold and drought stresses by regulating proline levels and reactive oxygen species scavenging activities [48].

OsbZIP72, a member of the basic leucine zipper (bZIP) transcription factor family, is an ABRE binding factor in rice. Transgenic rice overexpressing OsbZIP72 showed a hypersensitivity to ABA, elevated levels of expression of ABA response

gene such as LEAs, and an enhanced ability of drought tolerance. These results suggested that OsbZIP72 plays a positive role in drought resistance through ABA signaling [49]. Transgenic rice overexpressing OsbZIP23, another member of the bZIP family, showed significantly improved tolerance to drought and high-salinity stresses and sensitivity to ABA. GeneChip and real-time polymerase chain reaction analyses revealed that hundreds of genes were up- or downregulated in the rice plants overexpressing OsbZIP23, indicating that OsbZIP23 is a major player of the bZIP family in rice for conferring ABA-dependent drought and salinity tolerance [50].

The DREB transcription factors, which specifically interact with C-repeat/DRE (A/GCCGAC), play an important role in plant abiotic stress tolerance by controlling the expression of many cold and drought-inducible genes in an ABA-independent pathway. Three novel DREB genes, OsDREB1E, OsDREB1G, and OsDREB2B, were isolated from rice [51]. Transgenic rice plants analysis revealed that overexpression of OsDREB1G and OsDREB2B in rice significantly improved their tolerance to water deficit stress, while overexpression of OsDREB1E could only slightly improve the tolerance to water deficit stress, suggesting that the OsDREBs might participate in the stress response pathway in different manners.

Overexpression of TERF1 (encoding a tomato ethylene response factor) in transgenic rice resulted in an increased tolerance to drought and high salt [52]. The authors associated the enhanced tolerance with the accumulation of proline and the decrease in water loss. Furthermore, TERF1 was found to effectively regulate the expression of stress-related functional genes Lip5, Wcor413-l, OsPrx, and OsABA2, as well as regulatory genes OsCDPK7, OsCDPK13, and OsCDPK19, under normal growth conditions. *cis*-Acting elements such as DRE/CRT and GCC box exist in TERF1 targeted gene promoters. Similarly, overexpression of a trehalose-6-phosphate phosphatase gene OsTPP1 conferred stress tolerance in rice and resulted in the activation of stress-responsive genes [53].

An aluminum (Al^{3+}) tolerance gene TaALMT1 was overexpressed in transgenic wheat under maize ubiquitin promoter [54]. The transgenics showed increased TaALMT1 expression, malate efflux, and Al^{3+} resistance compared to untransformed controls. Some T_2 lines showed greater Al^{3+} resistance than ET8, an Al^{3+}-resistant reference genotype. Increased drought tolerance was reported in transgenic wheat expressing *Vigna aconitifolia* Δ^1-pyrroline-5-carboxylate synthetase (P5CS) cDNA that encodes the key regulatory enzyme in proline biosynthesis under the control of a stress-induced promoter complex (AIPC) [55]. Drought stress tolerance was accompanied by accumulation of proline in transgenic plants.

30.6 Proteomics

The transcriptome analyses of gene expression at the mRNA level have contributed greatly to our understanding of abiotic stress tolerance in plants. However, the level of mRNA does not always correlate well with the level of protein, the key player in the

cell [56]. Therefore, it is insufficient to predict protein expression level from quantitative mRNA data. This is mainly due to posttranscriptional regulation mechanisms, such as nuclear export and mRNA localization, transcript stability, translational regulation, and protein degradation. Proteome studies aim at the complete set of proteins encoded by the genome and thus complement the transcriptome studies.

Several researchers have used the proteomics approach to identify specific proteins involved in rice stress response. The proteome response of the plasma membrane (PM) to environmental stresses was studied using a subcellular proteomics approach, monitoring changes in abundance of PM-associated protein in response to salinity [57]. The proteome was extracted from a root plasma membrane-rich fraction of a rice salt-tolerant variety, IR651, grown under saline and normal conditions. Comparative two-dimensional electrophoresis revealed that 24 proteins were differentially expressed in response to salt stress. Most of the proteins identified were involved in several important mechanisms of plant adaptation to salt stress, including regulation of PM pumps and channels, membrane structure, oxidative stress defense, signal transduction, protein folding, and the methyl cycle. These results point to the suitability of proteomics approach in identification of stress-regulated proteins.

In another study, a proteomic approach was adopted to investigate the low-abundant proteins in rice leaf in response to cold stress. Rice seedlings were exposed to different temperatures, such as 5 or 10 °C, and samples were collected after different time courses. The researchers were able to identify some novel proteins, such as cysteine proteinase, thioredoxin peroxidase, a RING zinc finger protein-like, drought-inducible late-embryogenesis abundant, and a fibrillin-like protein [58]. Another group of researchers also used proteomics approaches to get new insights into chilling stress responses in rice. Rice cultivar Nipponbare was treated at 6 °C for 6 or 24 h and then allowed to recover for 24 h. The temporal changes in total proteins in rice leaves were examined using two-dimensional electrophoresis [59]. The researchers were able to identify 85 differentially expressed proteins using mass spectrometry analysis that were involved in several processes including signal transduction, RNA processing, translation, protein processing, redox homeostasis, photosynthesis, photorespiration, and metabolisms of carbon, nitrogen, sulfur, and energy. Interestingly, gene expression analysis of 44 different proteins by quantitative real-time PCR showed that the mRNA level was not correlated well with the protein level. This underlines the importance of proteomics in identification of key components in stress tolerance. The same group had previously used proteomic successfully to investigate the salt stress-responsive proteins in rice cv. Nipponbare roots. They were able to identify six novel stress-responsive proteins involved in regulation of carbohydrate, nitrogen, and energy metabolism, reactive oxygen species scavenging, mRNA and protein processing, and cytoskeleton stability [56].

Several studies have suggested a critical role of protein phosphorylation in salt stress response in plants. A study analyzed the differential expression of rice phosphoproteome under salt stress [60]. Seventeen differentially upregulated and eleven differentially downregulated putative phosphoproteins were identified. The same group further identified 31 salt stress differentially regulated proteins, the

majority of which have not been reported in the literature. Thus, proteomics is indeed a valuable tool in providing new insight into plant response to abiotic stress.

Cell wall proteins (CWPs) are important both for maintenance of cell structure and for responses to abiotic and biotic stresses. To determine differentially expressed CWPs in wheat under flooding stress, gel-based proteomic and LC–MS/MS-based proteomic techniques were used [61]. Eighteen proteins were found to be significantly regulated in response to flood by gel-based proteomics and 15 proteins by LC–MS/MS-based proteomics. Among the flooding downregulated proteins, most were related to the glycolysis pathway and cell wall structure and modification. However, the most highly upregulated proteins in response to flooding belong to the category of defense and disease response proteins. Among these differentially expressed proteins, only methionine synthase, beta-1,3-glucanases, and beta-glucosidase were consistently identified by both techniques. The downregulation of these three proteins suggested that wheat seedlings respond to flooding stress by restricting cell growth to avoid energy consumption; by coordinating methionine assimilation and cell wall hydrolysis, CWPs played critical roles in flooding responsiveness. The implication of different drought treatments on the protein fractions in grains of winter wheat was examined using ^{1}H nuclear magnetic resonance spectroscopy followed by chemometric analysis [62]. Principal component trajectories of the total protein content and the protein fractions of flour, as well as the ^{1}H NMR spectra of single wheat kernels, wheat flour, and wheat methanol extracts, were analyzed to elucidate the metabolic development during grain filling. The results from both the ^{1}H NMR spectra of methanol extracts and the ^{1}H HR-MAS NMR of single kernels showed that a single drought event during the generative stage had as strong an influence on protein metabolism as two consecutive events of drought. In contrast, a drought event at the vegetative growth stage had little effect on the parameters investigated.

30.7 Metabolomics

Even after the completion of the whole-genome sequencing in many plants, networks of gene to metabolite are largely unknown. To reveal the function of genes involved in metabolic processes and gene-to-metabolite networks, the metabolomics-based approach is regarded as a direct way. In particular, integration of comprehensive gene expression profile with targeted metabolite analysis is shown to be an innovative way for identification of gene function for specific product accumulation in plants [63].

Metabolomics represents the exhaustive profiling of metabolites contained in organism. Proteomics and transcriptomics are both considered to be a flow of media concerning genetic information. In contrast, metabolomic should be thought as being concerned with phenotype [64]. Perturbations including environmental change, physical stress, abiotic stress, nutritional stress, mutation, and so on lead

to changes in the metabolome. Analysis of these changes serves to fine-tune our knowledge on plant response to environmental changes, physical stress, abiotic stress, nutritional stress, mutation, and so on.

Capillary electrophoresis–mass spectrometry (CE–MS) and capillary electrophoresis diode–array detection (CE–DAD) were used to analyze the dynamic changes in the level of 56 basic metabolites in rice foliage at hourly intervals over a 24 h period [65]. They found that in response to environmental stress, glutathione and spermidine fluctuated synchronously with their regulatory targets.

Overexpressing YK1gene, the homologue of the HC toxin reductase (HCTR) gene, in transgenic rice was accompanied by an increase in the amounts of NAD(P)(H). Besides HCTR activity, YK1 also possessed dihydroflavonol-4-reductase activity [66]. The overexpression of YK1 was found to induce the activation of enzymes in the NAD synthetic pathway, which resulted in an increase in the amount of NAD(P)(H). These results implied that the coupled increase in DFR activity and amounts of NAD(P)(H) may contribute to biotic and abiotic stress tolerance. A metabolite profiling of YK1 transgenic rice was done by CE/MS [67]. They analyzed several metabolites of glycolysis, the tricarboxylic acid (TCA) cycle, and the pentose phosphate pathway. In addition, the concentrations of sugars and ions were quantified. Their results indicated that in YK1 overexpressing plants, the concentrations of *cis*-aconitate, isocitrate, and 2-oxoglutarate were higher in leaves, whereas those of fructose-1,6-bisphosphate and glyceraldehyde-3-phosphate were lower in roots. In seeds, the amounts of free amino acids and metals were altered, whereas sugars in seeds were kept constant. While the overexpression of YK1 was associated with only slight changes in the amounts of several metabolites analyzed, glutathione derivatives were substantially increased in suspension cultured cells.

Impact of nitrogen (N) and sulfur (S) deficiency on N and S remobilization from senescing canopy tissues during grain filling in winter wheat was studied using transcriptomic and metabolomic approaches [68]. Nuclear magnetic resonance (NMR) metabolite profiling revealed significant effects of suboptimal N or S supply in leaves but not in developing grain. Analysis of amino acid pools in the grain and leaves revealed a strategy whereby amino acid biosynthesis switches to the production of glutamine during grain filling. Glutamine was found to accumulate in the first 7 days of grain development, prior to conversion to other amino acids and protein in the subsequent 21 days. Transcriptome analysis indicated downregulation of the terminal steps in many amino acid biosynthetic pathways. Their results indicated that vegetative tissue N has a greater control over the timing and extent of nutrient remobilization than S.

30.8
Conclusions and Perspectives

The progress of "omic" technologies during the past decade has been spectacular. After sequencing the complete genome of *Arabidopsis* in 2002, the technology has

catapulted, significantly reducing the time and cost required to sequence the complete genome of a higher plant. The next-generation sequencing technologies have generated an information explosion that scientists all over the world are earnestly exploring. Genomics, transcriptomics, proteomics, and metabolomics investigate different facets of a given scientific issue such as abiotic stress tolerance, but complement each other. Integration of phenotypic, genetic, transcriptomic, proteomic, and metabolomic data will enable accurate and detailed gene network reconstruction. This will ultimately result in the elucidation of the molecular pathways involved in complex phenotypic traits. A better understanding of genetic and cellular mechanisms behind abiotic stress tolerance would facilitate generation of transgenic plants with desired traits with little or no undesired/unforeseen effects.

Rice: Genomics-Assisted Breeding for Drought Tolerance

Prashant Vikram, Arvind Kumar, Alok Singh, and Nagendra K. Singh

Rice is a major source of global food calories. Increasing population pressure, unpredictable rainfall patterns, shrinking fresh water resources, and increased frequency of severe drought spells in recent years are the reasons behind putting concerted efforts toward breeding drought-tolerant rice cultivars much needed by the rice farmers. Attempts to breed rice for stress environments have made limited progress so far, but success with recent research on identification of major QTL (quantitative trait loci) for grain yield under drought shows that genomics-assisted breeding could be a viable alternative to enhance grain yield under drought. Major QTL with consistent effects on grain yield under drought and different drought-related traits have been mapped on rice chromosome 1, 2, 3, 9, and 12 and search is on for the genes underlying these QTL. Direct selection for yield under drought has emerged as an important criterion for both conventional and molecular breeding approaches. Transgenic rice with overexpression of transcription factors such as *DREB1* and *SNAC1* has shown considerable promise, but its use in breeding is still impeded.

31.1
Introduction

Rice is the most important food crop of the world, cultivated in an area of about 150 million ha. Despite huge annual production of over 550 million ton, only about 4% of the total production is traded in international markets. In Asia, rice supplies 35–60% of the total food calories [1]. In countries where rice is the major food source, including China, India, and Indonesia, the average annual rate of population growth (1.7%) has been higher than 1.2% average growth in rice production [2]. According to FAO estimates, the world population would be around 9.8 billion by 2050 and 75% more food would be required to feed the additional population [3]. Global warming and unpredictable rainfall patterns in recent past have led to severe drought spells causing huge yield losses and severe shortage in food production in several parts of the world.

Improving Crop Resistance to Abiotic Stress, First Edition.

Rice is a semiaquatic plant that is grown under four different cropping environments: irrigated, rain-fed lowland, rain-fed upland, and deep water [4]. Irrigated rice is by far the most common ecosystem constituting 55% of the acreage and 75% of the production globally [1]. The rain-fed lowland rice constitutes the second most important ecosystem sharing 25% of the global rice area. These are fields that do not receive irrigation water, but there are bunds around the fields that allow the water to accumulate on the field surface when there is rain [1]. Deep-water rice is planted in the areas that are naturally flooded during the rainy season. This rice represents about 8% of the total rice-growing area and here rice seeds are broadcasted a few weeks before the beginning of the monsoon season [1]. Rain-fed upland, also called dry land, rice is the type grown in areas where good soil drainage combined with an uneven land surface makes the accumulation of water impossible. Upland rice represents around 12% of world acreage and is the rice ecosystem with the lowest yields of all [1].

Rice production losses due to drought are common in more than 23 million ha of rain-fed area in South Asia, Southeast Asia, and Sub-Saharan Africa [5, 6]. In severe drought years, total rice production losses have reached as high as 40%, valued at US$650 million in the eastern Indian states of Jharkhand, Orissa, and Chhattisgarh alone [7]. In India, the 2002 drought affected 55% of the country's area and 300 million people when rice production declined by 20% from the interannual baseline [8]. Recent drought in 2009 has resulted in 16% reduction in rice production leading to high price rise and food security concerns. In 2004, a severe drought affected more than 2 million ha of the cropped area in Southeast Asia affecting the livelihood security of over 8 million people [8]. Drought also affects production in millions of hectares dependent on surface irrigation, where river flows and water impounded in ponds and reservoirs may be insufficient to irrigate the rice crop [9]. Water deficit is predicted to be a major challenge for sustainable rice production in future due to progressive climate change processes [100]. Despite drought being a major constraint to rice production, little success has been made in developing drought-tolerant rice cultivars. Most of the improved cultivars grown in drought-prone areas are the varieties originally bred for irrigated conditions and are highly susceptible to drought. Predicted increase in incidence of drought due to climate change presses the need to develop drought-tolerant high-yielding cultivars [10–12].

Drought may simply be defined as reduction in yield due to shortage of water [13]. Drought in the rice crop is classified on the basis of growth stage of the crop facing drought. There may be four kinds of drought: (i) seedling stage drought, (ii) vegetative stage drought, (iii) intermittent drought, and (iv) reproductive stage or terminal drought. Reproductive stage drought is the most devastating in terms of yield reduction [14]. Drought tolerance has long been regarded as a complex trait related to various physiological and biochemical parameters. These may include root traits, osmotic adjustment (OA), and maintenance of plant water status. QTL for these component traits and yield under drought have been identified and are being employed in molecular breeding of rice.

31.2
Morphophysiological Basis and Breeding for Drought Tolerance in Rice

Rice plant employs several mechanisms to deal with the drought stress and these mechanisms vary widely from one cultivar to other. Plants may adopt shorter life cycle to escape or avoid drought or they may have phenological adaptations, for example, thick cuticles for reduced evapotranspiration and long and thick roots to enable the plant to fetch water from deeper soil layers. Physiological traits such as osmotic adjustment to maintain cell turgor pressure during dehydration and ability to recover from desiccation are also important components of drought tolerance [15, 16]. Regarding traits for breeding drought tolerance in rice, there are two important considerations, the stress responsiveness of the trait and maintenance of plant water status (Figure 31.1, [17]).

Rice is a highly drought-susceptible plant. One of the reasons for this is its very thin layer of epicuticular wax that is about 20% of that in sorghum, a relatively drought-tolerant crop [15]. The resistance of rice cuticle to water loss is, therefore, low and it loses water even when its stomata are closed [18, 19]. Upland rice cultivars that are relatively more drought tolerant usually have a thicker epicuticular wax layer than the irrigated rice cultivars, indicating that the wax layer plays an important role in drought resistance. Osmotic adjustment is another well-known phenomenon that enables plants to survive water stress, but application of this trait in rice breeding is still under debate. Some scientists believe that it can be an important part of the solution leading to development of drought-tolerant rice [15, 20], whereas others are skeptical about the usefulness of this approach [18].

In upland varieties, a deeper root system enables rice plants to extract more water from the lower soil layers under drought conditions [21]. In most cases, the number of roots may not matter, but thickness and length of the roots help large xylem vessels to extract moisture even under severe stress [15, 18]. Root-to-shoot weight ratio becomes quite important in this case. Higher the root-to-shoot weight ratio, the more a rice cultivar is likely to be tolerant to drought. However, partitioning of carbon between source (shoot) and sink is important here because if too much carbon is utilized for the root growth, then yield is likely to be adversely affected [22].

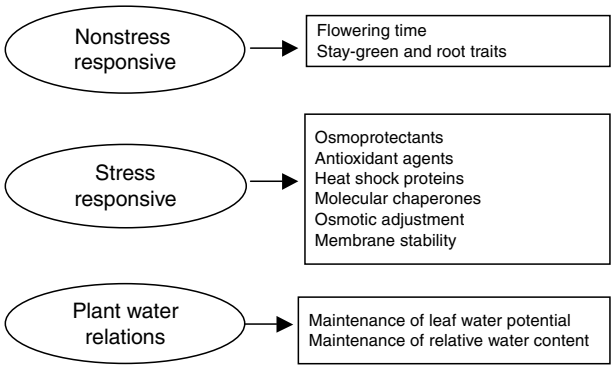

Figure 31.1 Different categories of drought tolerance traits in rice.

Lack of effective selection criteria for component traits of drought tolerance and low heritability of grain yield under stress are cited as major reasons for the slow progress in breeding for drought tolerance and the use of secondary traits for yield improvement [23–31]. Gains in yield by selecting for secondary traits have not yet been clearly demonstrated in rice. Significant scientific progress over the last 6 years in (i) stress genomics, (ii) breeding and phenotyping methodology [12, 32, 33], and (iii) better understanding of the drought tolerance mechanisms [18] has made it promising to develop drought-tolerant varieties with high yield potential. Recent studies at International Rice Research Institute (IRRI) have demonstrated the effectiveness of direct selection for grain yield under drought stress [12, 13, 34–36]. Direct selection for grain yield under drought has led to release of two breeding lines developed at IRRI, namely, IR74371-70-1-1 and IR74371-54-1-1, for cultivation in India and Philippines, respectively, in 2009.

Breeding line IR74371-70-1-1 was developed at IRRI from IR55419-04*2/Way Rarem cross, IR55419-04 being the drought-tolerant donor, and distributed to National Agricultural Research and Education Systems (NARES) partners in 2003. A selection from this line, IR 74371-70-1-1-CRR-1, was first tested at several locations in IRRI-India Upland Rice Shuttle Breeding Network (URSBN). It was nominated for testing under the All India Coordinated Rice Improvement Program (AICRIP) by Central Rainfed Upland Rice Research Station (CRURRS) of ICAR from 2005 to 2007. In the AICRIP trials, it showed yield advantage of 29.2 and 19.1% over the national and regional check varieties under drought-affected situations. It has an average yield advantage of 0.5 ton ha^{-1} under moderate drought and 1.0 ton ha^{-1} under severe drought over IR64. It was released by the name "Sahbhagi Dhan" for cultivation in drought-prone Jharkhand and Orissa states of India.

31.3 Mapping of QTL for Drought Tolerance in Rice

Quantitative trait loci (QTL) have been identified for almost all drought-related traits in rice. Around 20 different mapping populations have been screened both for drought-related secondary traits and for yield under drought (Table 31.1). Slow progress in breeding for drought-tolerant rice varieties has been attributed to failure to identify QTL with large and consistent effects on yield that could be used for marker-assisted selection [16, 37–42]. Most of the mapping populations studied for the identification of secondary traits associated with drought tolerance have been derived from parents that do not differ very widely for drought tolerance. Many traditional varieties and land races of rice adapted to drought-prone areas have high level of drought tolerance, but they have rarely been used as parents in the QTL mapping studies. Many of the mapping populations used for QTL mapping are derived from indica/japonica crosses because they show higher marker polymorphism [43].

Recent research at IRRI in partnership with NARES using well-characterized drought-tolerant donors as one of the parents in the mapping/breeding populations

Drought resistance traits	IR20/Nootripathu	[66]

has identified QTL with major and consistent effect on rice yield under drought [58, 59, 65]. Bernier *et al*. reported a QTL on chromosome 12 (q$DTY_{12.1}$) in the Vandna/Way Rarem population that explained 51% of the genetic variance for yield under drought [59]. Till now this QTL has shown the largest effect for grain yield under drought in several genetic backgrounds. The q$DTY_{12.1}$ also showed large and consistent effect in target environments in a wide range of moderate to severe drought situations [67, 68]. A major QTL for grain yield under lowland drought, explaining 32% of the phenotypic variance, was reported on rice chromosome 1 in CT9993/IR62266 population [58]. Subsequent studies have identified major QTL with consistent effect on grain yield under lowland drought on chromosome 2 (q$DTY_{2.1}$) and 3 (q$DTY_{3.1}$) in Apo/2*Swarna mapping population. The $DTY_{2.1}$ and $DTY_{3.1}$ QTL explain 13–16 and 31% of the phenotypic variance of the trait, respectively, rendering them useful for marker-assisted breeding for yield under lowland drought stress [65]. Recently, a common QTL for yield under drought (q*DTY1.1*) has been reported in three different mapping populations involving Indian drought-tolerant variety N22 [63, 64].

In case of new rice for Africa (NERICA), drought tolerance QTL have been introduced from *Oryza glaberrima* into *O. sativa*, producing better-adapted alien introgression lines for drought-prone areas of African continent [48]. QTL for yield have also been identified in *O. rufipogon* and other wild rice species that may provide a source of new genes for drought tolerance [45, 48, 69, 70]. This approach also opens up opportunities for the application of genomics for the identification of drought tolerance genes. Comparative genome analysis shows that some of the drought tolerance QTL identified in rice have their homologues in other crop species, for example, barley and maize, indicating that genes conferring drought tolerance in one grass species may have a similar effect on another species of this family. These genes seem to be conserved in many different grass species during the course of evolution; therefore, knowledge gained from the research carried out in rice will be useful in breeding other cereal crops and vice versa [16].

31.4 Meta-Analysis of Drought Tolerance QTL in Rice

A large number of minor QTL for different drought-related traits have been mapped on almost all the 12 rice chromosomes. Therefore, the use of bioinformatics tools has become imperative for the identification of consensus QTL and candidate genes. Meta-analysis combines the results of several QTL mapping studies and provides narrow confidence intervals for meta-QTL. This simplifies the identification and positional cloning of the candidate genes. Meta-analysis is usually applied to multiple mapping populations, but it can be applied to a single population as well [71]. Combining QTL data from studies employing different mapping populations would be extremely helpful in identifying candidate genes by positioning consistent QTL with more precision. Meta-analysis of QTL enables us to work out "hot spot" regions in the genome. Within those regions, one can look for the gene(s) underlying QTL

more precisely. This approach has already been applied for the analysis of root trait QTL in rice [72]. Interestingly, a QTL mapped on the long arm of chromosome 1 for grain yield under drought in different populations emerged as one of the hot spots for the root trait QTL in the meta-analysis [72].

31.5 Marker-Assisted Selection and Pyramiding of Drought Tolerance QTL in Elite Rice Cultivars

A large number of QTL have been identified in rice for drought tolerance and yield under drought, but their introgression in the popular varieties of rice has just begun. The major drawback in this approach is the linkage drag – transfer of undesired traits along with the trait of interest due to their tight genetic linkage. One of the most successful examples of marker-assisted backcross breeding in rice for abiotic stress tolerance is introgression of *Sub1* gene for submergence tolerance into popular mega variety of rice "Swarna" to create Swarna-*sub1*, where three kinds of markers were used: (i) a gene-based functional marker for the selection of favorable *Sub1* allele, (ii) two markers flanking the QTL to eliminate the linkage drag, and (iii) random background markers for fast recovery of the genetic background of the recipient variety during backcrossing [73]. Drought-tolerant donors in most populations screened for the QTL analysis are traditional varieties with low-yield potential, poor response to high-input management, early duration, taller plants, and sometimes carrying undesirable characteristics such as high grain shattering. One or more of such undesirable traits may be located near the drought QTL regions, hence a potential linkage drag in breeding for drought tolerance.

Despite the large number of drought tolerance QTL identified, limited attempts have been made for the introgression of these QTL into high-yield breeding lines [43, 69]. The limited success in the past may be due to involvement of minor QTL explaining very small proportion of the total phenotypic variation (5.6–17.7%) and lack of adequate fine mapping to develop tightly linked markers for breeding applications. As a result, the desirable genes could be lost due to recombination between gene for the trait and the marker during backcrossing [74]. Recent progress in identification and fine-mapping of major QTL for yield under drought has paved the way for introgression of such QTL in mega rice varieties through marker-assisted backcrossing in the near future.

Marker-assisted selection (MAS) could be applied with some modification of strategies such as single large-scale marker-assisted selection (SLS-MAS) and marker-assisted recurrent selection (MARS) [75, 76]. The main features of SLS-MAS are that (i) MAS could be performed at F2 or preferably F3 populations derived from elite lines, (ii) flanking markers are less than 5 cM away from the QTL, and (iii) QTL chosen should explain large proportion of the phenotypic variation and be stable across environments. This involves a four-step procedure: (i) identification of elite lines outstanding for the trait of interest, (ii) identification of the most favorable genomic regions for each parental line, (iii) intercrossing of elite lines to develop

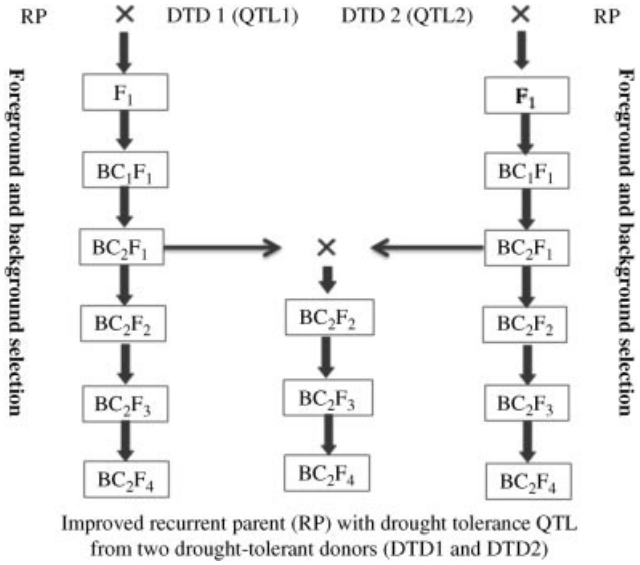

Figure 31.2 Schematic plan for simultaneous but stepwise method for transfer of drought tolerance QTL/genes from multiple donors in rice (A. K. Singh, Genetics, IARI, New Delhi).

segregating populations, and (iv) selection of plants homozygous for the favorable alleles at target loci.

Pyramiding of QTL is another approach for breeding drought-tolerant rice. A large number of QTL introgression lines (ILs) could be created in elite backgrounds using backcross (BC) breeding, each of which carries different genomic segments for improved drought tolerance from known donors. The ILs are then intercrossed to pyramid all QTL into one variety (Figure 31.2). A drawback of this approach is the linkage drag from donor parents used for the introgression of different QTL. Therefore, this needs to be approached with utmost care, particularly when targeting introgression of several QTL into one line [77].

31.6 Comparative Genomics for Drought Tolerance

Comparative mapping of the genomic regions across species is an interesting alternative for the identification and positional cloning of the candidate genes underlying drought tolerance QTL. QTL for leaf water potential, relative water content, and other drought-related traits have been identified on barley chromosome 7 H [78]. Leaf water potential and RWC QTL are also identified at orthologous position on rice chromosome 8 in the C039/Moroberekkan mapping population [44]. A major gene called *Or* controlling osmoregulation has been identified at the same orthologous position in wheat chromosome 7A [79]. The synteny and colinearity of genes among cereals is much more complex with many exceptions, and it is difficult

to find comparable QTL map locations in cereals due to polyploidy and transposition of genes [80]. However, such analysis is possible by microsynteny analysis for similar QTL regions in different cereals as shown in the above example of the *Or* gene.

31.7 Transcriptomics and Proteomics for the Identification of Drought Tolerance Genes in Rice

Since hot spots for drought tolerance QTL in the rice genome are known, it is now relatively simple to identify differentially expressed candidate genes in these regions for understanding drought tolerance in rice. *In silico* analyses have been carried out for the QTL regions flanked by the molecular markers and candidate genes identified through functional homology. A study has identified 48 candidate genes on rice chromosome 1 between markers RM212 and RM319, of which 16 were suggested for their potential role in drought tolerance [81]. Similar *in silico* analyses have been done and candidate genes identified on chromosome 1, 2, 4, 8, and 9 [82]. Several transcription factor genes, for example, *CBF/DREB1*, *DREB2*, *RD29B*, *RD22*, *ICE1*, *CDPK*, *ABF3*, *CBF3*, and *SNAC1* have been studied for their differential expression and regulatory role under drought stress [83–86]. Some of these genes have been transferred to rice through transgenic approach to validate their role in drought stress tolerance (Table 31.2).

Table 31.2 List of transcription factors genetically transformed in rice for drought tolerance.

Gene	Trait	References
HVA1 (barley group 3 LEA protein)	Drought and salt	[87]
P5CS, encoding pyrroline-5-carboxylate synthetase	Drought	[88]

OsDHODH1	Drought, salt	[100]
ONAC045 (NAC gene)	Drought, salt	[101]

Most of the genes presumed to be involved in the drought tolerance are involved in (i) signal transduction, (ii) osmotic adjustment, and (iii) transcriptional regulation of the stress response pathway, for example, *DREB1* and *SNAC1*. Transgenic rice with overexpression of *SNAC1* gene showed 22–34% higher seed setting than control plants [83]. However, successful commercialization of these transgenic lines is still questionable due to complex gene interactions. Despite considerable progress in the development of transgenic rice lines, their impact on enhancing drought tolerance under field conditions is still awaited. These lines need to be tested in field drought environments and for their biosafety and other regulatory issues prior to their deployment in popular rice varieties through marker-assisted backcross breeding. Screening of transgenic plants for drought tolerance has been usually done under controlled glasshouse, but selection for drought-tolerant rice varieties is advocated in the target drought-prone environments [102, 103].

Proteomics approach has also been followed by some workers, and more than 2000 proteins were analyzed by 2D electrophoresis [104]. Drought-induced changes were observed in actin depolymerizing factor (ADF), which is a chloroplastic glutathione-dependent dehydroascorbate reductase. ADF concentration was higher in drought-tolerant cultivars before stress and it increased further in leaf blades, leaf sheaths, and roots after exposure to drought, suggesting that ADF could be one of the target proteins for drought tolerance [105]. Differentially expressed proteins could be worked out through protein profiling of the mapping populations.

31.8 Conclusions

Rice is a semiaquatic species highly susceptible to drought. Global warming, unpredictable rainfall patterns, and climate change would cause more severe stress situations in the rain-fed agriecosystems in future. Efforts for developing drought-tolerant rice varieties through conventional breeding by direct selection for grain yield under drought have yielded some success, and molecular breeding approaches are now beginning to be employed for introgression of major QTL for grain yield under drought. Genes underlying these QTL are being deciphered using genomics approaches. Transgenic rice plants have also been developed with transcription factors such as *DREB1* and *SNAC1*, but these need to be evaluated under field drought environment to validate their actual potential for increasing rice production. However, drought tolerance is a complex trait and discovery of useful alleles of the genes involved in the drought response pathway requires extensive use of genomics approaches and high-precision phenotyping employing modern phenomic facilities in addition to repeated field phenotyping in the target environment.

Rice: Improving Cold Stress Tolerance

Kodiveri Muthukalianan Gothandam

Rice plant normally grown in tropical and temperate climatic zones is often threatened by cold stress and is especially sensitive to chilling stress at the seedling and reproductive stages. Low temperature at the seedling stage can result in poor germination, stunted seedlings, yellowing or withering, and reduced tillering. Unpredictable cold snaps at the reproductive stage delay heading and result in pollen sterility, which was thought to be one of the key factors responsible for the reduction in grain yield of rice. Cold stress prevents the expression of full genetic potential of plants owing to its direct inhibition of metabolic reactions and, indirectly, through cold-induced osmotic, oxidative, and other stresses. In this chapter, various aspects of improving rice cold tolerance are discussed.

32.1
Introduction

Rice is one of the three important cereals and it is produced annually at worldwide levels of more than 600 million ton. Unlike the other major cereals, more than 90% of rice is consumed by humans. Approximately, half the world's population derives a significant proportion of their caloric intake from rice consumption. As little new land is available to increase rice cultivation, larger yields will be needed to meet the anticipated higher demand. On the other hand, temperature is a major factor that limits the geographical locations suitable for growing rice plants. Plants exhibit a maximum rate of growth and development at an optimum temperature or over a diurnal range of temperatures. When ambient temperature deviates from the optimal, physiological, biochemical, metabolic, and molecular changes occur within plants. This is an effort of plants to maximize growth and developmental processes and maintain cellular homeostasis during such adverse conditions. Under increasingly stressful conditions, plants experience progressively more abnormal, impaired, or dysfunctional cellular and whole-plant processes until the cardinal temperatures for survival are reached [1]. At the extremes of the natural temperature range of a plant, the degree of physiological, cellular, metabolic, and molecular dysfunction becomes so severe that it leads to death. Plants feel stress under both

high and low temperature exposure. Mesophilic temperate plants possess inducible temperature stress tolerance. During high-temperature exposure, stress tolerance can be induced by exposure to short-term elevated temperature and this is known as acquired thermotolerance [2], while at lower temperatures, stress tolerance can be induced by exposure to reduced temperature and this is known as chilling tolerance and/or cold acclimation. Chilling tolerance is the ability of a plant to tolerate low temperatures (0–15 °C) without injury or damage [3], while cold acclimation is an enhanced tolerance to the physical and physicochemical vagaries of freezing stress [4]. Both cold acclimation and chilling tolerance involve an array of biochemical, molecular, and metabolic processes [2, 5, 6]. Exposure of plants to temperature stress leads to the modification of metabolism in two ways. First, plants try to adjust their cellular metabolism altered due to rising or falling of temperatures. Temperature stress changes the structure, catalytic properties, and function of enzymes [7] and membrane metabolite transporters. Interestingly, regulatory mechanisms of plants become active and function to restore normal metabolite levels and, most importantly, metabolic fluxes [8, 9]. Second, the modifications of metabolism in response to temperature stress are mainly linked to enhanced tolerance mechanisms. Many metabolites are thought to have important properties that could contribute to induced stress tolerance [10]. In this chapter, emphasis is placed on the general response to the cold stress, and various factors involved in cold acclimation and their roles in cold tolerance are discussed.

32.2 Effect of Cold Stress on Rice

Rice is widely cultivated in different natural environments. Compared to other cereal crops such as wheat (*Triticum aestivum*) and barley (*Hordeum vulgare*), rice is much more sensitive to low temperature as a result of its tropical origin [11]. For rice, temperatures lower than 20 °C decrease both the speed and the percentage of germination. Plants exposed to cold stress show various phenotypic symptoms that include reduced leaf expansion, wilting, and chlorosis (yellowing of leaves) and may lead to necrosis (death of tissue). The phenotypic symptoms of rice seedlings and mature plants upon exposure to cold stress are shown in Figure 32.1.

With regard to the genetic bases for cold tolerance in cultivated rice, few major genes, such as Chs1 [12], Cts1 [13], and Cts2 [14], are reported to confer cold tolerance at the seedling stage; however, recent quantitative trait locus (QTL) analyses revealed that numerous QTL for cold tolerance are present on the rice genome [15–21], suggesting that adaptation to cold climates might involve complex features in physiological and genetic mechanisms.

Cold stress also severely affects the reproductive development of plants and this has been seen in rice plants at the time of anthesis (floral opening), which leads to sterility in flowers. Male sterility is the most severe consequence among the many chilling-induced agronomic damages in rice production. The developmental stages from pollen formation to fertilization are the most vulnerable to low temperature through-

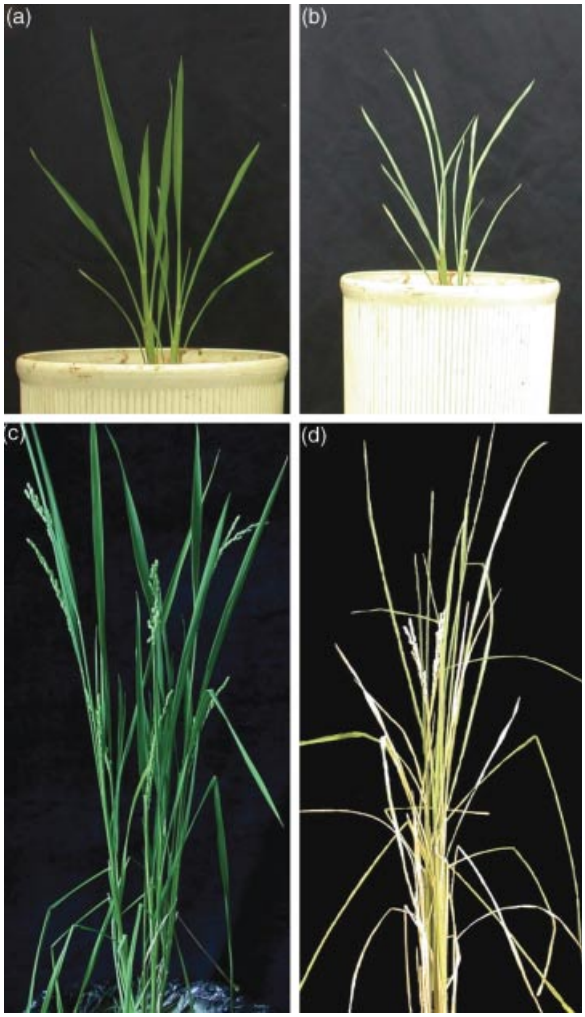

Figure 32.1 Effect of cold stress on rice seedlings and mature plant. Rice seedlings were exposed to 4 °C for 12 h and then allowed to recover. Mature rice plants were exposed to 4 °C for 36 h and allowed to recover. Damage due to cold stress is seen as wilting, chlorosis, and necrosis. (a and c) Unstressed. (b and d) Cold stressed.

out the life cycle of rice plants [22, 23]. It has been reported that the young microspore stage in pollen development was the most sensitive to low temperature [24]. Exposure of rice plants at the tetrad stage to a moderately low temperature (12 °C) for 4 days resulted in male sterility in 80% of spikelets [22, 25]. Microscopic observation of developing rice anthers suggested that one possible reason for the male sterility after low-temperature treatment was the failure of anther development. The observed abnormalities included the cessation of anther development, the arrest of pollen

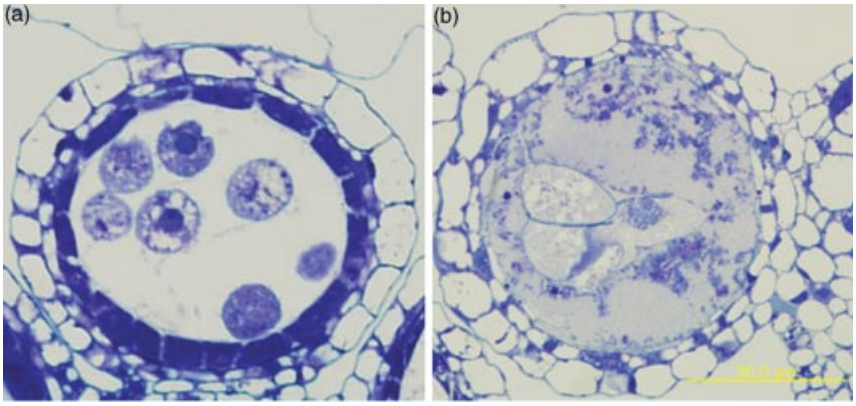

Figure 32.2 Cytological analysis of rice anther development (uninucleated stage) under cold stress. Rice plants were exposed to 16 °C, 10 h daylight. Cold stress resulted in abnormal swelling of tapetum layer and this abnormal swelling further dilated into the locular space, leading to abortion of microspores. (a) Unstressed (control). (b) Cold stressed.

development, anthers remaining within the flowers after anthesis, and partial or no dehiscence. Cytological observation revealed a dilation of tapetal layers in chilling-treated rice anthers [22, 24]. The dilation of tapetal layer was accompanied by a vigorous augmentation of cytoplasmic organelles such as mitochondria, proplastids, golgi bodies, and endoplasmic reticulum [22]. Chilling temperature treatment also affects the physiological status of anthers. Unpredictable cold snaps at the reproductive stage delay heading and results in pollen sterility, which was thought to be one of the key factors responsible for the reduction in grain yield of rice [24, 26–29]. The cytological observations of the tapetum under cold stress are shown in Figure 32.2.

32.3
Effect of Cold on Plant Physiology

Each plant has its unique set of temperature requirements that are optimum for its proper growth and development. A set of temperature conditions that are optimum for one plant may be stressful for another plant. Chilling-sensitive plants characteristically exhibit structural injuries and may suffer from metabolic dysfunction when chilled [30]. Chilling ultimately results in loss of membrane integrity, leading to solute leakage. Integrity of intracellular organelles is also disrupted, leading to the loss of compartmentalization and reduction and impairing of photosynthesis, protein assembly, and general metabolic processes. The physiological change in response to exposure to low temperature that triggers tolerance against freezing is known as "cold acclimation." The primary function of cold acclimation is to stabilize the integrity of cellular membranes against freezing-induced injury [31]. Cold acclimation also results in physical and biochemical restructuring of cell membranes through changes in the lipid composition, induction of other nonenzymatic proteins,

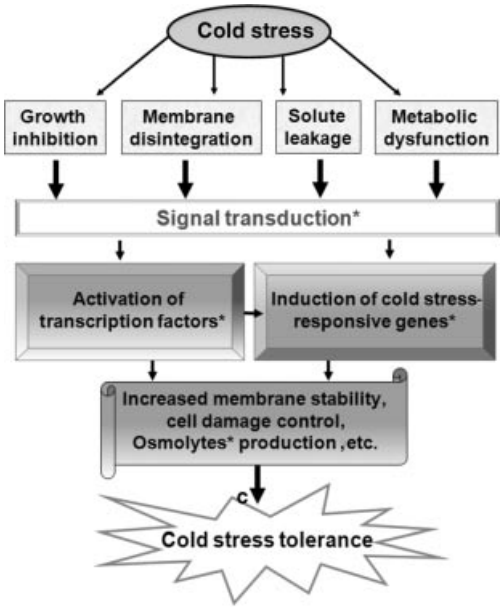

Figure 32.3 Cold stress response is perceived by plants through a signal transduction that leads to the activation of transcription factors and cold-responsive genes. Components involving in the rice cold stress tolerance are discussed in detail in the chapter (indicated by an asterisk in the figure).

enhancement of the antioxidative mechanisms, increased cellular sugar levels, and accumulation of cryoprotectants [32]. The stress response mechanism involves enzymes with biochemical roles that are believed to be major components of cellular defenses to protect cells against potential membrane damage [33]. These enzymes, such as Δ^1-pyrroline 5-carboxylate synthase, adjust the osmotic potential and thereby enhance the stability of cell membranes by increasing the desaturation of fatty acids in membrane lipids [34]. All these modifications help the plant to withstand and surpass the severe dehydration associated with cold stress. The responses of rice plants during cold stress and acclimation mechanisms are shown in Figure 32.3.

32.4
Transcription Factors in Rice Cold Stress

Understanding the mechanisms by which plants perceive environmental signals and transmit the signals to cellular machinery to activate adaptive responses is of fundamental importance to biology. Molecular studies have identified many genes that are induced or upregulated by stress [35–37]. Gene expression profiling using cDNA microarrays or gene chips has identified many more genes that are regulated by cold, drought, or salt stress [38–40]. Although the signaling pathways responsible

for the activation of these genes are largely unknown, transcriptional activation of some of the stress-responsive genes is understood to a great extent. In rice, numerous transcription factors have been found to play important roles in response to cold stress. The best characterized regulon of cold stress responses in plant contains transcription factor C-repeat binding factor/dehydration-responsive element binding factor (CBF/DREB) and its cold-inducible target genes, known as COR (cold-regulated gene), KIN (cold-induced gene), RD (responsive gene to dehydration), or LTI (low-temperature-induced gene) [41–49]. The promoters of RD29A (also known as COR78/LTI78) genes contain both ABRE and dehydration-responsive element (DRE)/CRT factors [50, 51]. Transcription factors belonging to the EREBP/AP2 family that bind to DRE/CRT were termed CBF1/DREB1B, CBF2/DREBC, and BF3/DREB1A [51, 54]. These transcription factor genes are induced early and transiently by cold stress and, in turn, activate the expression of target genes. Similar transcription factors DREB2A and DREB2B are activated by osmotic stress and may confer osmotic stress induction of target stress-responsive genes [53]. Several bZIP, bHLH, WRYK, MYB, NAC family members are involved in improving cold stress [55].

32.5
Improving Cold Stress Tolerance in Rice

Screening for genes involved in cold tolerance is an important initial step. Large numbers of studies are done on engineering cold stress tolerance in rice, essentially using compounds such as compatible solutes, membrane transporters, regulators of signal transduction or transcription, and cold-responsive genes.

For improving the cold stress tolerance in rice, any one or a combination of the following methods can be done:

1) Overexpression of transcription factors and cold stress-responsive genes
2) Increasing the production of osmolytes
3) Overexpression of cold stress signal transduction cascade genes

32.5.1
Overexpression of Transcription Factors and Cold Stress-Responsive Genes

Overexpression or enhanced expression of transcription factor could activate the genes involved in cold stress pathway. For example, overexpression of the transcription factor CBF1 leads to the induction of entire group of cold tolerance gene. All the cold tolerance-related genes contain a similar regulatory element in their promoters, the C-repeat (CRT) element/dehydration-responsive element/low-temperature-responsive element (LTRE). In this method, the transcription factor CBF1 directly binds to the CRT/DRE/LTRE elements in the promoter, and by activating transcription, it increases the expression of the corresponding genes involved in cold tolerance (Figure 32.4).

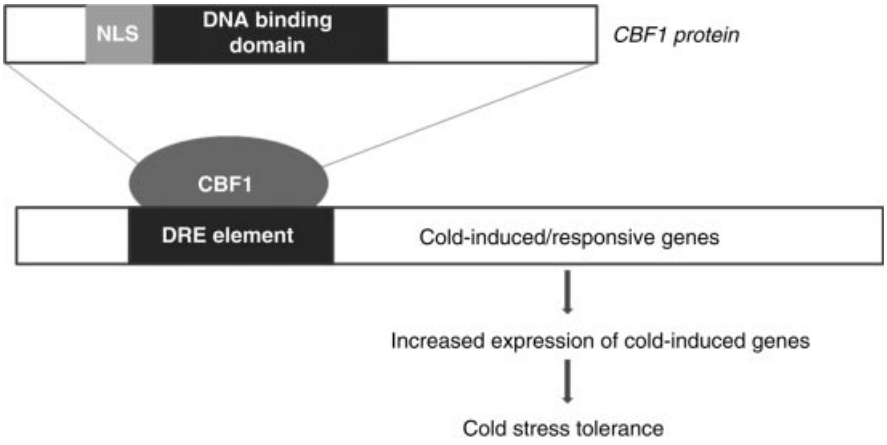

Figure 32.4 A number of cold-induced/responsive genes contain the DRE element in their promoters that is bound by transcription of the CBF family that activates the transcription. Overexpression of a single CBF gene induces the several cold-induced/responsive genes. NLS, nuclear localization signal.

Overexpression of zinc finger genes such as OsISAP8, OsCOIN, and OsISAP1 confers cold stress tolerance at the seedling stage [23, 56, 57]. Overexpression of OsbHLH1, OsDREB1/CBF, ROs-bZIP, SNAC2, and OsNAC6 also enhanced transgenic seedling resistance to chilling stress [49, 58–62]. Overexpression of OsMYB4 and OsMYB3R-2 significantly increased tolerance to freezing stress in transgenic *Arabidopsis* [63–65]. While in rice plants overexpression of OsMYB3R-2 led to higher transcript levels of several G2/M phase-specific genes, including OsCycB1;1, OsCycB2;1, OsCycB2;2, and OsCDC20.1, cold resistance mechanism in rice by OsMYB3R-2 could be mediated by regulating the cell cycle. Signaling components and metabolic regulators have also been shown to be involved in stress responses.

In rice, 33 aquaporins were reported by Sakurai *et al.* [66] and, more recently, 38 aquaporins by Forrest and Bhave [67]. Rice aquaporins are classified into four major families on the basis of their amino acid sequences: the plasma membrane intrinsic proteins (PIPs), tonoplast intrinsic proteins (TIPs), Nod26-like intrinsic proteins (NIPs), and the small and basic intrinsic proteins (SIPs). These aquaporins when overexpressed in rice, it constitutively overexpressed in the leaf and root of transgenic plants, interacts with members of the subfamily, thereby improving the water balance of plants under low temperatures and resulting in the improved chilling tolerance of plants [68].

OsLti6 genes (OsLti6a and OsLti6b) encoding hydrophobic proteins homologous to *Arabidopsis* RCI2 enhanced tolerance to chilling stress in rice seedlings [46]. There are several reports regarding the enhanced tolerance of cold stress in rice. A list of transcription factors and genes improving the cold tolerance in rice is given in Table 32.1 and the rice genes showing tolerance in other plants are listed in Table 32.2.

Table 32.1 List of transcription factors and genes involved in enhancing the cold stress tolerance in rice.

32.5.2 Increasing the Production of Osmolytes

Particular interest has been focused on metabolites that can function as osmolytes. Osmolytes are involved in the regulation of cellular water relations and reduction of cellular dehydration. Their compatible solute behavior allows them to stabilize enzymes, membranes, and other cellular components. Osmolytes are also involved in retailoring of membrane lipid composition to optimize the liquid/crystalline physical structure necessary for proper membrane function and energy sources. Such stress-responsive metabolites particularly include soluble sugars, amino acids, organic acids, polyamines, and lipids [10, 94]. Plants experience cold or chilling stress at temperatures from 0 to 15 °C. Under such situations, plants try to maintain homeostasis to acquire freezing tolerance and this involves extensive reprogramming of gene expression and metabolism [4, 95].

A wide range of compatible solutes are produced by plants. These compounds fall into two broad classes: (i) sugars and sugar alcohol and (ii) zwitterionic compounds. The first class includes sugar alcohols such as mannitol, sorbitol, pinitol, and D-ononitol and oligosaccharides such as trehalose and fructans. The second class includes amino acids such as proline and quaternary ammonium compounds such as glycine-betaine. Overproduction of various compatible solutes has been tested in rice, for example, glycine-betaine, trehalose, and proline, to achieve significant cold tolerance. A list of compounds improving rice cold tolerance is given in Table 32.3.

Table 32.3 List of compatible solutes conferring cold tolerance in rice.

Compatible solutes	Mode of action	References
Glycine-betaine	Increase in glycine-betaine	[69, 96–98]
Trehalose	Trehalose accumulation and activation of stress-responsive genes	[73, 99–101]
Proline	Accumulation of free proline	[75, 82]

A few osmolytes are discussed here; for example, OsTPP1, a gene encoding a trehalose-6P phosphatase in rice, when overexpressed in rice confers cold stress tolerance by trehalose accumulation and by activation of stress-responsive genes.

Free proline is known to be one of the compatible osmolytes preventing dehydration in response to freezing and drought stress. Increase in proline content occurs in many plant species during cold acclimation. Proline is also known to protect membranes and proteins against the adverse effects of temperature extremes. Rapid catabolism of proline upon relief of stress may provide reducing equivalents that support mitochondrial oxidative phosphorylation and the generation of ATP for recovery from stress and repair of stress-induced damage. Our recent report indicated that overexpression of proline-rich protein OsPRP3, which increases the free proline content in the transgenic plants, leads to the enhancement of the cell wall integrity in the cold-tolerant plant and confers cold tolerance in rice [82]. Moreover, proline-rich protein/glycoproteins are thought to play an integral role in extracellular matrix structure of many plant cells by adding mechanical strength to the cell wall and assisting in proper wall assembly.

32.5.3
Overexpression of Cold Stress Signal Transduction Cascade Genes

Plants are continuously exposed to various environmental stimuli during their life cycle. To maintain their life from such stresses, several mechanisms for sensing stimuli and activating immune responses are evolutionarily conserved. Particularly, MAPK cascades are well known as a universal signal module consisting of a MAPK kinase kinase (MAPKKK) that mediates the phosphorylation of a MAPK kinase that in turn phosphorylates a MAPK. The MAPK phosphorylation system serves as a link in various ways between upstream receptors and downstream targets and thereby controls many important cellular functions [102, 103]. MAPKs participate in signal perception and transfer and then induce rapidly and correctly necessary information for adaptation from different stimuli including cold stress. For example, in rice, two components of an MAPK pathway, OsMEK1 and OsMAP1, are induced by low temperature and involved in low-temperature stress [104], and also overexpression of OsMAPK5 conferred tolerance to cold stress in rice seedlings.

In addition to MAPKs, in rice CDPKs (CaM domain-containing protein kinases) are found to be upregulated by cold. Stress-responsive CIPK genes encoding

calcineurin B-like protein interacting protein kinases such as OsCIPK03, OsCIPK12, and OsCIPK15 also play important roles in improving the tolerance to chilling stress in rice [105]. The comprehensive analysis of CDPKs in rice shows that OsCPK4, OsCPK5, and OsCPK13 (OsCDPK7) are upregulated in response to cold [106]. The overexpression of OsCDPK7 in rice resulted in improvement of cold, salt, and drought stress tolerance [107]. In another study, the overexpression of OsCDPK13 and calreticulin interacting protein (CRTintP1) conferred cold tolerance to rice [77].

32.6 Conclusions and Perspective

Cold stress signaling is an important area with respect to increasing the productivity in rice. Therefore, the basic understanding of the mechanisms underlying the functioning of stress genes is important for the development of transgenic plants. Each stress is a multigenic trait, and therefore their manipulation may result in alteration of a large number of genes as well as their products. A deeper understanding of the transcription factors regulating these genes, the products of the major stress-responsive genes, and crosstalk between different signaling components should remain an area of intense research activity in future. The knowledge generated through these studies should be utilized in making transgenic plants that would be able to tolerate stress condition. In the improvement of crops, it is very important to perturb the natural machinery as minimum as possible and activate the stress genes at the correct time. Therefore, it is desirable that appropriate stress-inducible promoters should drive both stress genes and transcription factors, which will minimize their expression under a nonstressed condition, thereby reducing yield penalty. The product of these genes should also be targeted to the desired tissue as well as cellular location to control both timing and intensity of expression.

Maize: Physiological and Molecular Approaches for Improving Drought Tolerance

Ishwar Singh, Thirunavukkarasu Nepolean, Rajyalakshmi Ambika Rajendran, and Mariko Shono

Maize is a C_4 crop with a high rate of photosynthetic activity, leading to high grain and biomass yield. It is predominantly a cross-pollinating species, a feature that has contributed to its broad genetic and morphological variability and geographical adaptability. Economically, the most important types of maize are grown for grain and fodder or silage production. However, in the tropics, grain is primarily used for human consumption. FAO predicts that an additional 60 Mt of maize grain will be needed from the annual global harvest by 2030. The demand for maize as an animal feed will continue to grow faster than the demand for its use as a human food, particularly in Asia, where a doubling of production is expected from the present level of 165 Mt to almost 400 Mt in 2030.

33.1
Introduction

One of the focal points of global food security is the ability to produce the crop all year round in variable climatic conditions, including unpredictable rainfall, low soil moisture, excess soil moisture, excess heat, and so on. Among all, drought poses a major hindrance to this objective in many tropical countries [1]. The ability of plants to tolerate moisture stress condition is crucial for sustaining the agricultural production worldwide. Recent studies of molecular and genomic experiments have increased the understanding of the regulatory and functional networks controlling the drought stress response and have led to practical approaches for developing drought tolerance in plants [2].

From an application point of view, it is important to select genotypes that are able to optimize water harvest and use water efficiently, while maximizing yield in relation to the dynamics of the drought episodes prevailing in each target environment. The objective of this review is to consolidate the current emerging trends of physiology, molecular breeding, and functional genomics that would be influential in integrating breeding and genetic engineering approaches for development of drought-tolerant genotypes in maize.

Improving Crop Resistance to Abiotic Stress, First Edition.

33.2
Basic Concept of Drought Tolerance and its Significance

Drought is a meteorological term and can be defined as the absence of adequate moisture necessary for normal plant growth and to complete the life cycle. Drought in agriculture is due to shortage of water in the root zone, resulting in yield reduction, which is the principal concern of this chapter. The lack of adequate moisture leading to water stress is a common occurrence in rain-fed areas, brought about by infrequent rains as well as inadequate and poor irrigation [3]. Growth and other processes are progressively retarded as soil water content decreases below field capacity. However, most of the plant physiological processes are influenced directly by plant water stress and only indirectly by soil and atmospheric water stress. As much as 17–60% loss in maize yield could be recorded per year in tropical countries due to moisture stress. Hence, the conservation of the soil moisture is essential in the dry season of the crop growth [4].

The term drought tolerance relates to ultimate yield rather than to the capacity of the plant to survive in water-limited conditions [5]. Tolerance consists of drought avoidance and dehydration tolerance that are ultimately measured by the reproductive success of the species [6]. Those plants able to reproduce are represented in the next generation. For grain crops, the measure is similar but determined as yield per unit area of land. Drought avoidance strategies in plants include deep rooting traits, conservative use of available water to ensure that the grain filling is completed, crop life cycle to match rainfall, and short-duration genotypes to escape from the drought. Dehydration tolerance involves plants' ability to partially dehydrate but remain viable and resume growth when water is available.

33.3
Impact of Drought on Phonological Phases of Maize

Moisture stress particularly affects the ability of the maize plant to produce grain at three critical stages of growth: early in the growing season (seedling emergence), at flowering, and during mid-to-late grain filling. Moisture stress during flowering and pollination leads to pollen and silk sterility, inadequate partitioning of source, and improper mobilization from source to sink, which in turn cause maximum yield penalty (Figure 33.1). In fact, silking or the onset of the reproductive stage is the most sensitive stage and will result in 100% yield loss when moisture stress is accompanied with heat stress [7]. In India, moisture stress, particularly at reproductive stage, has been identified as the most important limiting factor of maize production and productivity.

In tropics, moisture stress at the beginning of a season can damage plant stands; however, crop can revive when it gets water. On the other hand, grain yield reductions from mid-to-late grain filling are not nearly as severe as those produced by a similar stress during flowering.

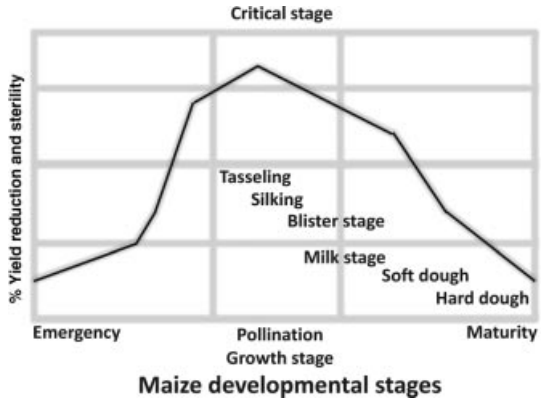

Figure 33.1 Impact of drought stress at different stages of maize development [8]. Reprinted from [8] with kind permission from ASA, CSSA, and SSSA Book Publishing.

Reduction of plant water status to the wilting point during the preflowering, flowering, and postflowering stages results in yield reduction by 25, 50, and 21%, respectively [9]. Silk growth, kernel size, and number appear to depend directly on the flow of photosynthates produced during the 3 weeks of extreme sensitivity period that bracket flowering [10]. Drought also lessens the capacity of developing kernels to use available assimilates because of the impaired functioning of a key enzyme acid invertase [11, 12]. Once kernels enter the linear phase of biomass accumulation about 2–3 weeks after pollination, they develop the capacity to access reserve assimilates stored in the stem and husk. If kernels successfully reach this stage, they will normally grow to at least 30% of the weight of kernels on unstressed plants, even in the presence of severe moisture stress [13]. Plants also respond and adapt to water deficit at both cellular and molecular levels, for instance, by accumulation of osmolytes and proteins specifically involved in stress tolerance. The physiological mechanisms involved in cellular and whole-plant responses to water stress, therefore, generate considerable interest.

33.3.1
Physiological, Morphological, and Metabolic Changes Induced by Drought

During drought, certain morphological, physiological, and metabolic changes occur in response to drought that allow the plant to avoid water loss by continuous water uptake at reduced water potential or to tolerate a reduced tissue water content [14]. Numerous physiological and biochemical changes occur in response to drought stress in various plant species. Changes in protein expression, accumulation, and synthesis have been observed in many plant species as a result of plant exposure to drought stress during growth. The physiological responses of plants to a deficit of water include leaf wilting, a reduction in leaf area, leaf abscission, and the stimulation of root growth by directing nutrients to the underground parts of the plants.

Plant cells are required to maintain water balance. To maintain this water balance, plants absorb water when water potential is negative. Cells can decrease their water potential through the accumulation of solutes, such as sugars, amino acids, organic acids, and ions, especially potassium (K^+). As cellular enzymes are severely inhibited by the presence of ions, these must be removed from the cytosol (the ground fluid substance of the cell) and stored in special storage cell organelles, the vacuoles. Plants resort to many adaptive strategies in response to abiotic environmental stresses such as dehydration and excessive osmotic pressure. These adaptive mechanisms include changes in physiological, morphological, and biochemical processes.

33.3.2 Physiological Changes

Physiological changes at the cellular level associated with drought stress include accumulation of osmolytes, turgor loss, reduction in photosynthetic activity, and changes in membrane fluidity. Abscisic acid (ABA) production is also induced and leads to a further loss of stomatal turgor. The resulting stomatal closure causes a concomitant decrease in CO_2 availability in the leaves, and hence in assimilates availability to the plant [15].

During moisture stress, the xylem vessels give up contents such as ABA to the leaf apoplast, thereby increasing the hormone concentration in this compartment. ABA is carried with the transpiration stream inside the leaf around and through the mesophyll cells so that it reaches the stomatal guard cells of the epidermis that contain ABA receptors with external (and possibly internal) loci in their plasma membranes. Once bound, the hormone induces an internal signal transduction cascade, usually involving increase in both externally and internally sourced cytoplasmic calcium, which eventually reduces the osmotic potential of guard cells via loss of K^+ and Cl^- with stomatal closure as a consequence [16].

Although the photosynthetic machinery has a range of photoprotective mechanisms to dissipate excess light energy, the continued exposure of leaves to excessive excitation energy can lead to photoreduction of oxygen and the generation of highly toxic reactive oxygen species (ROS), such as superoxides and peroxides. These free radicals are harmful compounds causing chemical damage to DNA and proteins and can therefore have lethal effects on cellular metabolism [17]. Plants have evolved several strategies to deal with ROS, including the production of chemical antioxidants such as ascorbic acid, glutathione, and α-tocopherol that directly remove potentially damaging electrons from the ROS, and also peroxidases and superoxide dismutases that scavenge the electrons enzymatically [18].

Another adaptive mechanism for protection against drought is the maintenance of turgor during periods of drought by adjusting the osmotic pressure of cells. There are two main routes whereby this can be achieved. First, the cell can sequester ions into cellular compartments. Second, specialized osmolytes such as proline, glycine-betaine, mannitol, trehalose, ononitol, and ectoine can be synthesized to readjust cellular osmotic potential. These osmolytes are also active in scavenging ROS, especially if they are targeted to the chloroplast [19]. Other specialized organic

molecules can be used to protect cellular membranes against physical damage and proteins against unfolding. Dehydration induces the partitioning of amphiphilic molecules such as glycosylated flavonols and hydroquinones into membranes; these compounds increase membrane fluidity and depress phase transition temperatures [15]. During extreme desiccation, tolerant plants synthesize large amounts of nonreducing disaccharides, such as trehalose, which can substitute for water by satisfying hydrogen bonding requirements of polar amino acid residues at protein surfaces and maintain the folded active states of the proteins.

Maturation proteins, which are induced in response to ABA or dehydration, also protect plants under stress by stabilizing cell membranes. Heat shock proteins (Hsps) and molecular chaperones, as well as late-embryogenesis abundant (LEA) protein families, are involved in plant abiotic stress tolerance [20]. High temperature, salinity, and drought stress can cause denaturation and dysfunction of many proteins. Hsps and LEA proteins help to protect against stress by controlling the proper folding and conformation of both structural (i.e., cell membrane) and functional (i.e., enzymes) proteins. Proteins synthesized in response to drought stress are called dehydrins (dehydration induced) and belong to the group II LEA proteins. The dehydrin family of proteins accumulates in a wide range of plant species under dehydration stress, which range in size from 9 to 200 kDa. Dehydrin proteins have been characterized as hydrophilic, heat stable, macromolecular stabilizer, free of cysteine and tryptophan, responsive to ABA, prevent denaturation of cellular proteins, and rich in lysine. They accumulate along with other LEA proteins in response to a particular stress and have been proposed to play an important role in membrane protein stability and osmotic adjustment. A proposed role of dehydrin-like proteins in drought stress has been the protection of cells from dehydration stress. Dehydrin-like proteins may also have a role similar to compatible solutes in osmotic adjustment. Another possible role of stress proteins is to bind with the ions accumulated (ion sequestering) under drought stress and to control solute concentration in the cytoplasm.

33.3.3 Morphological Changes

Plants exposed to sublethal abiotic stress conditions exhibit a broad range of morphogenic responses that include inhibition of cell elongation, localized stimulation of cell division, and alterations in cell differentiation status [21]. As such, abiotic stress stimuli negatively affect plant growth and development through the arrest of the cell cycle machinery. Abiotic stress perception activates signaling cascades that stimulate cell cycle checkpoints, resulting in an impaired G1-to-S transition, slowing down of DNA replication, and delayed entry into mitosis [22]. Water stress induces meristem shortening in leaves of maize and prolongs the cell cycle duration as a result of reduced CDK activity [23]. In plant tissues, water potential and content are maintained close to the unstressed level by increasing uptake or limiting loss, so that loss and uptake rates of water remain balanced. Such a balance is achieved in the short term mainly by developmental and morphological traits, such as stomatal closure that is paralleled by a decreased photosynthetic rate [24]. Indeed, stomatal

closure in response to drought stress restricts CO_2 entry into leaves, thereby decreasing CO_2 assimilation and water loss from the leaves and affecting mesophyll metabolism [25].

In the longer term, the root/shoot ratio, the tissue water storage capacity, the cuticle thickness, and the water permeability are perceived to be the potentially important target traits, of which change in root growth is the most crucial for crop plants to maximize water uptake [26]. Highly water-stressed maize plants respond by rolling the leaf early in the day. The stress-induced morphogenic response is postulated to be part of a general acclimatization strategy, whereby plant growth is redirected to diminish stress exposure [7].

33.3.4 Metabolic Changes

The plant defense response to drought stress is associated with the synthesis of osmoprotectants, osmolytes, or compatible solutes. The accumulation of several organic solutes according to the metabolic responses has drawn much attention.

Solutes that accumulate in the cytosol and do not interfere with enzymatic reactions comprise sugar alcohols (mannitol and sorbitol), the amino acid proline, free amino acids, and sugars in roots and shoots, and glycine-betaine. The synthesis of these compounds by the plant enhances tolerance to drought [27]. Osmoprotectants are small neutral molecules that are nontoxic to the cell at molar concentration and that stabilize proteins and cell membranes against the denaturing effect of stress conditions on cellular functions [28].

The compatible solutes may be classified into two categories: (1) nitrogen-containing compounds such as proline and other amino acids, quaternary ammonium compounds, and polyamines; (2) hydroxy compounds, such as sucrose, polyhydric alcohols, and oligosaccharides [29]. The plant's response to drought is accompanied by the activation of genes involved in the perception of drought stress and in the transmission of the stress signal. One group of genes encodes proteins to protect the cells from the effects of desiccation. These genes include those that govern the accumulation of compatible solutes, passive transport across membranes, energy-requiring water transport systems, and protection and stabilization of cell structures from desiccation and damage by ROS [30]. The second group of genes activated by drought consists of regulatory proteins that further regulate the transduction of the stress signal and modulate gene expression. At least four independent stress-responsive genetic regulatory pathways are known to exist in plants, forming a highly complex and redundant gene network [2, 30]. Two of the pathways are dependent on the hormone ABA, while the other two are ABA independent. These pathways are also implicated in the perception and response to additional stress factors, including cold, high temperature, and salinity.

Mannitol is a major photosynthetic product in many algae and higher plants, enhancing tolerance to water deficit-induced stress primarily through osmotic adjustment [31]. Its mechanisms are likely to involve the scavenging of hydroxyl

radicals (OH^-) and the stabilization of macromolecules [32]. Water deficit alters the synthesis and partitioning of metabolically important carbohydrates in plants. Some of these effects on carbohydrate metabolism might be required for the photosynthetic assimilation of carbon and its conversion to metabolically usable forms. Other stress-induced changes in carbon metabolism might reflect adaptations for stress tolerance [33]. For example, raffinose family oligosaccharides (RFOs), such as raffinose, stachyose, and galactinol, play important roles in the desiccation tolerance of plants. Raffinose accumulates in vegetative tissues under drought stress [34]. RFO biosynthesis requires the presence of galactinol, which is formed by galactinol synthase (GolS) from UDP-Gal and myoinositol. Galactinol is the galactosyl donor for the biosynthesis of raffinose from Suc by raffinose synthase (RafS). Because galactinol has not been assigned any function in plants other than acting as a galactosyl donor for RFOs synthesis, GolS potentially catalyzes a metabolic key step for RFO synthesis. Overexpression of one of them causes an increase in endogenous galactinol and raffinose, as well as an improvement in drought tolerance [35]. Fructans are polyfructose molecules that are soluble carbohydrates and are located in the vacuoles of many plants. Fructan metabolism plays a significant role in drought stress tolerance in plants [36]. As these compounds are soluble, they might play a role in the osmotic adjustment of natural fructan accumulators by varying the degree of polymerization of the fructan pool. Trehalose (α-D-glucopyranosyl-1, 1-α-D-glucopyranoside) is an innocuous, scentless, nonreducing disaccharide and melliferous nonreducing disaccharide containing two glucose residues bound in an α,α-1,1-glycosidic linkage. It is the nonreducing nature of trehalose that determines its high stability to acid, alkali, and heat. Trehalose can become glass state structure by combining two water molecules. Its hydroscopic property is more than three times of sucrose, maltose, glucose, and fructose. In cells, the high tolerance of trehalose to dehydration provides protection to proteins and biomembranes from drying, freezing, and heating. Accumulation of proline is a widespread plant response to environmental stresses, including low water potential. Proline has a clear role as an osmoticum. In particular, because of its zwitterionic, high hydrophilic characteristics, proline acts as a "compatible solute," that is, one that can accumulate to high concentrations in the cell cytoplasm without interfering with cellular structure or metabolism. There is presently no clear agreement on the function of drought-induced accumulation, although a role in osmoregulation seems likely. Other functions of proline accumulation have also been proposed, including statabilization of macromolecules, a sink of carbon and nitrogen for use after relief of water deficit, radical detoxification, and regulation of cellular redox status by proline metabolism [37]. Glycine-betaine, a quaternary ammonium compound, is a very effective compatible solute. In higher plants, glycine-betaine is synthesized from choline (*Cho*) via betaine aldehyde (BA). Glycine-betaine balances the osmotic pressure between outside and inside of cells to cope up with osmotic stress and hence maintains turgor. Moreover, glycine-betaine also protects physiological processes such as photosynthesis and protein synthesis under drought conditions [38].

33.4
Role of ABA in Drought Tolerance

ABA, a plant stress hormone, induces the closure of leaf stomata (microscopic pores involved in gas exchange), thereby reducing water loss through transpiration and decreasing the rate of photosynthesis. These responses improve the water use efficiency of the plant on the short term. ABA plays an important role in seed maturation and dormancy, as well as in the adaptation of vegetative tissues to abiotic environmental stresses such as drought and high salinity [39].

33.4.1
ABA-Dependent Signaling

Drought stress induces *de novo* synthesis of the phytohormone ABA that plays an important role in the adaptation of vegetative tissues to abiotic stresses, such as drought and high salinity, by promoting stomatal closure in guard cells [40]. Many ABA-inducible genes contain a conserved, ABA-responsive, *cis*-acting element, designated ABRE (PyACGTGGC), in their promoter regions. Reversible protein phosphorylation is an early and centrally regulated event in ABA signal transduction, at least in the guard cells. Upon drought stress, the ABA-responsive 42 kDa kinases are activated, thereby phosphorylating the conserved regions of ABA-responsive element binding protein (AREB)/ABFs. Several SNF1-related protein kinases 2 (SnRK2s) such as ABA-activated protein kinase (AAPK) [41] and OST1/SRK2E in *Arabidopsis* [42] were reported as AAPKs. All these kinases phosphorylate *in vitro*, a motif in the so-called "Constant" subdomains found among basic-leucine zipper (b-ZIP) transcription factors (TFs), including AREB1, AREB2, and ABI5 [43]. Some b-ZIP TFs may also be the targets of calcium-dependent protein kinases (CPKs).

Abiotic stress activates the production of intracellular ROS. When the increase in ROS is relatively small, the housekeeping antioxidant capacity is recruited to reset the original balance between ROS production and scavenging, thus reestablishing the redox homeostasis [44]. Otherwise, ROS is sensed by membrane-localized kinases that eventually activate the MAPK (Figure 33.2). MAPK regulates gene expression by altering the TF activity through phosphorylation of serine and threonine residues, whereas ROS is regulated by oxidation of cysteine residues [45]. Changes in gene expression play an important role in plant drought stress response, and many stress-induced genes are known or presumed to play roles in drought resistance. For many of these genes, the hormone ABA is a key signaling intermediate controlling their expression in an ABA-dependent or ABA-independent manner (Figure 33.3), as shown largely by the analysis of ABA-deficient and ABA-insensitive mutants in *Arabidopsis* [46].

33.4.2
ABA-Independent Signaling

The TFs DREB1 and DREB2 (Figure 33.4) are important in the ABA-independent drought-tolerant pathways that induce the expression of stress response genes.

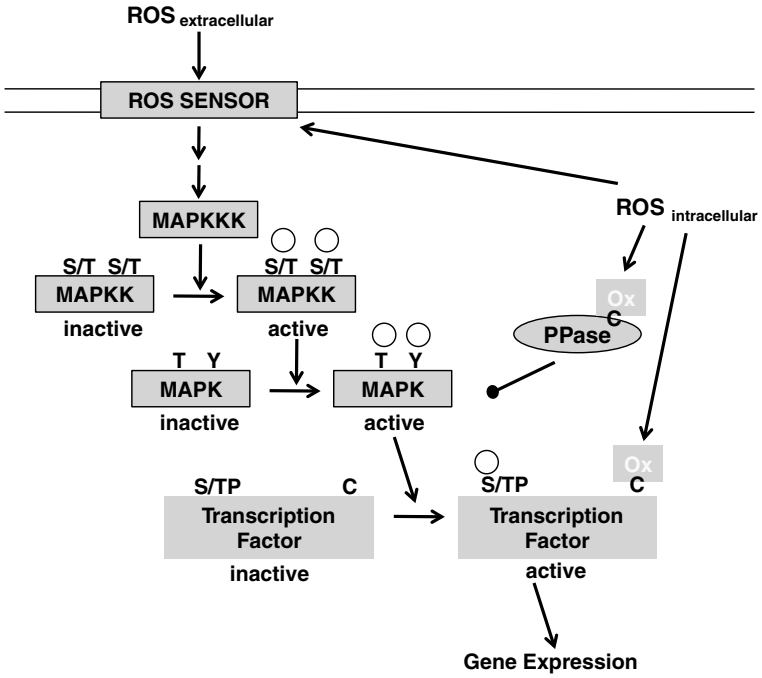

Figure 33.2 Cellular ROS signaling in plants [45].

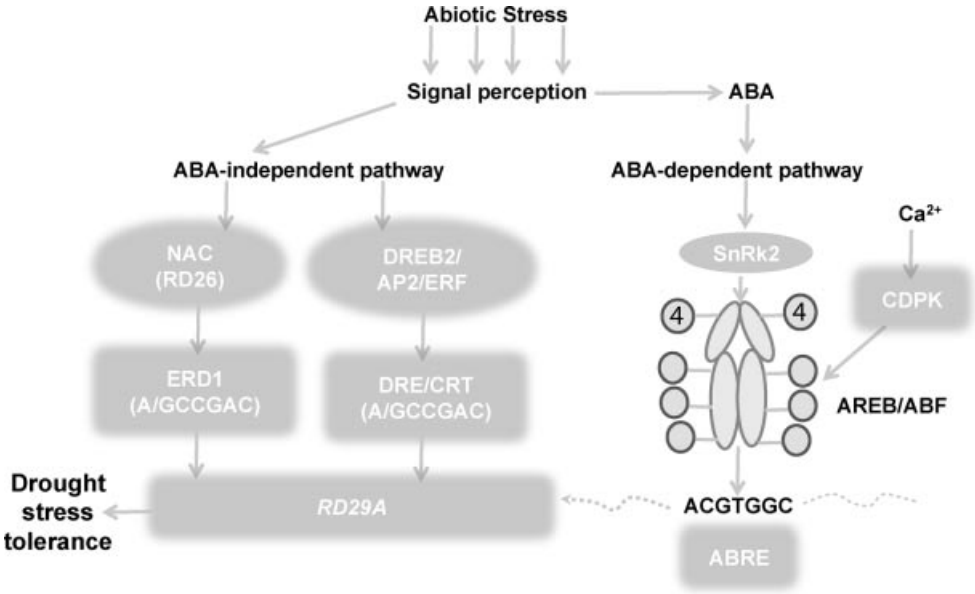

Figure 33.3 ABA-dependent and ABA-independent signaling in plants [46].

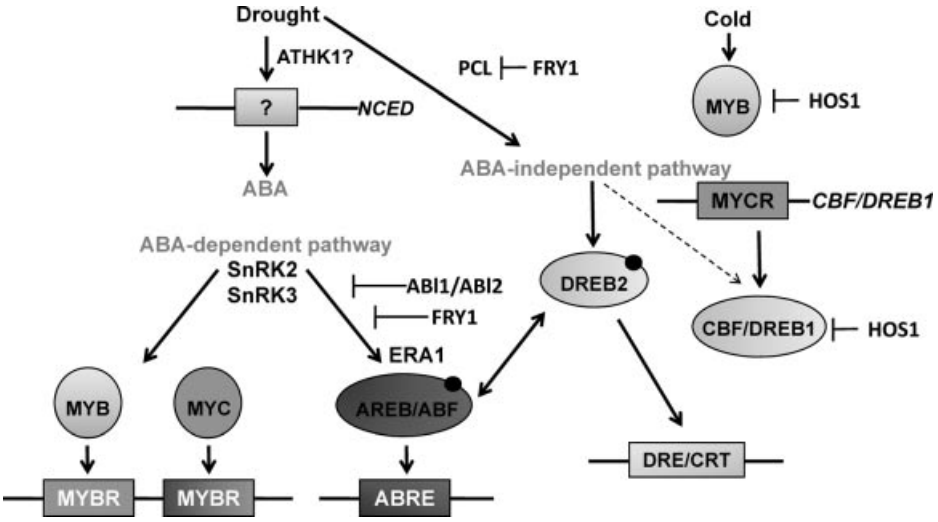

Figure 33.4 Effect of cold, salt loading, and dehydration on expression of stress-related genes leading to striking improvements in plant tolerance [40].

Overexpression of the native form of DREB1, and of a constitutively active form of DREB2, increases the tolerance of transgenic *Arabidopsis* plants to drought, high salinity, and cold. Although these genes were initially identified in *Arabidopsis* plants, their presence and role in stress tolerance have been reported in many other important crops including maize, indicating that this would be a conserved, universal stress defense mechanism in plants.

Abundance of cationic peroxidases induces lignin biosynthesis in the xylem vessels and induces cell wall stiffening that might strengthen the xylem vessels and prevent any further cell expansion either to better withstand the tension occurring during water stress or to restrict water loss from internal tissues [47]. Furthermore, in water-stressed plants, the levels of many amino acids in the sap increase transiently and a number of amino acids also accumulate only under severe water stress. Metabolic changes associated with drought stress include modifications in solute concentration and protein–protein and protein–lipid interactions [48]. Production of phytoalexins, activation of the general phenylpropanoid pathway, and induction of lignin biosynthesis have evolved as adaptation mechanisms to water deficit. Salicylic acid, methyl salicylate, jasmonic acid, methyl jasmonate, and other small molecules produced as a result of stress can also serve as signaling molecules activating systemic defense and acclimatization responses [49], whereas others protect plants from oxidative damage associated with a variety of stresses, such as ascorbic acid, glutathione, tocopherols, anthocyanins, and carotenoids, by scavenging the generated active oxygen intermediates. Knowledge of the physiological and biochemical responses to severe water deficit conditions has been exploited for drought stress tolerance in plants.

33.5
Developing Drought-Tolerant Maize

Unlike relatively static abiotic stresses such as soil salinity or acidity, drought stress in most maize growing areas is strongly dependent upon stochastic weather processes. Transient stresses give rise to complex genotype × year, genotype × season and genotype × season × year, genotype × season × year × management interactions since stress tolerance varies among genotypes and throughout the season of the cropping period. With the advent of combine yield monitors, within-field spatial variation in yield has become much more obvious to the farmer and often relates to variation in soil texture and plant available water.

The application of genetics to improve drought tolerance and provide yield stability is an important part of the solution to stabilizing global maize production. This does not imply that agronomic interventions that aim to maximize water availability at key growth stages are not critically important since genetic solutions are unlikely to close more than 30% of the gap between potential and realized yield under water stress [50]. However, improved genetics can be conveniently packaged in a seed and therefore more easily and completely adopted than improved agronomic practices that depend more heavily on input availability, infrastructure, access to markets, and skills in crop and soil management. Fortunately, under stressful conditions, the performance advantage of modern elite germplasm over its less improved and older counterparts becomes larger, and much of the observed genetic gain in yield during the past 30 years has been attributed to greater stress tolerance rather than to an increase in yield potential *per se* [51–53]. Physiology, coupled with genomics, offers promise of improving the rate of gain for key traits, and especially those such as drought tolerance that are difficult to phenotype, the baseline for comparison must be the rate of improvement obtained through established selection systems. Thus, it is instructive to consider rates of gain in drought tolerance resulting from conventional selection in a large hybrid development program that relies on extensive multi-environment testing to identify superior progenies.

To do this, however, the association between genotype and phenotype must be better understood and quantified so that our ability to predict phenotypic performance from genetic information for many traits observed in an array of environments is greatly improved. Genomics, or the study of the function and structure of specific genetic sequences accompanied by high-throughput laboratory-based analysis of DNA [54], is considered a key to comprehending gene–phenotype associations at the level of candidate genes and sequences. This will be critically important for quantitative traits such as drought tolerance, where performance is regulated by many loci and subject to multiple genotype × environment (G × E), gene × gene (G × G) interactions (epistasis), and gene × gene × environment (G × G × E) interactions.

Identification and measurement of secondary traits associated with grain yield provides a guide to specific mechanisms that contribute to grain yield under drought. Thus, water depletion patterns, leaf rolling, and canopy temperatures are indicative of root exploration and water extraction capacity, and chlorophyll concentration is a

measure of functional stay green [55]. Some secondary traits are associated with specific developmental stages such as flowering, while others, such as photosynthetic rate, are indicative of plant growth throughout the life cycle of the crop. Ideally, secondary traits should be correlated with grain yield under stress, highly heritable, easy to measure, and stable over time. A short anthesis-silking interval (ASI) is indicative of general tolerance to reduced photosynthesis per plant at flowering in many cases [56]. To understand the genotypic differences in water acquisition, a distinction must be made between the fine lateral roots, usually with diameters smaller than 0.8 mm [57], and their larger parental axile roots. In the fibrous root system of maize, axile roots emerge from the stem, guaranteeing a wide vertical and horizontal distribution of the root system, away from the plant basis, while lateral roots are of major importance for the efficient short-distance exploitation of water and nutrients [58]. A series of correlated phenotypes that have associations with grain yield under drought conditions are precocity, plant stature, chlorophyll content, root morphology and conductivity, glucose, sucrose, dehydrin, ABA, and ABA glucose ester measured on leaves, ear tips, and silks harvested at different developmental stages.

Drought tolerance that impacts crop yield can be assessed reliably only in the field. Managed stress environments, where the severity and timing of drought stress are controlled in a manner relevant to target environment conditions, are essential for approaches aimed at achieving genetic progress for drought tolerance. Accurate water management in the absence of rain allows stress intensity to be adjusted so the expression of genetic variability for key secondary traits is maximized and the pattern of stress, targeted at specific growth stages, can be repeated. The detection of genotype $\times$ stress level interactions for drought tolerance provides essential evidence for the presence (and absence) of unique, adaptive mechanisms among genotypes. Generation of such interactions requires the application of relatively severe stress levels that, in some cases, are more severe than those experienced in the target population of environments. A well-watered control is generally needed to monitor for losses in yield potential associated with selection for stress tolerance.

Comparison of performance in these contrasting environments provides the critical data required to predict yield stability of genotypes. Care must be exercised, however, when designing water stress regimes to ensure that the genetic correlation between the managed stress environments and the target population environment remains positive and reasonably large. Under managed stress environments, standard plot management techniques often require adjustment to enhance uniformity within trials. Particularly critical is the establishment of uniform stands to ensure evenness of water availability per plant. As plants remove soil water, differences in root volume per plant and in transpiring leaf area can exaggerate plant-to-plant variability. Blocking by flowering date is important in maize because of its susceptibility to stress imposed at flowering. If entries vary widely in time to silk, the most "tolerant" may simply be those that flower earlier than the mean and thus escape stress that intensifies with time. Finally, time trends in data can occur when variables such as canopy temperature are measured using handheld infrared thermometers [59]. As soil water is depleted, spatial variability generated by differences in

soil texture becomes increasingly obvious and can obscure genotypic differences. The use of uniform land is obviously the best solution, and knowledge of these patterns generated over time can be used to select the most uniform plot sites. The use of incomplete block designs such as row/column or alpha (0, 1) designs [60] or augmented designs provides a method to adjust data for the effects of within-replicate spatial variation when dealing with large entry numbers [55]. Spatial trends in data arise from soil heterogeneity as well as unintentional management factors that can be identified within a linear mixed model analysis framework. In addition, data can be adjusted for these effects by incorporating appropriate model terms and identifying appropriate variance structures for spatial trends [61]. Linear mixed models can be used for estimating variance components and determining best linear unbiased predictors (BLUPs) for genotypes from unbalanced data sets.

33.6
Modern Tools to Improve Drought Tolerance in Maize

Integrating molecular approaches of the latest advances in biotechnology, genomic research, and molecular marker applications with conventional plant breeding, plant physiology, and biochemistry could increase significantly the potential for genetic gain under water-limited conditions (Figure 33.5).

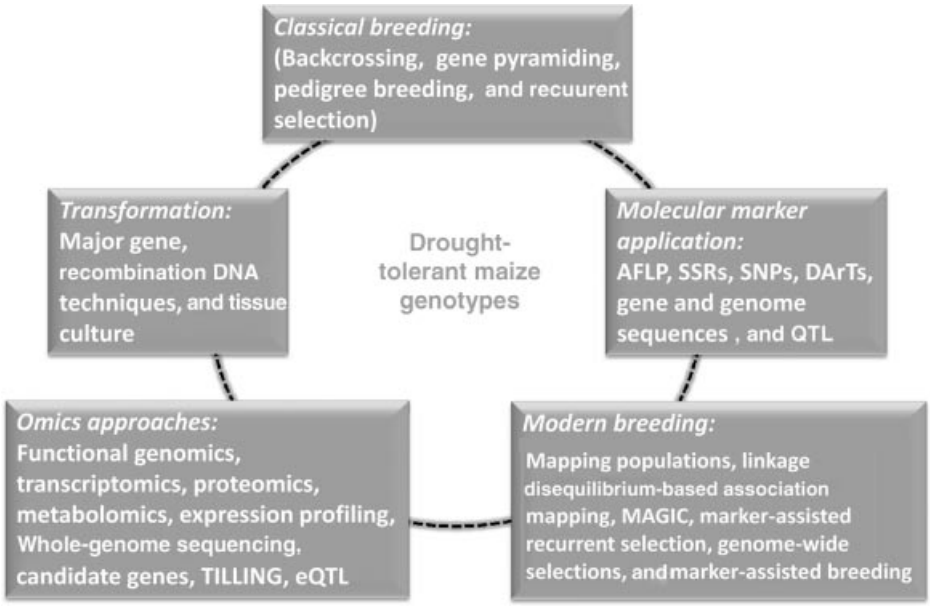

Figure 33.5 Development of drought-tolerant maize genotypes by integration of classical and modern tools.

Changing maize genetic improvement from an empirical to a knowledge-based process involves investing heavily in the use of high-throughput recombinant DNA technology, genomics, and bioinformatics tools. The utility of these tools has, in turn, been increased by advances in DNA sequencing capacity and in database development and management. The availability of organized dense genetic maps based on molecular markers and the awareness of the particulate nature of the inheritance of quantitative traits have fostered an interest in the genetic dissection of drought tolerance. Ideally, this involves associating genetic variation at the sequence level with observed phenotypic variation and ensuring that those specific sequences imparting tolerance are present in subsequent generations.

Genetic mapping with dense marker maps can be used to identify the number and genetic positions of quantitative trait loci (QTL) associated with a specific trait under drought stress. In addition, this process can be used to estimate effects of the segregating QTL and their contributions to trait variation (individually and in combined QTL models) and to obtain estimates of their stability across environments (QTL × environment interactions) and across genetic backgrounds (QTL × genetic background interactions).

The responses of the genotypes to drought stress are governed by the activity of several genes involved in diverse pathways, including "constitutive" QTL and "adaptive" QTL. DNA-based markers located in such genomic (bin) locations could potentially serve as informative "anchor" markers for molecular marker-assisted selection (MAS) as well as functional genomics. In addition to the consensus QTL, analysis of individual genes, transcriptome profiling, and *in silico* mapping leads to identification of specific candidate genes with significant influence over drought stress tolerance in maize, many of which colocalize with the consensus QTL for drought tolerance. Lebreton *et al.* [62] were the first to attempt to apply QTL analysis to obtain genetic insights into the drought tolerance response in maize. Since then, a number of reports of QTL associated with specific traits under drought stress have been indicated using diverse mapping populations [63–66]. The reports have targeted grain yield and its components, ASI, root traits, and measures of plant water use and status, such as stomatal conductance, and leaf and xylem ABA content [67].

Progress of trait is attributed to the number of major QTL identified per trait, the magnitude of observed phenotypic variance that they generally express individually, their interaction with the environment, and difficulty of epistasis evaluation [68]. For complex traits such as drought tolerance, many QTL identified in elite lines developed by breeding programs are likely to be context dependent due to the effects of several gene and environmental interactions. Therefore, although we can mendelize quantitative traits, the value of the QTL alleles will need to be determined for the specific situation to which they are to be applied. Capacity for precision phenotyping under repeatable but representative levels of stress in the field is lagging far behind the capacity to generate genomic information and will limit progress in generating gene–phenotype associations for traits.

MAS experiments based only on the QTL involved in the expression of yield components would be inefficient because only a few of the QTL are stable across environments. A MAS experiment should consider the QTL involved in the expres-

sion of secondary traits of interest correlated with the yield under drought. If it is possible, the selected QTL should be stable across environments and account for a large percentage of the phenotypic variance. Therefore, an efficient MAS strategy should take into account the most suitable QTL from different traits as an index [69]. Many studies clearly indicate the colocation of the QTL influenced including key traits such as grain yield, ASI, root traits, and ABA accumulation across different genetic backgrounds [5]. In maize, MAS has been used to introgress QTL alleles for reducing ASI.

Compared to modern cultivars, which are usually selected for high-input environments where water supply is often not a major limiting factor, wild species show morphophysiological features for survival and adaptation to drought conditions. When considering exploiting alleles from wild species for drought adaptive features, a careful evaluation in terms of yield, once they are backcrossed in elite accessions, is important [68].

Information about QTL in tropical maize can be applied to increase heritability and favorable gene action to design optimum transgenic strategies for crop improvement. Marker-assisted selection also accelerates the use of transgenes in commercial cultivars, typically achieved through marker-assisted backcrossing [70]. An updated compilation of mapped QTL and major genes associated with abiotic stress tolerance including drought in maize and other plants is available at www.plantstress.com [71]. Other useful Web resources are www.generationcp.org, http://rarge.gsc.riken.jp/, and http://rootgenomics.missouri.edu/ [5]. Identification of universal drought QTL and putative candidate genes could be valuable for further analysis and utilization [72].

33.7
Functional Genomics of Drought Tolerance

Functional genomics uses mostly multiplex techniques to measure the abundance of many or all gene products such as mRNAs or proteins within a biological sample. Functional genomics includes function-related aspects of the genome itself such as mutation and polymorphism (e.g., single-nucleotide polymorphic (SNP)) analysis, as well as measurement of molecular activities. The latter comprise a number of "omics" such as transcriptomics (gene expression), proteomics (protein expression), phosphoproteomics (a subset of proteomics), and metabolomics (analysis of metabolites).

Functional genomics provides important information for evaluating stress perception, signal transduction, and defensive responses, the role of potential candidate genes, and the pathways in which they are involved. Intensive studies have already led to the discovery of promoter regulatory elements, such as DRE (dehydration-responsive elements) or ABRE (ABA-responsive elements), involved in both dehydration and low-temperature-induced gene expression [73], as well as identification of several key transcriptional factors interacting with such promoters [74]. With the advent of genomics-related technologies, necessary tools to identify the key gene

networks that respond to drought stress and those relating to the regulation of adoptive events occurring during stress are now becoming available [75].

Cloning a drought-related QTL substantially contributes toward a better understanding of the genetic and functional basis of the response of a plant to drought. Furthermore, the sequence responsible for the QTL becomes available for genetic engineering and mining for the most desirable alleles within germplasm collections. Until now, two approaches have been mainly used for the molecular dissection of a QTL: positional cloning and association mapping [76].

Positional cloning begins with the production of a large population in a near-isogenic lines (NILs) where only the target QTL segregates. A large number of progenies (>1000) capturing all possible recombination events and molecular markers in the target region enable us to identify the genetic and physical interval cosegregating with the QTL. The availability of the genome sequence facilitates the connection between genetic and physical information. When the genome sequence is not available, genomic libraries (e.g., BAC clones) are used. A maize domestication locus, teosinte glume architecture (*tga1*), which encodes a transcriptional regulator, was the first maize gene positionally cloned, using a population of over 3000 individuals [77]. Among the quantitative traits affecting drought tolerance, particular attention has been devoted to the concentration of ABA, in view of its pivotal role in regulating other molecular and morphophysiological processes involved in the adaptive responses. Differences among NIHs (near-isogenic hybrids) for leaf ABA and other morphophysiological traits were not affected by water regimes. On average, the QTL allele for high leaf ABA markedly reduced stomatal conductance and root lodging [78]. Candidate genes or sequences that cosegregate with the QTL are then functionally tested with reverse genetics tools (e.g., knockout mutants, RNAi, and targeting induced local lesions in genomes (TILLING)) and ectopic expression.

Association mapping based on linkage disequilibrium (LD) seeks to establish a statistical association between allelic (or haplotype) variation at a locus and the phenotypic value of a trait across a large enough sample of unrelated accessions [79]. The LD approach offers two distinct advantages: the survey of multiple alleles in a single analysis and avoidance of the time-consuming preparation of mapping populations. In the presence of high LD (~100 kb or more), association mapping can provide only coarse mapping information; however, when LD is low (~10 kb or less), the resolution power is sufficiently high to assign a QTL to an interval containing one or a few genes. Analysis of candidate genes has already provided interesting results [79, 80]. Association mapping should greatly benefit from the introduction of high-throughput platforms that are able to profile a multiplex of SNP markers. Techniques such as EcoTILLING [81] are also available to streamline the identification and scoring of new alleles at target genes or sequences.

Major challenges for gene discovery include the following:

- The large size of the maize genome
- Variation in genome size and gene order
- The high incidence of multicopy genes
- Transposons and other repetitive sequences making up a large portion of the genome

The wealth of active transposable elements residing in the maize genome plays an important role in functional genomics. In addition to serving as molecular tags for mutated genes, these transposons tend to knock out genes into which they are inserted. Mutant libraries constructed using transposon tagging, T-DNA insertion, and chemical and physical mutagenesis provide materials that can be screened for base changes in any genes by reverse genetics methods such as TILLING [82].

Strategies have been developed so that subtle changes such as point mutation generated by EMS can be detected easily. In the basic TILLING method, pollen is mutagenized by treatment with EMS. These mutagenized lines serve as a general reverse genetic resource. Weil and Monde [83] provided a detailed protocol for maize TILLING including TILLING mutagenesis, tissue collection, DNA preparation, 2D pooling, and detailed TILLING workflows. As the maize genome is completely sequenced, advances in reverse genetics technologies including TILLING, EcoTILLING, and massively parallel DNA resequencing provide excellent methods for identifying mutations in a wide variety of traits and biological processes [84]. EcoTILLING is a way to survey how much allelic diversity there is for a given gene target and where that diversity is located (intron versus exon).

Gene expression experiments have identified several hundred genes that are induced or repressed during drought. Both cDNA- and oligonucleotide-based gene expression profiling platforms are used to examine the effects of drought stress on yield potential of maize [85]. The expression QTL (eQTL) mapping involves expression profiling as measured by mRNA transcript abundance for a large number of genes that are each treated as a quantitative phenotype likely to be conveyed by multiple genes and influenced by environmental factors. These expressional profiles then constitute a marker-based fingerprint of each individual in a segregating population and can be subjected to conventional QTL analysis [86], albeit interpreted in the spatially and temporally specific context in which the data are collected. The procedure is called mapping of eQTL, that is, genetic locus where allelic variation affects the level of gene expression. Overlapping expression profiles and coordinate expression indicated that genes relevant to stress resistance and such data sets form an excellent resource for identifying candidate genes [87] through positional cloning or association mapping. Transcription profiling has increasingly become an important genomics tool for gene functional analysis. Expression patterns of some genes in several stress response-associated pathways, including abscisic acid, jasmonic acid, and phenylalanine ammonia lyase, are positively responsive to drought stress. However, the cost of profiling the large number of samples required to identify eQTL is still too high for routine application of this approach. The expression is most often quantified in terms of the amount of mRNA in a microarray-based analysis, but the same principle has been applied to genetic control of the protein level. Microarrays have become an important technology for the global analysis of gene expression. Implemented in the context of a well-designed experiment, cDNA and oligonucleotide arrays can provide high-throughput simultaneous analysis of transcript abundance for hundreds, if not thousands, of genes. Microarrays are being used to assess gene expression in plants exposed to the experimental manipulation of air temperature and soil water content in the root zone. Analysis often includes

characterizing transcript profiles for multiple posttreatment sampling periods and categorizing genes with common patterns of response using hierarchical clustering techniques. In addition, microarrays are also providing insights into developmental changes in gene expression associated with root elongation in maize [88].

The identification of candidate genes for the QTL and the elucidation of their functional role can be facilitated by combining QTL maps with the so-called functional maps (i.e., maps enriched with genes potentially involved in controlling the target trait or with fully annotated genomic sequences). An important part of new gene discovery through EST and genome sequencing is the annotation of those genes to assign putative functions [89]. In the absence of empirical data for a particular gene in the appropriate target organism, gene annotation software can predict a function using data from rice, *Arabidopsis*, and other organisms based on similarities for intron/exon sequence and structure plus likely protein domains (www.maizesequence.org). One can BLAST maize sequences against the cereal and other species databases to generate predicted functional information. In forward and reverse genetics approaches, maize is characterized by excellent mutagenesis resources in the form of well-studied transposon systems, and new techniques for induced mutations are also being applied [90].

Maize is one of the model systems for genetic research. The genome size of the maize is 2300 Mb, which is fivefold larger than rice but eightfold smaller than wheat [91]. The sequencing of maize was recently completed by a U.S.-based consortium of researchers [92]. The complete genome of B73, an important commercial crop variety, was decoded. The 2.3 billion base sequence – the largest genetic blueprint worked out for any plant species – includes more than 32 000 protein-coding genes spread across 10 chromosomes of maize. The transposable elements are the most abundant parts of the sequence, spanning almost 85% of the genome and dispersed nonuniformly across the genome. The Maize Genome Sequencing Consortium has generated a reference genome sequence that was integrated with both physical and genetic maps. Using a previously published integrated genetic and physical map, combined with genomic sequence, new sequence-based genetic markers, and an optical map, the researchers have picked a minimum tiling path (MTP) of 16 910 bacterial artificial chromosome (BAC) and fosmid clones that were used to sequence the maize genome. The new integrated physical and genetic map covered 2120 Mb (93%) of the 2300 Mb genome, of which 405 contigs were anchored to the genetic map, totaling 2103.4 Mb (99.2% of the 2120 Mb physical map). Using all available physical, sequence, genetic, and optical data, a golden path (AGP) of chromosome-based pseudomolecules, referred to as the B73 reference genome sequence version, was generated [93].

The completion of the maize genome sequence provides the most essential resource to move easily from gene to mutant phenotype and back. There are several methods such as gene cloning, gene expression profiling, TILLING/EcoTILLING and transposon tagging, and SNP haplotypes to target loci for experimentally determining gene function [94]. Traditionally, gene discovery in maize has employed transposon tagging, EST searches, and comparative genomics, and due to increase in genomic resources, positional cloning is increasingly being used for both qualitative

and quantitative traits. Now with the physical maps for maize, the large numbers of available markers, and conservation of synteny across the cereal genomes, it is feasible to consider a less time-consuming chromosome walk rather than cloning by transposon tagging [95].

The length and breadth of the utility of genome sequencing in crop research has increased with the availability of new-generation sequencing (NGS) technologies. This new-generation techniques will increase the throughput tremendously while reducing the cost multiple times [96, 97]. The data generated through NGS techniques have opened new era of maize genome analysis and provide sequence information of the germplasm that are genetically diverse so as to uncover the genetic potential of the unexplored genotypes. Getting enormous amount of data cheaply in no time has extended its applications beyond just reading the order of bases. Microarrays are being replaced by sequence-based method in gene expression studies. The ability to sequence the whole genome of many organisms will allow large-scale comparative and evolutionary studies [98]. Sequencing technology is developing very rapidly and already the third-generation sequencing platforms are being made available such as "real-time sequencing" (www.pacificbiosciences.com).

Genomics and bioinformatics allow us to investigate sequence colinearity in the main crops [99] and compare their gene order and content with those of model species whose genomes have been sequenced, such as rice and *Arabidopsis*. The colinearity between *Arabidopsis* and maize [100] has been eroded to such an extent that the *Arabidopsis* sequence does not appear to be of much help for the identification of related genes in maize. Conversely, comparative mapping between rice and maize [101] as well as other cereals [102] provides valuable opportunities to exploit high-resolution collinear maps to facilitate the positional cloning of maize QTL and identify candidate genes and to establish whether sequences with high homology are so because they represent orthologous loci.

Transcriptomics, proteomics, and gene expression studies have identified the activation and regulation of several stress-related transcripts and proteins that are generally classified into two major groups. One group is involved in signaling cascades and in transcriptional control, whereas members of the other group function in membrane protection, as osmoprotectants, as antioxidants, and as ROS scavengers [103]. Manipulation of genes that protect and maintain cellular functions or that maintain the structure of cellular components has been the major target of attempts to produce plants that have enhanced stress tolerance [104].

Progress in the mass-scale profiling of the transcriptome, proteome, and metabolome has allowed a more holistic approach in investigations of drought tolerance based on the measurement of the concerted expression of thousands of genes and their products. High-throughput mRNA profiling has been applied to investigate the changes in gene expression in response to dehydration [105]. An example of how transcriptome analysis can advance our understanding of the physiology underpinning drought-related traits has been recently provided by the expression profiling of primary root apices in maize [106]. Collectively, the transcriptome profiling experiments conducted on drought-stressed plants have highlighted the central role of TFs while unveiling the complex hierarchy of the regulatory network that differentially

modulates the expression of dehydration signature genes in a tissue-specific manner. In this respect, laser captured microdissection is a major technical breakthrough: the technique allows the profiling of specific cell types [107] – a feature particularly important when investigating genes encoding for TFs expressed weakly and in a cell type-specific fashion.

The importance of metabolic changes during plant responses to abiotic stress suggests that detailed metabolite profiling may provide valuable insights into stress response mechanisms. Deciphering gene function can also be facilitated by information gathered through profiling the proteome and metabolome. Profiling the proteome of a mapping population offers the opportunity to identify PQL (protein quantity loci) influencing protein quantity. In water-stressed maize, the *Asr1* gene, a putative TF, has been shown to colocalize with a PQL for the ASR1 protein and a QTL for ASI and leaf senescence [108]. With regard to metabolomics, the present technology enables the profiling of ~2000 metabolites in a single sample [109]. The susceptibility of early developing grain to water stress is a major problem in maize, where a shortage of assimilate supply has been indicated as the likely cause for insufficient grain filling and sterility [110]. In this respect, invertase activity in the developing kernel has been shown to be an important limiting factor for grain yield in maize exposed to drought [111]. Among the QTL for invertase activity described in maize, one is mapped near *Ivr2*, an invertase-encoding gene [112]. Furthermore, collocation between the activities of two enzymes (sucrose-P synthase and ADP-glucose pyrophosphorylase) involved in carbohydrate metabolism and corresponding structural genes has been reported in young maize plants subjected to water deficit [113]. The increase in *Hsp* expression under conditions of abiotic stress was studied extensively using functional genomics and proteomics in different plant species [114]. Genomics-based approaches can contribute novel information to identify candidate genes and elucidate their functions and regulation under water-limited conditions.

33.8
Genetic Engineering Approaches for Improving Drought Tolerance

Although not a crop plant, *Arabidopsis* has played a vital role in the elucidation of the basic processes underlying stress tolerance, and the knowledge obtained has been transferred to a certain degree to important food plants. Many of the genes known to be involved in stress tolerance have been isolated initially from *Arabidopsis* [115]. Two general strategies for the metabolic engineering of abiotic stress tolerance have been proposed: increased production of specific desired compounds or reduction in the levels of unwanted (toxic) compounds [116]. However, modulation of a single enzymatic step is usually regulated by the tendency of cell systems to restore homeostasis, thus limiting the potential of this approach. Targeting multiple steps in the same pathway could help to control metabolic fluxes in a more predictable manner [117]. Effort heavily depends on the development and utilization of drought-tolerant germplasm resources, which is far from plentiful and bottlenecks maize

improvement. Therefore, germplasm enhancement and development is foundationally important for maize improvement [118, 119]. Transgenic operation is a useful technology to overcome reproductive isolation among species and utilize beneficial exotic genes.

Acquired plant tolerance to abiotic stress can be achieved both by genetic engineering and by conventional plant breeding combined with the use of molecular markers utilizing QTL, Hsp, LEA, and ROS (Figure 33.6). The tolerance of the transgenic offspring is not strong enough to meet the requirement of maize production, as the mechanism of these exotic genes is not adaptive to physiological metabolism of maize. It is the key step to explore new exotic gene with strong tolerance and adaptive mechanism to maize [121–123]. Seed of improved cultivars has shown itself to be an effective means of delivering conventional and transgenic traits that contribute to improved yield and its stability.

Many loci for genes that control tolerance to abiotic stress in plants have been identified by genetic analysis [124, 125]. However, many genes that control agronomically important traits remain to be identified and modified to generate new varieties with desirable traits. There is evidence that transgenic plants in which the expression of a single gene has been modified have enhanced tolerance to abiotic stress [126]. Ideally, modification of a single gene should confer tolerance to more than one form of abiotic stress [127].

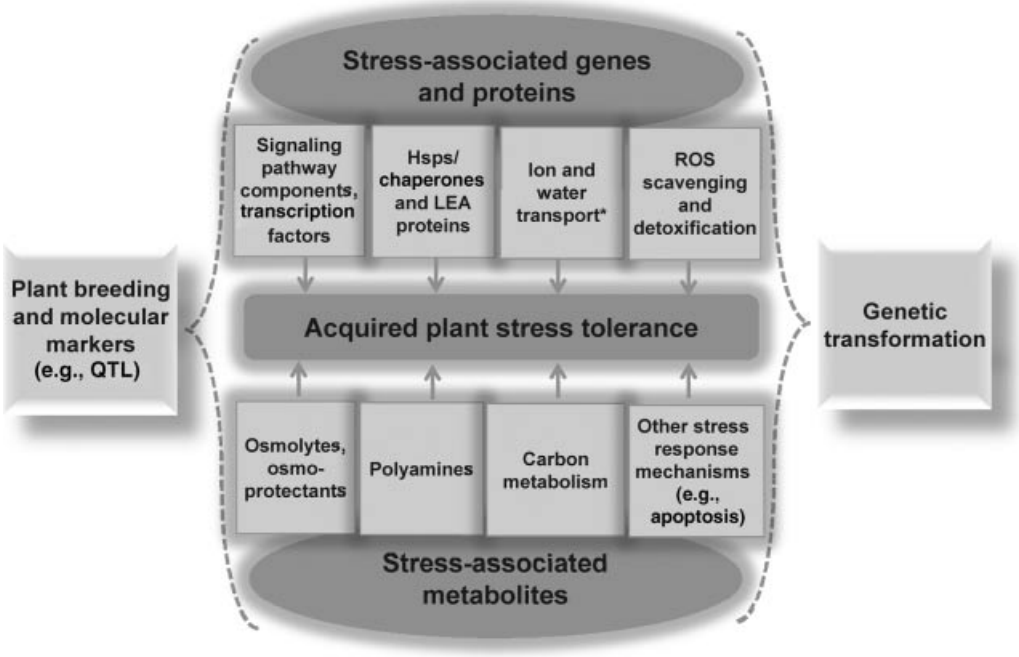

Figure 33.6 Approaches to improve stress tolerance [120].

SOD, dehydration-responsive element binding (DREB), and some other stress-tolerant genes have been used to transform maize for drought tolerance improvement. A new sequence of trehalose synthase gene *TPS1* was cloned from *Saccharomyces cerevisiae* using the method of homologous amplification. Sequence analysis showed that its similarity to formerly reported sequence of gene *TPS1* was as high as 99.3%. The putative protein of this sequence had the same conserved contigs with the protein sequences of trehalose synthases in many eukaryotic and prokaryotic organisms. This sequence was used as exotic gene to construct a stress-inducible expression vector and transform embryonic calli of maize mediated by *Agrobacterium*. After screening and regeneration, one fertile plant was detected to be positive using specific PCR amplification and sequencing of the amplified product [128]. Quan *et al*. [129] transformed maize with *betA* gene from *Escherichia coli* encoding choline dehydrogenase, a key enzyme in the biosynthesis of glycine-betaine. The transgenic maize plants accumulated higher levels of glycine betaine and were more tolerant to drought stress than wild-type plants (nontransgenic) at germination and the young seedling stage [130].

Multiple transgenic approaches include the use of polyol compounds such as mannitol [131] and sorbitol [132]; dimethylsulfonium compounds such as dimethylsulfoniopropionate and glycine-betaine [127]; sugars such as sucrose, trehalose [133], galactinol [34], ononitol [134], and fructan [135]; or amino acids such as proline [136] and ectoine that serve as osmolytes and osmoprotectants [7]. Therefore, it has been hypothesized that engineering the introduction of osmoprotectant synthesis pathways is a potential strategy for improving the stress tolerance of crop plants [48]. The genetic engineering of metabolic pathways for the production of osmolytes, such as mannitol, fructans, trehalose, proline, and glycine betaine, among others, might increase resistance to drought, but the mechanism by which these osmolytes provide protection is not completely understood [137]. Usually, the osmolytes are localized in the cytoplasm of plants. The active accumulation of osmolytes decreases the osmotic potential of cell and maintains cell turgor. Other responses, such as the production of scavenging ROS and the induction of chaperone-like activities that protect protein structure and metabolic detoxification, are also being reported during drought stress [138].

Metabolic engineering has allowed the introduction of biosynthetic pathways of glycine-betaine from microorganisms into maize. Indeed, maize accumulated higher levels of glycine-betaine when transformed with the beta gene from *E. coli* that encodes choline dehydrogenase, a key enzyme in the biosynthesis of glycine-betaine [129]. An assortment of genes with diverse functions are induced or repressed by these stresses [139]. Most of their gene products may function in stress response and tolerance at cellular level. Significantly, the introduction of many stress-inducible genes via gene transfer resulted in improved plant stress tolerance [2, 140].

Genetic engineering of plants for tolerance to extreme abiotic stresses could be achieved by the regulated expression of stress-induced TFs, which, in turn, would regulate the expression of a large number of relevant downstream genes [141]. TFs have been used to elicit multiple biochemical and developmental pathways that regulate drought tolerance, thereby improving performance during drought under

laboratory and greenhouse conditions [2]. The best stress-responsive TFs are the C-repeat binding factor (CBF)/dehydration-responsive element binding proteins that belong to the AP2/ethylene-responsive element binding protein family [142]. These factors enhance or modulate the expression of genes with a CBF/DRE box in their promoters and define a major stress tolerance pathway, in addition to the ABA biosynthesis/response pathway. On the other hand, the promoter of the early response to dehydration 1 (*ERD1*) gene contains *cis*-acting element(s) involved in ABA-independent stress-responsive gene expression [143]. Positive reports on the use of TFs to improve drought resistance in model and crop plants are based on laboratory and greenhouse conditions rather than field conditions; hence, the use of TFs in enhancing drought tolerance in crop plants should be considered with caution. Therefore, there is a need for understanding the basic molecular mechanisms influencing drought tolerance and grain yield under field stress conditions [7]. Till date, various genes and TFs crucial for stress tolerance have been studied [144].

Recently, drought tolerance in transgenic maize plants under field conditions has been enhanced through overexpression of NF-YB [144], which is part of a ubiquitous TF composed of three distinct subunits, NF-YA (HAP2), NFYB (HAP3), and NF-YC (HAP5) [145]. The NF-Y complex is also known as the HAP or the CAAT complex that acts in concert with other regulatory factors to modulate gene expression in a highly controlled manner. The overexpression of a maize CAAT box TF (ZmNFYB2) imparted significant tolerance to drought, resulting in increased yield. Most important, in field trials, the transgenic lines gave higher grain yields than control lines under drought conditions [7]. Engineering upstream signaling components of drought stress pathways might be another promising way to obtain drought stress tolerance. Indeed, constitutive expression of NPK1, a tobacco MAPKKK, in maize enhanced drought tolerance, as demonstrated by higher photosynthesis rates and higher kernel weight in the transgenic plants than those of the nontransgenic controls under greenhouse dehydration conditions [146]. The stress adaptation responses contribute to a yield advantage in maize that is grown within drought environments. The application of this technology is therefore expected to have the most significant impact on severely water-limited maize production systems [144].

33.9 Conclusions

The occurrence of drought varies unpredictably according to years, seasons, places, and within fields, so maize genotypes able to withstand stress throughout their life cycles at no cost to yield potential are the need of the hour. The use of genetics and genomics within an integrated framework that relies heavily upon critical input from disciplines such as plant breeding, crop physiology, crop modeling, and precise field phenotyping is sought. This integration of quantitative knowledge arising from diverse, but complementary, disciplines will allow researchers to more fully understand genes associated with drought tolerance in maize and more accurately predict the consequences of modulating expression levels of those genes.

Knowledge-based approach can improve maize production for the drought-prone weather and to develop more focused field screening techniques that increase rates of gain for yield and its stability under conditions of variable and unpredictable water stress. It is thus essential to test newly developed genotypes to multiple stresses and to carry out extensive field studies under a large range of conditions that assess tolerance as absolute yield increases. As a number of measures are in place to ensure the safe and responsible design of field tests, especially the transgenic approach, excessive precaution should not become a barrier to using all the tools available to us for a more sustainable agriculture.

Barley: Omics Approaches for Abiotic Stress Tolerance

Nicola Pecchioni, Justyna Anna Milc, Marianna Pasquariello, and Enrico Francia

Abiotic stresses such as frost, drought, salinity, hypoxia, and mineral deficiency or toxicity frequently limit growth and productivity of temperate cereal crops, for which barley (*Hordeum vulgare* L. ssp. *vulgare*) could represent a model. Improving barley resistance to such constraints is thus fundamental in view of the expected climate change for minimizing the gap between potential and actual yield (the so-called "yield gap"), increasing the yield stability, and guaranteeing the sustainability of the crop. As different omics technologies have been developed during the past few decades, they enabled systematic analysis of changes that occur in plants in response to abiotic stresses. In this chapter, we focus on the "omics" contribution to the improvement of abiotic stress tolerance in barley. After a brief summary of the most relevant abiotic stresses that limit the crop yields worldwide, successful genomics approaches have been described, starting from the exploitation of germplasm resources. Structural and functional approaches that helped in understanding the mechanisms and the genetic bases of abiotic stress tolerance, when applied to barley and model species (mainly *Arabidopsis*, rice, and *Brachypodium*), have been reviewed as an important step toward crop tolerance improvement. Quantitative genetics and genetical genomics of abiotic stress tolerance have been discussed, as they represent both a huge source of information and a challenge for future holistic approaches. Then, we present an overview of the contribution of other omics sciences (e.g., proteomics, epigenomics, metabolomics, ionomics, and phenomics). In the last section, integrative (systems) biology, together with a series of strategies for the future, is proposed and discussed.

34.1
Abiotic Stresses Relevant for Barley

Throughout their domestication and breeding, man has driven the genetic improvement of cereals toward high yields in different environments. Notwithstanding, physical or abiotic stresses, particularly drought, low temperatures and salinity, impose major limitations on cereal productivity worldwide. Trying to synthesize

Improving Crop Resistance to Abiotic Stress, First Edition.

some of its academic definitions, Levine [1] described "stress" as an adaptation syndrome to stressors, or stress stimuli; these disturb the homeostasis of an organism, which in turn, through a complex processing system, responds to the stress. In Levine's view, stress is then a complex concept consisting of three main subclasses, the input (stress stimuli), the processing systems, including the organism's subjective experience of stress, and the output (stress responses), with the basic difficulty that these subclasses interact. To quote Larcher, ". . .stress can be described as a state in which increasing demands made upon a plant lead to an initial destabilization of functions, followed by normalization and improved resistance. If the limits of tolerance are exceeded and the adaptive capacity is overtaxed, permanent damage or even death may result" [2]. According to Pahlich [3], a plant physiologist would consider how plants have to cope permanently with adverse environments, then stress is not an exception but rather a normal situation of plant life. However, for a plant breeder, the influence of stressors on the agricultural plant communities is one of the major known limits of their yield potential.

In the case of barley, *Hordeum vulgare* L. ssp. *vulgare*, abiotic stresses are responsible for significant grain yield losses on a global scale. Yet, under severe stress conditions, barley, as fourth world cereal in terms of harvested area, after wheat, rice, and maize, is one of the most important sources of energy for both humans and animals. Average world barley yield is of 2.8 ton ha^{-1}, according to FAO estimates (http://faostat.fao.org/), while its yield potential would be above 6.7 ton ha^{-1}, as measured for Argentina by Abeledo *et al.* [4]. The wide yield gap is significantly due to abiotic stresses, particularly drought and nitrogen, together with biotic ones, besides other technical and social limitations [4]. Globally, barley is cultivated in 54 129 438 ha (FAO's estimates for 2009), and its geographic distribution suggests how abiotic stresses have driven evolution, distribution, and ecology of both crop and whole genus *Hordeum*. In fact, the *Hordeum* species are diffused in temperate, subtropical, and arctic areas, from the sea level to heights of more than 4500 m a.s.l. in the Andes and Himalayas [5]. The same could be true for cultivated barley, widespread from the Northern boreal countries, as the last crop encountered before grassland toward the polar circle, up to the margins of the deserts [6].

From a physiological point of view, the different strategies adopted by plants to cope with stressful environments can be classified into the mechanisms of stress escape, avoidance, and tolerance [7]. The ability of barley to grow in very cold environments of cultivation is mainly an escape strategy: in the short summer of such climate regions only spring genotypes with a very short life cycle are grown. In totally different environments, the short growth cycle allows barley to set seed after rainfall winter growth, in dry and warm springs across the Mediterranean countries, when durum wheat also fails. Synchronizing life cycle to seasonal changes thus allows barley to escape extremely stressful conditions, although environmental adaptation also involves barley plant's ability to avoid or tolerate stresses such as frost, drought, or low soil fertility. From a breeding point of view, stress tolerance can be described as the capacity to maintain a constantly high yield, regardless of any environmental adversity (a concept known as yield stability).

A comprehensive classification of the abiotic (physical) stresses should comprise nutrients (nutrient imbalance); light (high light, UV, and darkness); water (deficit and flooding) and hypoxia; temperature (frost, chilling, and heat); salt; heavy metals and other chemicals; and mechanical (wind and touch). Among them, the most important and frequent stresses barley has to cope with are the following. Cold (frost) during winter, in the early vegetative phases, damages the fall-sown barley in the Northern Hemisphere. Drought and salt limit rain-fed barley yields in the Mediterranean, subtropical, and inner continental arid and semiarid areas of the world, from the vegetative to the grain filling phase, more often in the reproductive phase of its cycle. In the same areas, often barley experiences nutrient stress, particularly due to nitrogen deficiency. Cold stress in the reproductive phase is quite infrequent, except in certain regions of Australia where it is commonly due to cold winds [8]. Again in Australia, barley is exposed to toxic effects of imbalanced (excess) soil micronutrients such as boron [9]. In East Asia, when the barley crop is cultivated in paddy fields with a rice–barley double cropping system, it is often exposed to water damage and consequent soil hypoxia due to the Asian monsoon climate [5].

It is often underestimated that plants most often experience a combination of different abiotic stresses instead of a single physical stress. This is due to the complexity of the physical and biotic factors that affect and characterize natural and agricultural systems. For example, barley plants are exposed to heat and drought, drought and nutrients, salt and drought, rather than simply to drought. As a consequence, while generally abiotic stress "omics" experiments have often been performed by molecular biologists under controlled conditions (growth chambers, hydroponics, etc.), field experiments hold the greatest value for reality of the combined stress conditions. As it will be demonstrated in the chapter, a common part of the plant response/tolerance to multiple stresses surely exists. This was indirectly deduced by very similar cellular damages from different stresses. But it was also demonstrated, for example, by the improved tolerance to multiple abiotic stresses acquired by plants transformed by single key transcription factors such as *DREB1A* (dehydration responsive element binding 1A) [10] or *TaERF1* (*T. aestivum* ethylene-responsive factor 1) [11]. On the other hand, Mittler [12] correctly addressed the existence of specific responses to multiple stresses. He underlined how recent studies revealed that plants response to a combination of two different abiotic stresses has a unique component that cannot be directly deduced if each stress is applied individually. Notably, Rizhsky *et al.* [13] highlighted the plasticity of the genome of *Arabidopsis thaliana* (L.) Heynh. (hereafter, *Arabidopsis*), demonstrating its ability to respond to a combination of drought and heat stresses. Besides genes that were commonly or specifically induced by each single environmental factor, 454 transcripts were exclusively induced in plants exposed to both stresses simultaneously [13].

Moreover, it should be considered that there can be under natural conditions three kinds of recognized interactions between stresses: (i) no interaction, for example, between heat and chilling; (ii) positive interaction, for example, between light and ozone stresses; and (iii) negative interaction, for example, between

drought and nutrient. In other combined stresses, the kind of interaction is not known [12].

The cultivated and wild barley species within the *Hordeum* genus are part of the Triticeae tribe in the Poaceae family. Representing strategic main food and feed commodity crops in the Triticeae, wheats (bread and durum) and barley are among the First World crops in terms of cultivated areas and product quantities (with barley and wheat ranking sixth and ninth, respectively; http://faostat.fao.org/). Other cultivated members of the tribe of lower importance are rye, triticale, emmer, einkorn, and minor wheat species.

Among temperate cereal crops, it is well known that winter barley types are less tolerant to frost damage than winter wheat or winter rye and triticale. On the other hand, barley seems more adapted than wheat to shallow and poorly fertile soils or to arid environments [5]. Stanca *et al*. [5] and Walia *et al*. [14], on the basis of previous studies, clearly classify barley as more salt-tolerant than wheat, and as salt-tolerant member of the tribe. Barley (*H*. *vulgare* L.) could be considered a good model for the Triticeae among the temperate cereals, to study plant response to adverse environmental conditions. Its inbreeding behavior and diploidy make the genetic and genomic studies easier to perform compared to the polyploid wheats. The above cited wide range of adaptations, the availability of large genetic stocks, and the extended genome colinearity, not only with other members of the tribe but also with the genome of *Brachypodium distachyon* (L.) Beauv. (hereafter *Brachypodium*), are additional advantages for barley as a model [15, 16].

The "omics" approaches hitherto applied to understand the impact of environmental stressors on the final phenotype are here reviewed in the model diploid cereal barley, with the hope that they will help drive the "developmental trajectory" [1] of future cultivars to resilience under stress.

34.2
Genomics Approaches for Abiotic Stress Tolerance in Barley

Abiotic stresses influence plant growth and severely limit their yield potential, as already underlined. Although the genomes of Triticeae are large and still poorly characterized relatively to the model species, the diversity in the cultivated and wild gene pools for the Triticeae tells us that there is room for achieving greater tolerance. Research efforts have been and are mostly directed toward a better theoretical understanding of the genetic basis of the adaptive response of plants to stress. The complexity of abiotic stress responses, networks of signaling pathways, and interconnecting processes were dealt *in primis* with broad approaches of genomics coupled with bioinformatics [17, 18]. Therefore, the wide spectrum of genomics resources developed during the past two decades to facilitate the systematic analysis of the barley genome are reviewed here, with special emphasis to the best exploitation of theoretical knowledge for applied purposes. We are in fact convinced that the applied aspect of genomic research would deserve in coming years constantly increasing attention.

34.2.1
Genomics for the Exploitation of Barley Germplasm Resources

Plant genetic resources (PGRs) have been useful for both breeders and research community, at least since the first decades of the last century, for useful trait introgression. Plant germplasm collections respond today to the pressing need of preserving biodiversity, at its three recognizable levels. If, in fact, we would like to define the concept of biodiversity, we would better divide it into the three levels of intraspecific ("genetic"), interspecific, and (eco)system biodiversity (modified from Ref. [19]). This last one depends and causes at the same time a series of interactions between organisms, and between them and the physical stressors. From a conservation perspective, the intraspecific variation (in case of *H. vulgare* L.) can be more easily maintained in *ex situ* collections, both private and public, since its maintenance in the agricultural areas for a crop species cannot be pursued regardless of economic considerations. The interspecific one should be instead better preserved *in situ*; under such a condition, a natural dynamics of the diversity can, in fact, be maintained, in all the environmental stimuli, rather than in a "fixed" environmental situation like that of a germplasm collection. However, conservation *in situ* has the necessity of a land conservation project, and for the social and economic obstacles often encountered in such projects, crop relatives and other plant species are preserved in gene banks also at the interspecific level.

In the genomic era, the most valuable sum of the *ex situ* and *in situ* resources should be viewed at least as the primary (GP1) and secondary (GP2) gene pools. In the Harlan's concept, these two comprise (1) both cultivated and wild species easily crossable with the cultivated ones (GP1); (2) species that can be cross-bred only with difficulty with the cultivated one (GP2). In case of barley, GP1 is composed of *H. vulgare* L. ssp. *vulgare* cultivars and landraces, together with the wild *H. vulgare* L. ssp. *spontaneum* (K. Koch) Thell. accessions, while GP2 is composed only of the species *H. bulbosum* L. [20].

The greatest genomic value of the primary and secondary gene pools should be that of an immense "barley metagenome," boldly extending the proper concept of metagenome [21]. Such a value recently increased because of the advent of second-generation sequencing [22], and in the next decade could further increase with the availability of the third-generation sequencing technologies [23]. Because of its large genome, in the near future, at least the resequencing of the "gene space" of barley gene pools should allow "fishing" a huge reservoir of alleles for their transfer to the future barley cultivars. Apart from the technical limits described in Section 34.2.2, the association between allele variation and precise phenotypic variants should be taken into careful consideration as a bridle to the enthusiasm for genome resequencing. On the other hand, a bright development work and the use of prebreeding materials would be necessary. In fact, it has been demonstrated both in rice and in tomato how useful variation can be hidden in wild materials with lower phenotypic value [24].

Systematic collection of barley diversity on a worldwide scale started in the early twentieth century, after the Vavilov's theory and inputs [25]. Major collections (holding more than 10 000 accessions) are being conserved in Australia, Brazil,

Canada (Plant Gene Resources of Canada – PGRC), China (CAAS – Chinese Academy of Agricultural Sciences), Ethiopia, Germany (Leibniz Institute of Plant Genetics and Crop Plant Research – IPK), Japan (Okayama University), Mexico, Russian Federation (Vavilov Institute), South Korea, Sweden (Nordic Gene Bank), Syria (ICARDA – International Center for Agricultural Research in the Dry Areas), the United Kingdom, and the United States (USDA-ARS – United States Department of Agriculture, Agricultural Research Service). In the initial phase of development of the Global Strategy for the *Ex Situ* Conservation and Use of Barley Germplasm, ICARDA was commissioned by the Global Crop Diversity Trust, with major input from the IPK, Gatersleben, Germany, to coordinate the development of a global inventory of barley genetic resources in *ex situ* collections. It was demonstrated that the total of barley germplasm holdings at 47 major barley collections (those with more than 500 accessions) was of 402 000 accessions, and if 28 minor collections are also considered, the global total would rise to 405 000. Of the 290 820 accessions for which germplasm type is known, 15% are wild relatives, 44% are landraces, 17% are breeding materials, 9% are genetic stocks, and 15% are cultivars [26].

The Nordic Gene Bank *Hordeum* collection consists of 45 species and about 13 000 accessions. Furthermore, NGB stores many special collections, including the about 10 000 accessions of barley mutants, and the collection of near-isogenic lines (NILs) of wheat, oat, and barley with different resistance genes in a standard genetic background [27]. The barley genetic stock collection at USDA-ARS consists of over 2000 accessions collected worldwide. The accessions are entered as GSHO (genetic stock of *Hordeum*) on the GRIN (Germplasm Resources Information Network) database. Also remarkable is the public availability for the research community of the Oregon Wolfe Barley (OWB) population of 94 doubled haploids (DHs) [28] that were derived from the F1 of a cross between the dominant and the recessive parental marker stocks developed in 1972 at Brandon, Canada, by R.I. Wolfe. Ninety-four Oregon Wolfe Barley Genetic Stocks are also included in the GRIN database (GSHO 3325–3418). The European Barley DataBase (EBDB, http://barley.ipk-gatersleben.de/ebdb) is a central activity of the Barley Working Group and includes about 155 000 accessions from 23 European countries and about 38 000 additional accessions from three non-European gene banks, Australia (the Australian Winter Cereals Collection – AWCC), Syria (ICARDA), and Japan (Barley Germplasm Center). Moreover, more than 1000 accessions from the International Barley Core Collection (BCC) are documented [29]. Such a collection, which contains both wild and cultivated genotypes, was developed thanks to an international coordinated effort [30], and could be valuable for allele mining.

A database on barley genes and genetic stocks (BGS, http://ace.untamo.net/) was also developed using AceDB and the data model is similar to the one used in GrainGenes. This server contains information on morphological barley mutants and their genetic background. Hyperlinks to some gene banks holding the mutant accessions and parents (ARS/GRIN/NSBC or NGB) have been added to facilitate easier access to stock material containing specific alleles.

From a phenotypic point of view, diversity for abiotic stress tolerance can be found in various genetic stocks [5]. For example, Nevo [31] reported that the root system of

the barley direct ancestor *H. vulgare* L. ssp. *spontaneum* penetrates deeply into the warm steppes and deserts. A large number of Asian cultivated barleys were tested for tolerance to hypoxia in terms of water sensitivity, pregermination and postgermination flooding. From the 1980s, a great number of barley accessions have also been evaluated for salt tolerance in different experiments and under different stress conditions [5]. From one of such *H. vulgare* L. ssp. *spontaneum* accessions, CPI-71284-48, the "wild" allele of the *HvNax3* gene reducing shoot Na^+ accumulation is going to be cloned by colinearity analysis with rice and *Brachypodium* [32].

For any project involving allele diversity mining, two approaches are possible. The former is based on sequencing, while the latter is based on EcoTilling. In both cases, at least for the moment, the experiments have been driven by trait – and underlying genes – priority [33]. Moreover, since the "true" allele mining should include the coding, noncoding, and regulatory regions of a gene, the availability of full genomic sequences of the target genes should be available. To realize the potential of allele mining in genetic resources, some of the international research institutes maintaining crop germplasm collections have initiated studies to characterize the allelic diversity of crop plants. In perspective, although many hurdles still need to be overcome, the success of allele mining strategies is expected to result in a real quantum leap in the use of PGRs. At present, however, allele mining seems to be still a quite underexploited approach to unlock the diversity in the collections of the world gene banks [34]. The few examples of allele mining available in literature for barley mostly focused on cultivated germplasm. These efforts were concerned with few genes, mostly amylase and others not involved in abiotic stress response, apart from the allele survey of the couple *VRNH-1/VRN-H2*, regulating the vernalization requirement and partially involved in frost stress tolerance, in 429 spring, facultative, and winter European varieties [33, 35].

One challenge for allele mining in barley PGRs, as well as in other species, is an appropriate selection of genotypes. In fact, screening the entire collection would be helpful to find rare alleles, for sure, but this would be an enormous task for a research institute. Hence, a prioritization of genotypes should be done, like the development of core or even minicore collections [36], as the BCC, which could constitute the starting materials for the mining efforts. Moreover, as already underlined, accurate phenotyping methods are needed to increase the efficiency of allele mining. Finally, efficient computational tools are necessary to ensure the access to useful alleles [37]. Other issues that should be solved are then the demarcation and characterization of putative promoter regions and the reduction of the cost per data point when analyzing allele sequence variants.

34.2.2
Barley Structural Genomics Resources

Barley "H" genome, as those of the other cultivated Triticeae, is a large genome of >5000 Mb, according to Bennett and Smith [38]. However, we would like to reinforce the concept of barley as a genomic model for wheats, for the reasons discussed in Section 34.2.1, and because barley science provided experimental results that

assumed a general importance for understanding the Poaceae and plant biology [16]. In the time space between the end of the past century and the first decade of the twenty-first century, which has seen the first plant small- and medium-sized genomes fully sequenced, it has partially closed the gap between the size of large genomes, such as barley and wheat, and the technological feasibility of sequencing them at reasonable costs, through next-generation sequencing (NGS) [22]. Although so far it is not definitely demonstrated that large genomes like barley that feature >80% of repetitive DNA can be fully sequenced, recent research efforts created new barley genomic resources that bring the goal closer [16]. It was thus shown that NGS technologies can be suitable to determine gene content of barley BAC clones [39], can support automated repeat annotation of barley genomic DNA [40], can lead to correctly assembled BAC clone *de novo* sequences [41], and can allow by whole-genome shotgun (WGS) the characterization of the composition of the barley genome [42]. These first glances at the composition of the barley genome promise future advancements toward understanding of barley biology, including that of abiotic stress response. The availability of a fully ordered reference genome sequence could, in fact, provide a physical "harbor" to link in a more coherent network the other genetics and omics discoveries about abiotic stress biology. The steps and resources that led to the present situation of the barley structural genomics, particularly those relevant to abiotic stress response, are reviewed here.

Resources for barley structural genomics have improved over the past two decades, initiated in 1991 with the release of the first barley genetic map [43]. Now, about 70 barley maps with a large number of molecular markers are available, and a comprehensive overview of published genetic map resources in barley can be obtained from the GrainGenes database at http://wheat.pw.usda.gov/ggpages/map_summary.html. In recent years, there has been a significant progress in both marker density and convergence, leading to consensus maps for the species. Consensus maps containing 1230 markers (RFLP, AFLP, SSR, and SNP) from three doubled haploid populations [44] and 3458 markers (RFLP, AFLP, and SSR) from six mapping populations [45] were recently developed. Varshney *et al.* [46] produced a 775 SSR consensus map by joining six independent maps. The latest technological developments in barley genomics and genetics include the Diversity Arrays Technology (DArT), which allowed for the simultaneous analysis of several hundred gene loci and resulted in a high-density map of barley molecular markers linked to agricultural traits [47]. Wenzl *et al.* [48] created a consensus map containing 2935 markers combining DArT with RFLP, SSR, and STS from nine mapping populations. Hearnden *et al.* [49] combined 1000 SSR and DArT markers on a map from a wide cross. Potokina *et al.* [50] combined SNP and other transcript-derived markers to position 1596 loci on the "Steptoe" × "Morex" linkage map.

Another step forward from genetic maps to genome knowledge was taken thanks to expressed sequence tag (EST) sequencing, later with EST assembling, and particularly with their anchoring to genomic positions. The first initiative of systematic EST sequencing to establish a public EST database on wheat and barley has

been the ITEC (International Triticeae EST Cooperative), proposed at the Ninth International Wheat Genetics Symposium held at Saskatoon, Saskatchewan, in August 1998 (http://avena.pw.usda.gov/genome/). ITEC, starting with only six wheat ESTs and a handful of other Triticeae ESTs on record in 1998, was the first to produce thousands of barley ESTs, among others, from a cold-induced leaf cDNA library [51]. Later, Zhang *et al.* [52] generated more than 100 000 barley ESTs from 22 cDNA libraries representing tissues at various developmental stages, and with this began large-scale sequencing programs for the development of ESTs from various cDNA libraries. Today, progress made in the past 12 years has resulted in the generation of 502 620 ESTs for *H. vulgare* ssp. *vulgar*e covering different cDNA libraries from various stages of plant development and tissues, challenged with abiotic and biotic stresses (http://ace.untamo.net/ release 100110, October 1, 2010). The alignment of these ESTs led in the past decade to the identification of 43 306 tentative consensus (TC) sequences and 39 502 singletons (http://compbio.dfci.harvard.edu/cgi-bin/tgi/gimain.pl?gudb=barley, Release 11.0, April 14, 2010). Searching the annotations with the abiotic stress-related keywords, one can find 11 entries for "drought," 9 for "water stress," 74 for "salt," 123 for "cold," and 37 for "heavy metal."

At the same time, a broad range of online bioinformatic tools and databases have been developed. These, such as Gramene (http://www.gramene.org), GrainGenes (http://wheat.pw.usda.gov), PlantGDB (http://www.plantgdb.org), and HarvEST (http://harvest.ucr.edu), help scientists to formulate and test their genomic hypotheses and to share their results with the barley research community, through the publication of genetic loci where the ESTs have been mapped thanks to different efforts. In fact, on the one hand the *in silico* expression studies on the EST data sets [52] provided snapshots of the transcriptome of diverse plant tissues at different stages, aiding in gene discovery, and allowed identification of metabolic and regulatory networks [18, 53]. On the other hand, several mapping projects were targeted to establish EST-based molecular maps [44, 49, 54, 55]. Among the first maps, the functional genetic map of Tondelli *et al.* [54] was based on three different mapping populations and on regulatory candidate genes (CGs) for abiotic stress tolerance; an integrated barley transcript map comprising 1000 EST-based markers and 200 anchor markers from previously published data was generated by mapping them in three DH populations, as a tool for the integration of genetic and physical mapping information [55]. Recently, nearly 3000 ESTs were mapped on a high-resolution transcript linkage map of barley created using a single DH mapping population and only PCR-based assays [56]. A dense consensus map based on transcribed gene SNPs derived from four mapping populations was also developed by utilizing the Illumina GoldenGate assay (Illumina Inc., San Diego, CA) [57], and Schulte *et al.* [16] estimated that the number of nonredundant barley genes mapped so far reached more than 5000. Eventually, in the near future the strategy used in the small genome species rice could be adopted for barley, where the available reference genome sequence allowed a high-throughput genetic mapping, on a gene-by-gene basis, by whole-genome sequencing of a segregating population [58].

At present, the high-density molecular maps based on gene-derived markers constitute the genetic scaffold for barley physical genome mapping. During the past years, core public resources have been established by generating bacterial artificial chromosome (BAC) libraries [59]. Libraries from cultivar "Morex" [60], "Cebada Capa" [61], and "Haruna Nijo" [62] have been reported, with several others already constructed and being in the making. The BAC libraries represent a useful tool not only for physical map construction but also for isolating several genes of agronomic interest by positional cloning. As one of the last examples of such use for abiotic stress tolerance, Shi *et al*. [63] developed a BAC library of the barley doubled haploid line "CS134," which contained tolerance alleles from the genotype "Sahara" at four boron tolerance loci, and one of the BAC clones facilitated isolation of the boron tolerance gene *BOT1* at its locus on chromosome 4H. As already outlined, EST dense maps can function as a framework for physical mapping of barley. One of the first efforts in physical mappping of the barley genome concerned the assignment of physical positions to the mapped ESTs, to chromosome arms, by using cytogenetic stocks, such as barley–wheat addition lines [64]. Such low-resolution physical mapping approach is a useful first step in developing BAC contigs for genome sequencing. However, better estimates of physical arrangements of BAC clones would be necessary in case of an ordered sequencing strategy. In the past years, increasing evidence has been found that genes are not randomly distributed across the barley genome, but are confined to a "gene space," which mainly covers the distal parts of the chromosomes [59]. Experimental evidences for the existence of a gene space has been gained from screening a barley BAC library with EST-derived probes, which showed a significant nonrandom distribution across the BAC clones [65]. The existence of a gene space also enables the researchers to focus analysis on gene-rich regions. By following an NGS sequencing strategy, Wicker *et al*. [39] were able to identify gene-containing "Morex" BACs by 454 sequencing. Some time later, by an alternative strategy, through the screening of the "Morex" BAC library using EST-derived, pooled "overgo" probes, Madishetty *et al*. [66] also identified the gene-containing barley BACs. Hybridization using "overgo" probes is an established approach for screening arrayed BAC libraries, which consists in annealing two 24-base or 22-base oligonucleotides with an 8-bp overlapping region and filling in the overhanging bases with Klenow enzyme and radiolabeled nucleotides. The probes that result from this procedure can be multiplexed and are characterized by low background hybridization; Madishetty *et al*. [66] have improved the yield of "overgo" positive clones using reduced levels of radioisotopes and enzyme.

The identified gene-rich BACs have been selected from cultivar "Morex" to initiate sequencing of all gene-containing regions of the barley genome by an international effort, coordinated through the International Barley Sequencing Consortium (IBSC, http://barleygenome.org). The international consortium was composed of eight founding institutions from six countries and was established in 2006; it was joined by China in 2010. Owing to the cost and technical difficulties, an immediate start could not be made with sequencing of the entire large complex genome of barley, as explained by its high content of repetitive DNA [16]. Therefore, a stepwise approach

was chosen that included the preparation of the necessary genomics and bioinformatics tools. The envisaged stepwise procedure should combine the strengths of map-based sequencing of a minimal tiling path with paired-end WGS sequencing [16]. To test the feasibility of the NGS methods for *de novo* sequencing, Wicker *et al.* [39] used 454 technology to sequence four barley BAC clones and compared the results with those from ABI Sanger sequencing. All gene-containing regions were covered efficiently and with high quality. Then, a pool of barcoded barley BACs was sequenced using the GS FLX platform and assembled correctly. It was shown that the gene-containing regions seem to assemble completely and uninterruptedly, thus making this approach suitable for detecting complete and positionally anchored genes [41]. The building of a genome-wide physical map of barley genome (*H. vulgare* L. ssp. *vulgare* cv. "Morex") is based on high information content fingerprinting (HICF) of BAC clones that are provided from five different BAC libraries (2x *Hind*III, *Eco*RI, *Mbo*I, and random sheared [67]). Cultivar "Morex" had been chosen as a genomic reference because numerous resources have already been generated using this genetic background. The complete physical map will comprise a 13–14-fold haploid genome coverage. In order to anchor the BAC contigs to the genetic map of barley, so far more than 6000 marker/BAC relationships were established. Anchoring is performed by PCR- and/or hybridization-based screening of BAC libraries with gene-based and genomic DNA-based marker types [68]. An IBSC goal is to obtain 10 000 mapped barley genes anchored, and high anchoring throughput can be obtained by means of available multiplex marker platforms as DArT and the Golden Gate assay [16]. In parallel, using low-pass shotgun sequencing, Wicker *et al.* [40] generated more than 500 Mb of Illumina/Solexa sequences from barley total genomic DNA, representing about 10% of genome equivalent. Then, to obtain a whole-genome sequence sample, two runs of 454 (GS20) snapshot sequencing on genomic DNA of barley cv. "Morex" were performed by Wicker *et al.* [42], which yielded approximately 1% of a haploid genome equivalent. Almost 60% of the sequences turned out to represent known transposable element (TE) families, while another 9% represented novel repetitive sequences. IBSC initiated the sequencing of the barley genome in 2006, but the time for its completion is hard to estimate (minutes of the IBSC Business Meeting at Plant Animal Genome XVIII, January 2010; http://barleygenome.org).

34.2.3
Role of Model Species

Many recent advances in genomics research have been based on model species. In the case of grasses, although the feasibility of sequencing large genomes like that of barley has been demonstrated, the main role of the model grass genomes of rice and false brome (*Brachypodium*) is in the synteny-based genomic research. Recently, increased genomic data for cereals allowed Bolot *et al.* [69] to propose a model for the evolution of the grass genomes from a common ancestor. On the basis of their data, an "inner circle" comprising five ancestral chromosomes was defined providing a new reference for the grass chromosomes and new insight into their ancestral

relationships and origin. In barley, Mayer *et al*. [70], through comparison against the reference genomes of rice (*Oryza sativa*) and sorghum (*Sorghum bicolor*), and against wheat (*Triticum aestivum*) and barley expressed sequence tag data sets, estimated the presence of 4600–5800 genes on chromosome 1H. They identified conserved gene content between chromosome 1H, known syntenic regions of both rice chromosomes 5 and 10, and sorghum 1 and 9. Informed by the syntenic relationships between the two reference genomes, genic barley sequence reads were integrated and ordered to deduce a virtual gene map of barley chromosome 1H. Recently, a collinear structure, although with variations in the number of *CBF* elements (14 in barley, 9 in *Brachypodium*, and 3 in rice), was described between the *FR-H2* frost tolerance locus of barley and the corresponding *CBF* clusters of rice and *Brachypodium* [71].

Besides the synteny-based genomic studies, the model species *Brachypodium* deserves a particular interest for the abiotic stress biology since it is a temperate wild grass species [72], evolved in an ecological situation very similar to that of wheat and barley and therefore most likely exposed to a very similar array of stimuli. Its small genome size has been entirely sequenced; Sanger sequencing was used to generate 9.4× coverage and the final assembly of 83 scaffolds covers 271.9 Mb. Sequence scaffolds were aligned to a genetic map to create pseudo-molecules covering each chromosome [73]. Moreover, the false brome species presents self-fertility, a short life cycle, diploidy in the ecotypes, the subject of genomic studies, and simple growth requirements [74]. Genetic and genomic research resources for *Brachypodium* have evolved with the development of diploid inbred lines [75] and the establishment of a high-efficiency transformation system [76]. Genes most suitable for normalizing the gene expression data in *Brachypodium* have been identified [77]. Diverse collections of *Brachypodium* accessions are valuable resources for examining the natural variation of important traits such as its tolerance to abiotic stresses. The wide phenotypic variation in *Brachypodium* in response to drought stress has been recently explored and can be used to identify genes and alleles for the complex trait of drought tolerance [78].

34.2.4
Barley Functional Genomics Approaches for Abiotic Stress Tolerance

A major aim of functional genomics is to understand on a genome scale the metabolic and transcriptional networks within the structural and functional contexts of cells, tissues, and organs in a time course. Two approaches can be distinguished for studying the function of "stress genes." The first "functional" approach, considers stress genes as those crucial for response to a given stress, implying that mutational gain or loss of function of genes involved should result in altered stress tolerance. The second, the "inducible" approach, considers stress genes as those induced under the stress conditions and is based on the study of their modulation under stress, through differential screenings and displays and microarray methodologies [79].

In case of the functional genomics of barley's response to abiotic stresses, the most investigated field has been the "inducible" one, with a considerable amount of transcriptomic data generated. In comparison, less information derived from the

functional approach, as well as for the not-easy technical route that barley transformation takes. However, significant functional genomic resources such as TILLING (targeting-induced local lesions in genomes) populations have been produced, and these might be valuable tools for demonstration of hypotheses about the mechanisms of tolerance.

34.2.4.1 **Reverse Genetics Platforms**

To aid the "functional approach" analysis, efficient transformation systems and genome-wide systems for reverse genetics were developed for barley, including transgenic insertional mutagenesis and nontransgenic platforms such as TILLING [59]. All these systems were transferred to barley a few years after their initial development as mature technologies in *Arabidopsis* [80].

As far as transgenic insertional mutagenesis is concerned, the initial necessary step was the establishment of an efficient transformation system. The first studies of successful barley transformation in the early 1990s used biolistic techniques, followed after few years by *Agrobacterium*-based techniques to introduce DNA to immature embryos; these remain the target tissue of choice for obtaining high transformation efficiencies. *Agrobacterium*-mediated transformation of barley has now become more efficient in recent years with the development of new methods and protocols making high-throughput experiments more achievable [81]. As an alternative, *Agrobacterium*-based transformation system that uses microspore cultures as the target tissue was developed [82]; using this approach, homozygous doubled haploid plants can be obtained at high frequency through chromosome doubling. The successful introduction of Ac/Ds elements to knockout gene functions [83, 84] was the beginning of the establishment of gene tagging functional genomics in barley. The two-component maize transposon system *Ac/Ds (Activator/Dissociator)* is a widely used system for transposon-based insertional mutagenesis in plants, exported from maize to other species. In a heterologous two-element system, the nonautonomous Ds element may be activated by crossing the Ds-containing plant with an individual carrying the transposase gene (AcTPase) [85].

After the first results of Koprek *et al.* [83] and Scholtz *et al.* [84], insertional mutagenesis approaches in barley were thus used in the last decade to create both gain-of-function [86] and loss-of-function [87, 88] mutant platforms. The former approach, the last one achieved in the species in order of development, involves a random genomic insertion of either promoter or enhancer sequences that produce novel, dominant mutations by overexpression of endogenous genes (activation tagging). As regard activation tagging in barley, Ayliffe *et al.* [86] developed a tagging system where a modified Ds element containing two maize polyubiquitin promoters (UbiDS) was utilized for activation of transcription of adjacent flanking sequences. This study demonstrated the feasibility of activation tagging in barley, an approach particularly useful in large cereal genomes where gene redundancy may preclude gene identification through recessive loss-of-function mutations.

The systematic development of transgenic barleys overexpressing candidate genes for abiotic stress response could also have, other than an applied value, a theoretical

value, for validation of their functions in relation to abiotic stress tolerance. The possibilities for increasing tolerance to abiotic stresses by genetic transformation with candidate genes are enormous, while it is notable that the actual production of transgenic plants with demonstrably improved abiotic stress tolerance had been slow and limited to few species [89, 90]. Still there are only a few reported applications of transgenic barley for improving tolerance to abiotic stresses. Very recently, Morran *et al.* [91] generated transgenic wheat and barley plants expressing the TaDREB2 and TaDREB3 *T. aestivum* DREB transcription factors, with both constitutive (double 35S) and drought stress-inducible (ZmRab17) promoters. They obtained resistance to both drought and frost stresses, and the induction of other *CBF/DREB* genes, together with a large number of stress-responsive *LEA/COR/DHN* (late-embryogenesis abundant/cold-regulated/dehydrin) genes. Transgenic barley plants expressing *ALMT1* (Al-activated Malate Transporter 1) gene of wheat that encodes a malate transporter associated with malate efflux and aluminum (Al) tolerance were developed [92]. The results demonstrated that *ALMT1* was able to confer tolerance to Al in acidic soils. Barley genes had been more widely used to improve stress tolerance once introduced in other transgenic plants. For instance, expression in rice of the barley *HvHVA1*, a LEA gene, was one of the first reports of genes conferring tolerance to salt stress in plants [93]. The same transgene allowed rice to stand water deficit [93, 94], while transgenic overexpression of *HvCBF4* in rice resulted in an increase in tolerance to drought, high salinity, and low temperature without stunting growth [95].

A limit of the use of transgenesis to systematically modulate in barley the expression of the inserted genes is intrinsic in the methodology; that is, the reported experiments are based on hypotheses of action for single genes. Moreover, in the barley private breeding sector, a high-throughput transformation system similar to the "FAST Corn" system of maize (http://www.pioneer.com) does not exist. The technology consists in introducing large numbers of transgene combinations into corn quickly, potentially thousands per year, and using automated handling and precise digital imaging technologies to assess how specific transgenes affect a plant throughout its life cycle. The Pioneer maize seed company used the FAST Corn technology in the recent years, with which drought-tolerant transgenic hybrids were developed (DroughtII program, http://www.pioneer.com). However, a transient assay system based on bombarded leaf epidermis was developed and proved to be useful, to directly assess gene function in barley and wheat suffering from powdery mildew, a biotic stress caused by the fungus *Blumeria graminis* [96, 97]. This system, which can be used not only for transient overexpression of genes but also for transient-induced gene silencing (TIGS), has been further developed using GATEWAY technology in order to enhance throughput [98]. It is worth mentioning such a system of reverse genetics since a number of barley mRNAs homologous to drought response genes were selected and targeted by TIGS in microprojectile-bombarded barley leaves showing the value of the TIGS system for functional prescreening of a larger number of dehydration stress-related candidate genes [99].

As regard to the generation of loss-of-function mutants for barley functional genomics, a system for targeted gene tagging and local saturation mutagenesis based

on maize transposable elements (Ac/Ds) was reported [88]. With a long-term objective to develop and make available to the research community a comprehensive set of Ds insertion lines in barley containing a single Ds element assigned to a genomic position, on a barley linkage map, two complementary approaches were applied. In the first approach, a set of Ds-inserted lines was created by reactivating few original single-copy Ds plants by crossing them with AcTPase expressing plants and then recovering the transposed lines. Because it is known that Ds element tends to transpose at genomic positions close to the original Ds locus, to increase the number of genomic regions where it would have been possible to inactivate genes by local transposition, a second set of Ds-inserted lines was created. These lines were obtained by introducing Ds-carrying T-DNAs via *Agrobacterium* transformation. Single Ds insertions were then mapped genetically to verify the chromosome coverage. Sequence analysis of flanking regions for transposed Ds and T-DNA inserted Ds revealed a predominant insertion into nonredundant, gene-containing regions of the barley genome. Moreover, the observed high transposition frequencies demonstrated that the Ds launch pads could provide a solid base for functional genomics in barley [88]. In their study, Singh *et al*. [87] generated 100 multigenerational barley Ds insertion lines since no previously published data had been available in barley or wheat regarding the capability for consecutive Ds remobilization during generation advance. It was demonstrated that observed frequencies of reactivation of primary, secondary, tertiary, and quaternary TNPs (transposants–transposons insertion lines) could be sufficient for a saturation mutagenesis approach using Ds.

A gene trap system based on Ac/Ds was reported in barley as a valuable tool for knockout mutation, as well as forward and reverse genetic screens [100]. Gene trapping is a high-throughput insertional mutagenesis approach, in which a gene-trapping cassette consisting of a reporter gene and/or selectable genetic marker is used. The gene traps are characterized by splice acceptor sites and sometimes by an intron upstream of the reporter gene coding region. Such a structure facilitates the expression of in-frame reporter protein fusions regardless of insertion into intron or exon sequences. Until then, gene trap and enhancer trap approaches in monocots had exclusively been reported in rice; Lazarow and Lutticke [100] thus expanded the number of genomics tools available to the barley research community. The frequent transposition of the gene trap construct and the observed efficient expression of the reporter gene demonstrated that this approach could represent a significant step toward large-scale gene trapping in the crop.

Although insertional mutagenesis is a powerful, much more scalable tool for generating novel mutants, it has some limitations. These include the impossibility of studying the function of multigene families, the difficulty to reach genome saturation, and the possible parallel disruption of several genes due to the multiple insertions [85, 101]. These obstacles can be overcome by posttranscriptional gene silencing (PTGS), an RNA-mediated systemic silencing mechanism that permits to specifically silence or knock down the expression of targeted gene in plants. The discovery of the RNA interference (RNAi), in which double-stranded RNAs (dsRNA) trigger degradation of a target mRNA containing homologous sequence [102], led to the development of different and efficient dsRNA-mediated gene silencing

methods [85]. In plants, a particularly effective method for induction of dsRNA-silencing is transformation with a chimeric gene construct producing hairpin RNA (hpRNA). Such construct consists of inverted regions of the target gene sequence, separated by an appropriate spacer, which were shown to activate RNAi pathways in almost 100% of the transformed plants [103]. In a study by Wang *et al.* [104], in which plants were transformed in an attempt to create transgenic barley protected against the pathogen BYDV (barley yellow dwarf virus), out of 25 independent barley lines transformed with the BYDV-PAV hpRNA construct, 9 showed extreme resistance to the virus, and the majority of these contained a single transgene. However, hpRNA technique cannot be applied to genes whose silencing may block plant regeneration or result in embryo lethality. To solve these problems, Guo *et al.* [105] developed a chemical-inducible Cre/loxP (CLX) recombination system to trigger conditionally RNAi in plants, by the expression of an intron-containing inverted repeat RNA. They showed that it can be used to induce silencing of both transgenes and endogenous genes at different developmental stages, at high efficiency, and without any detectable secondary effects. The Chimeric REpressor gene-Silencing Technology (CRES-T) system was developed as a novel method for gene silencing, in which a transcription factor, which was converted into a strong repressor by fusion with the SRDX repression domain, suppresses the expression of target genes overcoming endogenous and functionally redundant transcription factors. In this way, dominant negative phenotype could be induced in genes causing agronomically desirable traits [106]. Repression of IDEF2, a novel transcription factor of rice and barley, which specifically binds to the iron deficiency-responsive *cis*-acting element 2 (IDEF2), obtained by the RNAi technique and CRES-T, was reported to cause aberrant iron homeostasis in rice [107]. A recent example of RNAi technique applied to study plant response to abiotic stress is an RNAi-induced CBF depletion in the Versailles core collection of *Arabidopsis*, characterized by strong variability in *CBF* gene expression after a cold exposure [108]. RNAi lines targeted against three *CBF* genes were produced in eight different accessions to examine the quantitative contribution of *CBF* expression to plant freezing tolerance. Analysis indicated a tight coregulation between *CBF1* and *CBF3* expression levels, while expression of *CBF2* seemed to be regulated in an independent way. The analysis of freezing tolerance of the RNAi lines also showed clear variation in the effect of downregulation of *CBF* expression among natural accessions.

Virus-induced gene silencing (VIGS) strategies have proven very useful in the analysis of gene function in dicot plants, but still only few demonstrations of effective VIGS in monocots have been reported. These include some examples of studies in barley, although not related to abiotic stress response, where barley stripe mosaic virus (BSMV) – the most effectively used virus in monocots for VIGS [109] – was used as a vector for silencing of barley phytoene desaturase (*PDS*) gene [110], for silencing of barley P23k involved in secondary wall formation [111], and finally for silencing of genes required for resistance toward *B. graminis* [112].

Targeting-induced local lesions in genomes was developed as a reverse genetics strategy that provides an allelic series of induced point mutations in genes of interest. This strategy, which allows rapid mutational screening to discover induced lesions,

has different advantages over other methods, as it does not require transformation or RNAi techniques and it can be applied to many crops. In barley, a TILLING resource has been generated using ethylmethanesulphonate (EMS) chemical mutagenesis of "Optic," a European two-row malting variety [113]. A few years later, an EMS TILLING population comprising 10 279 M2 mutants in the two-rowed malting cultivar "Barke" was developed at IPK Gatersleben [114], which has been used in the generation of other genomic resources in barley (~150 000 ESTs, DH mapping population). The TILLMore [115] population is the third, sodium azide-mutagenized TILLING collection of 5 000 M3 mutants of the cultivar "Morex", which is available at the University of Bologna [116]. A mutagenized population of about 10 000 lines (M3) has been recently developed in the Danish barley variety "Lux" by means of sodium azide. The population was used for detection of induced point mutations in two dehydrin genes *DHN12* and *DHN13*, as a proof-of-concept of the usefulness of such a TILLING resource for high-throughput mutation discovery [117].

34.2.4.2 **Transcriptional Profiling**

The transcriptome is by definition a set of all transcripts in one or a population of cells at a specific developmental stage or physiological condition. With present technologies, it allows to comprehensively profile all the information provided by the complete set of RNA transcripts (mRNAs, noncoding RNAs, and small RNAs), to understand gene structure including splicing patterns and other posttranscriptional modifications. It enables, therefore, to study the changes in barley gene expression under abiotic stress conditions. Diverse technologies have been developed to study the transcriptome, following hybridization- and sequence-based approaches; as is well known, the former consists in the hybridization of retrotranscribed RNAs with custom-made or commercial high-density (oligo) microarrays, while the sequence-based approaches directly determine the transcribed nucleotide sequences (for a review see Refs [118, 119]).

34.2.4.2.1 **Available Platforms** The availability of barley EST resources led to the development of the first generation of platforms for transcriptome analysis, from cDNA-based to oligonucleotide-based Affymetrix and Agilent microarrays. The Affymetrix 22 K Barley1 GeneChip [120] represented approximately 20 000 barley unigenes; annotation information for the Barley1 array is hosted on the NetAffx Analysis center at Affymetrix company. Moreover, HarvEST is functioning as an EST database-viewing software in support of the Affymetrix Barley1 GeneChip, enabling probe set annotation export, graphical displays of probes on unigenes, and other "Search the Barley Chip" functions. HarvEST Barley, Version 1.77 (January 9, 2010), has several additional features: barley genetic map viewer, including rice and *Brachypodium* synteny view, "Morex" BACs anchored to nearly 50% of the 2943 mapped SNP loci, and other few more. Barley Gene Expression Array on the Agilent Platform was developed in a 4 × 44 K slide format, using Agilent's 60-mer SurePrint technology. It has a comprehensive transcriptome coverage with 43 803 barley probes represented and content sourced from RefSeq, UniGene, TIGR Transcript Assemblies, and TIGR Gene Indices (http://www.genomics.agilent.com).

The increasing number of studies on plant transcriptomes, mainly in the past decade, has led to an accumulation of profiling data; and this in turn led the scientific community to provide itself with Web-based searchable databases to store the wealth of transcriptomic data. On the top of the already cited HarvEST bioinformatic tool, the online Plant Expression Database (PLEXdb), previously known as BarleyBase (http://www.plexdb.org), has been created to store, visualize, and statistically analyze Barley1 GeneChip data [121]. It provides public access to experiments done with GeneChip hybridizations from barley and to the barley transcriptomic atlas – a data set available for the research community that was generated from two barley genotypes, "Morex" and "Golden Promise," using a diverse series of tissues [53]. The WebComparator (http://contigcomp.acpfg.com.au/) is a web-based graphical interface that permits comparison of expression profiles of homologous genes across a wheat and barley tissue series. The search can be done for "probe name" or "function" and results include the homologous cluster relevant to the query probe set, a comparison of expression profiles and annotations [53, 122]. Genevestigator V3 (http://www.genevestigator.com) is another Web-based resource with diverse applications, from cancer and other human diseases to the model plant *Arabidopsis*, to crop plants. It offers a unique collection of gene expression data for a variety of commercial crop species (maize, wheat, rice, barley, and soybean), together with a set of specifically developed analysis tools that are accessible online [123].

The transcript profiling approaches based on hybridization are quite high throughput and relatively inexpensive. However, several limitations of these methods can be observed such as reliance upon existing knowledge about genome sequence, a fact for which they could be named "closed" systems; possible high background levels due to cross-hybridization; and a limited dynamic range of detection given by both background and saturation of signals. Moreover, comparing expression levels across different experiments can be difficult and requires sophisticated normalization methods [118, 119].

To overcome these drawbacks, in contrast to microarray methods, sequence-based approaches directly determine the cDNA sequence and for this reason they could be named "open" systems. Different techniques were developed and used in barley, including cDNA-AFLP [124], serial analysis of gene expression (SAGE) [125], massively parallel signature sequencing (MPSS), and "iGentfier," which combines elements of tag sequencing such as SAGE or MPSS and fragment display [126], allowing analysis of samples in high throughput using capillary electrophoresis equipment. Recently, the NGS methods led to development of a new approach for both mapping and quantifying transcriptomes called RNA-Seq (namely, RNA sequencing) that is expected to revolutionize in the short term the transcriptomic research. Total RNA is converted by reverse transcription (RT) into cDNAs with adapters attached to one or both ends. The output of RNA-Seq is usually composed of millions of reads of 30–400 bp, depending on the DNA sequencing technology used. Any high-throughput sequencing technology can be utilized for RNA-Seq, and the Illumina IG1, Applied Biosystems SOLiD, and Roche 454 Life Science systems have already been applied for this purpose, as reviewed by Wang *et al*. [118]. The reads resulting from the sequencing are either assembled *de novo* without a reference

genomic sequence or aligned to a reference genome, or to reference transcripts, to produce a genome-wide picture of transcription of both the level of expression and the transcriptional structure for each gene [118]. RNA-Seq does not necessarily depend on any prior sequence knowledge; there is no need for design of probes that must be based on prior sequence or secondary structure information. Therefore, this feature makes this method particularly attractive for nonmodel species. The technique has also other technical, expected advantages, such as higher sensitivity and greater range of detectable expression. Moreover, it has been demonstrated that 454-based transcriptome sequencing is a valid method for the high-throughput identification of gene-associated SNPs [127]. This technique has been applied to several plant species, from models *Arabidopsis* [128] and *Medicago truncatula* [129], to horticultural and field crops, for instance, cucumber [130] and soybean [131], either to study the gene expression and genome annotation or to create an organism-wide gene expression atlas. As regard the application of this technique to studies on stress tolerance, the use of 454/FLX sequencing of *Gossypium* transcriptome in genotypes characterized for contrasting drought tolerance by Asif and colleagues was reported by Thakur and Varshney [132], who reviewed challenges and strategies for NGS. Asif's analysis involved comparison of aligned tags using R statistics, followed by PCA and Biplot analysis. Several activities of the IBSC aim at extensive RNA-Seq in barley, as reported in the minutes of the IBSC Business Meeting at Plant Animal Genome XVIII, January 2010 [133]; however, still no published data are available.

The development and the use of efficient bioinformatic tools for analysis of transcript profiling data is an important issue that deserves a separate discussion, but not addressed here for space constraints. The availability of all these platforms, not only in *Arabidopsis* but also in crops like barley, led to significant studies of response to various abiotic stresses in the species, as reviewed here, although, as underlined before, mostly under single stress conditions.

34.2.4.2.2 **Transcriptional Profiling of Cold Stress in Barley** A set of EST sequences, obtained from a cDNA library of cold acclimatized leaves of cultivar "Nure," was delivered to the ITEC [51, 134]. The EST sequencing work, performed on a non-normalized cDNA library from cold-treated leaf tissue of a cold-tolerant variety, already showed, in a sort of *in silico* expression profiling experiment, that about 8–10% of the randomly chosen and sequenced cDNA clones from the leaf tissues had significant levels of homology with known *COR* (cold regulated) or other stress-related genes. A cDNA microarray developed from that collection of EST clones was thus used for expression profiling to more understand the cold acclimation genomic response [135]. Sequence alignment of the differentially expressed cDNA clones indicated that the most abundant *COR* mRNAs identified during EST sequencing were similar to *COR413*, *BLT4*, and *BLT14* gene families, and together represented about 4% of the nonnormalized barley transcriptome at low temperature [134]. These gene families were among the upregulated redundant clones identified in the microarray experiment. Different stress conditions (two cold treatments, three dehydration treatments, salinity, high light, and two copper treatments) imposed as single stresses, although including a combination of abiotic stresses, were studied

using a second cDNA microarray, consisting of more than 300 selected sequences directly or indirectly related to abiotic stress response [136]. Clones were selected on the basis of several previous publications concerning stress-related sequences, for instance, some ITEC-derived ESTs, or because they were involved in metabolic pathways known to be affected by abiotic stresses (sugar, lipid, and amino acid metabolisms) or because they belonged to families known to be involved in plant response to environmental factors, for instance, CBF-like and other AP2-related transcription factors. When the cold-tolerant cultivar "Nure" was challenged with a combination of stresses, the response was unique and different from that when two stresses were applied singularly, as it was demonstrated by Rizhsky *et al.* [13] in *Arabidopsis* by an oligo array experiment. In response to low temperature and in the presence of light, the repression of LHC (light harvesting complex) was observed coupled with the upregulation of genes coding for enzymes involved in the amino acid metabolism. On the other hand, genes coding for enzymes involved in the pathway leading to proline synthesis (P5CS – δ-1-pyrroline-5-carboxylate synthetase – and ornithine aminotransferase) were found upregulated after cold treatment independent of a light. The comparative analysis of the abiotic stress response in barley pointed out the existence of a group of three cold-specific sequences (dehydrins: *DHN5*, *DHN8*, and *COR14b*) induced only at low temperature and in all cold treatments, regardless of the presence of light or copper; these sequences could be considered as markers of the barley low-temperature response. Finally, the induction of different genes, such as some dehydrins, or proteins with heavy metal binding domains that are induced under many stress conditions, suggested a general role of a cluster of genes in abiotic stress response [136].

To identify barley genes involved in response to low temperature, to investigate the interactions among stress responses to cold and drought, and to specifically test the hypothesis that the dehydrin (*DHN*) multigene family can serve as an indicator of the entire transcriptome response, the responses of the cold-susceptible cultivar "Morex" to low temperature including chilling, freeze–thaw cycles, and deacclimation over 33 days, as well as to gradual drought was studied with Barley1 GeneChip [137]. The results obtained indicated that the majority (50%) of transcriptome changes at low temperatures are part of a general stress response common to chilling and freezing, while only smaller parts were specific either to chilling or to freezing. Since the intersection between frost- and drought-responsive genes was bigger than that of chilling- and drought-modulated genes, this suggested an important element of osmotic stress response to freezing stress condition. Three clusters of dehydrins with similar expression patterns were identified by hierarchical clustering analysis; those upregulated by drought stress but not by low temperature, those induced by both drought and low temperature, and the third cluster that did not respond to low temperature or drought, as already reported [136, 137]. Genes involved in biogenesis of cellular components, cell cycle, and DNA processing, protein modification, and destination and cellular transport were among genes induced exclusively by low temperature. Some of these changes were thought as probably related to mechanical stress induced by ice crystal formation in plant tissue. The mechanisms for cell rescue and defense including oxidative stress responses were activated. Genes

induced in response to both drought and low temperature included those involved in osmotic stress signal perception such as genes encoding phospholipid biosynthetic enzymes and calcium signaling proteins. Moreover, changes in transcripts involved in protection of membranes and proteins (accumulation of osmoprotectants such as galactinol and proline), genes coding for proteases and protease inhibitors important for protein homeostasis, and genes coding for polyamines were observed [137].

Transcription profiling of either genetic mutants or transgenic plants represents a powerful tool for dissecting the derived molecular networks. Barley genetic stocks offer a unique collection of chloroplast-deficient mutants, most of them characterized at genetic and biochemical levels. Thanks to them, the involvement of the chloroplast in the signal transduction pathway of the cold stress was demonstrated [138]. Those results were confirmed by wide-scale transcriptional profiling by the Barley1 GeneChip of cold-acclimated wild-type barley versus four chloroplast-defective mutants. Transcript profiling showed that 66.9% of the wild-type cold-regulated genes were either not or not correctly cold regulated in the mutants demonstrating that the chloroplast has a major role in the control of molecular adaptation to cold. Moreover, a fully operational chloroplast rather than a specific step in chloroplast development is required for normal cold-dependent regulation of the transcriptome. Three main pathways of the wild-type cold-regulated genes were identified: cold-regulated genes that were unaffected by any chloroplast mutation (including the *CBF*–C-repeat binding factor; transcription factors; and many genes known to be under *CBF* control), cold-regulated genes constitutively induced in all mutants (although to different levels), and finally, cold-regulated genes belonging to signaling pathways disrupted in all mutants, whose expression consequently was not (or only marginally) responsive to cold. These results brought the conclusion that the factors derived from the chloroplast in addition to CBFs are required to promote the full suite of molecular changes associated with cold acclimation [139] to withstand frost.

34.2.4.2.3 **Transcriptional Profiling of Drought Stress in Barley** The experimental conditions that have been applied in drought stress transcriptional profiling studies differ substantially as far as the dynamics and/or intensity of the water stress treatments applied are considered. Therefore, it is important to verify the correspondence of changes in expression profiles occurring under different experimental conditions mimicking drought conditions in the field [140]. In most cases, expression profiling for the response to water deficit has been performed on plants subjected to high-intensity stress treatments, frequently applied in a very short time, the so called "shock-like" (DHSH) treatments [136, 141]. Under such conditions, examples of significantly drought-affected genes in barley leaves, induced by stress, were those involved in the jasmonate biosynthesis (e.g., AOS – allene oxide synthase), together with the jasmonate-regulated genes (jasmonate-induced proteins – JIPs – and methyl-jasmonate-inducible lipoxygenase). Two arginine decarboxylases were induced (also in roots), possibly reflecting the altered synthesis of polyamines. LEA/dehydrin protein and metallothionein encoding transcripts, as well as P5CS involved in proline biosynthesis and some ABA (abscisic acid)-responsive proteins, were also found to be induced. In turn, most drastic downregulation was observed for

photosynthesis-related genes [141]. Dehydration was also shown to regulate several genes involved in glutathione biosynthesis pathway [136].

The use of "shock-like" treatments, however, may prevent the identification of some long-term responses that might play an important role in plant adaptation to drought under field conditions. A cDNA microarray mainly derived from dehydration-shocked barley leaf tissues was used to monitor expression changes in leaves of barley plants subjected to slow drying conditions in soil and after rehydration. The results were compared with those obtained under shock-like conditions (DHSH), showing changes in expression profiles according to the dynamics of the dehydration treatment [140]. The majority of the transcripts were, in fact, regulated only by one of the drought treatments, and the gradual dehydration of leaves led to a lower number of differentially regulated transcripts, with lower fold changes in expression levels when compared to the DHSH treatment. The changes in gene expression observed under DHSH were in agreement with results of other authors obtained under shock conditions [141]. Only a small portion of transcripts showed similar changes regardless of the shock-like/gradual type of water stress. These few common genes included upregulated genes coding for metallothionein-like proteins, some involved in jasmonic acid (JA) biosynthesis and in osmoprotectant synthesis. The results suggest that caution should be exerted when transcriptome information obtained under conditions of water deficit induced in a very short time is used to understand how plants may regulate gene expression in response to a water deficit developed under more naturally induced drought conditions. The same caution should be used when the same information would be aimed to identify candidate genes for QTL of field-related traits with an adaptive role in drought. Ideally, a correct strategy could be to carry out both types of treatments in time course experiments for a recording of transcript dynamic changes through the different conditions of water deficit [140].

Different experiments on barley response to drought stress have been conducted using the Barley1 GeneChip since the first study by Close [142], where the response of "Morex" barley to water deprivation stress was analyzed at different stages of stress. Barley1 GeneChip profiling of barley response to drought and cold enabled identification of genes responsive exclusively to drought among those involved in transcriptional regulation, including basic leucine zipper (bZIP) proteins, homeodomain-leucine zipper (HD-ZIP), and MYB family members [137]. The changes in the expression of transcription factors were mostly in the early stages of the treatment modulation of transcription [142]. Genes for downstream protection mechanisms induced by drought stress included those coding for several LEA proteins that are typically induced by osmotic stress or exogenous application of ABA. Dehydrin genes were reported to be expressed mainly during the most severe stages of the stress treatment [142]. Heat shock protein (HSP) genes, generally involved in cell rescue and defense mechanisms, were also induced. The induction of genes by combined drought and cold reported by Tommasini *et al.* [137] has been already reviewed above.

The study by Close [142] was performed, in the same manner as the one by Tommasini *et al.* [137], on the cultivar "Morex," cold susceptible, and not drought tolerant. In order to investigate the nature of a tolerance response to drought stress, expression profiling of the tolerant versus susceptible varieties was investigated, for

example, in case of cDNA-AFLP profiling of wild barley genotypes [143]. One of the differentially expressed transcript-derived fragments (TDFs) was selected as a promising candidate gene for water stress tolerance, sequenced, and characterized. The deduced amino acid sequence of the corresponding gene (called *HSDR4-H. spontaneum* dehydration-responsive) was homologous to rice Rho-GTPase-activating protein-like (Ras homologue-GTPase-activating protein-like) with a Sec14 p-like (phosphatidylinositol/phosphatidylcholine transfer protein-like) lipid binding domain. Analysis of *HSDR4* promoter region enabled identification of a new miniature inverted repeat transposable element (MITE), and different putative stress-related binding sites for transcription factors such as MYC, MYB, LTRE (low-temperature-responsive element), and GT-1, suggesting a role of the *HSDR4* gene in tolerance to drought stress. Moreover, the *HSDR4* gene was mapped to the long arm of chromosome 3H between markers EBmac541 and EBmag705, in a region that had been previously shown to affect osmotic adaptation in barley [143]. A recent comprehensive transcription profiling of differentially expressed genes between drought-tolerant and drought-sensitive barley genotypes in response to drought stress during the reproductive stage with Affymetrix Barley1 GeneChip [144] enabled the identification of three distinct groups of drought-responsive genes. The first group consisted of genes expressed exclusively in drought-tolerant genotypes under drought stress, encoding proteins that may be involved in drought tolerance, through (a) controlling stomatal closure via carbon metabolism (NADP malic enzyme and pyruvate dehydrogenase); (b) synthesizing the osmoprotectant glycine-betaine (CSMO – C-4 sterol methyl oxidase); (c) generating protectants against reactive oxygen species (aldehyde dehydrogenase and ascorbate-dependent oxidoreductase); and (d) stabilizing membranes and proteins (heat shock proteins and DHN3). The second group was composed of genes abundantly expressed in tolerant varieties (versus susceptible ones), both under drought and control conditions, and thus possibly belonging to a constitutive resistance mechanism. They were coding for proteins involved in signaling, such as calcium-dependent protein kinase (CDPK) and membrane steroid binding protein (MSBP), antisenescence, and detoxification (glutathione transferase) pathways. Finally, a third group of genes including those encoding P5CS, protein phosphatase 2C-like protein (PP2C), and several chaperones were differentially expressed in all genotypes, both tolerant and susceptible, under drought; thus, they more likely represented general drought-responsive genes in barley.

Most genome-wide transcriptional profiling studies on drought stress in barley and in other cereals have focused on the response of vegetative organs [137, 140, 144]. However, drought affects all stages of plant development and the reproductive stage is the most sensitive in temperate cereal crops. Understanding how drought affects reproductive development is crucial for improving yield in environments characterized by terminal drought. This notwithstanding, the response of the spike transcriptome to drought stress has been largely overlooked. The photosynthetic organs of the spike are the major suppliers of carbon to the developing seeds, and barley varieties, truly tolerant to drought, have a better chance of achieving normal seed size when available water is reduced during grain filling. The transcriptomes of

lemma, palea, awn, and seed of barley were thus compared using the Barley1 GeneChip. The results obtained suggested that among the spike organs, the lemma and the palea could be more actively tolerant to drought stress compared to the awn [145].

One of the most common responses to drought stress is accumulation of osmolytes. What is particularly interesting, the proline synthesis pathway driven by arginase and ornithine aminotransferase, and not the P5CS, seems to be preferred in barley spike during drought stress [145]. A similar situation was reported by Atienza *et al.* [136] under shock-like drought stress conditions.

34.2.4.2.4 **Transcriptional Profiling of Salt Stress in Barley** Large-scale approaches including differential display [146] and different microarray platforms [141, 147, 148] have been employed to identify genes responding to salinity stress in plants. Differential display analysis enabled identification of salt-inducible genes expressed strongly in roots and rarely or weakly in barley leaves. These genes included those coding for proteins involved in signal transduction (e.g., MAPK – mitogen-activated protein kinase; transcription factors; receptor protein kinase; and PP2A-protein phosphatase 2A), typical stress tolerance genes (encoding glutathione reductase, thioredoxin-like protein, and heat shock proteins), and genes coding for membrane transporters, members of the P450 family, enzymes involved in RNA metabolism or function, and enzymes of sugar or amino acid metabolism [146].

A salt stress has at least two components: an osmotic one and an ionic one. Therefore, studies should try to distinguish the effects of osmotic components on global gene expression from that of the ionic stress components. Two microarrays composed of spotted cDNAs that included drought- [141] and salt-responsive [147] clones have been used to investigate the expression of salt- and drought-induced genes in barley leaves and roots. In the former study, however, probably due to pronounced natural salt tolerance of the barley line used for experiments, and for the mild salinity stress conditions applied, a relatively small number of salt-regulated transcripts were identified; moreover, only a small number of transcripts showed overlap between drought and salinity response. Upregulated transcripts under both stresses included those enzymes of the biosynthetic pathway that lead to jasmonate (AOS), P5CS, and several transcripts known to accumulate under abiotic stress conditions such as metallothionein-like protein, early-responsive dehydration 1 (ERD1), or germin-like protein. Common downregulated transcripts included transport proteins such as lipid transfer protein (LTP) and an ATP binding cassette (ABC) transporter, while increase in ubiquitin-related transcripts in roots characterized the salt stress response [141]. The results of Ueda *et al.* [147] demonstrated that the majority of 52 genes differentially expressed under pure osmotic stress were differentially expressed also under salt stress. Some of those genes such as the upregulated genes for P5CS, betaine aldehyde dehydrogenase 2 (BDH2), and plasma membrane protein 3 and the downregulated genes for water channel 2, heat shock protein 70, and phospholipase C were involved in a wide range of metabolic and signaling pathways, suggesting that during the initial phase under salt stress, several cellular responses are mediated by changes in osmotic potential [147].

Barley1 GeneChip was used to investigate the transcriptional response of the barley cultivar "Morex" to a salinity stress applied at seedling stage [148]. The level of stress was similar to the conditions found in agricultural systems in California, and the stress was imposed gradually over a 4-day period. This enabled reduction of the osmotic effect of salt stress, which is most important during the early stages of stress imposition, and allowed to focus the study on the ion-specific effects of salinity on gene expression, as opposed to osmotic shock effects. Some genes known to respond to other abiotic stresses including dehydration, osmotic stress, and exposure to low temperature were modulated, such as *DHN5*, dehydration-responsive gene *RD22*, late-embryogenesis abundant *LEA*, low-temperature-induced protein blt101/salt stress-induced ES13, a cold-regulated protein 2, and a CCAAT-binding transcription factor (*CBF-B/NF-YA* – CCAAT-binding transcription factor subunit B/nuclear transcription factor Y subunit A). The largest group of induced genes related to abiotic stress falls into the category of heat shock proteins. Genes coding for P5CS and phosphoethanolamine *N*-methyltransferase, two rate-limiting enzymes for accumulation of proline and glycine-betaine, respectively, were induced at all time points indicating that osmoprotection appears to be one of the mechanisms triggered in barley as a relatively early response. In contrast to the first functional studies, fewer genes responding to salinity stress were identified, likely due to the moderate level of stress and its gradual application; moreover, only few genes common with previous studies [141, 147] were detected. The differences could be explained by the different platform used for analysis, by the different genotypes of barley used, and by the significantly different stress conditions applied, long-term salinity stress [147] versus salt shock [141], versus early stage of gradual and moderate stress application [148]. A particularly noteworthy feature of the early-salinity stress response of barley at seedling stage was the change in expression level of genes related to JA biosynthesis such as *AOS*, lipoxygenase (*LOX*), allene oxide cyclase (*AOC*), lipase (phospholipase) together with JA-responsive genes such as those coding for jasmonic acid-induced proteins, hordothionins, *O*-methyltransferase (*OMT*), glutathione *S*-transferase, and selenium binding protein [148]. The JA pretreated salt-stressed plants were reported to accumulate strikingly low levels of Na^+ in the shoot tissue compared to JA untreated salt-stressed plants, still after several days of exposure to stress, and a pretreatment with JA was shown to alleviate the photosynthetic inhibition caused by salinity stress [14]. Expression profiling after a short-term exposure to salinity stress indicated a considerable overlap between genes regulated by salinity stress and JA application. Three JA-regulated genes, arginine decarboxylase, ribulose-1,5-bisphosphate carboxylase/oxygenase (rubisco) activase, and apoplastic invertase, were reported to be possibly involved in salinity tolerance mediated by JA [14].

In order to elucidate the mechanisms of salt tolerance in barley, the level of polymorphisms and differences in responses of two genotypes that differ in tolerance to salt stress were studied with Barley1 GeneChip [149]. "Golden Promise" accumulated lower shoot Na^+ compared to "Maythorpe" when growing under saline conditions and it was identified as salt tolerant. Such a response of salt tolerance in "Golden Promise" had been attributed to a single mutation at the *Ari-e* locus (on chromosome 5H) resulting from irradiation of "Maythorpe." However, the

expression profiling of salinity stress response of the two varieties was significantly different, with this difference being more apparent in the root comparison. Several of the JA biosynthetic pathway genes (*AOS*, *LOX2*, *LOX3*, and *OPR2* – oxophytodienoate reductase) were downregulated in response to salinity in "Maythorpe," while others like *AOC* and two JIPs were upregulated in "Golden Promise" but not in "Maythorpe" in response to stress, confirming previous results of JA involvement in salt stress resistance [14, 148]. JA appears thus to be an important component of heritable salt tolerance in "Golden Promise" and in barley in general. Two exchanger proteins were identified to be downregulated in "Maythorpe" roots in response to salinity stress (a Na^+/Ca^{2+} exchanger protein and a vacuolar cation/proton exchanger), and this might explain the low Na^+ accumulation trait of "Golden Promise," as salt tolerance in Triticeae is generally associated with Na^+ ion exclusion [150]. Only a low number of probes that are modulated in common in roots and shoots of two barley genotypes, corresponding to genes coding for P5CS, LTP, phosphoethanolamine cytidyltransferase, and dehydrin 7, probably take part in a general response of barley to salt [149].

A comparative functional genomics approach was successively applied to study barley response to salinity stress, to identify analogous and contrasting gene expression patterns between rice and barley, by using cDNA [151] and oligonucleotide microarray platforms [152]. Rice and barley are both members of Poaceae family, but they have a marked difference in salt tolerance. The differential regulation of a relatively larger number of genes in barley roots than in rice roots during the initial phase of salt stress suggested that barley root cells are more responsive to salt stress signals and that the divergent transcript profiles reflect fundamental differences in the biological responses to salt stress of those two species. The coordinated regulation of early synthesis of osmoprotectants proline and betaine, by *P5CS* and *BADH2* (betaine aldehyde dehydrogenase) genes, respectively, with regulation of water permeability (downregulation of water channels) could constitute a counterbalancing response to the initial decline in leaf water potential in barley under salt stress [151]. Divergences in rice and barley responses were confirmed by Barley1 GeneChip analysis of two rice and two barley susceptible and resistant genotypes [152]. Clustering analysis of differentially expressed genes revealed that there were no prominent gene clusters in rice and barley that had conserved expression patterns, while gene clusters with contrasting responses between barley and rice orthologues were identified. Genes involved in low-temperature response and acquired tolerance to freezing (*LOS2* – low expression of osmotically responsive gene 2), and in the H_2O_2-mediated programmed cell death (phospholipase Dδ), were among those upregulated in barley but repressed in rice. Activation of *PLDδ* decreases H_2O_2 cell death and improves stress tolerance. Genes related to cell wall biogenesis were repressed in barley, since high salt levels around roots could be expected to retard growth and cell wall biogenesis in the root tissue, while upregulated in rice. Moreover, several auxin-related genes were responsive, being downregulated in barley, but only to a small extent in rice. To increase the power of the comparative analysis approach, a data set generated in wheat roots during salt stress using the Affymetrix Wheat Array was chosen for *in silico* comparison. The overall

results showed that the transcriptional response to high salt is conserved to a significant degree between wheat and barley. But it is highly divergent in rice [149].

34.2.4.2.5 **Transcriptional Profiling of Nutrient and Metal Stress in Barley** Nitrogen is a crucial macronutrient required by plants, and development of crop varieties with high nitrogen utilization efficiency (NUE) adapted to low input management systems is mandatory for sustainable agriculture. The content of nitrogen intermediates is highly influenced by nitrogen availability. Moreover, nitrogen-containing compounds play an active role as metabolic scavengers of excess ammonium accumulated under stress [153]. Understanding the plant response to different nitrogen conditions is essential for the development of future approaches for NUE improvement. Notwithstanding, nitrogen deficiency stress is the most important nutrient stress limiting barley grain yield worldwide; a survey of bibliography did not recover, to our knowledge, any significant result in genome-wide functional studies in this species. Microarray and RNA gel blot analyses were performed to identify *Arabidopsis* genes responding to both low and high nitrate concentrations [154]. Genes associated directly or indirectly with nitrite reduction were most highly induced. Most of the known nitrate-regulated genes, including those encoding nitrate reductase, the nitrate transporter (NRT1), and glutamate synthase, were induced too; moreover, some other nitrate-induced genes were also found, including those encoding regulatory proteins, metabolic enzymes, such as transaldolase and transketolase of the nonoxidative pentose pathway, and proteins with unknown functions. Two genes, *AMT1* encoding an ammonium transporter and *ANR1* encoding a MADS-box factor, were repressed by nitrate. A high-density array of mineral nutrition-related cDNAs was used to study the response of tomato plants exposed to nitrate deprivation at different time points after nitrogen was withheld for 48 h [155]. One hundred and fifteen genes were found to be upregulated by nitrate resupply. Among these genes were included several previously identified as nitrate responsive, including nitrate transporters, nitrate and nitrite reductase, and metabolic enzymes such as transaldolase, transketolase, malate dehydrogenase, asparagine synthetase, and histidine decarboxylase. Moreover, some other nitrate-inducible genes, such as those coding for water channels, phosphate and K^+ transporters, genes potentially involved in transcriptional regulation, some stress response genes, and ribosomal protein genes were found induced. In wheat, the activity of three different enzymes involved in nitrogen assimilation, GS (glutamine synthetase), GOGAT (glutamine synthetase oxo glutarate), and GDH (glutamate dehydrogenase) under different nitrogen treatments, was analyzed and compared with gene expression profile of a Dof (DNA binding with One Finger) transcription factor. The elevated expression of *Dof 1* at the grain filling stage was proposed to be responsible for overexpression of the GS and GOGAT genes, thereby prolonging their activities [156]. As far as barley is concerned, the studies reported the isolation of the first *HvNRT2.1* and *HvNRT2.2* genes encoding putative NO_3^--inducible high-affinity transporters in higher plants [157]. Northern blot analysis of barley plants exposed to nitrogen starvation showed that the *HvNRT2* transcript accumulated rapidly in roots after NO_3^- was supplied [157]. Vidmar *et al.* [158] reported the isolation of two new cDNAs, *HvNRT2.3* and

HvNRT2.4, which are closely related to *HvNRT2.1* and *HvNRT2.2*. Moreover, the correlation between Northern blot patterns of the *HvNRT2* gene expression and $^{13}NO_3^-$ influx in response to various nitrogen sources confirmed the identification of the *HvNRT2* genes as participants in high-affinity NO_3^-. In a study by Wang *et al*. [159], a correlation of the level of 6-SFT (sucrose:fructan 6-fructosyltransferase) mRNA determined by Northern blot analysis with fructan accumulation induced by nitrogen deficiency in barley leaves was demonstrated suggesting that the changes in fructan levels under N stress are connected to the fructan synthesis rate that is controlled by 6-SFT.

Transcriptomic analyses in *Arabidopsis* [160], rice [161], and lupin [162] have shown that coordinated changes in the expression of numerous genes involved in various metabolic pathways, such as photosynthesis, carbon metabolism, nitrogen assimilation, and synthesis of protein and nucleic acids, take place in P-deficient plants. As regard barley no genome-wide transcriptional studies for functional genomics were reported.

Aluminum-resistant cultivars of barley rapidly secrete citrate from the roots in response to Al, and a good correlation between Al resistance and the amount of citrate secretion among different cultivars was reported. Microarray analysis with Barley1 GeneChip enabled identification of a candidate gene, *HvAACT1* (aluminum-activated citrate transporter) belonging to the multidrug and toxic compound extrusion (MATE) family, whose expression is constitutively higher in tolerant cultivar than in the susceptible one. The *HvAACT1* expression was shown not to be induced by Al exposure in neither of cultivars suggesting that it is constitutively expressed in the roots and that the secretion of citrate is mediated through the activation of HvAACT1 [163]. Four SNPs were found in the ORF of *HvAACT1* in 10 barley cultivars differing in Al resistance, but these SNPs could not explain the differential citrate secretion. In contrast, a good correlation was found between the expression of *HvAACT1* and the amount of citrate secretion in these cultivars. These results indicate that higher expression of *HvAACT1* rather than its sequence polymorphism is required for greater release of citrate. A recent study in wheat demonstrated that the expression of *ALMT1* (Al-activated malate transporter 1) may be controlled by the presence of the sequence repeats upstream of this gene. Furukawa *et al*. [163] suggest that the expression of *HvAACT1* might also be controlled by the promoter regions, a hypothesis that has to be investigated.

Microarray analysis with Barley1 GeneChip proved that barley plants survive in the presence of the toxic heavy metal $HgCl_2$ (mercuric chloride) through several mechanisms that include water uptake limitations, shoot and root growth regulation, increased expression of genes involved in the biosynthesis of several plant protection secondary metabolites, and finally through detoxification. Genes involved in detoxification and defense mechanisms induced in the presence of mercury include several cytochrome P450s, glucosyltransferases and glutathione *S*-transferases together with genes involved in amino acid metabolism (experiment submitted by Lopes to PLEXdb, 2009 [164]).

Genes coding for protein with heavy metal binding domain (metallothionein-like protein and heavy metal binding farnesylated protein), whose induction is common

to different stress responses have been found induced in response to the plant micronutrient copper (Cu) [136]. Excess copper stress conditions promoted a strong upregulation of genes coding for antioxidant enzymes such as peroxidase and ascorbate peroxidase, underlining the presence of a high oxidative stress. In fact, copper, although an essential metal, is also capable of catalyzing the formation of reactive oxygen species that can cause intracellular oxidative damage to lipids, proteins, and nucleic acids [136].

Both limiting and excess (toxic) soil concentrations of the essential micronutrient boron (B) represent major limitations to crop production worldwide. *Bot1*, a *BOR1* efflux transporter orthologue, was identified as the gene responsible for the superior boron toxicity tolerance of the Algerian barley landrace "Sahara" and located at the *Bot1* tolerance locus by high-resolution mapping. Compared to intolerant genotypes, "Sahara" contains about four times as many *Bot1* gene copies, produces substantially more *Bot1* transcripts, and encodes a BOT1 protein with a higher capacity to provide tolerance in yeast. *Bot1* transcript levels identified by QRT-PCR in barley tissues are consistent with a role in limiting the net entry of boron into the root and in the disposal of boron from leaves via hydathode guttation [165]. Barley1 GeneChip was then used to investigate transcriptome changes associated with boron toxicity in the susceptible barley cultivar "Hamidiye," revealing that B toxicity results in global changes in the barley transcriptome and involves networks of signaling or molecular responses [166]. Boric acid treatment resulted in modulation of genes involved in JA biosynthesis (most of them were upregulated) and JA-responsive genes (both upregulation and downregulation were observed). JA is one of the signaling molecules produced in an integrated signaling network and B toxicity might be inducing a response that is connected to the JA regulated response. The induction of JA-related or -responsive genes as a key feature of response to salinity in barley was reported [148]. Ozturk *et al.* [141] reported upregulation of genes encoding JA-responsive proteins under drought stress in barley. Moreover, boric acid-induced expression of genes encoding glutathione *S*-transferase, pathogenesis-related or senescence-associated proteins. Expression of genes coding for transcription factors, chaperones, and transport proteins were modulated [166].

A microarray containing 8987 rice ESTs was used to analyze the gene expression profile of barley roots grown under either low zinc (Zn) or low iron (Fe) stress. Inductions in expression of genes involved in the methionine cycle in both Zn-deficient and Fe-deficient barley roots were reported [167]. It was reported that Zn deficiency increases the secretion of metal chelators (MAs) that are known to be produced in grasses in response to iron deficiency. The levels of the *HvNAS1* (nicotianamine synthase), *HvNAAT-A*, *HvNAAT-B* (nicotianamine aminotransferase), *HvIDS2*, and *HvIDS3* (iron deficiency-specific) transcripts, which encode the enzymes involved in the synthesis of MAs, were increased in Zn-deficient roots. Studies on the genes involved in the methionine cycle showed that the transcripts of these genes were increased in both Zn-deficient and Fe-deficient barley roots, probably allowing the plant to meet its demand for methionine, a precursor in the synthesis of MAs. Analysis using the positron-emitting tracer imaging system (PETIS) confirmed that more ^{62}Zn(II)-MAs than $^{62}Zn^{2+}$ were absorbed by

the roots of Zn-deficient barley plants. These data suggest that the increased biosynthesis and secretion of MAs arise from a shortage of Zn and that secreted MAs are effective in absorbing Zn from the soil [167].

The most important result of expression profiling studies, from an application point of view, is the identification of candidate genes with an effect on tolerance or resistance. Such candidate genes, when coincident with quantitative trait loci (QTL) that have a significant effect in increasing stress tolerance under field conditions, are reinforced in their role as actors for real abiotic stress tolerance. In turn, this information may offer additional opportunities for a more effective application of marker-assisted selection (MAS), genetic engineering, and/or other genomics approaches for the release of stress-resistant cultivars.

34.2.5
Quantitative Genetics and Genetical Genomics of Abiotic Stress Tolerance

Plant tolerance to abiotic stress is largely grounded on quantitative genetic bases [168]. For this reason, the discovery of quantitative trait loci, controlling the genetic variation in the tolerance traits, and their manipulation via MAS are very important for obtaining the successful integration of genomics approaches in breeding programs. Since the first proof-of-concept of Sax in 1923, which demonstrated in bean the possibility to identify a genetic locus associated with the variation in a quantitative trait, plant science had to wait many decades for the availability of appropriate algorithms in the late 1980s, and of genetic molecular maps in the early 1990s. These two developments allowed plant scientists to start mapping the genomic regions that have a statistically significant impact on the quantitative variation of agronomically relevant traits. QTL mapping, from a conceptual point of view, represented an enormous breakthrough for plant biology since it made possible the dissection of the complex inheritance of quantitative traits, until that time only under speculative research, into "Mendelian-like" factors. In such a state, they could be identified, numbered, characterized, and validated, and were amenable to be selected through the linked flanking molecular markers and, eventually, to be cloned. This last significant step forward was achieved for cultivated plants in the first decade of this century.

Many studies in barley as in other cereals described important QTL imparting tolerance to adverse environmental stressors. These, as other many QTL responsible for pathogen quantitative resistance, quality traits, and yield, could be named today "phenotypic" QTL (phQTL). In fact, the two key elements to get an accurate genomic placement of quantitative phenotypic trait-driving loci are the availability of a complete and robust genetic map, together with a careful phenotyping for the trait (validated in more than a single experiment) of the experimental population that gave origin to the genetic map. The classical phQTL mapping approach is then a linkage mapping approach, in which the count of recombinants between marker loci takes to the genetic map construction, and the so-called "interval mapping" procedure [169] scans the genome by intervals, assigning a probability for the allelic variation at each interval to be associated with a trait variation. The statistical methods to calculate such

a probability score or, better, logarithm-of-the-odds (LOD) score evolved from the initial ML (maximum likelihood) mapping algorithm [169] to the regression mapping algorithm [170, 171]. QTL linkage mapping was joined in the past decade by QTL association mapping, named LD (linkage disequilibrium) mapping. With such a procedure, an LD-based genetic map, often starting from an integrated genetic map coming from different linkage mapping projects, is used to associate the allelic variation at the mapped loci with the phenotypic variation, both scored on an unrelated plant population. The first publication on the usage of LD in barley to explore the genome for mean yield and yield adaptability QTL is from Kraakman *et al.* [172]. The authors simply used Pearson correlation coefficients to evaluate the marker-trait associations and to derive the positions of QTL on an integrated barley genetic map.

To date, more than 1200 studies on plants have been published on mapping phQTL [173]. Such a wealth of information has been stored for barley in web-based resources such as mainly Graingenes (http://wheat.pw.usda.gov/GG2/index.shtml [174] and, although with few data, Gramene (http://www.gramene.org [175]), and Cerealab (http://www.cerealab.unimore.it [176]). These databases, however, also contain other genomics information, such as genetic maps, molecular markers, and DNA sequences. Interestingly, from Graingenes, directly accessible through the "Barley Boulevard," a "Barley QTL Community Curation Book" is downloadable as an MS Excel spreadsheet.

By merging and integrating diverse types of data and information across species and levels of biological complexity, the QTL databases enhance the potential to understand and utilize QTL information. Moreover, the accumulation of an impressive amount of phQTL data brought about the development of the concept of meta-analysis. "Meta-analysis" method enables to combine QTL results from different independent analyses, and was first described in general terms by Glass in 1976 [177]. This technique has been used mainly by researchers in medical, social, and behavioral sciences, and also in genetics and plant evolution (see, for example, Ref. [178]). Meta-analysis is an important tool in linkage analysis. The pooling of results across primary linkage studies allows greater statistical power to detect QTL and more precise estimation of their genetic effects and, hence, yields conclusions that are more conclusive than those of individual studies. The meta-analysis has, for example, been applied in rice to dissect the complex genetic structure of drought-related QTL, and in some cases was able to clarify the crucial question if overlapping loci displayed pleiotropy or close linkage between adjacent genes [179]. The main practical value of meta-QTL analysis is in the ability to provide an accurate estimate of QTL position that will be useful in marker-assisted selection and candidate gene identification [179]. The first attempt of QTL summary for abiotic stress tolerance in the Triticeae was made by Cattivelli *et al.* [180]; in this chapter, we propose an updated version of such a QTL survey, reported on a barley Bin-map [181] (Figure 34.1). The figure shows the "hot spots" of phQTL determining tolerance/adaptation to various abiotic stresses in barley, together with the approximate map positions of cloned genes underlying QTL, and likely candidates to explain tolerance components. It should be emphasized here the colocation between multiple QTL of abiotic stress

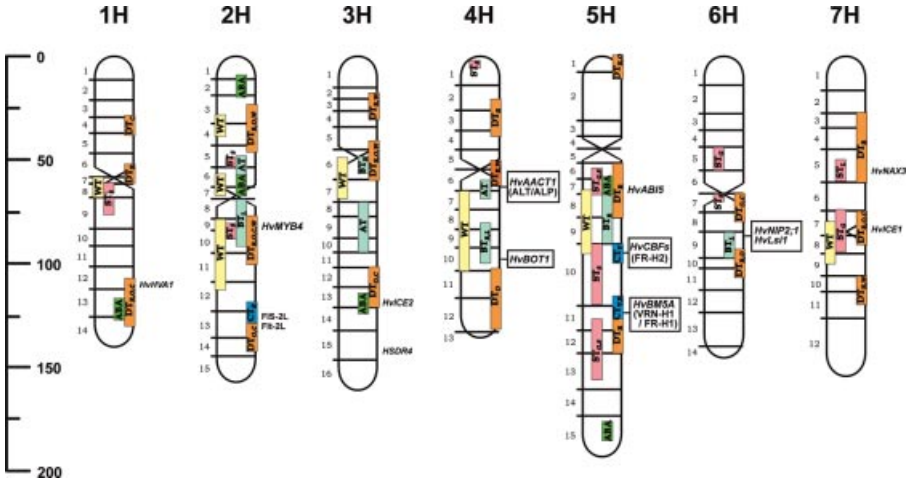

Figure 34.1 Summary of abiotic stress tolerance QTL mapped on the barley genome (see details in the text). Chromosome length, QTL map comparisons, and loci assignment to marker Bins are based on both the barley Bin map ([181] and http://barleygenomics.wsu.edu) and the consensus map of Marcel *et al*. [45]. Chromosome length is reported on the left in Kosambi cM. QTL: CT, cold tolerance at vegetative (V) and/or reproductive (R) stage; DT, drought tolerance measured as relative water concentration (R), osmotic potential/osmotic adjustment (O), carbon isotope discrimination (C), and water-soluble carbohydrate concentration (W); ST, salt tolerance at germination (G) or seedling (S) stage; BT, boron tolerance measured as root (R) and leaf (L) sensitivity; AT, aluminum tolerance measured as root elongation sensitivity; WT, waterlogging tolerance; ABA, abscisic acid response at germination. Cloned QTL, candidate genes to explain QTL, and major loci have been reported on the right of chromosomes. Their positions were derived from Graingenes (http://wheat.pw.usda.gov/GG2/index.shtml) and from the literature cited in the text. Gene names are reported in italics with the *Hv* prefix; major loci names in normal style; cloned QTL are in boxes.

tolerance and the two regulatory candidate genes *HvMYB4* and *HvABI5* on, respectively, Bin 9 of chromosome 2HL and Bin 7 of chromosome 5HL. *HvMYB4* maps in a region where loci for drought-related traits, waterlogging, boron toxicity, and salinity tolerance were discovered (see Section 34.2.5.2). Interestingly, the rice orthologous gene *OsMYB4* encodes an MYB transcription factor induced during exposure to low temperatures and other abiotic stresses [182]. *HvABI5* is a bZIP transcription factor, upregulated by ABA, which binds to *cis*-elements in the promoter region of the ABA- and stress-responsive COR/LEA effector genes *HVA1* and *HVA22* [183]. Notably, the involvement of *HvABI5* in abiotic stress tolerance was reinforced by the report of Kobayashi *et al*. [184], in which the authors found a positive role of a wheat *HvABI5* orthologue (namely, *Wabi5*) in response to low temperature, drought, and exogenous ABA treatment.

The accumulation in 20 years of a very large number of phQTL results for a wide range of traits and in the most important crop species led in the late 1990s to emerging concerns and discussions about some aspects of QTL mapping. Although

most of the worries have been solved (see, for example, Ref. [185]), a brief discussion about dependence on background effects, QTL × QTL, and QTL × E interactions deserves to be treated here since they are aspects of the genetic basis of quantitative traits that scientists and breeders have always to cope with. It is, in fact, quite obvious that different steps of a metabolic pathway leading to a phenotypic trait can negatively or positively interact; as it is quite obvious that allelic variants of a gene underlying a QTL, and present in a particular genotype, could act better, or exclusively, in a particular environment. Some studies dealt with the evaluation of both the effects, QTL × QTL and QTL × E, in barley [186], as in other plants. For example, Xu and Jia [187] evaluated the "Harrington" × "TR306" barley doubled haploid (DH) population "TR306" for QTL mapping in different environments for seven yield-related quantitative traits. They found that epistatic variance contributed to the genetic variance, but the cumulative contribution from significant epistatic effects was very small compared to that from the additive effects. The interaction between the genomic regions and the environment (QTL × E) has been investigated, for example, in a study by Comadran *et al.* [188] where the analysis of phenotypic and genotypic data for a different set of barley germplasm is described, with the phenotypic data being collected from yield trials grown across a wide range of Mediterranean environments subjected to varying levels of stress.

The existence of QTL interactions have both practical (MAS) and theoretical (genomics) implications; in the first case, they suggest to proceed for QTL identification in parallel with the breeding process. In the second case, they suggest the need to deepen the study of both simple and complex QTL networks, on a genome-wide basis.

34.2.5.1 Genetical Genomics of Abiotic Stress Tolerance

Since a QTL is by definition a genomic locus explaining part of the variation for any quantitative trait recorded in a plant population, the trait might be not only a field-recorded one but also the quantity of a protein, of a metabolite, or of a transcript. For example, in barley, a QTL for the accumulation of a cold-regulated (COR) protein, detected by Western blotting, was coincident with a QTL of frost tolerance [189]. If we extend this concept to a "omics" scale, we could outline the so-called strategy of "genetical genomics" [190]. Owing to such an approach, genetical genomics can generate in principle QTL maps from any method of genome-wide expression profiling based on mRNAs (eQTL), proteins (pQTL), or metabolites (mQTL).

An emerging application of transcriptome analysis is the identification of the so-called eQTL, namely, QTL that control the level of expression (hence the "e") of particular genes. Differentially expressed genes involved in metabolic or regulatory pathways and identified by means of high-throughput methods are treated as phenotypes, while allelic variants that underlie the gene expression changes are identified in genetically related lines. eQTL can thus be classified as *cis*- or *trans*-acting based on the location of the transcript compared to that of the eQTL influencing the expression of that transcript. eQTL that map to the same genetic location as the gene whose transcript is being measured generally indicate the presence of a *cis*-acting regulatory polymorphism in the gene (*cis*-eQTL). eQTL that map distant to the

location of the gene being assayed most likely identify the location of *trans*-acting regulators (*trans*-eQTL) that may control the expression of a number of genes elsewhere in the genome [191].

To date, the eQTL strategy has been successfully applied in sequenced model plants, such as *Arabidopsis* [192] and rice [193], and also in barley in response to *Puccinia hordei* infection [194]. However, genomic surveys of eQTL for abiotic stress tolerance are still rare, or at their very beginning, in crops [195, 196]. Although not related to abiotic stresses, an interesting eQTL discovery in barley has been reported by Potokina *et al*. [50]. The authors used the Affymetrix barley GeneChip to measure transcript abundance in embryo-derived tissue of germinating grains collected from 139 DH lines of the "Steptoe" × "Morex" population. A genome-wide QTL analysis based on expression data of about 16 000 transcripts was thus performed and more than 23 000 significant eQTL, affecting the expression of about 13 000 genes, were found [50]. Interestingly, several regions that had many more eQTL than expected by chance alone if one assumes a uniform distribution based on genes per centiMorgan were identified, and an eQTL hot spot on chromosome 5H Bin 1, affecting expression of more than 200 genes, were coincident with a major locus of grain hardness already mapped in the same population.

Expression QTL researches alone, however, may fail to dissect physiological traits. For instance, if a sequence polymorphism does not affect gene expression itself, although it leads to differences in protein stability, enzymatic activity, or metabolite production, an eQTL would not be detected at that locus. In these cases, as in general, the other genetical genomics approaches could be used for the parallel measurement of the abundance of thousands of proteins and metabolites, to map protein QTL (pQTL) and metabolite QTL (mQTL). Moreover, as another future development of the genetical genomics, transcript, protein, and metabolite profiling could be combined to extract the highest possible information from each data set. Unluckily, as far as we know, no or very few studies on protein or metabolic QTL mapping for abiotic stress tolerance/adaptation have been published in barley so far. A recent interesting example of the application of pQTL analysis in barley is the work of Witzel *et al*. [197]. The authors employed a two-dimensional gel electrophoresis to characterize the grain proteome deriving from a set of doubled haploid introgression lines (IL) in which the *H. vulgare* spp. *spontaneum* Hs213 represented the donor parent and *H. vulgare* spp. *vulgare* cv. "Brenda" the recurrent one. A total of 51 quantitative trait loci for protein expression (pQTL) were found. With the only exception of chromosome 3H, where no pQTL were detected, an evenly distribution of loci was observed. Mass spectrometry (MS) was also used to examine proteins underlying pQTL and the most expressed were those involved in metabolism and disease/defense-related processes [197].

In the past 2 years, several studies have been carried out at the metabolomic level in *Arabidopsis* and other most studied plant species, which have led to a far richer description of the natural variation of chemical composition in these species facilitating the identification of important sources of allelic variance for metabolic engineering. Meyer *et al*. [198] used gas chromatography–mass spectrometry (GC-MS) to study the primary metabolism of Columbia × C24 RIL population.

Although no single primary metabolite displayed a strong correlation with plant biomass accumulation, a metabolic signature composed of contributions from various metabolites was identified and abundance data allowed the detection of 157 metabolic QTL [198]. More recently, Rowe *et al.* [199] conducted a similar study on 210 RIL genotypes derived from the "Bayreuth" (Bay) × "Shahdara" (Sha) cross. The distribution of metabolite QTL across the genome included 11 QTL clusters; 8 of these clusters were associated with an epistatic network that regulated the plant's central metabolism. Since the same population was previously employed for global eQTL analysis, the authors compared the heritability of the mQTL they found with the results of West *et al.* [200] and showed that mQTL tended to be less heritable than the eQTL displaying a moderate phenotypic effect [199].

As a general consideration about the advancement of "omics" sciences in the study of quantitative variation, as well as of QTL mapping in general, such advancements could enable the cloning of most mapped QTL in plants. This will definitely finalize their mendelization, and move plant science to a step forward similar to that of the advent of QTL mapping. Another opportunity for the near future could be a better understanding of the QTL × QTL interactions on a genomic scale, together with the identification of the biological meaning for the QTL × E effects.

34.2.5.2 Genomic Regions Carrying phQTL for Abiotic Stress Tolerance

34.2.5.2.1 phQTL for Cold (Frost) Stress Tolerance As underlined in Section 34.1, Triticeae need to experience an acclimation period (hardening) to acquire a complete low-temperature resistance. In fact, it is during the hardening phase that the metabolic machinery of response to frost is activated [134, 201]. For this reason, functional genomics studies aiming to explore the key components of such molecular mechanisms have been conducted at low, nonfreezing temperatures (see, for example, Ref. [202]). On the other hand, as phenotypic evaluation for frost tolerance has a more applied significance, most QTL searches were done for tolerance to frost (Fr) conditions, both in the field and in the controlled environments. Although considered a polygenic trait, since the early 1990s, QTL mapping has led to the identification in barley of a relatively small number of quantitative trait loci having major effects on the ability of the plant to survive freezing (i.e., exposure to −11/−13 °C). Since the first reports, a large genomic region of chromosome 5H was highlighted as responsible for winter survival in the "Dicktoo" × "Morex" population, with one QTL mapped to the *VRN-H1* vernalization requirement locus [203, 204]. Later on, Francia *et al.* [189] developed the "Nure" (winter) × "Tremois" (spring) N × T linkage map and DH population as valuable genetic resources for the analysis of winter hardiness-related traits. They demonstrated that frost tolerance was controlled mainly by two linked QTL (*Fr-H1* and *Fr-H2*) rather than by one, both located on 5H, explaining a large part of phenotypic variation [189]. As far as we know, the N × T genetic system is the only population where both *Fr* QTL are segregating in the Triticeae since in wheat *Fr-A1* [205] and *Fr-A2* [206] were mapped in different genetic systems. It has also been shown by colinearity approaches that the two loci of chromosome group 5 are conserved in the Triticeae [207]. Tolerance at *FR-H2* appears

to be governed by a cluster of at least 12 *CBF* genes, which reside at this locus [54, 189, 208, 209], whereas *FR-H1* was found as overlapping with the *VRN-H1* vernalization response locus. At the moment, testing the hypothesis whether the effect of *Fr-H2* is either due to a "CBF number game", that is, due to a particular and critical number of *HvCBF*s acting in a coordinated manner, or due to the action of only one *HvCBF* is still underway. Knox *et al.* [210] showed that barley genotypes "Dicktoo" and "Nure," carrying a *vrn-H1* winter allele at *VRN-H1* harbor, increased copy numbers of *CBF* coding sequences in comparison to genotypes "Morex" and "Tremois" carrying a *Vrn-H1* spring allele. Sequencing bacteriophage lambda genomic clones from these four cultivars, alongside DNA blot hybridizations, indicated that approximately half the *CBF* orthologues at *FR-H2* are duplicated in individual genomes. One of these duplications discriminates winter (*vrn-H1*) genotypes from spring (*Vrn-H1*) genotypes, as the winter cultivars harbored tandem segmental duplications through the *CBF2A–CBF4B* genomic region and maintained two distinct *CBF2* paralogues, while the spring varieties harbored single copies of *CBF2* and *CBF4* [210]. An additional *CBF* gene, *CBF13*, was a pseudo-gene interrupted by multiple nonsense codons in "Tremois," whereas *CBF13* showed a complete uninterrupted coding sequence in "Dicktoo" and "Nure." Finally, DNA blot hybridization with wheat DNAs revealed that a greater copy number of *CBF14* also occurs in winter wheats than in spring wheats. Overall, these data indicate that variation in *CBF* gene copy numbers is widespread in the Triticeae and suggest selection for winter hardiness coselects winter alleles at both *VRN-1* and *FR-2*. To further reinforce the hypothesis on the main role played by the CBFs in the cultivated germplasm, in their work Tondelli *et al.* [54] mapped to chromosome 7H, loosely linked, two barley orthologues of the *AtFRY1* and *AtICE1* genes, putative upstream regulators of *CBF* genes in *Arabidopsis* [211, 212]. No QTL of cold tolerance were mapped on chromosome 7H, suggesting that allelic variation at these two CBF regulators are not important for the trait.

Vrn-H1 is one of the three vernalization genes loci required to determine barley growth habit [213, 214]. Limin and Fowler [215] suggested that the main vernalization gene in wheat, *VRN-A1 (VRN-1)*, which is induced during vernalization, plays an important role in decreasing the ability to cold acclimate with development. Since *FR-A1 (FR-1)* cosegregates with *VRN-1* in most genetic studies, until recently it was not clear if *FR-1* was an independent gene or just a pleiotropic effect of *VRN-1* [189, 216]. Notably, barley genotypes carrying the *vrn-H1* allele for winter growth habit express certain *CBF* genes at higher levels than genotypes carrying the *Vrn-H1* allele for spring growth habit [217]. Moreover, once the winter genotypes carrying the *vrn-H1* allele are vernalized, *CBF* transcript levels are dampened relative to levels detected in nonvernalized plants [217]. This suggests that *VRN-H1* somehow acts to repress expression of the *CBF*s at *FR-H2* and in turn decrease freezing tolerance. Recently, Dhillon *et al.* [218] used two diploid wheat (*T. monococcum*) mutants, maintained vegetative phase (*mvp*), which carry deletions encompassing *VRN-1*. The *Mvp/2* normal flowering plants showed reduced freezing tolerance and reduced transcript levels of several *CBF* and *COR* genes compared to the *mvp/mvp* never flowering plants. Diploid wheat accessions with mutations in the *VRN-1* promoter, resulting in

high transcript levels, showed a significant downregulation of *COR14b* under long days, but not under short days. These results suggested that *VRN-1* is required for the initiation of the regulatory cascade that downregulates the cold acclimation pathway. In the same study, Dhillon *et al.* [218] hypothesized that previously mapped *FR-1* on the chromosome 5A region was likely a pleiotropic effect of *VRN-1* rather than the effect of a separate closely linked locus.

Generally, in winter barley growing areas, frost is experienced at the vegetative stage of development. In Australia, the predominant frost damage occurs from radiation frost events in spring during the reproductive stages of barley and other cereals' development. Reproductive tissue is very sensitive and can be damaged by small subzero temperature drops ($\leq -2\,^{\circ}C$). QTL for reproductive frost tolerance were then identified by Reinheimer *et al.* [8] and by Chen *et al.* [219]. Reinheimer *et al.* [8] indicated that two chromosomes, 2H and 5H, were implicated in the genetic control of reproductive frost tolerance. The QTL on chromosome 2HL was identified for frost-induced floret sterility in two different populations at the same genomic location, named *Flt-2L*, which was not linked to previously reported developmental or stress-responsive loci. QTL on chromosome 5HL were identified for frost-induced floret sterility and frost-induced grain damage in all the three populations studied, coincident with *Fr-H1*/*Vrn-H1*. Similar results were obtained by Chen *et al.* [219]. Winter alleles at the *VR-H1* vernalization response locus on 5H were linked in coupling to reproductive frost tolerance.

34.2.5.2.2 **phQTL for Drought Stress Tolerance** Among the different abiotic stresses, drought is by far the most complex and devastating for crops on a global scale [220]. Because of its complex genetics, it is often considered the most difficult trait to improve. Drought stress might be defined as the condition in which the amount of water available for the plant or through rainfall or irrigation is not sufficient to cover the plant evapotranspiration demand [221]. As a consequence, the level of drought tolerance of a plant has been determined by a great number of traits over the past decades and also in barley, but not always physiologically meaningful. Jones [222], for instance, underlined how in the majority of the molecular studies, measurements of plant water status (e.g., relative water content, RWC) are often not made, although they would be needed for good and appropriate measurement of tolerance. However, final grain yield of a given genotype in drought environments, with equal length of growth cycle phases with respect to other genotypes, should be considered as the best target trait of tolerance (measured as adaptation to drought-prone areas) [188, 223]. In this view, in drought tolerance studies the time period of drought stress is also very important. The longer this period, the more drastic are the consequences on the yield. Moreover, the different crop developmental stages show different sensitivity to drought stress [224]. Adaptation of barley growth cycle, and corresponding variation at cloned genes/QTL driving such adaptation, is also extremely important for stable yields in drought-prone environments. Very recently, Francia *et al.* [225] showed that plant adaptation in terms of grain yield was primarily driven by the allelic constitution at three out of the four major candidate genes for flowering time segregating in the studied segregating

population (i.e., *Vrn-H1*, *Ppd-H2*, and *Eam6*). The interrelationships among a series of characters defining grain yield and its components were explored as a function of the length of the vegetative, reproductive, and grain filling developmental phases. In most of the 18 environments across the Mediterranean, the best performing (adapted) genotypes were those with faster development until early occurrence of anthesis; the study confirmed the crucial role of the period defining the number of grains per unit area in grain yield determination in Mediterranean environments.

In 2002, Ozturk *et al.* [141] identified a number of differentially expressed sequence tags (dESTs) and putative candidate genes for drought response. These genes and ESTs were later used by Diab *et al.* [226] to enrich the linkage map developed by Teulat *et al.* [227], in the "Tadmor" × "Er/Apm" barley cross. On this map, 68 phQTL for different phenotypic measurements of drought stress were identified [226], and the highest significant QTL were obtained for osmotic potential under irrigation (OPi) on chromosome 2H and for WSC100 (water-soluble carbohydrates at full turgor) under drought stress on chromosome 4H. Most of the dESTs identified by Diab *et al.* [226] were "effector" genes, while the study by Tondelli *et al.* [54] represented the first example of an integrated approach for mapping several regulatory candidate genes involved in (cold and) drought response of barley. The authors gave great emphasis to TFs and upstream regulators, rather than to structural genes, following the hypothesis that the trait of interest may be influenced by molecular variation in regulatory genes more than in the structural ones [228]. It could be worth mentioning that of the 12 drought tolerance QTL reported on their consensus map, Tondelli *et al.* [54] found positional association with several regulatory candidate genes on chromosomes 2H, 5H, and 7H, among which *HvABI5* on chromosome 5H, and with drought-induced effector genes on chromosomes 5H and 6H. More recently, Chen *et al.* [229] conducted drought resistance QTL mapping on 134 F4 families derived from a cross of two wild barley (*H. vulgare* spp. *spontaneum*) lines in moderate drought. In agreement with previous studies on cultivated barley, three phQTL for relative water content were identified on chromosomes 1H, 2H, and 6H, underscoring the importance of the 1H and 6H genomic regions for the maintenance of plant water status. In particular, the RWC-phQTL on chromosome 1H is coincident with that identified by Teulat *et al.* [230], while the RWC-phQTL on chromosome 6H was coincident with two QTL found under field conditions for RWC and carbon isotope discrimination, by Teulat *et al.* [227, 231]. A QTL for seedling regrowth rate (REG) identified by Chen *et al.* [229] on chromosome 4H is coincident with a QTL for RWC under Mediterranean field conditions [231]. A genomic region on chromosome 6H [229] corresponds to a previously identified QTL that control leaf osmotic potential and osmotic potential at full turgor, scored under Mediterranean field conditions [231]. Finally, Chen *et al.* [229] found a genomic region on chromosome 2H, near AFLP marker W3555-113, with QTL effects on leaf relative elongation rate (RER), second leaf length (L2L), and root length (RLE). This region might match both a QTL effect for RWC under Mediterranean field conditions [231] and a QTL for salt tolerance reviewed by Cattivelli *et al.* [180]. As was briefly summarized here, grain yield has been the subject of numerous QTL studies in barley, but most of these have been conducted in relatively high yielding environments. Comadran *et al.* [188]

assembled a population of 192 genotypes that represented landraces and old and contemporary cultivars from Europe and WANA (West Asia and North Africa). This population was grown in contrasting rain-fed and irrigated sites through the Mediterranean countries. By LD mapping, QTL exhibiting consistency across environments were detected in Bins 4, 6, 6, and 7 of barley chromosomes 3H, 4H, 5H, and 7H, respectively. The authors were able to detect between two and five significant QTL in severely stressed environments with field mean yields lower than 2 ton ha^{-1}. As one of the most interesting findings, one of the most consistent genomic regions was located in Bin 7 of chromosome 7H, where four out of the five significant associations came from the four Jordanian sites with mean grain yield ranging from 0.3 to 1.2 ton ha^{-1}.

34.2.5.2.3 **phQTL for Salt Tolerance** Barley is one of the most salinity-tolerant cereals, and barley cultivars display different levels of tolerance toward salinity [141]. As outlined in Section 34.1, salt stress has at least two components, an osmotic one and an ionic one, due to sodium (Na). Generally, barley plants are more sensitive to salinity at germination and young seedling stage, while they exhibit increased tolerance with age. No correlation was observed between salt tolerance at seedling and salt tolerance at germination stage in barley, suggesting stage-specific mechanisms [232]. Salt tolerance of barley has been of interest for a long time and has resulted in a considerable body of data from studies using physiological [233], genetic [234], and cytogenetic approaches [235]. The first evidences of salinity tolerance QTL date back to the second half of the last decade, and they are related to sodium tolerance at germination stage [232]. These authors reported that salinity QTL at the seedling stage were located on chromosomes 1H, 2H, 5H, and 6H in the DH lines of "Steptoe" × "Morex" and on chromosome 5H in the DH lines of "Harrington" × "TR 306." More recently, in the work of Witzel *et al.* [236], a QTL analysis of the Oregon Wolfe Barley ("DOM" × "REC") population germinating at different salt concentrations led to the identification of two chromosome regions on 5H and one on 7H associated with salt stress response. The same population was also used to identify via 2D-GE six protein spots with a differential abundance between the tolerant and the sensitive lines. Based on a dense barley transcript map [55], two of the more expressed proteins, Hsp 70 (heat shock protein 70) and Glc/RibDH (glucose/ribitol dehydrogenase), were assigned to a genetic location and colocalized with the identified QTL on chromosome 5H [236]. Other genomic experiments like those of transcriptional profiling in response to salt stress by Ozturk *et al.* [141], Ueda *et al.* [147], and Walia *et al.* [14, 148] allowed to find a significant selection of transcription factors and other candidate genes for salinity tolerance (see Section 34.2.4.2). These are a reservoir of coding sequences for explaining with genetical and genomic evidences each salt tolerance phQTL. In the near future, they could be used to improve resilience to an abiotic stress relatively easy to phenotype, on large numbers of plants, if compared to the others described.

34.2.5.2.4 **phQTL for Nutrient and Metal Stress Tolerance** Increasing the efficiency with which crops utilize nutrients, in particular N and P, represents an urgent priority

for ensuring a cost-effective and sustainable agriculture for the future. As regard nitrogen, nitrogen use efficiency (NUE) is a synthetic index that indicates the biomass nitrogen yield per unit of nitrogen consumption, calculated on the basis of a complete nitrogen balance. In case of cereals, worldwide NUE was estimated approximately 33%, and might be estimated by the equation NUE = (total cereal N removed – N coming from the soil + N deposited in the rainfall)/(fertilizer N applied to cereals) [237]. As a synthetic index, it depends on several known agronomic traits such as the extent of root–soil association, the root N uptake, the N metabolism, and the N translocation and remobilization from vegetative tissues to the grain. Although under high environmental influence, and depending upon agronomical practices, attempts to uncover the genomic regions associated with both NUE and nitrogen-related traits in maize and other crops have been made. QTL for tolerance to low N were mapped in barley. Several QTL for nitrogen-related traits, namely, QTL associated with nitrogen uptake, storage, and remobilization, were located practically on all chromosomes, although NUE was not calculated. Chromosomes 3H and 6H were especially important, for their QTL, alleles associated with inefficient N remobilization were also related to depressed yield [238]. No map comparisons between QTL and candidate genes were performed. In maize were reported a high number of QTL mapping studies for nitrogen-related traits (see, for example, Coque and Gallais [239]). A number of genes that encode enzymes involved in N and C metabolism were associated by mapping to QTL for vegetative development and for grain yield and its components [240]. These included genes for Gln synthetase (GS): Suc-P synthase, Suc synthase, and invertase (b-fructofuranosidase). The most notable outcomes of these studies were the colocation of a major grain yield QTL on maize chromosome 5 with the gene encoding cytosolic GS (*gln4* locus) and the correlation between the expression levels of the *gln4* alleles and the contributions of the respective QTL alleles at this locus.

Because of the low mobility of P in the soil, extensive QTL mapping work has been carried out to investigate the effects of root architecture on P uptake and use efficiency, although not in barley. A common feature of these studies was the finding that the QTL alleles for high P efficiency were associated with greater root surface area due to an increase in either root mass or root hair density. Interestingly, in rice, marker-assisted backcross breeding of the positive allele at *Pup1*, a major QTL on chromosome 12 for P uptake efficiency, provided introgressed lines with a three- to fourfold increase in P uptake [241].

The pattern of inheritance of tolerance to excess Al, phenotypically identified as better plant growth and biomass accumulation, has been explored in barley by different genetic approaches, including phQTL mapping, leading to the identification of a genomic region of highest importance on chromosome 4H. In this region, four major genes were identified and named *Alp*, *Pht*, *Alt*, and *Alp3*, outlining that this trait, different from other resistances to abiotic stresses, is not properly a quantitative trait in barley. The locus *Alp* conferring Al tolerance to cultivar "Dayton" was located on the long arm of chromosome 4H by crossing "Dayton" with the trisomic line "Shin Ebisu 16" [242]. The same chromosomal location (4H) of other proposed Al tolerance loci was confirmed including *Alt* from "WB229" by means of

amplified fragment length polymorphism (AFLP), SSR, and analysis of wheat–barley chromosome addition lines [243]. At present, the best candidate gene to explain the tolerant phenotype remains *Alp* gene that codes for a protein that belongs to the MATE family [244]. Furukawa *et al.* [163] reported an aluminum-activated citrate transporter gene in barley, *HvAACT1*, responsible for Al tolerance that also belongs to the MATE protein family. Recently, minor QTL effects for Al tolerance have been reported [245, 246], indicating the existence of a multigenic, quantitatively inherited component of excess aluminum tolerance in this cereal, besides the major gene effect (s). Particularly, Raman *et al.* [245] identified several phenotypic QTL for root elongation under excess Al stress on 3H, 4H, 5H, and 6H chromosomes in an F2 population from "Ohichi" × "F6ant28B48-16," whereas Navakode *et al.* [246] tested the Oregon Wolfe Barley (OWB) population and detected minor QTL effects located on 2H, 3H, and 4H chromosomes.

Boron (B) is an essential micronutrient for higher plants, but high levels of boron in the soil can seriously diminish grain yield in cereal crops. The stress damage consists in affecting root growth, thus restricting water extraction from the subsoil. Amelioration of the high B levels in soils is not always feasible; therefore, assisted breeding for B tolerance in barley has moved forward since the work of Jefferies *et al.* [9], who identified both a range of phenotypic assays for assessing different physiological aspects of boron tolerance and molecular markers for tagging loci for the trait. The source of alleles conferring B tolerance is "Sahara," an unadapted six-rowed barley landrace of Algerian origin. Jefferies *et al.* [9] identified four significant phQTL involved in different phenotypic aspects of B tolerance. A region on chromosome 2H was associated with leaf symptom expression, a 3H QTL influenced root growth suppression by boron toxicity, a region on 4H influenced boron uptake, root growth response, dry matter production, and leaf symptom expression, and a region on 6H was associated with B uptake. After validation through a backcross approach, the authors concluded that the chromosome 2H locus is the most important in controlling leaf symptom expression, while the chromosome 4H locus appears to be the most important in controlling B uptake, root length response, and dry matter production. A few years later, physiological studies assessed that a high level of tolerance to B toxicity is mediated by extrusion of B from the root [247], resulting in lower concentrations in roots and shoots. Based on the result obtained by Jefferies *et al.* [9], two of the four boron toxicity tolerance loci have been cloned so far. Sutton *et al.* [165] followed a map-based approach to isolate a CG for the 4H boron tolerance QTL. Using a population representing 6720 meioses and gene colinearity with the syntenic region on rice chromosome 3, they identified the *Bot1* gene, a putative integral transmembrane B transporter with similarity to bicarbonate transporters in animals [165]. Recently, Schnurbusch *et al.* [248] reported the cloning of a gene underlying the chromosome 6H B toxicity tolerance QTL. The gene, named *HvNIP2;1*, encodes an acquaporin from the nodulin-26-like intrinsic protein (NIP) subfamily, which corresponds to the previously described gene *HvLsi1* (low silicon 1), a silicon influx transporter in barley and rice [249]. Interestingly, the observed differences in mRNA levels of *HvNIP2;1* in "Clipper" and "Sahara" might be explained by a repeat insertion of ∼2 kb upstream of the translation codon in

"Sahara." The authors also hypothesized that such repeat insertion might be responsible for altered tissue- or cell-specific expression of *HvNIP2;1* in the root. Together, the findings of Sutton *et al.* [165] and Schnurbusch *et al.* [248] suggest a mechanism for barley tolerance to high soil B in which the reduced expression of *HvNIP2;1* limits B uptake and the increased expression of *Bot1* removes B from roots and sensitive tissues.

34.2.5.2.5 **phQTL for Waterlogging Stress Tolerance** Waterlogging conditions substantially cause to barley plant a hypoxic stress [5]. Barley germplasm showed significant differences in waterlogging tolerance [250], and locally adapted landraces could be major sources of tolerance to be used for breeding. However, studies of tolerance to flooding, namely, waterlogging, have been performed under notably different conditions, from paddy field trials to laboratory tubes, and at different growing stages. In turn, Stanca *et al.* [5] underlined how the genotypes resistant to water sensitivity of germinating seeds were different from those tolerant to flooding after germination. Waterlogging tolerance is, therefore, a complex trait, with different tolerant phenotypes to different stress conditions, from seed to adult plant developmental stages. Moreover, such a trait is affected by several additional (confounding) environmental factors, such as temperature, nutrient availability, soil type and subtopography, and possible presence of concurrent biotic stresses. Besides, breeding for flooding tolerance is difficult because of low heritability of the trait [251]. Little progress has been made since the last decade in mapping phQTL controlling waterlogging tolerance in barley. In these studies, many traits including the ability to produce high seed yield in flooded fields, leaf chlorosis, plant height, root biomass, and shoot biomass have been used as determinants of flooding tolerance. Among all the different criteria, leaf chlorosis after waterlogging has been one of the major indices used by researchers in different crops such as wheat [252], soybean [253], and barley. Li *et al.* [254] carried out a QTL analysis in two doubled haploid populations measuring the leaf chlorosis trait and found at least seven QTL for waterlogging tolerance in the barley genome. Three QTL on chromosomes 1H, 3H, and 7H were very stable and were validated under different stress durations, in different environments, and in different populations. Some of the detected QTL affected differently scored traits; for example, the QTL on chromosome 4H not only reduced leaf chlorosis but also increased plant biomass under waterlogging stress, whereas other QTL alleles such as those on chromosomes 2H and 5H both alleviated leaf chlorosis and improved plant survival.

Zhou [255] accurately phenotyped leaf chlorosis at early stages of waterlogging and plant healthiness including survival at late stages of the treatment for QTL mapping. Curiously, he found that both the significance and the extent of phenotypic effects of the QTL controlling waterlogging tolerance varied at different stages of treatment. At the very early stage (2 weeks) of waterlogging, only three minor QTL were identified, explaining a less than 30% of the phenotypic variation. As the duration of waterlogging increased, higher significant QTL were identified and these explained more than 50% of the variation. Some of the QTL found at different stages of waterlogging were different, but the two major QTL on chromosomes 2H and 4H identified at the

final stage of the stress treatment were coincident with two regions found at the early stages of the treatment.

34.3 The Contribution of other Omics Approaches

During the past few years, we have been part of the exciting progress the "omic sciences" have made in the dissection of complex traits in plants. Like genomics, proteomics and integrative omics have well demonstrated their potential to shed light on the molecular basis of plant phenotypes in model plant research (above all *Arabidopsis*). Conversely, for many crop species the situation is far less advanced since nucleic acids research has been largely favored to other "omics" research. However, a good deal of omic evidence had accumulated for crops and in particular for barley. The information obtained in such studies, when well established, will be of fundamental importance for (1) studying and modeling barley crop from an integrative systems biology perspective or (2) the identification of useful molecular/phenotypic variants conferring better adaptation to the environment. This section summarizes the contribution of the "other omics" to a comprehensive biological knowledge of barley abiotic stress tolerance.

34.3.1 Proteomics

The proteome can be defined as the entire complement of proteins, including the modifications made to a particular set of proteins, produced by an organism or a system. In other words, the structure and the functions of the proteome are studied through large-scale experiments by proteomics. Proteomic platforms have been applied to various aspects of cellular processes, not only to the identification of proteins but also to the determination of the protein expression profiles during development and under stress conditions, to the analysis of posttranslational modifications (PTMs), and to the study of protein–protein interactions. Temporal and spatial profiling of protein spots can be used to associate proteins with developmental processes and to group proteins with similar profiles.

Recent improvements in protein analysis methods have made possible the evaluation and identification of many more proteins and to exploit proteomic data in the context of stress response (for a review, see Ref. [256]). The use of a gel-free proteomics system in addition to a traditional two-dimensional gel-based system provides a vast amount of information on proteins expressed, and a detailed analysis of PTMs via mass spectrometry enables the uncovering of key signaling molecules. Moreover, significant results have recently been obtained through focused analyses, till the level of subcellular proteomes. Once technically possible, the tissue microdissection, or the subcellular components with dedicated extraction procedures, additional important information could be obtained by examining at proteomic level the tissues separately or by analyzing specific cellular components or organelles.

Some of the drawbacks encountered in plant proteomic studies relate to the following aspects. Plant tissues are difficult to disrupt due to the rigidity of cell walls, which are made of a complex assembly of polysaccharides. Protein extraction is also complicated by the presence of secondary metabolites, mainly polyphenolic compounds, which can cause protein precipitation, artificial spots, or streaking on two-dimensional gel electrophoresis (2D-GE), and charge heterogeneity [257]. Extremely abundant proteins such as rubisco (that constitutes approximately 30% of proteins in photosyntetically active leaves) can mask the detection of lower abundance proteins by MS, but reliable and robust methods to remove highly abundant proteins from plant tissue samples are still under development. A major challenge faced in the past by shotgun proteomics has been the protein inference problem (i.e., the assignment of identified peptides to the exact proteins from which they were derived). This is either due to the presence of multiple peptide in the same spot after 2D-GE or due to the identification of a set of redundant and homologous peptide sequences that in many cases could represent multiple proteins. Possible solutions to the inference problem have also been published in plant proteomics. For example, Grobei *et al.* [258] applied gene model–protein sequence–protein accession relationships to classify and eliminate ambiguities inherently associated with any shotgun proteomics data set and reported a conservative list of protein identification to seamlessly integrate data from previous transcriptomics studies. Moreover, proteotypic peptides (i.e., peptides that can be observed by MS and uniquely identify a specific protein or a specific isoform of a protein for the chosen targets) can be selected either using software tools to predict their sequences or accessing existing public data depositories [259].

Initially applied to *Arabidopsis*, functional proteomics has been devoted to the high-throughput identification of all of the proteins present in plant cells and/or tissues, in order to generate large-scale proteome data sets. Today, these include, for the plant model species, quantitative proteomics, subcellular proteomics, and various modifications and protein–protein interactions (for a review, see Ref. [260]). The different Web-accessible plant proteome-related databases are summarized on the web site of the proteomics subcommittee of the Multinational Arabidopsis Steering Committee (MASCP, http://www.masc-proteomics.org), under the heading of "Proteomic Databases and Resources." The proteome database is the basic platform from which proteome research addresses specific biological questions. In fact, integrated information about precise high-resolution proteome maps becomes a prerequisite for functional gel-based proteomics based on evaluating the changes in protein expression, and for exact protein identification in mutants and in stress-challenged plants.

Some excellent reviews have been published about the state of proteomic research in the context of crops (see, for example, Refs [256, 261]) and/or some specific crops such as the monocot rice [262] and the dicot soybean [263]. In particular for rice, the crop that has the advantage to be contemporarily a genomic model plant, a systematic proteomic analysis of leaves, roots, and seeds has been done and proteome maps developed by Koller *et al.* [264]. Data have been collected in the Rice Proteome Database, which catalogues rice proteins of different tissues and organelles ([265], http://gene64.dna.affrc.go.jp/RPD/).

The proteomic approaches used in barley so far focused basically on the seed proteome [266], rather than on abiotic stress metabolism. This is because barley is largely grown for malting, and for this purpose the seed development and germination are crucial. Proteome analysis during grain filling, maturation, and germination has been applied to describe in detail the protein changes occurring in the barley grain. Seed tissue subproteomes have also been analyzed, thus giving a spatial–temporal overview of the seed protein profiles. Although representing an investigation of seed proteome on a panel of superior malting quality cultivars and not related to physical stresses, the work of Finnie *et al.* [267] deserves mention because of the approach they followed. Interestingly, the authors showed that some spot variations measured by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF) peptide mass spectrometry were caused by amino acid differences encoded by single-nucleotide polymorphisms (SNPs). Coding SNPs were validated by mass spectrometry, expressed sequence tag, and 2D gel data. This demonstrated how coding SNPs can alter function of affected proteins and may thus represent a link between cultivar traits, proteome, and genome. In addition, this type of analysis can identify not only chromosome locations of transacting regulators of the proteins observed but also structural genes encoding the proteins themselves [268]. Expression of the peroxidase gene on chromosome 7H was reported to be affected by low-temperature and drought stresses [44, 267], and therefore, the presence or absence of the protein in different cultivars might be an indicator of stress tolerance.

34.3.1.1 Proteome Response to Temperature Stress

A wide range of proteomic studies of temperature tress in plants are in progress, using numerous methodologies, species, and stress conditions (for a review, see Ref. [269]). Despite results obtained so far, information on the systemic response to temperature stress is still limited because plant perception and response is often based on factors common to the response to other stresses. It is at least clear that high- and low-temperature stresses cause distinct proteome responses in plant tissues [269]. One of the key factors for heat tolerance is the heavy induction of heat shock proteins by their upstream transcription factors. Low temperature stress response is characterized by significant effects on chloroplast protein components and energy production, ROS detoxification, and accumulation of small osmoprotectant molecules synthesized by enzymes that are under the control of key transcription factor proteins (see Sections 34.2.4 and 34.2.5). Comparison of wheat cultivars with different heat tolerance levels identified low molecular weight (16–17 kDa) HSPs and other metabolic proteins in the wheat grain [270]. A quite comprehensive catalog of heat stress-responsive proteins has been provided for rice, although still not for barley, revealing that the majority of heat-affected proteins were small HSPs [271].

In barley, proteomic analysis of heat stress response has been performed on shoots [272]. Two spring-type cultivars, "Mandolina" (heat stress tolerant) and "Jubilant" (stress susceptible), were subjected to 40 °C for a short-term heat shock (2 h). Analysis of extracted proteins by 2D gel electrophoresis followed by MS/MS

identified several proteins being differentially expressed in both cultivars. Among them, distinct isoforms of several HSPs were found and in particular the expression of *S*-adenosylmethionine synthetase (SAM-S) was found to be upregulated in "Mandolina" compared to "Jubilant." Expression of SAM-S is known to increase under some stress conditions and the authors proposed it as a heat tolerance marker [272]. Two HSPs were unique to the susceptible cultivar, and one protein that dramatically decreased under heat stress was a 23 kDa oxygen-evolving protein of photosystem II, which is important for photosynthesis [272].

Stress duration is a key factor to the process of cold acclimation. In fact, plant response varies according to the length of low-temperature exposure: long-term (days to weeks) responses follow the process of cold acclimation and grant plants with the ability to survive freezing stress, while short-term (seconds to hours) responses are triggered by cold shocks. Moreover, stress intensity also characterizes the response to low temperatures; plants unable to acclimate and withstand freezing, such as rice or tomato, respond only to the above-zero temperature chilling stress. Several attempts have been made to understand the variation in cold response in the rice proteome, and a collection of recent literature can be found in Ref. [269]: mostly changes in the proteome of anther, leaf, and root tissues were investigated, producing a long list of proteins up- and downregulated in response to chilling stress in rice. These ranged from chaperonins and HSP proteins to elongation factors, ribosomal and ribonucleoproteins, from ATPases and ATP synthases, to dehydrogenase and decarboxylase enzymes [269]. On the contrary, for barley a limited or no information is available on proteome variation following exposure to low temperature. This could be in part due to the fact that the metabolic response of barley to cold stress has already been studied in much detail using genomics approaches. And this might suggest a potential limit of proteomic research that when large functional genomics data sets are already available, it does not add a lot to the qualitative knowledge of the metabolic pathways and gene products activated or repressed. However, the level of transcript abundance does not always correlate well with the level of the corresponding proteins, the key players in the cells. Transcription intensity of a gene gives only approximately its level of translation into a protein since abundantly transcribed mRNAs may be degraded rapidly or translated inefficiently, resulting in still lower abundance of protein [273]. Finally, proteomics could show in the future its higher value in identifying what such data sets cannot contain, such as protein–protein interactions, or PTM; as in the case of the barley response to low-temperature stress, where key transcription factors are acting.

34.3.1.2 **Proteome Response to Drought and Salt Stresses**

As we mentioned before, several proteomics studies have been performed on crops exposed to abiotic stresses, in particular rice. Apart from temperature stress, about one-fifth and one-third of the works reviewed by Salekdeh and Komatsu [261] dealt with drought and salt stresses, respectively. Unfortunately, most of the proteomics research on drought and salt tolerance has not been done in barley, where genomics has been the far most preferred approach. To keep proteomic studies relevant to the field situations, where crops may experience several constraints either simultaneously

or at different developmental stages, the speed with which drought stress is applied must be taken into account. For example, it is slower in soils compared to pots that tend to dry out faster. Equally important are the responses associated with severe water deprivation and subsequent rewatering because the metabolic machinery must be prepared to rapidly reinitiate growth upon water entering tissues and cells. In this regard, the proteome analysis of field-grown sugar beet plants performed by Hajheidari *et al.* [274] demonstrated the predominance of proteins related to ROS handling, protein folding, and stability. Another example was obtained in wheat (*T. aestivum* L.) comparing three different spring genotypes cultivated in the field under well-watered and drought conditions [275]. Phenotypically, the overall effect of drought was highly significant in terms of dry matter and grain yield. The authors detected and analyzed about 650 spots on 2D gels and more than 120 proteins with significant change under water deprivation in at least one genotype. It is worth noting that about two-thirds of the 57 proteins identified via MALDI TOF/TOF MS were Thioredoxin (Trx) targets. This is also in accordance with the link between drought and salt stress observed in transcriptional changes of the barley cultivar "Tokak" [141], where Trx played a key role. However, a higher drought tolerance of barley compared to wheat attributed either to specific mechanisms of adaptation to water deprivation or simply to a broader adaptation to the environment has still to be found.

The role of the proteins involved in reactive oxygen species detoxification during salinity stress has been studied by Witzel *et al.* [276]. They analyzed via 2D-GE the root proteome of two well-known genetic mapping parents, cvs. "Steptoe" and "Morex," which possess contrasting levels of salinity tolerance. Proteome maps of plants grown under nonsaline versus saline conditions revealed cultivar-specific and salt stress-responsive protein expression. In total 26 out of 39 2D-GE spots were identified via MS, and 2 proteins involved in the glutathione-based detoxification of ROS showed higher abundance in the tolerant genotype ("Morex"), while proteins involved in iron uptake were expressed at a higher level in the sensitive one ("Steptoe"). Of the proposed targets for barley salinity tolerance improvement an induced protein, which was more abundant in cv. "Morex," was identified as a putative target for Txr-mediated reduction [276]. In a follow-up experiment, Witzel *et al.* [236] combined proteome maps' comparison with a CG approach. As reported in Section 34.2.5.2, the authors mapped two major QT loci of salinity tolerance at germination stage in the Oregon Wolfe Barley "*DOM*" × "*REC*" population, one on chromosome 5H and one on chromosome 7H [236] (see also Figure 34.1). A search for candidates was then based on 2D-GE proteomic profiling of the mature grain of a subset of OWB lines, and six protein spots showing differential abundance between tolerant and sensitive genotypes were identified.

34.3.1.3 **Proteome Response to Metal and Nutrient Stress**

Proteomic methods based on classical 2D-GE provide a generally good visual output for protein profiling and comparative mapping of expressed proteins among biological samples. They have been extensively applied in various tissues and crop species, for example, soybean, in response to salt stress [277], rice root proteome in response to cold [278], and the seed proteome of wheat [279] and barley [266]. Second-

generation proteomics technologies have also been developed and, among them, the isobaric tags for relative and absolute quantitation (iTRAQ) technique represents an interesting system for quantitative proteomics after chemical labeling using stable isotopes. iTRAQ has found particular application in the study of crop proteomes against heavy metal stress at both plant [280] and subcellular [281] levels. For example, Patterson *et al.* [280] used the iTRAQ peptide tagging system to investigate the proteomic response to boron (B) excess in hydroponic growth solution of B-tolerant and B-intolerant barley cultivars. In particular, the authors found increased activities of three enzymes involved in siderophore production (related to iron deficiency) and suggested a potential link between iron, B, and the siderophore hydroxymugineic acid under B stress [280]. More recently, the vacuolar proteome of mesophyll cells of barley leaves was investigated in response to cadmium (Cd) stress [281]. This study pointed out that a c-tonoplast intrinsic protein (c-TIP) may have a specific function in Cd transport into the vacuole and play an important role in Cd^{2+} detoxification of barley leaf mesophyll cells. The proteomic study provided valuable insight into heavy metal stress biology of barley. However, it is quite a general opinion that still a deal of work remains to be done in the enormous and nebulous field of heavy metal toxicity in plants [282]. This includes identification of protein networks responsible for several processes inside the same response: translocation, biotransformation, and sequestration-related activities. Analyses of subcellular proteome, posttranslationally modified proteins, and/or redox proteome is expected to help in this big challenge [283].

Mineral nutrient deficiency is a factor severely influencing plant biomass production in many cultivation areas. Some interesting examples aimed to assess differences in nitrogen utilization by small-grain cereals have been obtained in wheat and rice crops both at the root [284, 285] and the leaf levels [286, 287]. In all cases, 2D-GE and mass spectrometry identification were applied to investigate the nitrogen stress-responsive proteome of widely contrasting cultivars and hundreds of protein spots were reproducibly detected. Among the proteins identified in the leaves were enzymes involved in carbon fixation and energy production, whereas nitrate reductase and glutamate dehydrogenase were the most influenced root-specific proteins. However, because a large number of spots with differential expression during the varying experiments/treatments and/or varieties still remained to be identified, a full picture of responses to difference in nitrogen utilization could not yet be made.

Although no examples concerning nitrogen stress as far as we know have been published on barley, we expect that advances in proteomic technologies will be of great help in the near future to clarify the role played by the barley proteome in response to N deficiency.

34.3.1.4 Roles of "Interactome" and Comparative Proteomics

It is increasingly clear that protein–protein interactions play a key role in all metabolic processes, and in particular in response to abiotic stress [261]. The (re)creation of interaction networks from proteomic data (the so-called "interactome") will thus provide novel insights into how cells perceive and transduce stress signals to activate

the appropriate cellular response, which could then be compared with and linked to genomics-inferred gene networks. In this regard, an important application, unique to proteomics research, is the ability to study posttranscriptional modifications, which can affect the activity and binding of a protein and alter its role within the cell. About 300 posttranscriptional modifications have been classified, including methylation, phosphorylation, glycosylation, acetylation, ubiquitylation, and so on. In particular, together with the interactome, the phosphoproteome and "glycomics" (if we would like to call in this way the comprehensive study of the entire complement of sugars) will soon become major areas in proteomics-related research.

Among other considerations with regard to future proteomics research, one deserving attention derives from the fact that as data on proteomic experiments accumulate, comparative analysis could be done. For example, Salekdeh and Komatsu [261] compared 56 abiotic stress proteome studies conducted by different research groups in crops. The authors found that the number of stress-responsive proteins identified diverged considerably from each other and only less than 20 proteins were commonly identified under different stress conditions. This divergence probably derived by the fact that many stress-responsive proteins still remain to be identified or that the sampling of tissues was not comparable between tissues and experiments. Even for similar type of stress, different levels of treatments and sampling times and sample preparation were applied [261]. Thus, at the moment, it is difficult to draw consistent conclusions from comparative crop proteomics studies. Only a higher conformity of proteome analysis between different groups of investigators, as well as the application of standard operation procedures, would facilitate comparability of results in barley as in other plants.

34.3.1.5 **Proteomic and Proteomic-Related Databases**

A number of resources for plant genomics accessible on the Web have appeared during the past two decades. The majority of them provide gateways for accessing comprehensive omics data and/or bioresources for the model plant *Arabidopsis* (e.g., TAIR, AraCyc, etc.). In addition, in recent years, several integrative databases on crop plants have been properly developed worldwide (for a recent review, see Ref. [85]). None of them is entirely dedicated to barley, and many include information on the major species rice and maize, together with sorghum. Within this context, we are going to describe here three interesting examples of integrative databases that, besides those about other crops, include relevant proteomics or proteomics-related information about barley. These are GabiPD [288], MetaCrop [289], and PlantTFDB [290].

GabiPD (http://www.gabipd.org, [288]) is a Web-accessible database developed in the frame of the German initiative for Genome Analysis of the Plant Biological System (Genomanalyse im biologischen System Pflanze, GABI) that allows integration of varied "omics" data types obtained from plant systems. The database includes information from 14 different angiosperm species with *Arabidopsis* as the most widely represented model species, followed by the crop plants, potato and barley. Genomic data comprise mapping information, sequences, and SNP/InDel information. Transcriptomics is represented by a large number of ESTs and corresponding

sequence trace files [288]. The flexible design of GabiPD allows for a high level of data integration, and eases cross-referencing the different data types among each other (e.g., mapping information, sequences, 2D gel images, and protein information). For barley, EST clustering results and corresponding information on a new 27 000 unigene set are accessible and downloadable. Annotated 2D gel electrophoresis images from *Arabidopsis* and *Brassica napus* L. have also been integrated as a type of proteomics data. Finally, the value of GabiPD is also further increased by integration with other general databases such as TAIR and GenBank, as well as by providing cross-links to secondary databases, such as ARAMEMNON (http://aramemnon.botanik.uni-koeln.de/) and PlnTFDB (http://plntfdb.bio.uni-potsdam.de/v3.0/).

MetaCrop (http://metacrop.ipk-gatersleben.de [289]) contains hand-curated information of about 40 major metabolic pathways in various crop plants with special emphasis on the metabolism of agronomically important organs such as seed and tuber. Species of both monocotyledons and dicotyledons are represented. The database offers an overview of fundamental biological processes because it integrates plant genomic (EST contigs) and pathway (pathway maps derived from KEGG) information. In particular for barley, MetaCrop contains information about 36 pathways, 291 enzymatic reactions, 7 transport processes, and 4 compartments derived from 382 references. Reactions incorporate information about involved enzymes (e.g., EC and CAS number), metabolites (e.g., CAS number, molecular weight, and chemical formula), stoichiometry, and detailed location (species, organ, tissue, compartment, and developmental stage). Furthermore, for central metabolism (sucrose breakdown, glycolysis, and TCA cycle), kinetic data are available for the reactions [289].

Several databases providing data sets of genes putatively encoding specific DNA binding transcription factors (TFs) have been developed in many plant species (for a summary, see Ref. [85]). Such focused databases are usually predictions based on computational methods, such as sequence similarity search and/or hidden Markov model search of conserved DNA binding domains. PlantTFDB (http://planttfdb.cbi.pku.edu.cn [290]) represents one such example. It contains information about 22 plant species of both monocots and dicots. In particular for barley, PlantTFDB classifies 778 TFs, which are clustered in 54 families (http://planttfdb.cbi.pku.edu.cn, October 2010).

34.3.2 Epigenomics

As already summarized in this chapter, results obtained since the pregenomics era have provided a basic picture of gene regulatory networks in barley response to abiotic stresses. However, both the genome size and the number of protein coding genes are not always directly related to the complexity of organisms. In many cases, different phenotypes are due to the modification of chromatin structure, which is governed by processes associated with epigenetic regulation. Genome imprinting [291], transcriptional gene silencing (TGS) induced by transgenes [292], and paramutation [293]

are just some of the well-known examples of epigenetic regulation of biological processes in plants. A comprehensive genome-wide catalogue of epigenetic control elements and how these vary across cell states could offer critical insight into the relationships with other "omics" sciences and between genotype, phenotype, and environment [294]. The term "epigenome" has been referred, for a given cell type, to the complete description of chemical changes to DNA and histones as they map onto the genome. The advent of molecular techniques such as chromatin immunoprecipitation (ChIP), and their combination with (1) genomic tiling array hybridization (ChIP-on-chip) and recently (2) massively parallel sequencing (ChIP-seq), has enabled global and whole-genome epigenetic profiling studies. These two main approaches can be viewed as standard technologies used for mapping chromatin state. On the one hand, ChIP-on-chip is ideal for targeted studies of promoters or specific loci, but for working on a genome scale it requires multiple arrays and large quantities of DNA. On the other hand, ChIP-seq is inherently genome-wide, can detect repetitive elements and allele-specific changes, requires few nanograms of DNA, and capitalizes on remarkable recent advances in sequencing throughput [295]. As expected, these approaches found important applications to investigate the mammalian epigenome [296], but during the past few years the study of the *Arabidopsis* epigenome has begun as well [297, 298]. We thus could expect that ChIP-on-chip and ChIP-seq will be applied soon also to the interrogation of the epigenome of many crop species, among them barley.

The process of a reversible control over gene expression and inheritance has also led to the belief that plants may have a flexible short-term strategy of the response to stress. For example, epigenetic regulation is also involved in stress-related memory formation. This retention has been evidenced not only for short duration, as in the case of acclimation to stress conditions, but also for longer times through stable, heritable chromatin modifications. During the past two decades, research on the epigenetic mechanisms involved in abiotic stress resistance has unraveled that regulation of stress-responsive genes often depends on three epigenetic controllers of chromatin remodeling (for a review, see Ref. [299]): (i) histone N-tails modifications; (ii) changes in DNA methylation state; and (iii) action of nonprotein coding RNAs. These will be briefly described in the following sections.

34.3.2.1 **Role of "Histone Code"**

In plants as in animals chromatin remodeling is the dynamic alteration of chemical reversible modifications at specific residues in the histone N-tails. It is operated by several histone modification enzymes, namely, histone acetyltransferases (HATs), deacetylases (HDACs), methyltransferases (HMTs), and demethylases (HDMs). Moreover, each histone has variants encoded by different genes. The combination of histone variants and their posttranslational modifications is referred to as "histone code," which determines the chromatin structure and thus regulates transcription. Most research on chromatin remodeling in plants has been carried out in *Arabidopsis* (for a review, see Ref. [300]), where at least 28 different histone modification sites have been identified so far. MS and ChIP analyses showed that enrichments of acetylation, certain phosphorylation, and ubiquitination usually correlate with gene activation,

while biotinylation and sumoylation generally repress gene expression [301, 302]. The consequences of histone methylation lead to highly complex outcomes depending on the N-tail residues that are modified, whether modifications occur in eu- or heterochromatin, and on the organism considered. In *Arabidopsis*, trimethylation of histone H3 Lys4 (H3K4me3) and acetylation of histone H3 Lys9 (H3K9ac) are generally positive markers of gene activation, whereas dimethylation of histone H3 Lys9 (H3K9me2) and trimethylation of histone H3 Lys27 (H3K27me3) are negative markers of transcription [301]. An initial event in the modification process is the recognition of H3K4me3 by effector proteins that contain a protein fold termed plant homeodomain (PHD). This interaction eventually leads to the introduction of other changes in the acetylation and methylation status of H3K4me3-containing promoters [303].

A variety of modifications of histone N-tails occur during stress responses [304, 305], with some combinations that seem to be common to several genes, and others that appear more gene-specific. Once again, the majority of the work has been done in the model plant *Arabidopsis*, highlighting histone stress-specific responses. Exposure to low temperatures progressively decreases H3K27me3 negative modification at the cold-regulated genes *COR15A* and *AtGOLS3*, and this alteration is maintained for up to 3 days after plants are returned to normal conditions [305]. Exposure to drought increases H3K4me3 and H3K9ac positive modifications at the coding region of the response to dehydration *RD29A*, *RD29B*, and *RD20* genes and *At2g20880*, an AP2 transcription factor [304]. At all four genes, these epigenetic marks correlate with enhanced transcription. In addition to these common modifications, enrichment in H3K23ac and H3K27ac has been reported in response to drought in the coding regions of *RD29B*, *RD20*, and *At2g20880*, but not in the coding region of *RD29A*, indicating a gene-specific way of action [304]. Recruitment of HATs to target promoters is mediated by direct or indirect interaction with transcription factors and/or by interaction with acetylated histone Lys residues on the target. This has been shown for the transcriptional adapter (ADA) and the Spt-Ada-Gcn5-acetyltransferase (SAGA) complexes in which AtGCN5 contributes to HAT activity. The recruitment of the ADA/SAGA-like complexes to regulate cold tolerance through chromatin remodeling in target genes has been shown to be mediated by the interaction with AtCBF1 [306].

Reports describing the involvement of the "histone code" and nucleosome occupancy in the regulation of stress-responsive gene expression are still rare in crops, and particularly in barley. One example is the induction of expression of the linker histone variant H1-S after exposure of tomato plants to drought [307]. H1-S appears to be involved in the negative regulation of stomatal conductance. In rice, expression of different members of the HDAC families is differentially regulated by abiotic factors such as cold, osmotic, and salt stress and by plant stress-related hormones such as abscisic acid, jasmonic acid, and salicylic acid (SA) [308]. As another example, both the acetylation and the methylation levels of histone H3K4 were altered on the rice submergence-inducible genes *ADH1* and *PDC1* (namely, alcohol dehydrogenase 1 and pyruvate decarboxylase 1) during a submergence treatment [309]. A simultaneous decrease in H3K4me2 levels and increase in

H3K4me3 together with histone H3 acetylation levels were observed on the 5′- and 3′-coding regions of *ADH1* and *PDC1* in stress conditions. These histone modifications recovered to the initial state after reaeration treatment.

Characterization of HATs in *Arabidopsis* revealed three families of HAT sequences in plants: the GNAT/MYST group (where GNAT is Gcn5-related *N*-acetyltransferases and MYST was named for its founding members: MOZ, Ybf2/Sas3, Sas2, and Tip60), the p300/CREB binding protein (CBP) coactivator family, and the TATA-associated factors – $TAF_{II}250$ family [310]. Twelve *HAT* genes were identified in *Arabidopsis*, of which five belong to the GNAT/MYST group, five to the CBP family, and two to the $TAF_{II}250$ family [310]. Full-length cDNAs encoding the putative protein sequences for the HvELP3 (elongation protein 3 of the GNAT group), HvMYST, and HvGCN5 homologous HATs of barley were recently obtained by Papaefthimiou *et al.* [311]. Expression analysis highlighted significant differences in abundance during different seed developmental stages and between two barley cultivars with different seed size. Application of exogenous ABA resulted in induced expression of *HAT* genes in barley seedlings, with *HvELP3* as the most affected one [311].

Eukaryotic HDACc are grouped into three major families based on their primary homology to the yeast HDACs: (1) the histone deacetylase HDA1 family; (2) the silent information regulator 2 (SIR2) family; and (3) the plant-specific family of histone deacetylase HD2 [310]. cDNA sequences encoding members of the HDA1 family and representing all four classes (I–IV) of the family were isolated and characterized in barley by Demetriou *et al.* [312]. Expression analysis demonstrated that they were expressed in all tissues and seed developmental stages. Differences in transcript abundance both in vegetative and in reproductive tissues were observed among the different genes suggesting functional diversification of the HDA1 members. Differential expression was also evidenced for some of the *HDA1* genes in two cultivars ("Caresse" and "Kos") differing for various traits, such as seed size and resistance to stress [312]. Sequence mapping and expression analysis of two full-length HD2 cDNAs from barley has also been obtained [313]. Both *HD2* genes were found to respond to treatments with ABA, JA, and SA, implying an association of these genes with plant resistance to biotic and abiotic stress.

PcG (Polycomb group) protein complexes methylate nucleosomal histone tails at specific sites, ultimately leading to chromatin compaction and gene silencing. Different PcG complex variants operating during different developmental stages have been described in plants [314]. Four barley *PcG* gene homologues, namely, fertilization-independent endosperm *HvFIE*, enhancer of zeste *HvE(Z)*, suppressor of zeste *HvSu(z)12a*, and *HvSu(z)12b* were recently identified and structurally and phylogenetically characterized [315]. Expression analysis of the barley *PcG* genes revealed significant differences in gene expression among tissues and seed developmental stages and between barley cultivars with varying seed size. Furthermore, *HvFIE* and *HvE(Z)* gene expression was responsive to the abiotic stress-related hormone ABA [315]. Interestingly, transgenic *Arabidopsis* lines cosuppressed for the musashi-1 *MSI1* gene, encoding a subunit of PcG protein complexes and chromatin assembly factor 1, showed increased drought stress tolerance phenotype that was most likely due to the increased expression of many ABA-responsive genes [316].

Finally, the ChIP assay demonstrated that the drought-inducible *RD20* gene is a direct target of MSI1.

34.3.2.2 **Role of DNA Methylation**

DNA methylation is a ubiquitous mechanism of heritable epigenetic modification that occurs, in both plants and animals, on the 5′ position of cytosine. As in the case of histone modifications, cytosine methylation is involved in dynamic regulation of gene transcription in response to developmental and environmental cues. Cytosine methylation may lead to epigenetic memory in the short and medium term through the formation of stable epialleles that are heritable across generations. Heterochromatin, repetitive sequences, and transposons are rich in methylated cytosine. In plants, 5-methylcytosine accounts for as high as 30% of the total cytosine content, and such epigenetic mark can be found at both symmetric (CpG and CpNpG) and asymmetric (CpHpH) sites (where N is any of the four DNA bases and H is A, C, or T). Three main DNA methyltransferase enzymes transfer and covalently attach methyl groups to cytosine: domain rearranged methyltransferase DRM2/DRM3, responsible for *de novo* DNA methylation in all contexts, maintenance DNA methyltransferase MET1, responsible for maintenance of CpG methylation, and chromodomain-containing methytransferase CMT3 responsible for maintenance of methylation of both asymmetric and CpNpG sites. Both the DRM2 and MET1 proteins share significant homology to the mammalian DNA methyltransferases DNMT3 and DNMT1, respectively, whereas the CMT3 protein is unique to the plant kingdom [317, 318].

While the biological roles of maintenance and *de novo* methyltransferases have been extensively studied in *Arabidopsis*, several studies in other crop species is beginning to unfold that stresses can induce changes in gene expression through cytosine hypo- or hypermethylation. Barley orthologues of the genes of three classes of DNA methyltransferase enzymes can be found in public sequence repository databases such as the TIGR Gene Index (http://compbio.dfci.harvard.edu/cgi-bin/tgi/). However, at present, no experimental results about the effect of abiotic stresses on them are available. The only study concerning the methylation cycle and its function in barley has been reported for the endosperm development [319]. Using a custom-made high-density macro array of 12 000 cDNA sequences expressed in developing grains and including major enzymes of the methylation cycle, the authors showed that the expression of genes encoding for the storage proteins prolamins was repressed by CpG hypermethylation.

In tobacco, DNA methylation is reduced in the coding region compared to the promoter region of a glycerophosphodiesterase-like gene *NtGPDL* after aluminum, salt, and cold stress treatments, and its reduction was correlated with the more abundant expression of NtGPDL protein [320]. Likewise, maize seedlings exposed to low temperature showed a genome-wide demethylation in root tissues [321]. In particular, a 1.8 kb fragment (ZmMI1) containing a part of the coding region of a putative protein and a part of a retrotransposon-like sequence was demethylated and transcribed only under cold stress. Even after 7 days of recovery, the methylation of the cold-stressed plants was not restored to the initial levels [321]. On the other hand,

osmotic stresses induced transient DNA hypermethylation in two heterochromatic loci in tobacco cell suspension culture [322] and drought stress induced DNA hypermethylation in pea [323].

As we mentioned briefly, histone modifications and DNA methylation might confer within-generational and transgenerational stress memory to the plant [305]. Specific histone modification-dependent pathways appear to mediate methylation of about two-thirds of the methylated loci in the *Arabidopsis* genome [299]. Thus, dynamic histone modification marks could be converted into DNA methylation marks, which are often more stable. However, large-scale analyses using ChIP-seq or ChIP-chip methods are necessary to increase our understanding of the phenomenon of stress memory and to understand whether such epigenetic changes might have an adaptive advantage for stress tolerance.

34.3.2.3 **Role of Nonprotein-Coding RNAs**

With the availability of complete genome sequences in many model plant species (like *Arabidopsis* and *Brachypodium*), the microarray technology has been particularly helpful in the design of platforms able to access and assess dynamic changes in transcriptomes, including short nonprotein coding RNA species. This is worth noting if we consider that differential regulation of expression, splice variations, and noncoding RNA have been proposed as the molecular mechanisms that can explain the huge phenotypic diversity generated in complex organisms using "only" $<$25 000 predicted genes per genome [324]. In particular, nonprotein-coding RNAs might be more abundant in the transcriptome than previously thought, and exerting a more important regulatory function through mechanisms such as antisense RNA or siRNA. For example, the whole-genome transcriptomes of *Arabidopsis* were analyzed with Affymetrix tiling arrays after exposure of plants to abiotic stresses such as dehydration, cold, heat, high-salinity, and osmotic stresses, as well as ABA treatment [325, 326]. Results revealed that thousands of transcripts from unannotated nonprotein-coding regions were up- or downregulated by these stresses. It was also estimated that about 80% of previously unannotated and upregulated transcripts in functional genomics experiments could arise from antisense strands of sense transcripts [325], and thus can influence whole-genome expression. Such high frequency could thus be expected for those crops whose genome sequence has already been unlocked, and in the near future also for barley.

It is now clear that a complex system of multistep regulation controls the various modifications that the mRNA goes through in the cell. For example, RNA helicases and alternative splicing factors, which are implicated in mRNA processing and metabolism, have a close-link with response to abiotic stresses [327]. A related key topic in gene regulatory systems in stress responses is the regulation of gene expression by small RNAs, for which plants have presumably developed unique features compared to animals (for a review, see Ref. [327]). Small noncoding RNAs 21–24 nt in length, double-stranded, namely, microRNAs (miRNAs) and small interfering RNAs (siRNAs), are ubiquitous repressors of gene expression. MicroRNAs are derived from single-stranded primary miRNA (pri-miRNA) transcripts synthesized from *MIR* genes. The pri-miRNA transcript forms a secondary structure

of an imperfectly paired hairpin, which is cleaved by a ribonuclease-like enzyme called dicer-like-1.

siRNAs are derived from long double-stranded RNAs of endogenous origin (i.e., miRNA-directed cleavage products of noncoding single-stranded RNAs, mRNA transcribed from *cis*-antisense gene pairs, mRNAs of heterochromatin, DNA repeats, and transposons) or exogenous origin (as a consequence of transgenes and viral pathogen infection). The process of gene downregulation by small RNAs can be further modulated if we assume that different mRNAs with weak target sites for miRNAs could effectively sequester a miRNA from its *bona fide* targets. Such an idea, put forward recently by Seitz [328], could explain how an increased number of transcripts susceptible to recognition by a given miRNA (present under a certain condition) can, in principle, counteract the accumulation of a particular miRNA, thus allowing the expression of a silenced mRNA.

Small RNA molecules are active players in the molecular response of plants to abiotic stresses, as they participate in the regulation of different pathways coping with environmental stress conditions (for a review, see Ref. [329]). Abiotic stresses not only induce the accumulation of novel antisense overlapping transcripts [325] but also lead to transcript production from transposons or pseudo-genes, which are another source of siRNAs [326]. A clear example of an endogenous siRNA involved in abiotic stress response is given by the nat-siRNA P5CDH–SRO5 [330]. Produced from two overlapping mRNAs, for D1-pyrroline-5-carboxylate dehydrogenase (P5CDH) and Similar to Rcd One 5 (SRO5), the P5CDH–SRO5 was shown to downregulate the expression of P5CDH through mRNA cleavage, leading to decreased proline degradation, enhanced proline accumulation, and salt stress tolerance. However, such regulatory system was shown to function only in *Arabidopsis* and not in other plants [330].

In recent years, large-scale "omics" screens have been applied to clarify the involvement of miRNAs in stress response. For example, Zhao *et al.* [331] carried out a global survey of miRNAs under drought stress in *O. sativa* by a microarray approach. The authors found that several miRNA profiles changed under stress, and focusing on the potential upstream regulatory sequences of the *miR-169g* (which showed significant upregulation), two adjacent dehydration-responsive elements were found. This suggested for MIR-169 a direct involvement in the regulation of the CBF transcription factors [331]. Again, in rice, massive parallel sequencing of small RNA libraries from control and stress-treated plants has allowed the identification of novel miRNAs. Comparing control, salt-, or drought-treated small RNA libraries, Sunkar *et al.* [332] identified 23 nonconserved miRNAs and proposed an additional 40 candidates; only 6 of the identified miRNAs were in common to other monocots [332].

Extensive studies for the identification and characterization of miRNAs are not yet available on barley with the exception of the work of Colaiacovo *et al.* [333]. Through a bioinformatic approach, the authors used the features of previously known plant miRNAs, accessed the public miRBase online catalog (http://www.mirbase.org), and systematically searched for barley miRNA homologues and targets in the publicly available ESTs database. In total, 156 miRNA mature sequences from 50 different

families significantly matched at least one EST sequence in barley, with miRNAs putatively orthologous to those of *Triticum* clearly overrepresented. Many previously known and several putatively new miRNA/target pairs were identified. When grouped into functional categories, the predicted miRNA targets allowed their classification in regulators of biological processes such as development and response to biotic and abiotic stress, with most of the target molecular functions related to regulation of transcription. The sequence of candidate *MIR* genes was also investigated and putative polymorphisms (SNPs/indels) were found, both in functional regions of miRNAs (mature sequence) and at miRNA target sites [333]. Such *MIR* genes could thus represent an interesting source for the future identification of functional genetic variability in the species.

Finally, it is worth mentioning here that small RNAs not only cause posttranscriptional gene silencing by cleavage, or translational repression of complementary target mRNAs, but they are also involved in transcriptional gene silencing. In fact, small RNA profiles revealed a direct correlation between the ability of genomic sequences to produce siRNAs and DNA methylation, with siRNAs supposedly involved in the methylation of at least one-third of methylated loci in *Arabidopsis* [297]. This would happen through a process called RNA-directed DNA methylation (RdDM). Specific histone deacetylases (HDACs) could represent a crucial point for the connection of small RNAs with DNA methylation and histone N-tail modification. It is the case, for example, of HDA6, which has been found involved in TGS [334] and RNA-directed DNA methylation (RdDM) [335].

34.3.3 Metabolomics

The metabolome could be defined as the "quantitative complement of all the low molecular weight molecules present in cells in a particular physiological or developmental state" (for a review, see Ref. [336]). Owing to the complex nature of compounds produced in each plant species, the plant metabolome represents an enormous chemical diversity [337]. Therefore, plant metabolomics is not only a great analytical challenge but also of great importance for plant biology since it is the final product of genes through proteins and through all their reciprocal interactions. Theoretically, metabolomic knowledge enables to explain in detail plant cellular systems and thus permits the researchers to project molecular breeding approaches in order to improve crop productivity of food, pharmaceuticals, biomaterials, and biomass for energy. Last but not the least, complete metabolic profiles can contribute to the understanding of the cellular system in response to changes in the environment. Moreover, genetic variations and changes in metabolite accumulation profiles can be treated as chemical phenotypes to identify loci and genes relevant for a specific metabolic pathway. A summary of metabolic profiling studies performed in plants and their related databases can be found in Ref. [85]. Two interesting examples deserve mention here: the Golm Metabolome Database – GMD (http://gmd.mpimp-golm.mpg.de [338]) and the MS/MS spectral tag – MS2T libraries (http://prime.psc.riken.jp/lcms/ms2tview/ms2tview.html [339]). Through GMD, users have public access to

more than 25 000 mass spectra libraries, metabolite profiling experiments, and related tools, while browsing MS2T researchers have open access to collections of phytochemical LC-MS2 spectra represented by 1 633 639 records from *Arabidopsis*, rice, wheat, and soybean. Containing wide-ranging data acquired from several "omics" research works, the mentioned databases represent crucial information resources and repositories not only for present plant metabolomics but also for further integration of metabolic profiles [85].

Given the large number of studies on the metabolic response of plants to abiotic stress that are accessible through the above-mentioned databases (for a review, see Ref. [340]), here we will mention briefly some of the more relevant. For example, metabolite profiling was used to understand the dynamics of the *Arabidopsis* metabolome in response to low-temperature stress. The metabolome was extensively reconfigured not only in plants overexpressing CBF3, as expected from the prominent role for the CBF cold response pathway in the hardening process [341], but also in plants with natural variation of freezing tolerance [342]. Basically, these data identified that enhanced freezing tolerance is associated with the downregulation of photosynthesis and hormonal responses and the induction of flavonoid metabolism, and provided evidence for naturally increased nonacclimated freezing tolerance due to the constitutive activation of the CBFs pathway. In the chilling-sensitive species rice, Morsy *et al.* [343] obtained a picture of the modification of oxidative products and antioxidative enzymes in combination with the carbohydrate metabolism and indicated a more direct involvement of the ROS-scavenging system in the tolerance process. Sanchez *et al.* [344] reviewed a selection of publications in the high-salinity stress field and by using GC time-of-flight MS profiles of polar fractions from the plant models, *Arabidopsis*, *Lotus japonicus* L., and rice demonstrated the power of metabolite profiling of conserved and divergent metabolic responses among these three species. The authors concluded that a change in the balance between amino acids and organic acids might be a conserved metabolic response of plants to salt stress [344]. Finally, one of the very few examples of application of metabolome profiling in barley in response to abiotic stress is represented by Roessner *et al.* [345]. The authors investigated via GC-MS the metabolite profiles in root and leaf tissues of an intolerant, commercial cv. "Clipper" and a B-tolerant Algerian landrace "Sahara." After exposure to elevated B (200 and 1000 μM in hydroponic solution), the number and amplitude of metabolite changes in roots were greater in the former than in the latter. In contrast, leaf metabolites of both cultivars responded only following high B treatment [345].

We have already pointed out that hundreds of genes related to various metabolic processes change their expression profile in response to P deficiency (see Section 34.2.4.2). However, limited information is available for global metabolite changes of P-deficient plants, especially for cereals. In barley, a nice example of nutrient stress metabolomics has been published by Huang *et al.* [346] who profiled polar metabolites from both shoots and roots of plants grown under various low phosphate conditions. Gas chromatography–mass spectrometry showed that P-deficient plants reconfigure their carbohydrate metabolism initially to reduce P consumption and salvage P from small P-containing metabolites when stress is

severe. Since data suggested that barley behaves as a P-inefficient plant in metabolic adaptation to low P environments, the authors proposed that the manipulation of metabolism through a shift in carbohydrate partitioning could provide a logical strategy for improving P efficiency in barley and perhaps in other cereal crops [346].

Combinatorial approaches that integrate metabolome and transcriptome data have elucidated regulatory networks acting in response to environmental stresses. Clear examples are from *Arabidopsis*, in which the metabolome was analyzed using various types of MS after cold and dehydration exposure, and metabolic profiles have been then combined into regulatory networks together with transcriptome data. Maruyama *et al.* [347] coupled microarray analysis of transgenic plants overexpressing genes encoding DREB1A/CBF3 and DREB2A transcription factors with the metabolic pathways that act in response to cold and dehydration. A similar approach was used by Urano *et al.* [348] to reveal ABA-dependent regulatory networks under dehydration stress conditions by integrating chemical phenotypic changes between wild-type *Arabidopsis* and a knockout mutant of the *NCED3* (9-*cis*-epoxycarotenoid dioxygenase) gene.

As already underlined, metabolite profiling data of segregating populations can also be treated as a quantitative trait for QTL mapping (Section 34.2.5.2). The derived mQTL are expected to enable the discovery of key genes involved in metabolic changes and would aid in the identification of genetic associations between metabolic and/or visible phenotypes [349]. This approach has been successfully applied to model plants and crop species such as *Arabidopsis* [199], poplar [350], and tomato [351]. In addition, correlative patterns between metabolic and genomic diversities can be reconstructed coupling data sets of genome-wide variation along with metabolome variation in germplasm collections representing natural variation [352]. Such strategy will have an even easier application in the near future thanks to the ever-increasing availability of high-throughput genotyping methods, including next-generation resequencing.

To our knowledge, none of the strategies of integration of metabolome data with other "omics" described in this section has been applied in barley, so far. However, we could reasonably hope we will soon learn about results from this new-edge research in crops such as barley, by possessing a wealth of genomic tools and data.

34.3.4
Ionomics

The ionome could be defined as the inorganic complement of cellular and organismal systems, and can be thought of as the inorganic subset of the metabolome. The study of changes in the ionome of an organism, through quantitative and simultaneous measurement of elements in response to "physiological stimuli, developmental state, and genetic modifications," constitutes the central ratio of ionomics (for a recent review, see Ref. [353]). Owing to its high-throughput character as a phenotyping platform, ionomic research enables a rapid generation of large data sets depicting the ionome status of many thousands of individuals. This can thus be

applied to the discovery of gene function (functional genomics) and to the assessment of the global physiological status of plants [354]. Among the several laboratory techniques that are available for application in ionomic research, the most exploited ones are those based on mass spectrometry (MS). In particular, inductively coupled plasma spectroscopy, both mass (ICP-MS) and optical emission (ICP-OES), allows for the parallel measurement of dozens of elements. Obstacles in detecting small differences in the ionome have been overcome over the years by improvements in these techniques [355].

Since the shoot ionome in a plant represents its mineral nutrient and trace element content, it is controlled by multiple physiological processes that start in the rhizosphere and end with phloem recycling and evapotranspiration [354]. Changes in any of these processes involved in inorganic ion transport from the soil solution to the shoot can have a potential effect on the different ionomic signatures. Such shoot ionomic signatures could be useful markers of a particular physiological condition they are associated with because the shoot is a much more accessible tissue for profiling than roots. Using a high-throughput elemental profiling and data handling pipeline to rapidly analyze the shoot elemental composition of thousands of *Arabidopsis* plants, Baxter *et al.* [355] identified and used multivariable ionomic signatures to study plant response to reduced Fe or P nutrition.

The implementation of an information management system able to control all aspects of the process is extremely important for any large-scale ionomics project, where hundreds or thousands of samples are analyzed over an extended period of time. Moreover, due to the complex interdisciplinary nature of large-scale ionomics research, large collaborative projects are required involving various principal investigators' laboratories, institutions, and field sites.

The huge amount of information generated by ionomics could be particularly useful in view of the availability of genome-wide knockout collections of many crop plants, of barley in our case, and in view of the development of high-throughput genotyping methodologies. Once identified, candidate genes could be rapidly tested for validation by screening for the ionomic phenotype of interest in various types of sequence-indexed insertion lines carrying a mutant allele of the gene of interest. This will be a way to control elemental composition, a critical issue both for plant growth and development and for nutrition of humans who use plants for food. In addition, one of the possible future applications of ionomics will be linked to the study of crop response to salinity and heavy metal stresses. We also think that this will be of particular interest to the barley community as it is, as mentioned, among the most tolerant among the species of the tribe Triticeae.

Disclosing the genetic architecture behind mineral ion homeostasis in plants is the critical first step toward understanding the biochemical networks that regulate the ionome. In this view, QTL for several ionomic traits could also be identified in various species. In *Arabidopsis*, rice, and maize, they have been mapped by the use of immortalized mapping populations such as DH lines. Traits as phosphate accumulation in seed and shoot [356], shoot cesium accumulation [357], shoot selenate accumulation [358], seed K, Na, Ca, Mg, Fe, Mn, Zn, and P accumulation [359], and sulfate accumulation [360] have been identified in *Arabidopsis*. In rice and maize,

these traits include P, Si, Na, and K accumulation (for a review, see Ref. [354]). In a recent paper, Buescher *et al.* [361] exploited the natural phenotypic variation present among 12 *Arabidopsis* accessions and 3 recombinant inbred line (RIL) populations grown in the presence of Li, Na, Co, Ni, As, Se, Rb, Sr, and Cd at subtoxic concentrations in several environments. Using high-throughput ICP-MS the concentrations of 17 different elements were analyzed and significant variation was detected between the accessions. Over a 100 QTL for elemental accumulation were identified, and interestingly environment alteration showed a strong effect on the correlations between different elements and the QTL controlling elemental accumulation. Once QTL have been identified with ionomics, genomics tools nowadays available for crop and model plants could be applied to locate the genes that underlie these loci responsible for the ionomic phenotypes and thus describe such traits in a novel way, that is, at the molecular level. The majority of the ionomic studies conducted to date have been limited to a small number of species with the exception of the report by Watanabe *et al.* [362] in which the authors conducted a broad survey of 42 elements in 670 plant species collected from 29 locations. In order to be able to fully understand the ionome, research needs to expand to more species including barley. In the near future, when the third-generation sequencing becomes an affordable reality, high-throughput ionomics phenotyping platforms, combined with other omics tools such as transcript profiling, proteomics, and metabolomics, will be critical for the possibility to fill the still existing gap between our knowledge of genotype and that of phenotype.

34.3.5 Phenomics

According to the International Plant Phenomics Network (IPPN, http://www.plant-phenomics.com) phenomics – that is, the physical and biochemical traits of organisms that change in response to genetic and environmental variation – aims to (1) develop, integrate, and provide novel technologies to analyze plant phenotypes; (2) provide quality assurance measures in the technologies used for plant phenomics; (3) identify gene functions and their relationship with environmental cues; (4) analyze the way environments affect plant structure and function; (5) quantify plant performance in specific environments in the laboratory and in the field; (6) develop new concepts on the interaction between plants and their environment (physical, chemical, and biotic); and (7) transfer novel technologies to applications in plant production and for the analysis of natural plant and ecosystem performance. Of particular interest for the future will be the effort of interaction between phenomics and the other "omics" technologies to approach plant performance in the environment in a holistic way both for basic and for applied research.

For different abiotic stress conditions, both the onset and the intensity of the stress applied can be defined and controlled in a clean manner during a phenotyping experiment. However, as far as studies on drought tolerance in plants are concerned, the level and onset of water deficit is more difficult to control and monitor than, for example, low temperature due to the fact that drought is a dynamic process and that a

combination of the available water in the soil and the plant's water status has to be considered. Jones [222] reviewed the various measures of water status used in plant and soil science with special emphasis: (i) for the mechanistic effects of water deficits on plants; (ii) for breeding of drought-tolerant plants; and (iii) for management of irrigation systems. The author came to the important conclusion that the role of water potential has received too much emphasis rather than cell turgor that can be measured in plants. In addition to this is the common observation that too often the molecular studies do not make an appropriate use of the necessary water status measurements for phenotyping [222].

During the last years, besides classical phenotyping methodologies used to estimate stress damage, some nondestructive image and data analysis became a possible alternative screening approach to be applied in both the lab and the field. In fact, traditional methods of measuring growth are time consuming and costly, especially if they should be recorded on many thousand genotypes as it is often necessary in large-scale omics research. Often, they also involve the destructive harvest of plants. The training of specialized personnel is also a prerequisite for precise and accurate phenotyping. Moreover, measurements of dynamic parameters, for example, stomatal conductance or photosynthetic rate carried out at a single developmental stage, and/or on a single leaf, may not be appropriate indicators of the average of the whole plant. Eventually, a variety of nondestructive spectroscopic and imaging techniques are now available to evaluate photosynthetic performance, plant function, and plant chemical composition, which are potentially scalable from the leaf to the canopy level [363]. Image acquisition constitutes only the first step in a complex high-throughput phenotyping process. High-throughput analyses of images and data are also essential for a functional workflow. Image analysis in plant phenotyping can take advantage of existing software, such as MatLab (MathWorks Inc.) or the free ware package ImageJ (http://rsbweb.nih.gov/ij/), and rely on expertise already developed in other areas. However, the employment of experts in image analysis and computer vision, together with efforts to convince the plant science community of the validity of using image-derived measurements as a valuable alternative to more traditional phenotyping methods, is necessary to promote the deployment of these new technologies [364]. The mentioned technologies can be particularly useful in controlled environments for temporal resolution and monitoring plant growth throughout the entire experiment. They can also enable the screening of large numbers of genotypes and the identification of small differences in growth rate or expression of certain traits [365]. However, phenotype validation of the results under real soil conditions and environments is necessary before selecting parents for breeding. As more and more plant genomes are being sequenced, there is no doubt that automated high-throughput or high-precision phenotyping will increasingly remain one of the major bottlenecks in crop research. Recently, in order to facilitate ways of automated phenotyping in the analysis of natural genetic diversity in cereal crops and in crop response to abiotic stresses, plant phenotyping platforms have spread worldwide. The Scanalyzer system developed by the LemnaTech company (http://www.lemnatec.com) since 1998 represents the most striking example in this field. It has found broad application in many research

areas of crop phenomics, ranging from plant growth and development to the investigation of the root system in either plant–plant or plant–microbe interaction. Concerning barley phenomics, two very recently established facilities deserve mention: the IPK Plant Phenomics Facility at Leibniz Institute of Plant Genetics and Crop Plant Research in Gatersleben (Germany) and the Australian Plant Phenomics Facility (APPF). Particularly relevant is the APPF, an AUSD 50 million project based on two nodes. One is located at CSIRO Plant Industry and ANU in Canberra and one is constructed on the Waite Campus of the University of Adelaide. At the former, new nondestructive phenomics technologies such as high-resolution infra-red imaging have been adapted for in-depth application to individual plants and for use in the field, and at the latter facility a "Plant Accelerator" provides automated, high-throughput, nondestructive imaging of plant populations in controlled environments. The key tools of the Plant Accelerator node are four "smart houses," which contain conveyor systems to deliver potted plants automatically to four imaging stations for high-resolution, multiaspect imaging (both in the visible and the infra-red wavelengths). Finally, from a collaboration between LemnaTech and KeyGene, a greenhouse service operation that combines high-throughput, noninvasive technology with trait interpretation to exploit phenotypic variation is accessible for service (PhenoFab Europe, http://www.phenofab.com).

In conclusion, high-throughput imaging coupled with plant management systems such as those cited above provides a valuable new tool system that allows a large number of measurements and a more precise dissection of plant responses to abiotic stresses into a series of component traits. Unraveling the genetic basis of these dissected traits will be significantly easier to deal with. In fact, trait dissection by means of high-throughput phenotyping could provide a significant new opportunity to understand the genetic bases of plant response to stress and, what is very important, to exploit this knowledge for the improvement of yield under a variety of stress conditions.

34.4
From Omics to Improved Abiotic Stress Tolerance: Present and Future Strategies

Barley environmental plasticity, largely acquired through its history of domestication and selection, allows the present germplasm to be cultivated from the Northern boreal countries up to the margins of the deserts and, of course, in the fertile temperate areas. Such a diffusion of the crop most likely represents, in terms of geographic parallels, the widest environmental adaptation for a cereal crop. Other species are more limited by the environment, both in colder and in dryer lands. Genetic improvement of barley capitalized on its ability to escape abiotic stresses more than to tolerate them, apart from the adaptation to higher soil salinities that could represent a true tolerance. In addition, a limit of this C3 species is the amount of biomass production (both total and relative to the water used) as its wide diffusion is often coupled with low or very low yields. Therefore, for barley, as for other commodity crops, the challenge to feed a growing world population is open. In view

of this scenario, Fedoroff *et al.* [366], urged to radically rethink agriculture for the twenty-first century, focusing the research efforts to obtain both process (technological) and product (breeding) solutions to cope with shortage of chemical inputs and increasingly fluctuating environmental constraints. The heart of such agricultural paradigms is to close the loops of nutrient flows, from microorganisms to plants, animals, and back, in agricultural systems powered and irrigated as much as possible by sunlight and seawater [366].

This chapter has reviewed the "omics" research of tolerance to abiotic stresses in barley. Genomics results have constituted the larger amount of information and knowledge achieved until now; and as underlined several times, the first approaches were directed toward single stresses and single spatiotemporal levels of the response. This is anyway expected when a researcher is facing an unknown and complex phenomenon: simplification allows reduction of unknown and unexpected variables. This notwithstanding, the omics awareness of the molecular response of barley to the most important abiotic stresses has been consistently growing. Two aspects of the success in dissecting the biological problem should deserve mention. The first is the constant advancement of technological platforms. For instance, in little more than 20 years, third-generation sequencing chemistries took the place of polyacrilamide gel sequencing. Without such a development, there would have been no chances to scale up the experiments and the obtained outputs to the global level. The second is the leading role played by the *Arabidopsis* research, "THE model plant" – as named by Street *et al.* [367] – that delivered many advanced results and hypotheses on response pathways, later verified in *H. vulgare*.

If we look at the many studies carried on the model species, we realize that the achieved omics results, in particular genomics, are impressive. We might consider the following series of milestones. After the identification of the first list of stress-induced genes, the regulons of key transcription factors for the active response to temperature and osmotic stress such as DREB1/CBF, DREB2, AREB/ABF, and NAC have been first identified and characterized in *Arabidopsis* and then found with similar structure and responsiveness in the grasses [368]. Genome-wide transcriptomic studies in *Arabidopsis*, available in the AtGenExpress resource, revealed the existence of a molecular crosstalk among the different abiotic stresses [369], more intense between salt and drought, and between abiotic and biotic stresses [370]. The first putative stress sensors as the histidine kinase AtHK1, and the existence of MAPK cascades for signal transduction, have been identified in *Arabidopsis* [18]. Since practically a decade of *Arabidopsis* abiotic stress research has been clearly in the postgenomics era [327], the availability of the complete genome sequence has facilitated access to essential information for all genes, like the gene products and their function, the transcript levels, putative *cis*-regulatory elements, and the presence of alternative splicing patterns. These data have been obtained from comprehensive transcriptome analyses, studies of full-length cDNA collections and T-DNA- or transposon-tagged mutant lines, under the enhancing frame of the genome sequence information [327]. Research in *Arabidopsis* also allowed to characterize a common, "universal," stress transcriptome, modulated by a broad range of stress conditions: cold, osmotic, salinity, wounding, and biotic. The common response

metabolism comprises the ROS signaling, JA-, and other hormone-regulated genes [371, 372]. It has also been possible, at cellular level, to draw a schema of common stress response pathway genes [372]. The discovery of the stress induction of new regulatory systems that depend on small noncoding RNAs [373], as well as of the contribution to stress responses of posttranscriptional regulations, has been achieved in the model plant [327]. Metabolomics studies allowed to uncover the reorganization of *Arabidopsis* metabolic network and to identify specific metabolites induced by a specific regulon; for example, the accumulation of sucrose, raffinose, galactinol, and myo-inositol linked to the *DREB1A* induction [374]. Protein analyses in the model species allowed to uncover the role played by key regulators through ubiquitination and sumoylation [327]. Studies on the role of Ca^{2+}, plant hormones, regulatory mechanisms involving small RNA molecules, chromatin modulation, and genomic DNA modifications have enabled us to recognize that plants have evolved highly sophisticated systems in response to complex abiotic stresses [327]. The increased emission, and a possible role for particular volatile organic compounds (VOCs) in mitigating the effects of the oxidative stress, has been demonstrated in the model plant [375, 376]. Quite recently, Matsui *et al*. [325] applied *Arabidopsis* Affymetrix tiling arrays to study the whole-genome transcriptome under drought, cold, high-salinity, and ABA treatments demonstrating that thousands of transcripts derive from the unannotated "intergenic" genome regions; these transcripts can be differentially induced by abiotic stresses. Moreover, results achieved in *Arabidopsis* revealed that the transcriptional response of root cells to environmental conditions is mediated by a smaller core set of genes that determines the root cell identity [377], demonstrating that differentiated cells in roots respond differently to various abiotic stresses.

On the trail blazed by *Arabidopsis* research, also in barley the large majority of research gave genomics precedence over other omics. Perhaps, the most significant and original contribution to the global knowledge of the response to abiotic stress of barley was due to the achieved genetic results. In many cases, the QTL responsible for tolerance to abiotic stresses were genetically mapped in barley, besides other crop species such as maize or rice. Figure 34.1 shows an updated summary of the "hot" genomic regions in barley for the presence of abiotic stress tolerance QTL. The figure illustrates how such important genomic regions are not randomly distributed through barley genome, rather they are concentrated on specific Bins, for instance, Bins 9 and 10 of chromosome 2H, or Bins 6–12 of chromosome 5H. On the one hand, this amount of information has allowed linking genomics with breeding, on the other hand, such studies sometimes showed, thanks to positional cloning of the QTL, that the types of mutations, genes, and metabolic pathways that cause the QTL effects are not distinct from those underlying Mendelian traits [378]. This should be sufficient to confirm the fascinating Robertson's hypothesis [379] of quantitative traits caused by smaller effect alleles of genes underlying the qualitative traits. Only a set of abiotic stress tolerance QTL, or their most likely candidate genes, have been cloned or identified in barley until now (reviewed in Ref. [378]), as barley still has not fully entered the postgenomics research phase like *Arabidopsis*. When this border will be crossed, it is expected that such an amount of genetic knowledge would allow either

the cloning of a higher number of barley QTL or the identification of candidate genes for important agronomic characteristics of cereals. This in turn could produce results economically far more relevant than those achieved by cloning *Arabidopsis* QTL.

In the next decade, "integration" is supposed to represent a scientific jump in unraveling abiotic stress tolerance. Such a concept could be contained in the integral view versus the differential view of genetics. A modern approach to genetic problems could, in fact, be integral rather than differential, in a sense analogous to the use of integration in mathematics. The integral view could be best defined as the complement to the differential, gene-centric approach. In the integral approach, a phenotype is more properly not due to a simple modification in DNA but due to such a modification buffered by networks of molecular interactions. These include, for example, the role of the detailed cellular structures of the egg cells, inherited together with the genomic information [380]. The successful so-called systems biology should then combine reduction and integration. Systems biology, which could be defined in different ways, emphasizing in turn the role of dynamic modeling or the integration of multidimensional data [381], is one of the future research fields for barley abiotic stress tolerance. The integration of information could mean both the integration of molecular levels, from nucleic acids to proteins and metabolites, and the spatial integration, from single cells to organs [377, 382], individuals, and ecosystems [383, 384]. Temporal integration could mean the study of the long-term stresses in addition to the shock ones [327], which should turn into plant adaptation. Finally, integration could mean combination of environmental stressors rather than single stresses [12, 374], also of abiotic versus biotic ones [371, 372]. This could lead to nonobvious molecular responses [13] and networks.

Among the first examples of integration of levels is the concept of genetical genomics, where global expression profiles are treated genetically in a segregating population [190]; advances in genetical genomics have recently reviewed by Joosen *et al.* [385]. Such an approach showed that local *cis*-acting eQTL, which in the majority of cases result from *cis*-regulatory variation in the genes under differential expression, range from one-third to half of the total number of eQTL, while *trans*-eQTL, which could be explained in variations in major regulators, for example, transcription factors, have been in some cases demonstrated to correspond to key regulators having pleiotropic effects on phenotypes, as in the case of the *ERECTA* locus of *Arabidopsis* [385]. Such kind of results can contribute to answer questions about the nature of pleiotropy [386].

A strong effect of epistasis was detected in a study aimed to unravel the genetic regulation of the variation in the *Arabidopsis* metabolome. The 11 QTL clusters found in their study by Rowe *et al.* [199] influenced the accumulation of more metabolites than expected, and 8 of these clusters were associated with an epistatic network most likely regulating the plant central metabolism. The authors were also able to identify two *de novo* biochemical networks [199].

Li *et al.* [387] showed how it is already possible to generalize the genetical genomics approach. Without increasing too much the complexity of the experiments (maximum 2 factors $\times$ 2 levels, according to the authors), environmental perturbations could be introduced into a genetical genomics experiment, to understand how QTL

effects differ across multiple environments of interest (e.g., different drought locations or application of drought stress at different growth stages) and how the genotype influences the response to environmental changes.

In the same integrative view, current technical advances in high-throughput shotgun proteomics, mass spectrometry-based, should eventually allow to integrate proteomics data into phenomics ones [259]. Weckwert [388] reviewed how multivariate statistics of high-throughput shotgun proteomics and metabolomics data in *Arabidopsis*, coupled with data dimensionality reduction, can identify biomarkers (metabolites and proteins) when they result in the most important variables. Accessions could be differentiated on the basis of common and different behaviors of metabolite–protein covariances. Moreover, integrative metabolomics and proteomics studies conducted on the same sample can show that biochemical regulation is reflected by the covariance of metabolite–protein networks.

The first results obtained from long-term stress in *Arabidopsis* would suggest the importance of epigenetic regulatory mechanisms [327]. Urano *et al*. [374] reviewed the induction and repression of pathways by metabolome analysis of *Arabidopsis* cell cultures, after long-term salt stress. Relevant results obtained from the integration of omics research include the discovery of metabolic regulatory networks [374], gene regulatory networks, their coexpression modules, and key "hubs" [367], or gene coexpression networks, modules, and key "nodes" [389]. Weston *et al*. [389] emphasize the importance of substituting the two paradigms of gene-to-phenotype and phenotype-to-gene with a new one that integrates both approaches. The authors illustrate the approach of gene coexpression networks, together with concept of genomic signature. They built weighted gene coexpression networks by appropriate algorithms on the basis of abiotic stress global expression data from AtGenExpress database. They were able to obtain a list of 4000 most connected genes, with most highly connected nodes (genes) that defined 6 groups of highly correlated coexpression patterns named "modules." Owing to the general "network theory" [390], genes within coexpression modules most often share conserved biological functions. Weston *et al*. [389] identified modules responsive to heat, cold, salt, two UV-B modules, together with a coexpression group of transcripts showing significant relationships with nearly all stress treatments, overrepresented with genes participating in signal transduction, including calcium-related ones and transmembrane receptors. Interestingly, the most connected "hub" gene of such a module was a previously uncharacterized ankyrin repeat family protein, possibly regulating SA signaling. The authors conclude that relating genomic information to genetic information would be crucial for exploring the full potential of the mechanisms shaping phenotypic development [389].

Therefore, genetical genomics could contribute significantly to the dissection of the gene regulatory networks of the cell in response to abiotic stresses. The identified *trans*-acting eQTL, with caution for false positives [173], could in fact be considered as major hubs of gene regulation [173, 385]. As in the case of a unique definition for systems biology, which still does not exist, the concept of "network" also seems to acquire different appellations, representations, and meanings in the available literature. This is probably both due to the different statistical approaches pur-

sued [367] and due to the different data that originate a network – for example, Yuan *et al.* [381] describe gene-to-metabolite, "interactomics", transcriptional regulatory and gene regulatory networks. Moreover, no common rule of representation of networks was established until recently; the only common graphical rule being the presence of "nodes" and lines of connection to other nodes. That is why Le Novere *et al.* [391] recently proposed a unified Systems Biology Graphical Notation (SBGN) to provide all systems biology an acknowledged way of graphical representation.

Urano *et al.* [374] presented a new and complex regulatory network for the response of *Arabidopsis* to abiotic stresses, which might substitute the more simplistic one, going from sensor to effector genes, through signal transducers and TFs. Such a model, which includes the control by small RNAs and by the mRNA turnover, also hypothesized a role in controlling gene expression for two kinds of cytoplasmic structures, the mRNA processing body and the so-called stress granule, which contains translation initiation factors. Very recently, Street *et al.* [367] identified 38 transcriptional modules in *Populus* leaves, finding overrepresented Gene Ontology (GO) categories in 71% of them, and individuating 18 modules conserved between *Arabidopsis* and *Populus*. Interestingly, the integrative omics approach predicted new leaf transcriptional regulators; a particularly strong hub was a transcription factor putatively belonging to the Trihelix family of plant-specific transcriptional activators, predicted to be involved in the regulation of all 55 photosynthesis genes overrepresented in transcriptional modules.

One of the more ambitious goals of the systems biology is the "virtual plant project," which is aiming to generate dynamic models of a plant to describe its biological processes at different levels, from molecular to ecological [381]. Very recently, a Web-based collection of informatics tools, named "ePlant," has been released, which allows, among other features, to display three-dimensionally biological data of the model plant *Arabidopsis*, such as the three-dimensional structure of more than 70% of the *Arabidopsis* proteome [392]. Such initial accumulation of results from integrative biology thus delivers a cautious optimism about the possibilities to deepen the knowledge about the barley tolerance to abiotic stresses.

34.4.1
From Omics to Systems Biology of Abiotic Stress Tolerance in Barley

Future barley omics efforts for understanding the biology of abiotic stress responses, beyond doubt, should follow as much as possible integrative approaches, to deliver results of general meaning for the grasses and temperate cereal crops in particular. The development of the so-called "systems biology" was needed to integrate multidimensional biological information into networks and models. Therefore, after Yuan *et al.* [381] we might simply define systems biology as the study of interactions between different biological components, using models or networks. However, the future development of systems biology in crop species such as barley depends on the level of genomics knowledge and data accumulated; for this reason, there are significant expectations from the efforts of the International Barley Sequencing Consortium [16]. The simple development of a unified online analytical environ-

ment, GeneNetwork (http://www.genenetwork.org), containing barley genotypic, phenotypic, and expression profiling data represents the first attempt of barley "systems genetics" [393]. Focusing on transcriptional regulatory networks could be of particular interest for (1) the validation of predicted hubs and modules, like that of DREB1/CBF; (2) for the discovery of "hidden" regulatory hubs (see, for instance, Weston *et al.* [389]); and (3) for studying network modulation in case of multiple imposed stresses, better if in field conditions.

Another interesting perspective in our opinion is a further exciting development of quantitative genetics, within a new, integrative omics frame, in three directions. In the first one, barley genetical genomics of abiotic stress tolerance could produce significant results, mainly by deploying transcriptional profiling and metabolomics data. This because both segregating populations are designed *ad hoc*, and large characterized samples of cultivated diversity are available. The discovery of *cis*- and *trans*-acting eQTL and mQTL should help clarify the existing networks at such molecular levels. Importantly, epistatic effects, most likely existing in such complex biological responses, could be uncovered in barley/abiotic stress systems as demonstrated by Rowe *et al.* [199] in *Arabidopsis*. The proposed generalized genetical genomics approach [387] could also be pursued to dissect conditional genetic variation, that is, G × E, occurring in the barley responses to abiotic stresses. After Kliebenstein [386], some studies reported initial evidence for intriguing bias of such conditional QTL toward paralogous gene pairs. As the second direction, the hypothesis of Orr [394] could be explored. For the author it is likely that, as an alternative to the Fisher's infinitesimal theory for quantitative trait loci (not demonstrated by the accumulated QTL mapping results in various organisms), the early evolutionary steps in the random adaptive walk to the optimum would tend to be longer than those that follow. Owing to Orr's theory then, the evolutionary model leads to the robust prediction that distribution of effect sizes is exponential; quantitative variation is determined by a few QTL of (relatively) large effect and a number of genes of progressively smaller effects [395]. If the summarized theory was confirmed, on the one hand the oldest adaptive variants in barley would tend to be associated with the largest effects and, on the other hand, a large part of minor QTL effects should still remain undetected. The first significant step in this direction has been made in maize [378, 386]. Since 2008, when a Nested Association Mapping (NAM) system had been developed, by crossing 25 different founders with a common tester line, Buckler *et al.* [396] identified 333 significant loci for flowering time in a NAM population of nearly 5000 lines, and the vast majority of QTL had small to moderate effects. The third short-term perspective could be the coupling of genome-wide association studies (GWA), when more complete genomic sequence will be available, coupled with NAM or other segregating populations, like the interesting "epigenetic RILs" (epiRILs) of *Arabidopsis* [397], taking the advantages of combining association with traditional linkage mapping studies. From another point of view, it could be surveyed how much structural variants such as copy number variants (CNVs) and Indels are diffused among barley genomes, to study their impact on phenotypic quantitative variation.

The first relevant constraint in such perspective studies is the further development of barley phenomics or of precise phenotyping for abiotic stress tolerance of large

numbers of genotypes. The second constraint could derive from the apparently contrasting results that show diffused phenotyping buffering in *Arabidopsis*. Joosen *et al.* [385] report a QTL study comparing transcript, protein, and metabolite data with phenotypic traits, where only a limited number of QTL hot spots with major, system-wide effects were detected, indicating that most of the genotypic variation was phenotypically buffered. Then phenotyping, together with a further development of phenomics, should be targeted to the dissection of complex phenotypes. These could, in fact, contain "hidden," nonobvious phenotypes. Tardieu and Tuberosa [398] reviewed such issue, describing how recent studies in maize first related response curves of leaf elongation rate to temperature, evaporative demand, and soil water status, which were stable characteristics of the genotypes under different experimental conditions. The parameters of these responses were calculated for lines of mapping populations and were then genetically analyzed. On the basis of these results, they also propose this procedure as a general two-step strategy, in which phenotyping platforms could dissect complex phenotypes into simpler ones, successively being coupled to quantitative genetics and modeling studies.

To support the theory of integrative versus differential genetics, Noble [380] submits to the reader some interesting arguments, such as the concept of the DNA genomic sequence as a database of templates rather than a program, and the concept of the self-maintenance of cell structure, because it is first subjected to physics laws rather than exclusively governed by the DNA. He also reports pioneer experiments of McLaren and Michie [399], which in 1958 demonstrated how skeletal morphology (number of tail vertebrae) of different strains of mice depended on that of the mother into which the fertilized egg cell was implanted, and it could not therefore be entirely determined by the genome. Integrative views of biology and genetics then have to include genetic determinism as a component of a wider picture, which takes into account shaping of the cell and the individual in relation to the environment. Such alternative ways of regulation of stress response could be pursued in barley in the coming years. For example, the demonstrated role of (maternal) chloroplasts in cold acclimation [139] could be further studied by a systems biology approach. Taking the indication in its broadest sense, deeper studies of the noncoding RNAs, of the *cis*-regulation, of the CNVs, and of the rest of the "dispensable" genome are emphasized here as a possible perspective.

Accumulation of results on stress-induced noncoding (nc-) RNAs strongly suggest to increase also in barley the study of such level of regulation, as a fundamental element to the systems biology of environmental responses. Microarray analysis and new sequencing technologies have, in fact, revealed that the majority of the genome is transcribed in many eukaryotes. Much of the RNA appears to be noncoding and an ongoing debate is how much of a functional role it has. Matsui *et al.* [325], by *Arabidopsis* Affymetrix tiling arrays, showed that more than 7000 transcriptional units (TUs) of the "intergenic" genome were induced, of which 1275 and 181 were up- and downregulated, respectively, by the drought, cold, and high-salinity stress or ABA treatments. Most of them were shown to be hypothetical nonprotein-coding RNAs, and about 80% of the TUs were antisense transcripts fully overlapping with sense transcripts. Lu and Huang [400] reviewed how microRNAs (miRNAs),

approximately 22 nucleotide long, could be involved in abiotic stress response, and some of them strongly upregulated by cold, dehydration, and salt; interestingly, *Arabidopsis* plants constitutively expressing miR399 accumulated more inorganic phosphate than the wild-type, suggesting a role in nutrient stresses. Yao *et al.* [401] showed that some small nc-RNAs were responsive to heat, cold, salt, and dehydration in the closely related species wheat (*T. aestivum* L.). The classification and systems organization of the various noncoding RNAs is still going on. Rymarquis *et al.* [402], for example, review the class of mRNA-like noncoding RNAs (mlnc-RNAs), >40 nucleotides long, which could also be involved in response to phosphorus deprivation. De Lucia and Dean [403] recently suggested to include in this already wide scenario of noncoding small RNAs (Section 34.3.2.3) a diffused presence of long (>100 nt) noncoding RNAs, intergenic, aberrantly processed, and antisense transcripts, which can affect chromatin regulation like the small noncoding RNAs. Long nc-RNAs could influence chromatin regulation and consequent gene expression by direct effects on transcription, by recruitment of chromatin modifiers, and by formation of silent nuclear compartments. Recent data suggest that they might have interesting roles in the phenotypic plasticity of plants: the silencing by cold (vernalization) of *FLC* (*FLOWERING LOCUS C*) floral repressor gene of *Arabidopsis* seems, in fact, due to in the early phase of vernalization the COOLAIR (cold-induced long antisense intragenic RNA) antisense transcripts [403].

Plant genomes also contain conserved noncoding sequences (CNS). They are enriched in known transcription factor or other *cis*-acting binding sites. Interestingly, they are usually clustered around genes. Gene regions that respond to external stimuli are particularly rich in CNS, although only rarely does this function involve small RNA binding. It has been estimated that about 4% of *Arabidopsis* gene content is CNS-rich; such a portion of the genome, physically not irrelevant, was named as the region of "Bigfoot genes." Most Bigfoot genes in plants are transcription factors or generally "regulatory" genes. Some cases are known, such as that of the *sphingosine kinase* gene conserved in grasses (rice, sorghum, and *Brachypodium*), with CNS 12 kb upstream and 2 kb downstream chromosome [404].

As sequence information of several grass genomes started to accumulate, comparative analyses revealed that the so-called "junk DNA," largely made of transposable elements, could be responsible of a huge amount of genome variation. In fact, both intergenic and local genic content varies not only between closely related species but also among individuals within the same species [405]. One striking evidence of the *cis*-regulative role played by intergenic noncoding regions is represented by the major flowering time quantitative trait locus *Vegetative to generative transition 1* (*Vgt1*) in maize. Through positional cloning and association mapping, Salvi *et al.* [406] resolved this QTL to a mutation in a ~2 kb noncoding region positioned 70 kb upstream of ZmRap2.7, an Ap2-like transcription factor involved in flowering time control. It is today not known if such *cis*-acting regions present in noncoding intergenic regions are diffused and have a role in barley environmental responses. However, there are recent evidences of a wide diffusion of *cis*-regulation in plants, not only epigenetic, coming from genetical genomics [385], allele-specific expression [407], and *Arabidopsis* tiling array experiments [408]. As we underlined at the

beginning of this paragraph, local eQTL could be the result of closely linked *trans*-acting factors, but more often by *cis*-regulatory variation that affect transcription initiation, rate and/or transcript stability [385]. To discriminate true *cis*-regulatory eQTL from local *trans*-regulation, allele-specific expression (ASE) assays can be performed in F1 hybrid. A pioneering allele-specific expression study has been performed in the inbreeder barley by Sanger single-base extension on five F1 hybrids between putatively drought tolerant and drought susceptible parentals, including a wild *H. vulgare* ssp. *spontaneum* line. The authors used a small set of 30 genes putatively involved in stress response and verified that 63% of these showed allelic differences in expression under drought stress in at least one cross, up to a 19-fold scale, inferred to be controlled by *cis*-acting regulatory variation. The high frequency of unequal allelic expression was also influenced by genetic background, developmental stage, and drought stress [407]. These evidences would suggest the barley research community to deepen the study of the existence of and the role of diffused *cis*-regulation in tolerance to abiotic stresses. For a further unequal allelic expression study, an RNA-seq strategy should be followed once a complete array of reference sequences for each barley gene would be available for each barley chromosome.

Copy number variation is one of the reasons for differentially expressed genes in diverse individuals of a species, and this could be of phenotypic relevance. In fact, as already observed in humans, copy number variants or presence/absence variants (PAVs), possibly encompassing coding sequences, may underlie major genetic variation in traits such as susceptibility to diseases and also environmental response [409]. By short-read mapping depth, Sudmant *et al.* [410] was able to accurately estimate the absolute copy number for CNVs in 159 human genomes, reveal population diversity for CNVs, and identify human-specific expansion of genes associated with brain development. In human and *Arabidopsis*, genome-wide association scans (GWAS) used SNPs; however, known CNVs, which account for over 15% of the assembled human genome, are not easily tagged by SNPs [411]. The authors suggest the use of tailored approaches, as new-generation arrays, to explore the full genome variability beyond the SNPs. Also in plants, CNVs and PAVs might contribute to the high levels of phenotypic diversity and plasticity observed; extended surveys of structural variations are available at present for *Arabidopsis* [412] and maize [413, 414]. Through comparative genomic hybridization (CGH) array, Swanson-Wagner *et al.* [414] identified 479 genes with higher copy numbers and 3410 genes with fewer or missing copy numbers compared to the inbred line B73. In comparison with teosinte, these variants were suggested to be ancient (in agreement with Belò *et al.* [413]) and to predate domestication; many of CNV genes belonged to gene families. Belò *et al.* [413] found them distributed along all maize chromosome arms, and both groups concluded that they might have a considerable impact on maize phenotypes. By the same CGH approach, DeBolt [412] identified regions of gene CNV across the *Arabidopsis* genome. The author sought to test whether *Arabidopsis*, grown under different temperature (relatively low and high) and stress regimes (salicylic acid spray) for five generations, displayed differences in CNV relative to a plant lineage growing under normal conditions. He documented exceptional rates of CNV over immediate family generational scales, and a propensity

for duplication and nonrepetitive CNVs occurrence, which was correlated with the greatest stress conditions. This led to the hypothesized potential CNV–environment interaction, contributing to adaptive capacity of plants. Knox *et al.* [210] documented in barley CNVs in the genomic region harboring the CBF transcription factors in frost-tolerant genotypes, possibly increasing both *CBF* and downstream target-gene expression, thus resulting in a selective advantage during winter. The question if changes in *CBF* copy number are due to human selection after domestication still remains unsolved, although evidence in maize might lead to hypothesize a more general ancient origin in plants.

A single plant genome sequence might not reflect the entire genomic complement of a species as in bacteria. The concept of plant "pan-genome" was thus introduced [415], including a core and a disposable fraction. The former is composed of both single-copy sequences (represented by most if not all genes) and transposable elements that are found among all individuals in a certain genomic location, the latter is made up of partially shared and/or nonshared DNA sequence elements. In particular, the dispensable genome mostly contains transposable elements of different types that, although present in multiple copies in each individual, can be found in a specific location only in some of them. Uncovering the intriguing nature and the functional role of the dispensable genome will ultimately represent a big step toward the unraveling of the processes that are at the basis of genetic and phenotypic variation.

The list of possible perspectives could not be limited, of course, to the ones that we presented here. Importantly, the described perspective aims should also take into consideration the expected/unexpected risks and limitations present in the necessary technologies. The first risk resides in the real capacity of barley science to reach a completely postgenomics era, as already emphasized. The second big challenge is the achievement of a sufficient bioinformatic capacity, both in terms of structures and relative computational capacities and in terms of tools and researchers, which for even large barley research groups could be a significant limit. In order to cope with this challenge, more and more barley omics research groups should try to join hands with or collaborate with bioinformatics groups. Notwithstanding the limitations, trying to scale up the knowledge of the tolerance mechanisms from loci/genes/metabolites to systems is one of the most interesting promises of systems biology of stresses. As summarized by Hirayama and Shinozaki [327], among the next challenges that systems biology will face there could be the identification of abiotic stress sensors, understanding the molecular basis of interplay among stresses (including biotic ones), identification of key factors connecting abiotic stress responses and developmental processes, studying long-term plant responses under multiple abiotic stress conditions in nature.

However, even if such promises from the integrative approaches will be met, at least in the model plants, still new tools and strategies are needed to improve barley for closing the yield gap, from actual to potential yields, in the presence of abiotic stresses. We present in Figure 34.2 an updated schema of the integration of "omics" in barley, to approach the improvement of abiotic stress tolerance through an integrative biology perspective. In particular, connections between omics

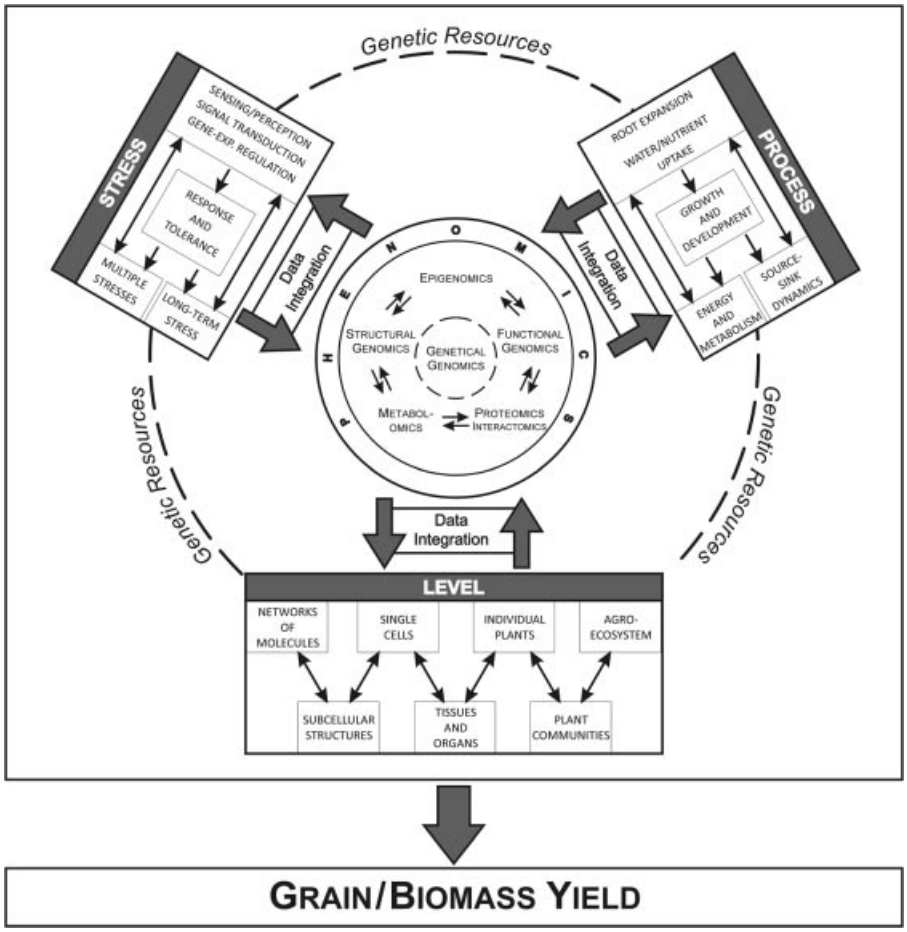

Figure 34.2 Proposed scheme of integration of "omics" sciences within a frame of systems biology, for the improvement of barley abiotic stress tolerance.

components, crop physiology, and barley genomics-assisted improvement have been introduced into the schema.

34.4.2 Integration of Omics with Crop Science

As for other crops, the ultimate objective for barley research is yield or, more precisely, potential grain/biomass yield. This is the first unquestionable difference from plant models like *Arabidopsis* or *Brachypodium*. The second difference lies in barley's relationship with the environment, through all its growth cycle till its final potential yield, and the interaction with the agricultural soil; hydroponics or other artificial growth conditions are not an option. It is worth noting that for the

identification of the genetic basis of adaptive variation, *Arabidopsis* research is still aiming as a perspective to reach ecologically realistic conditions, by simulating outdoor field experiments [327, 397]. For example, through a genome-wide association study, Bergelson and Roux [397] found that only 2 out of 25 candidate genes associated with flowering in *Arabidopsis* and measured under field conditions had also been proposed as candidate genes for flowering time scored under greenhouse conditions. The third difference is that barley, as a cultivated plant, went through a long history of domestication and breeding practically in all regions across the world, which led to a large number of genomic rearrangements named cultivars (see also Section 34.2) that are not available for the noncrop model plants. The last and maybe most striking difference, from a plant biology point of view, is that all barley relations with the environment should be considered as the interactions of a community of barley plants with the environment and between each other with respect to the environment. Although this is true in a certain aspect also for *Arabidopsis* and *Brachypodium* in nature, where they live in mixed interspecific communities, it is not the case of their experimental systems and studies, where the individual level has been practically always the highest level of investigation. Of course, all these differences cannot be taken in account for rice, the third genomic model of reference for cereals that in the four mentioned aspects can be considered identical to barley.

As a consequence of such differences, the phenotypic complexity compared to a noncrop model is significantly higher. Phenotypes at the crop (community) level are expected to be regulated by gene networks whose effects and expression could be highly dependent on environmental conditions and developmental stages. These phenotypes are achieved through multiple intermediate component processes and orchestrated feedback mechanisms, by both intra- and interplant competition and by interactions between stress factors. Because of the competition, a change of one component may result in an often unexpected, but negative, consequence on other components, and the final yield of a crop cannot be simply predicted from the yield of single plants grown in isolation [416]. For these reasons, the study of the dynamics of response to abiotic stresses in long-term experiments, in different developmental phases, and in field conditions of competition with other individuals, although representing a highly complex experimental scenario, could be crucial to obtain affordable data on regulation networks. This, in turn, would be useful to depict the reality of the crop. The importance of scaling up the systems biology from molecules to ecosystems has been emphasized recently. Raes and Bork [383], even if presenting a microbial ecosystems biology (easier to be dealt with), correctly underscore how any systems biology approach would need a "parts list," the connectivity between the parts, and the placement of such connectivity in a context of time and space. Keurentjes *et al.* [384], while presenting fascinating dynamic response scenarios in plants, where volatile organic compounds and insects are involved, invoke the challenge to generate accurate experimental data that can be used together with modeling concepts in a modeling–validation cycle. Very recently, Li *et al.* [417] studied the developmental dynamics of the maize leaf transcriptome using Illumina sequencing platform. They quantified transcript abundance along a leaf developmental gradient, detecting differential mRNA processing events for most maize

genes. The authors found that 64 and 21% of genes were differentially expressed along the developmental gradient and between bundle sheath and mesophyll cells, respectively. The data set they created could serve as the foundation for a dynamic systems biology approach for understanding photosynthetic development.

While ecosystems biology is still at its first steps, the discipline of crop physiology can be considered fully developed and available at present. Crop physiology, also defined as the physiology of the crop plant communities, was in fact directly supported by the described peculiarities of the crop systems. Crop physiologists have substantially developed models predicting the behavior of a crop at varying doses of external inputs, such as fertilizers, solar radiation, or water. At its beginning, de Wit introduced in the late 1960s–early 1970s into crop physiology the "general systems theory" of von Bertalanffy, first developed in the 1930s, and simulation methodologies of Forrester, acquired in the 1960s and initiated research for modeling the whole crop. The development of the whole-crop physiology modeling in the late 1960s was then analogous to the initiative for developing systems biology today, as regard the need for instruments that could summarize increasing quantities of experimental data.

A notable example of success of crop modeling to influence breeding is the development of the so-called "super rice" in China. Setter *et al.* [418] showed, thanks to a crop model, that thick erect final leaves displayed well above a low panicle were essential for high yields in rice. This ideotype concept, combined with the use of heterosis and of wider genetic resources, led in China to the release to farmers of several super rice varieties, both inbred and F1 hybrid, some of them widely grown in China [416]. Crop physiology design could help bring further success in rice yields. A few years ago, it was suggested that supercharging photosynthesis could be the only way to improve substantially yield potential in rice while not increasing the demand for water and nitrogen [419]. These authors strongly proposed introducing into rice the C4 biochemical pathway and modifying leaf anatomy so that the C4 system works at its best in this crop. To examine the hypothesis, a detailed crop model analysis was performed to assess the impact of the full C4 system introduced into C3 rice. The simulations, conducted under the conditions of the International Rice Research Institute (IRRI) experimental farm, envisaged a yield advantage of C4 versus C3 rice from 10.5 ton ha^{-1}, the maximum rice yield observed at the IRRI farm, to 13.1 ton ha^{-1}. This would represent an increase of 23%, a significant although lower than the 50% increase hoped for by Mitchell and Sheehy [419]. In addition, in contrast to these authors' proposition, owing to modeling conclusions, a higher nitrogen uptake would be needed to reach a higher yield because C4 photosynthesis responds more to leaf nitrogen than to the C3 routine under high light conditions.

Systems biology of plants should then try to add the last layer (crop community) of the hierarchical organization of living beings; this is necessary in view of the needed future contribution to food production and energy supply improvement. In the present situation, crop physiology showed its possibilities, although it did not make use at least until now, of information from lower hierarchical levels. There could be therefore, also for barley science, a need to follow the new route of "crop systems biology" [416]. The concept was proposed aiming at modeling complex crop-level

traits relevant to yield potential, by building links between "omics"-level information, underlying biochemical understanding, and physiological component processes. Developing crop systems biology could be demanding and with many challenges. Mapping the organization levels (parts) and the communication systems between these levels for the different key processes could become too complicated. However, a robust model may not be necessarily a complex one and much of the fine details may not be needed [420].

In the view of reducing complexity, the integration of genetic and genomics data into crop physiology models could represent a possibility. We are convinced that time is ripe for such an approach in barley, where a wealth of data are available on both sides, that of field adaptation to multiple stresses and that of genomics information. It could be simply needed, for instance, to refine crop physiology models introducing the genomic constitution as a further module of variation. On the basis of the qualitative genetic characterization of major flowering time genes in *Arabidopsis*, Welch *et al*. [421] proposed preliminary quantitative neural network model of flowering time control in this species. Similar modeling might be explored for phenology in barley both in temperate and in severely physically stressed environments. It is worth noting that scaling down to a lower level is not a one-directional process that "omicists" alone could do, without the modeling experiences of crop physiologists. For more complex candidate traits/processes than phenology, such as carbon assimilation, nitrogen assimilation, and stress tolerance response itself, a fine understanding of systems biology first could be more urgent.

34.4.3
Integration of Omics with Future Barley Breeding for Abiotic Stress Tolerance

In the opening pages of this chapter, we hoped that the knowledge of the barley tolerance to abiotic stresses obtained thanks to the omics research could have been used to implement MAS programs of new varieties. Engineering barley to abiotic stress tolerance could be a viable option, as well as for other plants, quite recently reviewed with its achievements and limitations by Vinocur and Altman [90]; however, this would be expected mainly for those countries with a fair law regulatory system. If we define MAS as the genotypic selection of individuals performed in addition and eventually substitution of phenotypic selection, it is obvious that we need detectable DNA variations in linkage to genes and QTL responsible for agronomically relevant traits. In this way, it would be possible to select DNA sequence variants (i.e., alleles of genetic markers) without the need to phenotype the agronomical effect of the gene/QTL (for a review, see Ref. [422]). Some concepts and observations can be derived from such a definition. First, this approach for barley improvement is based on the differential genetics theory [380]. On the basis of the gene-centric differential theory, in fact, different molecular, and eventually agronomical, field-scored phenotypes should correspond to different DNA variants at each gene. Such deterministic and simplistic vision of genetics is not anymore sufficient to describe the reality of complex phenotypes, as it was previously said. Consequently, MAS technology as it has been considered so far could not be anymore considered as totally valid. The

second observation is about which loci of barley should be selected. Figure 34.1 partly answers the question. Cloned genes, candidate genes to explain components of tolerance, described in the previous sections, are the first sequences whose positive variants could be selected. In addition to such key determinants with generally qualitative or major effects on tolerance, the genomic regions harboring positive alleles of QTL for abiotic stress tolerance could be introgressed, one by one, or "pyramided" in higher numbers into selected genotypes. In this case, classically two flanking markers for each QTL should be used since every QTL is mapped at one most significant locus, but with a confidence interval around the most likely position. Efficient MAS, verified and validated in the past years by a large number of plant breeders through the field performances of the marker-selected genotypes, is a demonstration that in this case the deterministic differential concept still holds, without the apparent need of an integrative approach to the matter. Examples of barley MAS based on a few key loci are very numerous, from tolerance to several biotic stresses (see, for example, Ref. [423]), to malting quality traits (see, for example, Ref. [424]), grain yield (see, for example, Ref. [425]), and tolerance to abiotic stresses (see, for example, Ref. [426–428]). Briefly, not every DNA polymorphism in a candidate gene is able to discriminate tolerant genotypes; every sequence variation, or, better, every SNP haplotype recognized in a gene sequence must be first validated as associated with superior phenotypes in a panel of donor and recipient breeding lines and cultivars, before considering it as an MAS tool. For example, while it was demonstrated that the *CBF* gene cluster at *FR-H2* was conferring frost tolerance in a "winter" × "spring" type barley cross (see Section 34.2.5.2), when the *CBF* polymorphisms were used for MAS in a panel of facultative, winter, and spring barleys [427], or in a panel of winter barleys [428], only few of them were found slightly associated with frost-tolerant genotypes. On the contrary, the mapping polymorphism of the current candidate gene for *Fr-H1* frost tolerance QTL, the vernalization gene *HvBM5A*(*VRN-H1*) [214] was indeed highly associated with tolerant phenotypes on the same panel of barleys, and could be used for MAS [427].

The effect of the selected allele in these cases is simply mechanistic; once inherited in a plant, it simply determines an improvement for the trait of such an individual. As underlined by Weston *et al.* [389], one of the major opportunities afforded by modern genomics technologies, which ecology was not able to afford, is in fact the potential to provide a mechanistic understanding of the processes by which genetic change translates into phenotypic variation and the resultant appearance of distinct physiological traits. For example, in medicine genomic information can be used to determine the physiological state (e.g., diagnosis) and predict phenotypic outcome (e.g., patient survival). It is then worth to be concluded that once composed in their positive allelic variants into a plant, a relatively small number of candidate genes playing major effects on stress tolerance, could be sufficient to significantly improve existing crop varieties. Notably in rice, the simple introgression by marker-assisted backcrossing of the cloned *Sub1* QTL of submergence tolerance successfully improved such a trait in a rice cultivar widely diffused in flood-prone Asiatic regions [429]. Recently, Francia *et al.* [225] demonstrated how a simple allelic combination of three candidate genes for the induction of flowering (that reside

at *VRN-H1*, *EAM6*, and *PPD-H2*) could be selected while keeping randomly unselected the rest of the genome. Through the regulation of the duration of the growth cycle phases, such an allelic combination was *per se* sufficient to gain $\sim$0.2 ton ha^{-1} compared to the average grain yield recorded for the "Nure" $\times$ "Tremois" population in 18 Mediterranean locations, from fertile to heavy drought environments. When such a few-gene combination would be inserted into low-cost MAS programs, it might constitute a precision stress "escape" breeding strategy, until now not pursued. The Generation Challenge Program nicely followed a similar aim, by producing a barley marker-toolbox accessible by laboratories of developing countries, which contains simple PCR-based markers for the introgression of key genes improving fundamental agronomic traits (The Generation Challenge Programme's Molecular Marker Toolkit is curated by V. van Damme, [430]). However, it might be investigated up to which number of such key loci should be cumulated into a genotype until either a plateau or a full potential yield is reached. The two issues were not investigated in detail in barley, at least with the specific aim of their theoretical validation.

Since some years, scaling up MAS has been suggested in crops till the genome level, namely, to perform genomics-assisted selection [431]. In principle, at least one polymorphism, or, to be more informative, one haplotype per barley gene could be used, reaching tens to hundreds of thousands scorable SNPs. Intermediate levels could also exist, in which, for example, all the abiotic stress-induced or related genes could be selected, rather than all the markers in the genome.

The efficiency of improving barley by genomics-assisted selection has still not been demonstrated. We could not consider in this chapter the big challenge to obtain through recombination in this homozygously cultivated selfer species a precise combination, in *coupling*, of positive alleles, at all loci. Then, at least theoretically, such a "designed" genome [432] could be obtained. Another heavy task before starting genomics-assisted selection is not absolutely trivial; the necessary step is to associate with a trait each locus that should be selected, and to identify the sequence variant (allele) with a putative positive effect on the trait. Once one would be able to obtain the desired allelic combination at thousands of loci, it could be verified which is the overall performance of the selected genotype; conversely, if there are or not interaction effects between the selected genes and the genetic background. In fact, it is possible that once constituted in its final shape, such a genomic ideotype not only would keep the promise to increase performances but also it could lose some and gain new interaction effects, which together would not allow it to reach the desired performance.

QTL MAS deserves a separate discussion. If the Orr's exponential theory is correct, the majority of the QTL that were mapped until now in barley could be major-to-moderate effect QTL, and still a significant part of the quantitative variation would be missing, contributed by a large number of minor-effect QTL. On the one hand, this would not exclude, at least for the moment, the Robertson's hypothesis about the Mendelian nature of genes underlying QTL, as a sort of "defeated" alleles of qualitative effect genes. As underlined by Collins *et al.* [378], the majority of the QTL cloned in barley and in other crops until today are in agreement with such a

theory. In this view, the major and moderate effect QTL could be the regulatory hubs identified by functional genomics in the stress response pathways, and by genetical genomics. On the other hand, the identification of a large number of minor QTL could be challenging, since crossing schemes such as NAM, coupled with a huge phenotyping work on thousands of genotypes, could be required. Another hypothesis should also be made on the nature of the minor QTL. If it could be verified that major-to-moderate effect loci are in general agreement with Robertson's theory and they are variants of Mendelian single genes, we might conclude that they reside in the so-called "core" genome [415], and this could be conceivable for all QTL that were acquired through the barley domestication history. It might be argued if CNV could be important for explaining the biological bases of QTL, as hypothesized in *Arabidopsis* [397, 412], and in one case in barley [210], and which of them and in which part of the genome could be relevant for adaptation to stresses. Then, it might be argued if minor QTL, once accurately mapped, would reside in the "dispensable" genome rather than in the core one. In other words, it could be verified if their nature is genic, structural-based, or based on noncoding regulatory regions.

The results of barley genome sequencing [16] could help verify the existence and characteristics of the dispensable genome also in this autogamous species and to compare its features with what has been observed in an allogamous species such as maize [415]; consequently, the hypothesis about the "real" nature of minor QTL could also be verified. To accomplish this task, genomics sequencing would need to be coupled with GWA and NAM studies on large populations, and with phenomics of tolerance to abiotic stresses [378, 397, 398].

We have already shown in these last sections how a redirection of the traditional "reductionist science" approach to a "systems biology" approach is required to face agricultural challenges in the future. Indeed, the bulk of the potential for future improvements in barley tolerance to abiotic stress lies in the elucidation and understanding of interactions of the various components of the biology of the plant in concert with all the parameters of the production environment. First of all, systems biology could tell us more about interactions about loci, and move molecular-assisted breeding from the differential view of genetics to a comprehensive integrative approach. Second, it might help take barley from actual to potential yields, a fact that could become more urgent in coming years. In fact, while it was demonstrated that a combination of few loci would be sufficient to reach elite material yields by MAS, as already said, genomics-assisted selection of an *a priori* fixed genomic allele combination (ideotype) might be not effective to reach potential yields. Interactions between coding loci, between these and noncoding loci, and between these and other factors, for instance, cellular structures, could play a significant role to reach the final phenotype. For instance, Joosen *et al.* [385] report a metabolome study where more than one-third of the compounds present in the RILs were not detected in either parent but were the most likely result of recombination of loci contributing to biosynthesis pathways. Systems biology, by integrating the information at the various molecular and structural levels, could also contribute to a better understanding and add components of stress avoidance [90] strategies to the genomics-assisted selection.

The last issue should be discussed: the potential need for new MAS tools at reasonable costs. As in other major crops, barley MAS is used both in the public and in the private sector, in Europe and in other countries, mainly for introgressing disease resistances and quality traits [422]. At present, different MAS platforms are available, based on different technologies, although in many cases they are not really cost-effective. In the case of SNP array platforms, they not always have sufficient flexibility for user-defined SNPs that might vary between different projects. If we focus on the barley and wheat seed market, we might realize that it is a market of self-pollinating crops in which conditions of agricultural economical crisis could lower the percentage of certified seed to less than 50% [433] and in which not all the seed companies would invest huge amounts of money due to the possible low returns of the investments. This notwithstanding, we believe that it is mandatory both to increase the precision of breeding by genomics MAS and to include abiotic stress tolerance into breeding targets. Moreover, there could be a place for the public research to produce high-throughput although flexible genotyping platforms, which at the same time could contain as much as possible the costs of genotyping.

Acknowledgment

The authors would like to acknowledge funding support from Fondazione Cassa di Risparmio di Modena, Progetto di Ricerca Internazionale FROSTMAP "Physical mapping of the barley Frost resistance-H2 (Fr-H2) locus."

Sugarcane: Physiological and Molecular Approaches for Improving Abiotic Stress Tolerance and Sustaining Crop Productivity

Ashok K. Shrivastava and Sangeeta Srivastava

Sugarcane, an important cash crop, due to its long duration, faces vagaries of all the seasons, and it is rather impracticable to provide favorable conditions for all the *critical stages*, spaced far apart temporally. Furthermore, overexploitation of natural resources and human activities have made our ecosphere prone to abiotic stresses that affect growth and development, chemical composition, and sugar synthesis and its accumulation in sugarcane, and ultimately affect sugarcane/sugar productivity. They also aggravate certain other abiotic and biotic stresses and affect the availability of seed cane. To defend the technological gains attained so far in sugarcane and sugar productivity, and to augment them further to face challenges of abiotic stresses physiological, breeding, and molecular approaches are important.

Among physiological approaches, criteria for selection of varieties (or parents for use in breeding programs) for tolerance to abiotic stresses are important. For management of abiotic stresses, physiological principles such as inducing hardiness, increasing the age of crop at the advent of stress, training roots to go vertically deeper in the soil, reducing the heat load and preventing further water loss from the soil, the use of moisture absorbers in the soil (which make it available during drought), and nutrient management are important in managing drought-affected and rain-fed canes. Increasing the age of the crop at the advent of waterlogging/flood (so that it suffers relatively lesser damage), planting *rayungans* or pre-germinated setts, preventing water from entering root zone, improving waterlogged soils by incorporating organic bulk manures, and using certain nutrients impart tolerance to waterlogged conditions. Control of rhizospheric salinity, management of waterlogging, adjustment of the ridge direction, the use of pregerminated setts and the use of trash veins system of planting, the use of certain nutrients can effectively manage salt-induced stress. For low-temperature tolerance, for reducing post-frost losses, altering planting time, frequent postmonsoon irrigation, and use of nutrients such as Si are important. For improving sprouting of stubble buds and productivity of winter-initiated ratoons, avoidance of low temperature for the exposed stubble (by covering with trash, polyethylene, and soil), and certain biochemical interventions using plant growth-regulating substances and nutrients appear promising. Nutrient deficiencies developed under rain-fed and saline–alkaline conditions can be effectively managed

Improving Crop Resistance to Abiotic Stress, First Edition.

by application of appropriate nutrient and organic matter in the soil. Silicates are useful in overcoming the effects of low temperature and toxicity of Al and Mn in the acidic soils.

Some *Saccharum* species and related genera possessing tolerance to abiotic stresses have been identified. Their use in breeding programs may lead to development of high yield, high sugar varieties tolerant to abiotic stresses. As in nature, more than one type of stresses often occur together or the prevalence of one stress may accentuate or aggravate the other, which further increases the losses, varieties possessing *tolerance to multiple stresses* will be desirable.

Some progress has also been made in molecular interventions for inducing tolerance to abiotic stresses in sugarcane. Genes and gene products induced during hypoxia/anoxia have been identified. Real-time RT-PCR profiling of EST clusters has helped in identification of several stress clusters showing higher expression levels under water deficit stress. Accumulation of osmolytes trehalose and proline also contributes to drought tolerance. Expression of heat shock proteins and dehydrins has a definitive role under high-temperature stress. Cold-inducible ESTs in sugarcane have shown induction of novel cold-responsive genes. There is a need to understand the mechanism of action of these stress-responsive genes as to how they help sugarcane to protect itself from various stresses.

35.1 Introduction

Being a long-duration crop, sugarcane faces vagaries of all the seasons. It is rather impracticable to provide favorable conditions for all the *critical stages*, spaced far apart temporally, so as to realize its optimal production potential. Furthermore, overexploitation of natural resources and human activities have made our ecosphere prone to abiotic stresses such as drought (and shortage of irrigation water), flooding/waterlogging, salinity, high and low temperatures, soil-related problems, emerging nutrient deficiencies, and pollution. Cyclone and winds, especially in coastal areas, also affect sugarcane productivity. The use of high-yield varieties, high intensity of irrigation, and fertilizer consumption, especially the lopsided use of nitrogen and pesticides in high production-intensive agriculture, has aggravated some of these problems [1]. Abiotic stresses affect growth and development, chemical composition, sugar synthesis, and its accumulation in sugarcane, and ultimately affect sugarcane/sugar productivity. They also aggravate certain other abiotic and biotic stresses and also affect the availability of seed cane (Figure 35.1). The impact of abiotic stresses may aggravate further due to global climate change. The IPCC has projected that global mean annual surface air temperatures by the end of this century is likely to increase in the range of 1.8–4.0 C; and it is very likely that hot extremes, heat waves, and heavy precipitation event may become more frequent in times to come [2].

Sugarcane requires large amount of water, but it cannot withstand "wet feet" and has certain temperature optima for various growth processes and stages of devel-

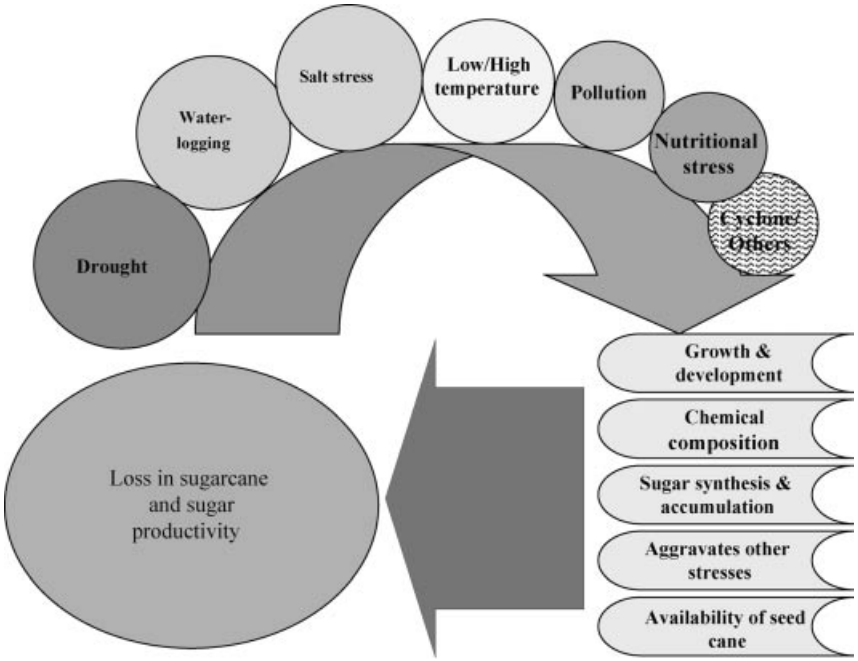

Figure 35.1 Abiotic stresses affecting sugarcane and sugarcane productivity (reproduced from Ref. [1]).

opment. Poor natural ripening conditions such as high temperature and excessive rainfall/soil moisture exist in most of the sugarcane growing areas of the world. In India, rain-fed agriculture mainly exists on marginal and submarginal lands, which suffer acute soil moisture stress, and is often accompanied by multinutrient (K and Zn) deficiencies. Low temperatures prevailing at harvest, especially in subtropical India, affect sprouting of stubble buds *vis-à-vis* productivity of the succeeding ratoon crop. Certain abiotic stresses are known to trigger off other abiotic/biotic stresses, and their cumulative impact further aggravates cane and sugar losses. Abiotic stress (es) leading to other abiotic stress(es) are as follows: waterlogging to salinity, alkalinity, and in some cases acidity, and Fe toxicity; drought to salinity; low temperatures to drought; salinity to B toxicity; high temperatures aggravate drought effects; and soil compaction leads to depressed uptake of nutrients. Abiotic stress also leads to some biotic stresses as follows: waterlogging to red rot, wilt, pineapple disease, stubble rot, accentuates white fly (especially, in N-deficient soils), scale insect, Gurdaspur borer, cut worm, and so on; drought accentuates damage due to pineapple disease and leaf scald; prolonged drought in acid soils (supplied with higher N) favor wilt development; heavy buildup of termites, shoot borer, pyrilla, mealy bugs, whiteflies, scale insects, mites, wooly aphids, and so on; salinity to salt blight, shoot borer; low temperatures to stem borer; nitrogen deficiency aggravates

white fly infestation and soil compaction leads to development of the early shoot borer [1].

Many instances in the past have been recorded when advent of abiotic stresses affected sugarcane and sugar production [1]. Recently, Central-south Brazil experienced severe drought in May–June 2010, which has resulted in decrease in sugarcane productivity by 9.1% and loss in sugarcane production to the tune of 18.7 million tons. Australia has also experienced "wetter-than-average" conditions that have both reduced sugar content and recovery [3]. In India, approximately 2.97 lakh ha of cane area is prone to drought, affecting the crop at one or the other stage of growth. Floods and waterlogging are serious problems in about 2.13 lakh ha in Eastern Uttar Pradesh, Bihar, Orissa, coastal Andhra Pradesh, and Kolhapur area of Maharashtra. Sugarcane is cultivated in about 7–8 lakh ha under saline (both in irrigated soils and in semiarid areas) conditions. Though the crop is moderately tolerant to salinity, the losses are significant [4]. Approximately, 16.9 lakh ha cane acreage (in Punjab, Haryana, and Western Uttar Pradesh) is prone to low temperatures; in nearly half this area (8.5 lakh ha), sprouting of the winter-initiated ratoons is affected and some areas also get occasional frost, affecting sugarcane productivity.

35.2
Physiological Approaches to Improve Tolerance of Sugarcane to Abiotic Stresses

The several tillers attached to a sugarcane plant (and leaves and roots) make a *physiologic compensatory continuum* that imparts the sugarcane plant an ability to tide over many abiotic stress conditions, gaps in the field, varying nutrient levels, infestation of pests, and so on [5]. Sugarcane has enormous compensatory ability to restitute the losses incurred due to waterlogging after such conditions are over as indicated by development of normal roots [6], increased rate of tiller elongation [7], and buildup of stalk dry weight [8]. Among physiological interventions, two types of approaches have been used: developing criteria for selection/identification of varieties possessing tolerance to abiotic stress conditions and imparting tolerance to a commercial variety to a particular abiotic stress.

35.2.1
Criteria for Selection of Varieties Possessing Tolerance to Abiotic Stress

Some of the physiological characteristics, which are related to the tolerance to a particular abiotic stress, could be effectively utilized for evaluation of clones/varieties so as to improve cane and sugar productivity under such conditions. These could also be beneficial in evaluation of progeny of a cross or even a biotechnological transformation through which transfer of a trait of economic importance is being attempted.

35.2.1.1 Drought Tolerance

- Thin-stalked varieties with more number of millable canes [9].
- Lower shoot:root ratio [10].
- Maintaining higher leaf sheath moisture (<76%) [11].
- Accumulation of free proline under water stress [12, 13].
- Release of more drought-induced electrolytes [14].

35.2.1.2 Waterlogging Tolerance

- Higher extension growth [1].
- Screening under simulated waterlogged conditions [15, 16].
- Sugarcane varieties (namely, Co 951, Co 975, and Co 62175) that retain higher stalk population and maintain top foliage green during flooding and after recession of floodwaters perform well under waterlogged conditions [17].
- Higher phenol oxidase activity [18].
- Less increase in alcohol dehydrogenase (ADH) activity during anoxia [19].

35.2.1.3 Tolerance to Salt-Induced Stress

- Pink pigmentation and waxiness in varieties [20].
- Selection in tissue culture: 0–5% differentiated callus of sugarcane is transferred to Murashige and Skoog medium containing 20% coconut water and 18–20 g l^{-1} NaCl. Survivors were isolated after 5 months. These were grown for additional 5–13 months in a medium containing 10–20 g NaCl l^{-1} and the resultant tolerant plants were field tested and evaluated for salt resistance [21].
- Single-bud setts of nearly uniform size are placed in jars containing 200 ml of NaCl solution (0, 2, 4, and 6 atmospheres of osmotic pressure). The sett is so placed that the bud remains just above the solution level. These solutions were changed every third day. On the 30th day, the setts were removed and shoot weight was recorded. The variety in which there was relatively minimum decline in shoot weight (as in the case of Co 449) was rated as salinity tolerant [22].
- At Central Soil Salinity Research Institute, Karnal (India), sugarcane germplasm is evaluated for tolerance to salinity–alkalinity at an ESP of 45 (pH 9.5) [23]. Evaluation of sugarcane varieties under sodic and saline conditions has also been done by observing performance in response to natural variation in ESP and EC in Australia [24] and in EC in Colombia [25].
- Ability to restrain Cl^- uptake and its accumulation in leaf laminae [26].

35.2.1.4 Tolerance to Low-Temperature Stress

- Proportion of leaf tissue that remained green after exposure to low temperatures [27].
- Bud mortality index, plant mortality index, and field performance [28]. It is a more comprehensive system.

- Subjecting setts/settlings to low temperatures: 3–5 °C for 9 h (setts) and 3–5 °C for 5 days (6–8 week-old settlings and change in osmotic concentration of sap intenseness was used to distinguish tolerant and susceptible varieties [29]. Freezing treatment (-2.5 ± 0.2 °C) for 6 h for 2 days in a deep freeze at 4–6 leaf stage of the settlings appeared to be desirable.
- Mannitol and isomaltotriose content in cane juice [30].
- Presence of certain peroxidase enzyme bands [31].
- Increase in lactic acid [32].
- Electrolyte leakage [33].

35.2.1.5 Tolerance to High Temperatures

- Subjecting samples of $+1$ leaf to high temperature (55 °C) in a water bath for 15 min and leaf tissue damage was assessed. Varieties least sensitive (<30% damage) were identified as tolerant to such conditions [34].
- First the leaf tissues is acclimated to heat and then exposed either to various temperatures for a set period of time (heat killing temperature) or to a given high temperature for various periods of time (heat killing time) and death of tissues is noted by electrolyte leakage by observing alterations in electrical conductivity. Tolerance is usually estimated as time or temperature required to kill 50% of the tissues [35].

Varieties/clones selected so could be used as tolerant variety in areas prone to a particular stress or may be used in breeding to impart the tolerance trait to particular abiotic stress.

35.2.2 Imparting Tolerance to a Commercial Variety to a Particular Abiotic Stress

35.2.2.1 For Drought Conditions

Drought is the most important water-related problem of sugarcane agriculture worldwide. It is caused by annual precipitation being less than the normal, late onset of monsoon, early withdrawal of monsoon, long intervening dry spell in the monsoon period, and declining groundwater levels at faster rate. Low and high temperatures and salinity and alkalinity also accentuate it. Types of drought experienced by a sugarcane crop [1] are as follows:

i) Occasional drought.
ii) Frequent drought: shortage of water and prolonged drought conditions as in Maharashtra and Telangana in Andhra Pradesh in India, Sindh Province in Pakistan, southern cane growing belt in China, and so on.
iii) Rain-fed conditions: characterized by frequent drought spells (leading to severe moisture stress in soil–plant system) and multinutrient (K and Zn) deficiencies.
iv) Experienced by the crop during dry spells in its growth cycle (available moisture is not sufficient enough to maintain growth); for example, April–June in

subtropical India, October–April in Lao PDR, Guatemala, June–August in Japan, June–September in Papua New Guinea, and so on.

Any initial setback received by the crop during summer for want of irrigation hampers tillering and the plant cannot compensate it later if the subsequent growth span is short. If it is experienced during ripening, overstands, as in subtropical India, cane yields decline and juice quality deteriorates. Magnitudes of losses increase if it is a flowered crop. It also affects the performance of succeeding ratoon crop. For areas prone to drought, following approaches have been adopted:

- **Inducing drought hardiness**: Soaking sugarcane setts in saturated lime solution (80 kg lime/1000 l) for 2 h a day before planting induced drought hardiness and improved cane yield. This is also helpful in areas with limited irrigation [36]. A sugarcane crop can also be hardened by withholding water for 30 days at 90 days after planting. As a result, the crop suffers less damage when it is required to face the actual moisture stress during hot summer months [37].
- **Increase the age of the crop at the advent of drought (so that it suffers less damage) – Early planting**: A sugarcane crop of relatively higher age, at the advent of drought (when the summer sets in) withstands drought better than a younger crop. In Andhra Pradesh, it is desirable to plant a 12 month crop in January to mitigate adverse effect of drought (in summer). The best time for planting an *adsali* crop is August/September for withstanding drought in the next summer [38].
- **Training the roots to go vertically deep (rather than superficially and laterally) in the soil**: Before the onset of drought, the roots must be trained to go vertically deep, rather than spread superficially and laterally so that they may obtain water from deeper layers in the soil. For such purposes, planting in deep trenches is desirable. In such trenches, soil moisture retention is improved by adding high dose of bulky manure like farm yard manure (FYM), compost, and so on before planting. In addition, trash must be spread to prevent surface evaporation of moisture. Deep trench method of planting resulted in higher cane yields at Vedapathimangalam, Tamil Nadu, where the crop experiences severe drought during formative phase [39]. Experience in subtropical India indicates that after planting in spring, it takes 40–45 days to complete germination and the crop is normally irrigated immediately after this. Delaying this first irrigation, within reasonable limits, also trains roots to go relatively deeper and impart some degree of tolerance to drought in the ensuing summer season (R.S. Verma, personal communication).
- **Nutrients imparting tolerance to drought**: A fertilized crop of sugarcane was relatively less prone to losses due to drought. In Argentina, during the drought of 1995, cane yield losses ranged from 10 to 45% (in plot fertilized with N at the rate of 100 kg ha^{-1}) compared to 12–60% in the plots raised without N fertilizer [40]. It has been observed that plants grown in a soil with K are less sensitive to wide variations in water supply [41] and the K requirement of plants centers around its four physiobiochemical roles: enzyme activation, anion neutralization, membrane transport, and maintenance of osmotic potential [42]. Its application also increased accumulation of free proline in sugarcane [43], which is an

indication of drought resistance. Sato *et al*. [44] noticed that P supply alleviates the negative effects of water deficit on sugarcane photosynthesis, possibly through the enhancement of proline content.

Under drought conditions, planting setts soaked in saturated limewater for 2 h induced drought hardiness and improved cane yield. In tropical India, under drought conditions, spraying urea + KCl (2.5% each) at 60, 90, and 120 days after planting (d.a.p.) improved cane yield [39]. Spraying of 2.5% K_2SO_4 during summer mitigated drought and improved cane yield by 10.7% [45]. Potassium application (60 kg K_2O ha^{-1}) + 2 irrigation in February and March before the onset of drought improved cane yield and juice quality [46]. At Coimbatore, where drought occurs during early stage of crop growth, application of potassium either in the soil (168 kg K_2O ha^{-1}) or its soil application (112 kg K_2O ha^{-1}) + foliar application (2.5% KCl spray at 45, 75, and 105 d.a.p.) improved both juice quality and sugar yield [47].

Si deficiency increased the rate of transpiration by 30% [48] and improved Si nutrition reduced the rate of transpiration [49], and application of Si could be helpful in imparting drought tolerance.

In rain-fed areas, which experience frequent drought spells, severe moisture stress results in soil–plant system. Besides the amount and distribution of rainfall, soil type and its depth affect the moisture availability for crop growth. Multinutrient deficiency (Zn and K) is also common in such areas. An optimal nutrient supply (N, P, K and Zn) ensured relatively deeper root system and helped in better adoption of crop *vis-à-vis* sustained productivity under such conditions [50]. Studies on other crops have shown that in rain-fed areas, under limited moisture conditions, application of phosphorus also improved crop productivity [51].

- **Reduce the heat load and prevent further water loss from the soil**: Application of trash mulch soon after emergence was very effective in reducing water evaporation from the soil and improved cane yields. Trash mulching during initiation of a ratoon crop leads to conservation of soil moisture and improved cane yield. The use of trash mulching in cane improved yield under drought-affected conditions in tropical India [45, 52–56]. In Australia, the use of green cane trash blanket improved yields under dry conditions. This was also associated with better moisture retention, no soil erosion, and better weed control [57].
- **Use of moisture absorbers in the soil that make it available during drought**: Application of organic amendments in the soil of FYM, press mud, coir waste, *etc*., ensures availability of some moisture during drought and improves cane yield under such conditions [54, 58]. Needless to mention that such amendments also improve soil physical conditions that enable desirable root spread and nutrient uptake. Besides organic amendments, the use of certain moisture absorbents (*Jalshakti*, *Stocksorb*, and *Alcosorb*), which absorb water many times of their weight, make it available subsequently to overcome drought [52, 58, 59].

- **Use of certain growth regulating substances**: Foliar spray of low concentration of ethrel (100 ppm) before likely onset of drought or soaking seed canes in it improved drought tolerance and reduced the loss of cane and sugar yield [60].

35.2.2.2 For Waterlogged Conditions

Under Indian conditions, following types of waterlogging are normally met with:

i) Soils waterlogged in rainy season (July–September in many sugarcane growing areas) at grand growth phase.
ii) Waterlogging due to high water table because of lateral seepage of water of river Ghagra (in Eastern Uttar Pradesh) affects all stages of growth.
iii) Water standing from May–July and soils saturated up to September (in Assam) affect late tillering stage and grand growth phase.
iv) Sugarcane growing in valleys and banks (*diara* lands) where crop is subjected to standing water 0.5–1.0m deep during July–September in north Bihar, Eastern Uttar Pradesh, and West Bengal.
v) Heavy rainfall accompanied by cyclonic winds during December/January in southeast coastal areas of Andhra Pradesh and Tamil Nadu (uprooting and lodging during ripening adversely affect cane quality).

If the crop is flooded with water standing more than 0.5 m deep or so for a longer time, nothing can be done except to plant waterlogging/flood-tolerant varieties, in areas frequently affected. For other types of waterlogging and stagnation of water (of less than 1 m), following approaches could be helpful:

- **Increase the age of the crop at the advent of waterlogging/flood (so that it suffers relatively lesser damage) – Early planting**: A sugarcane crop of relatively higher age, at the advent of waterlogging/flood will be damaged relatively lesser. In Kerala, a typical *eksali* zone and in Andhra Pradesh, in the areas liable to waterlogging, sugarcane is planted early on in the year so that the crop is sufficiently grown up by the time floods come in July–August [38, 61]. In Nayagarh (Orissa) where water remains standing for 30–40 cm from mid-July to end of September, in a study sugarcane was planted at monthly intervals on 15th day of each month from November to April. Cane and sugar yields were highest with cane planted on 15th November and it decreased with subsequent plantings [62].
- **Planting rayungans or pre-germinated setts**: In Kolhapur of Maharashtra, flooding during the establishment (or germination) is potentially devastating. By planting *rayungans* or pre-germinated setts, sugarcane productivity may be sustained to some extent [63].
- **Prevent water from entering root zone – Planting on ridges**: Waterlogged areas that tend to get inundated with 60–100 cm deep water, planting on ridges (in February/March) is beneficial. These are 45–60 cm high from soil surface and 90–120 cm from the bottom of the furrow in between. These furrows contain water and sugarcane remains much above it. This practice allows improvement in drainage and at the same time ensures some aeration for the roots as the root zone lies above water level. Such a planting method has sustained sugarcane produc-

tivity in waterlogged soils in Louisiana (USA) [64]. This method has also shown promise in studies conducted at Captainganj (Deoria in Eastern Uttar Pradesh), Marhowrah (Chapra), Barachakia (Motihari), and Chanpatia (Champaran) in Bihar, using sugarcane varieties CoS 8436 (early ripening), CoS 767 (mid-late ripening), and BO 91 (late ripening) [65]. In North Bihar, planting on raised seedbeds has given best results in waterlogged areas. Double-row planting along with raised beds has also improved cane yield [65].

- **Nutrients imparting tolerance to waterlogged conditions**: Under flooding or submergence, O_2 deficit in the rhizosphere results in decreased active ion uptake and nutrient deficiency develops. It has been seen that an increase in P content in the stalk was related to tolerance to flooding [66]. Application of 2% of N, under trench planting system, improved yields under such conditions. To sustain productivity of a ratoon crop, under such conditions 130 kg P_2O_5 along with 250 kg N ha^{-1} was beneficial [46].
- **Improvement of waterlogged soils by incorporating bulk organic manures**: Waterlogged soils could also be effectively managed by incorporating organic matter through FYM, compost, and green manuring in Saurashtra region of Gujarat. Application of press mud, coir waste, and groundnut shells are also beneficial under such conditions [67]. In another study, application of 3 ton ha^{-1} of press mud alone increased cane yield by 48% over waterlogged control [68].
- **Improving drainage**: In Gujarat, installing a subsurface drainage system, in a sugarcane area where water table normally fluctuated between 0 and125 cm during the year and remained near the ground surface during monsoon months improved productivity. The drainage system comprised of slotted PVC pipes laid with gravel envelopes installed at 20, 30, and 40 m drain spacing at a depth of 1 m. The improvement in sugarcane productivity was relatively more in closely spaced drains. The closer drain spacing reduced the period of water stagnation [69]. In Bichpuri Minor Command area of Uttar Pradesh, waterlogging and prolonged wetness are major crop production constraints. Here also to improve drainage, a network of surface drains and inverted siphons were constructed. This intervention led to 22% improvement in sugarcane productivity, besides an improvement in trafficking and workability in the standing crop [70]. In Haryana, proper and low frequency of irrigation protects land from high water table and secondary salinization [71]. In many coastal areas and valley soils in Puerto Rico, where internal drainage is a problem, deep tillage and installing subsurface drainage improved sugar yield [64].

35.2.2.3 For Salt-Induced Stress Conditions

In India, salt accumulation in the soils is one of the main threats to the sustenance of irrigated agriculture. Soil salinity associated with waterlogging is a common menace in all the major irrigation projects in the country. Although sugarcane has been claimed to be a highly salt-tolerant plant [72, 73], salinity, alkalinity, and acidity are important constraints to its productivity in many parts of the world.

Following approaches have been adopted to minimize yield reductions in sugarcane due to saline–alkaline conditions:

- **Control of rhizospheric salinity**: Reclamation of salt-affected soils is a two-step process involving displacing the Na held on soil exchange complex by application of a chemical amendment, such as gypsum (1.7 ton ha^{-1} to remove 1 meq Na^+ / 100 g soil), and removing this displaced sodium from the root zone by leaching with irrigation water. This may reclaim saline/alkaline soils and sustain their productivity. Gypsum requirement varies with soil type and pH [74]. In Andhra Pradesh, application of 3 ton ha^{-1} gypsum improved soil characteristics; however, 50% gypsum (1.5 ton ha^{-1}) in combination with rice husk followed by flushing with good-quality water gave the best results [75].

In Australia, on sodic soils, application of gypsum at 2 ton ha^{-1} with irrigation water improved cane yield by 20% in some of the sodic soils. Subsequent studies indicated that surface-applied gypsum (10 ton ha^{-1}) and dissolved gypsum (2 ton ha^{-1}) applied through irrigation water produced an additional 3.5 and 2.6 ton cane ha^{-1}, respectively [76]. Cane yields, in fully irrigated sodic soils (ESP < 25), were improved by up to 25% with application of gypsum at 10 ton ha^{-1} or 2 ton ha^{-1} annually dissolved in irrigation water. Reclamation of irrigated soil was also achieved by reducing the natural slope from 0.49 to 0.07% while maintaining the integrity of the topsoil [77].

In South Africa (Nkwaleni Valley), for reclaiming saline-sodic soils, 31 ton of gypsum per hectare and 6 ton of sulfur per hectare was used. In this trial, average yields of plant plus ratoon crops were 82 ton ha^{-1} (control), 99 ton ha^{-1} (addition of sulfur), and 100 ton ha^{-1} (addition of gypsum) [78]. In the saline soils of Clarendon Sugar Company, Morelands, Jamaica, application of S (330 kg ha^{-1}) reduced salinity [79].

Studies conducted in Taiwan indicated that approximately 65% of the salts (from a poorly drained and saline-sodic soil at Aoku) are removed from the soil to a depth of 100 cm by using 1000 mm of leaching water [80]. Reclaiming salt-affected soils by open ditch drainage was relatively more effective than the subsurface drainage [81]. Some models have also been developed to predict the amount of water needed to ameliorate and remove salt from a fine textured saline-sodic soil on which sugarcane was grown at Sanku farm of Chiali Sugar Mill in Taiwan [82].

Addition of molasses up to 48 qtl ha^{-1} can also be used to partially reclaim alkaline soils after which sugarcane may be planted [83].

Incorporation of bulk manures such as farm yard manure (25–40 ton ha^{-1}), press mud cake (5–7.5 ton ha^{-1}), compost (15–20 ton ha^{-1}), and green manure (using *Sesbania aculeata*) has enhanced the productivity of saline soils in Gujarat [84], Karnataka [85], Maharashtra [86], and Haryana [71]. In areas irrigated with saline water, trench planting and application of 25 ton ha^{-1} of FYM or press mud combined with trash mulching increased cane and sugar yields [87]. In Australia, at Favero Cane farm in Colevale, in salt-affected land (where cane yield was 40 ton ha^{-1}), application of 60–65 ton ha^{-1} of filter press mud increased the cane yield to 155–160 ton ha^{-1} in plant cane and 110 ton ha^{-1} in the succeeding ratoon crop. At another location,

Pioneer Mill area, the improvement was only by 20 ton ha^{-1}. Here although salinity remained twice as high as in the original soil causing severe inhibition of growth, after this treatment, soil retained more moisture and was friable rather than hard setting [88].

- **Managing waterlogging**: As mentioned earlier, waterlogging has led to salinity problem in many parts of Karnataka, Orissa, Haryana, and Punjab in India and in some other countries such as Egypt. Proper and low frequency of irrigation may protect the lands from buildup of high water table and secondary salinization. Besides, management practices for waterlogged areas should be adopted to prevent the spread of secondary salinization.
- **Adjustment of the ridge direction**: Maintaining ridge direction from east-to-west, in subtropical India where such problem exists, permits accumulation of salt on the top of the ridges and sugarcane setts may be planted on their slope [63].
- **Crop rotations**: Crop rotations provide a cultural means to keep the effects of salinity/alkalinity minimum and at the same time sustain productivity. In Maharashtra, crop rotations involving *dhaincha*–cane–cotton–onion and *adsali* cane–onion–cotton were promising [89]. Patil and Ghonsikar [86] have suggested sugarcane–cotton–rice–*Sesbania aculeata* as a desirable cropping rotation on partially reclaimed saline soils.
- **Use of pregerminated setts and use of trash-veins system of planting**: Using pregerminated setts has been recommended for saline–alkaline soils [63]. In alkaline soils, yields of sugarcane could be doubled by planting cane in deep (20–25 cm) furrows and packing trash in the furrows as soon as the germination is over and tillering starts [90].
- **Nutrient management**: Salt tolerance of crops varies with soil fertility. Experimental data support the view that standard fertilizer recommendations for nonsaline–alkaline conditions are also suitable for saline conditions [91]. Studies conducted in India indicated that N, P, and K fertilization to sugarcane on saline soils is usually observed to suppress the availability of toxic elements; K depressed Na, P, Mg, and Mo; and nitrogen increased K availability [92]. Application of additional P may increase plant growth under saline conditions [93]; however, high concentrations, which may be beneficial under nonsaline conditions, could cause injury to the plants [94]. It has been shown that high phosphorus supply, with salts, does not contribute to osmotic adjustment and instead accumulates in the cell walls [95].

In Hawaii, on some calcareous saline soils (Mamola and Molokai soils), application of DTPA Fe increased cane yields by 37.5% [96].

In sugarcane growing on saline–alkaline soils, deficiency of P, Fe, and Zn was a common occurrence. To overcome this Zende and Hapase [89] suggested the following measures:

- Enriched compost with super phosphate (2 kg P_2O_5 10 ton^{-1} compost) should be mixed in the soil before planting.
- 10–20 kg ha^{-1} of $FeSO_4$ should be added to soil before planting to counteract chlorosis. It may be sprayed three–four times if chlorosis is detected on growing crops (4 kg $FeSO_4$ 1000 l^{-1} water ha^{-1}). Iron chelates may be used.

- 10 kg ha^{-1} of $ZnSO_4$ should be mixed in the soil before planting. On the standing crop, it may be sprayed along with 4 kg ha^{-1} of $FeSO_4$ (two–three sprays at 8–10 days interval).
- Use ammonium sulfate as a source of N or add 2–5 kg sulfur with each bag of urea.
- Never allow the field to remain fallow particularly the reclaimed one. Even growing of certain grasses is beneficial.

K and Si enhanced salt tolerance in salt-sensitive sugarcane genotypes (CPF 243 and SPF 213) resulting in decreased Na^+ concentration and increased K^+ with an improvement in K^+/Na^+ ratio [97].

- **Acidic soils**: Acidity is a problem in sugarcane soils in Kenya, South Africa, Taiwan, and so on. In Kenya, a pH of 4.3–5.0 in low-lying areas and 6.0 in high lands is observed. In South Africa, most of the sugarcane soils tend to be acidic (pH 4.6–6.0) and suffer from internal drainage [64]. In India, acidic soils (with pH < 6.0) are found in Kerala, coastal Karnataka, Goa, parts of Orissa, Assam, submountainous Himalayan region, the *terai* of Uttar Pradesh and Bihar, and some parts of Madhya Pradesh and Andhra Pradesh. Crops growing on acidic soils suffer due to toxic effects of excessive Al, Fe, and Mn, high phosphate fixation, low rate of nitrification, low water holding capacity, and deficiency of Mo, Si, S, K, Ca, B, and Mg [63].

For acidic soils below pH 5.5, liming (1.2–2.0 ton ha^{-1} of lime such as CaO) is essential to correct nutrient imbalance. Instead of adding full dose at one time, 10–25% of lime requirement is added each year. Lime should be incorporated during fallow period or prior to monsoon and after this, 3–4 months time is allowed for reaction with the soil. In acidic soils of Kerala, variety Co 997 did not respond to lime applications with regard to yield, whereas yield of Co 785 increased with lime application in the first and second ratoons. In plant crop, however, yield declined sharply when 150 kg ha^{-1} of CaO was applied [98]. Studies conducted in the United States also indicated that liming acidic soils with dolomite (4.4 ton ha^{-1}) improved sugarcane productivity, and the relative improvement was rather more in a ratoon crop [99]. In Assam, in acidic soils with pH 5.5, variety Co 997 was more successful [63]. In Kenya, addition of gypsum ameliorated acidic soil and improved yields in plant and ratoon crops. At some of the locations such as Masaka, relative increase in yield was more in ratoons. In South Africa, application of 5 ton of lime + 5 ton of gypsum per hectare in acidic soil in the Kwazulu-Natal midlands improved sugarcane productivity [100].

In acidic soils (Ultisols) in Sumatra, application of phosphorus improved cane yield [101]. Application of silicon also alleviated Al and Mn toxicities [1].

35.2.2.4 Low Temperature

Effects of low temperature are bifold: (a) effects on physical, chemical, and biological properties of soil that indirectly influence growth and development (especially of the roots) and (b) direct effect on growth and development. In subtropical India, the problem of low temperature is twofold: effect of low temperature during ripening and

poor sprouting of stubble buds in a winter harvested crop leading to poor regrowth of succeeding ratoon crop and thus poor ratoon productivity [1]. Following approaches have been adopted to minimize yield reductions in sugarcane due to low-temperature conditions.

35.2.2.4.1 For Reducing Post-frost Losses

- **Preservation of seed cane and improving germination**: At the first sight of frost, canes were cut and buried in the field. The practice, however, was not beneficial as the lot of bud sprouts got damaged during handling for planting and due to termite attack. Clamping was also done to preserve seed cane, but the buds sprouted in severe frost. Activation of buds by placing cut setts for 24 h in fresh cow dung improved germination [1].
- **Altering planting time**: In Hualien area (Taiwan) for nearly 5 months (November to March), the mean temperature remained $<20\,^{\circ}C$, which affected growth and yield if cane was planted in August. Preponing planting (to June or July) ensured abundant sunshine and higher temperature that improved cane and sugar yield [102].
- **Frequent post-monsoon irrigation**: Frequent post-monsoon irrigation reduced the damage due to frost [11]. This is, however, helpful in light to moderate frost.
- **Reducing post-frost losses**: All the heavily frosted canes, as they do not recover, should be milled as soon as possible. In a field study conducted at Jalandhar, India, frost-susceptible sugarcane variety CoJ 70 was sprayed with 50 or 100 ppm of gibberellic acid before the onset of low-temperature stress. The results showed a significant increase in total chlorophyll, soluble sugars, proteins, and nitrate reductase activity in the leaf tissues and sucrose, purity, and commercial cane sugar percentage in the cane juice in the post-frost period [103]. In Florida, Ulloa and Anderson [104] have observed that application of calcium silicate improved tolerance of sugarcane to freeze damage.

35.2.2.4.2 Overcoming Poor Sprouting in Winter-Initiated Ratoons

- **Avoidance of low temperature for the exposed stubble**: In winter-initiated ratoons, poor sprouting could be overcome by spreading a trash cover [105–107], or by spreading a polyethylene cover [108] over the soil before the advent of low temperature phase. These may be removed after the low temperature phase is over [107, 108].
- **Biochemical manipulations using growth regulators/nutrients**: Plant growth regulators and certain nutrients have been used for improving stubble sprouting and productivity of winter-initiated ratoon crops of sugarcane (Table 35.1).
- **Maintaining optimal clump population**: Attempts should be made to maintain an optimal clump population (29 000 clumps ha^{-1}) in subtropical India [119]. Gaps should be filled by using stubble dugout from other fields, pre-germinated settlings, or the sprouts from the clumps of the same variety in the same field. Gaps should be filled in the early tillering phase as late transplants do not keep pace with the development of normal tillers [120].

Table 35.1 Use of plant growth regulating substances and nutrients for improving stubble sprouting and yield of winter-initiated ratoon crop.

S. No.	Country	PGR/nutrient	Reference
A. Application to the freshly harvested stubble (after harvest of plant crop)			
1.	Taiwan	Cycocel (10 kg a.i. ha^{-1})	[109]
		IBA (200 ppm) and Ethrel (1000 ppm)	[110]
2.	India (subtropical)	Cycocel (8 kg a.i. ha^{-1}); IBA (10 ppm)	[111]
		Cycocel (5 kg a.i. ha^{-1})	[112]
		Ethrel (2500 ppm) + gamma HCH (1 l ha^{-1})	[113]
		Ethrel (500 ppm); IBA (100 ppm) and TIBA (50 ppm)	[108]
		Formulation containing mixture of vitamins	[114]
B. Application to the preceding plant crop (15 days before harvest of plant crop)			
1.	Taiwan	Ethrel (1.44 kg a.i. ha^{-1})	[115]
2.	India (subtropical)	Ethrel (200 ppm) + Urea (4%)	[116]
		Glyphosate (0.16 kg a.i. ha^{-1})	[117]
		Application of 66 kg K ha^{-1} with last irrigation a month before harvest	[118]

35.2.2.5 High Temperatures

High temperature as a stress affecting sugarcane productivity could be visualized as (a) cultivation of sugarcane in hot and dry areas (as in Sudan and Malawi), (b) experiencing relatively higher temperatures at certain growth stages (early growth stage in a late summer planted crop, overstands), (c) pre-harvest burning of sugarcane, dumping bagasse, trash, and so on, and (d) gradually increasing temperatures due to global climatic change. In hot and dry areas, cultivation of tolerant varieties will be desirable [1]. Experience at the Indian Institute of Sugarcane Research, Lucknow, India, has indicated that the use of trash mulch in hot summer months reduced the soil temperature by 2–3 °C and thus may sustain the functioning of roots. As a result of late planting of sugarcane in summer months (April and May), owing to high temperatures, low RH, and scanty rainfall, the crop experiences heat stress and germination and early growth of the crop are affected. Irrigation immediately after planting improves germination and cane yield [121].

35.2.2.6 Nutrient Stress

The lopsided use of fertilizer NPK has led to both an imbalance in nutrient use and a decreased availability of secondary and micronutrients. Deficiency of S and some of the micronutrients has been well recognized and deficiency of K is increasing in Indian soils. Problems related to nutrients in sugarcane are chlorosis (a widespread nutritional malady), imbalance of nutrients, high sheath moisture (in peninsular India), and certain nutrient interactions (Zn deficiency is commonly encountered following P addition when cane is grown after paddy; excessive P fertilizer induced Zn deficiency in ripe canes; Mn deficiency is associated with soils high in Mg, Ca, and N; nutrient deficiencies, especially of K, may cause more uptake of Ca and lead to processing problems; cane grown in laterite soils of Orissa have higher amount of colloidal silica in juice [1]. Besides, certain abiotic stresses also induce nutrient deficiencies. In rain-fed areas, which experience frequent drought spells, multi-nutrient deficiency (Zn and K) is common. An optimal nutrient supply (N, P, K, and Zn) ensures deeper root system, helps in better adaptation of crop to sustain productivity under such conditions [50]. In saline–alkaline soils, deficiency of P, Fe, and Zn is of common occurrence, and remedial measures for this have been suggested by Zende and Hapase [89] as mentioned above.

Application of soluble silicates is beneficial in areas where sugarcane growth is affected by absorption of excess amounts of heavy metals like Mn [122].

35.3 Breeding Varieties Tolerant to Abiotic Stresses

35.3.1 Tolerance/Resistance to Abiotic Stresses in *Saccharum* Spp. and Related Genera

Earle [123] has mentioned that *Saccharum sinense* clones have strong root system and great power and ability to thrive on salt-affected soils. *S. barberi* clones exhibited

Table 35.2 Sugarcane varieties tolerant to various abiotic stresses.

Variety	Characteristics
Batjan	Vigorous growing, high tonnage, adapted to medium and poor soils
Cavengirie	Good yield on poor, dry lands
Co210	Adapted to hard, dry land, and waterlogging
Co 281	Cold resistant
C 46	Grew well in sandy *sabana* lands and adapted to shallow lime soils
Daniel Dupont	Early ripening and adapted to high altitudes
D 109	Withstood unfavorable conditions
D 117	Withstood salt-affected soils
EK 28	Thrived fairly well on a variety of soils
POJ 36; POJ 2725	Well adapted to poor and exhausted lands
POJ 213	Adapted to wide range of soils and withstood well wetlands and lack of drainage
POJ 2727	Adapted to dry, rocky lands
Uba	Maintained sucrose content and purity on alkaline soil than on acid soils

Source: Ref. [123].

considerable resistance to cold; thus, they are adapted to subtropical climates. He has also mentioned some of the then prevailing varieties that were tolerant/resistant to some of the abiotic stresses, poor soils, high altitudes, and so on (Table 35.2). These could be utilized as parents for breeding varieties tolerant to abiotic stresses.

In an evaluation of 28 clones of *S. spontaneum* for their tolerance to artificially created waterlogging, two clones, namely, SES 334 (Assam) and SES 340 (Manipur), had the best growth, tillering, and lush green foliage. There was a characteristic development of a large matrix of fibrous, negatively geotropic roots. On the basis of these observations, Srinivasan and Rao [15] suggested that these clones could be utilized as genetic donor to evolve waterlogging-tolerant sugarcane varieties. During waterlogged conditions (6 months of flooding), all the clones of *S. officinarum* quickly died. *S. barberi*, *S. sinense*, *Sclerostachya*, and *Erianthus* spp. were all susceptible but survived flooding. Several clones of *S. spontaneum*, *S. robustum*, and *Narenga* spp. were tolerant to waterlogging. It was generalized that clones with profuse development of fibrous, floating, negatively geotropic roots with aerenchyma were tolerant to waterlogged conditions. Such a trait, present in *S. spontaneum*, could be transmitted through crossing [16].

In the *World Germplasm Collection* maintained at SBI research station, Cannanore, India, following clones/varieties of various *Saccharum* spp. have been reported to be resistant to salinity [124]:

S. barberi: Katha, Coimbatore, Kewali-14-G, Khatuia-124, Kuswar, Ottur; Lalri, Nargori, and Pathri.
S. sinense: Khakai, Panshahi, Reha, and Uba-Seedling.
S. robustum: IJ-76-422, IJ-76-470, 28-NG 251, 57-NG-201, 57 NG -231, NG-77-34, NG-77-55, NG-77-136, NG-77-160, Ng-77-167, NG-77-170, NG-77-221, and NG-77-237.

Studies conducted at Karnal indicated that sugarcane variety Co 453 could be utilized as a best donor for imparting tolerance to salinity–alkalinity. Sugarcane variety Co 312 has also been used as a parent for imparting drought tolerance in sugarcane variety Co 87263 [125].

Generally, greater low-temperature tolerance was observed in high-fiber commercial clones [126] and regional selections of *S. spontaneum*, *S. sinense*, and allied genera, for example, *Miscanthus* [127]. Brandes [128] identified highly cold-tolerant clones of *S. spontaneum*; this trait was, however, lost through hybridization and backcrossing with *S. officinarum*. Roach and Maynard [129] found 3.9% of the progeny of 28 crosses between *S. spontaneum* and *S. officinarum* were freeze tolerant, but after backcrossing the frequency of tolerance in the progeny dropped to 0.5%. Dunkelman and Breaux [130] were, however, able to maintain an acceptable level of tolerance through two backcrossings. On the basis of this observation, Moore [131] concluded that if tolerant clones were used as recurrent parent, greater cold tolerance could be obtained in commercial varieties. Certain varieties of *S. spontaneum* were resistant to damage by prolonged low temperatures. One strain *Arbington Va Winter* remained green throughout [128]. At Houma in Louisiana (USA), sugarcane breeding strategies include (i) evaluation of parents and progeny for resistance traits such as cold tolerance and (ii) backcrossing and recombining progeny in a systematic manner that will concentrate genes associated with this trait. In 2002, 2169 progeny from 11 interspecific crosses between 10 *S. spontaneum* clones and 6 commercial varieties were evaluated. In February 2003, 10 crosses from SES 234 × LCP 85–384 were identified as expressing cold tolerance after a 3 h −5 °C freeze on January 2003. These selections expressed minimum levels of dead leaf tissue, few dead terminal buds, and no stalk damage. These were verified as interspecific hybrids using microsatellite DNA marker [132].

In 1982, Sikkim Himalayas were surveyed and clones belonging to *Miscanthus nepalensis*, *Erianthus fulvus*, *E. arundinaceus*, *E. procerum*, and so on were collected. The high-altitude forms of *M. nepalensis* and *E. fulvus* did not survive at Coimbatore. However, these were successfully established at the IARI Regional Research Station, Wellington [46]. Few clones of Co 7201 × *Erianthus* spp. continued to grow in winter at Karnal (in subtropical India) and some of these were both cold tolerant and resistant to red rot [133]. These could be utilized to impart low-temperature/cold tolerance.

Among other varieties developed from the cross of Co 281 (as a pistil parent) to POJ 2878 (as pollen parent) were PR 980 (widely used as a parent to impart drought and frost resistance), PR 1000 (used as a parent for imparting sucrose to the progeny), PR 1013, PR 1016, and PR 1028 (adapted to poorly drained and waterlogged conditions). In Reunion, it was used as a pistil parent to evolve variety R 397 [134]. At Coimbatore, Co 312 has been used as a parent to impart drought tolerance in variety Co 87263 [125]. In Mexico, in sugarcane breeding programs, emphasis is given on selection of varieties with deep root system and drought resistance, good proline under nonirrigated conditions, and resistance or tolerance to mosaic, rust, and smut.

They also look for varieties adapted to as high as 1300 amsl and annual rainfall from 300 to 2500 mm [135].

Saccharum species and related genera that may impart tolerance/resistance to abiotic stresses and nutrient use efficiency in sugarcane are given in Table 35.3.

Table 35.3 *Saccharum* species and related genera that may impart tolerance/resistance to abiotic stresses and nutrient use efficiency in sugarcane.

Characteristic	Genera/species	References
Tolerance/resistance to drought	*S. spontaneum*, *Narenga* spp. [a] *Erianthus* spp.	[136]
Tolerance/resistance to waterlogging	*S. robustum* *S. spontaneum*	[136]
Tolerance/resistance to cold (performance at high altitudes)	*Miscanthus* spp. *Miscanthus nepalensis*, *E. fulvus* *S. spontaneum* *S. barberi*	[46, 123, 128, 136, 137]
Tolerance/resistance to salinity	*Erianthus* spp. *S. barberi*, *S. sinense* *S. robustum*	[124, 137]
High nutrient use efficiency	*S. spontaneum* (IK 76-20, SES 24, IS 760164) *S. robustum* (51 NG 27) *S. sinense* (Khadaya) *S. officinarum* (UB-16)	[138]
Low nutrient requirement	*S. spontaneum*, *Erianthus* spp.	[136]
Robust growth under low input conditions	*Erianthus* spp.	[137]

a) When *E. arundinaceus* was used as a pollen parent, there was no significant reduction in sucrose content [134].

Some of the desirable features of indigenous canes growing in India, possessing tolerance to some abiotic stresses, which could be utilized in directed breeding are mentioned in Table 35.4 [139]. Of these only four (Chunnee, Katha, Saretha, and Kansar) have been utilized in breeding. Other indigenous varieties need to be utilized for developing sugarcane varieties tolerant to abiotic stresses.

This approach seems to be promising as the use of *Mandalaya*, a *S. spontaneum* clone from Burma, led to the success of Australian "Early CCS Canes Programme" and the use of another *S. spontaneum*, US56-15-8, led to development of LCP 85–384, a high yielding, high sugar, early ripening, less N requiring, and cold-tolerant variety of Louisiana [140].

Table 35.4 Desirable features of indigenous canes growing in India that could be utilized in directed breeding.

Variety	Tolerance to abiotic stress	Other associated desirable features
In subtropical India		
Chin, Chunnee, Raksi, Burra Chunnee, Baraukha	Flooding	Early ripening (harvested in December/January), high fiber, high sucrose
Agoul	Grew with less water (and manure)	
Hemja	Well adapted to early drought and late waterlogging	Heavy tillering, heavy yielder, high sucrose and purity, resistant to red rot and borers
Maneria, Chinia	Withstood waterlogging	Grew in irrigated areas, erect, high tillering, good sucrose content. Maneria was also tolerant to borers
Khari	Drought and waterlogging	Good germinator, heavy yielder, good ratooner
Sewari	Flooding	Early ripening
Katha	Wide adaptability to drought, rainfed, flooding, hot and dry climate, and to a lesser extent to frost	Early ripening, thin excellent tillering
Lalri	Frost	Hardy, good tillering, resistant to red rot
Khari, Ikhri, Khagri[a)]	Drought and waterlogging	
In tropical India		
Kalkya, Khadiya, Bansi, Sunnabile	Drought	Heavy tillering and ratooning ability
Nannal	Drought	

Source: Abridged from Ref. [139].
a) *Khagri* was able to grow 6 feet under water for over 3 months.

35.3.2
Varieties Developed/Identified Tolerant to Abiotic Stresses in India

In India, the All India Coordinated Research Project on Sugarcane has released some sugarcane varieties tolerant to abiotic stresses for commercial cultivation in various zones in India (Table 35.5).

Tew [142] and Shrivastava and Srivastava [1] have mentioned varieties tolerant to abiotic stresses used in various parts of sugarcane growing areas in the world.

Some of the sugarcane varieties possess *multiple abiotic stress tolerance* (Figure 35.2). There is need to elucidate physiological and biochemical characteristics associated with these varieties. Breeding programs must be tailored to breed such varieties, as in

Table 35.5 Sugarcane varieties (tolerant to abiotic stresses) released by the AICRP (Sugarcane) in India.

S. No.	Variety	Year of release	Cane yield (ton ha^{-1})	Sucrose (%)	Maturity group	Reaction to disease	Tolerance to abiotic stress
Peninsular zone (Madhya Pradesh, Gujarat, Karnataka, Kerala, interior Andhra Pradesh, and plateau region of Tamil Nadu)							
1.	Co 94008 (Shyama)	2002	119.8	18.3	Early	MR-red rot	DR, salinity, WA
2.	Co 8371 (Bhima)	2000	117.7	18.6	Mid-late	R-smut	DR, WL
3.	Co 87025 (Kalyani)	2000	98.2	18.3	Mid-late	R-smut	DR, WL
4.	Co 87044 (Uttara)	2000	101.0	18.3	Mid-late	R-smut	DR
5.	CoM 88121 (Krishna)	2000	88.7	18.6	Mid-late	R-smut	DR, MQL
6.	Co 91010 (Dhanush)	2000	116.0	19.1	Mid-late	R-smut	DR,RF
7.	Co 99004 (Damodar)	2007	116.7	18.8	Mid-late	MR-red rot	DR, salinity
8.	Co 2001-13 (Sulabh)	2009	108.59	19.03	Mid-late	MR to red rot, smut and wilt	DR, salinity stress
9.	Co 2001-15 (Mangal)	2009	112.99	19.37	Mid-late	MR to red rot and smut	DR, salinity and lodging
East-coast zone							
10.	CoC 01061	2006	110.8	17.4	Early	MR to red rot	DR
North-central zone (Eastern Uttar Pradesh, Bihar, and West Bengal)							
11.	Co 87263 (Sarayu)	2000	66.3	17.4	Early	R-smut, red rot	WL, RF, LIC
12.	Co 87268 (Moti)	2000	78.9	17.5	Early	R-smut, red rot	DR,WL, high soil pH
13.	CoSe 96234 (Rashmi)	2002	64.1	17.9	Early	MR-red rot	Stress conditions, in general
14.	CoSe 96436 (Jalpari)	2002	67.1	17.7	Mid-late	MR-red rot	WL
15.	CoLk 94184 (Birendra)	2008	76.0	18.0	Early	MR to red rot	DR, waterlogging
North-west zone (Punjab, Haryana, Rajasthan, western, and central Uttar Pradesh)							
16.	CoH 92201 (Haryana-92)	2000	70.0	18.2	Early	R-red rot	LPC
17.	CoS 95255 (Rachna)	2002	70.5	17.5	Early	MR-red rot	LPC
18.	CoPant 90223 (Pant 90223)	2000	73.3	18.5	Mid-late	MR-red rot	DR, WL, LT
19.	CoPant 93227 (Pant 93227)	2002	75.4	17.3	Mid-late	R-red rot	LIC, suboptimal environments

nature, more than one stress often occur together or the prevalence of one stress may accentuate or aggravate the other to further augment the losses.

35.4 Molecular Approaches

Selection and breeding using wide crosses are the best short-term approach for developing a stress-tolerant sugarcane variety. However, new molecular and biotechnological approaches may go a long way in developing transgenic plant for tolerance to a particular stress or multiple stresses. Epstein and Rains [143] have outlined the steps for a general program for developing a stress-tolerant plant using biotechnological/molecular approaches. It includes cloning of stress tolerance genes from microorganisms, recombinant DNA analysis of the structure of genes required for stress tolerance, development of a plant gene vector for stress tolerance gene transfer, cloning of stress tolerance genes using recombinant DNA technique, transferring these genes (segment) into a prevailing good commercial variety,

selection of stress-tolerant mutant plants using tissue culture and hardening of these plants, and evaluating their field performance.

There are many possibilities for the manipulation of genes to impart/transfer the stress resistance trait in high-yield varieties. Structural and functional characterization of environment stress-induced genes has contributed to a better understanding of how the plants respond and adapt to different abiotic stresses. Studies have shown that specific proteins, "stress proteins," accumulate in response to imposition of stress conditions, namely, drought, low temperature, high temperature, oxidative stresses, and so on.

Grover *et al.* [144] have reviewed various experiments conducted in the molecular biology of abiotic stress responses, which are triggered at different levels of hierarchy of the cellular organization, in different systems, namely, lower and higher plants and microbes. The molecular analysis of the stress responses has been carried out at the level of stress proteins, stress genes, stress promoters, transacting factors that bind to stress promoters, and signal transduction components involved in bringing about the stress responses. They have listed a large number of genes/proteins associated with tolerance to water stress, salt stress, anaerobic stress, high- and low-temperature stress, heat shock, and so on. The functional relevance of the stress-associated genes is being tested in different trans-systems in plant species. Some of these genes might be utilized in times to come to develop transgenic plants tolerant/resistant to various abiotic stresses. Traditional plant breeding techniques will be suitable for transfer of traits of stress tolerance. Such studies are also in vogue in sugarcane. These may help in sustaining sugarcane and sugar productivity under abiotic stress conditions in times to come.

35.4.1 Drought

Development of drought-tolerant sugarcane varieties through genetic engineering is a serious option for managing drought. Some candidate genes for drought tolerance have been identified, for example, dehydration-responsive transcription factor (DREB) genes that mediate transcription of several genes in response to water stress, genes encoding enzymes of the biosynthetic pathways of different osmolytes such as proline, glycine betaine, sorbitol, heat shock proteins (HSPs), late-embryogenesis proteins, and RAB (responsive to abscisic acid) proteins. Besides, osmotin, choline oxidase, annexin, and genes encoding superoxide radical (O^-), hydroxyl radical (OH^-), and hydrogen peroxide (H_2O_2) also have potential in drought tolerance [4].

Trehalose synthase (*Tsase*) gene (from *Grifola frondosa*) transferred into a sugarcane hybrid by *Agrobacterium tumefaciens* (strain EHA 105) imparted resistance to osmotic stress. Some of the transgenic plants showed improved tolerance to osmotic stress. After transplanting in MS medium containing 17.4% PEG 8000, the transgenic plants demonstrated improvement in tolerance to osmotic stress [145]. The use of a novel sugarcane ethylene-responsive factor, SodERF3, could be a valuable tool to assist the manipulation of sugarcane plants to improve their stress tolerance [146]. Increased expression of a gene encoding a peroxidase has been reported by Rodrigues *et al.* [147] in a drought-tolerant sugarcane cultivar. Catalase (CAT) enzyme is responsible for the reduction of H_2O_2 to H_2O and O_2, and a decline in peroxidase

activity is considered a limiting step to neutralization of reactive oxygen species (ROS) in sugarcane [148].

The cDNA-AFLP technique was used to identify differentially expressed genes in two sugarcane cultivars that had previously been classified as tolerant (TSP-054) or susceptible (TCP02-4589) to drought [149]. A total of 23 transcript-derived differentially expressed fragments (TDFs) were observed and 5 of these revealed high identity with stress-related genes previously reported in sugarcane, sorghum, rice, and corn. One TDF that was upregulated in the tolerant cultivar after 12 days of stress exposure showed complete identity with a drought-inducible gene (SoDip22) previously identified in sugarcane. A TDF that was downregulated in the susceptible cultivar also had high identity (87%) with a putative pentatricopeptide expressed in rice. After rehydration, the normal gene expression pattern was reestablished, thus demonstrating the ability of sugarcane to respond rapidly to changing environmental conditions.

Real-time reverse transcription–PCR profiling of selected expressed sequence tag (EST) clusters identified several sugarcane clusters that showed differential expression in response to biotic and abiotic stress conditions [150]. Twenty-five stress-related clusters have shown more than twofold relative expression during water deficit stress. All clusters that showed homology to osmotic stress or dehydration stress-associated proteins were significantly upregulated. A very high (~13-fold) induction during 9 h of dehydration stress was noted in the case of a salt stress-inducible Bzip protein. These might be delayed action genes working in the related pathways. Some clusters showed higher expression during 3 h and then a decline during 6 h and again expressed to significantly higher levels at later stages (9 h). This pattern of expression and delayed response of certain genes could be attributed to their tight regulation via other candidates involved in the pathway.

Iskandar *et al.* [151] analyzed expression of 51 genes implicated in abiotic stress in relation to sucrose accumulation by studying tissues of internodes of mature and immature stalks in a high sucrose accumulating sugarcane cultivar in normal and water stress conditions to compare effects of sucrose accumulation and water deficit. They identified a subset of stress-related genes including genes encoding enzymes involved in amino acid metabolism, a sugar transporter, and a transcription factor that are potentially associated with sucrose accumulation in stalk. Expression of these stress response genes in plants that were under water deficit stress revealed a different transcriptional profile that was correlated with sucrose accumulation. Besides, genes with homology to late-embryogenesis abundant (LEA)-related proteins and dehydrin were strongly induced under water deficit, but this did not correlate with sucrose content. The study indicated that while there was a change in stress-related gene expression associated with sucrose accumulation, different mechanisms are probably responding to the water-deficit-induced stress.

Upregulation of genes encoding for polyamine oxidase, cytochrome-*c*-oxidase, *S*-adenosylmethionine (SAM) decarboxylase, and thioredoxins, which directly or indirectly participate in the regulation of the intracellular redox status, have been demonstrated in sugarcane under drought stress [152], and may probably contribute to water-deficit-induced stress tolerance. Stress cluster 1 (putative oxidative stress

responsive) and stress cluster 15 (70 kDa heat shock protein) showed upregulation during 3–6 h of dehydration stress, but later on their expression decreased [150]. These genes might provide tolerance to stress in its initial stages. The accumulation of the osmolytes trehalose and proline also contribute to reduction in damage caused by accumulation of ROS and provide enhanced tolerance to drought [13, 153, 154]. Some of the sugarcane genes expressed under water deficit stress might be involved in the pathways that lead to the production of such osmoprotectants.

Jangpromma *et al.* [155] reported an unknown 18 kDa protein (p18) along with other stress-inducible proteins to be highly expressed in sugarcane leaves under drought conditions. The 2D-PAGE patterns of proteins were compared with those expressed in drought tolerant K86–161 and drought-susceptible Khon Kaen 1 cultivars. Mass spectrometry and comparison with known sequences, in the database, revealed that the proteins expressed only in stressed K86–161 were serine protease inhibitor and the one similar to replication protein A1. A group of proteins upregulated in K86–161 includes *S*-adenosylmethionine decarboxylase proenzyme (SAM), ubiquitin, and p18. Higher levels of chlorophyll and SOD in drought-tolerant than those in drought-susceptible sugarcanes are in agreement with a high level of p18 expression in drought-tolerant sugarcane. An accumulation of p18 appears to be in response to water deficit.

In plants, micro-RNAs are involved in the regulation of plant development and nutrition, responses to biotic and abiotic stresses, signal transduction, and protein degradation. The possible role of sugarcane microRNAs in the regulation of drought stress is being studied by Rojas *et al.* [156].

35.4.2 Waterlogging

Although physiological adaptations of crop plants to waterlogging/flooding (hypoxia or a anoxia) have been studied [157, 158], the molecular basis of such adaptations has not been completely understood [159]. However, some progress has been made in identifying genes and gene products induced during low oxygen conditions [159]. Low O_2-induced genes are characterized by the presence of an anaerobic response element (ARE) in the promoter [160]. It has been observed that about 20 anaerobic polypeptides are synthesized under hypoxia [161]. These may confer tolerance to hypoxia. A transcription factor, AtMYB2, which is induced by dehydration, salt stress, and exogenously applied ABA [162], is also induced by hypoxia. It is induced in root tissues and its induction coincides with the induction of ADH1Mrna. Attempt has also been made to use this transcription factor to affect the expression of anaerobic polypeptides (ANPs) produced during hypoxia. Dennis *et al.* [159] are of the opinion that AtMYB2 gene may enable the transgenic plants developed to recognize anaerobic conditions earlier, produce ANPs, and impart tolerance to hypoxia.

In an effort to elucidate the genes underlying plant responses to inundation, subtractive cDNA libraries were made from a highly adapted waterlogging-tolerant sugarcane variety, BO 91, grown under stress and normal conditions to identify the genes differentially expressed in waterlogging stress [163]. Major groups of ESTs were

related to stress (15%), catalytic activity (13%), cell growth (10%), and transport-related proteins (6%). A few stress-related genes identified were senescence-associated proteins, dehydration-responsive family proteins, heat shock cognate 70 kDa protein, and so on.

Plants with increased tolerance to waterlogging were obtained from callus lines that had been selected for resistance to ethionine, the toxic analogue of methionine, and to anaerobic conditions. Such identified plants may be used as donors to impart resistance to waterlogged conditions [164].

35.4.3 Salinity

Response of genotypes to callogenesis from leaf explants varied considerably under salt stress. A sugarcane genotype, BF-162, exhibited better regeneration of plantlets at all the salt levels than other varieties. The genotype CP 43/33 and *Triton* were relatively more sensitive to salt stress and regenerated only up to 0.9 g l^{-1} NaCl [165]. RAPD analysis of six salt-tolerant clones, regenerated from calli adapted to high salt medium, showed a DNA profile distinct from that of the original genotype. A unique DNA fragment of 995 bp, found only in salt-tolerant clones, showed sequence similarity to the genes involved in stress tolerance [166]. Embryogenic sugarcane (*S. officinarum* L.; cv. CoC 671) calli treated with different levels of NaCl accumulated higher amounts of free proline and glycine betaine [167]. Although the leached and retained Na^+ contents increased, the retained K^+ content decreased with increasing levels of NaCl. The growth retardation and reduced cell viability were associated with a conspicuous increase in Na^+ and a corresponding decline in K^+ concentrations. Such a mechanism implied that sugarcane could be considered as a Na^+ excluder. The accumulation of salt ions and osmolytes could play an important role in osmotic adjustment in sugarcane cells under salt stress. Moreover, NaCl priming treatments improved several aspects of plant growth and exhibited better tolerance of sugarcane seedlings to salt stress [168].

Accumulation of toxic ions in plant tissues modulates the levels of primary and secondary metabolites, which may be related to salinity tolerance [169]. Sugarcane clones exposed to salinity levels at the formative stage displayed a general tendency to accumulate Na^+ and Cl^- and little K^+, though the salt-tolerant clone CP 4333 accumulated less Na^+ and more K^+ compared to the salt-sensitive clone HSF 240, and thus showed a higher K^+: Na^+ ratio. Soluble phenolic, anthocyanin, and flavone levels were 2.5, 2.8, and 3.0 times greater in CP 4333 in comparison to HSF 240. The decrease in net rate of photosynthesis and most secondary metabolites in salt-sensitive clone indicated their relation with increased salt tolerance of sugarcane.

35.4.4 High-Temperature Stress

In recent times, higher temperatures are becoming more important as an abiotic stress. Studies have shown that enhanced synthesis of an oxidant by plant tissues

might increase tolerance to heat stress in soybean [170], and increase in saturated fatty acids of membrane increased their melting temperatures and imparted heat tolerance in *Arabidopsis* spp. [171, 172]. Most common molecular response of plants exposed to heat stress is the expression of heat shock proteins, which have a fairly wide range of molecular masses (10–250 kDa). They associate with various cellular structures or organelles to provide protection and act as molecular chaperones [173]. The dehydrin proteins (DHNs) are among other proteins that are classified as a group of late-embryogenesis abundant proteins, referred to as LEA group II, and typically accumulate late in embryogenesis or in vegetative tissues in response to environmentally imposed dehydrative forces, such as drought, salinity, and freezing [174]. Like most mesophytic species, sugarcane also shows sensitivity to supraoptimal growth temperatures despite the fact that it has higher temperature optimum compared to C3 species [175]. Expression of HSPs in the cultured sugarcane cells was noticed as a heat tolerance response [176]. In sugarcane seedlings subjected to heat stress, Wahid and Close [177] observed expression of three heat stress-induced DHNs with an apparent molecular mass of 21, 23, and 27 kDa under heat stress (48–72 h). The independent expression of these DHNs with reference to the changes in water relations of leaves suggested that they have a definitive protective role like other heat stress proteins.

There is need to characterize the genetic variability of specific HSPs across wide range of germplasm of *Saccharum* and related genera. Biochemical studies are needed to elucidate as to how these HSPs protect or allow restitution from high-temperature stress. HSPs appear to maintain the conformation of other protein structures [178]. The temperature range over which the apparent Michaelis–Menten constant for CO_2 (K_m) is minimal and stable is termed the thermal kinetic window [179]. There is a need to establish *thermal kinetic window* for sugarcane.

35.4.5 Low-Temperature Stress

For increasing productivity by enhancing stress tolerance, identifying relevant genes and characterizing their functions and regulation in response to low-temperature stress is important. Nogueira *et al.* [180] have identified 34 cold-inducible expressed sequence tags (ESTs) of which 20 were novel cold-responsive genes including cellulose synthase, ABI 3-interacting protein 2, a negative transcription regulator, and a phosphate transporter. Besides, 25 ESTs have also been identified that were downregulated during exposure to low temperatures. On the basis of the expression profiles of the cold-inducible genes and the data-mining results, sugarcane has two putative dehydrin-like proteins (WCOR410b and DHN2). These proteins could stabilize macromolecules and/or protect membranes against chilling damage [181]. Sugarcane ESTs encoding PPDK and NADP-ME proteins were induced by cold exposition, suggesting a possible maintenance of photosynthesis, even at low temperatures. It is possible that sugarcane putative antifreeze proteins can confer cellular membrane protection, reducing chilling injury.

In response to prolonged winter chill (PWC)-induced low-temperature stress, the tolerant sugarcane cultivars maintained relatively higher chlorophyll, carotenoid, N, and micronutrient and proline contents than the susceptible ones. Increased peroxidase activity was observed in the leaf and apical meristem in response to PWC-induced low-temperature stress along with the expression of some new isozyme bands of low molecular weight [182]. The photosynthetic rate is severely reduced under chilling temperature conditions [183]. The activity of photosynthetic enzymes such as sucrose phosphate synthase [184], NADP-malate dehydrogenase, and pyruvate orthophosphate dikinase activities [185] decreased when a cold-sensitive cultivar of sugarcane (*Badila*) was subjected to chilling temperatures (10 °C). The biochemical changes in response to cold treatment led to increased aspartate and alanine levels in the leaves of the cv. *Badila* plants. A complex antioxidant system has been suggested to act as a protective mechanism against chilling injury in sugarcane [186].

35.4.6
Nutrient Stress

The importance of K and P as essential elements for plant is undisputable; however, excess K [187, 188] and excess P [189] can result in a significant depression in sucrose concentration in sugarcane.

Sequence clusters homologous to plant high-affinity phosphate transporter genes have been identified from SUCEST data base. Identification and expression of genes associated with nutrient uptake and distribution may lead to the development of enhanced nutrient use efficiency of sugarcane, and economize the application of fertilizers to sugarcane crops [190].

35.4.7
Heavy Metal Stress

The use of tannery and industrial effluents, municipal waste-based composts, and biosolids' application in sugarcane fields and production of sugarcane on metal-polluted fills might create the problem of heavy metal stress for sugarcane cultivation [191, 192]. Pollution caused by pesticides, fertilizers, sewage sludge, industrial residues, and herbicides, which contain different concentrations of toxic metals, may severely affect sugarcane growth and metabolism [193]. Jain *et al.* [194] observed inhibitory effects of nickel at high levels (50 and 100 ppm Ni) on shoot and root growth, mitotic efficiency, metabolic attributes, and nutrient uptake of sugar cane (*Saccharum* spp. hybrid CoLk 8102). High concentrations of zinc (65 and 130 mg l^{-1}) were shown to increase lipid peroxidation in sugarcane, thereby affecting membrane integrity of leaves, root growth, and mitotic efficiency. The interference of Zn in normal mitosis could be related to an inhibition of DNA synthesis [195]. Higher chromium concentrations inhibited bud germination of sugarcane and induced chlorosis of young emerging settlings that turned necrotic at later stages. Biochemical studies revealed a decline in specific activity of catalase and an increase in

reducing sugar content in settlings supplied with chromium [196]. Mitotic efficiency of root tip cells of chromium treated setts declined and the frequency of aberrant mitotic phases increased *pari passu* to the increasing chromium concentration [197]. Root meristem assay of sugarcane settlings grown on crude and digested spent wash showed a detrimental effect on mitotic efficiency, induction of *de novo* chromosomal aberrations, namely, clump formation, chromosome stickiness, laggards, and micronuclei formation, and higher number of chromosomal abnormalities compared to those of control conditions [198].

35.5 Abiotic Stresses could also be Beneficial

Abiotic stresses are not always harmful; sometimes, these could be beneficial also. For example, in sugarcane the advent of low temperatures (which otherwise are unfavorable for growth) hastens ripening. When relatively higher temperatures prevail during ripening, cane does not ripen properly. Under these conditions, giving moisture stress by withholding water promotes ripening. Inducing drought hardiness by treating seed cane with salt solutions provides tolerance to drought to some extent. Flooding also controlled certain insect pests such as giant moth borer, *Castina licoides* [199], *Ligarus* grubs, and *Melanotus* [200]. In the scenario of global climate change, the increasing temperatures may not adversely affect the sprouting of the winter-initiated ratoon crop and its productivity.

35.6 Concluding Remarks

On the basis of the above discussions, one may conclude that the physiological, breeding, and molecular approaches will go a long way both in improving abiotic stress tolerance of sugarcane and in sustaining its productivity for the benefit of mankind. Compared to certain other less economically important crops, the research on the molecular and biochemical modifications that are involved in adaptation responses to various abiotic stresses in sugarcane are quite limited, and much more needs to be done [201]. Needless to mention that technological gains attained so far have not only to be defended but also to be improved upon to face challenges of climate change, marginalization of arable land, ever-depleting water resources, other abiotic stresses, and above all increasing human population.

Acknowledgement

Authors are grateful to Dr. R.L.Yadav, Director, Indian Institute of Sugarcane Research, for providing necessary facilities for this activity.

Sorghum: Improvement of Abiotic Stress Tolerance

Monika Dalal, Karthikeyan Mayandi, and Viswanathan Chinnusamy

Sorghum, the fifth most important cereal crop in the world, provides food, feed, fodder, fiber, and fuel. It is the second cereal crop and first C4 photosynthetic plant for which whole genome is sequenced. The importance of this crop will increase tremendously in future due to its better adaptability to abiotic stresses, which are expected to increase because of global climate change and diminishing fresh water supplies, coupled with increasing demand for food and bioenergy. The yield potential of sorghum is evident from the fact that production of sorghum has been maintained despite a steady decline in its area of cultivation over the past three decades. In fact, the true yield potential of sorghum has rarely been realized, as it is mainly grown in areas of low rainfall and resource-poor agronomic conditions. Owing to its ability to survive in water-limiting conditions, sorghum has majorly been studied for its drought resistance mechanism. The drought response in sorghum differs depending on the occurrence of stress during preflowering and postflowering. Postflowering response is associated with stay-green trait. Quantitative trait loci (QTL) for pre- and postflowering have been identified. However, the underlying genes that confer drought tolerance in sorghum have not been mapped. Moreover, other morphophysiological traits such as epicuticular wax content, osmotic adjustment, membrane stability, water use efficiency, or drought-related root traits that have been postulated to play a significant role in drought resistance in sorghum have been largely unexplored. Molecular genetic and physiological dissection of these traits will be of immense significance. Aluminum toxicity is a major problem in acidic soils. QTL and gene mapping approach led to the mapping of a Multidrug and Toxic Compound Extrusion (*MATE*) gene in sorghum. Later *MATE* family genes were identified as potential candidates that underlie aluminum tolerance QTL in maize. Since the rice, sorghum, and *Brachypodium distachyon* genome sequences are already available, and with impending maize genome sequence, there is an immense opportunity for comparative genetics and genomics to dissect abiotic stress tolerance mechanisms in cereals. This will accelerate the gene discovery among the cereal crops and will help improve other plant species as well. Thus, sorghum with its smaller genome, wide germplasm resource, well-studied genetics, C4 photosynthesis, and adaptability to

Improving Crop Resistance to Abiotic Stress, First Edition.

harsh environments represents optimal amalgamation for omics approaches to decipher drought resistance mechanism.

36.1 Introduction

Sorghum (*Sorghum bicolor* (L.) Moench) is the fifth most important cereal crop in the world after wheat, rice, maize, and barley. Known for its ability to survive harsh environments with prolonged drought period, sorghum is grown in arid and semiarid areas of the world. It is a staple food in parts of Africa and Asia and a major feed crop in the United States, Mexico, Australia, and South Africa. It has extensive variability such as grain sorghum, forage sorghum, and sweet stalk sorghum that provides food, feed, fodder, fiber, and fuel. Sorghum is produced by about 104 countries in the world. In 2009, Sorghum was grown on 43.74 million ha of land worldwide with a yield of 14 198 Hg ha^{-1} (http://Faostat.fao.org/; December 20, 2009). Average area under sorghum cultivation in Asia has declined from 26.19 million ha in the 1960s to 10.58 million ha in 2008. However, yield increased from 6935 Hg ha^{-1} in the 1960s to 10 377 Hg ha^{-1} in the late 2000s (http://Faostat.fao.org/ ; December 22, 2009). The yield potential of sorghum is evident from the fact that production of sorghum has been maintained despite a steady decline in its area of cultivation. In fact, the true yield potential of sorghum has rarely been realized, as it is grown mainly in areas of low rainfall and resource-poor agronomic conditions. Its ability to yield under such agronomic and adverse climate conditions is a proof of concept that sorghum is the crop of the future.

In the changing global scenario, the world population is expected to rise from present 6.6 billion to 8.7–11.3 billion in 2050 [1]. The global demand for cereal production will also increase by 60% [2]. This task is challenging as the yield potential of cereal crops has reached its plateau, and there is reduction in cultivable land and availability of fresh water for irrigation. These problems are further exacerbated by global climate change-associated increase in the frequency of heat stress, droughts, and floods that negatively affect crop yields [3]. Ability of crops to adapt and yield under such harsh environment will be crucial in determining the sustainability of food production in days to come. This will require a combination of adaptive agricultural strategy that includes new management and agronomic practices and further improvement in the genetic potential of productivity and abiotic stress resistance of crops. This also implies that lessons need be learned from plants that show high adaptability and tolerance to abiotic stresses.

Sorghum belonging to genus *Poaceae* and subfamily Panicoideae shares the tribe Andropogoneae with other major crops such as maize, sugarcane, and millets. The Andropogoneae species are native to tropical and subtropical climates, and are characterized by C4 photosynthesis, high rates of carbon fixation, high water and nutrient use efficiency, high biomass productivity, adaptation to diverse

environments, and have both annual and perennial life cycles. However, many of these species are polyploids with large complex genomes. Sorghum, besides having all the advantageous characteristics, has a diploid genome that is already sequenced [4]. Moreover, with its well-studied genetics, wide germplasm resource, lower level of gene duplication compared to other tropical cereals, and amicability for genetic transformation, sorghum can be an ideal system especially for grasses and plant genomics research as a whole.

36.2 Abiotic Stress Tolerance

Abiotic stresses limit the growth and productivity of crop plants to variable degrees depending on the time of onset, duration, and intensity of stress. It has been estimated that crops attain only about 25% of their potential yield because of the detrimental effects of environmental stresses [5]. During the second half of twentieth century, increase in crop productivity by plant breeding efforts kept in pace with the food demand of the increasing world population. This was achieved mainly by breeding programs aimed at increasing yield potential and disease resistance. However, the progress in breeding for abiotic stresses has been very slow as, first, the mechanism of abiotic stress tolerance was poorly understood and, second, the breeding in the past 50 years was more yield oriented [6]. Since the relative rate of yield increase for major crops such as rice and wheat is declining [7], there is a need to adopt and intensify the physiological trait-based molecular breeding approach for breeding abiotic stress-tolerant crops [8]. Physiological breeding, also known as analytical breeding, refers to selection for secondary traits that are associated with higher yield under optimal and/or abiotic stress environments [6]. On the basis of the physiological traits that contribute to yield in soil moisture-deficit environments, a general model for drought adaptation of wheat was proposed [8]. The model describes four main groups of traits relating to (i) preanthesis growth, rapid ground cover to shade the soil to prevent evaporation, and high assimilation capacity between jointing and lag phase, to permit accumulation of stem carbohydrates; (ii) high rooting depth and/or intensity to access water that would be expressed by a relatively cool canopy or favorable expression of water relation traits; (iii) water use efficiency (WUE), photosynthesis associated with refixation of respiratory CO_2; and (iv) photoprotection including energy dissipation, antioxidant systems, and anatomic traits such as leaf wax [8]. Though these traits have been proposed for wheat *per se*, it may apply to any crop improvement program aimed at drought tolerance. Yet not all the crops will have the best amalgamation of these traits. Sorghum with its stay-green trait, deep rooting system, better WUE, C4 photosynthesis, and high epicuticular wax (EW) represents one good system to study physiological traits related to drought tolerance. However, genetic and molecular analyses of these traits are in its infancy. The chapter describes the progress in abiotic stress tolerance research and prospects for genetic improvement of sorghum. It includes the physiological trait-based studies conducted in

sorghum in relation to drought, followed by cold, salt, and aluminum tolerance and the genetic and genomic resources for further progress in crop improvement in sorghum.

36.2.1 Drought Tolerance

Drought stress is one of the most critical stress affecting plants. Drought can be defined in multiple ways, be it meteorological, hydrological, or socioeconomical context. When drought is defined in relation to crops or agriculture, it refers to shortage of water in the root zone that reduces yield [9]. When a genotype yields higher than another genotype under severe drought, it is ranked relatively more drought tolerant.

Plants deal with stress in three different ways, namely, escape, dehydration avoidance, and dehydration tolerance. Drought escape is defined as the ability of a plant to complete its life cycle before severe soil and plant water deficit develops. Escape mechanism involves rapid phenological development (early flowering and early maturity) and developmental plasticity (variation in duration of growth period depending on the extent of water deficit). Dehydration avoidance is defined as the ability of plants to sustain high plant water status or cellular hydration under drought conditions. Crop plants avoid dehydration by enhanced capture of soil moisture by efficient root system and osmotic adjustment (OA), by limited crop water loss from transpiration and other nonstomatal pathways such as through the plant cuticle, reduced absorption of radiation by radiation reflection, and leaf rolling/folding or drying. Dehydration tolerance is defined as the capacity to sustain or conserve plant function even in relatively low tissue water potential. Cellular water deficit stress tolerance in plants depends on modification of metabolism, production of organic compatible solutes (proline, sugars, polyols, betaine, etc.), and expression of genes involved in membrane integrity, cellular homeostasis (ionic-, osmotic-, and metabolic homeostasis), stress damage control, and repair.

Traits associated with avoidance and tolerance can be constitutive (intrinsic traits that express constitutively) or adaptive (traits that express in response to stress). Depending on the occurrence of stress at vegetative or reproductive stage, sorghum exhibits preflowering and postflowering stress response, respectively. These two responses are apparently controlled by different genetic mechanisms [10]. Preflowering stress affects biomass, panicle size, grain number, and grain yield [11], while postanthesis drought leads to premature leaf and stem senescence, lodging, and reduced seed size [12]. Postanthesis drought also increases susceptibility of plants to biotic stresses such as charcoal rot (*Macrophomina phaseolina* (Tassi) Goidanich) and fusarium stalk rot (*Fusarium moniliforme* J. Sheld.) [12].

For preflowering drought tolerance, six distinct genomic regions were identified in sorghum recombinant inbred lines (RILs) derived from the cross between Tx 7078 (preflowering-tolerant, postflowering-susceptible) and B35 (preflowering-susceptible, postflowering-tolerant) genotypes [13]. These loci accounted for approximately 40% of the total phenotypic variation in yield under preflowering drought and were

detectable across a range of environments. Kebede *et al.* [14] identified four quantitative trait loci (QTL) associated with preflowering drought tolerance in sorghum from RILs derived from the cross, SC 56 × Tx 7000. The major QTL influencing preflowering drought stress tolerance accounted for 15 and 37.7% of the phenotypic variance under two different environments, suggesting a strong G × E interaction at this loci.

36.2.1.1 **Stay Green**

Postflowering drought response is associated with stay-green trait in sorghum. Stay green is basically retention of green leaf area at maturity (GLAM). Maintenance of stay-green trait during grain-filling stage under soil moisture-deficit stress condition constitutes an important component of drought tolerance [15]. The stay-green phenotype has been classified into five types [16]. In type A stay green, the initiation of senescence is delayed, but proceeds at the same rate as the wild type. Type B stay green initiates senescence at the same time as the wild type, but senescence proceeds at slower rate. The above two types are regarded as functional stay green as retention of greenness is associated with extended photosynthetic activity during grain filling. On the other hand, type C or "cosmetic" stay green retains chlorophyll almost indefinitely; however, the photosynthetic rate declines. Type D stay green is the greenness retained after the leaf death by abrupt freezing or drying. Finally, type E stay green contains higher chlorophyll content to begin with, but follows senescence at normal time and rate.

Functional stay green can be of immense importance as it has been correlated with higher grain filling and increased yield under postanthesis drought [12]. Moreover, there is no yield penalty associated with stay green under nondrought conditions [12]. Stay green has also been associated with higher leaf nitrogen content [17, 18], reduced lodging [12], lower susceptibility to charcoal rot [19], and higher levels of stem carbohydrates both during and after grain filling [12]. Thus, stay green contributes to various aspects of crop improvement and hence is a valuable trait for crops like sorghum where primary harvest can be grain, forage, juice, and/or fodder.

In sorghum, different stay-green sources are available that include B35 (BTx 642), SC 56, E36-1, and KS19 [14, 20–22]. In breeding, B 35 and KS 19 are the two main sources used for stay green [20]. These two genotypes represent two different types of functional stay green: B 35-derived lines have a greater leaf area at flowering and a normal rate of leaf senescence, whereas KS 19-derived lines have a smaller leaf area at flowering and a slower rate of leaf senescence [12]. Although the ability of leaves to delay senescence has a genetic basis in sorghum, the expression of the character is strongly influenced by environmental factors [23]. The selection for trait depends upon the occurrence of a prolonged period of drought stress during the grain-filling period to accelerate normal leaf senescence. Genetic studies also showed that stay-green trait is governed by genes that act at varied levels of dominance or additive effects. For instance, the inheritance of the onset of senescence was additive, but a slow senescence rate was found to be dominant over a fast rate [23, 24]. Furthermore, the three components of stay-green trait, namely, green leaf area at flowering, time of

Table 36.1 Summary of studies related to identification of QTL for stay-green trait in sorghum.

onset of senescence, and subsequent rate of senescence also appear to be inherited independently [12, 23].

Several studies have mapped QTL contributing to the stay-green trait (Table 36.1). Most of these studies used B35 or derivatives of B35 as the stay-green source [25–29]. These studies led to identification of four major QTL, namely, *Stg1*, *Stg2*, *Stg3*, and *Stg4*. QTL *Stg1* and *Stg2* are located on LG-03, *Stg3* on LG-02, and *Stg4* on LG-05, and account for 20, 30, 16, and 10% of the phenotypic variance, respectively [11, 27]. Among these, *Stg2* was found to be the most important QTL, followed by *Stg1*, *Stg3*, and *Stg4* [27]. *Stg2* was consistent in all the environments, in different genetic backgrounds, and explained the highest percentage of phenotypic variation (~30%) in three different studies [26–28]. The near-isogenic lines (NILs) derived from the cross between B35 and RTx 7000 were evaluated under drought conditions at postflowering stage for their expression of stay-green phenotype. Physiological analysis of four NILs containing individual QTL, namely, *Stg1*, *Stg2*, *Stg3*, or *Stg4*, showed that B35 alleles in each of these loci could contribute to the stay-green phenotype. It was found that NILs having the genomic DNA of B35 spanning the region of the *Stg2* were performing better than NILs having other QTL. NILs with *Stg2* were showing higher GLAM and SPAD values and lesser rate of leaf senescence over others [30].

Stay-green expression is affected by the degree of stress during grain filling, and other factors such as flowering time and sink strength. It can be better manipulated using a marker-assisted breeding approach [31]. Therefore, efforts have also been initiated to transfer this trait through marker-assisted backcrossing (MABC) into elite cultivars and study their expression in different background [22, 31]. However, precision of marker-assisted breeding depends on how tightly the markers are linked to the genes or QTLs involved. Therefore, fine mapping of stay-green QTL still remains a prerequisite. Fine mapping of QTL can be achieved by increasing marker

Table 36.2 List of selected genes in the corresponding *Stg2* QTL region of BTx623 (http://www.phytozome.net).

density within the chromosomal region of interest and/or increasing the number of segregating population for which phenotypic information can be obtained. With available genome sequence and genomics tools, increasing the marker density appears to be more straightforward approach. Many sequence-based markers (namely, SNPs) can be made. That will further help in fine-mapping the QTL. Simultaneously, integrated genomic approaches can be used for deciphering the stay-green trait in sorghum. For instance, location of *Stg2* on available physical map of sorghum between markers RZ323 and WG889 [27, 28] in third chromosome of sorghum consists of more than 200 genes (Table 36.2). Some of these genes are predicted to function in important physiological processes such as photosynthesis, leaf senescence, and abiotic stress response (Table 36.2) that may contribute to the stay-green phenotype. Expression profile of these putative candidate genes can be correlated with the stay-green trait. This will narrow down the search for genes responsible for the trait.

On the basis of *in silico* comparative genome analysis, a few markers have already been developed in *Stg* QTL of sorghum [32]. Moreover, QTL for stay-green trait in wheat and rice have also been identified [33, 34]. Hence, comparative studies can be used to expedite the process of identifying genes responsible for stay green not only in sorghum but also in other cereals.

In addition to functional stay-green genotypes, stay-green mutants are also reported in many different species including rice [35], soybean [36], tomato [37], *Phaseolus vulgaris* [38], pepper [39], *Festuca pratensis* [40], and so on. The impetus on

identifying gene responsible for stay-green phenotype in these mutants started with the finding of a single recessive nuclear gene, *sgr (t)*, from a rice mutant [35]. Later, two research groups reported that s*gr* is a senescence-associated gene encoding a novel chloroplast protein. It was shown that the stay greenness of the *sgr* mutant was associated with a failure in the destabilization of the light-harvesting chlorophyll binding protein (LHCP) complexes of the thylakoid membranes, which is a prerequisite event for the degradation of chlorophyll and LHCPs during senescence [41, 42]. This was followed by identification of orthologous genes responsible for the stay-green character in other mutants that include Mendel's *green cotyledon* mutant in pea, *green-flesh* (*gf*) and *chlorophyll retainer* (*cl*) mutations of tomato and pepper, respectively [43, 44]. Though *sgr* has been associated with type C or cosmetic stay-green phenotype, yet it gives an insight into the mechanism of dismantling of photosynthetic chlorophyll–apoprotein complexes. It also implies that if found orthologous in nature, identification of functional stay-green genes in one species will speed up their elucidation in other cereal crops as well.

36.2.1.2 **Epicuticular Wax**

Epicuticular wax forms an outer visible glaucous coating on many crop plants called as waxy bloom or bloom. The accumulation of wax varies greatly depending on species, organ, stage of development, and environmental conditions. EW is highly diverse in composition and structure. Its hydrophobic composition and distribution on many aerial organs of plants has been considered a potentially useful trait and has been associated with resistance to many diverse environmental stresses including drought, insect, and disease resistance [45–47].

Sorghum is distinct from other cereal crops due to its ability to produce profuse amount of epicuticular wax (EW or bloom) that is deposited on abaxial leaf blade and sheath and culms, especially during preflowering and at maturity stages. The wax composition of sorghum leaf sheath shows highest (96%) level of free fatty acids with chain length varying from 16 to 33 carbons, of which C28 and C30 represent 78 and 20% of the constituents, respectively [48]. Moreover, sorghum as a species has been reported to produce one of the highest amounts of leaf EW among cereal crops. Burow *et al*. [49] reported that on a per unit leaf area basis, sorghum produces an average of 1.9 mg dm^{-1}, while the reported value for rice (*Oryza sativa* L.) is 0.05 mg dm^{-1} [50]. Similarly, on per unit weight basis, sorghum produces approximately 52.7 mg g^{-1} wax, which is 3-fold higher than that of maize (17.0 mg g^{-1}) [51] and 1.5–2-fold higher than that of durum wheat (25–35.7 mg g^{-1}) [52].

The most common plant waxes are very long-chain aliphatic molecules, of mainly 16–34 carbons in length, that occur as free fatty acids, aldehydes, primary alcohols, alkanes, and esters [53]. However, there exists a difference in the biosynthetic pathway depending on the carbon length. Synthesis of fatty acids with 16 carbons or less, acyl chains is activated by a soluble plastidic acyl carrier protein (ACP) and elongated by a fatty acid synthase (FAS) complex that condenses acetyl groups from malonyl-ACP to growing acyl-ACP chains [54]. Acyl-CoA of 16C or 18C chain length is exported from plastid into endosplasmic reticulum for long-chain acyl-CoA

synthesis. Acyl chains that serve as direct wax precursors are activated by coenzyme A (CoA) and elongated by membrane-associated enzyme complexes called fatty acid elongases [55]. Elongases use malonyl-CoA as the two carbon donors instead of malonyl-ACP. Once synthesized, the very long acyl-CoA chains are catalyzed by other enzymatic reactions and form free acids, esters, aldehydes, and alkanes that constitute the EW [48]. Thus, being involved in early steps in the wax metabolic pathway, acyl-CoA elongases may serve as rate limiting and highly regulated reactions, and hence plays a pivotal role in overall plant cuticular wax biosynthesis [56]. Genetic analysis of *Arabidopsis* mutant led to the identification of two enzymes of FAE complex, namely, *ECERIFERUM6* (*CER6*, β-ketoacyl-CoA synthase) and *CER10* (enoyl-CoA reductase). CER4, fatty acyl-CoA reductase, synthesizes primary alcohol from very long-chain fatty acids. The WSD1, wax synthase/fatty acyl-CoA: fatty alcohol acyltransferase synthesizes wax esters. Most of this information on biosynthetic pathway of plant EW has been built on genetic analysis of *Arabidopsis* mutants [57]. Though a few genes have now been isolated and characterized in rice and maize [47, 58], none of the genes has been characterized at molecular level in sorghum. However, there have been some detailed genetic studies on chemically induced mutants in sorghum [48, 59, 60]. These mutants were designated *bloomless* (*bm*), which completely lacked visible waxes on sheath surfaces and *sparse-bloom* (*h*), those with reduced visible sheath waxes [59]. *bm* and *h* wax mutants produced significantly low wax load compared to wild type. It was found that all the 12 *bm* mutants had a reduction in the amount of C28 and C30 fatty acids that resulted in the reduction of total wax load relative to wild type [48]. On the basis of composition analysis, it was suggested that these sorghum mutants may have lesions that affect either C26 acyl-CoA elongation or acyl-CoA thioesterases. The molecular identity of these mutant loci still remains unknown. These wax mutants can be exploited for elucidating genes involved in the biosynthesis of the very long-chain fatty acids. Recently, a mapping population developed from a cross between BTx623 (wild type with profuse wax) and KFS2021 (a mutant with greatly reduced wax) was used for molecular mapping and characterization of a locus associated with production of profuse wax *BLOOM-CUTICLE* (*BLMC*) in sorghum [61]. The locus mapped to the terminal end of sorghum chromosome 10 was delimited to as small as 0.7 cM region. The analysis of putative genes in the *BLMC* region revealed the presence of an acyl CoA oxidase (a gene involved in lipid and wax biosynthesis) and seven other putative transcripts, among others [61]. Next to stomata, water loss from plants occurs through its cuticle. High cuticular wax minimizes nonstomatal water loss from the plants. The bloomless F_2 progenies of the cross showed a significant negative correlation between leaf epicuticular wax load with epidermal permeability and night-time conductance, suggesting that epicuticular wax may enhance water use efficiency of sorghum by regulating night-time water loss [49]. In addition to disrupting the epicuticular wax production, *blmc* mutation also reduced culm and leaf cuticle, and increased plant death rate in the field at anthesis [61]. This phenotype was similar to *bm22* mutant reported by Jenks *et al.* [60]. The *bm 22* mutant reduced both epicuticular wax and cuticle deposition that in turn was associated with increased epidermal conductance to water vapor and increased susceptibility to the

funga1 pathogen *Exserohilum turcicum* [60]. Thus, there seems to be a link between the pathways of epicuticular wax synthesis and cuticle formation. Cutin synthetic enzymes use C16 and C18 acyl-CoA pools as precursors, potentially the same precursors used in wax synthesis. As cuticle is involved in several different functions including inhibition of uncontrolled permeation of water, solutes, and gases, and protection from phytopathogens and so on, identification and characterization of gene affecting both cuticle and epicuticular wax can be of significant importance for both biotic and abiotic stress tolerance of sorghum.

36.2.1.3 **Osmotic Adjustment**

Osmotic adjustment and antioxidant capacity are the two traits that have been associated with drought tolerance mechanisms. OA refers to the lowering of osmotic potential due to the net accumulation of compatible solutes in response to water deficits. These compatible solutes may be various amino acids (e.g., proline), sugars (e.g., sucrose and fructans), polyols (e.g., mannitol and pinitol), quaternary amines (e.g., glycine betaine), ions (e.g., potassium), and organic acids (e.g., malate and citrate) [62]. There is a wide variation in OA in crop plants, and the solutes accumulated also differ by plant species [63]. Osmotic adjustment is an inherited trait and has been associated with sustained yield in water-limiting conditions in many crop plants [15]. In sorghum, two independent major genes (*OA1* and *OA2*), with some minor effects, have been reported to control the inheritance of OA in sorghum [64].

Glycine-betaine (GB) is an important osmoprotectant and its role in abiotic stress tolerance is demonstrated in several plant species. GB stabilizes the quaternary structure of proteins, stabilizes highly ordered state of membranes, and reduces lipid peroxidation under stress [65]. Betaine aldehyde dehydrogenase and choline monooxygenase catalyze the synthesis of GB in a two-step oxidation of choline via the intermediate betaine aldehyde. In sorghum, expression of *BADH1* and *BADH15*, encoding betaine aldehyde dehydrogenase, was found to be induced by water deficit and their induced expression coincided with GB accumulation [66]. Among cereal crops, maize and sorghum synthesize GB, while rice does not [67]. Moreover within maize and sorghum, there are certain genotypes that do not accumulate GB [68, 69]. To study the GB accumulation in sorghum, near-isogenic lines (NILs) that differ in their ability to accumulate GB were analyzed [69]. Labeling studies in sorghum demonstrated that the deficiency in GB accumulation was at the choline oxidation step [69]. However, a recent study suggests that low GB accumulation may not be due to the absence of choline monooxygenase; rather, it may be due to the nonavailability of substrate or lack of choline transporter [70]. Thus, mechanism of GB synthesis and accumulation in these lines of sorghum and maize still remains an enigma.

Besides GB, other solutes such as proline, K^+, sugars, Cl^-, and P, were also reported to contribute to osmotic adjustment in sorghum [66, 71]. Since phenotyping for OA trait is difficult due to methodological constrains of OA evaluation, it will be important to map OA QTL for different solutes, which can be transferred by marker-assisted selection (MAS) or transgenic approach to incorporate this trait for improvement of OA and osmoprotection in sorghum.

36.2.2
Cold Tolerance

Sorghum being native to tropical and subtropical regions of Africa [72] is well adapted to warm growing conditions. Cool temperatures during the early growing season are, therefore, a major limitation to growing sorghum in temperate areas. The development of sorghum cultivars with improved early-season cold tolerance would allow expansion of sorghum to these more northerly latitudes and would also allow for earlier planting in areas where it is being grown [73]. Moreover, improved emergence and early-season vigor would enable better stand establishment and protect against loss of seedlings during unexpected cold periods that are likely to become frequent due to climate change scenario. Though most of the available sorghum germplasm is of tropical origin, some of the sorghum landraces from temperate regions of China, referred to as "kaoliang," exhibit higher seedling emergence and greater seedling vigor under cold conditions than most sorghum cultivars [74–76]. However, these races lack desirable agronomic characteristics. Hence, efforts are being made to introgress desirable genes from Chinese landraces into elite lines by marker-assisted selection. A population developed from a cross between Chinese landrace "Shan Qui Red" (SQR, cold tolerant) and SRN39 (cold sensitive) was employed for QTL analysis of early-season cold performance in sorghum [77]. Two QTL, one on linkage group SBI-03 and the second on group SBI-07, for germination under cold and optimal temperatures were identified. Another QTL located on linkage group SBI-01 showed strong association with seedling emergence and seedling vigor scores under early and late field planting. The three QTL were validated across two populations [78]. Hence, these can be useful for marker-assisted breeding to improve early-season performance in sorghum.

36.2.3
Salt Tolerance

Salinity is one of the major abiotic stresses that adversely affect crop productivity and quality [5]. Saline soil is characterized by toxic levels of chlorides and sulphates of sodium. The problem of soil salinity exists in both irrigated and dry areas. In irrigated areas, poor quality of water or improper drainage or entry of seawater in coastal areas contributes to salinity. In arid and semiarid regions, it is the high evaporation and insufficient leaching of ions due to inadequate rainfall that leads to high salt accumulation in root zones [79]. Salinity restricts plant growth due to nutritional constrains, ion toxicity, and osmotic stress. Though sorghum has been characterized as moderately tolerant, it is more tolerant than maize [80, 81]. Moreover, its better suitability in arid and semiarid regions also makes it a suitable target for improvement in salt tolerance. The mechanism of salt tolerance has been studied in detail (reviewed in Refs [79, 82]), yet the complex genetic mechanism is a big hurdle to improvement of salt tolerance. In sorghum, diallel analysis, based on relative root length in salt-treated and control plants, showed both additive and dominance effects of NaCl [83]. A large genotypic variation for tolerance to salinity in sorghum has been reported [83–86]; however, no detailed studies have been carried out. Therefore, there is a need to explore this area of stress tolerance in sorghum.

36.2.4
Aluminum Tolerance

Aluminum (Al) is a light metal that makes up 7% of the Earth's crust and is the third most abundant element after oxygen and silicon [87]. Most of this Al occurs in the form of harmless oxides and aluminosilicates with only small amounts present in soluble forms in the rhizosphere. However, under acidic condition of soil (pH < 5), Al is solubilized into the phtotoxic trivalent cation, Al^{3+}. Aluminum toxicity primarily affects the root growth resulting in limited absorption of water and mineral nutrients [88], leading to a significant reduction in the quality of the grains on acid soils [89]. Acidic soil accounts for up to 50% of the world's potentially arable soils [90], of which larger part comes from tropic and subtropic areas of developing countries. A significant variation in Al tolerance is reported within some species [89]. In barley, Al tolerance appears to be monogenic [91], while in rice it is a quantitative trait [92]. Al tolerance is either simply inherited as single dominant gene in some genotypes of wheat or involves action of more than one gene in other genotypes [93–96].

Plants have evolved two physiological mechanisms to resist the effect of Al toxicity in acidic soils: exclusion of Al from the root apex and chelation mechanism. Exclusion mechanism is based on the external detoxification of Al, which protects the root apex against Al penetration. This is achieved by the secretion of organic acids from the root apex to the rhizosphere that modifies the pH and chelates the toxic Al^{3+} [97]. Chelation mechanism works on compartmentalization of aluminum ions by specific proteins, short-chain organic acids, phenolic compounds, and tannins that can bind and form complexes with Al^{3+}. These complexes are subsequently compartmentalized in the vacuole, thus reducing Al toxicity [98–100]. Among the two mechanisms, Al-activated exudation of organic acid – anions – from root apices is the best documented and characterized plant Al tolerance mechanism [87]. The exudation of organic acid may be species specific, such as malate from Al-tolerant cultivars of wheat [101], citrate from Al-tolerant cultivars of maize [102] and soybean [103], and oxalate from buckwheat [104] and taro [105]. However, some species such as *Secale cereale* (rye) may show exudation of both malate and citrate [106].

Transport of these organic acids occurs via anionic channels, the opening of which may be activated by Al. The first such transporter *ALMT1* (aluminum-activated malate transporter 1), responsible for malate efflux, was identified in wheat [107]. *ALMT1* represented a new family of membrane proteins and mapped to chromosome 4DL, corresponding to Alt_{BH}, a major aluminum tolerance locus in wheat and other members of the Triticeae tribe [108]. A new thrust came in to the Al tolerance research when Magalhaes *et al.* [109] reported a single locus, Alt_{SB}, which accounted for 80% of the Al tolerance phenotype in sorghum mapping population. Interestingly, the locus Alt_{SB} mapped on the sorghum chromosome 3, which is not homologous to the Triticeae group 4 chromosomes. Comparative mapping studies indicated that a major Al tolerance QTL on rice chromosome 1 might be orthologous to Alt_{SB}, whereas another QTL on chromosome 3 is likely to correspond to the Triticeae group 4 Al tolerance locus [109]. Therefore, it appeared that in rice that is one of the most Al-tolerant grasses [92, 110], the quantitative inheritance of Al tolerance may be a result of

two major QTL, which act as two independent and distinct major Al tolerance genes in Andropogoneae and Triticeae [109]. As Alt_{SB} appeared to be distinct from Alt_{BH}, positional cloning of Alt_{SB} was taken up that led to the identification of the gene encoding aluminum-activated citrate transporter, a member of the multidrug and toxic compound extrusion (*MATE*) family from sorghum [111]. Transgenic expression of *SbMATE* gene conferred Al tolerance in both *Arabidopsis* and wheat [111]. Simultaneously, in the same year another MATE protein, *HvAACT1*, an Al-activated citrate transporter that confers Al tolerance to barley, was reported [112]. MATE proteins are members of a large and complex family of transporters; functional members of this family were found first in prokaryotic organisms and later in eukaryotic organisms and are generally involved in the efflux of small organic solutes. Their identification in sorghum and barley subsequently led to the identification of several other plant MATE members that were implicated in citrate transport. These include *OsFRDL1* from rice [113], *AtMATE* from *Arabidopsis* [114], and *ZmMATE1* in maize [115], and a *MATE* gene implicated in citrate efflux has also been reported from wheat [116]. Though overall studies indicate that Al tolerance in plants is predominantly contributed by orthologous series of at least two major loci, detection of additional QTL or genes in the genomes of maize [117], rice [92], oat [118], and rye [119] indicates that these Al tolerance genes may also play a role in Al tolerance of plants.

In sorghum, Al tolerance appears to be a function of both allelic heterogeneity and nonallelic heterogeneity [120]. A wide range of phenotypic variation for Al tolerance was found, which was attributed to multiple alleles of Alt_{SB}. Even the two most tolerant sorghum cultivars, SC283 and SC566, which were found to rely on Alt_{SB} for their tolerance [109], showed a distinct phenotype, SC566, being significantly more tolerant than SC283 indicating that the SC566 allele is stronger than the SC283 allele [120]. As the correlation between *SbMATE* expression and Al tolerance in a panel having allelic diversity at the Alt_{SB} locus was highly significant [111], it was suggested that these allelic effects in part may be regulatory in nature. Moreover, transgressive segregation was also observed in a highly Al-tolerant breeding line, indicating the role of additive or codominant effects in sorghum Al tolerance [120]. Though identification of these nonorthologous and additive aluminum tolerance genes remains to be explored, the major gene Alt_{SB} from sorghum has been instrumental in revealing a new mechanism of aluminum tolerance in plant species. The major gene effect and allelic diversity at the Alt_{SB} locus can be exploited for improving Al tolerance of sensitive sorghum genotypes and other species.

36.3
Genetic and Genomics Resources of Sorghum

36.3.1
Germplasm Resources and Genetic Diversity

The plant genetic resources are defined as the "Genetic material of plants that is of value as a resource for the present and future generations of people" [121]. All

accessions of a particular crop species are expected to contain essentially the same genes. Differences in agricultural performance between accessions are thought to be due to allelic differences within the same gene set. Thus, genetic diversity in a crop is an important asset for improvement of its adaptive and agronomic traits. Genetic diversity is essential both for evolutionary history and for future evolutionary trajectory of a species. Most of the modern cultivars are having narrow genetic base making them vulnerable to potentially new biotic and abiotic stresses, the best example being the 1970 southern corn leaf blight (*Bipolarise maydays*) epidemic [122]. With a changing global climate scenario, exploitation and preservation of genetic diversity may become more evident for survival and sustainability of a crop.

Sorghum is a highly diverse species. There are three *S. bicolor* subspecies, cultivated types (ssp. *bicolor*), wild (ssp. *verticilliflorum*), and weedy types that are product of hybridization between domesticated and wild sorghums (ssp. *drummondii*). Furthermore, within ssp. *bicolor*, there are 5 races (i.e., bicolor, caudatum, durra, guinea, and kafir) and 10 intermediate races have been described on the basis of panicle and spikelet morphology [123]. Sorghum genetic resources are conserved at many centers around the world including India, China, the United States, Ethiopia, Sudan, and South Africa. At the global level, sorghum germplasm collections consist of approximately 168 500 accessions. International Crops Research Institute for Semi-Arid Tropics (ICRISAT), India, is a major repository for world sorghum germplasm with a total of 37 000 accessions from 91 countries [124]. To facilitate enhanced utilization of diverse germplasm in breeding program, a core collection of 2247 accessions was developed in 2001 [125]. As this core collection was found to be too large, a sorghum minicore with 242 accessions (10% of the core or 1% of the entire collection) was developed from the existing core collection [124]. A minicore collection thus may help in a precise evaluation and phenotyping for various traits.

Different molecular markers (RFLP, RAPD, AFLP, or SSR) have been used for molecular analysis of genetic diversity in sorghum germplasm [126–131]. These studies revealed that genetic diversity in sorghum is mostly influenced by racial and geographic origins [126, 127, 129, 131]. A worldwide core collection of 210 landraces representative of race, latitude of origin, response to day length, and production system was analyzed with 74 restriction fragment length polymorphism (RFLP) probes dispersed throughout the genome indicating that along with the geographical and racial genetic diversity, there were varying levels of diversity within specific morphological races. Among races, the highest diversity was exhibited by bicolor race and least by kafir [132].

36.3.2
Genetic Maps and QTL Mapping

Several studies identified QTL associated with various traits in sorghum including disease resistance [133], insect resistance [134], plant height and maturity [135], and drought tolerance (references given in Section 36.2.1). Two high-density linkage maps are also available [136, 137]. The linkage map created by Menz *et al*. [136] consists of 2926 loci on 10 linkage groups with a total genetic distance of 1713 cM, while map

developed by Bowers *et al*. [137] contained 2512 loci on 10 linkage groups, with a total genetic distance of 1059.2 cM. Later, these two maps have been aligned by identifying and mapping markers common to both populations [138]. On the basis of fluorescent *in situ* hybridization (FISH) of sorghum genomic BAC clones, a size-based nomenclature for sorghum chromosomes (SBI-01–SBI-10) and linkage groups (LG-01–LG-10) has been proposed [139]. A unified system of nomenclature for chromosome and linkage maps will benefit the validation and comparison of QTL across different backgrounds and environments. Recently, using the genome sequence more than 6500 simple sequence repeat (SSR) loci with publicly available primer sequences have been mapped *in silico* on sorghum genome [140]. This will facilitate the identification of markers representing the entire genome, which in turn will not only improve resolution in diversity analyses and linkage disequilibrium mapping but also help in fine mapping and marker-assisted breeding. Besides standard molecular markers such as RFLP and SSR, a new hybridization-based diversity array technology (DArT™) has also been developed for sorghum [141]. Recently, six-component mapping populations were used to integrate over 2000 unique loci, including 1190 unique DArT markers and 839 others, into a single consensus map with an average marker density of one marker/0.79 cM [142]. This consensus map, however, still has overall lower marker density compared to that one marker/0.59 cM and one marker/0.42 cM published by Menz *et al*. [136] and Bower *et al*. [137], respectively. DArT provides the advantage of being a cost-effective, high-throughput marker technology that is independent of sequence information and allows high multiplexing level for whole genome profiling.

36.3.3
Association Genetics

Association mapping, also called linkage disequilibrium (LD) mapping, refers to the analysis of statistical associations between genotypes, usually individual single-nucleotide polymorphisms (SNPs) or SNP haplotypes, determined in a collection of individuals, and the traits (phenotypes) of the same individuals [143]. First developed for human genetics, association genetics has now been used for dissecting complex traits in crop plants [144]. In plants, a collection of individuals refers to those that are derived from wild populations, germplasm collections, or subsets of breeding germplasm. The levels of genetic variation and linkage disequilibrium (LD) are critical factors both in association mapping and in identification of loci that have been targets of selection. Sorghum being largely a self-pollinating crop is expected to have higher levels of LD and homozygosity, which are suitable parameters for LD mapping [145]. Analysis of 27 diverse *S. bicolor* accessions for sequence variation at about 30 000 sites throughout the genome of *S. bicolor* indicates that the frequency of SNPs is about one-fourth of that observed in a comparable sample of maize accessions [146]. The extent of allelic associations, as assessed by pairwise measures of LD, is higher in *S. bicolor* than in maize, but lower than in rice and *Arabidopsis*. Hamblin *et al*. [147] demonstrated that in sorghum LD could extend up to 100 kb, but had largely decayed by 15 kb, meaning that targeted association mapping is possible in this species. To facilitate the association studies in sorghum, Casa *et al*. [148] have

characterized a panel of 377 accessions. These accessions were phenotyped for eight traits, and levels of population structure and familial relatedness were assessed with 47 SSR loci. The genotypic data for this panel along with appropriate statistical models for correcting for population structure and kinship are available for the entire sorghum community. Furthermore, efforts are being made to develop recombinant inbred populations for carrying out nested association mapping strategies in sorghum [148]. Recently, a few candidate gene-based association studies have been reported for various traits in sorghum such as plant height, brix, starch metabolism, and grain quality [149–152]. However, for complex quantitative traits such as drought stress, a genome-wide association mapping may be more useful. This will also require a genome-wide coverage of markers. Owing to their high density, SNPs play an important role in genome-scale linkage disequilibrium and association studies. About 1402 SNP alleles were reported by Hamblin *et al.* [146, 147, 151] through direct sequencing, while 2217 SNPs were detected in sorghum from analysis of loci from public EST databases [153].

36.3.4
Transcriptomics and Reverse Genetics

Besides sequence-based information, adaptive responses of sorghum have been monitored by genome-wide expression analysis under different stress conditions such as salinity, osmotic stress, or abscisic acid [154]. In addition, a sorghum Expressed Sequence Tags (ESTs) project has collected over 200 000 sequences from cDNA libraries derived from diverse tissues [155] and by December 2010, 209 828 ESTs were available at EST database of National Center for Biotechnological Information (NCBI). Various *in silico* genome-wide analyses of genes, promoters, or miRNAs are being performed that will help in identification and characterization of existing and new orthologues of these sequences [156, 157].

Additional resources for sorghum include mutant populations that are either being screened for target traits such epicuticular wax [158] or being developed as TILLING populations [159]. A TILLING population of 1600 lines has also been generated through EMS mutagenesis in sorghum genotype BTx 623 and its applicability has been evaluated on a subset of mutant lines [159]. Isolation of *Candystripe1* (*Cs1*), first active transposable element from sorghum, has potential for insertion mutagenesis and transposon tagging in sorghum [160]. The possibility of genetic transformation in sorghum [161–163] provides equal opportunities for both functional validation and crop improvement strategies. Moreover, the results of interspecific hybridization have been encouraging that will allow inclusion of allelic diversity in cultivated sorghum [164, 165].

36.3.5
Comparative Genomics

Besides using its own genetic and genomic resources, sorghum can be benefited by the high degree of genic colinearity and sequence conservation that prevails among

cereals [166, 167]. The syntenic relationship of sorghum with other cereals has become instrumental in the construction of genetic maps, verification of certain quantitative trait loci, identification of candidate genes underlying QTL, and genome evolution [109, 168–170]. Postgenome sequencing, enormous information is emerging from rice. The knowledge gained from rice can be used to accelerate progress in sorghum and sorghum in turn can benefit closely related large genomes such as maize and sugarcane. For example, analysis of miRNA in sorghum genome indicates that rice miRNA 169 g, which is upregulated during drought stress, has five sorghum homologues. Similarly, cytochrome P450 domain-containing genes, often involved in scavenging toxins such as those accumulated in response to stress, are more abundant in sorghum than in rice [4]. A detailed analysis of these duplicated genes may shed light on the adaptive nature of sorghum. On the other hand, sorghum genome has been found to be an excellent template for assembling the genic DNA of the autopolyploid sugarcane genome and Miscanthus × giganteus genome [171, 172]. Thus, with rice, sorghum and *Brachypodium distachyon* genome [173] sequences already available, and with impending maize genome sequence, there is an immense opportunity for comparative genetics and genomics to dissect abiotic stress tolerance mechanisms in cereals.

36.4 Prospects

Postgenome sequencing, there has been a phenomenal change in the prospects of sorghum research in general. The focus has been shifted to sorghum because of several inherent attributes that make it a highly promising system in this global climate change scenario. With the availability of whole-genome sequence, wide germplasm resource and diversity, high-density linkage maps, array of markers coupled with tolerance to drought and heat, and potential candidate as bioenergy crop, sorghum is poised for modeling a future crop. There are several traits that are best represented by sorghum and yet remain unexplored. For example, sorghum tends to arrest growth during periods of drought and grows rapidly when water is available, thus avoiding yield losses. The extensive root system of sorghum can penetrate 1.5–2.5 m into the soil and extend 1 m away from the stem. Roots harvest water and nutrients from soil and thus play an important role in adaptation to abiotic stresses. Several root QTL have been identified in rice and maize, yet no such efforts have been made in sorghum. Maybe the extensive root system of sorghum itself could pose difficulty in phenotyping. The availability of advanced phenotyping facilities and information generated from rice and maize root QTL studies can be exploited. Furthermore, sorghum apparently shows epicuticular wax values close to maximum that can be achieved by plants. Though genetic and chemical analyses of epicuticular wax mutants have been reported, molecular aspects are needed to be understood. Components such as membrane stability and water use efficiency require a thorough evaluation. Passioura [174] remarked, “Drought tolerance is a nebulous term that becomes more nebulous the more closely we look at it, much as a newspaper

photograph does when viewed through a magnifying glass." Thanks to the tremendous progress in understanding drought tolerance mechanisms during the past two decades, and the availability of high-throughput phenomics and genomics tools, today plant scientist hope that crop drought tolerance can be improved drop by drop, trait by trait, and gene by gene [175]. Hence, application of high-throughput "omics" approach to understand the abiotic stress-adaptive mechanisms of sorghum will help genetic improvement of abiotic stress tolerance in sorghum. The trait of seedling emergence and seed vigor under cold from Chinese landraces is associated with transfer of negative traits such as susceptibility to leaf diseases. Identification of QTL is being done; however, tightly linked markers need to be developed for precise introgression of this trait in elite cultivars. Though it has been claimed that sorghum is tolerant to heat, yet there is no systematic study to illustrate this trait in sorghum. Overall, the attributes of sorghum for abiotic stress tolerance are still unexplored. Though some physiological evidences are available and genetic studies have been initiated, yet detail understanding of molecular and physiological mechanism is necessary for improvement of sorghum and cereal family in general.

Acknowledgment

Our work related to drought stress was supported by grants from National Agricultural Innovation Project, Indian Council of Agricultural research, New Delhi, India.

Vegetable Crops (Chili Pepper and Onion): Approaches to Improve Crop Productivity and Abiotic Stress Tolerance

Nandkumar Kunchge, Kiran Kumar, and Prashant Firke

The changing environments pose serious challenges to global agriculture and place unprecedented pressures on the sustainability of agriculture production. Climatic changes have been influencing the severity of environmental stress imposed on vegetable crops. Vegetable production is threatened by various abiotic stresses such as increased soil salinity, drought, temperature fluctuations, and so on. Success in breeding for varieties better adapted to abiotic stresses depends upon the concerted efforts by various research domains including plant and cell physiology, molecular biology, genetics, and breeding. The use of modern molecular biology tools for elucidating the control mechanisms of abiotic stress tolerance and for engineering stress-tolerant crops is based on the expression of specific stress-related genes. In this chapter, we have reviewed the studies reported on various factors responsible for abiotic stress in plants especially in vegetables with reference to chili pepper and onion. Physiological and molecular changes at genetic level during the stress response of plants are discussed briefly. This chapter emphasizes on the recent efforts to improve abiotic stress tolerance in crop plants by employing some of the stress-related genes and transcription factors in chili pepper and onion plants. The conventional breeding methods can be complemented by an array of biotechnological tools to augment vegetable production by saving time and resources. Molecular and genomics analyses have facilitated gene discovery and enabled genetic engineering using several functional or regulatory genes to activate specific or broad pathways related to abiotic stress tolerance in plants. There is a clear and urgent need to introduce stress tolerance genes into crop plants, in addition to establishing gene stacking or gene pyramiding.

37.1
Introduction

The human society has developed for thousands of years under one climatic state, and now a new set of climatic conditions are taking shape. These conditions are

Improving Crop Resistance to Abiotic Stress, First Edition.

consistently warmer, and some areas are likely to see more extreme events like severe drought, torrential rain, and violent storms. While year-to-year changes in temperature often reflect natural climatic variations such as El Niño/La Niña events, changes in average temperature from decade to decade reveal long-term trends such as global warming.

Global warming and climate change have been widely accepted as facts. The changing environments pose serious challenges to global agriculture and place unprecedented pressures on the sustainability of horticulture industry. Adapting horticulture to future conditions is essential to meet the need of growing population and increasing demand for fruits, vegetables, and other horticultural products. Therefore, the development of horticultural crops that can cope with heat, cold, drought, and other climate extremes brought by a warming planet may well be the single most important step we can take to adapt to the changes we face today and in the future. In addition, it is estimated that more than 20% of all cultivated lands around the world contain levels of salts high enough to cause stress on crop plants, a situation worsened by global warming.

The tropical vegetable production environment is a mixture of conditions that varies with season and region. Climatic changes will influence the severity of environmental stress imposed on vegetable crops. Moreover, increasing temperatures, reduced irrigation water availability, flooding, and salinity will be major limiting factors in sustaining and increasing vegetable productivity. Extreme climatic conditions will also negatively impact soil fertility and increase soil erosion. Thus, additional fertilizer application or improved nutrient-use efficiency of crops will be needed to maintain productivity or harness the potential for enhanced crop growth due to increased atmospheric CO_2. The response of plants to environmental stresses depends on the plant developmental stage and the length and severity of the stress [1]. Plants may respond similarly to avoid one or more stresses through morphological or biochemical mechanisms [2]. Environmental interactions may make the stress response of plants more complex or influence the degree of impact of climate change.

37.2 Effect of Salinity

As the earth becomes less fertile after increased salinization of soil and water, in addition to drought, the importance of finding a way to improve crop yields will be vital to the survival of humans [3]. Drought and salinity are becoming increasingly prevalent such that severe salinization encompassing more than 50% of all cultivable land is projected by 2050 [4]. Vegetable production is threatened by increasing soil salinity particularly in irrigated croplands that provide 40% of the world's food. Excessive soil salinity reduces productivity of many agricultural crops, including most vegetables that are particularly sensitive throughout the ontogeny of the plant. According to the United States Department of Agriculture (USDA), onions are

sensitive to saline soils, while cucumbers, eggplants, peppers, and tomatoes, among the main crops of AVRDC – The World Vegetable Center, are moderately sensitive. In hot and dry environments, high evapotranspiration results in substantial water loss, thus leaving salt around the plant roots that interferes with the plant's ability to uptake water. Physiologically, salinity imposes an initial water deficit that results from the relatively high solute concentrations in the soil, causes ion-specific stresses resulting from altered K^+/Na^+ ratios, and leads to a buildup in Na^+ and Cl^- concentrations that are detrimental to plants [5].

Plant sensitivity to salt stress is reflected in loss of turgor, growth reduction, wilting, leaf curling and epinasty, leaf abscission, decreased photosynthesis, respiratory changes, loss of cellular integrity, tissue necrosis, and potentially death of the plant [6, 7]. Salinity also affects agriculture in coastal regions that are impacted by low-quality and high-saline irrigation water due to contamination of the groundwater and intrusion of saline water as a result of natural or manmade events. Salinity fluctuates with season, generally high in the dry season and low during rainy season when freshwater flushing is prevalent. Furthermore, coastal areas are threatened by specific, saline natural disasters that can make agricultural lands unproductive, such as tsunamis, which may inundate low-lying areas with seawater. Although the seawater rapidly recedes, the groundwater contamination and subsequent osmotic stress cause crop losses and affect soil fertility. In the inland areas, traditional water wells are commonly used for irrigation water in many countries. The bedrock deposit contains salts and the water from these wells is becoming more saline, thus affecting irrigated vegetable production in these areas.

37.3
Effect of High Temperature on Abiotic Stress

Temperature limits the range and production of many crops. In the tropics, high-temperature conditions are often prevalent during the growing season and, with a changing climate, crops in this area will be subjected to increased temperature stress. Analysis of climate trends in tomato-growing locations suggests that temperatures are rising and the severity and frequency of above-optimal temperature episodes will increase in the coming decades [8]. Vegetative and reproductive processes in tomatoes are strongly modified by temperature alone or in conjunction with other environmental factors [9]. High-temperature stress disrupts the biochemical reactions fundamental for normal cell function in plants. It primarily affects the photosynthetic functions of higher plants [10]. High temperatures can cause significant losses in tomato productivity due to reduced fruit set, and smaller and lower quality fruits [11]. Preanthesis temperature stress is associated with developmental changes in the anthers, particularly irregularities in the epidermis and endothesium, lack of opening of the stromium, and poor pollen formation [12]. Hazra *et al.* [13] summarized the symptoms causing fruit set failure at high temperatures in tomato; these include bud drop, abnormal flower development, poor pollen production,

dehiscence, and viability, ovule abortion and poor viability, reduced carbohydrate availability, and other reproductive abnormalities. In addition, significant inhibition of photosynthesis occurs at temperatures above optimum, resulting in considerable loss of potential productivity.

37.4
Abiotic Stress in Drought Conditions

Unpredictable drought is the single most important factor affecting world food security and the catalyst of the great famines of the past [14]. The world's water supply is fixed, thus increasing population pressure and competition for water resources will make the effect of successive droughts more severe [15]. Inefficient water usage all over the world and inefficient distribution systems in developing countries further decreases water availability. Water availability is expected to be highly sensitive to climate change and severe water stress conditions will affect crop productivity, particularly that of vegetables. In combination with elevated temperatures, decreased precipitation could cause reduction of irrigation water availability and increase in evapotranspiration, leading to severe crop water stress conditions [16].

Vegetables, being succulent products by definition, generally consist of greater than 90% water [17]. Thus, water greatly influences the yield and quality of vegetables; drought conditions drastically reduce vegetable productivity. Drought stress causes an increase in solute concentration in the environment (soil), leading to an osmotic flow of water out of plant cells. This leads to an increase in the solute concentration in plant cells, thereby lowering the water potential and disrupting membranes and cell processes such as photosynthesis. The timing, intensity, and duration of drought spells determine the magnitude of the effect of drought.

37.5
Abiotic Stress due to Freezing Temperature

Freezing temperature greatly limits the geographical distribution of cultivated plants and often causes severe losses in agriculture production. Biotechnology offers new strategies that can be used to develop transgenic crop plants with improved tolerance to freezing stress. A number of genes have been isolated and characterized that are responsive to freezing stress. The designed genotype should be better than the available ones and must reach the farmers. Transgenic technologies have opened up many exciting possibilities to improve products with added value with application in food, agriculture, animal husbandry, environment, medicine and industry. It also offers uncommon opportunities for improvement in genetic potential of plants and animals by introduction or removal of gene or genes that regulate a specific trait.

The conventional breeding methods complemented by an array of biotechnological tools can be used to augment vegetable production by saving time and resources. Molecular and genomic analyses have facilitated gene discovery and enabled genetic engineering using several functional or regulatory genes to activate specific or broad pathways related to abiotic stress tolerance in plants [18]. The potential outcome can be in the form of development of specific vegetable varieties that are more resistant to biotic and abiotic stresses, enhanced nutritional level of food items, enhanced shelf life of perishable farm produce, conversion of organic waste into biofuels.

37.6
Abiotic Stress-Tolerant Variety Development in Vegetables

AVRDC – The World Vegetable Center has developed tomatoes and Chinese cabbage with general adaptation to hot and humid tropical environments and low-input cropping systems since the early 1970s. This has been achieved by developing heat-tolerant and disease-resistant breeding lines. The Center has made significant contributions to the development of heat-tolerant tomato and Chinese cabbage lines and the subsequent release of adapted, tropical varieties worldwide. The key to achieving high yields with heat-tolerant cultivars is the broadening of their genetic base through crosses between heat-tolerant tropical lines and disease-resistant temperate or winter varieties [19]. The heat-tolerant tomato lines were developed using heat-tolerant breeding lines and landraces from the Philippines (e.g., VC11-3-1-8, VC 11-2-5, Divisoria-2) and the United States (e.g., Tamu Chico III, PI289309) [20]. However, lower yields in the heat-tolerant lines are still a concern.

More heat-tolerant varieties are required to meet the needs of a changing climate, and these must be able to match the yields of conventional, nonheat-tolerant varieties under nonstress conditions. A wider range of genotypic variation must be explored to identify additional sources of heat tolerance. An AVRDC – The World Vegetable Center breeding line, CL5915, has demonstrated high levels of heat tolerance in Southeast Asia and the Pacific. The fruit set of CL5915 ranges from 15–30% while there is complete absence of fruit set in heat-sensitive lines in mean field temperatures of 35 °C. Genetic studies at AVRDC – The World Vegetable Center indicate that heat tolerance in CL5915, based on fruit set and fruit number per cluster, is controlled by additive and dominant effects [21]. However, bimodality of fruit set distribution and recovery of tolerant lines in early backcross generations suggests that only a few major genes and modifiers may control the heat tolerance trait [22, 23]. Since then new breeding lines have been developed from CL5915 and other sources that exhibit increased heat tolerance. In Egypt, CL5915 lines were best combiners for percentage fruit set and total yield in hybrids developed from heat-tolerant and heat-sensitive lines [24].

Germplasm evaluation for heat tolerance at AVRDC – The World Vegetable Center conventionally relied upon field screening during the hot and humid season, with measurement of fruit set and yield. Generally, less than 1% of the screened lines or accessions exhibit a high level of heat tolerance [25]. Although field screening is

effective, the accuracy and speed of the process could be improved through the use of molecular markers.

Unfortunately, using classical breeding to select plants with greater resistance to abiotic stresses is inhibited by the difficulty of working with a trait that is controlled by several genes [3]. Since there are similar physiological changes that occur in drought and freezing, the types of genes that are expressed in the plants defense are similar [26]. Fortunately, the molecular biology behind the gene expression that provides cold acclimation in plants is being characterized more comprehensively [26]. Studies on cold-regulated gene expression in *Arabidopsis* have shown that many of the genes are regulated by the *CBF/DREB1* transcription factors (TFs). It is believed that the COR proteins that are regulated by *CBF*/DREB1 increase the production of membrane-stabilizing proteins and sugars [27]. Using genes that code for transcription factors is a promising method for genetic engineering because many of the ways in which plants can adapt to cold, drought, oxidative stress, and extreme temperatures is through transcriptional control [4, 28]. Transcription factors that are a part of the regulon to help prevent the effects of abiotic stress have been constitutively overexpressed to promote a greater amount of tolerance. Many of the studies in commercial crops were based upon *Arabidopsis* because not only the structural proteins but also the entire stress tolerance regulons are conserved, making it a valuable model for biotechnological research [28].

The purpose of this chapter is to provide a compendium of TFs related to the abiotic stress and development of transgenic crops that have been modified to reduce the effects of abiotic stress. All of the crops overexpress a gene that codes for a transcription factor that will activate a gene and a stress response to re-establish cellular homeostasis [4]. It is important that stress responses to abiotic factors are studied because it will help take further the study of functional genomics. The use of transcription factors discussed here in genetic engineering could be a vital feature of agricultural biotechnology.

37.7
Role of Transcription Factors in Plant Stress Tolerance

Plant stress responses are regulated by multiple signaling pathways that activate gene transcription and its downstream machinery. Plant genomes contain a large number of transcription factors; for example, *Arabidopsis* dedicates about 5.9% of its genome coding for more than 1500 TFs [29]. Most of these TFs belong to a few large multigene families, for example, MYB, AP2/EREBP, bZIP, and WRKY. Individual members of the same family often respond differently to various stress stimuli; on the other hand, some stress-responsive genes may share the same TFs, as indicated by the significant overlap of the gene expression profiles that are induced in response to different stresses [30–34]. Some key examples are discussed below.

The dehydration-responsive transcription factors (DREB) and C-repeat binding factors (CBF) bind to DRE and CRT *cis*-acting elements that contain the same motif (CCGAC). Members of the CBF/DREB1 family, such as CBF1, CBF2, and CBF3 (or

DREB1B, DREB1C, and DREB1A, respectively) are themselves stress inducible. DREB/CBF proteins are encoded by AP2/EREBP multigene families and mediate the transcription of several genes such as rd29A, rd17, cor6.6, cor15a, erd10, kin1, kin2, and others in response to cold and water stress [31, 35–39].

A significant improvement in stress tolerance was found upon overexpression of a single TF in engineered *Arabidopsis thaliana* plants. *Arabidopsis* cold acclimation is associated with the induction of COR (cold-regulated) genes by the CRT/DRE *cis*-regulatory elements [40]. Jaglo-Ottosen *et al*. [41] showed that increased expression of *Arabidopsis* CBF1 induces the expression of the cold-regulated genes cor6.6, cor15a, cor47, and cor78, and increased the freezing tolerance of nonacclimated *Arabidopsis* plants. *Arabidopsis* transformation with the DREB1A gene [42] driven either by the strong constitutive promoter of the cauliflower mosaic virus (35SCaMV) or by a DRE-containing promoter from the dehydration-induced gene (rd29A) resulted in a marked increase in tolerance to freezing, water, and salinity stress. Similar to the CBF1 transgene, constitutive expression of DREB1A transcription factor resulted in an increased expression of its downstream targeted genes, such as rd29A, rd17, cor6.6, cor15a, erd10, and kin1. Overexpression of CBF3 in *Arabidopsis* also increased freezing tolerance and, more interestingly, resulted in multiple biochemical changes associated with cold acclimation: elevated levels of proline and total soluble sugars, including sucrose, raffinose, glucose, and fructose [43]. Plants overexpressing CBF3 also had elevated D1-pyrroline- 5-carboxylate synthetase (P5CS) transcript levels, suggesting that the increase in proline levels had resulted, in part, from increased expression of the key proline biosynthetic enzyme P5CS.

Components of the *Arabidopsis* CBF/DREB cold response pathway were also found in *Brassica napus* and other plant species [44]. Constitutive overexpression of the *Arabidopsis* CBF genes in transgenic *B. napus* plants induced expression of orthologues of *Arabidopsis* CBF-targeted genes and increased the freezing tolerance of both nonacclimated and cold-acclimated plants. Recently, expression of *Arabidopsis* CBF1 in tomato plants has been shown to confer elevated tolerance to chilling and oxidative stress [45]. However, the expression of COR genes was not induced, while reactive oxygen species (ROS) scavenger genes, for example, CAT1, were activated. Recently, a close CBF/DREB1 homologue, CBF4, was isolated in *Arabidopsis*. The expression of CBF4 is rapidly induced during drought stress and by abscisic aid (ABA) treatment, but not by cold, thereby distinguishing it from CBF/DREB1 transcription factors. Overexpression of CBF4 under the constitutive CaMV35S promoter resulted in the expression of cold- and drought-induced genes under nonstress conditions, and the transgenic *Arabidopsis* plants showed more tolerance to freezing and drought conditions [46].

ABA signaling plays a vital role in plant stress responses as evidenced by the fact that many of the drought-inducible genes studied to date are also induced by ABA. Two TF families, bZIP and MYB, are involved in ABA signaling and its gene activation. Many ABA-inducible genes share the (C/T) ACGTGGC consensus, *cis*-acting ABA-responsive element (ABRE) in their promoter regions [47, 48]. Several ABRE binding proteins, including rice TRAB and *Arabidopsis* AREB/ABF and ABI5, which interact with ABRE and regulate gene expression, have been isolated [49–53].

Recently, Abe *et al.* [55] showed that the *Arabidopsis* MYB transcription factor proteins, AtMYC2 and AtMYB2, function as transcriptional activators in ABA-inducible gene expression, suggesting a novel regulatory system for gene expression in response to ABA, other than the ABRE-bZIP regulatory system.

Constitutive expression of ABF3 or ABF4 demonstrated enhanced drought tolerance in *Arabidopsis* plants, with altered expression of ABA/stress-responsive genes, for example, rd29B, rab18, ABI1, and ABI2 [54]. Several ABA-associated phenotypes, such as ABA hypersensitivity and sugar hypersensitivity, were observed in transgenic plants. Moreover, salt hypersensitivity was observed in ABF3- and ABF4-overexpressing plants at the germination and young seedling stage, indicating the possible participation of ABF3 and ABF4 in the salt response at these particular developmental stages. Improved osmotic stress tolerance in 35S:AtMYC2/AtMYB2 transgenic plants, as judged by an electrolyte leakage test [55], is yet another example of how plant engineering with transcriptional activators of ABA signaling can provide a means of improving plant stress tolerance.

37.8
Utilizing Heat Stress Transcription Factors to Increase Heat Stress Tolerance

Heat is another abiotic stress that can affect the way a plant develops, even as a seedling. Heat stress transcription factors (*HSF*) are expressed to induce the production of chaperones used to protect proteins from forming negative physiological interactions, such as conformational change in protein structure [56, 57]. This function of *HSF*s can be used to increase longevity under heat stress by introducing genes that code for *HSF*s in one plant and overexpress them either in the same plant or in a different species [58]. The sunflower gene *HaHSFA9* has recently been transferred into tobacco with a *DS10* promoter [58]. The *DS10* promoter was used because it provides two orders of magnitude greater expression than a *35s* promoter without the common adverse effects such as decreased yield and size, and seed specificity [58]. Modifying tobacco with *DS10:HaHSFA9* from sunflower gave its seeds the ability to overexpress the production of *HSP*s, thereby increasing tolerance to heat stress [58]. Seven days after the heat treatment at 50 °C a handful of the controls germinated (0–6%), whereas $24 \pm 5\%$ of the DS10:Ha*HSF*A9-transformed plants germinated [58]. It is important to note that because the *HSF*s are conserved among many other plants, future experiments can be formulated to provide seed heat stress/deterioration resistance using orthologous factors [58].

Similar to osmotic stress, the heat shock response is primarily regulated at the transcriptional level. Thermoinducibility is attributed to conserve *cis*-regulatory promoter elements (HSEs) that are the binding sites for the *trans*-active heat shock factors [59]. The HSEs share a common consensus sequence "nGAAnnTTCnnGAAn." Plant HSFs, which are further categorized into three classes, A, B, and C, appear to be a unique family containing a number of members: 21 from *Arabidopsis*, more than 16 from tomato, and 15 from soybean [60]. Hsps are chaperones, which function during both normal cell growth and stress conditions;

therefore, it is not surprising that HSFs provide diverse functions that differentially control the activation of heat shock genes [59, 61, 62]. It has been shown that overexpression of HSF1 and HSF3 (class A) leads to the expression of several hsp genes conferring thermotolerance in transgenic plants [63, 64]. In tomato plants, overexpression of HsfA1 resulted in heat stress tolerance, while HsfA1 antisense plants and fruits were extremely sensitive to elevated temperatures [62]. Analysis of the transgenic plants disclosed that HsfA1 has a unique role as a master regulator for the synthesis of other HSFs such as HSFs A2 and B1 as well as Hsps. HSFs may also play a role in controlling cell death. The rice spl (spotted leaf) gene spl7 encodes a class-A HSF and the spl7 transgenic rice showed no lesions (spotted leaf) or delay in development of lesions [65]. The experiment suggested that spl7 might participate in controlling cell death that is caused by environmental stresses such as high temperature.

These studies demonstrate the important role of TFs in the acquisition of stress tolerance, which may ultimately contribute to agricultural and environmental practices. Although plant transformation with stress-responsive TFs permits over-expression of downstream stress-associated multiple genes, it may also activate additional nonstress genes that adversely affect the normal agronomic characteristics of a crop. One common negative effect of TF-modified plants is the growth retardation in transgenic plants that constitutively express TFs [42, 45, 54, 55]. For example, a positive correlation was found between the levels of DREB1A expression, the level of expression of the target gene RD29A, and the degree to which plants growth is stunted [38]. These negative effects can be partially prevented by the use of stress-inducible promoters that control the expression of the TF [42].

37.9
Other TFs Used to Increase Stress Tolerance

It has recently been determined that *Oryza sativa* can become more stress tolerant of drought and salt at the vegetative stage by transforming the plant with *SNAC11* and a CaMV 35s promoter [66]. In addition, there was 17.2–24.0% greater fertility (seed number) in the transformed rice than the negative control after 5 days of severe and moderate salt stress. In addition to phenotypic results, the expression levels of the *SNAC11* gene were determined using a Northern blot [66]. It was possible to determine the localization of expression of *SNAC11* by incorporating GFP in the construct. The expression levels in the transgenic plants were located mainly in the leaves where there was curling, which helped in closing stomata and inhibiting water loss [66]. Another novel gene that controls a transcription factor inhibits the effects of cold, salt, and drought stress in rice is *OsCOIN* (*O. sativa* cold inducible) [67]. By controlling the gene with a CaMV35s promoter and transforming the rice with *Agrobacterium*, it was possible to increase tolerance to cold, salt, and drought stress [67]. Moreover, 2 week-old rice was exposed to a temperature of 4 °C for 60, 71, and 84 h and allowed to recover for 2 weeks where it was found that a significantly greater percentage of *OsCOIN* transgenic rice grew than the wild

type [67]. In addition, the results from a 20 day-long salt stress test showed that *OsCOIN* transgenic rice germinated 35% faster and taller than the wild-type rice [67]. Also, it was determined that proline concentration in the cell helped determine *OsCOIN*'s ability to function [67].

Lettuce (*Latuca sativa* L.), one of the most popularly grown vegetables, worldwide, is limited in productivity by its own ability to fight off the effects of drought and cold temperatures [68]. Recently, lettuce has been successfully transformed with *Arabidopsis* ABA-responsive binding factor3 (ABF3) gene so the crop can overexpress the genes necessary to tolerate drought and cold [69]. Again, using *Agrobacterium*-mediated transformation, a construct was obtained containing not only the gene of interest, ABF3 (under maize ubiquitin promoter), but also gfp gus and the selectable marker hph under a 35S promoter [69]. ABF3 can be used to improve lettuce tolerance as a seedling and an adult, as the wild-type lines were significantly more vulnerable to the stresses used [69]. The Southern blotting was performed by digesting genomic DNA with *HindIII* and probing with ^{32}P *ABF3*. This study determined the inheritance of the T1 progeny to be 3: 1 in transgenic lines with a single copy of the *ABF3* [69].

Plants resist water or drought stress in many ways. In slowly developing water deficit, plants may escape drought stress by shortening their life cycle [70]. However, the oxidative stress of rapid dehydration is very damaging to the photosynthetic processes, and the capacity for energy dissipation and metabolic protection against reactive oxygen species is the key to survival under drought conditions [70, 71]. Tissue tolerance to severe dehydration is not common in crop plants but is found in species native to extremely dry environments [35]. Genetic variability for drought tolerance in *Solanum lycopersicum* is limited and inadequate. The best sources of resistance are other species in the genus *Solanum*. The Tomato Genetics Resource Center (TGRC) at the University of California, Davis, has assembled a set of the putatively stress-tolerant tomato germplasm that includes accessions of *S. cheesmanii*, *S. chilense*, *S. lycopersicum*, *S. lycopersicum* var. *cerasiforme*, *S. pennellii*, *S. peruvianum*, and *S. pimpinellifolium*. *S. chilense* and *S. pennelli* are indigenous to arid and semiarid environments of South America. Both species produce small green fruit and have an indeterminate growth habit. *S chilense* is adapted to desert areas of Northern Chile and often found in areas where no other vegetation grows [72, 73], has finely divided leaves and well-developed root system [74], and has a longer primary root and more extensive secondary root system than cultivated tomato [75]. Drought tests show that *S. chilense* is five times more tolerant of wilting than cultivated tomato. *S. pennellii* has the ability to increase its water use efficiency under drought conditions unlike the cultivated *S. lycopersicum* [75]. It has thick, round waxy leaves, is known to produce acyl sugars in its trichomes, and its leaves are able to take up dew [72].

Transfer and utilization of genes from these drought-resistant species will enhance tolerance of tomato cultivars to dry conditions, although wide crosses with *S. pennellii* produce fertile progenies, *S. chilense* is cross-incompatible with *S. lycopersicum* and embryo rescue through tissue culture is required to produce progeny plants. Research at AVRDC – The World Vegetable Center and other institutions is in

progress to identify the genetic factors underlying drought tolerance in *S. chilense* and *S. pennellii*, and to transfer these factors into cultivated tomatoes.

Related wild tomato species have shown strong salinity tolerance and are sources of genes as coastal areas are common habitat of some wild species. Studies have identified potential sources of resistance in the wild tomato species, *S. cheesmanii*, *S. peruvianum*, *S pennelii*, *S. pimpinellifolium*, and *S. habrochaites* [76–78]. Attempts to transfer quantitative trait loci (QTL) and elucidate the genetics of salt tolerance have been made using populations involving wild species. Elucidation of mechanism of salt tolerance at different growth periods and the introgression of salinity tolerance genes into vegetables would accelerate development of varieties that are able to withstand high or variable levels of salinity compatible with different production environments.

37.10
A Review of Abiotic Stress Tolerance in Chili Pepper

Pepper is a member of the family Solanaceae, which is one of the largest families in the plant kingdom and includes more than 3000 species [79]. The Solanaceae family includes important crops, such as pepper, tomato, tobacco, potato, and eggplant and has been widely cultivated over the years for human nutrition and health. *Capsicum* species are consumed worldwide and are valued because of their unique color, pungency, and aroma. *Capsicum* peppers include *Capsicum annuum*, *C. chinense*, *C. baccatum*, *C. frutescens*, and *C. pubescens* and are cultivated in different parts of the world. Of these, the varieties of the chili pepper plant species *C. annuum*, having a modest size diploid genome ($2n = 24$), are the most heavily consumed due to their nutritional value and spicy taste [80]. The chemical that is primarily responsible for the pungency of *C. annuum* has been identified as capsaicin [81], which elicits numerous biological effects and is the target of extensive investigation. The pepper production is influenced by many abiotic factors such as high temperature and salinity. In pepper, high-temperature exposure at the preanthesis stage did not affect pistil or stamen viability, but high postpollination temperatures inhibited fruit set, suggesting that fertilization is sensitive to high-temperature stress. In pepper, salt stress significantly decreases germination, shoot height, root length, fresh and dry weight, and yield. Yildirim and Guvenc [82] reported that pepper genotypes Demre, Ilica 250, 11-B-14, Bagci Carliston, Mini Aci Sivri, Yalova Carliston, and Yaglik 28 can be useful as sources of genes to develop pepper cultivars with improved germination under salt stress. In Tunisia, the root system of salt-tolerant cultivar "Beldi" was unaffected by salt stress. In addition, "Beldi" significantly out-yielded other test cultivars at high salt treatments.

Hong *et al.* [83] reported the isolation of pepper GDSL-type lipase (*CaGLIP1*) gene and functionally characterized, from pepper leaf tissues infected by *Xanthomonas campestris* pv. *vesicatoria* (*Xcv*). GDSL-type lipase is a hydrolytic enzyme whose amino acid sequence contains a pentapeptide motif (Gly-X-Ser-X-Gly) with active serine (Ser). The *CaGLIP1* gene was preferentially expressed in pepper leaves during the

compatible interaction with *Xcv*. Treatment with salicylic acid, ethylene, and methyl jasmonate induced *CaGLIP1* gene expression in pepper leaves. Dehydration and wounding mediated by sodium nitroprusside, methyl viologen, high salt, and mannitol also induced early and transient *CaGLIP1* expression in pepper leaf tissues. Virus-induced gene silencing of *CaGLIP1* in pepper conferred enhanced resistance to *Xcv*, accompanied by the suppressed expression of basic PR1 (*CaBPR1*) and defensin (*CaDEF1*) genes. During seed germination and plant growth, the *CaGLIP1* transgenic plants showed drought tolerance and differential expression of drought- and ABA-inducible genes *AtRD29A*, *AtADH*, and *AtRab18*. ABA treatment differentially regulated seed germination and gene expression in wild-type and *CaGLIP1* transgenic *Arabidopsis*. Overexpression of *CaGLIP1* also regulated glucose- and oxidative stress signaling. These results indicated that CaGLIP1 modulates disease susceptibility and abiotic stress tolerance.

A gene encoding a putative guanosine 5′-diphosphate (or 5′-triphosphate) 3′-diphosphate ((p)ppGpp) synthetase, designated PepRSH (*Pep*per *RelA*/*SpoT* homologue), was isolated from hot peppers by Kim *et al*. [84]. *PepRSH* was found to contain 5 introns and 6 exons and a 2166-bp open reading frame encoding a protein of 721 amino acids; this protein displayed significant homology to other plant. (p)ppGpp synthetase *PepRSH* transcripts were highly accumulated in nonhost resistance response-induced leaves and in leaves following induction with salicylic acid, methyl jasmonate, wounding, hydrogen peroxide, and ultraviolet B. The expression of *PepRSH* was also influenced by abiotic stresses, such as flooding and high salinity. The deduced PepRSH protein has a putative chloroplast-targeting transit peptide at its N-terminus, and immunolocalization studies verified the translocation of PepRSH to the chloroplast. The predicted PepRSH protein is markedly similar to known plant and bacterial RSH proteins. Expression of a putative (p)ppGpp synthetase domain in an *Escherichia coli* single mutant ($RelA^{-}SpoT^{+}$) complemented growth of the mutant, but not of an *E. coli* double mutant ($RelA^{-}SpoT^{-}$), demonstrating that PepRSH has (p)ppGpp synthetase activity only in the (p)ppGpp synthetase domain. Site-directed mutagenesis of the conserved histidine and aspartic acid (HD) site in the putative HD domain of PepRSH revealed that the histidine and aspartic acid dual sites were critical residues for the (p)ppGpp synthetase activity of PepRSH protein. Mutation of the HD site limited the tolerance of bacteria to both salt and osmotic stress. Their results indicate that pepper plants have a (p)ppGpp regulatory system that is similar to that of bacteria and that may transduce stress-related signals through the regulation of (p)ppGpp by PepRSH localized in chloroplasts.

Chung *et al*. [85] experimented with full-length Capsicum annuum calcium-dependent protein kinase 3 (CaCDPK3). cDNA clone was selected from the chili pepper expressed sequence tag database. CaCDPK3 belongs to a multigene family in the pepper genome gene was rapidly induced in response to various osmotic stress factors and exogenous abscisic acid application in pepper leaves. Moreover, CaCDPK3 RNA expression was induced by an incompatible pathogen and by plant defense-related chemicals such as ethephon, salicylic acid, and jasmonic acid. The biochemical properties of a CDPK3 were investigated using a CaCDPK3 and

glutathione *S*-transferase (GST) fusion protein. The recombinant proteins retained calcium binding ability and displayed autophosphorylation activity *in vitro* in a calcium-dependent manner. Furthermore, transient expression studies showed that CaCDPK3 fused with soluble modified green fluorescent protein (smGFP) localized to the cytosol in chili pepper protoplasts. The CaCDPK3 was implicated in biotic and abiotic stresses in pepper plants.

Cho *et al*. [86] isolated three different cDNA clones (pCaXTH1, pCaXTH2, and pCaXTH3) from water-stressed hot pepper that encode XTH (Xyloglucan endo-transglucosylase/hydrolase that has been recognized as a cell wall-modifying enzyme, participating in the diverse physiological roles) homologues. RT-PCR analysis showed that three CaXTH mRNAs were concomitantly induced by a broad spectrum of abiotic stresses, including drought, high salinity, and cold temperature, and in response to stress hormone ethylene, suggesting their role in the early events in the abiotic-related defense response. Transgenic *Arabidopsis* plants that constitutively expressed the CaXTH3 gene under the control of the CaMV 35S promoter exhibited abnormal leaf morphology; the transgenic leaves showed variable degrees of twisting and bending along the edges, resulting in a severely wrinkled leaf shape. Microscopic analysis showed that 35S-CaXTH3 leaves had increased numbers of small-sized cells, resulting in disordered, highly populated mesophyll cells in each dorsoventral layer, and appeared to contain a limited amount of starch. In addition, the 35S-CaXTH3 transgenic plants displayed markedly improved tolerance to severe water deficit and to a lesser extent to high salinity in comparison to the wild-type plants. These results indicate that CaXTH3 is functional in heterologous *Arabidopsis* cells, thereby effectively altering both the cell growth and the response to abiotic stresses. Although the physiological function of CaXTHs is not yet clear, there are several possibilities for their involvement in a subset of physiological responses to counteract dehydration and high-salinity stresses in transgenic *Arabidopsis* plants.

An *et al*. [87] isolated and functionally characterized the pepper (*C. annuum* L.) gene *CaPMEI1*, which encodes a pectin methylesterase inhibitor protein (PMEI), in pepper leaves infected by *X. campestris* pv. *vesicatoria* (*Xcv*). *CaPMEI1* transcripts are localized in the xylem of vascular bundles in leaf tissues, and pathogens and abiotic stresses can induce diVerential expression of this gene. PuriWed recombinant CaPMEI1 protein not only inhibits PME but also exhibits antifungal activity against some plant pathogenic fungi. Virus-induced gene silencing of *CaPMEI1* in pepper confers enhanced susceptibility to *Xcv*, accompanied by suppressed expression of some defense-related genes. Transgenic *Arabidopsis CaPMEI1* overexpression lines exhibit enhanced resistance to *Pseudomonas syringae* pv. *tomato*, mannitol, and methyl viologen, but not to the biotrophic pathogen *Hyaloperonospora parasitica*. Together, their results suggest that *CaPMEI1*, an antifungal protein, may be involved both in basal disease resistance and in drought and oxidative stress tolerance in plants.

A full-length cDNA clone of the *Capsicum annuum* ankyrin-repeat domain C3H1 zinc finger protein (CaKR1) was identified in a chili pepper by Seong [88] and his group using the expressed sequence tag (EST) database. The deduced amino acid sequence of CaKR1 showed a significant sequence similarity (46%) to the ankyrin-repeat protein in very diverse family of proteins of *Arabidopsis*. The gene was induced

in response to various biotic and abiotic stresses in the pepper leaves, such as salicylic acid (SA) and ethephon, as well as by an incompatible pathogen. CaKR1 expression was highest in the root and flower, and its expression was induced by treatment with agents such as NaCl and methyl viologen, as well as by cold stresses. These results showed that CaKR1 fusion with soluble, modified green fluorescent protein (smGFP) was localized to the cytosol in *Arabidopsis* protoplasts, suggesting that CaKR1 might be involved in responses to both biotic and abiotic stresses in pepper plants.

The same research group of Seong [89] reported the full-length cDNA of *CaAbsi1* from pepper encodes a presumptive protein of 134 amino acid residues that has homology to a putative zinc finger protein in its C-terminus. The deduced amino acid sequence has 50% homology to *O. sativa* NP001049-274, the function of which is unknown. Expression of *CaAbsi1* was reduced in response to inoculation of nonhost pathogens. On the other hand, it was induced 1 h after exposure to high concentrations of NaCl or mannitol, and 6 h after transfer to low temperature. Induction also occurred in response to oxidative stress, methyl viologen, hydrogen peroxide, and abscisic acid. Their results suggest that *CaAbsi1* plays a role in multiple responses to wounding and abiotic stresses.

Choi *et al.* [90] isolated and functionally characterized the pathogen-responsive CaM gene, *Capsicum annuum* calmodulin 1 (*CaCaM1*), from pepper (*C. annuum*) plants. The cellular function of *CaCaM1* was verified by *Agrobacterium* spp.-mediated transient expression in pepper and transgenic overexpression in *A. thaliana*. *Agrobacterium* spp.-mediated transient expression of *CaCaM1* activated ROS, nitric oxide (NO) generation, and hypersensitive response (HR)-like cell death in pepper leaves, ultimately leading to local acquired resistance to *X. campestris* pv. *vesicatoria*. *CaCaM1*-overexpression (OX) *Arabidopsis* exhibited enhanced resistance to *P. syringae* and *H. parasitica*, which was accompanied by enhanced ROS and NO generation and HR-like cell death. Treatment with the calcium channel blocker suppressed the oxidative and NO bursts and HR-like cell death that were triggered by*CaCaM1* expression in pepper and *Arabidopsis*, suggesting that calcium influx is required for the activation of *CaCaM1*-mediated defense responses in plants. Upon treatment with the CaM antagonist, virulent *P. syringae* pv. *tomato*-induced NO generation was also compromised in *CaCaM1*-OX leaves. Together, these results suggest that the *CaCaM1* gene functions in ROS and NO generation are essential for cell death and defense responses in plants.

37.11
Transgenic Chili Pepper for Abiotic Stress Tolerance

Chatzidimitriadou *et al.* [91] reported the stress tolerance and regeneration capability of transgenic pepper plants carrying a *sod* gene, encoding a tomato chloroplast-localized Cu/Zn SOD protein. The expression of the sod gene was confirmed by enzymatic staining following polyacrylamide gel electrophoresis (PAGE), revealing a "novel" band, which could represent a heterodimeric enzyme. Transgenic T1 and T2 progeny plants were exposed to different oxidative stresses, including Methyl

viologen (MV), and drought and found to have an increased resistance to oxidative damage. Furthermore, the SOD-carrying transgenic pepper plants showed increased levels of regeneration efficiency compared to the wild-type pepper plants. Pepper is a recalcitrant species in terms of its *in vitro* regeneration ability, but it could be extremely useful for the development of pharmaceuticals. Their approach enables the extent of the use of pepper for genetic transformation and the production of high-value products in plants particularly the large fruit varieties.

37.12
Abiotic Stress Tolerance in Onion (*Allium cepa L.*)

The genus *Allium* is an important member of onion family (Alliaceae; subfamily Allioideae) [92]. Alliums represent a major group among bulbous crops and these have been cultivated for food and medicine or religious purposes. They are consumed raw or cooked as a vegetable or as a pickle and also as dehydrated product in the form of powder, flakes, or bulbs [93, 94]. Most of these crops are strongly flavored and are characterized by sulfur-containing compounds, which impart them their distinctive smell and pungency.

Onion has the primary center of origin in central Asia and secondary center in the Near East. It is an important commercial vegetable crop grown worldwide. In terms of global weight of vegetables produced, at nearly 28 million ton per annum, only tomatoes and cabbage exceed bulb onions in importance [95]. In terms of area, India ranks first in the world with over 480 000 ha accounting for around 21% of the world area under onion cultivation. Globally, the country occupies the second position after China in onion production with a production share of around 14%. Besides India and China, the other major onion producing countries are Turkey, Pakistan, Brazil, the United States of America, Iran, Spain, and Japan. India accounts for more than 70% share in the export of fresh onions. Productivity, however, is at around 11.4 million ton ha^{-1}, which is lower than the world average of 17.3 million ton ha^{-1}. In India, onion is extensively cultivated over a large area spread almost throughout the country. Despite the development of impressive irrigation potential, which ensured food security to India during the past three decades, agriculture in India is still considerably affected by climatic variability. Shortage of onions and potatoes in 1998 and gluts of onions, potatoes, rice, and wheat in 2000 in India were largely due to variable climatic conditions [96]. The commonly cultivated alliums and their areas of cultivation in India are presented in Table 37.1.

Abiotic stress includes drought, heat, flood, salinity, mineral deficiency, toxicity, and chilling or freezing stress. The nature and magnitude of stress vary. These stresses are linked with natural phenomenon and their scale varies at temporal and spatial dimensions. There is hardly a landmass in the world that is not influenced by one or the other of these stress factors. Drought, salinity, extreme temperatures, and oxidative stress are often interconnected and may induce similar cellular damage. They are very complex stimuli that possess many different yet related attributes, each of which may provide the plant cell with quite different information. These abiotic

Table 37.1 Cultivated alliums and their areas of cultivation in India.

Common name	Botanical name	Chromosome number (2n)	Areas of cultivation
Common onion	A. *cepa* var. *cepa* L.	16	Throughout India
Shallot	*A. cepa* var. *aggregatum* G. Don	16	Himalayas, Peninsular India
Welsh onion	*A. fistulosum* L.	16	Western Himalayas, Northeast region
Chinese chives	*A. tuberosum* Rottl. ex Spreng.	32	Western Himalayas Northeast region
Garlic	*A. sativum* L.	16	Throughout India
Leek	*A. ampeloprasum* var. porrum (L.) J. Gay	32	Western Himalayas
Chives	*A. schoenoprasum* L.	16, 24, 32	Western Himalayas

factors lead to a series of morphological, physiological, biochemical, and molecular changes that adversely affect growth and productivity of crop plants [97]. For example, low temperature may immediately result in mechanical constraints, changes in the activities of macromolecules, and reduced osmotic potential in the cellular milieu [98]. Onion is a shallow-rooted crop plant that is predominantly grown under rain-fed conditions and is, therefore, exposed to frequent droughts during its ontogeny. There are no studies available on abiotic stress-tolerant onion. Also, no single germplasm/variety or hybrid of onion has been developed/released for cultivation in those regions affected by above-mentioned stresses. Few workers have studied the effect of fructans, polyamines, and glutathione *S*-transferases on abiotic tolerance in onion, which are elaborated here.

37.13 Role of Fructans in Freezing and Drought Tolerance

Sucrose and starch are the primary vegetative storage carbohydrates in tropical and subtropical grasses, while temperate and cool zone grasses mainly accumulate fructose polymers called fructans. Numerous studies have been published that attempted to correlate fructan concentrations with freezing and drought tolerance. Fructan is considered a short-term storage carbohydrate that has been implicated for many years in stress tolerance mechanisms in plants. Fructans (polyfructosylsucrose) consist of polymers of Fru attached to Suc and serve as an important storage carbohydrate in approximately 15% of flowering plant species [99]. The fructan residues are either linked by a (2–1) b-d-glycosidic bond, as in inulin derived from *Cichorium intybus* L. [100], or by a (2–6) b-d-glycosidic bond, as in levans (e.g., *Phleum pratense* L. [101]). In most grasses, branched fructans containing both types of linkages are produced (e.g., *Triticum aestivum* L. [102]). The effect of fructans on

Table 37.2 Five types of fructan in plants showing a representative plant species in which the respective type of fructan has been identified.

Type	Representative species	Linkage (β)	Initial trisaccharide
Inulin	Chicory, Jerusalem artichoke	2-1	1-ketose
Levan	*Dactylis glomerata*	2–6	6-ketose
Branched	Wheat, barley	2-1 and 2-6	1- and 6-ketose
Inulin neoseries	Onion, asparagus, Lolium	2-1	6G-kestotriose (neokestose)
Levan neoseries	Lolium, oats	2-6	6G-kestotriose (neokestose)

liposomes has indicated that a direct interaction between membranes and fructans is possible. This helps to prevent leakage when water is removed from the system either during freezing or during drought. Five types of fructans have been identified in plants (Table 37.2).

In Liliaceae, such as onion and asparagus, a different type of inulin is present, namely, the inulin neoseries. These are linear with 2–1 linkages but with the glucose molecule between two fructosyl subunits [103]. Fructan synthesis is initiated when photosynthesis exceeds demand, reportedly when sucrose levels in sink organs reach a critical level [104]. Synthesis is complex due to differences between species in linkages, branching patterns, and sizes; however, a model for synthesis in plants that includes four fructosyltransferases has been proposed [105]. An enzyme capable of synthesizing 6G-kestose (neokestose) in onion was first described by Shiomi [103] and was cloned by Vijn *et al*. [106].

Soluble solids such as sucrose, glucose, fructose, and fructans are the primary nonstructural storage carbohydrates in onion [107, 108] that are used for regrowth of the plant in spring. Lower solid onions accumulate essentially no fructans and tend to be soft with low pungency, whereas onions with higher soluble solids tend to be firm and highly pungent. Fructans start to accumulate at the onset of bulbing, which coincides with increased fructosyltransferase activity [109, 110]. During growth, the fructan content of bulbs increases, but by the end of the growth season a decline in fructan content is observed [109]. Storage of onion bulbs leads to a further decrease in fructan levels and sprouting is induced [111]. This phenomenon severely reduces storage time for onion.

During cultivation, harvesting, handling, transportation, packaging, and storage, onion bulbs are exposed to different treatments, atmospheric conditions, and temperatures, all of which can affect their growth [112], their quality, and their physiological characteristics [113, 114]. The results of these effects could be responsible for several reactions and for stress causing important biochemical changes in the bulb tissues. Fructans are accumulated during the bulbing stage and then are catabolized during the regrowth and the sprout development of the bulbs [115]. They may have been implicated in protecting plants against water deficit by drought or low temperature, in inducing resistance to drought or cold stress, and in acting as osmoregulators [116]. Fructan accumulation during periods of reduced growth under

low but nonfreezing conditions (cold acclimation) has frequently been correlated with an increase in freezing tolerance [117, 118]. This correlation stimulated research to explain how fructan might be involved in protection from freezing stress.

37.14
Role of Polyamine and Abscisic Acid Interaction during Stress Tolerance

Polyamines (PAs), important growth regulatory polycationic molecules, have long been established to be involved in a wide range of plant growth and development processes such as embryogenesis, root development, flowering, tuber formation, senescence, and fruit ripening. They have also been implicated in plant responses to abiotic and biotic stresses [119, 120]. Commonly occurring PAs in higher plants include putrescine2^+ (Put), spermidine3^+ (Spd), and spermine4^+ (Spm) that are protonated at cytoplasmic pH. PAs appear to play a role in cell division, but not in cell elongation [121, 122]. Likewise, ABA regulates an array of plant processes and mediates plant responses to a variety of abiotic stresses [123]. ABA is also known to inhibit mitotic cell division [124, 125]. Since the levels of both PAs and ABA increase in plant tissues in response to abiotic stresses, a possibility of interaction between them in the regulation of plant processes including mitosis exists. The interaction between PAs and ABA in the regulation of mitosis and thereby growth is quite likely in view of the fact that both effectors are known to increase in concentration in plant tissues under abiotic stress conditions. Mahajan and Sharma [126] have reported such interactive effects of PAs and ABA on mitosis in terms of mitotic index and also measured catalase (CAT) activity to understand the involvement of redox metabolism in mediating the effects of PAs and/or ABA on mitosis in the root tips of onion. These interactions may be of significance for plant survival under stressful growth conditions. Since CAT decomposes H_2O_2, produced in higher concentrations in plant tissues in response to diverse abiotic stresses, altered CAT activities may be taken as changed cellular redox status.

37.15
Role of Antioxidants in Salt Stress in Onion

A majority of crop plants are relatively salt sensitive and are unable to tolerate low level of salinity [127]. Shanon [128] has also found a wide range of variability in salt tolerance between a number of agronomic species. Growth and yield of onion were affected when the irrigation water salinity exceeded 3 mS cm^{-1} [129]. Other investigators reported that high levels of salinity reduced onion vegetative growth, yield, and quality [130, 131].

Salt imposes several kinds of stresses upon plant. It causes drastic changes in the water potential, ion toxicity, ion imbalance, and oxidative stress [132–135]. Salt stress induces an oxidative stress via cellular accumulation of damaging active oxygen species (AOS) including superoxide radicals, hydrogen peroxide, and

hydroxyl radicals [136, 137]. AOS cause oxidative damage to different cellular components including membrane lipid, protein, and nucleic acid [138, 139]. Plants cope with this by producing enzymatic and nonenzymatic antioxidants [4, 140]. Among nonenzymatic antioxidants, glutathione has been indicated to scavenge oxygen species and improve seed germination and seedling growth under salt stress [141–143].

Glutathione is a tripeptide [α-glutamyle cysteinylglycine], which has been detected virtually in all cell compartments [142]. A wide range of biotic and abiotic factors induce plant GST expression. These include herbicides, heavy metal, pathogen attack, ethylene, ozone, plant growth factor auxin, salicylic acid, and hydrogen peroxide [144]. Environmental stresses such as osmotic stress [145], low temperature [146], saline stress [147], and cadmium [148] also induce GST expression in plant. Therefore, GSTs are thought to play vital roles in the diversity of stress physiologies through some other functions as well as GST-mediated detoxification. A protective role of these enzymes is suggested in the enzymatic upregulation of plant GSTs as being one of the important parameters under environmental conditions for cellular survival.

The GST activity in onion bulb has been enriched compared to other vegetable crops [149]. Onion bulb GSTs consist of five components including GSTa, GSTb, GSTc, GSTd, and GSTe [150]. Among these, GSTa and GSTb, with low activity, were termed as minor GSTs, and GSTc, GSTd, and GSTe, with high activity, were termed as dominant GSTs. In onion bulb, quercetin-4′-glucoside and quercetin-3,4′-diglucoside were also reported as physiological inhibitors of the dominant GSTs [150–152]. The 1-chloro- 2,4- dinitrobenzene (CDNB) conjugating activities of GSTc and GSTd, and to a lesser extent GSTe, were highly sensitive to the inhibitors, particularly quercetin-4′-glucoside. It has been reported that the activity level of the dominant GST, GSTe, was found to change over time of storage of onion bulb. The most studied endogenous substrate, anthocyanin that has been reported to have a positive correlation with GST accumulation, is also a strong inhibitor of the GSTs [153, 154]. Therefore, endogenous inhibitory substrates of onion GSTs might also affect the activity levels of the GSTs in onion bulb. Salama and Mutawa [155] studied the effect of NaCl on plasma membrane in the absence and presence of glutathione in onion. Glutathione ameliorated NaCl-induced plasma membrane changes and maintained its permeability and cell viability. The ameliorative effect of glutathione was more pronounced when added together with salt. The alleviating effect of glutathione might be through scavenging active oxygen species and hence lipid peroxidation produced under salt stress.

Although onion flavor intensity has been studied in response to various growing conditions, little is known about its response to salt stress. Improving the content of active compounds (volatile sulfur compounds, ascorbic acid, carbonyl compounds, vitamins, and flavonoids) is the most important pharmaceutical strategy and could be enhanced through different environmental stresses in some vegetables [156]. Moreover, salt stress may affect soluble solid content (SSC), bulb pungency as measured by total pyruvate (TPY), bulb sulfur (S) and sulfate (SO_4) accumulation, and flavor precursors and their biosynthetic intermediates in onion [157].

37.16
Genetic Transformation in Onion

Genetic engineering and *in vitro* regeneration protocols are two collaborative equipment to complement conventional *Allium* breeding and to develop high yield, biotic/abiotic stress resistant/tolerant cultivars, adapted to local ecological conditions [158–161]. Eady *et al.* [162] were the pioneer in *Agrobacterium tumefaciens*-mediated gene transformation and regeneration of *A. cepa*. Eady *et al.* [163] momentously achieved herbicide-resistant onion *A. cepa* and developed transgenics in *A. porrum* and *A. sativum* using *A. tumefaciens*-mediated transformation. Zheng *et al.* [164] followed similar methodology for development of a reproducible transformation system in *A. sativum* and production of transgenics resistant to beet armyworm (*Spodoptera exigua* Hubner). In a most recent experiment, transgenic chicory plants harboring the onion 6G-FFT under the control of the cauliflower mosaic virus 35S RNA promoter produced inulin of the neoseries in addition to linear inulin [106]. Sucrose Suc 1-fructosyltransferase (1-SST) is the key enzyme in plant fructan biosynthesis since it catalyzes *de novo* fructan synthesis from Suc. Vijn *et al.* [165] have cloned 1-SST from onion by screening a cDNA library using acid invertase from tulip as a probe. Expression assays in tobacco protoplasts showed the formation of 1-kestose from Suc.

Onion is an excellent system to study carbohydrate accumulation because recurrent selection has produced low and high fructan accumulating populations. For example, the onion population "Southport White Globe" was subjected to phenotypic recurrent selection for higher fructan content, shifting the population mean from 17 to >23%. Major QTL on chromosomes 5 and 8 are significantly (LOD > 3.5) associated with higher fructan concentrations.

37.17
Conclusions and Prospects

Plants have evolved mechanisms to respond at the morphological, anatomical, cellular, and molecular levels for avoidance of and/or tolerance to various abiotic stresses. In response to stress, plants respond by gene expression leading to cellular homeostasis and detoxification of toxins, ultimately aiming at recovery of growth. These adaptive mechanisms can be investigated by molecular, biochemical, and physiological studies. This chapter summarizes the recent efforts to improve abiotic stress tolerance in crop plants by employing some of the stress-related genes and transcription factors. Various transcription factors are involved in the regulation of stress-inducible genes. Functional genomic studies may provide tools for dissecting abiotic stress responses in plants through which networks of stress perception, signal transduction, and defense responses can be examined from transcriptomic through proteomic to metabolomic profiles of stressed tissues. A well-focused approach combining the molecular, physiological, and metabolic aspects of abiotic stress tolerance is required for bridging the knowledge gaps between the molecular or cellular expression of the genes and the whole-plant phenotype under stress.

There is a clear and urgent need to introduce stress tolerance genes into crop plants, in addition to establishing gene stacking or gene pyramiding. Transgenic research has opened up a new opportunity in crop improvement allowing the transfer of desirable gene(s) across species and genera for developing transgenic plants with novel traits, such as built-in protection, improved nutritional qualities, and so on. Efficient transformation system in Chili pepper and onion is a major limitation for developing transgenic plants. Although progress in improving stress tolerance has been slow, there are a number of reasons for optimism. The use of transgenes to improve the tolerance of crops to abiotic stresses remains an attractive option. Options targeting multiple gene regulation appear better than targeting single genes. This can be done by either combining multiple genes of a single protective pathway or by combining key regulatory genes of different protective pathways.

Acknowledgments

We thank Drs. Narendra Tuteja and Renu Tuteja for encouraging us to write this chapter, Dr. Bishwanath Mazumdar for reading and making scientific corrections, and Mr. Indranil Jiwane for helping us in citing references. We also thank Mr. Sameer Agrawal and Mr. Suresh Agrawal, respectively, Managing Director and Chairman of Bejo Sheetal Seeds Pvt. Ltd., without whose motivational and financial support it was not possible to write this chapter. We apologize if some references have not been cited due to space constraint.

Vegetable Crops: Improvement of Tolerance to Adverse Chemical Soil Conditions by Grafting

Giuseppe Colla, Youssef Rouphael, and Mariateresa Cardarelli

Owing to limited availability of arable land and the high market demand for vegetables around the world, Solanaceae and Cucurbitaceae crops are frequently cultivated under unfavorable soil conditions. These include salinity, alkalinity, heavy metals, and excessive amount of trace elements. Plants exposed to adverse chemical soil conditions exhibit various physiological and biochemical disorders leading to stunted growth and severe yield loss. One way to avoid or reduce losses in production caused by adverse soil chemical conditions in vegetables would be to graft them onto rootstocks capable of reducing the effect of external stresses on the shoot. Grafting is an integrative reciprocal process and, therefore, both scion and rootstock can influence tolerance of grafted plants to adverse soil chemical conditions. Grafted plants grown under adverse soil chemical conditions often exhibited greater growth and yield, higher photosynthesis, better nutritional status, and lower accumulation of Na^+ and/or Cl^-, heavy metals, and excessive amount of trace elements in shoots than ungrafted or self-grafted plants. This chapter gives an overview of the recent literature on the response of grafted plants to adverse soil chemical conditions and the mechanisms of tolerance to adverse soil chemical conditions in grafted plants related to the morphological root characteristics and the physiological and biochemical processes. The chapter will conclude by identifying several prospects for future research aiming to improve the role of grafting in vegetable crops grown under abiotic stress conditions.

38.1
Introduction

Soil chemical factors such as salinity, alkalinity, heavy metals, and excessive amount of trace elements are common abiotic stresses limiting crop productivity in many parts of the world. At present, a third of irrigated land in the world is affected by salinity and alkalinity problems [1, 2], while many soils are contaminated by heavy metals.

Improving Crop Resistance to Abiotic Stress, First Edition.

According to the US Salinity Laboratory, when the electrical conductivity (EC) of solution extracted from a soil at its saturation water content is greater than 4 dS m^{-1} and the exchangeable sodium percentage (ESP) is less than 15, the soil is considered saline. Salinity occurs in both nonirrigated and irrigated lands as a result of evapotranspiration of saline underground water or due to the use of irrigation water of poor quality. Soil salinization is common especially in arid and semiarid regions where the amount of rainfall is insufficient for leaching. The salinization process is particularly evident under greenhouse conditions where the lack of leaching by rainfall and the high fertilizer application rates result in a dramatic increase in the electrical conductivity value of soils, especially when poor-quality water is used [3]. Although NaCl is usually the most abundant salt in saline soil, other elements (e.g., Ca^{2+}, Mg^{2+}, K^{+}, SO_4^{2-}, and NO_3^{-}) can be presented in different combinations depending on the source of salinity and the solubility of the salts [4]. Moreover, the saline water may contain high concentrations of trace elements that can be harmful to most vegetable crops (e.g., B > 1–2 mg L^{-1}). Under saline conditions, crop performance may be adversely affected by water deficit arising from the low water potential of the soil solution (osmotic effect) and by salinity-induced nutritional disorders associated with excessive ion uptake or nutrient imbalance by nutrient availability, competitive uptake, and transport or partitioning within the plant (ionic effect) [5, 6]. The pH of saline soil is usually around neutrality or slightly alkaline. However, higher pH values (>8) are observed in saline soils with ESP greater than 15 (saline–sodic soils) due to the high content of sodium carbonate. Plant growth in sodic soils is depressed mainly by high pH and bicarbonate, and often by low soil permeability to water, poor aeration, and mechanical impedance. However, alkaline soils are often not associated with salinity, especially when the source of alkalinity is $CaCO_3$ that buffers the soil in the pH range 7.5–8.5 (calcareous soils). Calcareous soils are generally characterized by low bioavailability of plant nutrients, high concentrations of $CaCO_3$ and soil solution HCO_3^{-}, high pH, and almost no exchangeable H^{+} [7, 8]. Bicarbonate ions reduce the plant growth by interfering negatively with the uptake of macroelements, in particular P, K, and Mg [9]. For instance, in alkaline soils, P is largely unavailable to plants due to the formation of metal complexes (e.g., Ca–P and Mg–P), rendering P only sparingly soluble. Moreover, the concentration of HCO_3^{-} interacts strongly with the availability of several micronutrients, especially Fe^{2+}, and it is often considered to be the primary factor responsible for chlorosis of plants on calcareous soils [10] leading to serious yield and quality losses. Reduction in iron availability is due to the incapacity of sensitive plants to acquire and to transport iron toward shoots. Iron deficiency reflects upon the physiology and biochemistry of the whole plant, as iron is an important cofactor of many enzymes, including those involved in the biosynthetic pathway of chlorophylls [7]. Thus, under iron deficiency conditions, the reduction in leaf iron concentration is often accompanied by a marked reduction of chlorophyll levels [11, 12], by a significant, although less intense, decrease in the chlorophyll fluorescence [11, 12] and by a reduction in photosynthesis [7].

Contamination of soil and water by heavy metals and excessive amount of trace elements is one of the most troublesome environmental problems faced by mankind

nowadays. Heavy metals are getting importance for their nondegradable nature and often accumulate through tropic level causing a deleterious biological effect. Anthropogenic activities such as mining, ultimate disposal of treated and untreated waste effluents containing toxic metals as well as metal chelates [13] from different industries, and the indiscriminate use of heavy metal-containing fertilizers (e.g., triple superphosphate, animal wastes, and sewage sludge) and pesticides (e.g., Cu-containing fungicides) in agriculture resulted in contamination of soils and in deterioration of water quality, rendering serious environmental problems posing threat to human beings [14]. Some of the metals such as Cu, Fe, Mn, Ni, and Zn are essential as micronutrients for plants, while many other metals such as Cd, Cr, and Pb have no known physiological activity, but they are proved detrimental to plant growth beyond a certain limit, which is very much narrow for some elements such as Cd (0.01 mg/L), Pb (0.10 mg/L), and Cu (0.050 mg/L) [15]. Inhibition of root elongation is in many cases the most sensitive parameter of heavy metal toxicity. Excessive levels of heavy metals in plant tissues can also cause a range of morphological and physiological disorders, such as reduction in shoot growth [16], photosynthetic activity [17], and uptake of mineral nutrients [18]. Moreover, it may result in chlorosis and necrosis, and damage to plasma membrane permeability that leads to ion leakage [19]. Finally, vegetables cultivated in contaminated soils may exhibit high levels of heavy metals in the edible parts posing serious health risks to humans [20]. Numerous attempts have been made to overcome the problems due to adverse soil chemical conditions by traditional breeding programs, but commercial success has been very limited. At present, the major efforts are being directed toward the genetic transformation of plants. Although the expression of a single gene seems to lead in some cases to an improvement in the crop adaptation to some adverse soil chemical factors [21], the development of tolerant genotypes normally requires the transfer of several genes due to the multigenic trait of abiotic stress tolerance [22]. As a rapid alternative to the relatively slow breeding methodology aimed at increasing vegetable crop tolerance to an abiotic stress, grafting of high-yield genotypes onto selected rootstocks could be a promising tool. Grafting is commonly applied to vegetable crops belong to Solanaceous crops (tomato, eggplant, and pepper) and Cucurbits (watermelon, melon, and cucumber) in Japan, Korea, China, and several European and American countries [23]. The main purpose of grafting is to control soil-borne diseases and nematodes [24]; in addition, grafting may increase the nutrient and water use efficiency (WUE), enhance plant vigor and yield, and improve tolerance to environmental stresses such as high salinity, low and high temperatures, drought, flooding-induced hypoxia, alkalinity, and excessive amount of heavy metals and trace elements [23].

In this chapter, we emphasize the potentiality of vegetable grafting as a tool to mitigate the detrimental effects of adverse soil chemical conditions such as salinity, alkalinity, heavy metals, and excessive amount of trace elements on vegetable crop performances. The role of grafting in the improvement of growth, yield, and product quality under such soil abiotic stresses is reported. Various mechanisms involved in the increased tolerance to salinity, alkalinity, heavy metals, and excessive amount of trace elements are also discussed.

38.2 Salinity

38.2.1 Effects on Grafted Plants

38.2.1.1 Growth and Yield

It is well established that crop growth and yield decrease with increasing salinity [25]. Reduced yield under saline treatments is attributed to a rapid, osmotic phase that inhibits growth of young leaves, and a slower, ionic phase that accelerates senescence of mature leaves [6]. Osmotic stress can also induce premature senescence via stomatal closure and carbohydrate accumulation in source tissues due to decreased demand from sink organs. Improvement of growth and yield was observed in many grafting combinations of fruit vegetables grown under saline conditions. Moreover, it has been demonstrated that the level of tolerance of grafting combinations depends on the salt type and concentration, exposure time, and growing conditions. Generally, the positive effect induced by rootstock on shoot saline tolerance increases with the level of stress as observed in tomato [26], where grafting "Moneymaker" onto either "Radja" or "Pera" improved tomato fruit yield compared to self-grafted plants of "Moneymaker" when plants were grown at 50 mM NaCl, whereas there was no effect of either rootstocks or grafting *per se* on fruit yield in the absence of or at 25 mM NaCl. The yield increase over self-grafted plants was around 40% whereas in the earlier study [27] using a different scion ("Jaguar"), the increase was 80% at the same salt concentration indicating a different salt tolerance of the genotypes. These results suggest that the salt tolerance of the shoot depends on the root system, independent of the genotype used as a scion, although the positive effect of rootstock may show a different degree depending on the higher or lower exclusion ability of the shoot genotype. Similarly, in eggplant (*Solanum melongena* L.) grafting cultivar "Suqiqie" onto "Torvum Vigor" (*S. torvum* Swartz) improved the growth performance under saline stress conditions [28, 29]. The better crop performance in grafted Solanaceous crops grown under saline conditions has also been recorded on several Cucurbits such as watermelon, melon, and cucumber. Grafting watermelon "Fantasy" cultivar onto plants "Strongtosa" rootstock (*Cucurbita maxima* Duch. × *C. moschata* Duch.) reduced the decrease in shoot weight and leaf area caused by the increase in salinity in comparison with ungrafted plants [30]. Moreover, other experiments demonstrated that grafted "Crimson Tide" watermelon onto *C. maxima* and two *Lagenaria siceraria* rootstocks had higher plant growth than ungrafted plants under saline conditions (8.0 dS m^{-1}, [31]). In cucumber (*Cucumis sativus* L.), grafting cultivar "Jinchun No. 2" onto bottle gourd rootstock "Chaofeng 8848" (*L. siceraria* Standl.) alleviated the negative effect of salinity on shoot dry weight [32]. In a similar study, cucumber plants cultivar "Jinchun No. 2" grafted onto figleaf gourd (*C. ficifolia* Bouché) and "Chaofeng Kangshengwang" had higher fruit number and marketable fruit yield compared to the self-grafted plants at all salt levels (30 and 60 mM NaCl). Similarly, two melon cultivars (*C. melo* L.) grafted onto three hybrids of squash (*C. maxima* Duch. × *C. moschata* Duch.) exhibited higher yield compared to ungrafted ones when grown

under saline conditions (4.6 dS m^{-1} [33]). However, other researchers [34, 35] recorded that the sensitivity to salinity was similar between grafted and ungrafted melon plants as a result of the different *Cucurbita* rootstocks used in these studies. Salt tolerance of grafted plants can vary significantly in relation to the salt composition and growing system. For instance, cucumber plant "Jinchun No. 2" grafted onto "Chaofeng Kangshengwang" (*L. siceraria* Standl.) was tolerant to salinity when grown in hydroponics using NaCl as salt source, while "Chaofeng Kangshengwang" failed to increase grafted plant tolerance to salinity when grown in substrate culture using macronutrients as salinity source [36].

38.2.1.2 **Photosynthesis and Water Relations**

Under saline conditions, the low osmotic potential of soil solution restricts water availability and water uptake and thus reduces the root hydraulic conductance and causes a significant increase in the stomatal resistance and reduction in CO_2 photosynthetic assimilation. Stomatal opening and photosynthesis, which are K^+-dependent physiological processes, can also be reduced by NaCl saline conditions as a result of the decreased absorption of some nutrients (e.g., K) and the increased content of the Na^+ and Cl^- in the leaves. Under saline conditions, salt-tolerant grafted plants exhibit higher photosynthetic rate per unit area and higher leaf area resulting in a greater photosynthetic capacity of the plant than ungrafted or self-grafted plants. For instance, in a watermelon experiment [37], the leaf area and the net assimilation of CO_2 under saline conditions were higher in grafted plants of cultivar Tex onto *Cucurbita* hybrid "Ercole" than in ungrafted "Tex" plants. Similarly, it was demonstrated [38] that grafted cucumber plants had higher net photosynthesis, stomatal conductance, and intercellular CO_2 concentrations under NaCl stress than self-rooted plants. Moreover, under moderate and severe salt stresses, tomato-grafted plants of "Hezu903" onto "Zhezhen" rootstock showed higher net CO_2 assimilation rate than nongrafted and self-grafted plants [39]. Water use efficiency, calculated as the ratio of net assimilation of CO_2 to transpiration, usually increased in moderately salt-stressed plants, owing to the fast decrease in transpiration rate. For instance, grafting tomato "Hezu903" onto "Zhezhen" rootstock increased the WUE under saline conditions in comparison to the ungrafted and self-grafted plants [39]. The higher WUE is important for salt tolerance since a high WUE may reduce the uptake of salt and alleviate the water deficiency induced by salinity [40, 41]. Water content maintenance and transpiration are crucial to plants under salinity stress. Water deficit associated with salinity can increase the leaf water content as a result of the transpiration rate reduction due to the stomatal closure. For instance, at 100 mM of NaCl, higher leaf water content was observed in grafted tomato plants of "UC-82B" onto "Kyndia" rootstock compared to the self-grafted plants; the better leaf water content was associated with a lower shoot growth reduction in grafted plants [42].

38.2.1.3 **Fruit Quality**

In general, salinity reduces the yield of vegetable crops but in many instances improves their quality [43]. Many investigations have shown that increased salinity produces fruit with a higher content of sugars and organic acids, and higher dry

matter, providing a basis for better taste and high nutritional value. Grafting can increase or decrease the fruit quality depending on the scion–rootstock combination, the salt composition, and the growing conditions [44]. For instance, the dry matter, soluble solid content, and titratable acidity were lower in melon fruits (*C. melo* L.) of cultivar "Cyrano" grafted onto "P360" *Cucurbita* hybrid rootstock than in ungrafted ones regardless of the level of salinity [35]. In other experiments on tomato, the soluble solid content of fruits was similar in both grafted and ungrafted tomato plants and increased with NaCl stress level. On the contrary, it has been reported that grafting tomato cultivar "Moneymaker" onto "Radia" rootstock increased both yield and fruit quality parameters (soluble solids and titratable acidity) in comparison to self-grafted "Moneymaker" grown under saline conditions. Similarly, grafting cucumber cultivar "JinchunNo. 2" onto "Figleaf Gourd" (*C. ficifolia* Bouché) and "Chaofeng Kangshengwang" (*L. siceraria* Standl.) improved fruit quality under NaCl stress owing to an increase in contents of soluble sugar and titratable acidity and a decrease in the percentage of nonmarketable fruits [32]. It is interesting to note that in the cucumber experiment, the detrimental effects of *Cucurbita* rootstocks on fruit quality observed in the previous melon experiment was compensated by an increase in soluble sugar under salt stress, which was probably a consequence of a lower accumulation of saline ions (Na^+ and Cl^-) that led to a high accumulation of soluble sugar involved in the osmotic adjustment.

Since saline stress activates a physiological antioxidative response [45], it has been reported that ascorbic acid levels increase with salinity, as part of the detoxification of free radicals, and similarly moderate salt stress enhance the level of other antioxidants such as carotenoids (e.g., lycopene and β-carotene), which have been recognized as beneficial in preventing widespread human diseases, including cancer. Grafting can enhance the content of antioxidants in fruits depending on grafting combinations and salt concentration as observed in tomato, where the concentration of ascorbic acid in fruit juice of cultivar "Fanny" remained unchanged with grafting at 0 mM NaCl [46], whereas when NaCl was increased to 30 mM a significant increase was observed for grafted "Fanny" plants onto tomato rootstock "AR-9704." Moreover, an increasing in carotenoids (lycopene and β-carotene) was also observed in two tomato cultivars ("Fanny" and "Goldmar") grafted onto a tomato hybrid rootstock "AR-9704" under saline conditions. Similarly, vitamin C increased by grafting cucumber cultivar "JinchunNo." onto "Figleaf Gourd" and "Chaofeng Kangshengwang" in comparison to self-grafted plants, whether saline-challenged or not. Grafting can improve the mineral content of the fruits under saline conditions, which is interesting from a nutritional point of view because fruits and vegetables are important source of minerals in the human diet (e.g., 35, 24, and 11%, respectively, of the total K, Mg, and P dietary intake of humans) [47]. For instance, it has been reported that under saline conditions fruit K content was higher in cucumber cv. "Jinchun No." grafted onto "Figleaf Gourd" and "Chaofeng Kangshengwang" in comparison to self-grafted plants. Moreover, it has also been observed that salt-tolerant grafting combinations exhibited a decrease in Na and/or Cl contents in fruits in comparison to the self-grafted plants, which represents a positive quality aspect due to the negative effects of high dietary intake of Na and Cl on human health.

38.2.2 Mechanisms of Salt Tolerance in Grafted Plants

38.2.2.1 Root Characteristics

Generally, salinity induces a rapid reduction in root growth and an increase in root to shoot dry weight ratio due to a greater reduction in shoot growth; the high root to shoot ratio under saline conditions appears to be an adaptive strategy to increase the nutrient uptake and the ratio of water absorption by water-transpiring organs. Maintaining root growth under saline conditions was correlated with salt tolerance in tomato. Salt-tolerant grafted plants often exhibit a better root growth and higher root to shoot ratio than ungrafted or self-grafted plants. For example, grafted tomato plants had a less decrease in root dry mass at 100 and 150 mM of NaCl than ungrafted plants [39]. Similar results were observed in grafted cucumber plants [32, 48] and in grafted watermelon plants [31, 37] exposed to salt stress. Therefore, the better growth performance of grafted vegetable crops could be explained, at least to some extent, in terms of root growth under salinity stress.

38.2.2.2 Salt Exclusion and Root Retention

The main long-term damage caused by salinity in glycophyte crops is the excessive accumulation of Na^+ and Cl^- in leaves that causes a wide variety of physiological and biochemical alterations inhibiting plant growth and production. The increased salt tolerance of grafted vegetables has often been associated with lower Na^+ and/or Cl^- contents in the shoot. Two mechanisms could explain the decrease in shoot toxic ion (Na^+ and/or Cl^-) concentrations in grafted plants: toxic ion exclusion by the roots, and toxic ion retention and accumulation within the rootstock. Root retention involves the storage of Na^+ and/or Cl^- in vacuoles, which can protect cytosolic enzymes from the damaging effects of salt accumulation [49]. The electrochemical H^+ gradients generated by H^+ pumps in the tonoplast (H^+-ATPase, H^+-PPase) provide the energy used by tonoplast-bound Na^+/H^+ antiporters (NHX) to couple the passive movement of H^+ to the active movement of Na^+ into the vacuole [50]. The H^+-ATPase and H^+-PPase activities of root tonoplast membrane are less inhibited under NaCl stress in salt-tolerant grafted plants than in self-grafted plants as observed in tomato experiment [51]. Experiments conducted on melon plant grafted onto different hybrids of squash (*C. maxima* Duch. × *C. moschata* Duch.) revealed that the concentrations averaged 11.7 times those in the shoots of plants grafted with pumpkin rootstocks. Quantitative analysis indicated that Na exclusion of squash hybrid roots plays a more significant role in its restricted accumulation in the shoot of grafted plants, compared to its retention in the roots: Na exclusion was 69–79%, while the Na root retention was only 37–54% [52].

38.2.2.3 Osmotic Adjustment

Salt tolerance and further growth in a saline soil require a reduction in internal plant water potential below that of the soil in order to maintain turgor and water uptake. In fruit vegetables in which salt exclusion (glycophytes) is the principal mechanism of salt tolerance, either the synthesis of metabolically compatible solutes (e.g., sucrose,

proline, and glycine betaine) or the uptake of inorganic ions (e.g., K^+, Ca^{2+}, and NO_3^-) must be increased (osmotic adjustment). Unlike Na^+ and Cl^-, these osmotically active solutes are not harmful to enzymes and other cellular structures even at high concentrations (hence "compatible solutes"). Although the biosynthesis of organic compatible solutes is energetically more expensive than the accumulation of Na^+ and Cl^- take-up from the soil, plants can benefit from the reduction of the detrimental effects induced by high accumulation of Na^+ and Cl^-. Moreover, compatible osmolytes may protect plants by scavenging oxygen-free radicals caused by salt stress [53, 54]. It has been reported that salt-tolerant grafted plants of tomato and cucumber exhibited a better osmotic adjustment under NaCl stress through a higher accumulation of soluble sugars and proline in leaves than self-grafted plants [32]. Moreover, grafted plants have higher leaf K^+ accumulation, which seems related to the higher salt tolerance than self-grafted plants [32, 48].

38.2.2.4 Antioxidant Defense System

Salt stress reduces the photosynthesis rate increasing the formation of reactive oxygen speciess (ROS) such as superoxide radicals (O_2^-) and hydrogen peroxide (H_2O_2). These ROS are highly reactive and can seriously disrupt normal metabolism through oxidative damage to lipids, proteins, and nucleic acids [55]. Plants have evolved an efficient defense system by which the ROS is scavenged by enzymatic and nonenzymatic antioxidant defense mechanisms.

Enzymatic antioxidants include superoxide dismutase, catalase, ascorbate peroxidase, monodehydroascorbate reductase, dehydroascorbate reductase, and glutathione reductase (GR). The most commonly known nonenzymatic antioxidants are glutathione (GSH), ascorbate (AsA), carotenoids, and tocopherols [55, 56]. An efficient antioxidant system is an important factor for the enhanced salt tolerance of grafted plants. For instance, the increased salt tolerance of cucumber plants grafted onto *C. ficifolia* was associated with the increased superoxide dismutase and peroxidase activities under saline conditions induced by major nutrients [36]. Similarly, the higher antioxidant capacity of grafted plants under salt stress has been observed in other fruit-bearing vegetables such as tomato, eggplant, and watermelon [39, 48]. Nonenzymatic antioxidants were also found to contribute to the salinity tolerance in grafted vegetables. The glutathione and ascorbate contents in the leaves of grafted eggplants are found to be significantly higher than those in self-grafted plants under NaCl stress [28].

38.2.2.5 Phytohormone Biosynthesis

Changes in phytohormones or their precursors' concentrations, such as cytokinins (CKs), abscisic acid (ABA), the ethylene precursor 1-aminocyclopropane-1-carboxylic acid (ACC), and auxin indole 3-acetic acid (IAA), are associated with a response of plants to salinity. It has been suggested that at least part of the growth depression by salinity was caused by inadequate phytohormone production. Generally, the levels of CKs decrease while ABA increases in response to salinity. Abscisic acid plays a central role both in root to shoot and cellular signaling under salt stress and in the regulation of stomatal conductance. Under salt stress, a transient loss of leaf turgor stimulates ABA

synthesis and causes stomatal closures stimulating leaf senescence. CKs are assumed to be synthesized mainly in the roots and transported to the shoots via the xylem. CKs are implicated in controlling both shoot growth and leaf senescence. Some rootstocks exhibited a higher CKs biosynthesis that improved salt tolerance of scion by increasing vegetative and fruit growth and by delaying leaf senescence and maintaining stomatal conductance and PSII efficiency, thereby avoiding or delaying the accumulation of toxic ions [57]. Moreover, the ratio between CKs and ACC was positively correlated with leaf growth and PSII efficiency in a grafting tomato experiments, where tomato cultivar was grafted onto rootstocks from a population of recombinant lines derived from *S. lycopersicum* × *S. cheemaniae* cross and grown under moderate saline conditions (75 mM NaCl) [58]. Phytohormones also play an important role in maintaining root growth under salt stress condition and in increasing root to shoot ratio. The greater partitioning of assimilates to roots under saline condition has been attributed to a decrease in CK concentrations and an induced basipetal transport of auxin from shoot to root with a concomitant change in the activity of the sink-related enzyme cell wall invertase. Moreover, the increase in root to shoot ratio due to a differential growth response of root (maintenance) and shoot (inhibition) under salinity was associated with a relative increase and decrease in the auxin IAA concentration, respectively [58]. Polyamines [putrescine (Put), spermidine (Spd), and spermine (Spm)] are small cationic molecules that accumulate in plants under salinity stress. They are involved in the regulation of many basic cellular processes such as DNA replication and transcription, cell proliferation, modulation of enzyme activities, membrane rigidity, and stabilization [59]. In grafted tomatoes and eggplants, it has been reported that the ABA and total polyamine contents are significantly higher than those of self-grafted plants under NaCl stress [60, 61]. In addition, the Spd and Spm contents, as well as (Spd + Spm)/Put value, were higher in grafted melon and cucumber plants than in self-grafted plants under NaCl stress [62].

38.3 Alkalinity

38.3.1 Effects on Grafted Plants

38.3.1.1 Growth and Photosynthesis

Researchers have demonstrated that plants respond to elevated $NaHCO_3$ concentrations in soil or in growing medium solution with decreased shoot and root growth [63–65]. Shoot growth inhibition is associated with a decrease in the number of leaves, fresh and dry mass, and shoot elongation [66]. For instance, significant depression in shoot and root biomass production was observed in bicarbonate-treated watermelon plants, and that effect varied as a function of grafting combination [67]. Under alkaline conditions (pH 8.1), shoot and root biomass weight reductions in comparison to control (pH 6.0) were significantly lower in watermelon cultivar Ingrid grafted onto *Cucurbita* rootstocks "PS1313" and "P360" than that in

ungrafted watermelon plants, whereas the root to shoot ratio of biomass increased in ungrafted plants. The former study showed that the watermelon plants grafted onto *Cucurbita* rootstocks had less change in root to shoot ratio than those grafted onto bottle gourd rootstocks and the ungrafted plants under alkaline conditions. The lower shoot reductions in grafted plants, especially in those grafted onto pumpkin rootstocks, was related to the capacity of maintaining a higher net CO_2 assimilation in response to bicarbonate stress compared to ungrafted plants. In addition to reduced net photosynthetic rates, leaf area decreased in response to an increase in alkalinity in the nutrient solution especially in ungrafted watermelon plants. The restriction of leaf area may be the result of the suppressed net photosynthetic rates since the latter effect reduces the available assimilates for leaf growth.

38.3.1.2 **Nutrient Uptake**

Alkaline soils represent a serious concern for iron acquisition by plants since under these conditions the range of inorganic iron availability is around 0.1–10% of the normal requirement for optimal plant growth [68]. Colla *et al.* [67] observed that roots of grafted and ungrafted watermelon plants accumulated larger amounts of Fe than leaves, suggesting that the critical process leading to chlorosis in alkaline soils is Fe uptake from the root apoplast into the symplast, which can be impaired by the alkaline apoplastic pH due to high bicarbonate concentration [10, 69]. Grafted watermelon onto pumpkin rootstocks enhanced the uptake and translocation of Fe toward the shoot in comparison with ungrafted plants. The higher uptake and accumulation of Fe in watermelon plants grafted onto pumpkins was the main mechanism that reduced the detrimental effect of alkalinity (Fe deficiency) on plant growth. Moreover, bicarbonate ions may interfere with the uptake and transport of other essential nutrients (e.g., P, K, and Mg) and thereby disturbing nutrient composition of plants [7]. On the basis of the nutrient composition of plant tissues, it has been demonstrated that watermelon grafted and ungrafted plants responded differently to pH level, as has been observed for growth parameters. For ungrafted plants, the high pH level (8.1) in the nutrient solution caused significant decrease in macronutrient leaf concentration especially for P compared to plants grafted onto pumpkin rootstocks. Consequently, the improved crop performance of watermelon plants grafted onto pumpkin rootstocks was attributed not only to their strong capacity to accumulate Fe in the aerial part under alkaline conditions but also to their ability to improve the uptake and transport of P to the shoot [67].

38.3.2
Mechanisms of Alkalinity Tolerance in Grafted Plants

38.3.2.1 **Root Exudation**

Plants respond to deficiency of many macro- and micronutrients with increased root exudation, for example, to, P [70], K [71], Zn [72], and Cu [73]. Since organic acids efficiently solubilize/mobilize many metal cations such as Ca, K, and Mg [74], Al and Fe [74, 75], and Mn [76], the purpose of this increased exudation could be to increase the solubilization of deficient nutrients. Certain rootstocks can improve the uptake of

several macro- and micronutrients under alkaline conditions through a greater exudation of organic acids. For instance, watermelon plants grafted onto pumpkin rootstocks exuded more citric and malic acids than ungrafted ones especially under bicarbonate-enriched solutions [67]. These results support the hypothesis that uptake of nutrients (e.g., P and Fe) from the nutrient solution by pumpkin rootstocks was facilitated by exudation of organic acids from roots. Similar results were observed in other experiments on *Cucurbita* plants where the root exudation of organic acids (especially citric acid) increased under P depletion leading to an enhanced P uptake especially in *C. pepo* ssp. *ovifera* [70].

38.3.2.2 **Root-Reducing Capacity**

Higher plants have developed various specific and nonspecific mechanisms to increase the solubility and uptake of Fe in the rhizosphere. In the root cell plasma membrane, two different oxidoreductases capable of transferring electrons from the cytosol to several external electron acceptors (ferricyanide or ferric chelates) are involved in Fe acquisition. One oxidoreductase reduces only Fe(III) to ferricyanide, and the other is capable of reducing both ferric chelates and ferricyanide. This latter reductase, called Fe(III)-chelate reductase (FeCH-R), is induced or stimulated by iron-deficiency stress and is responsible for generating Fe(II) prior to uptake by dicotyledonous and nongraminaceous monocotyledonous plants [77]. Therefore, Fe uptake and thus the nutritional status of this micronutrient depends greatly on FeCH-R activity. It has been reported that some rootstocks have the potential to improve the Fe uptake through a higher FeCH-R activity. For instance, tomato and watermelon plants grafted onto *S. lycopersicum* variety "TmKnvf$_2$" and *C. maxima* variety "Dulce maravilla" rootstocks, respectively, exhibited a higher FeCH-R activity in the roots compared to ungrafted plants [78]. The higher FeCH-R activity in the roots of grafted watermelon plants was associated with a higher Fe content in leaves. Increases in FeCH-R activity is frequently observed in dicots cultivated under alkaline conditions, and this has been assumed to arise from an inducible plasma membrane-bound FeCH-R enzyme(s) [79–81]. However, no significant differences were observed in root FeCH-R activity between grafted and ungrafted watermelon plants grown under alkaline conditions, although the grafted watermelon plants onto *Cucurbita* hybrid rootstocks exhibited a higher leaf Fe concentration than ungrafted plants [67].

38.4
Heavy Metals and Excessive Amount of Trace Elements

38.4.1
Effects on Grafted Plants

38.4.1.1 **Growth and Yield**

Heavy metals such as cadmium, nickel, and chrome and excessive amount of trace minerals such as copper manganese and boron in soil and water are toxic to plants even at very low concentrations, or may accumulate in plant tissues up to a certain

level without visible symptoms or yield reduction [19, 82]. Rouphael *et al.* [19] have demonstrated that grafting cucumber onto the commercial rootstock "Shintoza" (*C. maxima* Duch. × *C. moschata* Duch.) mitigated the adverse effects of excessive Cu supply on plant biomass and fruit yield. In fact, shoot and root biomass weight reductions in control plants were clearly lower in grafted than in ungrafted plants, whereas the root to shoot ratio increased in ungrafted plants as a result of Cu stress conditions. Boron toxicity can also be mitigated by grafting onto suitable rootstocks, as indicated by an experiment with melon (*C. melo* L.) plants, which were exposed to five different B concentrations ranging from 0.1 to 10 mg L^{-1} in the irrigation water [34, 83]. The nongrafted melon plants were more sensitive to excess boron supply than the grafted ones (*C. maxima* Duch. × *C. moschata* Duch."TZ-148") in terms of fruit yield and dry weight accumulation in shoots and roots [34, 83].

38.4.1.2 **Fruit Quality**

Fruit vegetables are characterized by rather low rates of heavy metal and trace mineral translocation to the fruit [84]. However, contaminated vegetables are frequent in the market due to environmental pollution caused by human activities. For instance, a survey in Japan showed that approximately 7% of eggplant fruits contain cadmium concentrations above the international limit for fruiting vegetables. It was suggested that grafted plants could be used to prevent the entry of heavy metals and excessive amount of trace minerals into the supply chains via plants under unfavorable conditions [44]. Arao *et al.* [85] conducted a study to develop a method to reduce Cd concentration in eggplant fruits. They showed that grafting onto *S. torvum* reduced eggplant fruit Cd concentration by 63–75% in Cd-polluted soil and unpolluted soil compared to grafting onto *S. melongena* and *S. integrifolium*. The accumulation of Cu in fruit tissue of cucumber plants grown under Cu-enriched solution was significantly lower in plants grafted onto the "Shintoza"-type rootstock (*C. maxima* Duch. × *C. moschata* Duch.) in comparison to that of ungrafted plants [19]. Similarly, the concentrations of B, Zn, Sr, Mn, Cu, Ti, Cr, Ni, and Cd in the fruits of melon plants irrigated with marginal water were lower in the grafted plants onto the commercial *Cucurbita* rootstock "TZ-148" than in ungrafted plants [86].

38.4.2
Mechanisms of Tolerance in Grafted Plants

The enhanced tolerance of grafted vegetables to heavy metals and excessive amount of trace element has often been associated with root exclusion and/or to the restricted translocation from roots to shoots. Arao *et al.* [85] observed that grafting *S. melongena* plants onto *S. torvum* reduced the leaf and stem Cd concentrations by 67–73% in comparison to self-grafting or grafting onto *S. integrifolium*, in both Cd-polluted and unpolluted soils. The Cd concentration in xylem sap collected from stems of *S. torvum* was 22% of that in stems of *S. melongena*, indicating an appreciable restriction of the Cd translocation from root to shoot in the former. However, the concentrations of Cd in the roots of *S. melongena* and *S. torvum* were similar when the plants were exposed to identical external Cd levels [20]. These results indicate that *S. torvum* restricts

specifically the translocation of Cd to the shoot and not the Cd uptake by the roots. Genotypic differences in the ability of the root to prevent Cd translocation to the shoot have been reported also for soybean by means of grafting experiments [87]. According to Mori *et al.* [20], the restriction of Cd translocation to the fruit of eggplant grafted onto *S. torvum* in comparison to self-grafted *S. melongena* seems to be related to the process of xylem loading. Yamaguchi *et al.* [88] attempted to elucidate the molecular mechanisms governing the reduced Cd uptake by *S. torvum* and found that dehydration-related transcription factors and aquaporin isoforms are potential constituents of Cd-induced biochemical impediments. Other results have shown that the rootstock significantly affects gene expression in the scion, thereby indicating that some signals transported from the root to the shoot may also influence the Cd uptake and translocation [89]. Edelstein *et al.* [83] recorded that grafting melon onto the commercial *C. maxima* Duch. × *C. moschata* Duch. rootstock "TZ-148" reduced the boron concentration in the leaves of grafted plants in comparison to ungrafted plants. The lower boron concentration could be the result of mainly the differences in the properties of the root systems of the two plant types. Boron could accumulate and bind in the root system, which would limit its movement toward the shoot, as reported for some fruit trees [90, 91]. It should be noted, however, that in the current study boron concentrations in the root systems of both grafted and ungrafted melon plants were relatively low and, moreover, the boron concentrations in the roots of the ungrafted plants were similar to or higher than those in the roots of the grafted ones. Thus, it can be concluded that the lower boron concentrations in the leaves of the grafted plants than in those of the ungrafted ones were not the result of greater boron accumulation and attachment in the roots of the grafted plants than in those of the ungrafted ones [83]. Grafting cucumber cv. "Akito" onto the commercial rootstock "Shintoza" restricted the uptake and translocation of Cu to the shoot [19]. The leaf Cu concentration in grafted plants treated with a nutrient solution containing 47 and 94 μM Cu increased by 138 and 181%, respectively, in comparison to plants supplied with 0.3 μM Cu, while in ungrafted plants the increase in the leaf Cu level was 235 and 392%, respectively. Rouphael *et al.* [19] attributed the improved crop performance of grafted cucumber plants to the ability of the squash rootstock to restrict the accumulation of Cu in the shoot. These results indicate that Cu toxicity in cucumber cultivated in environments with too high Cu levels in the root zone may be partly mitigated by grafting onto the rootstock "Shintoza." Similarly, Savvas *et al.* [92, 93] found that the transport of Cu to the leaves of tomato "Belladona" was also restricted when the plants were grafted onto the "He-Man" rootstock (*S. lycopersicum* L. × *S. habrochaites* S. Knapp & D.M. Spooner). However, the concentration of Cu was significantly lower not only in the leaves but also in the roots of plants grafted onto "He-Man" in comparison to self-grafted "Belladona" plants.

38.5
Concluding Remarks and Future Perspectives

For decades, vegetable grafting has been successfully practiced in many Asian countries, and it is becoming increasingly popular in Europe as well. This chapter

concludes that grafting is an effective way to mitigate the detrimental effects of adverse soil chemical conditions such as salinity, alkalinity, heavy metals, and excessive amount of trace elements on vegetable crop performances particularly in Cucurbitaceae and Solanaceae. The increased tolerance of grafted plant to adverse soil chemical conditions was due to the use of tolerant rootstocks. Several effective rootstocks are mentioned and already in practical use, or used in breeding programs. The mechanisms involved in the advantageous response of specific stress-tolerant rootstocks are manifold and partly still unknown. Augmentation of this knowledge may help to select and breed appropriate rootstocks that improve the adaptability of fruit vegetable crops to salinity, alkalinity, heavy metals, and excessive amount of trace elements. The agronomical and physiological processes implicated in the tolerance of grafted plants to adverse soil chemical conditions have received much attention, but the biochemical and molecular processes involved remain relatively unknown. So, a thorough investigation should be conducted with the aim of providing biochemical and molecular knowledge on the metabolism of grafted plants grown under adverse soil chemical conditions. Finally, researchers, extension specialists, and seed companies need to work together to integrate this modernized technology as an effective tool for producing high-quality vegetables under adverse soil chemical conditions.

Grain Legumes (Soybean, Chickpea, and Peanut): Omics Approaches to Enhance Abiotic Stress Tolerance

D. Srinivas Reddy, Pooja Bhatnagar-Mathur, Vincent Vadez, and Kiran K. Sharma

Legumes rank third in world crop production, and abiotic stress is the major constraint to crop productivity. Biotechnological applications including all "omics" have been the direct and potential approaches for improving abiotic stress tolerance in grain legumes and requires knowledge of stress response at molecular level, which includes gene expression to protein or metabolite and its phenotypic effects. Genome-wide expression profiling studies have been carried out in the legumes to identify the candidate genes and regulatory networks among abiotic stress responses. Among the grain legumes, although soybean has been more intensively studied, more recently, sensitive and tolerant varieties of chickpea and peanut have been characterized under abiotic stress conditions. Nevertheless, proteomic studies in response to abiotic stress in legumes are still very limited with only *Medicago truncatula* and soybean protein reference maps available. Some of the major QTL controlling abiotic stress tolerance in legumes have been mapped for a major QTL for salt tolerance in soybean and drought tolerance-related traits in peanut. Although, *Agrobacterium*-mediated gene transfer has been reported in all the major legume crops, so far only one legume, that is, soybean, has been commercialized. Transgenic technologies for improved abiotic stress tolerance involving regulatory genes have proved more efficient than using single or multiple functional genes involved in stress tolerance. Hence, the current advances in "omics" technologies and availability of the genome sequences of model legumes and soybean offer great potential to improve the stress tolerance of the legume crops. This chapter attempts to provide a detailed discussion about the different "omics" approaches and their applications for abiotic stress research on major legumes.

39.1
Introduction

Legumes represent the most utilized plant family with 20 000 species and are among the most important crops worldwide, having major impacts on agriculture, the

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

environment, and human/animal nutrition and health [1]. Legumes rank third behind cereals and oilseeds in world production [2] that accounts for 27% of the world's primary crop production [1]. Grain legumes constitute an important dietary constituent for humans and animals and these alone contribute 33% of the dietary protein nitrogen (N) needs of humans [3] besides being a source of income and livestock feed. These perfectly match the requirements of small-scale, low-income farmers in the developing countries where they accounted for 61.3 million hectares in 2002, compared to 8.5 million hectares in developed countries [2]. In order of rank, common beans (*Phaseolus* spp.), pea (*Pisum sativum* L.), chickpea (*Cicer arietinum* L.), broad bean (*Vicia faba* L.), pigeonpea (*Cajanus cajan* L.), cowpea (*Vigna unguiculata* L.), and lentil (*Lens esculentum* L.) constitute the primary dietary legumes [4]. Moreover, grain legumes, predominantly soybean (*Glycine max* L.) and peanut (*Arachis hypogeae* L.), are also a major source for vegetable oil, providing more than 35% of the world's processed vegetable oil.

Abiotic stress is the major constraint to crop productivity in the semiarid tropics (SAT) that include parts of 55 developing countries, populated by about 1.4 billion people, where grain legumes are mainly cultivated. Abiotic stress, which includes multiple stresses such as drought, salinity, waterlogging, high temperature, chilling, and so on are the primary causes of crop losses worldwide, reducing average yields for most major crop plants by over 50% [5, 6]. Only 10% of the global arable land can be classified under the nonstress category, which implies that crops grown on the other 90% of arable lands experience one or more environmental stresses [7]. Furthermore, crops under abiotic stress are usually more susceptible to weeds, insects, and diseases, which considerably increase the losses [8].

The grain legumes constitute important food and oilseed crops of the SAT, are mostly grown in low-input, rain-fed agriculture, and suffer from drought due to insufficient, untimely, and erratic rainfall in these climates that becomes major constraints to crop productivity. Several of the abiotic stresses associated with legume crops also directly affect symbiotic interactions and therefore limit their growth. Water deficits continue to be the major abiotic factor that affect crop yields globally [9] and are likely to worsen with the projected rapid expansion of water-stressed areas of the world encompassing 3 billion people by 2030 [10]. Moreover, in legumes such as peanut (*A. hypogaea*), Brazil nuts (*Bertholletia excelsa*), and faba bean (*V. faba*), aflatoxin contamination is a common occurrence during preharvest drought stress [11, 12]. In addition to drought, soil salinity is another major problem affecting the total nitrogen uptake and soil nitrogen contribution [13] resulting in reduced yields. Hence, there is a crucial need to increase the abiotic stress tolerance in legumes, which is a major challenge in crop improvement programs for enhancing yield stability. Although conventional plant breeding and enhanced management strategies have addressed several constraints that limit crop productivity or quality, there are situations where the existing genetic resources lack the required traits. Yield losses due to constraints like drought are highly variable in nature depending on the stress timing, intensity, and duration. Moreover, location-specific environmental stress factors such as high irradiance and temperature make breeding for drought

tolerance difficult through conventional approaches. Cutting-edge, knowledge-based breeding practices complemented adequately by genomics and genetic transformation technologies could lead to simpler and more effective gene-based approach for improving abiotic stress tolerance in the grain legumes. Application of biotechnological approaches has a potential to contribute efficiently to solve or reduce these problems in the grain legumes, thereby contributing to sustainable agriculture, especially in the SAT.

39.2 "OMICS" in Legumes and Abiotic Stress

Biotechnological approaches such as tissues culture, *in vitro* mutagenesis, marker-assisted breeding, and genetic transformation can speed up and overcome major bottlenecks of classical plant breeding due to the lack of natural sources of resistance and sexual incompatibility. However, successful application of biotechnology to abiotic constraints requires a good biological knowledge of both the target species and the mechanisms underlying tolerance to these stresses. Mechanisms of responses to stress can be measured at many different levels from the whole plant to the molecular level. The type, length, and severity of the stress have more influence on the plant response to stress [14]. Since responses are controlled by the plant genome, recent efforts have focused on the molecular response of the plant to water deficits [15]. Until a few years, the research on plant stress responses was focused on model plants such as *Arabidopsis*, and not much work was done on the legumes. However, since substantial similarities exist between the two crops, the knowledge on stress responses of *Arabidopsis* were used as source of information for legume research. Nevertheless, there are also significant fundamental differences like all physiological processes that differ and must be exploited to unravel the specific mechanisms involved in abiotic stress tolerance in the legumes [16]. Since the large genome size and the polyploidy of some legumes have hampered this goal, recent progress in legume biology has been greatly enhanced by the development of model systems to investigate the genetics of nodulation and other important processes such as resistance or tolerance to stresses. The two model legume plant systems, *Lotus japonicus* and *Medicago truncatula*, due to their small and diploid genomes, autogamous nature, short generation times, and prolific seed production were the obvious choices [17, 18]. Since then, powerful genetic and genomic tools have been developed that include genome sequencing [19], isolation of expressed sequence tags (ESTs) [20, 21], and establishment of genetic and physical maps for each model species [22, 23]. The increasing wealth of genetic and genomic data and the high degree of synteny between legume genomes [24, 25] make these two species valuable models for the molecular genetic study of the biotic and abiotic constraints that hamper legume crop yields. Furthermore, the soybean genome sequence and the high synteny between soybean and the model legumes have a potential to facilitate positional cloning and other genetic procedures for these studies.

While sequence information is invaluable and a necessary starting point, it is insufficient to answer questions concerning gene function, regulatory networks, and the biochemical pathways activated in response to stresses. To address these questions, more comprehensive approaches, including quantitative and qualitative analyses of gene expression products are necessary at the transcriptomic, proteomic, and metabolomic levels. This comprehensive knowledge about the genes involved in stress response and tolerance will further allow a more precise use of marker-assisted selection (MAS) and transgenics [7]. Since the "omics" involves genomics and functional genomics, genetic engineering, transcriptome profiling, proteomics, and metabolomics describing an organism's genome contribution to its overall phenotype, the recent progress made in these areas has considerably contributed to better understanding of the molecular and genetic basis of stress response that has been an important bottleneck for molecular and transgenic breeding. So far, a significant progress has been made in research on the abiotic stress tolerance of major legumes including soybean, chickpea, and peanut as discussed in the following sections.

39.3 Transcript "OMICS"

A eukaryotic cell contains ~15 000–30 000 distinct mRNAs with a prevalence ranging from one to several thousands in a total mass of ~100 000 mRNAs [26]. About 50% of the transcript population is made up of a relatively small number (some hundreds) of abundant transcripts representing only 1% of the different mRNA species, and the other half contains the "rare" mRNAs [27]. The set of all the messenger RNAs (mRNAs) in a cell/tissue/organism is referred to as the transcriptome and investigation of populations of mRNAs is thus called "transcriptomics." A genome-wide expression profiling is a powerful tool for studying genes involved in various biological phenomena, identifying the candidate genes, and revealing the molecular crosstalk of gene regulatory networks among abiotic stress responses.

Plants undergoing abiotic stresses in general face dehydration at the cellular level and hence almost 50% of the genes activated by these stresses including drought, salinity, or ABA treatment are common. Cellular water deficit in a plant stress triggers many changes in gene expression that in turn define its response to a particular environmental condition. The induced genes in response to cellular water deficit stress constitute different functional categories such as metabolism, transport, signaling, transcription, hydrophilic proteins, and the unknown, including the repression of genes involved in plant growth and development, such as photosynthesis-related genes. Broadly, the genes responding to abiotic stress can be categorized into two classes based on their response in terms of timescale or based on their involvement in tolerance; some respond immediately within seconds or minutes, while others respond later, in hours, days, or even weeks [28]. This allows for the speculation that the early responsive genes may provide initial protection and

regulate gene expression by being involved in amplification of signals and signal transduction. These include various protein kinases and genes encoding transcription factors, whereas the genes that respond later may be involved in adaptation to stress conditions, such as heat shock proteins, LEA proteins, ROS scavenger proteins, and so on [14, 28].

The genomic approaches allow changes induced by abiotic stresses on a global scale to be analyzed at the level of the whole organism. Much more extensive gene expression studies have been performed in *Arabidopsis*, and the resulting knowledge can also be used in legumes through comparative genomics. For example, Ishitani *et al*. [29] selected 100–200 genes from the *Arabidopsis* database and showed that at least 3 DREB-like genes, thought to be key transcriptional regulators of drought and/or cold tolerance, were present in common bean. Similarly, in *Arabidopsis*, analysis of the transcriptome changes occurring during cold, drought, and salt stress in a survey of 7000 genes showed a shared response for a majority of cold and drought stress-regulated genes, supporting the hypothesis that a common set of signal transduction pathways are triggered during different stress responses [30]. Around 11% of the stress-inducible genes are potential transcription factors further confirming the relevance of gene regulation in stress adaptation [31].

The *Arabidopsis* model is likely to be very different from legumes in terms of responses to stress in relation to grain filling, nitrogen utilization, fixation, and transport, root architecture, and interactions, all physiological processes that are fundamentally different in legumes. Hence, the usefulness of developing a legume model has become increasingly relevant in recent years. Moreover, the induction of gene expression by environmental stress must be exploited to unravel mechanisms dealing with abiotic stress tolerance in the agriculturally important grain legumes. In legumes, the gene expression patterns following biotic stresses have been more extensively studied than those following abiotic stresses. With respect to abiotic stress, gene expression analyses have been mainly based on studies with cloned genes [32]. Significant progress is being made at the genetic and genomic levels using the model legume *M. truncatula* through macro- and microarray analysis, reverse genetics, genome sequencing, and other high-throughput techniques [33, 34]. The analysis of almost 200 000 ESTs of *M. truncatula*, isolated from many different libraries constructed from diverse stages and treatments, was facilitated by searchable databases such as MtDB2 [35] and the TIGR Gene Index (http://www.tigr.org).

The advent of next-generation sequencing platforms [36], most recently the "third generation" (also called "next–next generation" or NGS) sequencing systems will enable plant genome to be sequenced within hours. The NGS approaches allow deciphering the cell's transcripts on the sequence level, which will truly revolutionize the research of organisms that are not now in line for genomic sequencing. This approach could circumvent the problems posed by extremely large genomes such as legumes. The next-generation sequencing not only is a dramatic advance over capillary-based sequencing but also presents significant challenges in assembly and sequence accuracy due to short read lengths, method-specific sequencing errors, and the absence of physical clones. However, the promise of much lower sequencing cost

with the now proven concept of next-generation expressed sequence tag sequencing will allow assessment of plant genomes at least at the functional level [37]. At ICRISAT, these NGS approaches are being used to develop EST-based markers to map the QTL for stress response in grain legumes. Recent reports have also shown that transcriptomic tools are a good option for legume breeding to environmental stresses as discussed in the next sections.

39.3.1 Soybean

Among the grain legumes, soybean has been more intensively studied and according to the legume information system data, over 1.3 million ESTs were developed from different cDNA libraries, which is the largest in number among the individual grain legume ESTs. The availability of a large number of EST and BAC sequences facilitated the discovery of new SNP and SSR markers in soybean toward the construction of high-resolution genetic maps. Besides, using a modified cDNA-AFLP technique in soybean, 140 differentially expressed cDNA fragments were obtained by comparing control and isoosmotic treated plants where some of the responsive genes encoded for ion transporters, transcription factors (TFs), and redox enzymes [38].

39.3.2 Chickpea

Chickpea is the most important food legume of semiarid tropics (SAT) and taxonomically one of the closest crops to the model legume *Medicago*. Sensitive and tolerant varieties of chickpea have been characterized under abiotic stress conditions, although very little is known about the genes involved in these responses. However, the characterization of genes involved in the differential behavior of these cultivars may constitute a good basis to extrapolate these results to other grain legumes. Five differentially expressed cDNAs were identified using differential display reverse transcriptase PCR (DDRT-PCR) under drought conditions with drought-tolerant cv. ICCV2 and drought-susceptible cv. ILC3279 of chickpea [39]. Moreover, 319 unique ESTs available from different libraries have been analyzed for differences in transcript profiling during drought stress treatment in two chickpea varieties having contrasting levels of drought tolerance (*C. arietinum* cv. PUSABGD72 and ICCV2). These ESTs were clustered in four groups according to their expression patterns [40].

A transcriptional profiling study in chickpea under drought, cold, and high salinity was carried out using cDNA microarray approach to look at the gene expression in the leaf, root, and/or flower tissues in tolerant and susceptible genotypes [41]. The differentially expressed transcripts in response to the particular stress were analyzed and a transcriptional change of over twofold was observed for 109, 210, and 386 genes after drought, cold, and high-salinity treatments, respectively. Among these, 2, 15, and 30 genes were consensually differentially expressed between tolerant and

susceptible genotypes studied for drought, cold, and high salinity, respectively. The differentially expressed genes coded for various functional and regulatory proteins, highlighting the multiple gene control and complexity of abiotic stress response mechanism in chickpea.

Two nonnormalized cDNA libraries from the seedling leaves of a drought-tolerant chickpea cultivar under PEG-treated and nontreated conditions have been constructed where 92 differentially expressed genes were identified [42]. Most of the upregulated genes were related to drought tolerance, while the downregulated genes were mainly involved in the photosynthesis. A set of over 2800 chickpea ESTs have been generated from a library constructed after subtractive suppressive hybridization (SSH) of root tissue from two closely related chickpea genotypes possessing different sources of drought avoidance and tolerance, ICC4958 (tester) and Annigeri (driver), respectively [43]. A total of 106 EST-based markers were designed from 477 sequences with functional annotations that were tested on *C. arietinum*. Forty-four EST markers were polymorphic when screened across nine *Cicer* species (including the cultigen) [44]. The chickpea root EST database developed in these studies provide researchers with a major new resource for data mining associated with root traits and drought tolerance [43]. More recently, a total of 20 162 drought- and salinity-responsive ESTs were generated from 10 different root tissue cDNA libraries of chickpea and 177 new EST-based SSR markers were developed [45].

Besides, SuperSAGE analysis for gene expression in chickpea roots in response to drought was carried out resulting in sequencing of 80 238 of 26 bp tags [46]. Among these tags, 7532 (43%) UniTags were more than 2.7-fold differentially expressed and 880 (5.0%) were regulated more than 8-fold upon stress resulting in unambiguous annotation of 22% (3858) of these tags. Microarray analysis of these 3000 annotated UniTags confirmed 79% of the tag-based results, whereas RT-PCR confirmed the SuperSAGE data in all cases. This is the first study to prove the potential of SuperSAGE technology for molecular breeding in the nonmodel crops. However, lack of availability of a chickpea reference genome limits the value of SuperSAGE tags, as only a fraction of them could be annotated.

39.3.3 Peanut

In peanut, differential DDRT-PCR has been used to identify differentially expressed genes in peanut grown under drought stress versus irrigation conditions where some drought-responsive mRNA transcripts were identified based on expression pattern [47, 48]. Besides, DDRT-PCR studies have been carried out with transgenic peanut events overexpressing rd29A:DREB1A to detect the differentially expressed transcripts under abiotic stress [49]. Here, 51 differentially expressed transcripts were identified under stress treatments; among them 35 transcripts were newly expressed, 11 were upregulated, and 5 were downregulated. In the BLAST search of differentially expressed partial cDNAs, only 17 clones showed a significant similarity to the ESTs in the database, indicating that the majority of the cDNAs cloned in this study may be novel and needs further research to identify their role in stress response. These

results also suggested that the increased plant tolerance against drought stress in transgenic peanut may not be attributable only to the expression of DREB1A-targeted cold-responsive (COR) genes identified in *Arabidopsis* [49].

In a recent study, six different cDNA libraries were constructed from developing peanut seeds at three reproduction stages (R5, R6, and R7) from a resistant and a susceptible cultivated peanut genotype, "Tifrunner" that is susceptible to *Aspergillus* infection with higher aflatoxin contamination and resistant to *tomato spotted wilt virus* (TSWV) and "GT-C20" that is resistant to *Aspergillus* with reduced aflatoxin contamination and susceptible to TSWV. The developing peanut seed tissues of these genotypes were challenged by *Aspergillus parasiticus* and drought stress in the field and 21 777 high-quality EST sequences were generated from cDNA clones of 6 libraries [50]. Similarly, EST libraries for cultivated peanut were developed from leaves of peanut line C34-24 (resistant to leaf spots and TSVW) and immature pods of peanut line A13 (tolerant to drought stress and preharvest aflatoxin contamination). A total of 1825 ESTs, 769 from the C34-24 and 1056 from the ESTs were identified and 44 EST-derived simple sequence repeat (SSR) markers have been characterized for cultivated peanut [51]. A total of 6264 high-quality ESTs were generated from leaves and roots of a wild peanut *Arachis stenosperma*, and 188 microsatellite markers have developed form these ESTs [52].

More recently, nearly 700 genes were identified in subtractive cDNA library from gradual process of drought stress adaptation in peanut. This study also showed the functional importance of HSP70 gene and key regulators such as Jumonji in drought stress response [53]. A high-density oligonucleotide microarray for peanut has also been developed using 49 205 publicly available ESTs and tested the utility of this array for expression profiling in a variety of peanut tissues [54]. Over 108 putatively pod-specific/abundant genes, as well as transcripts, whose expression was low or undetected in pod compared to peg, leaf, stem, or root were detected. Several transcripts that significantly overrepresented in the peanut pod included genes responsible for seed storage proteins and desiccation (e.g., late-embryogenesis abundant proteins, aquaporins, legumin B), oil production, and cellular defense [54].

39.4 Prote"omics"

Since the 1990s, genomics has been the most active research field in biological science generating a huge amount of information, while structural genomics has emerged at the methodological level to understand gene expression and function. A complete knowledge of the proteins expressed by the genome of a cell, tissue, or organism at a specific time point (proteome) is necessary to understand the biology of a cell or an organism. The proteome reflects the actual state of the cell or the organism and is an essential bridge between the transcriptome and the metabolome. Proteins act directly on biochemical processes, and thus must be closer to the phenotype, compared to DNA-based markers. Although research on plant responses to stress on the DNA or RNA level provided an important insight into stress tolerance, the

proteomics approach is very important in evaluating stress responses since the mRNA levels may not always correlate with protein accumulation [55]. In addition, many proteins are modified by posttranslational modifications such as phosphorylation, glucosylation, and ubiquitinylation, which significantly influence protein functions. Proteomics, understood as protein biochemistry on an unprecedented and high-throughput scale, is becoming a promising and active approach in this postgenomic period. However, its application to plants is rather limited compared to other biological systems [56].

Compared to analysis of the transcriptome, analysis of the plant proteome in response to abiotic and biotic stresses is still limited, although good technical progress has been achieved in the separation of proteins and their identification by mass spectrometry. Studies have evaluated changes in protein levels in plant tissues in response to stresses [57, 58]. However, these studies have mainly focused on nonlegume species such as *Arabidopsis* and rice [57] and some legumes recently [56]. As a result, only a handful of studies have been carried out in legumes, although in the next few years there should be a significant increase in the number of legume species and stresses analyzed. So far, pea has been more intensively studied, with the analysis of induced protein expression in roots in response to salt [59] and to cadmium stress [60]. Recently, *M. truncatila* has been the subject of several proteomic studies that represent the most extensive proteomic description of *M. truncatula* suspension cells to date and provide a reference map for future comparative proteomics and functional genomics studies of biotic and abiotic stress responses [61].

39.4.1 Soybean

Some reference maps of soybean that are available in the proteomics database provide a starting point for ongoing functional genomics studies associated with biotic/abiotic stress in soybean. The Soybean Proteome Database is aimed to be a data repository for functional analyses of soybean responses to flooding injury that is recognized as a major constraint for the establishment and production of this plant. The latest release contains 21 reference maps of soybean (*G. max* cv. Enrei) proteins electrophoresized on two-dimensional polyacrylamide gels of which the samples were collected from several organs, tissues, and organelles. These reference maps included 7311 detected proteins and 532 identified proteins, or proteins for which a sequence or peptide peak has been determined. The Soybean Proteome Database also integrates multiple "omes," where an "omics" table reveals relationships among 106 mRNAs, 51 proteins, and 89 metabolites that vary over time under flooding stress. The tabulated metabolites are anchored to a metabolome network. A unified temporal profile tag attached to the mRNAs, proteins, and metabolites facilitates retrieval of the data based on the temporal expression profiles. A graphical user interface based on dynamic HTML facilitates viewing of both the metabolome network and the profiles of multiple "omes" in a uniform manner. The entire database is available at http://proteome.dc.affrc.go.jp/soybean/ [62].

39.4.2 Chickpea

Most of the earlier understanding of dehydration-responsive cellular adaptation in chickpea has evolved from transcriptome analysis and the comparative analysis of dehydration-responsive proteins, particularly proteins in the subcellular fraction, is limited. Bhushan *et al.* [63] have initiated a proteomics approach to identify dehydration-responsive ECM proteins in JG-62, a drought-tolerant variety of chickpea where the dehydration-responsive temporal changes in ECM proteins revealed 186 proteins with variance at a 95% significance level. The comparative proteomics analysis led to the identification of 134 differentially expressed proteins that include predicted and novel dehydration-responsive proteins. This study, for the first time, demonstrated that over a 100 ECM proteins are presumably involved in a variety of cellular functions, namely, cell wall modification, signal transduction, metabolism, and cell defense and rescue, and impinge on the molecular mechanism of dehydration tolerance in plants. Since the nuclear proteins constitute a highly organized, complex network that plays diverse roles during cellular development and other physiological processes. Another study provided insights into the complex metabolic network operating in the nucleus during dehydration in chickpea [64]. Approximately, 205 protein spots were found to be differentially regulated under dehydration; mass spectrometry analysis allowed the identification of 147 differentially expressed proteins, presumably involved in a variety of functions including gene transcription and replication, molecular chaperones, cell signaling, and chromatin remodeling. The dehydration-responsive nuclear proteome of chickpea revealed a coordinated response, which involves both the regulatory and the functional proteins.

39.4.3 Peanut

In peanut very few proteomic studies were conducted on stress response; in a recent study with selected tolerant and susceptible peanut genotypes from the US minicore collection were analyzed for changes in leaf proteins under water deficit stress [65]. A total of 102 protein bands/spots were analyzed by matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry (MALDI-TOF MS) and by quadrupole time-of-flight tandem mass spectrometry (Q-TOF MS/MS) analysis. Forty-nine nonredundant proteins were identified that implicated a variety of stress response mechanisms in peanut. It was observed that lipoxygenase and 1L-myo-inositol-1-phosphate synthase, which aid in inter- and intracellular stress signaling, were more abundant in tolerant genotypes under water deficit stress. Here, the acetyl-CoA carboxylase, a key enzyme of lipid biosynthesis, increased in relative abundance along with a corresponding increase in epicuticular wax content in the tolerant genotypes suggesting an additional mechanism for water conservation and stress tolerance. In addition, there was a marked decrease in the abundance of several photosynthetic proteins in the tolerant genotype along with a concomitant decrease in net photosynthesis in response to water deficit stress.

39.5 Metabol"omics"

Undoubtedly, transcriptomic and proteomic data are important steps in deciphering a complex biological process, but they are still insufficient since most biological processes are ultimately mediated by cell metabolites. Metabolomics is considered to provide a direct "functional readout of the physiological state" of an organism. Besides, alternative mRNA splicing, protein turnover rates, and posttranslational modifications that modulate protein activity imply that changes in the transcriptome or proteome do not always correspond to alterations in the cell metabolome [66]. Target analysis, metabolite profiling, and metabolic fingerprinting are different conceptual approaches in metabolomics that can be used for a large range of applications, including phenotyping of genetically modified plants, substantial equivalence testing, determining gene function, and monitoring responses to biotic and abiotic stresses. Metabolomics can therefore be seen as bridging the gap between genotype and phenotype. Metabolic changes underpin plant development and responses to applied stresses, and that metabolic information reflects biological endpoints more accurately than transcript or protein analysis. Hence, the only way to the complete understanding of both gene function and molecular events controlling complex plant processes is to analyze the transcriptome, the proteome, and the metabolome in an integrative manner [67].

In legumes, the metabolomic approach has been used in *M. truncatula* suspension cells to determine the responses to various stimuli [68]. Although, large-scale comprehensive metabolomic studies are difficult, a number of targeted analyses have been performed to assess the involvement of subsets of metabolites in various stresses. Although the preliminary results from combining metabolic approaches with transgenics indicates the potential of increasing intrinsic stress resistance levels in legume crops and strengthens the potential role of biotechnology in crop improvement [69, 70], it must be emphasized that most metabolic pathways are interconnected in highly complex networks. Thus, modulating one metabolic pathway may have negative impacts on another, leading to concomitant deleterious traits in the modified crop. Large-scale metabolic analyses are therefore necessary to observe the metabolic networks important for plant growth and development under a range of environmental conditions.

39.6 Gen"omics"

Genomics involves the development of molecular markers for genetic diversity analysis and it provides novel opportunities to manipulate QTL through marker-assisted selection to develop improved cultivars. The use of genetic and genomic analysis to help identify DNA regions tightly linked to agronomic traits in crops, the so-called 'molecular markers, can facilitate breeding strategies for crop improvement. The use of molecular markers for the indirect selection of improved crops can

speed up the selection process by alleviating time-consuming approaches of direct screening under greenhouse and field conditions.

39.6.1 Soybean

The availability of the soybean genome sequence in combination with the integrated genetic and physical maps are valuable resources providing soybean researchers powerful and efficient genomic tools to identify and characterize genes or QTL for agronomic traits of soybean, facilitating marker-assisted breeding and soybean improvement. In soybean, *G. max* (L.) Merr., substantial genetic variation exists for salt response. In order to identify QTL associated with salt tolerance in soybean, lines from the cross of "S-100" (salt tolerant) × "Tokyo" (salt sensitive) were evaluated in saline fields where each line was characterized with RFLP markers and an initial QTL single-factor analysis was completed. These results were used to identify genomic regions associated with the trait and to saturate the selected genomic regions with SSR markers to improve mapping precision. Subsequently, a major QTL for salt tolerance was discovered near the Sat_091 SSR marker on linkage group (LG) N. The strong relationship between the SSR marker alleles and salt tolerance suggested that these markers could be used for marker-assisted selection in commercial breeding [71] (Table 39.1).

Table 39.1 List of major identified QTL associated with abiotic stress in important legume crops.

Legume	Abiotic stress	Marker type	References
L. culinaris	Cold	RAPD	[156]
	Winter hardiness	SSR	
	Winter hardiness	SSR, RAPD AFLP	[157]
G. max	Manganese toxicity	SSR, RAPD	[158]
	Salt stress	SSR	[71]
	Waterlogging	SSR	[159]
	Phosphorus deficiency	SSR, RFLP, EST	
	Phosphorus deficiency	SSR	[160]
Medicago sativa	Aluminum toxicity	RFLP	[161]
A. hypogaea	Transpiration	SSR	[74]
	Transpiration efficiency	SSR	
	Specific leaf area (SLA)	SSR	
	SPAD chlorophyll meter reading (SCMR)	SSR	
	SPAD at stage of harvest	SSR	

SPAD: chlorophyll content; RAPD: random amplified polymorphism DNA; RFLP: restriction fragment length polymorphism; AFLP: amplified fragment length polymorphism; SSR: simple sequence repeat; EST: expressed sequence tag.

39.6.2
Chickpea

MAS is being deployed in chickpea at ICRISAT to introgress QTL alleles associated with a large root size into elite germplasm [72]. Terminal drought can curtail chickpea yield from 20% to more than 50%. Hence, a deep root system capable of extracting additional soil moisture should positively impact yield in drought-prone areas [73].

39.6.3
Peanut

At ICRISAT, the first genetic map for cultivated peanut (*A. hypogaea*), an amphidiploid (4X) species, was developed that its utility demonstrated for molecular mapping of QTL controlling drought tolerance-related traits and establishing relationships with diploid AA genome of groundnut and model legume genome species. In order to develop a genetic linkage map for tetraploid cultivated groundnut, 1145 microsatellite or simple sequence repeat (SSR) markers available in public domain as well as unpublished markers from several sources were screened on two genotypes, TAG 24 and ICGV 86031, which are parents of a recombinant inbred line mapping population. As a result, 144 (12.6%) polymorphic markers were identified that amplified 150 loci. A total of 135 SSR loci could be mapped into 22 linkage groups (LGs) [74] (Table 39.1).

39.7
Functional Genomics

Large-scale analysis by using different "omics" technologies are providing extensive data sets that will help identify potential candidate genes for an increase in intrinsic resistance and/or tolerance levels in important legume crops. Identification of these candidate genes may allow their direct application in crop improvement through MAS or genetic engineering. However, in most cases, the roles of these candidate genes remain unknown and it will be important to carry out functional studies as a preliminary step toward their use in genetic improvement. To date, the *Arabidopsis*, rice, *M. truncatula*, and *L. japonicus* genomes have been sequenced and the genome sequencing projects of some other plants is underway. The traditional pursuit of a gene starting with a phenotype (forward genetics) has paved the way for the opposite situation where the gene sequences are known but not their functions. The challenge is to decipher the function of thousands of genes identified by genome projects where reverse genetics methodologies will be the key tools. The ability to knockout genes or suppress their expression are powerful tools to determine the function of a gene. This can be done by antisense RNA suppression, targeted gene replacement, insertional mutagenesis, gene silencing through RNAi, and targeted induced local lesion in genome (TILLING) approaches.

39.7.1
Gene Silencing Approaches

Antisense RNA suppression requires considerable effort for any given target gene before even knowing whether it will be successful [75]. In *Arabidopsis*, collections of random T-DNA (over 225 000 independent *Agrobacterium* T-DNA insertions) or transposable element insertion mutants are available [76]; such a collection does not exist yet for the legumes. Targeted gene replacement via homologous recombination has not yet been reproducibly achieved for higher plants. Although collections of T-DNA mutants may be very useful, they produce a limited range of allele types and do not always produce null alleles [77, 78]. Recently, the use of the tobacco retrotransposon Tnt1 has been successfully applied for large-scale insertional mutagenesis in *M. truncatula* that promises to be a useful tool for functional genomics [79].

The term RNA silencing broadly has been adopted to describe phenomena such as posttranscriptional gene silencing (PTGS) in plants, quelling in fungi, and RNA interference in animals [80]. Researchers have developed different RNA silencing strategies as tools for selective knockout of targeted genes. Virus-induced gene silencing (VIGS) has been developed to suppress plant gene expression through infection with virus vectors that harbor a target region of the host gene [80, 81]. There are vectors available that have the ability to support VIGS in plants [82, 83]; these have not yet been used extensively in legumes.

Since VIGS in peanut is not yet feasible, 25 peanut water deficit stress-induced cDNAs were characterized in a heterologous species *Nicotiana benthamiana* [84]. Increased membrane damage was seen under water deficit stress in most of the silenced plants signifying that many of these stress-induced genes were important to confer drought tolerance. Under water stress, silencing of homologue of flavonol 3-*O*-glucosyltransferase (F3OGT), a homologue of alcohol dehydrogenase, a homologue of salt-inducible protein, and a homologue of heat shock protein 70 showed more visible wilting symptoms compared to the controls. Interestingly, downregulation of two genes, homologous to aspartic proteinase 2, and Jumonji class of transcription factor showed relative drought-tolerant phenotypes. Moreover, F3OGT-silenced plants showed more wilting symptoms, membrane damage, and chlorophyll degradation than any other type during water deficit. These results demonstrated that VIGS approach can be used to characterize and assess the functional relevance of water-deficit-stress-induced cDNAs in a heterologous species.

39.7.2
TILLING

The limitations of RNA silencing or insertational mutagenesis can be overcome by TILLING that combines chemical mutagenesis with a powerful screening method for potential mutations [75, 85, 86]. The generation of phenotypic variants without introducing foreign DNA in the plant makes TILLING very suitable not only for functional analysis but also for agricultural applications. The TILLING facility for collection of mutants is available for *L. japonicus* [87] and *M. truncatula* (U.C. Davis,

USA; CNRS, Gif-Sur-Yvette, France). TILLING facilities are also being extended to a wider variety of legumes including soybean and peanuts.

39.8 Transgenomics

The use of transgenic technology or "transgenomics" potentially offers a more targeted gene-based approach for gaining valuable information to understand the mechanisms governing stress tolerance, providing a complementary means for the genetic enhancement of field crops, thereby alleviating some of the major constraints to crop productivity in developing countries [88]. Tissue culture has been repeatedly described as difficult in grain legumes. Regeneration from both organogenesis and embryogenesis has been reported to be recalcitrant in this plant group [89, 90] and has been attributed as a major constraint in transgenic development for many legumes. Since advances in molecular genetics, for example, gene overexpression, gene suppression, promoter analysis, and T-DNA tagging require efficient transformation systems [91]. Implementation of robust protocols for regeneration in legumes is therefore a necessary condition for genetic transformation.

In plants, upon exposure to abiotic stress, a number of genes are turned on resulting in increased levels of several osmolytes and proteins that may be responsible for conferring a certain degree of protection from these stresses. Therefore, it may be necessary to transfer several potentially useful genes into the same plant in order to obtain a high degree of tolerance to drought or salt stress. Novel genes accessed from exotic sources of plants, animals, bacteria, and even viruses can be introduced into the crop through various genetic transformation methods [9] with the possibility of controlling the timing, tissue specificity, and expression level of transferred genes for their optimal function.

The feasibility of using *Agrobacterium tumefaciens*-mediated gene transfer has been an important breakthrough in legume transgenic research although the rate of recovery of transgenic lines is still low in many cases [90, 91]. To date, genetic transformation has been reported in all the major legume crops such as *Vigna* species, *C. arietinum*, *C. cajan*, *Phaseolus* spp., *Lupinus* spp., *Vicia* spp., *P. sativum*, and soybean. Despite being crucial to tropical agriculture, transgenic grain legumes with an exception of soybean have not moved out from laboratories to large farm lands compared to their counterparts, "cereals" [92]. For example, the increase in tolerance to aluminum toxicity in transgenic alfalfa [93] and cyanamide toxicity in transgenic soybean [94] demonstrates the potential of this approach in legumes (Table 39.2). At ICRISAT, efficient transformation protocols have been developed for legume crops including groundnut, pigeonpea, and chickpea. A more exhaustive review of the application of transgenesis to overcome abiotic stresses in plants is provided in Ref. [9].

Various transgenic technologies for improved stress tolerance have been developed involving the expression of functional genes including those encoding for enzymes required for the biosynthesis of osmoprotectants [95–97] or modifying membrane lipids [98, 99], late embryogenesis proteins [100], and detoxification

Table 39.2 Selective reports on production of abiotic stress-tolerant transgenic legumes.

Gene	Protein	Source(s)	Cellular role	Transhost	Promoter used	Performance of transgenics	References
NTR1 (nectarin1)	Jasmonic acid carboxyl methyltransferase	*B. campestris*	Methyl jasmonate	*G. max*	CaMV35S		[119, 120]
Cah	Cyanamide hydratase	*Myrothecium verrucaria*	Cyanamide hydratase	*G. max*	*A. thaliana* actin-2 promoter	Tolerance to cyanamide toxicity	[94]
DREB1A	DRE-binding protein	*A. thaliana*	Transcription factor	*A. hypogaea*	*A. thaliana* RD29A promoter		[112]
DREB1A	DRE-binding protein	*A. thaliana*	Transcription factor	*C. arietinum*	*A. thaliana* RD29A promoter		[Development of transgenic chickpea for drought tolerance (ICRISAT unpublished data).]
p5cs	O1-pyrroline 5-carboxylate synthase	*V. aconitifolia*	Proline biosynthesis	*C. arietinum*	CaMV35S		[122]
codA	Choline oxidase A	*Arthrobacter globiformis*	Glycine-betaine biosynthesis	*C. arietinum*	CaMV35S with a chloroplastic transit peptide		[121]
GmDREB1	DRE-binding protein	*G. max*	Transcription factor	*M. sativa*	*A. thaliana* RD29A promoter	Salt tolerance	[137]
WXP1	AP2 domain	*M. truncatula*	Wax biosynthesis	*M. sativa*	CaMV35S	Tolerance to drought	[162]
MDH	Malate dehydrogenase	*M. sativa*	Malate dehydrogenase	*M. sativa*	CaMV35S	Tolerance to aluminum toxicity	[93]

fe-sod	Fe-superoxide dismutase	*N. plumbaginifolia*	Dismutation of reactive oxygen intermediates in chloroplasts	*M. sativa*	CaMV35S with a chloroplastic transit peptide	Showed increased Fe-SOD activity, which was associated with increased winter survival	[163]
mn-sod	Mn-superoxide dismutase	*N. plumbaginifolia*	Dismutation of reactive oxygen intermediates in mitochondria	*M. sativa*	CaMV35S with a chloroplastic and mitochondrial transit peptide	Showed significantly greater survival in field under water stress and in winter	[100, 164]
sod	Superoxide dismutase	*N. plumbaginifolia*, *P. sativum*	Dismutation of toxic reactive oxygen intermediates	*M. sativa*	CaMV35S	Showed increased regrowth after freezing stress	[165]

enzymes [101]. A widely adopted strategy has been to engineer certain osmolytes for their overexpression in plants to develop stress-tolerant crops [102–107]. However, the approaches involving the transfer of a single functional gene have not proven very effective in improving plant tolerance beyond the short-term effects that have been reported [108, 109]. Hence, multiple mechanisms to engineer water stress tolerance have been utilized and studies involving regulatory genes have been more efficient [108–112].

39.8.1 Soybean

The first report of soybean (*G. max*) transformation was published in 1988 where both *Agrobacterium*-mediated transformation [113] and particle bombardment method were used [114]. At present, soybean is the only transgenic legume crop that is under commercial cultivation. Roundup ready soybean was the first transgenic soybean resistant to herbicide, commercially released in the United States in 1996 by Monsanto company (http://www.monsanto.com/history.asp), which was grown commercially in seven countries, the United States of America, Argentina, Canada, Mexico, Romania, Uruguay, and South Africa in 2001 [115]. Globally, herbicide-tolerant soybean occupied 33.3 million hectares, representing 63% of the global transgenic crop area of 52.6 million hectares for all crops by 2001 [115]. There have been numerous excellent reviews on gene technology applications in soybean [91, 116–118]. Recent reports on transgenic soybean for abiotic stress tolerance include transformation with coding sequence for cyanamide hydratase (Cah), an enzyme that converts toxic cyanamide to urea, from the soil fungus *Myrothecium*. Cah expression detoxified cyanamide in leaf callus and embryogenic cultures of soybean as well as in whole plants as shown by cyanamide resistance [94]. Another study on the constitutive expression of *nectarin1* (*ntr1*) gene from *Brassica campestris* in transgenic soybean resulted in enhanced accumulation of methyl jasmonate (MeJA). *NTR1* gene encodes jasmonic acid carboxyl methyl transferase, which is an important plant regulator involved in plant development that regulates the expression of plant defense genes in response to various stresses such as wounding, drought, and pathogens. The higher levels of MeJA in the transgenic soybean plants conferred tolerance to dehydration during seed germination and seedling growth as reflected by the percentage of the fresh weight of seedlings. In addition, the transgenic soybean plants also conferred better capacity to retain water than wild-type plants when drought tolerance was tested using detached leaves [119, 120].

39.8.2 Chickpea

Since it is believed that osmoregulation is one of the best strategies for abiotic stress tolerance, especially if osmoregulatory genes could be triggered in response to drought, salinity, and high temperature. A prokaryotic osmoregulatory choline oxidase gene (*codA*) has been targeted at the chloroplasts to enhance the potential

of photosynthetic machinery of chickpea to withstand oxidative damage. Chloroplasts from plants of transgenic lines were evaluated for their efficacy to withstand photoinhibitory damage where the loss in PS II activity in chloroplasts of wild-type plants exposed to high light intensity was significantly higher than that in chloroplasts of transgenic chickpea. The results indicated that H_2O_2 produced by *codA* as a by-product during synthesis of glycine-betaine is responsible for building stronger antioxidant system in chloroplasts of transgenic chickpea plants [121]. Similarly at ICRISAT, the P5CSF129A gene encoding the mutagenized *D1-pyrroline-5-carboxylate synthetase* (P5CS) for the overproduction of proline was introduced in chickpea. The accumulation of proline in several of these transgenic events was more pronounced and increased significantly in the leaves when exposed to water stress along with a decrease in free radicals as measured by a decrease in the malonaldehyde (MDA) levels, a lipid peroxidation product [122]. However, the overexpression of proline appeared to have no beneficial effect on biomass accumulation since only a few events showed a significant increase in the biomass production toward the end of the progressive drying period. In any case, the overexpression of P5CSF129A gene resulted only in a modest increase in the transpiration efficiency (TE), thereby indicating that the enhanced proline had little bearing on the components of yield architecture that are significant in overcoming the negative effects of drought stress in chickpea. These results agree with the previous reports in other crops [123–125]) and, in our own assessment, the gene affecting single protein might be less efficient in coping with water-limiting conditions [122].

To address the multigenicity of the plant response to stress, a strategy to target transcription factors that regulate the expression of several genes related to abiotic stress was considered. Regulatory genes or transcription factors, more specifically those belonging to the AP2/ERF family, have previously been shown to improve stress tolerance under lab conditions by regulating the coordinated expression of several stress-related genes in heterologous transgenic plants [111, 112, 126]. Hence, a large number of transgenic plants of chickpea carrying the *DREB1A* transcription factor from *Arabidopsis thalianna*, driven by a stress-inducible promoter from *rd29A* gene from *A. thaliana*, have been developed [Development of transgenic chickpea for drought tolerance (ICRISAT unpublished data).].

39.8.3 Peanut

The transfer of individual genes to plants, for acquiring higher stress tolerance, has so far had only a limited impact. However, the simultaneous transcriptional activation of a subset of those genes, by transferring transcription factors, has been revealed as a promising strategy [127, 128]. Using transgenic plants carrying regulatory genes, specifically those belonging to the AP2/EREBP family (DREB1A), proved an efficient method to improve the abiotic stress tolerance of crop plants [111, 112, 126]. The overexpression of *DREB1A* under the control of a constitutive promoter was detrimental when stress was not applied, although it had a positive effect on plants under stress. The use of the stress-inducible promoter from rd29A, instead of the

CaMV35S promoter, to overexpress *DREB1A* minimized the negative effects on plant growth [111]. Since improving the water use efficiency (WUE) of a plant is a complex issue, efforts to breed groundnut genotypes for high TE and stomatal conductance have obtained limited success. At ICRISAT, the transgenic groundnut plants carrying *DREB1A* transcription factor from *A. thaliana* driven by a stress-inducible promoter from *rd29A* gene also from *A. thaliana* have been shown to improve drought tolerance under greenhouse conditions [112]. A few transgenic events with contrasting responses have been selected for further detailed studies on the gas exchange characteristics of leaves. Besides, the biochemical responses of plants under identical conditions of water stress have been examined critically to further understand the mechanisms underlying environmental stress resistance in these transgenic events [109].

39.8.4
Candidate Genes from Legumes

There are several reports on candidate genes being cloned from legumes and tested in model plants for abiotic stress tolerance (Table 39.3). These advances suggest good prospects for developing transgenic legumes with enhanced tolerance to abiotic stress in the near future. There have been reports on manipulating the expression of pea DNA *helicase45* or the glyoxalate pathways conferring high salinity tolerance in tobacco [129, 130]. Similarly, ectopic expression of the *AhNCED1* gene (which results in oxidative cleavage of *cis*-epoxycarotenoids) in *Arabidopsis* improved the water stress tolerance levels by causing accumulation of endogenous ABA [131]. Besides, a *CarNAC1* gene (for NAM, ATAF1,2, and CUC2) was isolated from a cDNA library constructed from chickpea (*C. arietinum* L.) seedling leaves treated by polyethylene glycol and has been found to play important roles in plant development and stress responses [132]. Another cDNA clone encoding a dehydrin gene, *cpdhn1*, was isolated from a cDNA bank prepared from ripening seeds of *C. pinnatifidum* [133]. Since the gene expression was induced not only during seed development but also in leaves in response to drought, chilling, and salinity and to treatment with ABA or methyl jasmonate, the CpDHN1 protein may have a role in tolerance to a variety of environmental stresses, both abiotic and biotic. In another effort, a *CAP2* gene from chickpea encoding a novel AP2 family transcription factor that increased under dehydration has been characterized [134]. The CaMV35S promoter-driven expression of CAP2 in tobacco resulted in increased tolerance to dehydration and salt stress than the wild-type plants. Besides, transgenic plants expressed higher steady-state transcript levels of abiotic stress response genes NtERD10B and NtERD10C and auxin response genes IAA4.2 and IAA2.5, indicating a mutual interrelation between plant growth and development and abiotic stress response pathways and a probable involvement of CAP2 in both the signaling pathways.

Several transcription factors of AP2 family including DREB homologue and ERF transcription factors have been isolated from soybean and were characterized by their expression in transgenic plants. GmDREB2 [135] GmDREB3 [136] from soybean was expressed in *Arabidopsis* and has shown tolerance to drought and salt stress, whereas

GmDREB1 enhanced salt tolerance in transgenic *medicago* [137]. Besides, three more DREB homologues were identified in soybean, namely, GmDREBa, GmDREBb, and GmDREBc. While *GmDREBa* and *GmDREBb* genes were induced by salt, drought, and cold stresses in the leaves of soybean seedlings, the expression of *GmDREBc* was apparently induced in roots by salt, drought, and abscisic acid treatments [138]. In another study, expression analysis of ERF transcription factors in soybean showed that nine unigenes belonging to six ERF family subgroups were induced by both biotic/abiotic stresses and hormone treatment, suggesting that they were involved in crosstalk between biotic and abiotic stress-responsive signaling pathways. Overexpression of two full-length soybean genes GmERF057 and GmERF089 from two different subgroups enhanced the tolerances to drought, salt stresses, and/or pathogen infection of the tobacco plants [139]. Moreover, transcription factors of MYB.family GmMYB76, GmMYB177, and GmMYB92 [140] and of bZIP family GmbZIP44, GmbZIP62, and GmbZIP78 were isolated from soybean and tested in transgenic *Arabidopsis* for their role in stress tolerance [141]. Over 64 *GmWRKY*genes from soybean were identified that expressed differentially under various abiotic stresses. For example, GmWRKY21 responded to cold stress, while GmWRKY54 conferred salt and drought tolerance, possibly through the regulation of DREB2A and STZ/Zat10 [142]. Also, six GmPHD genes encoding Alfin1-type PHD finger proteins were identified in soybean and their expressions responded differentially to drought, salt, cold, and ABA treatments. Another gene GmCHI (chilling inducible) has been assumed to be regulated by ABA-dependent signal transduction pathway during cold acclimation in soybean. Overexpression of *GMCHI* in *Arabidopsis* under the control of CaMV35S promoter enhanced the tolerance to cold, drought, and NaCl stresses [143]. In another report, GmGT-2A and GmGT-2B, "GT" element binding transcription factors belonging to the trihelix family genes, were cloned from soybean and their overexpression improved plant tolerance to salt, freezing, and drought stress in transgenic *Arabidopsis* plants [144]. Transgenic *Arabidopsis* plants overexpressing the GmPHD2 showed salt tolerance compared to the wild-type plants by diminishing the oxidative stress through regulation of downstream genes [145]. Similarly, an ectopic expression of a soybean antiquitin homologue gene GmTP55 (closely related to the stress-induced plant antiquitin-like proteins belonging to the ALDH7 family) in both *Arabidopsis* and tobacco has been shown to confer tolerance to salinity during germination and to water deficit during plant growth [146].

39.9 Phen"omics"

Although occupying the last position in a long and wide array of gene-based "omics" approaches, phenomics, which can be viewed as a "modern phenotyping counterpart," is critical to the gene-"omics" approach. Indeed, it is often and wisely considered that unless the phenotypic expression of plants displaying different genomic/metabolomic/proteomic/transcriptomic/transgenomic content is properly understood and characterized, and then accurately and precisely measured, there is

little chance that any of the approaches above can be successful. There is unfortunately an increasing gap between the knowledge on the genotype and that on the phenotype [147] that urgently needs to be tackled. What is often viewed in the phenomics is the possibility to harness new technology to increase the throughput of "traditional" phenotypic assessments. While this has indeed a tremendous potential, it also bears the risk of making phenotyping a technology-driven activity generating (many) numbers, rather than a question/hypothesis-driven approach to the understanding of plant response to stress. In what follows, we attempt to lay out the basic principles that should be considered when attempting "phenomics" characterization for focusing on the type of abiotic stress (e.g., drought, salinity, etc.).

39.9.1 Relevant Protocols to Assess Plant Response to Stress: Drought as a Case

There have been a number of studies that explain the importance of using relevant protocols to assess drought stress response [108] or in the approach to look at specific traits that are likely to be beneficial under water limitation, like root systems [148]. In short, the principle of exposing plants to stress is about ensuring that the kinetics of stress impositions are relevant to those that plants would face in natural environments. The use of rapid stress imposition (uprooting, exposure to PEG, growth in very small pots, etc.) is not suitable to properly characterize plant response to stress, and especially to acquire knowledge on the genes involved in the plant response, as these are likely to be different from the genes that would be expressed under natural conditions. Therefore, while applying water stress, it is essential to have a rigorous control and record of the stress intensity and the kinetics of stress imposition. One school of thought proposes to look at stress intensity from the angle of the soil moisture available for transpiration [149], as it has the great and powerful advantage of allowing comparison across all plant species, across environments. Unfortunately, rarely care is taken for this index in many gene-based studies. The other school of thought is to measure leaf water potential as an indicator for stress intensity. It has the drawback of being more labor intensive and less sensible than simple gravimetrics of soil moisture measurement [150, 151], but has the value of providing information on leaf water status that can be useful for understanding the other "omics" responses. In any case, any of these two "stress indicators" is a key requirement to make any sense of "omics" responses to water deficit. Equally important is the need to measure the environmental conditions under which plants are assessed. Much of the gene-based "omic" work takes place in glasshouse or growth chamber environment, where it is essential to assess air temperature, humidity, and light intensity to understand the physical drivers of plant water use.

39.9.2 Relevant Protocols Used to Extract "Omics" Products in Grain Legumes

In recent past, a large number of studies have attempted to identify genes responsible for stress response. Besides the fact that there are often thousands of genes that are

expressed, making the choice of key ones, if any, the conditions under which the plants are challenged to stress are often questionable. One such example is a recent study [40] that reports 319 unique ESTs from two contrasting lines of chickpea, with 70% of these being more than twofold abundant in the tolerant cultivar. The protocol used to challenge the plant was withdrawal of irrigation at 12 days after sowing, for a period of 3, 6, and 12 days. Here, the plants were grown in pots (3L) containing a composite soil, without any indication of the soil water capacity. Besides, no measurement of soil moisture was done and only relative water content was measured, putatively as a control for moisture stress. In another study on chickpea [45], attempts were made to expose plants to stress conditions that were similar to those of the natural conditions. Here, a dry-down technique was used to expose the plants to a progressive water stress, similar to the one in the field conditions, by partially compensating the daily water loss and ensuring that water stress symptoms (apparent from a decrease in plant transpiration) do not occur until at least 10 days after stress imposition, that is, similar to the field conditions. In such experiments, the soil moisture, which indicates the level of stress, is kept rigorously constant across genotypes tested. It allows replication of the experiment across environments or plant materials. Moreover, the contrasting materials were also challenged for salinity tolerance. The protocol used here was the very same protocol as used to screen genotypes for seed yield under salt stress. Since the physiological analysis also indicates that reproduction is likely the most sensitive process under salt stress, the flower tissue samples collected during the study for genotyping.

Similarly, work has been carried out in peanut to identify ESTs involved in the contrasting drought response in two genotypes (TAG24 and ICGV86031) (unpublished – EST sequence posted in Genbank). While TAG24 appears to have a high threshold of soil moisture where its transpiration declines, ICGV86031 clearly declines transpiration at lower soil moisture (dryer soil). Such differences are expected to play a causal role in the transpiration efficiency differences between these two lines. To identify possible genes responsible for that response, a standard dry-down protocol was used [153, 154], where tissue sampling was performed precisely when genotypes displayed phenotypic differences (differences in the transpiration relative to the control) during the stress. These two examples illustrate that relevant protocols are needed to mimic as closely as possible the natural conditions, to extract genes that are most likely to be involved in the response under natural conditions.

39.9.3
Adaptive versus Constitutive Genes

In most of the cases, the gene-based "omic" approaches tend to be influenced a lot by the idea that stress tolerance "results" from different stress-responsive genes intervening in the case of tolerant entries and being absent/unexpressed in sensitive lines. However, as far as water limitation is concerned, plants exposed to water deficit usually behave like fully irrigated plants until about 60% or more of the soil moisture has been depleted [152]. So, understanding how plants control plant water use before

stress symptoms appear is even more important than understanding how plants respond when they are left with only 40% or less of the soil water. A recent study on pearl millet shows this is critical for the terminal drought tolerance [153, 154]. Here, differences in leaf conductance under fully irrigated conditions were identified and related to the yield-based differences under stress. So, this means that genotypes have an array of development and functioning characteristics displayed under nonstressed conditions that can determine how well they would be adapted to a situation of stress. In the example of pearl millet cited above, a lower leaf conductance under fully irrigated conditions would simply limit water use when water is available and make it available for the grain filling period, a time when soil moisture has receded and plants are under stress. Therefore, constitutive traits become critical to consider in the "omic" approaches, including phenomics, to first identify their mechanisms (e.g., a slower leaf expansion rate or smaller leaf size) and then the related genes involved in development or functioning processes (e.g., a limited leaf conductance) that predispose particular genotypes to be better equipped to face a forthcoming water limitation.

39.9.4 Physiology Integration in a Novel Context of Environment-Specific Breeding

The growing genotype–phenotype gap is in part explained by a generational change in plant biologists, who have turned away from disciplines of physiology–biochemistry to molecular genetics, and by the belief that a single gene approach of "tolerance gene" identification would solve all problems. Rather, there is a clear need to have the phenotypic information guiding the gene-based "omics" work. Hence, phenomics should in part include a reductionist approach to break down integrated measurement of traits such as yield or biomass into smaller, more heritable components or traits, closer to the identification of cell- or organ-based mechanisms responsible for the integrated response differences. Again, molecular "omics" offer the potential for easier and more reliable way of predicting phenotypes with the condition that robust phenotype–genotype relationships have first been demonstrated. In any case, a reductionist approach to understand the mechanisms of tolerance to abiotic stress is needed to progress toward the identification of genes involved. It also fits the likely evolution of breeding approach from a one-variety-to-fit-all-situation to environment-specific breeding where it will be critical to understand/identify particular characteristics making a genotype adapted to particular environments.

Physiology as a discipline is an integral component of such a breeding perspective. The approaches and protocols that are developed by "phenomists" need to be adapted, or adaptable, to the requirement of a breeding program: these need to be large scale, simple, and applicable to a large number of entries, which is a prerequisite for QTL mapping, either through RIL population or through association panels. At the same time, these need to be capable of assessing cell- or organ-based mechanisms having potential importance. For instance, recent work in pearl millet indicates that lower leaf conductance leads to having water left in the soil profile to support seed filling, and this is attributed to differences in root hydraulics [154], for which precise

protocols are needed. This is a prerequisite to identify the genes involved in a cell- or organ-based mechanism.

39.9.5 Addressing Complexity of Plant Response to Abiotic Stress

Phenomics is also about addressing the complexity of plant response to stress. For instance, crop success under terminal drought could be explained by genotype's capacity to extract water deeper from the soil profile and make this water available for critical periods. In parallel, having water available for critical periods could be explained by differences in the pattern of water use (less water use) before reaching such critical development stages. The later could lead to less water use, while the former could lead to earlier/more water use. So, while this small example illustrates the need to target specific mechanisms, it also stresses on the need to look at different traits in a comprehensive manner. The difficulty lies in having an experimental approach that is enough reductionist to accurately phenotype cell- or organ-based actions, while being sufficiently integrated to have such reductionist measurements coupled to "integrated" measurements that have a meaning for the breeding community. At ICRISAT, work is ongoing where the initial target is to unravel the functionality of rooting traits in a way that their actual combination with terminal water deficit can be understood [148, 155]. As the work progresses, the initial focus on roots, root functionality, and water capture is getting complemented by a component of understanding of the regulation of water use by the crop canopy. Hence, modeling is surely a critical component of the breeding program, to reintegrate the pieces of the phenomics puzzle in a comprehensive and relevant framework. With the present phenomics development, allowing for measuring more and more, modeling remains a sort of safeguard that helps target what phenotype matters more than those that matter less. At the same time, the combination of phenomics and modeling offers a great potential of rapidly assessing the value of certain phenotypes on plant performance.

39.10 Conclusions

Over the years, biotechnology has emerged as a promising tool to overcome stresses in plants; but to date progress has been limited in legumes. Biotechnological applications, including all "omics," were direct and potential approaches for improving abiotic stress tolerance in grain legumes where the existing germplasm lacks the required traits for conventional breeding. However, successful application of "omics" to abiotic constraints requires knowledge of stress response at molecular level, which includes gene expression to protein or metabolite and its phenotypic effects. Availability of genome sequence of model legumes and soybean has a potential to facilitate positional cloning and other approaches and their applications for abiotic stress research on legumes. A genome-wide expression profiling with next-gener-

ation sequencing approaches could circumvent the problems posed by extremely large genomes like legumes.

Compared to analysis of the transcriptome, analysis of the plant proteome and metabolome in response to abiotic stresses is still limited to *M. truncatula* and protein reference maps of soybean to stress responses are now available. More recently, there are few proteomics studies on peanut and chickpea available, and they have to be extensively carried out in all grain legumes for abiotic stress tolerance. Moreover, the recent progress in the mass-scale profiling of the genome, transcriptome, proteome, and metabolome (i.e., "omics") offers the possibility of investigating the concerted response of thousands of genes to drought and other abiotic stresses. Hence, the research dealing with other strategies such as MAS or even classical breeding will be able to take advantage of the results being gathered from these "omics" technologies.

The mapping of abiotic stress QTL in legume is still at an early stage and gene pyramiding has not been applied yet. Nevertheless, with the establishment of the model legumes, *M. truncatula* and *L. japonicus*, there is now applicable information on legumes. Among the grain legumes, soybean has been more intensively studied, and the availability of more numbers of ESTs and genome sequences will facilitate mapping of major QTL in other legumes. The use of transgenic technology potentially offers a more targeted gene-based approach not only for gaining valuable information but also improving stress tolerance in legumes. However, the genetic engineering options addressing plant resistance to abiotic stress, mainly in relation to drought, have been confined to experimental laboratory work and to single gene approaches, lead to marginal stress improvement in grain legumes. Hence, there is a need for identification of candidate genes for abiotic stress tolerance in legumes that will allow their direct application in genetic engineering. Hence, multiple mechanisms to engineer abiotic stress tolerance and studies involving regulatory genes under the control of stress-inducible promoters have a potential to improve stress tolerance in grain legumes. Also, since only transgenic soybean has been commercialized in developed countries, there is a need to address the regulatory issues for transgenics' deployment in developing countries. Needless to point out that the current advances in tissue-derived techniques, genetic transformation and MAS, together with the advances in powerful new "omics" technologies offer a great potential to improve this situation. Besides, a thorough and meaningful assessment of phenotypic expression to understand the mechanisms of adaptation to stress is needed before genes responsible for these mechanisms can be identified and tagged. Indeed, it is now possible to target almost all legume crops with a variety of biotechnological approaches for genetic improvement.

Fruit Crops: Omic Approaches toward Elucidation of Abiotic Stress Tolerance

Pravendra Nath, Vidhu A. Sane, Mehar Hasan Asif, Aniruddha P. Sane, and Prabodh K. Trivedi

Abiotic stresses are likely to affect yield potential of crop plants greatly and globally in next 50–100 years by way of inevitable increment in atmospheric CO_2 concentration, salinity, drought, heat, flooding, chemicals in soil, and so on. These stresses affect the whole plant resulting in a stress response wherein plants divert their resources toward adapting to changed environment. This entails a major change in their gene expression, proteins, metabolites, and so on. There is an urgent need to understand how plants respond to these stresses and adapt for their survival. In order to address this problem, it is imperative to understand the global changes occurring in plants at all levels during stress condition. Omics approaches offer such tools that can analyze changes at genomic, transcriptomic, proteomic, and metabolomic levels. Such studies have primarily been carried out in model plants such as *Arabidopsis*, rice, *Populus*, and so on whereas information on fruit crop is lacking. We review here the progress made in understanding various stress responses in fruit crops using one or the other omics approaches. With the availability of whole-genome sequences of tomato, papaya, and grape, and whole transcriptome of tomato, grape berries, grapefruit, apple, and peach initiated, it should be possible to decipher gene regulation during stress response in fruit crops. Proteome and metabolome analyses of few fruits are also in progress, which should help answer several important questions regarding stress response in fruit plants. With the availability of these data, efforts are being made to identify genes and pathways that can be engineered to produce transgenic fruit crops resistant to abiotic stress.

40.1
Introduction

Plants have much higher genetic potential for yield than we realize. This unrealized potential could be attributed mainly due to environmental conditions that do not

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

support their full yield potential. This has been substantiated time and again by examining native or wild cultivars against domesticated ones [1]. Abiotic stresses are one of the major causative factors that affect plant yield. Drought, salinity, cold, heat, flooding, and chemicals are the most common abiotic stresses that affect plant growth, development, and its yield potential. These stresses have been shown to either bring about osmotic stress or oxidative stress or both that disrupts functional and/or structural proteins and membranes [2]. Salinization of arable land is increasing and expected to result in 50% land loss by 2050; greenhouse effect that is contributing to global warming is expected to increase temperature by 3–5 °C in the next 50–100 years resulting in higher frequencies of heat waves, tropical cyclones, floods, and prolonged drought conditions [3]. These climate changes are surely to affect crop nutrition, efficient water uptake, and finally the yield [4]. In order to address these issues vis-à-vis yield potential, a careful combination of various approaches need to be applied to improve significantly the abiotic stress tolerance in crop plants. Molecular biology has deciphered several fundamental questions and we are now beginning to understand that acclimatization of plants to abiotic stress conditions is a highly complex and coordinated process involving recruitment of several hundred genes and a strong signaling system. Strategic use of novel genes for transfer could be one of the key factors in developing crop plants resistant to abiotic stress. Recently, many plant genomes have been sequenced and others are in progress. Interestingly, 20–40% genes have been accounted for no known functions [5]. Many of these are species specific making them potential candidates for stress adaptability [6]. Omic approaches have now become inevitable not only in elucidating the regulation of various pathways and gene functions but also in assigning a specific role to a gene, its possible usage, and its biotechnological feasibility. Genomics, transcriptomics, proteomics, and metabolomics are some of the modern tools in biology that have been introduced recently and utilize high-end equipment to carry out these analyses in a short period of time with high accuracy. How plants respond to various abiotic stresses by way of their expression at genome, transcriptome, proteome, and metabolome levels has been depicted in Figure 40.1. The application of these omic approaches either singly or in combination has answered several questions of plant biology paving the way for future research.

Most omic approaches have so far been applied to major crop plants both cereals and legumes or model plants like *Arabidopsis*. In this chapter, we have tried to review the recent progress in omic approaches that have been applied to understand the mechanism of stress tolerance in fruit crops including tomato. Though exact data are not available, substantial losses in fruit crops occur due to abiotic stress conditions the world over. For example, deficit irrigation (DI) to mandarin plants could reduce fruit yield up to 40% in some cultivars, whereas only 27% reduction was observed in some other cultivars depending upon their rootstock [7]. Not only yield but also the quality of fruit may be affected due to abiotic stress condition. When strawberry plants were irrigated differently with various concentrations of saline, they differed in their antioxidant capacity and other biochemical contents such as glutathione, phenol, anthocyanin, and so on [8]. There are many other studies as well indicating

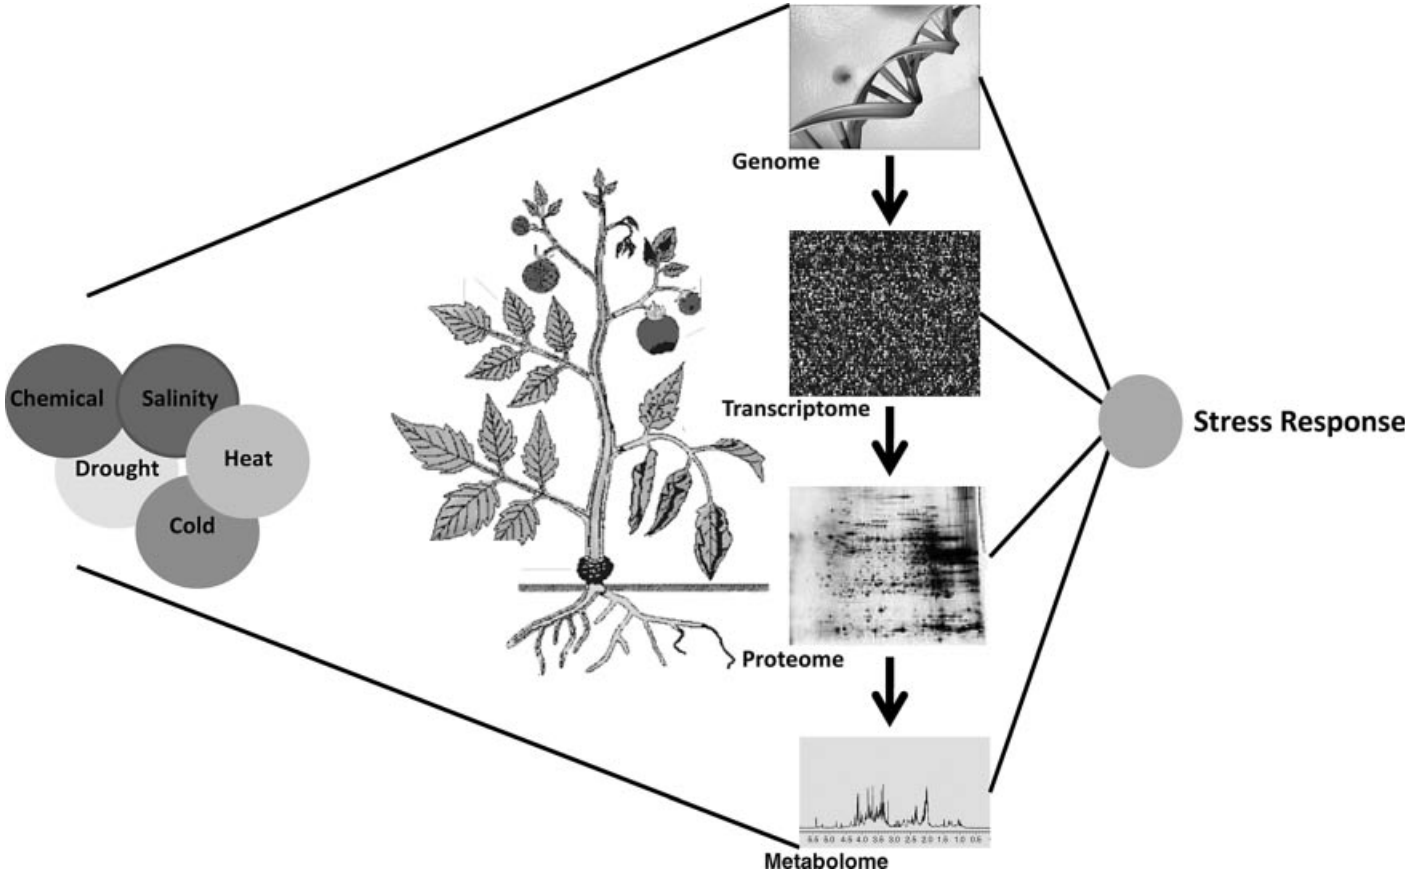

Figure 40.1 Schematic representation of various abiotic stresses affecting whole plant, which may alter homeostatic balance at various levels such as genome, transcriptome, proteome, and metabolome. These alterations together constitute stress response.

that yield loss in fruit crop due to abiotic stress conditions could be very high. In the following sections, we have reviewed the recent status of omic approaches in elucidating stress-related response of fruit plants.

40.2 Genomics and Transcriptomics of Fruit Crops

The depiction of entire genome of at least papaya, grape, and tomato has been completed and it is likely that the genomes of banana and apple will be available soon. The project on citrus fruit genome has already been initiated by the USDA and will be a part of Tree Fruit Genome Database. Work on identifying various QTL including those related to stress is in progress. Genes that are involved in chromatin modeling and epigenetic control are also being identified [9]. However, except in the case of tomato [10], not much progress has been made in other fruits with respect to identification of various QTL related to stress. This could be due to the fact that the sequences became available only recently and mostly as draft sequences. The annotations are still being carried out and we hope to see some good progress in coming years. However, with the advent of high-throughput technologies, the global analysis of the transcriptome is possible and being carried out in some cases. Out of that, the microarray analysis is one such technique that gives us an idea of the global transcriptome profile during any event/treatment. At the moment, the microarray chips for fruit species are available only for tomato, *Vitis vinifera*, and citrus fruits. Other techniques such as differential display, subtractive hybridization, and now transcriptome sequencing are being employed to study whole transcriptome profiles of species for which the genome sequence is not known. In this chapter, we have reviewed how certain genes that are related to abiotic stress have been identified by various researchers utilizing one or the other available technique.

The response to abiotic stresses such as heat, cold, drought, salinity, and so on in fruit crops is mediated by several genes and proteins. Prominent among these are transcription factors of the AP2 domain/ERF family that are activated in these stresses. Studies in recent years have led to identification of ERFs in tomato such as DREB3 that was shown to be activated by salinity, heat, and cold [11]. Another ERF, the JERF3, showed early response to both cold and salt within 10 min of respective treatments [12]. The tomato TERF1 gene was also identified as a salt-responsive gene [13]. The pepper ERF gene CaERFLP1 is induced by salt and in tomato the LeCBF1 gene, another AP2/DREB-type gene and a homologue of *Arabidopsis* CBF1 gene, was induced within 30 min of cold treatment although overexpression of the gene in tomato did not impart cold tolerance to plants [14]. Another transcription factor, SlAREB1 encoding a bZIP transcription factor, was induced in response to salt, cold, drought, and ABA [15]. The phenylalanine ammonia lyase gene (SlPAL5) was also shown to be expressed in response to salinity, cold, and osmotic stress. Besides transcription factors, several other genes have been identified that respond to one or the other stresses.

Cold stress is one of the commonly endured stresses by fruit plants, either during development or during storage. Many of the commercially available fruits are susceptible to cold stress resulting in major economic losses. Whole-transcriptome analysis in tomato, grape berries, grapefruit, apple, and peach has shown the involvement of genes related to various metabolic pathways to be regulating cold stress. Weiss and Egea-Cortines [16] characterized the effect of cold stress (6 °C for 48 h) in tomato fruits (MicroTom) during ripening using subtractive PCR. In this study, they identified many housekeeping genes that were upregulated during cold stress, such as genes involved in protein synthesis (25S ribosomal RNA, ribosomal proteins L10, L27, S11, S13, and an rRNA-encoded homing endonuclease), actins, senescence-associated protein (SGN-U43780), and genes related to carbohydrate metabolism (starch phosphorylase (SGN-U148218), triosephosphate isomerase (SGN-U145276), oraldo/keto reductase (SGN-U179653)). Several chloroplast (chlorophyll A–B binding protein SGN-U69362) and mitochondrial encoded genes (ATPsynthase beta chain SGN-U106411) were also upregulated by the cold stress. Among the known genes, dehydrin was found to be upregulated in cold stress; this dehydrin clustered with cold-induced dehydrin genes from other species. A study on the chilling effect on grapefruit during storage [17] showed a large number of genes and many pathways to be affected. Chilling stress (5 °C) for 2 weeks resulted in differential expression of 7500 genes with significant p values (≤ 0.005), and induction or repression of transcript levels to at least fourfold. They also studied the effect of preconditioning of chilling at 16 °C before transferring to 5 °C. This led to the identification of a chilling regulon. This group of transcripts defined the basic transcripts involved in natural responses of citrus to low temperature. In the chilling regulon, a massive downregulation of transcripts related to cell wall and defense against pathogens, photosynthesis, respiration, protein metabolism, DNA and RNA metabolism, secondary metabolism, water channels, and senescence was identified. They also found that chilling activated various adaptation processes resulting in significant changes in transcripts encoding membrane proteins, lipid, and sterol metabolism, carbohydrate metabolism, stress stimulus, hormone biosynthesis, and DNA binding and transcription factors. Study of leaf, bark, xylem, and root tissue cDNA libraries from Royal Gala apples in control, drought, and cold stress showed significant changes in gene expression [18]. In the case of cold stress libraries, changes in gene expression were observed in dehydrin and metallothionein-like proteins, ubiquitin proteins, a dormancy-associated protein, a plasma membrane intrinsic protein, and an RNA binding protein. A large number of unique genes expressed in the leaf in response to cold were also observed in this study.

A recent study on transcriptome profiling of banana during drought stress was done by cross hybridization using rice Affymetrix gene chip [19]. A total of 2910 transcripts, with a more than twofold differential expression, were observed. Many of the differentially regulated genes identified in this study have been known to be involved in biotic and abiotic stresses in other plant species as well. The differentially regulated transcription factors were from DREB, ERF, MYB, BZIP, and bHLH families. Fifty-two drought-sensitive transcripts were homologous for QTL associated with drought tolerance in rice too. The categories of differentially regulated

genes belong to cellular metabolism, response to biotic and abiotic stresses, protein metabolism, transcription, transport signal transduction, and so on. In a study on anthocyanin biosynthesis during drought stress in grapevines (*V. vinifera* L.), it was found that there was a strong correlation between the gene expression of anthocyanin pathway and the anthocyanin content [20]. The expression of the genes encoding enzymes of the flavonoid pathway and related transcription factors were studied. The authors noted that at least 84% of the total variation in anthocyanin content was explained by the linear relationship between the integral of mRNA accumulation of the specific anthocyanin biosynthetic gene UDP-glucose:flavonoid 3-*O*-glucosyl-transferase (UFGT) and the metabolite content during time series from véraison through ripening. The genes of the flavonoid pathway chalcone synthase (CHS2, CHS3) and flavanone 3-hydroxylase (F3H) also showed high correlation. The genes coding for flavonoid 3′,5′-hydroxylase (F3′5′H) and *O*-methyltransferase (OMT) were also upregulated in berries from dehydrated plants. The authors suggested that the interrelationship between developmental and environmental signaling pathways was magnified during water deficit. In this case, water stress induced genes of flavonoid and brassinosteroid pathway that actively promotes fruit maturation and anthocyanin biosynthesis. The whole-transcriptome analysis of Royal Gala apple fruit tree also suggests the upregulation of genes related to stress categories such as heat shock, dehydrins, peroxidases, and lipid transfer protein photosynthesis [18].

40.3
Proteomics of Fruit Crops

Proteomic studies of plant response to abiotic stress include analyses of the effects of high light, extreme temperatures, water deficit, salinity, and the presence of heavy metals or toxic chemicals in the environment. Study of proteomics has allowed the identification of novel genes and the characterization of their regulation and function. Some of the high-end techniques have made proteomic studies possible with a high degree of accuracy. Mass spectrometry (MS) is one powerful method for the characterization of proteins. Intact proteins are ionized by electrospray ionization (ESI) or matrix-assisted laser desorption/ionization (MALDI) and then introduced to a mass analyzer using either time-of-flight (TOF) MS or Fourier transform ion cyclotron resonance (FT-ICR). These two types of instruments are preferable because of their wide mass range and mass accuracy. Shotgun proteomics is another method of identifying proteins in complex mixtures using a combination of HPLC with mass spectrometry. In shotgun proteomics, the proteins in the mixture are digested and the resulting peptides are separated by liquid chromatography (LC). Tandem mass spectrometry is then used to identify the peptides. Prior to mass spectrometry, proteins are fractionated by 2D electrophoresis.

In recent years, proteomics has been proven to be a powerful method to explore the protein changes in fruit during development and ripening [21–23]. On the other hand, there is still a lack of information about harvested fruit senescence and fruits under abiotic stress using proteomic analysis. Proteomic analysis is difficult in fruits

where protein content is less and carbohydrates are in abundance. In addition, studies in fruits are also restricted due to annual reproductive cycle of most plants. Also, proteomics relies on availability of genomic sequence data for use in protein identification and this information is lacking for most of the fruits [24]. Despite various difficulties, good work on fruit proteomics has been published in recent years.

A comparative proteomic approach has been adopted in combination with physiological and biochemical analysis of tomato leaves responding to waterlogging stress. Waterlogging resulted in increases in relative ion leakage, lipid peroxidation and *in vivo* H_2O_2 content, whereas the chlorophyll content was decreased [25]. A total of 52 protein spots were differentially expressed, wherein 33 spots were identified by matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry or electrospray ionization tandem mass spectrometry (ESI-MS/MS) analysis. A number of novel proteins were differentially expressed or appeared only in the PEG-fractionated protein samples, indicating that PEG fractionation system can be used as a versatile protein fractionation technique in proteomic analysis to identify novel or low-abundant proteins from all kinds of plant species. The identified proteins are involved in several processes, namely, photosynthesis, disease resistance, stress and defense mechanisms, and protein biosynthesis. On the basis of their results, Ahsan *et al.* [25] suggested that transcription levels are not always concomitant to the translation level.

Growth inhibition in acid soils due to Al stress affects crop production worldwide. To understand mechanisms in sensitive crops that are affected by Al stress, a proteomic analysis of primary tomato root tissue, grown in Al-amended and non-amended liquid cultures, was performed by Zhou *et al.* [26]. DIGE-SDS-MALDI-TOF-TOF analysis of these tissues resulted in the identification of 49 proteins that were differentially accumulated. Most of these proteins were of defense and detoxification category. Proteomic analysis of shade-avoidance response in tomato leaves was carried out by Hattrup *et al.* [27]. Protein expression differences were investigated using two-dimensional differential in-gel electrophoresis and nanoflow high-performance liquid chromatography–tandem mass spectrometry. A large group of proteins related to metabolism and respiration were greatly reduced in accumulation in shade-grown plants, and there was also evidence of significant proteolysis occurring. Four stress-related proteins appeared to be constitutively expressed as a result of heat acclimatization, while three distinct stress-related proteins accumulated as part of the shade-avoidance response.

The characterization of proteins isolated from skin tissue is apparently an essential parameter for understanding grape ripening. Therefore, proteome profile of grape skin during maturation was developed by Lucker *et al.* [28]. Three different stages of ripening were taken to assess protein distribution in grape skin during ripening. Proteome analysis revealed that proteins involved in photosynthesis, carbohydrate metabolisms, and stress response were being overexpressed at the beginning of color change; however, at the end of color change, proteins involved in anthocyanin synthesis were overexpressed. Proteins involved in defense mechanisms like chitinase and b-1,3-glucanase isoforms were prevalent at the time of fruit harvest. The

differences observed in proteome maps showed that significant metabolic changes occur in grape skin during this crucial phase of ripening.

Grimplet *et al.* [29] studied the changes in protein expression in grape berry tissues during drought. The authors carried out comparative 2D-PAGE analysis on grape pulp, skin, and seed under well-watered and water deficit conditions. Water deficit condition altered the levels of approximately 7% of skin and pulp proteins, but no significant change was observed on seed protein expression. In skin, high levels of peptidases and α and β subunits of proteasome indicated that drought stress increases protein turnover in grape. Selected enzymes for flavonoid biosynthesis and reactive oxygen detoxification enzymes were also more abundant in berry skin of grapes grown under water deficient condition, whereas grape flesh showed increased levels of enzymes such as isoflavone reductase, glutamate decaroxylase, and endo-chitinase. Comparison of mRNA levels and protein expression patterns suggested that posttranscriptional processes govern protein accumulation.

Lara *et al.* [30] studied the effect of high temperature both on peach quality and on carbon metabolism. A comparative analysis of the peach mesocarp proteome variations was carried out using 2D differential gel electrophoresis (2D-DIGE) and several candidate proteins were identified that might be correlated with chilling injury symptoms. Lara *et al.* [30] detected 57 differentially expressed proteins; 67% of these were of defense and stress response categories. High temperature repressed polyphenol oxidase and ascorbate peroxidase. These enzymes are involved in browning process during chilling injury in peach, which reduces taste and nutritional value of the fruit. Qin *et al.* [31] worked on mitochondrial proteome during fruit senescence. On the basis of their studies on apple, they concluded that fruit senescence is correlated with the dynamic alterations in the mitochondrial proteome. Mitochondrial proteins involved in carbon metabolism, and stress response, tricarboxylic acid cycle, and electron transport chain were found differentially expressed during fruit senescence. The levels of many mitochondrial proteins were significantly reduced during oxidative stress. The group analyzed the mitochondrial proteome variations upon exposure to high oxygen (100%) to understand the regulatory effect of ROS in senescence. Activity of manganese superoxide dismutase was reduced after high oxygen exposure, accompanied by an increase in oxidative protein carbonylation (damaged proteins). A novel protein, mitochondrial porin, was downregulated during oxidative stress and its dysfunction was directly correlated with impairment of mitochondrial function. Proteome data obtained for apple senescence suggested that ROS might regulate fruit senescence by changing expression profiles of specific mitochondrial proteins and impairing the biological function of these proteins.

Wang *et al.* [32] worked on climacteric fruit Jujube common in China. They found that oxalic acid (OA) at the concentration of 5 mM could delay Jujube fruit senescence by reducing ethylene production, repressing fruit reddening, and reducing alcohol content. They used a proteomics approach to compare soluble proteome of Jujube fruits treated with water or 5 mM OA for 10 min. A total of 25 differentially expressed proteins were identified by using electrospray ionization quadrupole time-of-flight tandem mass spectrometry (ESI-Q-TOF-MS/MS). Analyses of differentially

expressed proteins suggested that OA treatment might affect ethanol and ethylene metabolism, resulting in delay in senescence and increase in resistance of Jujube fruits against fungal pathogen as alcohol dehydrogenase and 1-aminocyclopropane-1-carboxylic acid synthase were significantly suppressed in OA-treated Jujube fruit.

40.4 Metabolomics of Fruit Crops

The constituents of the metabolome reflect the cellular processes that control the biochemical phenotype of the cell, tissue, or whole organism. Metabolomics, which denotes the study of all metabolites produced in an organism, can be treated as the ultimate level of postgenomic analysis because it can reveal modulation in metabolite fluxes controlled by changes within gene expression measured using transcriptomics and/or by analyzing the proteome that elucidates posttranslational control over enzyme activity. Metabolic changes are a major feature of plant genetic modification during plant development as well as biotic and abiotic stress [33, 34]. Therefore, measurements of intracellular metabolites, whether qualitative or quantitative, can reveal the biochemical status of an organism and in turn can be used to monitor stress response [35]. Metabolomics could contribute significantly to the study of stress biology in plants and other organisms by identifying different compounds, such as the by-products of stress metabolism, stress signal transduction molecules, or molecules that are part of the acclimation response of plants.

Metabolomics is complicated by the huge diversity of metabolites in any given species especially in the case of plants that encompass approximately 100 000–200 000 metabolites [36]. Though a number of metabolomic approaches are being used to characterize metabolome of organisms, at present it is impossible to quantitate all the metabolites within a cell, tissue, or organism of any kingdom in any system. This could be due to the fact that no single extraction technique or analytical instrument can isolate and detect every metabolite within a biological sample [37, 38]. It is assumed that a comprehensive plant metabolic profile should include a minimum of carbohydrates, amino acids, organic acids, lipids/fatty acids, vitamins, and various other compound classes such as phenylpropanoids, terpenoids, alkaloids, and glucosinolates along with secondary metabolites that vary according to the species under study [37]. A combination of several different analytical methods, encompassing different separation methods such as gas chromatography (GC) or liquid chromatography and other analytical instruments are required. Mass spectrometry is most widely used because of its high sensitivity and propensity for generating structural information. Nuclear magnetic resonance (NMR) is also a powerful technology because of its reproducibility and robust quantification ability, despite the fact that it has low sensitivity compared to MS. Major approaches used in plant metabolomics research include metabolic fingerprinting, metabolite profiling, and targeted analysis [38, 39]. Metabolomics data handling, analysis, and mining and its integration with other omics platforms have been dramatically improved in recent years because of the development of an array of publicly available bioinformatics tools.

Alterations in the metabolome of a wide number of species in response to a broad range of stresses have been analyzed [40–44]. However, most of these studies have been carried out on nonfruit crops. In fruit crops, very few studies have been carried out for metabolite profiling for the purpose of breeding and stress response. Schauer *et al*. [45] carried out metabolic profiling of leaves and fruit of wild species tomato to survey genetic variation in *Solanum lycopersicum*. Subsequently, metabolite profiling was applied for identification of pericarp metabolite QTL [39] using a set of well-characterized tomato introgression lines [46]. This study resulted in the identification of over 880 metabolite QTL that were stable over two independent harvests, thus highlighting the power of metabolite profiling as a tool for dissecting the genetic basis of metabolism. The same tomato introgression line population was also recently phenotyped at the level of fruit volatiles, which are believed to be key determinants of taste, resulting in the identification of 25 QTL for 23 compounds [47]. Moreover, a detailed analysis of one of the introgression lines (IL8–2-1), which contained massive increases in the volatiles phenylacetaldehyde and phenylethanol, enabled the elucidation of the biosynthesis pathway of phenylethanol [47]. Tikunov *et al*. [48] used nontargeted metabolite profiling using comparative multivariate analysis of a set of 94 contrasting tomato (*Lycopersicon esculentum* Mill.) genotypes covering the variation in the germplasm of commercial tomato varieties. The analysis was based on the profiles of all volatiles that could be detected by the analytical method SPME-GC-MS, which revealed 322 different compounds in the entire genotype set. This covers approximately 80% of the 400 tomato volatile compounds, which have been detected in tomato fruit using different analytical methods. Mintz-Oron *et al*. [49] studied gene expression and metabolism in tomato fruit surface tissues, cuticle, which plays a key role in the survival of plants by serving as the interface between plants and their biotic and abiotic environment. The study revealed unique sets of genes and metabolic pathways consisting of a diverse range of metabolites that are active in the peel at various stages of fruit development and may play an important role in stress response.

A metabolomics approach combining (1)H NMR and gas chromatography–electrospray ionization–time-of-flight mass spectrometry (GC-EI-TOFMS) profiling was employed to characterize melon (*Cucumis melo* L.) fruit [50]. Data analyses revealed several gradients of metabolites in fruit flesh that can be related to differences in metabolism and indicated the suitability of multiblock HPCA for correlation of data from two (or potentially more) metabolomics platforms. The same group also studied metabolic acclimation of melon to hypoxia [51]. Direct (1)H NMR profiling of juice of fruit flesh collected from different locations revealed several gradients of metabolites, for example, sucrose, alanine, valine, GABA, and ethanol, with increase in concentrations from the periphery to the center of the fruit. GC-MS profiling of ground samples revealed gradients for metabolites not detected using (1)H NMR, including pyruvic and fumaric acids. The quantification of adenine nucleotides highlighted a strong decrease in both ATP and ADP ratios and the adenylate energy charge from the periphery to the center of the fruit. These concentration patterns are consistent with an increase in ethanol fermentation due to oxygen limitation and were confirmed by observed changes in alanine and GABA concentrations, as well as other markers of hypoxia in plants.

Global metabolic profiling of "Granny Smith" apple peel was employed for evaluating metabolomic alterations resulting from prestorage UV-white light irradiation [52]. Apples were bagged midseason to restrict sunlight, harvested at the preclimacteric stage prior to bag removal, and treated with fluorescent UV-white light for different time points. Analysis of methanolic extracts from peel samples collected immediately after irradiation or following cold storage were evaluated using GC-MS and LC-UV/vis-MS, respectively. The profile including more than 200 components, 78 of which were identified, revealed changes in the metabolome provoked by UV-white light irradiation and cold storage. Analyses of individual components selected using principal component analysis (PCA) models showed distinct temporal changes, before and after cold storage, related to prestorage irradiation in a diverse set of primary and secondary metabolic pathways. The results demonstrate metabolic pathways associated with ethylene synthesis, acid metabolism, flavonoid pigment synthesis, and fruit texture are altered by prestorage irradiation, and many of the alterations are detectable after 6 months of cold storage in air.

Metabolic fingerprinting of salt stress in tomato was used to identify metabolic changes in fruits under salinity stress [53]. The authors studied two tomato varieties subjected to salinity stress. Whole fruit flesh extracts were fingerprinted using FT-IR spectroscopy. Metabolic fingerprints were analyzed using unsupervised (PCA) and supervised (DFA) algorithms. PCA was not able to discriminate between control and salt-treated groups in any variety, while DFA was able to classify control and salt-treated groups in both varieties [53]. The authors also employed a GA to identify the regions within the FT-IR spectrum that are important for classification. These regions corresponded to saturated and unsaturated nitrile compounds, cyanide-containing compounds, and other nitrogen-containing compounds. In a recent study, it has been shown that salinity stress improves fruit quality of tomato by increasing assimilable metabolism through accumulation of sucrose, citrate, malate, and glutamate in red fruit [54]. To elucidate the mechanisms underlying this phenomenon, Yin *et al.*, [55] studied transport of carbohydrates into tomato fruits and the regulation of starch synthesis during fruit development in plants exposed to high levels of salinity stress. Growth with 160 mM NaCl doubled starch accumulation in tomato fruits compared to control plants during the early stages of development, and soluble sugars increased as the fruit matured. Tracer analysis confirmed that elevated carbohydrate accumulation in fruits exposed to salinity stress was confined to the early development stages and did not occur after ripening. Salinity stress also upregulated sucrose transporter expression in source leaves and increased activity of ADP-glucose pyrophosphorylase (AGPase) in fruits during early developmental stages. The results indicated that salinity stress enhanced carbohydrate accumulation in the form of starch during the early fruit development and is responsible for the increased soluble sugars in ripe fruit.

An integrated study of the early and late changes in transcript and metabolite profiles revealed differences in the dynamics of grapevine response to water and salinity stress [56] and also exhibited differences in molecular response to water deficit and salinity. GC-MS profiling and anion-exchange chromatography with UV

detection revealed that concentration of glucose, malate, and proline is higher in water deficit-treated plants than in salt-stressed plants. These differences in metabolite levels were correlated with differences in transcript levels of many genes involved in energy metabolism and nitrogen assimilation, suggesting a higher demand in water-deficit-treated plants to adjust osmotically, detoxify ROS, and cope with photoinhibition than in salt-stressed plants [56].

All omic-related studies have similar objective of either identifying specific QTL for a set of characters and use it for generating suitable hybrid or identifying a gene/transcription factor that can control/exhibit desired character. In the following section, we have tried to review some of the fruit transgenics that have been generated out of the genes shown to be involved in abiotic stress.

40.5 Stress-Related Fruit Transgenics

Various omic approaches have paved the way for identification of target genes/molecules that are associated with abiotic stress in fruit plants. In an effort to genetically engineer fruit crops for enhanced abiotic stress tolerance, several genes have been used. Because of the relative ease of tomato transformation, most of the studies have been carried out on tomato. Various plants such as *Arabidopsis*, rice, and so on have been used as the source of genes. *Arabidopsis CBF1* gene encoding a drought responsive transcription factor was used to generate transgenic tomato plants that showed tolerance to cold stress, salinity, and drought [58]. However, the use of the CaMV35S promoter for driving expression of the *CBF1* gene caused retarded growth. When the CaMV35 S promoter was replaced by the ABA responsive *HAV22* gene promoter, the transgenic tomato plants showed normal growth but enhanced tolerance to the stresses such as salinity, cold, and drought. Many reports have shown that drought tolerance is associated with increased accumulation of trehalose. The engineering of the trehalose-6-phosphate synthase gene from yeast into tomato under the 35S promoter to increase levels of trehalose indeed led to tolerance to water stress in tomato [58], although there were several developmental changes in the plant morphology. Expression of the *Capsicum anuum PIF1* gene encoding the pathogenesis-induced factor in tomato caused upregulation of several genes from different metabolic pathways and stress responses as deduced by microarray that included genes involved in cold stress. Transgenic plants were tolerant not only to *Pseudomonas syringae* pv. tomato DC 3000 but also to cold stress [59]. Expression of the rice Myb transcription factor gene *OsMYB4* in tomato led to tolerance to drought stress although not to cold stress unlike in rice [60]. The expression of the same gene in apple led to plants being tolerant to both drought and cold stresses. The stress response was associated with higher levels of osmolytes such as glucose, fructose, sucrose, and proline under unstressed conditions as well as during early stages of cold exposure [61]. Transgenic plants, however, were shorter in height compared to control plants. Recently, a detailed insight was obtained into the functioning of the ABA-induced Myb1 gene in tomato, *SlAIM1*, in abiotic stress

(salinity) and oxidative stress, and responses to ABA. RNAi plants with lower levels of *SlAIM1* showed increased susceptibility to salt and oxidative stress, while ectopic expression of *SlAIM1* led to tolerance to these stresses [62]. The mechanism underlying these responses appeared to be through changes in sensitivity to ABA and regulation of ion fluxes such that higher expression levels of the gene caused decreased accumulation of Na^+, while downregulation of the gene caused increased accumulation of Na^+ in tissues. Overexpression of another transcription factor from capsicum CaKR1 (encoding an ankyrin repeat Zn finger domain protein) in transgenic tomato generated plants that showed enhanced tolerance to salinity and oxidative stress through increased activity of *LeSOD2* and *LeAPX2* and *LeAPX3*. Salt tolerance in tomato was engineered by expressing the *Arabidopsis* AtNHX1 gene that encodes a vacuolar Na^+/H^+ antiporter [63]. Tomato plants expressing the *Arabidopsis* AtIpk2 beta gene, encoding an inositol polyphosphate 6-/3-kinase, showed tolerance to cold, drought, and oxidative stress [64]. Other stress-associated compounds such as glycine-betaine have also been enhanced by engineering tomato plants with plastid-directed expression of choline oxidase genes. Transgenic plants showed higher levels of tolerance to oxidative stress [65]. In an interesting study, Orsini *et al.* [66] recently showed that constitutive expression of prosystemin, a wound-inducible polypeptide, decreased stomatal conductance and reduced growth under normal growth conditions, but under conditions of high salt, plants maintained higher stomatal conductance and were tolerant to salt. This indicated that activation of wound responses could counter salt stress. Another gene encoding the *Arabidopsis* tryptophan synthase beta1 (AtTSB1) conferred tolerance to Cd stress in transgenic tomato plants through higher levels of tryptophan [67]. Other genes, such as wheat vacuolar pyrophosphatase gene (TVP1) and the wheat vacuolar sodium antiporter gene (TNHX1), were introduced into tomato and shown to confer salt tolerance [68]. The plants, besides showing higher chlorophyll levels under saline conditions, showed a well-developed root system in TVP1 overexpressing plants.

Apart from tomato, other fruit crops have also been used for manipulation of abiotic stress response. The apple spermidine synthase gene *MaSPD1* was introduced into pear (*Pyrus communis*). The transgenic pear showed enhanced tolerance to salinity, osmotic stress, and increased copper stress. Part of the tolerance was explained by altered polyamine levels, especially higher spermidine levels in transgenic plants, and a greater capacity to withstand oxidative stress as observed by increased SOD and glutathione reductase levels [69, 70]. The increased spermidine levels were responsible for tolerance to increased aluminum concentrations in soil [71] and other heavy metals due to an effect on relieving oxidative stress [72]. An increase in polyamine levels (spermine and spermidine) and tolerance to heat stress due to enhanced antioxidant enzyme activity and reduced lipid peroxidation was also achieved in transgenic tomato by introduction of the yeast SAM decarboxylase gene [73]. In another study, constitutive expression of the heat shock gene *HSP21* in tomato resulted in greater protection to PSII from temperature-dependent oxidative stress. In addition, plants showed earlier accumulation of carotenoids [74].

40.6 Conclusions

The yield potential of all crop plants including fruit plants is greatly affected by the abiotic stress conditions such as drought, water deficit, cold, heat, flooding, and chemicals. These abiotic stresses bring about osmotic stress and/or oxidative stress that disrupt functional and/or structural proteins and membranes. In many cases, it has been observed that wild relatives of the cultivated crops could withstand these stresses and survive. This indicates that these plants acclimatize by altering their physiology through differential expression of genes that results in accumulation of certain proteins and metabolites. In order to identify those genes, proteins, and metabolites, it is important to look into global changes in transcripts, proteins, and metabolite profiles during abiotic stress conditions. Omic approaches offer such kind of analyses where entire transcriptome, proteome, and metabolome can be studied under one set of conditions. Several high-end equipments are available that either singly or in combination can give accurate measurements of transcripts, proteins, and metabolites. Abiotic stress and fruit yield and quality are relatively newer areas where not much study has been done. Though whole-genome sequences are available for papaya, grape, and tomato, and for other fruits such as banana, apple, and citrus will be available shortly, most studies have so far been done with respect to identifying genes that are expressed differentially during different kinds of abiotic stresses. Only in some cases, global transcriptome, proteome, or metabolome have been analyzed. Transgenic tomato, apple, and pear plants have been raised with one or the other genes that conferred resistant to abiotic stresses. The whole-genome sequencing of various fruit and other plants has indicated that 20–40% of genes account for no known functions. We make an optimistic assumption that at least some of these genes are involved in stress tolerance and manipulation of these genes may lead to transgenics resistant to abiotic stress.

Cassava Genetic Improvement: Omics Approaches for Facing Global Challenges

Yoshimi Umemura, Rane Jagadish, Motoaki Seki, Yoshinori Utsumi, Jarunya Narangajavana, and Manabu Ishitani

Cassava is a staple food crop that ensures food security and is a source of income generation for poor farmers in the tropics of many Asian and African countries that are highly prone to harsh and unfavorable environments especially in the context of climate changes. Improving tolerance to abiotic stresses such as drought in this crop is a big challenge as it has substantial tolerance to drought compared to other crops. There has been little investment in employing advanced breeding technology for genetic improvement of cassava, though we have now an increased access to emerging advanced tools in genomics, transcriptomics, phenomics, proteomics, and metabolomics for that can enhance our capacity to understand stress responses and tolerance in plants.

In this chapter, we have reviewed challenges and opportunities for improving productivity of cassava by integrating omics with conventional breeding. The chapter highlights efforts and vision of International Center for Tropical Agriculture (CIAT; http://www.ciat.cgiar.org/) toward a comprehensive evaluation of germplasm, establishment of the transformation and phenotyping platform, and development of genomic tools for deriving the requisite information for developing effective strategies for molecular breeding for high-yield and high-value cassava under stress conditions. The chapter also deals with possible strategies to accelerate development of elite cassava cultivars by integration of the advanced technologies.

41.1
Introduction

Cassava is an important tropical crop both for food security and for income generation for poor farmers in many Asian and African countries, where its production is more than 240 million ton a year [1]. This crop serves as the primary food source for more than 750 million people across the world. Cassava is well adapted to semiarid conditions and it needs adequate soil moisture mainly during

Improving Crop Resistance to Abiotic Stress, First Edition.

planting. After establishment, it can withstand several months of drought. Generally, it is not irrigated, but in some areas responds markedly to irrigation [2]. However, severe limitation of soil moisture can bring down the cassava yield significantly [3–5]. So, the task of improving the productivity of this drought-tolerant crop under soil moisture stress environments is more challenging than for other crops.

In several investigations supported by the Generation Challenge Programme (GCP: http://www.generationcp.org/), in Brazil, Colombia, Tanzania and Ghana, contrasting cassava varieties have been screened and evaluated under drought environments and physiological traits associated with drought tolerance have been identified [6–8]. Among these, there are traits related to developmental regulation that permits the most drought-tolerant lines to optimally partition resources for storage root initiation and maintenance during drought. However, despite substantial accumulation of basic knowledge of cellular and molecular level, there is no significant progress toward development of drought-tolerant varieties mainly because of limited success in dissecting the complex mechanisms underlying tolerance to drought.

Recent remarkable innovations in omics-based research such as phenomics, genomics, transcriptomics, and application development can provide us new opportunities to resolve the complexities associated with drought tolerance. Furthermore, these advances in science can also provide us crucial resources to promote research both in crop plants and in model plants [9–12]. All kinds of "omics," arrays, and high-throughput technologies can now make it possible to carry out genetic and genomic analysis for the investigation of gene function associated with phenotypic changes on a larger scale to accelerate crop breeding.

In this chapter, we have reviewed the recent efforts to improve cassava especially for drought tolerance and have presented perspectives for integrating the knowledge that has been accumulated through the traditional research and the current advanced technologies to improve cassava genotypes with an efficient and targeted approach.

41.2
What Makes the Cassava More Tolerant to Drought?

Cassava tolerates prolonged drought that often exceeds 5 months. This has been attributed to partial closure of stomata, deep rooting systems, and small leaf canopy. These traits make cassava a desirable and adaptable crop, as a source for food and feed, in the hot and dry tropics that are highly prone to predicted adverse global climate changes [13, 14].

Recent review by El-Sharkawy [8] reveals several attempts made at understanding the mechanisms involved in the drought tolerance in cassava and its possible application in breeding programs for enhancing its productivity [8]. Some of the traits relevant to drought tolerance have been listed in Table 41.1. The challenge of further improving cassava for the productivity of harvestable roots now largely lies in

Table 41.1 Plant traits contributing to drought tolerance in cassava.

Trait	Contribution to drought and productivity	Conditions under which it is useful
Photosynthesis	High rate of photosynthesis under favorable conditions and maintenance even under prolonged drought conditions and recovery	General
Tight stomatal control	Protection from both low soil moisture and high evaporative demand	Hot environment with no soil moisture in deeper soil profile
Plant vigor	High vegetative vigor enables plants to recover from drought	Intermediate drought conditions
C3–C4 intermediate mechanisms	These characteristics, collectively, underpinned the high photosynthetic rate (P_n) in normal air ($P_n > 40\,\mu mol\,CO_2\,m^{-2}\,s^{-1}$) in high irradiances (>1800 μmol $m^{-2}\,s^{-1}$ of photosynthetic active radiation), high leaf temperature from 30 to 40 °C, and in high atmospheric humidities observed in cassava grown in favorable environments [6, 15]	Environments where high evaporative demand exist
Shoot morphological adjustments	During prolonged water deficits, cassava reduces its canopy by shedding older leaves and forming smaller new leaves leading to less light interception	Intermediate drought
Leaf area index	Optimum leaf area for longer period during the drought and after recovery	Normal and intermediate drought conditions
Deep roots	Cassava slowly extracts soil moisture from deeper layers of soil	Drought environments with moisture stored in deeper layers of soil
Predawn leaf water potential	Relative to unstressed plants	Intermediate drought

our efforts to phenotype known and unknown traits of drought tolerance. This can be accomplished through optimized and novel phenotyping techniques that can generate highly reliable data on plant response and stress environments for complementing genomic information.

41.3 Phenomics for Trait Discovery

Breeders' eye approach with large dependence on empirical selection for yield, disease, and pest resistance has significantly contributed to historical jump in food production during the Green Revolution in the past. However, scope for continuing this approach is gradually diminishing as evident from the recent yield plateau in many of the staple foods such as rice, wheat, and maize. The rapidly developing genomic knowledge and genotyping capacity can offer us opportunities to improve crop varieties in a much more targeted way to grow them in harsh environments, for more productivity with fewer inputs. Genomics and transcriptomics in combination with bioinformatics can offer great opportunity to generate knowledge about the function of the genome, unraveling genomic pathways, but more importantly, to identify useful diversity, genes, and alleles and transfer these rapidly into adapted varieties. However, these new approaches and tools need to be sufficiently complemented by screening protocols that can facilitate generation of high-quality data on plant phenotypes under given stress environment. This necessarily should include understanding and management of stress environment and rapid and noninvasive procedures to measure response of the large number of genetically diverse genotypes created through conventional breeding or genetic engineering approaches. These efforts with new terminology, "phenomics," have now become the focal point of much of the agricultural research aiming to get benefits from advances in genomics.

One of the major tasks in phenomics is the determination of plant responses to stress in well-defined environment that can clearly reveal the genetic variation. This will lead to trait discovery that can be eventually associated with gene(s) through quantitative trait locus (QTL) cloning or/and transgenic approach. In addition, the phenomics should focus on inherent gaps in understanding the magnitude of drought stress in terms of duration of soil moisture stress and level of soil moisture during a specific growth period in crops such as cassava.

In a classical example of a field evaluation, it was shown that the reduction in root yield in response to 120 days of drought imposed 60 days after planting could reduce the yield marginally compared to the control in which soil moisture level was maintained at field capacity. In this experiment, some of the genotypes had more grain yield compared to control even after exposure to the drought [8]. Furthermore, compared to the control, water stress across all varieties caused a reduction in total biomass by 12%, no change in fresh root yields, a reduction in dried root yields by 3.4%, a reduction in dry matter contents by 3.3%, and an increase in the harvest index by 10%. Without any doubt, these data clearly demonstrate cassava's ability to tolerate prolonged water stress when it is induced gradually at an early stage of growth and also its ability to recover from drought. However, the magnitude of drought stress, the duration, and critical phase of growth in such experiments need a review as possibly the soil moisture deficit was not sufficient enough to cause substantial impact on productivity of cassava genotypes, to elucidate genetic variation in the response, which is fundamental to further genetic improvement. Alternatively, control plants did not have sufficient scope to express their yield potential. Hence, we suggest that

the challenge of further improving the productivity of cassava under moisture stress should consider a reoriented phenotyping protocol.

1) To dissect traits contributing to components of crop productivity under soil moisture deficit [16].
2) Cassava root yield = water uptake × water use efficiency × partitioning to roots that can be harvested.
3) To impose drought at critical stage of growth that determines productivity of crop.
4) The time when number of productive roots determined.
5) Root bulking.
6) To reduce the influence of phenological variation in understanding genetic variation in drought response, through staggered sowing.
7) To differentiate genetic variation in recovery from drought stress.
8) To understand the yield gap in the target environment that needs to be covered by genetic improvement of traits associated with high root yield. The traits listed in Table 41.2 may be considered depending on the nature of drought stress.

41.4
How Cassava Genomics Tool will help Develop Drought-Tolerant Variety

In 2007, CIAT and RIKEN initiated an international collaborative research project and since 2009, a 3-year cassava research project, between RIKEN (Japan, PI: Dr. Motoaki Seki), CIAT (Colombia, PI: Dr. Manabu Ishitani), and Mahidol University (Thailand, PI: Dr. Jarunya Narangajavana), which is supported by the Japanese government, has started to develop an integrated cassava genome analysis platform for the global cassava research community and to apply it to molecular breeding for cassava improvement. In the collaborative work, the following cassava genomics tools are being developed: (1) large-scale collection of full-length cDNAs ([17], unpublished data), (2) cassava oligoarray analysis platform containing more than 30 000 genes, and (3) cassava database of international standard. For the collection of full-length cDNA clones, we have selected three genetically diverse varieties, namely, KU50 (*Manihot esculenta* Crantz), MEcu-72 (*M. esculenta* Crantz), and MPer 417-003 (*M. esculenta* peruviana). KU50 is a commercial cultivar developed in Thailand, which is extensively grown in Southeast Asia. MEcu-72 is one of the naturally occurring wild landraces in Ecuador reported to be resistant to whiteflies by CIAT [18]. MPer 417-003 is a wild species from Brazil, which is probably involved in the evolution of cassava cultivar, *M. esculenta* Crantz. The MPer 417-003 has strong resistance to insects such as mealybugs, mites, and whiteflies [19]. One of the objectives to choose these varieties is to understand common mechanisms of drought tolerance in cassava and use this knowledge for the improvement of other crops mainly because cassava has some features that allow it to cope with stress better than other crops, for example, high stomatal sensitivity to environmental humidity [20] and quick recovery after stress [21]. Another objective is to identify novel traits and superior genes using genetic diversity existing in cultivated and wild species of cassava. So far, we have obtained 19 968, 29 952, and 19 968 end sequences of full-

length cDNA clones from KU50, MEcu-72, and MPer 417-003, respectively and some of the sequences are not present on Phytozome Web site (www.phytozome.net/cassava), the cassava genome database. Using a set of unique genes from the expressed sequence tag (EST) collections, an oligoarray analysis platform is being developed with more than 30 000 genes. These genomic and transcriptomic tools enable us to dissect traits of importance for cassava improvement in a comprehensive way. We believe that the platform could be applied for any cassava variety including wild cassava species and will be useful to cassava research community globally.

In 2009, the first annotated draft cassava genome sequence became available at the Phytozome Web site (www.phytozome.net/cassava). The genome sequencing project has been initiated through the DOE-JGI Community Sequencing Program (CSP) by a 14-member consortium including DanForth Plant Center and CIAT. Furthermore, the University of Arizona has started a new project funded by the Bill & Melinda Gates Foundation in collaboration with DOE-JGI, 454 Life Sciences, and the University of Maryland, Baltimore, to develop a genome variation database that will provide breeding tools such as markers. This variation database with comprehensive genome information from different cassava genotypes will help make breeding schemes more efficient through marker-assisted selection (MAS) (http://www.bio5.org/news/news_release/13-million-grant-ua-bill-melinda-gates-foundation-will-fund-next-phase-cassava-res). The full-length cassava cDNA sequence information derived from different cassava varieties will significantly contribute to cassava genome sequence annotation and help know the source of genetic variation in different cassava species. The high quality and correct annotation of the genome sequence can further accelerate identification of useful genes and promoters associated with traits contributing to drought tolerance in cassava through QTL, transcriptomic analysis (e.g., DNA microarrays), and transgenic approaches. In *Arabidopsis* and rice, molecular responses to drought stress have been intensively analyzed and several key genes involved in the drought stress response and tolerance have been identified [22]. As most of the knowledge that has been obtained so far in *Arabidopsis* and rice can be applied to other plants [23, 24], cassava homologues of the drought stress-related genes in *Arabidopsis* and rice can allow us to look at genetic difference in terms of gene and gene duplication between *Arabidopsis*, rice, and cassava in terms of drought stress response and its tolerance among the plant species.

41.5
Gene Discovery for Drought Tolerance in Cassava

QTL mapping becomes a standard procedure in quantitative genetics [25] and recent technical progress in the area of molecular biology and genomics have allowed us to identify QTL gene. There are two major strategies for the QTL cloning: one is through positional cloning and another is through association mapping. Because of a long growth cycle and complex genetic nature of cassava, gene discovery through QTL cloning was not an easy task in the past and this will drastically change once all the genomic sequences and genomics tools become available through current global

efforts as described above. The tools will help develop fine genetic mapping, physical mapping, or markers, which are strongly associated with trait of interest for cassava improvement [26–28]. In addition, plant comparative genomics and transcriptomics approach will largely benefit from research advances described above to discover key genes associated with traits of interest [29–32]. Especially, sequence homology or similarity can serve as a strong evidence for detecting functional elements in genomic sequences. Here, we give an example to identify cassava genes, which may have molecular and physiological functions similar to those of genes in other plants.

It was recently reported that transgenic cassava expressing *IPT* gene, which encodes isopentenyl transferase from *Agrobacterium tumefaciens*, under the control of the *Arabidopsis* promoter of the senescence-induced *SAG12* gene, could trigger a series of metabolic changes such as cytokinin metabolism that increased drought resistance [33]. This study not only could prove the feasibility of delayed leaf senescence of woody cassava but also could reveal mechanisms underlying the control of cytokinin homeostasis in cassava leaves. However, the origin of the IPT gene used in this study was *A. tumefaciens*, a bacterium. Therefore, we carried out homologue search by BLAST program and phylogenetic analysis by NJ method to identify orthologue genes of IPT in cassava, and nine sequences were identified from cassava genome database as shown in Figure 41.1. Generally, *IPT* genes are classified into bacterial type or plant type according to their amino acid sequences [34]. Interestingly, plant-type *IPT* genes in *Arabidopsis* are strongly involved in the cytokinin metabolism in contrast to bacterial-type *IPT* genes [34–36]. As shown in Figures 41.1 and 41.2, all the nine genes identified as cassava *IPT* genes belong to the plant-type IPT group. Furthermore, some cassava EST sequences, which partially encode the plant-type *IPT* genes, are now available. We are trying to isolate full-length cassava cDNAs encoding plant-type *IPT* genes for developing drought-tolerant cassava cultivars using transgenic approach.

It is recognized that traditional breeding is most unlikely to provide all solutions for improving the crop to meet the varying needs of small farmers and commercial production in the tropics [39, 40]. The transgenic technologies can accelerate integration of desired traits into farmer preferred cultivars and landraces, as well as elite breeding lines. Hence, this technique is one of the options to get maximum benefit from major advances occurring in the genomics for improvement of cassava, which is a long-duration crop. Transgenic technologies allow beneficial traits to be transferred from one cassava cultivar to another and from wild relatives to cultivated *Manihot*, circumventing species boundaries and the problems of outcrossing and inbreeding depression, inherent to this vegetatively propagated crop.

The first series of cassava transgenic technologies were reported in 1996 [41–43]. Since then, the transgenic technologies have been improved [44, 45] and utilized to produce genetically transformed cassava expressing traits such as reduced cyanogenic content [46–48], enhanced starch production [49, 50], insect resistance [51], virus resistance [52–56], and herbicide resistance [57, 58]. Recently, it has been reported that transgenic cassava expressing *IPT* gene from *Agrobacterium* increased drought resistance as mentioned in the previous section [33]. The transgenic plants were useful both to investigate drought resistance in cassava and to increase storage

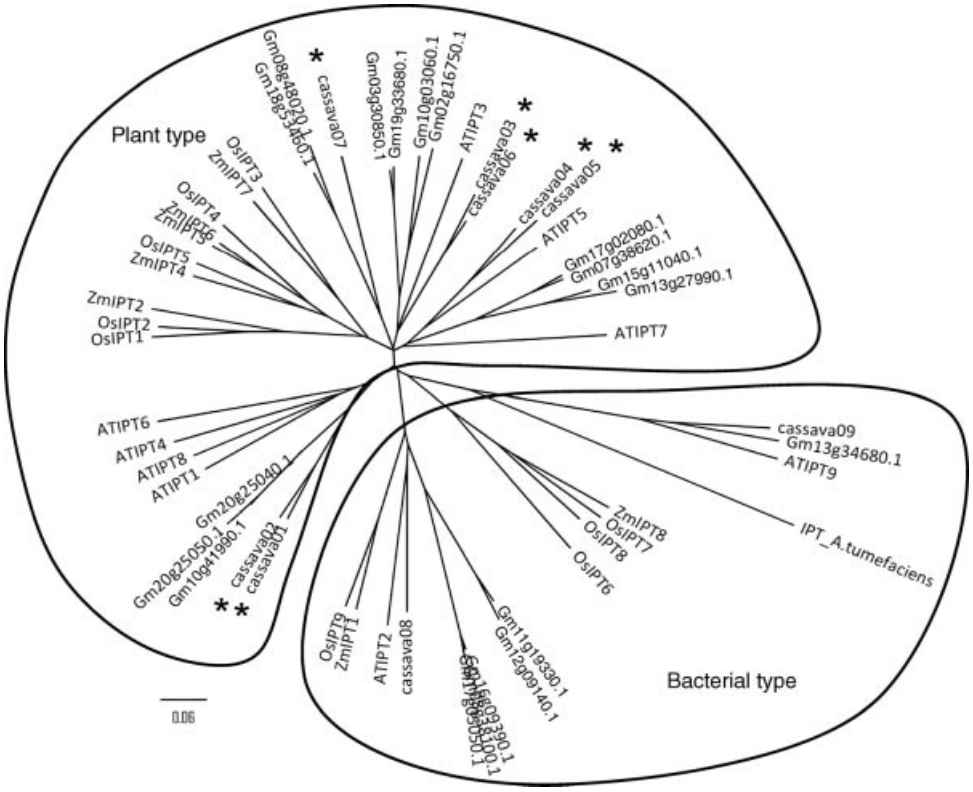

Figure 41.1 Phylogenetic tree of *IPT* genes. The amino acid sequences of the *IPT* genes (9 identified *IPT* homologous genes in *M. esculenta* (cassava), 19 *IPT* homologous genes in *G. max* (Gm) and 9 genes in *A. thaliana* (At) [34], 9 genes in *O. sativa* (Os) [37], and 7 genes in *Z. maiz* (Zm) [38] were aligned by ClustalX2 and the phylogenetic tree was constructed using the NJ method. *IPT* gene in *A. tumefaciens* is a query for the BLAST search. Asterisks show the plant type putative *IPT* genes identified from cassava genome database (phytozome). *IPT* genes are classified into bacteria type or plant type according to their amino acid sequences [34].

root production in semiarid regions and leaf biomass as vegetable and animal feed. Furthermore, Saelim *et al.* [59] have established a marker-free cassava transformation protocol using a cassava cultivar, KU50, which is extensively grown in Southeast Asia. This is the first demonstration of the efficacy of the system in promoting excision of *ipt* marker gene in cassava species, with the consequent rapid production of marker-free transgenic plants [59]. The high efficiency of this system should facilitate pyramiding a number of transgenes by repeated transformation without having to undergo laborious, expensive, and time-consuming processes of sexual crossing and seed production. The generation of marker-free, thus environmentally safe, genetically modified cassava clones should also ease the public concerns regarding the use of transgenic cassava in both food and nonfood industries. Technologies for transformation of plants are in high demand and are being increasingly employed by large seed and agrochemical sectors. Most of the academic research groups lack

infrastructure, logistics and human resources necessary to establish middle to high-throughput transformation pipeline for their own target crop. CIAT has been working in transgenic research on cassava and rice for more than a decade and has scaled up its facilities to include confined fields for field evaluation, and it has been uniquely placed to evaluate the gene technology with a generic permission from National Biosafety Committee of Colombia. The CIAT has now established the Transformation Platform to host all the in-house or collaborative research projects that aim to evaluate transgenic technology for important crops such as rice and cassava. The strategy is to accelerate evaluation of gene technology through transformation and phenotyping platforms by employing scaled up infrastructure, expertise, and knowledge with the ultimate objective of complementing conventional crop improvement technology for cassava.

41.6
Proteomics and Metabolomics Approach in Cassava

Several groups have shown the profiles of protein pattern of a storage root [60], fibrous and tuberous root [61], plant–pathogen interactions [62], and secondary somatic embryogenesis [63] in cassava by using a technology of two-dimensional gel electrophoresis. Recently, Li *et al.* [64] provided a new insight into the proteomic patterns in the somatic embryos, plantlets, and tuberous roots [64]. These investigations have paved the way for a comprehensive, system-wide analysis of cassava. Large-scale proteome data sets are an important resource for a better understanding of protein functions in terms of not only growth and development but also response to environmental changes.

Metabolomics aims to understand metabolic systems based on comprehensive and integrated approaches that take advantage of recent advances in instrumentation to characterize metabolites. Metabolomic approaches can allow us to conduct parallel assessments of multiple metabolites and can facilitate quantitative analysis of particular metabolites with major advantages over chemical-level phenotyping and diagnostic analysis. The plant metabolome represents an enormous chemical diversity due to the complex set of metabolites produced in each plant species [65, 66]. Various sources of information on metabolomics have played a crucial role in metabolome research and its synergistic integration with other omics approaches. Metabolomics information for cassava has not been launched yet, but for other plants, there are Web sites on metabolome resources such as TAIR (http://www.arabidopsis.org/portals/metabolome/index.jsp), the KEGG PATHWAY Database (http://www.genome.jp/kegg/pathway.html) [67–69], the Plant Metabolic Network (PMN) (http://www.plantcyc.org/), PlantCyc including AraCyc and PoplarCyc (http://www.plantcyc.org:1555/PLANT/server.html) [70], KaPPA-View (http://kpv.kazusa.or.jp/kappa-view/) [71, 72], and PRIMe (http://prime.psc.riken.jp/) [73]. However, the analysis of the ESTs for full-length cDNAs from abiotic and biotic stress-treated cassava tissues mentioned in the previous section has revealed that some of EST sequences encode novel plant genes and they do not belong to any pathways that are already known in plants (unpublished data). It indicates a

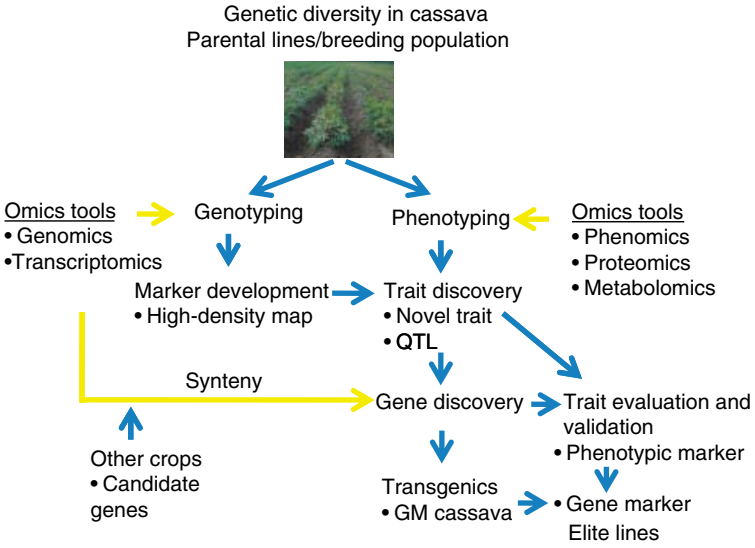

Figure 41.2 Gene discovery for a particular trait is the key to accelerating genetic improvement of cassava; however, genotyping and phenotyping tools are the major prerequisites that can determine the success. Recent advances in genomics can ensure high-density genetic maps, while precision phenotyping is essential for identifying the key traits associated with desired phenotype of plants. This will also determine the precision of association between the trait of interest and the QTL. Omics tools such as genomics and transcriptomics can facilitate both high-quality genotyping and discovery of candidate genes by assessing synteny with other crops. Phenomics, proteomics, and metabolomics can improve efficiency of trait discovery. Thus, the gene discovery will be the product of integration between efficient genotyping and phenotyping. It is necessary to further carry out trait evaluation and identify precise phenotypic marker to carry forward the gene discovery into useful gene marker and to support marker-aided selection in the cassava breeding program.

possibility of the existence of some novel pathways related to stress tolerance in cassava. Therefore, cassava metabolomics, which is a great analytical challenge, can serve as an immensely important tool to design molecular breeding strategies for improvement of the productivity and value of cassava in the near future.

41.7 Future Perspectives

Earlier investigations have often indicated the relationship of some of the physiological traits with root yield of cassava under water deficit environment. The concepts evolved so far need to be validated and transformed into crop improvement tools to ensure precise phenotyping for trait discovery and gene identification. Phenomics platform with tools and techniques that are emerging out of advances in digital imaging and image analysis can significantly help in phenotyping long duration plants such as cassava with reduced cost. These noninvasive rapid methods can greatly complement

research efforts of both the genomic analysis platform and the transformation platform to enhance our understanding about molecular mechanisms of drought tolerance in cassava. However, these technologies and knowledge that can save time and money in developing elite cultivars have not been effectively integrated into cassava breeding programs. This can be partially because of heterozygosity and long growth cycle, which are the major constraints in cassava breeding programs. Furthermore, as shown in Figure 41.2, the key lies in integration of genomics, transcriptomics, metabolomics, proteomics, and other large-scale "omics" data with systems biology approaches, and it can open new avenues for engineering cassava to enhance yields, improve nutritional value, and overcome the problems of postharvest physiological deterioration as well as biotic and abiotic stresses.

Through integrated omics approach, gene markers can be identified rapidly and at low cost in the near future. Furthermore, MAS that focuses on key traits contributing to drought tolerance can become more robust for accelerating genetic improvement of cassava. Since drought tolerance is a highly complex trait, pyramiding multiple sources of genes for drought tolerance into a set of new progenitors can lead to a much desirable impact. CIAT will increasingly adopt technologies evolving from recent developments in single-nucleotide polymorphisms (SNPs) to accelerate the application of MAS strategies in cassava breeding programs. Marker genotyping based on SNP resources are being developed by using next-generation sequencers (NGS) such as 454 DNA sequencer and Illumina genome analyzer. The computational discovery of EST-based SNPs and/or EST-SNP markers is now in progress for numerous species [74–82]. EST data sets for full-length cDNA, which we have obtained (see Section 41.5), will serve as an important resource for discovery of SNPs, especially for locating expressed genes onto a genetic map. This will lead topositional cloning of genes of interest that can be useful as efficient markers for accelerating improvement of cassava for tolerance against abiotic and biotic stresses.

Acknowledgments

We thank Dr. Sankaran Murugan for discovering genes related to drought tolerance. This work was supported in part by Strategic Funds for the Promotion of Science and Technology of the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan.

Tomato: Grafting to Improve Salt Tolerance

Paloma Sanchez-Bel, Isabel Egea, Francisco B. Flores, and Maria C. Bolarin

Salinity is considered one of the main factors that limit crop productivity, and development of crop species tolerant to this abiotic stress is vital to meet the growing food demand through sustainable agriculture. Therefore, the greatest challenge in the coming years is to increase crop production in such abiotic stress-affected lands as occur in areas affected by salinity. Tomato is considered one of the most economically important vegetable crops in the world, but unfortunately it is salt sensitive. The commercial success obtained through traditional breeding programs with regard to salinity tolerance has been very scarce because of the complexity of the plant response to the stress. One way of avoiding or reducing losses in production caused by salinity in high-yield genotypes would be to graft them onto rootstocks capable of reducing the effect of external salt on the shoot. This strategy could also provide the plant breeder with the possibility of combining good shoot characteristics with good root characteristics and of studying the contribution of genes transcribed in the roots to their performance on the shoot. This chapter gives an overview on the main physiological processes involved in the salt tolerance response of grafted tomato plants and illustrates how grafting can enhance salt tolerance in tomato, determined by fruit yield, a key agronomic parameter. Moreover, it is important to highlight that the salt tolerance conferred by the rootstock to the shoot genotype in terms of fruit yield seems to be a heritable trait. However, it is still necessary to conduct a good deal of research work in order to simplify the process of rootstock selection, as different results may be obtained depending on the shoot and root genotypes, as well as the salt levels and exposure times of the grafted plants.

42.1
Introduction

Tomato is considered one of the most economically important vegetable crops in the world. Abiotic stresses, like those caused by soil salinity, have a huge impact on tomato production and mainly affect arid and semiarid regions. Development of tomato plants tolerant to stress is vital to meet the growing food demand through

Improving Crop Resistance to Abiotic Stress, First Edition.

sustainable agriculture. Therefore, the greatest challenge for the coming years will be to increase crop production in abiotic stress-affected lands [1].

In traditional breeding programs, commercial success has been very limited due to the complexity of the trait: salt tolerance is complex genetically and physiologically [2]. Even when halophytic species exist in the gene pool, as it is the case of tomato, the development of salt-resistant cultivars has been slow [3]. Two major problems are encountered in breeding for salt tolerance: the definition, or selection criteria, for salt tolerance and the efficient use of the wild germplasm to increase the salt tolerance of the crop [4]. The selection of appropriate genes to obtain salt-tolerant varieties is a difficult task because salt resistance is a complex character controlled by a number of genes or groups of genes and involves a number of component traits that are likely to be quantitative in nature. Thus, in the *Solanum* genus, the existence of accessions of halotolerant wild species (e.g., *Solanum pennellii*, *S. cheesmaniae*, and *S. pimpinellifolium*), and their sexual compatibility with the cultivated species (*S. lycopersicum*), should have permitted the genetic dissection of the tolerance character by traditional methods. The studies carried out to date have provided valuable information (reviewed by Cuartero *et al.* [5]). Unfortunately, despite the wealth of genetic variation within the pool of tomato wild-related species, it is still not known which are the key genes determining the high tolerance level in those plants, and it is not possible to conclude that true halotolerant cultivars have been obtained. Moreover, both the distortion of the segregation, a common fact in interspecific crosses, and the difficulties inherent to the evaluation of plants under saline conditions have made the analysis difficult. As a consequence, we still do not know which are the main genes determining salt tolerance in the wild species of tomato. The problem arising while obtaining salt-tolerant varieties is the choice of the genetic material to introduce, taking into account that new cultivars bred for salt tolerance not only have to be salt tolerant but also have to achieve the same attributes of productivity and quality as observed in modern cultivars [6, 7]. Given the rapid increase in molecular biology techniques, a key question is whether such techniques can aid the development of salt resistance in plants.

The introduction of genes conferring salt tolerance to elite cultivars or elite parents of current hybrids, by transformation, is a very attractive idea because, hypothetically, susceptible but productive cultivars should be converted into tolerant cultivars while maintaining all the very valuable traits present cultivars possess. In recent years, transgenic approaches have been employed to produce plants with enhanced salinity tolerance by overexpression of genes controlling different tolerance-related physiological mechanisms [1]. However, given the nature of the genetically complex mechanisms of abiotic stress tolerance and the potential detrimental effects, approaching this strategy with reasonably successful possibilities is extremely difficult [2, 8]. Therefore, more efforts are needed in developing transgenic tomato with overexpression/silencing of specific genes in order to evaluate their putative positive effect in enhancing drought and salt tolerance, with the final goal of circumventing the increasing problem of scarcity of water of good quality in tomato cultivation [9].

But solving a problem as complex as the profitable use of saline water in irrigated agriculture requires more than one strategy. For generating tolerant cultivars, a set of cultural techniques, each contributing to a certain degree to developing plant tolerance to the deleterious effects of salt, need to be assessed to verify the positive effects of their application [3]. Some of those strategies, such as the application of chemical fertilizers at levels somewhat above the optimum for freshwater irrigation, the application on the nutrition solution of chemical adjustment, or leaching salts to deeper soil layers have doubtful compatibility with preservation of the environment, seed priming, or seedling conditioning.

Finally, another possible cultural practice in order to avoid or reduce yield losses caused by salinity would be to graft cultivars onto rootstocks able to reduce the effect of external salt on the shoot. This strategy of grafting could also provide growers the opportunity to combine the best shoot characters with the best root characters and researchers the possibility of studying the contribution to the shoot performance of genes expressed in the roots and vice versa, and their interaction. In this respect, grafting provides an experimental means to juxtapose diverse genotypes, to test for transport of hormones, signals, or metabolites [10], and to demonstrate the mobility of RNAs and proteins through the phloem. It is important to point out that growers would exploit immediately a technique like this if that allows them to use saline conditions in the culture, while retaining the yield and quality of crop varieties for which they already have established markets.

42.2
Formation of the Rootstock–Scion Union

Grafting of two plants so that they grow as a single individual is an ancient horticultural technique that can combine valuable traits of different genotypes. Grafting is an established method of vegetative propagation for many forest trees and is widely used in horticulture to propagate ornamentals. Grafting is not limited to woody species, but it is also used for some vegetables crops [11, 12]. Among the most grafted horticultural species are the cucurbits (watermelon, melon, and cucumber) and the Solanaceae (tomato, eggplant, and pepper).

The agricultural use of grafting is considerably restricted to closely related taxa because of incompatibility. Grafting partners may belong to the same species, genus, or family. For successful grafting to take place, the vascular cambium tissues of the rootstock and scion plants must be placed physically in contact with each other. Both tissues must be kept alive until the graft has taken place, usually within a period of few weeks [13, 14].

Several authors have defined the sequence of structural events during the healing of the graft in herbaceous plants. An overview of this sequence would be as follows: (i) the scion tissue with meristematic activity is placed in intimate contact with rootstock tissue in such a manner that the cambial regions of both are able to interconnect through the callus bridge. Thus, new parenchymatous cells proliferate from both

rootstock and scion producing the callus tissue and filling up the spaces between the two components connecting the scion and the rootstock. (ii) New cambial cells differentiate from the newly formed callus, forming a continuous cambial connection between rootstock and scion. Furthermore, prior to the binding of vascular cambium across the callus bridge, initial xylem and phloem may be differentiated. The wound-repair xylem is generally the first differentiated tissue to bridge the graft union, followed by wound repair phloem. (iii) In the last step of the graft process, the newly formed cambial layer in the callus bridge begins typical cambial activity forming new vascular tissues. Production of new xylem and phloem thus permits the vascular connection between the scion and the rootstock [13, 15]. Although the time in which each process of grafting occurs depends on various factors such as the grafted species and variety, many authors observed that the differentiation of callus parenchyma to form new cambial cells begins between days 4 and 8 and is fully developed after 15 days [14, 16].

Observation of the structure of the graft union in tomato showed formation of xylem and phloem vessels through the scion–rootstock union 8 days after grafting [14]. In addition, root hydraulic conductance, L_0, indicates that the graft bond is fully functional 8 days after grafting.

Many studies have suggested that peroxidases play a role in lignification [17, 18]. Fernandez-Garcia *et al.* [14] showed that total peroxidase activity increased during development of control and grafted tomato plants. However, grafted plants showed more activity than controls, which is in accordance with the increased lignification observed in the graft union by histochemical analysis. Moreover, grafted tomato plants showed a significant increase in H_2O_2 at day 8 [14]. Lignification is a process that requires H_2O_2 and cell wall peroxidases to bring about polymerization of lignin. In addition, H_2O_2 may serve as an immediate mechanism for disease resistance in response to pathogens and it could play an important role in wound response and cell apoptosis [19–21].

Graft incompatibility includes failure to unite into a strong scion–rootstock connection, failure of the grafted plant to grow in a healthy manner, or premature death following grafting. Physiological incompatibility may be either due to lack of cellular recognition, wounding responses, and growth regulators or due to incompatible toxins, but the ultimate biological nature of this grafting incompatibility is not known [22]. In tomato, our group observed in one graft combination between two cultivars, P73 as scion and Pera as rootstock, that although grafting was successful leaf morphological alterations began to appear after a certain period of time (between 20–25 days after grafting), which seemed to be associated with hormonal imbalance (Figure 42.1). Thus, Aloni *et al.* [23] found that the disruption of rootstock–scion connections in incompatible grafting occurred approximately 25 days after grafting and proposed that the main cause of incompatibility is the occurrence of hormonal imbalance, primarily of auxins and ethylene in the root system following the establishment of grafting connections. Recently, Aloni *et al.* [13] showed a schematic presentation of a possible mechanism for grafting incompatibility in melon plants, indicating that incompatibility may result from basipetal auxin transport to the rootstock where it induces ethylene production and oxidative stress. This oxidative stress may be activated also in compatible grafting.

Figure 42.1 Leaf and apex alterations observed in tomato-grafted plants (cv. P73 used as scion and cv. Pera used as rootstock) (b–e), compared to nongrafted plants of both cultivars that showed no abnormal characteristics on such vegetative organs (a and f).

These authors suggested that exogenous application of indole acetic acid (IAA) transport blockers, abscisic acid (ABA), ethylene antagonist agents, or antioxidants may reduce grafting incompatibility by reducing oxidative stress in the root and therefore enabling its growth.

42.3
The Use of Grafting in Tomato

The application of grafting began in the 1920s, initially to limit the effects of soil pathogens such as *Fusarium oxysorum* [24]. Application and use of grafting in diverse plant species of horticultural importance have risen with the increased use of improved soil mix or substrate, farmer's preferences for better seedlings, efficient management of nursery systems, lower prices of grafted seedlings, and efficient nationwide delivery, and/or transportation system [25]. This technique has been widely used to enhance nutrient uptake [26, 27], to induce resistance against drought [28, 29], to boost resistance to low and high temperatures [29–31], to bring about resistance against heavy metal contamination [27, 32], to improve alkalinity tolerance [33], and to increase synthesis of endogenous hormones [13, 34]. Grafting has also been used as a tool to study various aspects of plant biology including apical dominance [35], nodulation [36], flowering [37], dwarfing [38], and characterization of mutants [39].

In relation to salt tolerance, it is possible to find several studies that use grafting as a tool to improve salinity tolerance of tomato either through its direct application or indirectly through the detection of QTL in support of conventional breeding [14, 40–47]. These

studies suggest that grafting provides an alternative way to improve salt tolerance by reducing the ionic stress [41, 43, 44, 48, 49] and by improving the photosynthesis performance and the antioxidant systems [47]. Cultivated tomato species is a glycophyte, thus screening for rootstocks that confer resistance to salinity to the scion is mainly directed to combinations of interspecific grafts. Tomato is compatible with a wide range of genera and species. For example, it has been grafted on potato (*S. tuberosum*) producing tomato fruits and potato tubers [50]. Although intergeneric, interspecific, and intervarietal combinations are possible, the use of halophytes as rootstocks show major problems due to the different sizes and growth rates and the compatibility between the genotypes used. Therefore, the use of interspecific hybrids as rootstocks may be a better strategy to study and integrate the agronomic, physiological, and genetic components of salt tolerance conferred by the rootstock to the scion [46]. Furthermore, grafting provides a direct way to transfer salt tolerance traits from the wild species into the domestic tomato by using recombinant inbred lines (RILs) derived from interspecific crosses as rootstocks [43]. Previous studies with tomato suggest that grafting did improve plant adaptation to salt stress [40, 41].

Grafting could be a promising tool to raise fruit quality under both nonsaline and saline conditions [32, 51, 52]. Although more studies are necessary, the results obtained by our group on this aspect are remarkable. Results obtained with tomato-grafted plants showed that grafting may be an effective agricultural approach to improve fruit quality under both control growth conditions and salinity, but careful screening for optimal rootstocks is a key question, as the fruit quality of the shoot depends, at least partially, on the root system [53]. These results are very interesting, as it is known that simultaneous increase in both fruit yield and soluble solids content, a main fruit quality parameter in tomato, in commercial tomato cultivars is a difficult task [6]. This is due to the inverse relationship generally found between both parameters, which seems to become stronger under saline conditions [54]. In this study, however, the beneficial effect induced by the rootstock on the fruit quality of the shoot genotype was not associated with any negative effect on the fruit yield under saline conditions. But the rootstock was even able to induce significant increases in fruit soluble solids content and titratable acidity not only under saline conditions but also when the grafted plants were grown under unstressful conditions [53]. These results suggest that grafting may be a valid strategy to improve fruit quality.

42.4
Physiological Processes Involved in Salt Tolerance of Grafted Tomato Plants

The salinity response of grafted plants may be different depending on the main predominant effect induced by salinity as this abiotic stress acts on plants in two ways: high concentrations of salts in soil make it harder for roots to absorb water, resulting in an osmotic stress the main symptom of which is dehydration; and high concentrations of salts within the plant can be toxic, causing an ionic stress the main symptom of which is leaf chlorosis and swelling due to the excess of sodium ion. Moreover, if the plant is not able to reach homeostasis and adapt to these salinity

conditions, oxidative stress arises as a result of the excessive production of reactive oxygen species in cells, leading to senescence and death. In a recent review of the role of grafting in plant crops under saline conditions, it was shown that grafted plants deploy numerous and diverse physiological and biochemical mechanisms in order to cope with salt stress [33].

The first phase of the plant growth response results from the effect of salt outside the plant. The immediate effect on the plant of the high concentrations of saline solutes in soil is the loss of turgor, and the main plant morphological process depending on turgor is cellular expansion. Therefore, leaf expansion and root elongation are the morphological processes that are more sensitive to the osmotic stress caused by salinity in plants. The cellular and metabolic processes involved are common to drought-affected plants. To cope with this situation, one key mechanism displayed by stressed plants with the aim of restoring the water uptake and cell turgor is osmotic adjustment. The plant needs to accumulate solutes to maintain cell volume and turgor, so the response to turgor reduction is osmotic adjustment, a major component of the response to salt stress in affected plants. The main solutes contributing to osmotic adjustment are inorganic solutes, which are taken up from the substrate and transported to the shoot, and organic solutes, which are synthesized by the plant. Na^+ and Cl^- are energetically efficient osmolytes for osmotic adjustment, but they must be compartmentalized into the vacuole to minimize ion cytotoxicity. Within the cytoplasm, osmotic adjustment is achieved by accumulation of the so-called compatible osmolytes. Some compatible osmolytes are essential elemental ions, such as K^+, but the majority of these are organic solutes, especially sugars (mainly fructose and glucose), organic acids, and other metabolites such as trehalose, proline, inositol, glycine, and betaine that have an osmoprotector role, too [55–57].

Since the long-term damage caused in cultivated tomato by salinity is ionic toxicity due to the excessive accumulation of Na^+ and Cl^- in leaves [3], it is a reasonable supposition that useful rootstocks should be able to reduce the uptake and transport rates of saline ions to the shoot (a trait often termed "salt exclusion"). The enhanced salt tolerance of grafted plants has often been associated with lower Na^+ and/or Cl^- content in the shoot [33], as has been observed in tomato [41, 43]. This indicates that tolerance induced by rootstock is related to the ionic stress rather than to the osmotic stress. However, in contrast to the cultivated species *S. lycopersicum* that generally excludes toxic ions [44, 58], most wild accessions seem to have an ionic inclusion mechanism because they accumulate higher concentrations of Na^+ and Cl^- in their leaves [59]. It is necessary to keep in mind that the use of organic solutes for osmotic adjustment is energetically much more expensive than the use of saline ions proceeding from the substrate [60]. The ATP requirement for the biosynthesis and/or transport for accumulation of solutes in leaves was assessed by Ravens [61] at 3.5 units for Na^+, 34 for mannitol, 41 for proline, 50 for glycine-betaine, and about 52 for sucrose. In this respect, salt tolerance may always be associated not only with low Na^+ concentration in the leaves but also with the capability of the tissue to tolerate Na^+. While the most tolerant genotypes of many species are those with better abilities to prevent excessive ion accumulation, the leaves of halophytes do contain

high salt concentrations [62], which are necessary to adjust the leaf water relationships with low external potentials, and halophyte plants use the cheapest solutes from an energetic point of view [63]. Tissue tolerance to Na^+ involves the storage of Na^+ in vacuoles, to avoid its accumulation in cytosol, preventing alterations in the activities of cytosolic enzymes [64]. Electrochemical H^+ gradients, generated by H^+-pumps located at the plasma membrane (H^+-ATPase) and the tonoplast (H^+-ATPase, H^+-PPase), provide the energy used by the plasma membrane- and tonoplast-bound Na^+/H^+ antiporters to couple the passive movement of H^+ to the active movement of Na^+ out of the cell and into the vacuole, respectively [65]. Such a situation seems also to occur in grafted tomato plants when grown at low-mid levels of salt, as the higher the fruit yield, the higher the contribution of inorganic solutes, including the saline ions, to the osmotic potential [43, 44]. Then, breeding for Na^+ accumulation, rather than exclusion, could be a more effective strategy for improving salt tolerance of conventional crop plants.

In addition to its known components of osmotic effect and ion toxicity, salt stress is manifested by an oxidative stress, all of which contribute to its deleterious effects [66, 67]. When plants are not able to adapt or to tolerate salinity conditions, the availability of CO_2 within the leaf is restricted and fixation of it is inhibited. This short supply of CO_2 is due to the high density of closed stomata of stressed plants. Plants tend to close stomas in response to drought and salt stress in order to avoid losing water by evaporation. The alteration in CO_2 fixation induces the impairment of ATP synthesis. Under these conditions, the concentration of the final electron acceptor $NADP^+$ is generally very low, which leads to an excess of excitation energy in the photosystems. High-energy states may be dissipated by either nonphotochemical quenching (e.g., xanthophyll cycle) or alternative processes, such as photorespiration [68]. If not dissipated, electrons accumulate in the electron transport chain and are transferred to oxygen (Mehler reaction), generating reactive oxygen species (ROS). Because of their high reactive potential, ROS are harmful to many cellular components when a certain threshold is exceeded (e.g., proteins, DNA, and lipids). This abnormal accumulation of ROS constitutes the starting point of oxidative stress. With regard to photosynthesis, under stressful conditions the electronic flow ceases and as a consequence photoinhibition is favored, but ROS accumulation also induces the photooxidation of photosystems I and II [69]. Plants have defensive mechanisms and utilize several strategies to overcome salt-mediated oxidative stress. Plant enzymatic defenses against oxidative stress include antioxidant enzymes promoting ROS scavenging such as catalases, superoxide dismutases, and peroxidases participating in the glutathione and ascorbate cycles [66, 70]. The biochemical defense system also includes nonenzymatic components such as carotenoids, ascorbate, glutathione, and tocopherols. A correlation between antioxidant capacity and salinity tolerance has been reported in tomato through comparative studies between cultivated and wild species [67, 71, 72]. According to Colla *et al.* [33], antioxidants can be used as markers of salinity tolerance in grafted vegetables. In tomato, the alleviation of oxidative damage in grafted tomato plants under NaCl stress originated from the increase in activities of catalases and enzymes involved in the ascorbate–glutathione cycle such as ascorbate peroxidase, dehydroascorbic reductase, and glutathione reductase [47].

Therefore, an efficient antioxidant system is an advantage for enhancing salt tolerance of grafted plants. Nevertheless, in contrast to the negative significance given to the increased ROS production, implying a harmful process, recent studies have shown that ROS play a key role in plants as signal transduction molecules involved in mediating adaptive responses to abiotic stress, suggesting that ROS signaling is an integral part of the response of plants to salinity [73, 74].

42.5
The Rootstock Improves Salinity Tolerance at Agronomical Level

In most studies on the role of grafting in salinity tolerance of crop plants, the salinity responses of the grafted plants have been studied mainly on the basis of plant growth but not on the basis of fruit yield [29]. Only in some cases, such as melon and cucumber, there are studies showing the salinity effect in grafted plants on fruit yield [33]. However, to our knowledge, the only results on the grafting effect in salinity tolerance of tomato on the basis of fruit yield have been obtained by our research group [40, 43, 44]. The most important question to elucidate is whether fruit yield may be increased in grafted plants grown under salinity. For example, when a commercial tomato hybrid like Jaguar was grafted onto the roots of several tomato genotypes, the positive effect of grafting on the fruit yield was found when electrical conductivity (EC) levels in the irrigation water increased (because of its increasing salt contents), with fruit yield significantly higher in all grafted combinations than that of the self-grafted cultivar (Figure 42.2). It is interesting to note that the important effect induced by some rootstocks on the salt tolerance of the shoot genotype was determined by means of fruit yield, as occurred in the plants grafted onto two of the four tomato cultivars assayed as rootstocks, Radja and Pera. Thus, while the self-grafted commercial hybrid plants reduced their fruit yield by 50% at 7.5 dS m^{-1}, the graft combinations onto Radja and Pera were able to maintain their yields around 90% at this salt level, compared to the plants grown at 2.5 dS m^{-1} (control conditions).

As we said elsewhere, although intergeneric, interspecific, and intervarietal combinations in grafting are possible, the use of halophytes as rootstocks show major problems due to the different sizes and growth rates and the compatibility between the genotypes used. Therefore, the use of interspecific hybrids as rootstocks may be a better strategy for investigating the agronomic, physiological, and genetic components of salt tolerance conferred by the rootstock to the scion. Different studies have been carried out by using a commercial tomato hybrid *S. lycopersicum* cv. Boludo as scion and as rootstock two RIL populations developed from a cross between a genotype of *S. lycopersicum* var. cerasiforme, as female parent, and as male parents two salt-tolerant lines belonging to the wild tomato species *S. pimpinellifolium* (123 lines) and *S. cheesmaniae* (100 lines). In these studies, our group corroborated the positive effect of the rootstock on fruit yield, as in both populations there were rootstock lines that raised the fruit yield of the commercial hybrid under saline conditions [46]. Taken together, the set of results obtained by our research work and discussed in this section highlights the effectiveness of grafting to enhance fruit yield in tomato.

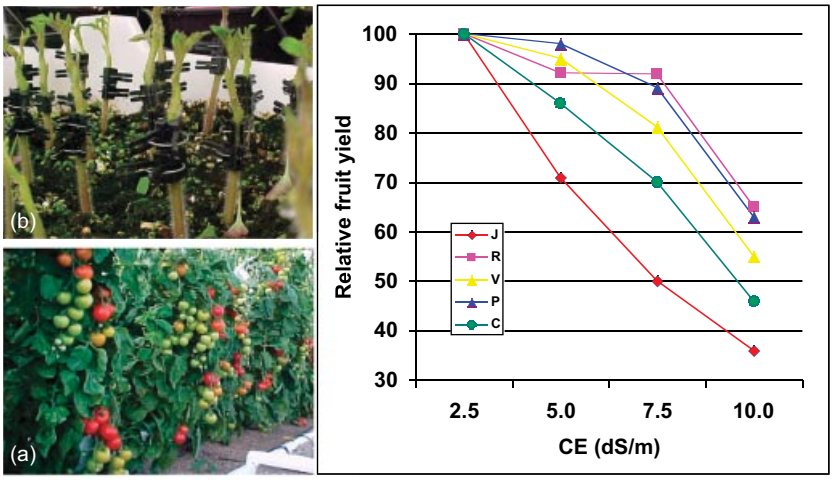

Figure 42.2 Tomato plants grafted onto different rootstocks when grafting was established (a) and at the end of growth cycle (b). Relative fruit yield comparison between self-grafted plants of a commercial tomato hybrid (cv. Jaguar, J) and Jaguar grafted onto different cultivars used as rootstocks (R, cv. Radja; V cv. Volgogradskij; P, cv. Pera; and C, commercial rootstock) at increasing levels of electrical conductivity of the irrigation solution. At the first level, the EC resulted from the sum of irrigation water EC (1.0 dS m^{-1}) plus the nutrient solution; in the following levels (5.0, 7.5, and 10.0 dS m^{-1}), the EC was increased because of the addition of 25, 50, and 75 mM NaCl, respectively, to the irrigation solution.

42.6
Genetic Basis of Salinity-Tolerant Rootstocks

The grafting strategy could also provide the plant breeder with the possibility of combining good shoot characters with good root characters and studying the contribution of genes transcribed in the roots to their performance in the shoot. An interesting approach to clarify how genes govern the tolerance to salt is the combination of segregation analysis of markers and phenotyping of lines to detect QTL. If it were possible to reveal molecular markers tightly linked to the genes governing salt tolerance, their favorable alleles could be selected in segregating populations by those markers and eventually incorporated into salt-tolerant cultivars. These markers closely linked to QTL alleles may reveal masked alleles and facilitate the introduction of genetic material without the disadvantages associated with traditional methods. The prospects of modifying a phenotype through conventional breeding have more possibilities of succeeding if it is incorporated with one or few defined regions of crucial importance than if generating a desired phenotype depends upon changes in a large number of genes, each with a small effect and scattered all over the genome. The identification of QTL has, therefore, practical importance to attempts to enhance stress tolerance.

Efforts on salt tolerance dissection using tomato experimental populations have been made taking into account different kinds of traits; however, in the case of crop plants, it is ultimately the yield under specific field conditions that will determine whether or not a gene or combination of genes (or QTL) is of agronomic importance. Experimental populations and the assays performed with them using grafting have already been discussed in the previous section, when these were used to test grafted plants with tolerance to salinity [46]. As already mentioned, salt tolerance in terms of fruit yield was studied by QTL analysis using the same RIL populations of F9 lines developed from a salt-sensitive genotype of *S. lycopersicum* var. cerasiforme, as female parent, and two salt-tolerant lines, as male parents, from *S. pimpinellifolium* and *S. cheesmaniae* [4]. Contrary to the expected, it was found that the wild allele (i.e., from the wild salt-tolerant genotype) was advantageous only at one total fruit yield QTL on chromosome 10 (*tw10.1*, near the salt-specific *fn10.1*). In fact, it was found that the advantageous allele at all fruit yield QTL came from the cultivated, salt-sensitive species. Therefore, other approaches in raising tolerance to salt using wild germplasm need to be considered.

Next, the rootstock effect on the fruit yield of a grafted tomato variety was genetically analyzed under salinity using as rootstock the previous RIL populations [46]. It is shown that the fruit yield increase induced by rootstock under salinity is a heritable trait governed by at least eight QTL. The most relevant component was the number of fruits. Thus, most of the detected QTL involved in salinity tolerance correspond to this component. In general, QTL genetic effects have a rather low degree, with contributions from 8.5 to 15.9% at most, and the advantageous allele comes from the wild, salt-tolerant species. To our knowledge, this is the first QTL analysis of the rootstock effect on the scion fruit yield. It is shown that the salt tolerance alleles from wild species can be more easily used to improve salt tolerance of the cultivated species through their utilization in tomato rootstock breeding programs [46].

42.7 Conclusions and Future Perspectives

There are rootstocks able to induce salt tolerance in tomato-grafted plants, an observation made on the basis of the determination of fruit yield, a most important agronomical trait. As discussed in this chapter, grafting practices offer the possibility of avoiding or reducing yield losses caused by salinity by means of grafting cultivars onto rootstocks able to reduce the effect of salt on the shoot. What is more, at the same time, is that it induces the development of salt tolerance to be conferred by a suitable rootstock and it allows to retain desired features of the shoot, such as fruit production and quality, which are essential parameters from the agrofood industry perspective. The main challenge here is the selection of the right rootstock, that is, the one that counteracts the negative effects of salt on the scion without affecting the levels of production and quality of the shoot. However, in order to simplify the process of rootstock selection, it would be very interesting to identify

the main rootstock characteristics able to reduce the negative effects of salinity on the shoot genotype in shorter time, in order to avoid crop losses in the grafted plants at the initial period of stress. Moreover, screening for a trait associated with a specific mechanism of the plant response to salinity is preferable to the screening for salt tolerance itself, as measuring the effect of salt on crop yield of a large number of lines is very difficult and complex. However, it is very important to take into account that the salinity response of tomato varies not only with genotype but also with salt levels and exposure times. Probably, the different and even contradictory results found in the literature may be, at least partially, due to either the stress level or the exposure time applied was not sufficient to show net differences among distinct grafted plants. Finally, the importance of osmotic tolerance mechanism to salt tolerance must be considered, which has not received as much attention as the ion exclusion mechanism, as it could be equally crucial in providing salt tolerance to tomato plants. From this perspective, more studies are required in order to arrive at the selection of the rootstock traits able to induce salt tolerance in the osmotic phase of this abiotic stress.

Tomato: Genomic Approaches for Salt and Drought Stress Tolerance

Benito Pineda, José Osvaldo García-Abellán, Teresa Antón, Fernando Pérez, Elena Moyano, Begoña García Sogo, Juan francisco Campos, Trinidad Angosto, Belén Morales, Juan Capel, Vicente Moreno, Rafael Lozano, Mari Carmen Bolarín, and Alejandro Atarés

Tomato is considered one of the most economically important vegetable crops in the world, particularly in temperate areas. Abiotic stresses as those promoted by salt accumulation and water deficiency entail significant losses of productivity. Despite the great efforts for increasing tolerance in such species of agronomic interest as tomato, the results so far obtained both with conventional breeding methods and with some biotechnological approaches have been rather scarce due to the complexity of the response to salt and drought stress. Moreover, only a small number of genes playing important roles in tolerance mechanisms to drought and/or salinity have been identified so far. Thus, novel tomato genes involved in abiotic stress tolerance need to be isolated and functionally characterized to help increase the level of salt and drought tolerance by means of gene transformation. This chapter focuses on the applications of genomic tools to the genetic dissection of those complex traits in tomato and related halotolerant wild species. First, the opportunities and limitations of the genome-wide expression profiling approaches to identify the genes associated with the stress response are discussed. Likewise, the advances achieved through forward and reverse genetics approaches such as insertional and chemical mutagenesis, TILLING, and other gene tagging approaches are reviewed. Hopefully, the combined use of all these genomics tools will lead to important advances in the genetic and physiological mechanisms of tolerance to drought and salinity in tomato, thus allowing the proper design of future breeding programs.

43.1
Introduction

Tomato is considered one of the most economically important vegetable crops in the world. Abiotic stresses, like those promoted by soil salinity and water deficiency, have a huge impact on tomato production and mainly affect arid and semiarid zones. Although production losses are very difficult to estimate, it is considered that drought

Improving Crop Resistance to Abiotic Stress, First Edition.

is a major abiotic stress that affects agriculture in 45% of the world's geography, where 38% of the world population resides [1]. Moreover, 20% of the irrigated agricultural lands are considered saline, yet production losses are higher due to the continuously increasing secondary salinization brought about by the low-quality water used for irrigation [2]. This risk will increase as the population increases because cities and industry will pay for the best quality water, leaving the worst to agriculture. Development of crop plants tolerant to stress is vital to meet the growing food demand through sustainable agriculture. Therefore, the greatest challenge for the coming years will be to increase crop production in abiotic stress-affected lands.

Despite the economic relevance of tomato, the mechanisms that govern responses to these abiotic stresses in this horticultural species are not well characterized, and only a very small number of genes playing a role in tomato tolerance to salinity and drought have so far been identified. Similarly, despite the existence of a great wealth of sources of variation in salinity and drought tolerance in accessions of tomato wild species, we still do not know the main physiological processes determining their ability to grow and reproduce in stressed lands and still less about the key genes controlling the high level of tolerance. Results from several laboratories have shown that it is possible to increase the level of salt and/or drought tolerance through a transgenic approach; however, it is not possible to conclude for the moment that cultivars with a sufficient level of tolerance from an agronomic point of view have been obtained via genetic transformation. In order to overcome the present limitations, it would first be necessary to perform the genetic dissection of those complex traits in tomato and related halotolerant wild species, which in turn would enable the identification of the targets for future breeding programs. In this respect, large-scale programs based on the use of genomic approaches should usher in a new era in the knowledge of the genetic and physiological bases of the response and mechanisms of tolerance to salinity and drought, thus allowing the design of more effective strategies for breeding for abiotic stress tolerance in tomato.

43.2
Tolerance Mechanisms to Drought and Salinity in Tomato and Related Wild Species

Tolerance to drought and salt stress is a complex phenomenon at both the whole-plant level and the cellular level, and intense research efforts have focused on understanding the physiological basis of tolerance in higher plants [3–7]. In physiological terms, drought and salinity share osmotic stress, such as a decrease in soil water availability under drought or a decrease in water potential of soil solution under salinity, causing osmotic stress, which leads to decreased water uptake and loss of turgor [8]. Drought and salt stresses also provoke oxidative stress, which leads to the acceleration of reactive oxygen species (ROS) scavenging systems [9]. The differential effect induced by salinity is the toxic effect of the salt induced by the root uptake and shoot transport of saline ions. While the osmotic effect starts immediately after the imposition of salt stress (i.e., before the saline ions are taken up by the roots), the toxic effect starts later when the saline ions are transported to the shoot and build up to

toxic levels within the leaves. However, the timescale over which ion-specific damage is manifested depends on the salt sensitivity of the genotype and the stress level [10]. Although the two phases are generally separated in time for most plants, it is also possible for ion toxicity to take effect during the first phase itself and for osmotic effects to persist in the second phase [11, 12].

43.2.1
Physiological Response to Osmotic Stress Induced by Drought and Salinity

Drought and salinity are known to induce stomatal closure, slowing CO_2 assimilation and, consequently, reducing the photosynthetic rate, although the causes of decreased photosynthetic rate under abiotic stress are still not well established, and there remains substantial controversy about the main physiological targets responsible for photosynthetic impairment [13, 14]. In addition to the effects on CO_2 diffusion, ATP synthesis and reductant status, abiotic stresses can also negatively affect the Calvin cycle by reducing the content and activity of photosynthetic carbon reduction cycle enzymes, including the key enzyme Rubisco. In tomato, the photosynthetic rate and the carbohydrate availability do not seem to be the first limiting factors for plant growth under saline conditions. Rather, these are the distribution and the use of photoassimilates in the sink organs [15, 16].

One important mechanism of the maintenance of water uptake and cell turgor under drought and salinity is osmotic adjustment. One important difference between drought and salinity is the main solutes contributing to osmotic adjustment. Under drought stress, the compatible solutes (or osmolytes), together with K^+ and NO_3^-, are the most important ones contributing to the osmotic adjustment, while under salinity the most important solutes are the saline ions. The use of organic solutes for osmotic adjustment is energetically much more expensive than the use of the saline ions proceeding from the substrate [17], which could make tomato more sensitive to the osmotic component of NaCl than the ionic component [18]. Thus, in the salt-tolerant wild tomato species, the greater salt tolerance has been associated with high Na^+ accumulation in leaves and fruits [19, 20], through the use in the main of the cheapest solutes from an energetic point of view for osmotic adjustment. Within the cultivated species, the salt tolerance is not always associated with low Na^+ concentration in the leaves. Thus, a direct relationship between the fruit yield and the accumulation of leaf saline ions was found in tomato when plants are grown at low-mid levels [21]. Other evidence on the importance of the osmotic component in the salt tolerance of tomato was apparent when the salt response of tomato transgenic lines with different expression levels of *HAL1* gene, involved in Na^+ regulation, was studied. In plants of a homozygous line proceeding from a transgenic plant with a very high expression level of *HAL1* gene, the fruit yield under saline conditions not only did not increase but was also even lower than that of azygous plants, and this in spite of the much lower Na^+ uptake and Na^+ translocation to shoot maintained over time in the homozygous line [12]. The deeper physiological characterization of these plants allowed it to be elucidated that the greater ability of Na^+ exclusion in the homozygous line caused another type of osmotic problem, as leaves required an

increased synthesis of organic solutes to maintain osmotic balance, thus leading to growth penalty that negatively reflected on fruit yield. These results demonstrate the importance of considering the osmotic component of salt stress in tomato.

With respect to the role of osmolytes in drought and salinity, plants accumulate many metabolites in the cytoplasm to increase their osmotic tolerance against water loss from the cells induced by drought and salt stress, especially soluble sugars (mainly fructose and glucose) and organic acids [22]. Accumulation of compatible solutes such as proline, glycine-betaine, and trehalose has also been proposed as playing a role in tolerance to abiotic stress by protecting protein and membrane structure, regulating redox status, or acting as a scavenger of ROS [23–26]. Trehalose is present in some desiccation-tolerant higher plants [27] and the quaternary ammonium compound glycine-betaine is accumulated in numerous halophytes from several families [28–30]. Proline is one of the most studied osmolytes in tomato, as its concentration increases significantly after stress exposure, although consensus has not been reached on the relationship between stress tolerance and accumulation of proline [31]. Thus, proline increase in the leaf was deemed to be a symptom of salt injury rather than a trait of salt tolerance, whereas the opposite response was also observed, mainly when the salt tolerance mechanisms were studied at short term [32, 33]. Santa-Cruz *et al.* [34] observed a higher proline accumulation in the salt-tolerant species *Solanum pennellii* after 24 h of salt treatment, which was associated with the compensation of lower pH in the cytoplasm of the stressed cells. Taken together, the changes induced by stress in the osmolyte contents may vary depending on the intensity, duration, and progression rate of stress; proline changes may show adaptive responses of the plants in order to reestablish osmotic homeostasis at the short mid-term, but they may also show a defense strategy of the plant to tackle the harmful effects induced by stress after a long exposure and may be even part of the damage caused by the stress.

43.2.2
Physiological Response to Oxidative Stress Induced by Drought and Salinity

When plants are exposed to drought and salinity and the availability of CO_2 within the leaf is restricted and/or the synthesis of ATP is impaired, the concentration of the final electron acceptor $NADP^+$ is generally very low, which leads to an excess of excitation energy in the photosystems. High-energy states may be dissipated by either nonphotochemical quenching (e.g., xanthophyll cycle) or alternative processes, such as photorespiratory metabolism [35]. If not dissipated, electrons accumulate in the electron transport chain and are transferred to oxygen (Mehler reaction), generating ROS. Because of their high reactive potential, ROS react with, and damage, many cellular components (e.g., proteins, DNA, and lipids), constituting oxidative stress. ROS also inactivate the photochemical reaction center of PSII, causing photoinhibition. It has been proposed that most environmental stresses inactivate PSII by inhibiting the mechanisms of repairing photodamage rather than by directly attacking it [36]. Plants have defensive mechanisms and utilize several biochemical strategies to overcome drought and salt-mediated oxidative stress. Plant enzymatic defenses include antioxidant enzymes such as the phenol peroxidase, ascorbate

peroxidase, glutathione peroxidase, superoxide dismutase, and catalase that, together with other enzymes of the ascorbate-glutathione cycle, promote the scavenging of ROS [37, 38]. The biochemical defense system also includes carotenoids, ascorbate, glutathione, and tocopherols. Several authors have suggested that the function of sugars, poliols, glycine-betaine, and proline could be to protect cells against the hydroxyl radical [39]. A correlation between antioxidant capacity and salinity tolerance has been reported in tomato through comparative studies between cultivated and wild species [25, 40, 41].

In contrast to the negative term used for the increased ROS production, implying a harmful process, recent studies have shown that ROS play a key role in plants as signal transduction molecules involved in mediating responses to abiotic stress, suggesting that ROS signaling is an integral part of the adaptation response of plants to drought and salinity stresses [42, 43]. Thus, H_2O_2 seems to modulate the activities of many components that contribute to cell signaling, including Ca^{2+} and K^+ channels [44]. Although the sources of ROS under stress, mechanisms of ROS detoxification, and the role of ROS in stress signaling are all active areas of research and have been extensively studied and reviewed [43, 45], more studies are necessary before any definitive conclusion can be reached about the role of the ROS production under stress in tomato. Perhaps, ROS levels could be the key factor, producing favorable action (signaling) at low concentrations and oxidative stress at high ROS concentrations.

43.2.3
Plant Response to Ionic and Nutritional Stress Induced by Salinity

Ionic stress due to the accumulation of toxic saline ions, especially Na^+ and Cl^-, induces a nutritional stress due to the altered nutrient uptake, especially of K^+ ions. Thus, salt tolerance of the cultivated species has generally been correlated with an efficient Na^+ and Cl^- exclusion mechanism and with a better maintenance of leaf K^+ concentration. In most studies on salinity, it has not been possible to determine whether the toxic effects observed are due to Na^+ and Cl^- or both. In tomato, it is interesting to point out that similar relationship between fruit yield and leaf ionic concentrations for Na^+ and Cl^- were observed, which suggests that the toxic effects are, at least in the long term, due to the contribution of both ions [21]. Despite a wide body of literature, the mechanisms that govern tomato response to salt stress are not well characterized, and a very small number of genes playing a role in the transport of saline ions have been identified to date [46, 47]. Anion Cl^- transporters are not known in tomato yet, and the most important advances in the transport processes have been achieved for the Na^+ and K^+ transport [48, 49].

According to Plett *et al.* [50], salinity tolerance in plants is derived from the contributions of three components: tolerance to the osmotic stress imposed by salinity, exclusion of Na^+ from the shoot, and tissue tolerance of the Na^+ accumulated either by vacuolar storage or by tolerance to cytoplasmic Na^+. It is likely that all three components operate simultaneously and interact to a greater or lesser extent to provide a plant with its overall salinity tolerance. The osmotic tolerance mech-

anism for salt tolerance, which has not received as much attention as the Na^+ exclusion mechanism, appears to be equally important in providing salt tolerance to tomato plants. It has been reported that the salt-tolerant wild species and some tomato genotypes show growth stimulation on addition of NaCl to a growth medium when NaCl is rapidly accumulated and employed preferentially as an osmoticum, both in the leaves or vegetative organs [10, 21] and in the fruits [20]. Thus, the Na^+ transport to the shoot and its accumulation in leaves may be a more effective strategy than exclusion for improving tolerance of tomato when moderately saline waters are used for irrigation.

However, it is necessary to take into account that mechanisms to tolerate potentially toxic levels of Na^+ in the leaf tissues may be valid up to a certain salinity level, but not when the limit of tolerance to cytoplasmic Na^+ is exceeded. In tolerant genotypes, the Na^+ uptake was not proportional to external salinity, but was curtailed at high salinities or longer time [21, 51]. Moreover, sometimes the major differences in Na^+ accumulation are mainly observed when the concentrations are expressed on a dry weight basis instead of on a cell water basis, such as was observed by comparatively studying the response of cultivated and wild tomato species at the cell and whole-plant level [19]. Taken together, the salinity tolerance mechanisms in tomato and, especially, in wild tolerant species seem to be mainly associated with their increased capacity to uptake water throughout osmotic adjustment, diluting the toxic ions and maintaining shoot growth.

In spite of the advances in the tomato gene identification involved in the Na^+ and K^+ homeostasis in past years, more advances are necessary to understand the role and regulation of some genes involved in the reestablishment of ion homeostasis under salt stress. In this respect, tomato is a very good model for studying long distance transport of saline ions because of its physiological and anatomical structure, as tomatoes have ways of partitioning the salt arriving at the shoot, either retaining it in the leaf base or stem and preventing Na^+ from reaching the photosynthetic tissues or directing salt away from younger leaves toward older ones [10]. Recently, Olías *et al*. [49] showed that the relevant role of *SlSOS1* gene was associated with the partitioning of Na^+ in plant tomato shoot. Another important factor is to maintain a low ratio of Na^+ to K^+ reaching the shoot tissues, although tomato appears to have a poor correlation between salinity tolerance and Na^+/K^+ ratio [12, 52]. However, K^+ ions are one of the essential elements required for growth, as alterations in K^+ can disturb the osmotic balance and the function of stomata and some enzymes, and consequently more advances are necessary in order to fully understand the transport processes of this important nutrient under stress conditions [53].

43.2.4
Long-Distance Signaling Pathways and their Relationship with Drought and Salinity Response

There is evidence for a variety of long-distance signaling pathways, involving hormones and nutrient ions moving in the xylem sap, which regulate the plant growth under abiotic stress [54, 55]. It is well known that drought and salinity induce

stomatal closure and that this process is mediated by abscisic acid (ABA) and possibly by other signals generated in response to abiotic stress [35]. It has been suggested that earlier and higher ABA accumulation at short term is related to increased tolerance to drought stress. In support of results for a growth-promoting role of ABA in tomato, Makela *et al*. [56] showed that shoot growth of an ABA-deficient tomato mutant was affected by salt stress during the first phase (osmotic phase) to a significantly greater extent than its ABA-producing wild type. In a recent study, the higher drought tolerance induced by the overexpression of a tomato dehydrin (*TAS14*) was associated with a rapid increase in ABA in leaves [12], which corroborates the role of ABA in the tolerance. The action of ABA may be involved in the suppression of ethylene production [57–59]. Moreover, ABA-induced accumulation of compatible solutes, as proline, can be crucial for dehydration avoidance [60]. Thus, at the level of the organism, it seems that a main function of ABA is to coordinate the various aspects of abiotic stress response [31, 61].

43.2.5
Tolerance to Drought and Salinity Varies with the Developmental Stage

An important factor to be taken into consideration at the time of evaluating the tolerance to drought and salinity is that the tolerance at one stage of plant development is often not correlated with tolerance at other developmental stages [10]. Thus, efforts have been made to identify QTL for salinity tolerance during seed germination, vegetative growth, and later stages in tomato [46]. The overall results support the suggestion that different genetic and physiological mechanisms contribute to salt tolerance during different stages of plant development. This complicates indirect selection and comparison of results coming from different experiments and researchers. Furthermore, it requires knowledge of the physiological traits contributing to the tolerance at different plant developmental stages.

In comparison to the research conducted during seed germination and the vegetative stage, limited research has been conducted to identify QTL for salt tolerance during reproductive development in tomato [62, 63]. It is interesting to point out that a QTL involved in Na^+ accumulation has been recently identified in RIL lines proceeding from the cross between the cultivated and the wild species *S. cheesmaniae* [52]. For osmotic stress, it would be of agricultural importance to evaluate the tolerance at vegetative and reproductive developmental stages, which are key water-demanding periods of growth. Furthermore, it should be taken into account that the incidence of stress is unpredictable and plants may be exposed to drought stress at any time during their life cycle under field conditions.

In order to answer the questions "what is known so far and what remains to be known," it is essential to recognize the important work done in the past decade, as well as the important advances described here. However, more advances are necessary to understand the mechanisms underlying drought and salinity in tomato. Moreover, to obtain the knowledge required to develop genotypes with enhanced tolerance to field conditions, it is very important to combine the descriptive power of physiological analysis with the new tools of functional genomics that have emerged in

recent years, including the high-throughput methods for transcriptomic, proteomic, and ionomic analysis. Using this integrated analysis would make it possible to elucidate the dynamics of plant metabolism in the context of the plant–environment system as a whole.

43.2.6
Tomato Genes Involved in or Related to Salinity and Drought Tolerance

Although studies in model species such as *Arabidopsis* have led to important advances in the drought and salinity tolerance, the main genes involved in the tolerance process have to be identified in crops or wild species since the role could vary according to the species, as seems to occur with the *SlSOS1* gene [64]. Recently, Nagata *et al.* [65] performed a comparative molecular biological analysis of membrane transport genes in different organisms, ranging from bacteria to animals and plants. They compared the numbers of membrane transporter genes in *Arabidopsis* and rice. According to these authors, although many transporter genes are similar in these plants, *Arabidopsis* has a more diverse array of genes for multiefflux transport and for response to stress signals, while rice has more secondary transporter genes for carbohydrate and nutrient transport. After stress perception, plants must trigger signal transduction cascades, which in turn activate stress-responsive genes and ultimately lead to changes at the physiological and biochemical levels (Figure 43.1). The majority of studies have aimed to decipher the function of genes encoding downstream components (effectors), such as those coding for antiporters, heat shock proteins, superoxide dismutases (SODs), and LEA proteins, rather than upstream components (regulators), such as those coding for transcription factors and kinases.

Since the most important effect induced by salinity for a long term is the toxic effect, most approaches have been directed to studying cation transporters and their regulation, especially the Na^+ transporter genes, such as *SOS1*, *HKT*, and *NHX*. Thus, the tomato genes belonging to the SOS pathway, homologues to *SOS1*, *SOS2*, and *SOS3* genes from *Arabidopsis*, were isolated [49, 64]. SlSOS1, which encodes a putative Na^+/H^+ antiporter from tomato, highly homologous to *AtSOS1*, seems to play a relevant role in maintaining ion homeostasis in tomato, as *SlSOS1*-silenced plants were more sensitive to salt stress than wild type (WT) and showed higher Na^+ accumulation in leaves and roots and K^+ deficiency [49]. These authors concluded that besides its main action in extruding Na^+ out of the root, *SlSOS1* is critical for the partitioning of Na^+ in plant tomato shoot, retaining Na^+ in the stems, and preventing Na^+ from reaching the photosynthetic tissues. Preliminary experiments with transgenic tomato plants constitutively overexpressing *SlSOS2* and *SlSOS3* suggest a relevant role for these genes in tomato salt tolerance [64]. On the other hand, two tomato *HKT*genes, *SlHKT1.1* and *SlHKT1.2*, encoding putative Na^+ or K^+ transporters, have also recently been isolated (Belver, unpublished results). Olías *et al.* [49] proposed that the transport function of the *SOS1* and *HKT* systems in tomato may be coordinated to achieve Na^+ and K^+ homeostasis.

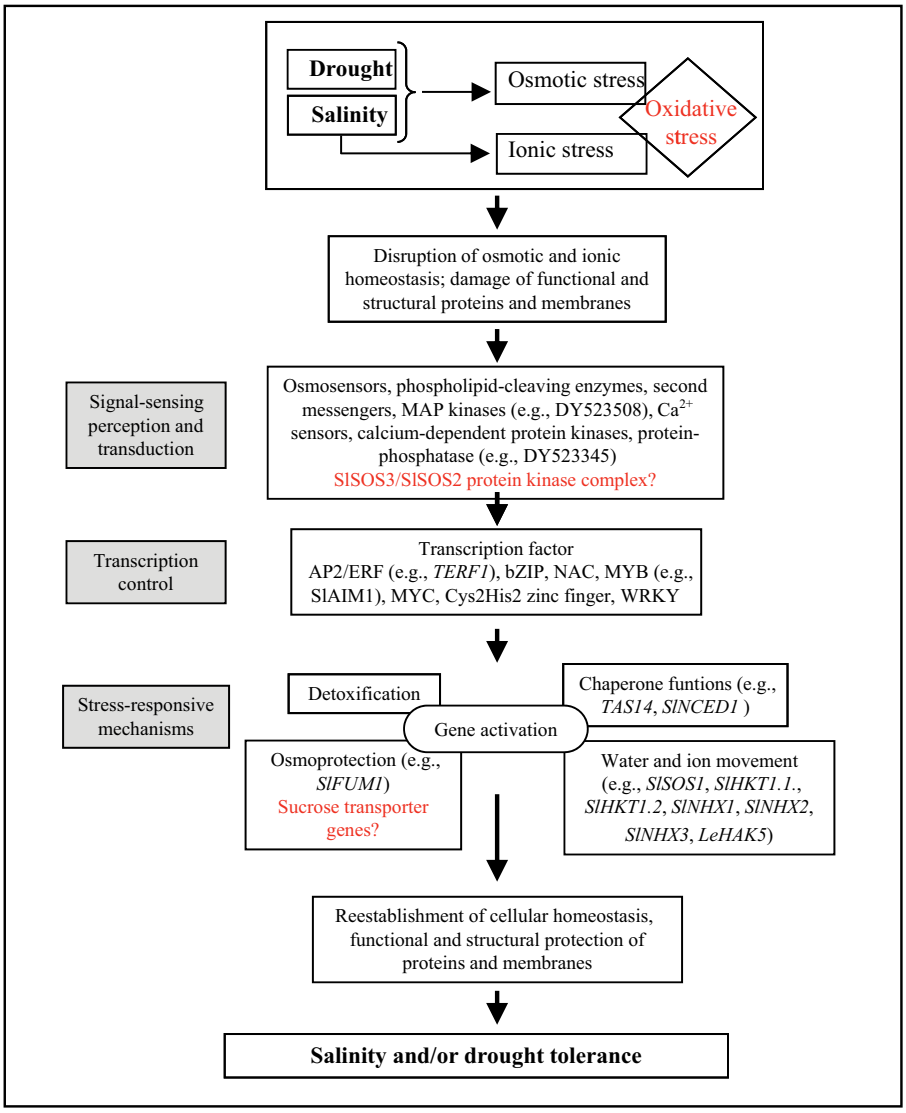

Figure 43.1 Generic pathway under salinity and drought stresses, where the regulator and response genes identified so far in tomato are included along with some genes whose role in tolerance is not yet sufficiently known.

Important work has been carried out by Pardo's Group in order to determine the role of NHX antiporters, which were thought to mediate the compartmentalization of Na^+ into vacuoles [66]. Recently, they showed that transgenic tomato plants over-expressing *AtNHX1* had larger K^+ vacuolar pools under all growth conditions tested, but no steady enhancement of Na^+ accumulation was observed under salt stress [111]. In tomato, the *SlNHX1*, *SlNHX2*, and *SlNHX3* (*LeNHX1*, *LeNHHX2*,

and *LeNHX3*, respectively, in the NCBI database) genes that encode NHX antiporters were also identified, and the function of some of them, such as SlNHX2, was studied [67].

Molecular approaches have allowed the identification of a tomato K^+ transporter, *LeHAK5* [68]. However, the low levels of the *LeHAK5* expression in K^+-starved plants grown with NaCl showed no correlation between root K^+ concentrations and transcript accumulation. The regulation of the expression of this gene was further associated with a more negative electrical potential difference across the plasma membrane of root epidermal and cortical cells, and the depolarized root plasma membrane potential of tomato plants grown with NaCl prevented the induction of *LeHAK5* produced by K^+ deprivation [48]. Therefore, under salt stress, the beneficial effect of a K^+-uptake system with a high discrimination between K^+ and Na^+ seems to be missing, although more studies are necessary in order to elucidate the main genes involved in the K^+ transport mechanisms under drought and salinity [69].

There is even more limited knowledge on the role of regulator genes, for example, protein kinases and transcription factors. In a study focused on identifying salt-responsive genes in the root tissues of tomato seedlings, 24 cDNAs corresponding to early induced transcription factors were isolated [70]. Furthermore, several components of the phosphorylation/dephosphorylation cascades, such as a protein phosphatase 2C (DY523345) and a MAPKKK (DY523508), were identified as being upregulated at the later stages of the salt stress response [70]. More recently, the ABA-induced *SlAIM1* gene, which encodes a R2R3MYB transcription factor, has also been cloned [71]. *SlAIM1* RNAi plants accumulate more Na^+, whereas the overexpression lines accumulate less Na^+ relative to wild-type plants, suggesting that *SlAIM1* regulates ion fluxes. Furthermore, a previously uncharacterized connection was observed between ABA, Na^+ homeostasis, oxidative stress, and pathogen response, suggesting *SlAIM1* has a function in both biotic and abiotic stress responses and in the existence of a crosstalk between these stress responses in tomato [71].

With respect to genes playing a role in water deficit stress tolerance of tomato, the involvement of ASR stress response proteins in physiological adaptation of wild tomato to dry climates is strongly supported by different studies [72]. Some of the most studied proteins that accumulate in response to drought stress in higher plants are the group 2 LEA proteins or dehydrins. In tomato, the expression of *TAS14* gene, which shows sequence similarities to other dehydrins, is upregulated by ABA, salt, and osmotic stress [73]. We have observed that the overexpression of *TAS14* in transgenic tomato plants improves drought and salt tolerance and that the tolerance is associated with a rapid ABA increase in the leaves of transgenic plants after applying the stress (unpublished results). In the wilted mutant, *flacca* (*flc*), induced by X-ray irradiation, it was shown that the genetic lesion impaired the last step of ABA biosynthesis. The mutant has played an invaluable role in elucidating many important features of ABA biosynthesis [74], it being known that ABA is an essential mediator in triggering the plant response to dehydration, cold, and osmotic stress. Recently, Tung *et al.* [75] cloned the tomato *SlNCED1* (*LeNCD1* in the NCBI Database) gene and demonstrated that the overexpression of this gene, which is the WT allele of

the classical ABA-deficient tomato mutant *notabilis*, enhances the water use efficiency in tomato. However, these plants exhibited important developmental alterations and greatly reduced growth, which shows the adverse consequences of a very high ABA accumulation for long term. Tung *et al*. [75] suggested that only more moderate increases in ABA biosynthesis are likely to be useful in the context of agriculture. Furthermore, valuable work has been carried out by Botella's group using mutagenesis (EMS) to identify plant genes required for salt tolerance in tomato [76, 77]. Thus, Rosado *et al*. [78] showed that crosstalk occurs between the ABA and the ethylene signaling pathways in tomato and that the *TSS2* and *TOS1* loci appear to be regulators of this crosstalk. From a spontaneous mutant (*Aco1*) of the wild tolerant species *S. pennellii*, Nunes-Nesi *et al*. [79] cloned its homologue of tomato, *SlFUM1* gene, which has an important role in the stomatal function and consequently in the osmotic tolerance.

Furthermore, several sucrose transporter genes (*LeSUT1*, *LeSUT2*, and *LeSUT4* in the NCBI database) were isolated from tomato and it has been shown that their inhibition affects tomato fruit development [80]. Although the role of sucrose transporters in the abiotic stress response of tomato has not been studied yet, these genes might be involved in the tomato responses to water stress, as plants use mainly sugars to reduce leaf osmotic potential and avoid dehydration under these conditions.

Taking into account the scant number of tomato genes identified to date in relation to salinity and, especially, water deficit stress (Figure 43.1), the identification of new genes playing pivotal roles in the response/tolerance mechanisms to drought and/or salinity is a priority objective.

43.2.7
Increasing Salt Tolerance through a Transgenic Approach: Advances and Limitations

Survey of Previous Results

In numerous papers published from the early 1990s onward, several authors have claimed enhancement of drought and salt tolerance through either overexpression of endogenous genes or, more frequently, heterologous expression of genes that supposedly act on different mechanisms involved in the process [6, 10].

Genes that have proven quite effective in providing stress tolerance using a transgenic approach belong to different categories (Table 43.1). Preliminary research in this field focused mainly on the overproduction of metabolically compatible (organic) solutes [27, 60, 81] in transgenic plants. In this respect, trehalose biosynthesis in transgenic tobacco, *Arabidopsis*, potato, or rice improved drought or salt tolerance [82]. In tomato, the yeast gene for *trehalose-6-phosphate synthase* (*TPS1*), driven by the 35S promoter of CaMV, has been used to enhance stress tolerance [83]. Under drought, salt, and oxidative stress *TPS1* tomato plants improved tolerance with respect to the wild type. However, the plants displayed abnormal phenotypes due to trehalose-6-phosphate accumulation. It has been reported that these problems can be overcome by using a microbial TPS-TPP fusion gene together with a stress-inducible promoter, directing the gene product into chloroplasts [84–87], or using a different type of trehalose biosynthetic gene (trehalose phosphorylase) that bypasses

Table 43.1 Relevant examples of genes conferring salt and drought tolerance in tomato.

Gene/Source	Function	Phenotype observed	References
TPS1/Yeast	Osmoprotection (trehalose-6 phosphate synthase)	Enhanced tolerance to drought and salt	[84]
BADH-1/Sorghum	Osmoprotection (glycine-betaine)	Maintenance of the osmotic potential under salt stress	[88]
BADH/*A. hortensis*	Osmoprotection; glycine-betaine	Improved salt tolerance	[90, 91]
KatE/*E. coli*	Oxidative stress (catalase)	Tolerance increased to the photooxidative stress induced by drought	[97]
APX/Pisum sativum	Oxidative stress (ascorbate peroxidase)	Tolerance increased to the oxidative injury induced by salt stress	[93]
HAL2/Yeast	Cation-sensitive nucleotidase required for sulfate assimilation and RNA processing	Salt tolerance in calli and rooting	[96]
HAL1/Yeast	Ion transport	Increased K^+ accumulation and higher salt tolerance under salt stress	[104, 105]
AtNHX1/*A. thaliana*	Ion transport Compartmentalization of Na^+ in vacuoles Compartmentalization of K^+ in vacuoles	High level of salt tolerance High level of salt tolerance	[109] [111]
AVP1/*A. thaliana*	Ion transport (vacuolar H^+-pyrophosphatase)	Enhanced recovery of plants in drought conditions	[117]
SlNHX2/tomato	Ion transport (tonoplast K^+/H^+ antiporter)	Silencing of *SlNHX2* increased sensitivity to NaCl	[67]
SlSOS1/tomato	Ion transport (plasma membrane Na^+/H^+ antiporter)	Silencing of *SlSOS1* increased sensitivity to NaCl	[49]
CBF1/*A. thaliana*	Transcriptional regulation (CRT/DRE-binding protein)	Enhanced tolerance to chilling, water deficit, and salt stress	[149–151]
CaKR1/pepper	Transcriptional regulation (Ankyrin repeat domain zinc finger)	Enhanced tolerance to salt and oxidative stress	[133]
Osmyb4/rice	Transcriptional regulation (MYB transcription factor)	Enhanced tolerance to drought stress and virus disease	[134]

the trehalose-6-phosphate [89]. On the other hand, glycine-betaine has been shown to protect higher plants against salt/osmotic stresses by playing an osmolyte role and protecting the photosystem II (PSII) complex under salinity [24]. In tomato, it has been reported that transgenic plants with the BADH gene from *Atriplex hortensis* improved salt tolerance [90]. Notably, it has been shown that the accumulation of glycine-betaine in genetically modified plants of tomato is more effective in the chloroplasts than in the cytosol [91], in a similar way to that previously observed in rice [92].

Another strategy to increase the level of salt tolerance has been the transfer of genes codifying different kinds of proteins functionally associated with the protection of macromolecules, such as LEA proteins, osmotin, chaperones, mRNA binding proteins [93–95], or with the protection of metabolism key enzymes [96].

Salinity and drought are well established as inducing oxidative stress. In tomato, the overexpression of the *Escherichia coli* catalase encoded by the *katE* gene increased the tolerance to the photooxidative stresses imposed by drought stress or chilling stress [97]. Interestingly, it has been reported that the coexpression of more than one gene involved in oxidative stress protection in both the chloroplasts and the cytosol gives rise to plants with increased tolerance to different types of abiotic stress [98–100].

Genetic manipulation with genes encoding membrane proteins involved in the uptake and transport of water and ions, such as water channel proteins and ion transporters, has been an alternative approach [101–103]. Thus, overexpression of yeast gene *HAL1*, a regulator of K^+ transport, in tomato resulted in increased K^+ accumulation and higher salt tolerance under salt stress [104, 105]. As ion transport across the tonoplast into vacuoles is energized by a proton moving force [106], the strategy based on the use of antiporters has generated large expectations in recent years. By overexpressing the vacuolar antiporter *AtNHX1*, a high level of salt tolerance was reported in genetically modified plants of *Arabidopsis* [107] and canola [108]. In tomato, Zhang and Blumwald [109] reported similar fruit yields in both 200 mM NaCl-treated transgenic plants overexpressing *AtNHX1* and the control plants grown under normal conditions (5 mM NaCl). However, these results have been questioned [10, 110] as has the action mechanism of *AtNHX1* gene [66]. Thus, Leidi *et al*. [111] have shown that the overexpression of *AtNHX1* in tomato can increase salt tolerance without enhancing Na^+ accumulation into vacuoles; these authors suggest that this tolerance derives from the significant role that the *AtNHX1* antiporter plays in K^+ homeostasis by capturing K^+ in the vacuoles.

New *AtNHX* genes have been cloned and characterized [112–115] and significant efforts have been carried out to identify the orthologous genes in different species, including tomato, and to perform the functional analysis, usually by overexpression and silencing in genetically modified plants. Recently, Rodriguez-Rosales *et al*. [67] studied the function of the tomato K^+/H^+ antiporter *LeNHX2* using 35S-driven gene overexpression of a histagged LeNHX2 protein in *Arabidopsis thaliana* and *LeNHX2* gene silencing in tomato. Transgenic *Arabidopsis* plants overexpressing the histagged tomato antiporter *LeNHX2* exhibited inhibited growth in the absence of K^+ in the growth medium, but were more tolerant to high concentrations of Na^+

than untransformed controls. When grown in the presence of NaCl, transgenic plants contained lower concentrations of intracellular Na^+, but more K^+, compared to untransformed controls. On the other hand, silencing of *LeNHX2* in tomato plants caused both significant inhibition of plant growth and fruit and seed production and an increased sensitivity to NaCl.

It has also been reported that the overexpression of a vacuolar H^+-pyrophosphatase (*AVP1*) from *A. thaliana* in transgenic plants of the same species increases the level of salt tolerance [116]. In tomato, the overexpression of *AVP1* resulted in greater pyrophosphate-driven cation transport into root vacuolar fractions, increased root biomass, and enhanced recovery of plants from an episode of soil water deficit stress. The more robust root systems allowed transgenic tomato plants to take up greater amounts of water during the imposed water deficit stress, resulting in a more favorable plant water status and less injury [117].

Likewise, a higher level of salt tolerance has been described through the overexpression of genes that codify plasma membrane Na^+/H^+ antiports cloned from different sources (e.g., *AtSOS1* from *A. thaliana*, [118]; *SOD2* from *Schizosaccharomyces pombe*, [98, 119]; *nhaA* from *E. coli* [120]; and *OsSOS1* from *Oryza sativa* [121]. Using posttranscriptional gene silencing, Olías *et al.* [49] evaluated the role played by *SlSOS1*, the functional homologue of *AtSOS1*, in salt tolerance of tomato. Transgenic tomato plants with reduced expression of *SlSOS1* exhibited reduced growth rate compared to WT plants under saline conditions.

Other targets in this field have been regulatory genes, such as transcription factors and those codifying signal transduction components or receptor-related proteins [122, 123]. Cloning of genes codifying transcription factors is a promising field, as they lie upstream with respect to many other genes. Recent research has led to the identification of several transcription factor families (e.g., AP2/ERF, bZIP, NAC, MYB, MYC, Cys2His2 zinc finger, and WRKY) that are important in regulating stress plant responses, including not only different kinds of abiotic stresses but also pathogen-induced defense responses, various physiological processes, hormonal signaling pathways, and several developmental processes [123–130]. For example, it has been documented that ERF proteins integrate signals from different plant hormone pathways and play roles in stress responses [131, 132]. Huang *et al.* [133] reported a novel member of ERF proteins from tomato designated tomato ethylene-responsive factor 1 (*TERF1*). Overexpression of *TERF1* in tobacco activated the expression of GCC box-containing pathogen-related genes and also gave rise to the typical ethylene triple response. Further investigation indicated that transgenic *TERF1* tobacco exhibited salt tolerance. In another work, Seong *et al.* [134] reported enhanced resistance to *Phytophthora infestans* and salt and oxidative stress tolerance in tomato plants overexpressing *CaKR1* gene, which encodes an ankyrin repeat domain zinc finger and is involved in transcriptional regulation in response to pathogens and abiotic stresses. Likewise, tomato plants overexpressing the rice *Osmyb4* gene, coding for a MYB transcription factor, acquired a higher tolerance to drought stress and viral disease [135].

In the search for different approaches, it has been suggested that genes codifying calcium sensors [136] or even DNA helicases and RNA helicases [137, 138] could be

involved in the salt tolerance process. The role of siRNAs under stress conditions is also under study [139, 140]. Finally, the knowledge of processes related to DNA/RNA metabolism and G-protein signaling pathways could be useful in elucidating the less known stress signaling networks and thereby be helpful in engineering salinity tolerance in crop plants [23].

Overall, the results obtained in this field show that the expression of different kinds of genes in transgenic plants can increase salinity and/or drought tolerance, at least to some extent (Table 43.1). Unfortunately, it is not possible to conclude for the moment that true tolerant cultivars (i.e., with a sufficient tolerance level from an agronomic point of view) have been obtained via transformation.

43.2.7.1 Aspects Related to the Evaluation of Transgenic Plants

When performing the evaluation of genetically modified plants or the functional analysis of a tolerance-related gene, it would be advisable to take into consideration some questions, such as the procedure for evaluating tolerance to salinity or drought, the plant material used for the evaluation, and the complexity of those traits.

Regarding the procedure for evaluating the tolerance to salinity, if the published results are scrutinized, some of the methods of evaluation of transgenic materials appear to be of doubtful value [110]. Responses to salinity are frequently studied with small samples, in the very short term, by using shock treatments and, moreover, data collected for very specific growth periods, in spite of the fact that salt sensitivity of tomato depends on the growth stage [10, 51]. The usefulness of *in vitro* tests, frequently used for the evaluation of salt tolerance, could also be questioned because transpiring conditions have a major influence on Na^+ transport and tolerance [141]. However, a clear relationship between tolerance to salinity *in vitro* (callus) and *in vivo* (plants grown in greenhouse) has been observed for cultivated and wild tomato species [105, 142]. *In vitro* tests can provide complementary information on the effect of some transgenes (e.g., genes involved in ionic homeostasis) and can be useful for the preselection of transgenic lines (if an *in vitro* and *in vivo* correlation has been previously shown), but they should not be used as the only criterion to determine the degree of salt tolerance.

The plant developmental stage can also be a critical issue for the evaluation of water deficit stress tolerance as seedlings, young (e.g., 2–4 leaves), and older plants will show different levels of relative tolerance. Drought stress can be imposed *in vitro* by raising the osmotic pressure (e.g., mannitol and sorbitol) or using, *in vivo* or *in vitro*, chemical agents (e.g., polyethylene glycol) limiting root water availability. In both cases, it is essential to avoid unnatural treatments leading to artifactual results. Drought tolerance is more frequently evaluated by reducing the level of water or mineral solution, in which case it is necessary to decide the level of water reduction, length treatment, and the nutrient supply during the stress period. Alternatively, the drought stress can be imposed as watering/dehydration cycles, in which case it is necessary to select the number of cycles and length of each cycle. Treatments performed in walking chambers may produce different results in the greenhouse. In any case, the relative humidity in the environment is of crucial importance as it affects stomatal closure and the water status of the plant. Moreover, as stated above, it

should be taken into account that in nature the incidence of stress is unpredictable and plants may be exposed to drought at any time during their life cycle. As a result, the evaluation for drought stress tolerance can be even more difficult than for salinity.

Another important aspect in the evaluation of saline or water deficit stress tolerance is the plant material to be used. The use of TG1 plants (primary transformants) is questionable because epigenetic effects (which are very important in some cases) may lead to erroneous conclusions. The evaluation in TG2 avoids the above problem, but it is necessary to take into account that this is a segregant progeny. In the authors' opinion, the best materials are the homozygous and azygous lines obtained in TG3. Thus, each homozygous line should be compared with two controls: the WT and the corresponding azygous line without the transgene. Positional effects can generate great differences in the expression of a given transgene in independent transgenic lines, indicating the necessity of selecting those with the best expression for the trait [143]. Dose effects of the transgene can be estimated by comparing the behavior of homozygous lines with that of hemizygous lines (i.e., those derived from the sexual crossing between the homozygous and the azygous lines). The relative tolerance of these lines can be estimated in the short and mid-term, although, finally, the long-term response (estimating yield with quantitative data) must also be reported.

Apart from all these considerations, in evaluating the tolerance of transgenic crops, it is important to perform long-term experiments, focus on growth and yield, and provide quantitative data [7, 110].

43.2.7.2 Overexpression versus Spatial and Temporary Modulation of Gene Expression

The choice of promoters can significantly affect the result of a transgenic manipulation [7]. Overexpression has so far been the most widely used strategy for increasing salinity or drought tolerance in transgenic plants. The underlying idea is that by overexpressing a certain gene or by expressing it in a constitutive way it would always have a positive effect on the phenotype. But increasing evidence supports the idea that sometimes strong and constitutive promoters (e.g., CaMV-35S) involve a high energetic cost and yield penalty in transgenic plants [12, 105, 143, 144] and, in other cases, the beneficial effects of the transgene are masked by pleiotropic effects derived from the use of strong promoters [145–147]. Evidence from research in this field supports the advantages of using inducible promoters [85, 130, 148, 149].

Thus, Kasuga *et al.* [147] overexpressed the cDNA encoding *DREB1a* under the control of a 35S promoter in transgenic *Arabidopsis* plants. As a result, transgenic plants exhibited improved tolerance to drought, salinity, and freezing stresses. However, constitutive expression of *DREB1a* resulted in severe growth retardation under normal growing conditions. In contrast, expression of *DREB1a* gene under the control of a stress-inducible promoter *rd29A* led to minimal effects on plant growth under normal growing conditions and provided even greater tolerance to abiotic stress treatments. Similar results have been observed in tomato. Hsieh *et al.* [150, 151] reported that the use of a 35S promoter to drive the expression of *Arabidopsis CBF1* in tomato improved tolerance to cold, drought, and salt loading,

at the expense of growth and yield under normal growth conditions. Lee *et al*. [152] expressed the *Arabidopsis CBF1* driven by three copies of an ABA-responsive complex (ABRC1) from the barley HAV22. Transgenic tomato plants exhibited enhanced tolerance to chilling, water deficit, and salt stresses in comparison to untransformed plants; but under normal growing conditions the ABRC1-CBF1 tomato plants also maintained normal growth and yield similar to the untransformed plants. Likewise, the constitutive expression of genes encoding compatible solutes often causes abnormalities in plants grown under normal conditions, for example, constitutive overproduction of molecules such a trehalose [145], polyamines [146], or mannitol [153]. The use of stress-inducible specific promoters may protect transgenic plants from such growth abnormalities [154].

When the scientific literature is critically reviewed, it is difficult to estimate the proportion of genes whose overexpression in tomato transgenic plants leads to undesirable pleiotropic effects and/or yield penalty, as in most cases data on salinity or drought tolerance of transgenic plants are not accompanied by a thorough phenotypical characterization, and, even less, fruit yield with and without stress conditions. Our results on the functional analysis of several genes putatively related to salinity and drought have revealed that the overexpression of some of them is linked to these kinds of collateral and undesirable effects while others are not. For example, as stated above, the expression of *HAL1* gene driven by 35s promoter enhanced the level of salt tolerance, but this positive effect was counteracted by yield penalty under control conditions [104]. However, the tomato transgenic plants overexpressing the dehydrin *TAS14* gene did not exhibit morphological or significant growth differences compared to wild-type plants when the former were grown under unstressed conditions, which indicates that in this case the yield was not penalized under normal conditions [12].

In any case, the use of inducible or specific promoters will be essential when tackling the cotransference and coexpression of several genes to avoid homology-based gene silencing [10, 144]. It is to be expected that the identification of new *cis*-regulator elements, which allow a proper expression in time and space, will be a major target in the near future [10, 101, 154, 155].

43.2.7.3 **Complexity of the Trait and Sources of Genetic Variation**

Salt and drought tolerance are complex traits [6, 7, 23, 156]. If one takes into account the diversity of mechanisms involved, the question that immediately arises is whether the introduction of a single gene can produce a sufficient level of tolerance or whether it is necessary to introduce several genes involved in different processes (e.g., osmotic adjustment, osmoprotection, ionic homeostasis, oxygen free radical scavenging, stress response, restoration of enzymatic activity, photorespiration, etc.). Of course, a particular gene (e.g., one that codes a transcription factor) can have a cascade effect, thus modifying the expression of many genes. Alternatively, the expression of a gene involved in the compartmentalization of ions in the vacuoles may alleviate toxic effects. Even so, it seems unlikely that a single gene could affect all the processes influenced by salinity. What is most likely is that the transfer and expression, in a coordinated way, of a series of genes, each of which

would affect one of the principal mechanisms of the process, would produce tolerant plants. The problem is that there is still no clear idea of which genes have to be transferred.

In this respect, rather than looking for salinity or drought tolerance-related genes in sensitive species, such as *Arabidopsis*, it would be better to focus on tolerant plants. As far as salinity is concerned, Flowers and Colmer [29] have recently reviewed the mechanisms of salt tolerance in halophytes, plants that are able to survive and reproduce in environments where the salt concentration is around 200 mM NaCl or more. The authors have proposed that research should be concentrated on a number of "model" (halotolerant) species that are representative of the various mechanisms that might be involved in tolerance. Nevertheless, as these halophytes are evolutionarily far from the main crop species, from a breeding point of view it would perhaps be better to take advantage of the existence of halotolerant accessions of wild species related to a given crop. In this respect, in the genus *Solanum* there are accessions of wild species (e.g., *S. pennellii*, *S. cheesmaniae*, and *S. pimpipinellifolium*) with a high level of tolerance to salinity and/or drought [10]. Unfortunately, despite the wealth of sources of variation, it is still not known which are the key genes determining the high tolerance level in those plants.

43.2.8
Genomic Tools for the Genetic Dissection of those Complex Traits

43.2.8.1 Transcriptomics, Proteomics, and other "Omic" Approaches

Some "omic" approaches should provide very useful information with respect to the genes actually involved in salinity and drought tolerance. Gene, metabolite, and protein discovery is being revolutionized through the combination of genome sequencing, microarray analysis, and other "omic" approaches [157]. Thus, transcriptomic analysis provides the expression profiles of hundreds or thousands of genes. At present, this kind of approach is being used to identify those genes that are up- or downregulated in response to saline or other types of abiotic stresses [10]. In this sense, several transcriptomic studies in model species such as *Arabidopsis* and rice have revealed new stress-related pathways in addition to the previously well-described stress-related genes [158]. Valuable information on the involvement of transcription factors in root apex response to salt stress has also been obtained in the model species *Medicago truncatula* [159]. To this purpose, the authors used two complementary transcriptomic approaches. Forty-six salt-regulated TF genes were identified using massive quantitative real-time PCR TF profiling, whereas Mt16K$^+$ microarray analysis revealed 824 genes (including 84 TF) showing significant changes in their expression in salt-treated root apexes.

In tomato, Wei *et al.* [160] observed changes in the accumulation of a number of different RNA from salt-treated and nontreated roots and identified 20 cDNAs that are responsive to salt treatment. The results indicated that the majority of the salt-induced changes in the root mRNA profile occurred in an ABA-independent manner. Using microarray analysis focused on early-response genes after salt stress in the cotyledons and shoot tip of tomato seedling (cv. Money Maker), Zhou *et al.* [161]

found 1757 genes regulated by salt, of which 563 were downregulated and 1194 were upregulated. Using a similar approach, Ouyang *et al.* [70] identified 201 nonredundant genes that were differentially expressed upon 30 min of severe salt stress in two cultivated tomato genotypes with different levels of salt tolerance. Interestingly, a large number of early-response genes regulated by salt stress encoded unknown proteins, indicating that there is still a great deal to discover about the mechanism of the salt tolerance in tomato. At present, we are studying the differences in the regulation of salt tolerance between cultivated tomato and its related wild salt-tolerant species *S. pennellii* using microarray analysis. It is interesting to point out that a higher number of genes with salinity (100 mM NaCl applied for 24 h and 7 days) changed their expression level in cultivated tomato, compared to the wild tolerant species, with a predominance of genes upregulated over genes downregulated. However, in wild species an induction of the expression of putative key genes occurred in response to saline stress, including several families of transcription factors, drought response genes, such as aquaporins and dehydrins, and genes involved in bioenergetics and membrane ion transport, including some ATPase subunits [162].

Transcriptomic analysis can be useful both for identifying new stress-related pathways and genes regulated by stress encoding unknown proteins (and putatively new functions) and for inferring the main mechanisms responsible for different stress tolerance between cultivated and wild species. Nevertheless, these methods usually lead to an overestimation of the number of genes supposedly involved, which makes the identification of relevant genes among an enormous number of other genes with purely secondary or irrelevant functions more difficult. Despite this, it is foreseeable that transcriptomics will become a valuable tool in the near future. However, in order to fulfill the expectations created in this field, it would be sensible to take into account the state of development at which the stress treatment is applied as well as the intensity and exposure time to stress. On the other hand, rather than apply these approaches to model (salt-sensitive) species, it would be better to apply them in both crop species and halotolerant accessions of related wild species and thus, by comparison, try to identify the genes responsible for tolerance [10, 163].

The rapid expansion of new molecular "omics" tools has opened up new perspectives in the identification of the major determinants involved in salt and drought tolerance. Thus, the proteomic analysis of plant under normal and stressed conditions (salt or drought stress) can play an important role in qualitatively and quantitatively studying the changes in protein expression patterns [164, 165]. There have been observed water deficit stress-induced changes in polypeptide accumulation in the leaves and roots of different species including tomato [166]. Likewise, salt stress resulted in the altered synthesis and accumulation of a number of prominent polypeptides in tomato roots [167]. Recently, Chen *et al.* [169] carried out a proteomic analysis to investigate the molecular differences between two tomato phenotypes differing in their salt tolerance to salinity. They identified 23 salt stress response proteins, classified into 6 functional categories, and almost all of these proteins increased their abundance in the salt-tolerant phenotype. These authors

also evaluated the effect of exogenously applied glycine-betaine and found that this compatible solute could alleviate the inhibition of tomato growth induced by salt stress by changing the expression abundance of six proteins in the salt-tolerant phenotype and two proteins in the salt-sensitive phenotype compared to salt-stressed seedlings.

Microarray analysis and proteomics of plant stress tolerance report on the regulation of many genes simultaneously through changes in transcript levels and protein levels, respectively. However, it has been reported that microarray studies provide no information about changes in the corresponding protein expression patterns [165]. Only poor or moderate correlation between changes in the levels of specific mRNAs and their corresponding proteins has been reported in studies involving yeast (*Saccharomyces cerevisiae*) [169] or *Arabidopsis* [170, 171]. A combination of microarray and proteomic analysis can indicate whether gene regulation is controlled at the level of transcription, translation, posttranslational modification, or protein accumulation. Although proteomics in higher plants is still in its infancy compared to prokaryotes, yeast, and humans [165], it is foreseeable that it may serve to shed light on some of the mechanisms of salt and drought stress tolerance.

Furthermore, by comparing the behavior of salt-sensitive and salt-tolerant genotypes (e.g., cultivated species versus accessions of the related tolerant wild species), ionomic approaches [172] can provide new insights both into the key mechanisms responsible for ion homeostasis and into the underlying cause of the different ability to use saline ions in the osmotic adjustment of halotolerant genotypes. Moreover, ionomics can be a valuable tool for thoroughly characterizing new mutants altered in the level of salt tolerance.

Large-scale programs based on the use of these omic approaches should usher in new era in the knowledge of the genetic and physiological basis of the response and mechanisms of tolerance to salinity and drought, thus allowing the design of more effective strategies for breeding cultivated species for abiotic stress tolerance. However, in order to fulfill these expectations it is necessary to focus these genomic tools to identify the main determinants of tolerance, avoiding background noise that can mask what actually is essential. Transcriptomic analysis has so far provided a general picture of genes that are down- or upregulated under abiotic stress situations as well as the number of genes belonging to different functional categories whose expression is significantly changed. Though this is a valuable information, it does not provide the basis to design a breeding program (e.g., via transgenesis), as it is very difficult to tackle the functional analysis of the hundreds (or thousands) of genes whose expression changes under abiotic stress. Thus, in the near future the most important challenge in transcriptomic analysis is to shed light on which are the key or pivotal genes responsible for salinity and drought tolerance. In the same way, the most important objective in proteomic and ionomic studies should be to clarify the main physiological processes determining the tolerance to those kinds of abiotic stress. In other words, research in this field must not be focused on increasing the complexity of traits that themselves are very complex but, on the contrary, on identifying the targets for future breeding programs.

43.2.8.2 Posttranscriptional Gene Silencing (PTGS) Large-Scale Programs

Major advances have been achieved in the study of mechanisms of PTGS and high-throughput systems are available to infer gene function [154, 173, 174]. For example, to help identify the functions of genes in rice, Miki and Shimamoto [175] developed a gateway vector, pANDA, for RNA interference of rice genes. Analysis of rice genes using this vector showed that suppression of mRNA expression was observed in more than 90% of transgenic plants examined. Hilson *et al.* [176] generated a collection of gene-specific tags (GSTs) representing at least 21 500 genes that can be used to create RNAi vectors for functional genomics studies. Preliminary analysis showed effective silencing for three genes coding for vacuolar-type H^+-ATPase subunit B3, a component of cellulose synthase and pentatricopeptide repeats [176]. According to Xiong and Zhu [177], RNAi is very efficient as an alternative to knockout mutants in components of stress signaling pathways. To the best of our knowledge, a similar strategy has not yet been applied to the tomato. However, we foresee that if systematically applied on a large-scale program for tomato and tolerant accessions of related wild species, this approach would be particularly valuable for the identification of genes related to stress response (cultivated species) or genes involved in different mechanisms responsible for salinity and drought tolerance (related wild species).

Moreover, after the identification through microarray analysis of the hundreds of genes that are differentially expressed under stress conditions, the use of a PTGS-based strategy could be particularly valuable in discriminating the key genes from those that have a merely secondary role in the tolerance process.

43.2.8.3 Spontaneous and Induced Mutants

In order to overcome the difficulties in performing the genetic dissection of these complex traits, the use of mutants as genomic tools needs to be one of the main research areas in the coming years. One of the key factors explaining our present knowledge in several areas of plant development lies in the detection and characterization of mutants altered in developmental traits, for example, those affected in tomato fruit development and maturation [178–181].

Mutagenesis in *Arabidopsis* has been employed to identify genes involved in salt tolerance [182] and thanks to the identification of *salt overly sensitive* (*sos*) mutants and the cloning and characterization of the *SOS* genes, an important and novel signaling pathway, called the SOS pathway that mediates ion homeostasis and salt tolerance, has been discovered [183–187]. Salt-tolerant mutants in *Arabidopsis* have likewise been obtained [188, 189].

By comparison, the number of mutants affected in the level of salt tolerance in species other than *Arabidopsis* that are already available to the scientific community is rather few. Occasional spontaneous mutants or, alternatively, those generated by chemical (e.g., EMS) or physical (e.g., X- and δ-rays or fast neutrons) methods could provide the basis for advancing in the knowledge of physiological processes related to salt tolerance. For example, by analyzing tomato salt-hypersensitive (*tss*) mutants, Borsani *et al.* [76] were able to identify two loci, the *TSS1* and *TSS2*. Of these, the *TSS1* locus is essential for potassium nutrition and salt tolerance, while *TSS2* plays an important role in the interactions between salt tolerance and abscisic acid signaling.

However, in the absence of obvious candidate genes, isolation of the gene altered in the mutant through a positional cloning strategy supposes huge effort. Fortunately, we can today overcome these problems by using alternative approaches.

43.2.8.4 Targeting Induced Local Lesions in Genomes Approaches

There is no generally applicable method as yet to generate a plant bearing a mutant allele of a concrete gene. Despite several technical advances, homologous recombination in plants is a technology that is still far from being considered efficient and applicable to all putative predicted genes of a given genome [190]. The completion of the genome sequence project of several cultivated plant species such as rice, cucumber, melon, and more recently tomato (http://solgenomics.net/) opens up a new era where high-throughput reverse genetic approaches are needed to meet the demand of functional genomics as well as new breeding programs.

Targeting induced local lesions in genomes (TILLING), initially developed for *Arabidopsis*, has been used successfully for high-throughput screening of libraries mutagenized with EMS or other chemical mutagens in several plant and animal species [191]. The TILLING method is based on the detection of single-nucleotide polymorphisms (SNPs) induced by the mutagen, which presumably affects the genes of interest. Induced mutations were initially identified by denaturing high-performance liquid chromatography (dHPLC), which detected conformational changes induced in heteroduplex originated by an SNP [192]. Sensitivity of the selection method was optimized later using mismatch-specific endonucleases CEL1 or ENDO1 [193, 194], which cleave at mismatches within heteroduplexes formed between mutant and wild-type DNA strands. Recently, two novel, sensitive, and very high-throughput mutation screening techniques used in human genetic diagnostic – conformation-sensitive capillary electrophoresis (CSCE) and high-resolution melt curve analysis (HRM) – have been successfully described to detect novel mutations in EMS mutagenized libraries of tomato [195]. The results obtained by Christian Bachem's group demonstrated that both new methodological approaches are fast and reliable and permit identification by TILLING of several new alleles in genes responsible for fruit quality such as phytoene synthase, which is involved in the synthesis of the characteristic red color of fruits, and sucrose synthase 2, a gene that participates in sucrose metabolism in young fruits. This group also identified 19 mutations in the coding sequence of the tomato proline dehydrogenase (ProDH) gene, with the aim of inactivating this proline degradation enzyme. Unfortunately, the effect of all these mutations on the sequence of the corresponding enzymes has not been reported; even if some of the mutations may be silent, due to synonymous substitution, others should be senseless or nonsense mutations. It is expected that inactivation of ProDH will increase proline content in all plant cells and the effect, if any, of proline accumulation in tomato resistance to abiotic stress will be determined.

43.2.8.5 Insertional Mutagenesis and Gene Traps

Insertional mutagenesis with T-DNA or transposable elements is a basic tool for the identification of genes and the analysis of their functions. With respect to insertional

mutagenesis with T-DNA, we can approach the tagging of genes by using a simple construction with a marker gene. In this way, the integration of T-DNA within the structural sequence or the controlling elements of a given gene will lead to its disruption and the consequent loss-of-function or, depending on the characteristics of the T-DNA-insert, gain-of-function, or change in its level of expression [196]. Detecting the mutant phenotype in TG1 (in the case of dominant, semidominant, or additive effects) or TG2 (recessive), as the gene is tagged by the T-DNA, means its cloning can be easier.

By comparison with classical insertional mutagenesis, the trapping systems [197] can be particularly useful for the identification of genes related to salt tolerance. The advantage of using enhancer, promoter, or gene traps resides in its self-dual nature. Like any other T-DNA, these traps act as insertion mutagens, and when T-DNA is integrated into an endogenous gene in the appropriate orientation, the reporter gene lies under the control of the regulatory elements of the tagged gene. Thus, by analyzing the reporter gene expression, one can get a precise picture on the space-temporal expression pattern of the endogenous gene tagged by the trap. In this respect, trapping strategies bring great advantages to insertional mutagenesis, allowing identification of functionally redundant genes, those expressed at multiple development states (generating confusion during phenotyping), genes whose disruption causes early lethality, and genes whose disruption causes such a soft phenotype that it may not be detected (in this case, the reporter expression provides a clue to identify the phenotype during evaluation). In addition, gene identification is independent of the expression level of the gene, thus avoiding the risk of rejecting low expressed genes even though they have major effects on the phenotype. Finally, this is the best way to identify genes that are activated or repressed in response to either an external stimulus or biotic and abiotic stress situations [196].

Using an enhancer trap (kindly provided by Dr. Thomas Jack, Department of Biological Sciences, Dartmouth College, USA) and a promoter trap (developed in the laboratory of Drs Rafael Lozano and Trinidad Angosto), a collection of 3500 T-DNA lines of tomato has been generated (unpublished results). Following a preliminary scrutiny of a sample of this collection of T-DNA lines, we have detected several salt-hypersensitive tomato mutants [198]. At first, we focused on the search of mutants altered in Na^+ absorption and transport since the plant needs to recover the ionic homeostasis in order to keep growing in a saline medium for a long term. One of the mutants most sensitive to ionic stress was detected by *in vitro* screening (Figure 43.2). We have also studied the effect of salinity in mutants altered on photosynthesis. Some of these mutants could help to clarify the putative role of chloroplasts in Na^+ scavenging from the cytoplasm [199]. Most of the hypersensitive tomato mutants are recessive, but there are some with dominant heredity. Among them, one mutant exhibits a hypersensitive reaction under salinity (i.e., lower growth, markedly wilted leaves, and few, seedless fruits). The tagged gene codes a MYB-type transcription factor. The involvement of MYB transcription factors in the response to these kinds of stresses has been previously described in model species [123, 159, 200, 201], although up to now there is only one MYB-TF identified in tomato with this possible function [71]. Moreover, we have cloned the tagged gene in another mutant, which

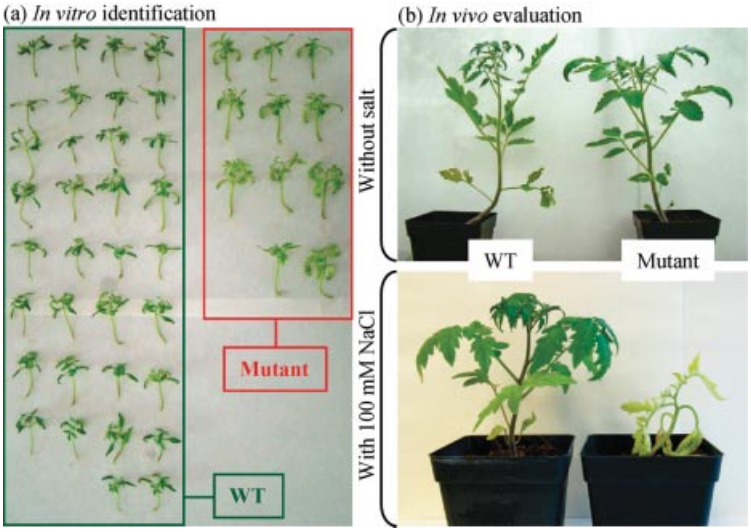

Figure 43.2 (a) A recessive mutant of tomato was identified *in vitro* (on MS medium supplemented with 100 mM of NaCl) as hypersensitive to salt. (b) The salt sensitivity of the tomato mutant was corroborated *in vivo*: Under control conditions, the phenotype and plant growth of the wild-type and tomato mutant were similar, whereas the negative effect induced by salinity was clearly greater in the mutant than in the wild type after 20 days of treatment with 100 mM of NaCl.

shows homology with a MAP-KKK protein of *Arabidopsis* that negatively regulates tolerance to salinity [202].

Apart from the insertional mutagenesis program in tomato, a cultivated species usually considered as moderately tolerant to salinity, our main objective is to identify some of the genes responsible for the high level of drought and salt tolerance in accessions of the related wild species *S. pennellii*. In order to achieve this objective, we developed an efficient transformation method (Pineda, unpublished results), which has allowed us to generate 2800 T-DNA lines of the wild species with enhancer or promoter traps. We have scrutinized T-DNA lines with reporter gene expression in stomata since the control of the stomata aperture contributes to drought tolerance [203]. We have detected a mutant of *S. pennellii* that is altered in root development and that could be interesting since tolerance to water stress is sometimes related to root mass. Moreover, we have already detected four hypersensitive *S. pennellii* mutants to water deficit stress. Interestingly, in one of these mutants the expression of the reporter gene increases after stress in stomata and transporting vessels (Figure 43.3). The scrutiny of this collection is under way to identify new mutants altered in the level of saline and water deficit stress (mainly hypersensitive). Taking into account that the collection of T-DNA lines is going to expand progressively, the identification of new drought and salt tolerance-related genes is expected in the near future.

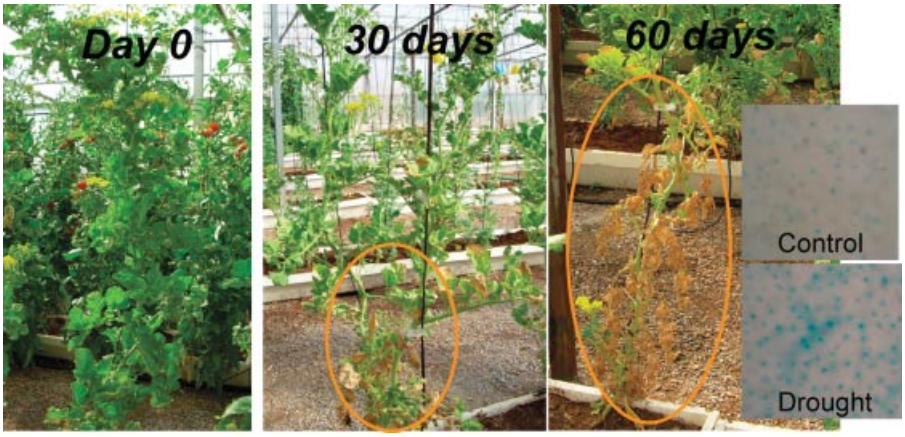

Figure 43.3 A dominant mutant of the wild species *S. pennellii* with positive GUS expression in stomata is sensitive to drought stress. The plants were subjected to several dehydration–rehydration cycles (30 and 60 days of treatment); moreover, the reporter gene (GUS) expression is enhanced in stomata after exposure to drought stress.

The identification of insertion mutants altered in the level of salt or drought tolerance may be particularly useful in the identification of key or pivotal genes involved in different tolerance mechanisms. Likewise, in-depth physiological studies, as well as the use of transcriptomic and proteomic approaches on these mutants, may provide valuable information on the key physiological processes altered in these mutants. We foresee that the combined use of all these genomics tools will allow the genetic and physiological dissection of those complex traits, thus allowing the proper design of future breeding programs.

43.3 Conclusions and Perspectives

In the genus *Solanum*, there are accessions of wild species with a high level of tolerance to salinity and drought. Unfortunately, despite the wealth of sources of variation, there is need to advance our understanding of the mechanisms underlying drought and salinity response in tomato and to elucidate how plants coordinate their responses to overcome drought and salinity. One of the main challenges for the near future is to shed light on which are the differential physiological mechanisms between cultivated and tolerant wild species under stress conditions.

Research in recent years has mainly used genetic transformation as a tool to develop stress-tolerant tomato plants. Although it has been shown that the expression of different kinds of genes in tomato transgenic plants can increase salinity and/or drought tolerance, it is not possible to conclude for the moment that true tolerant cultivars from an *agronomic* point of view have been obtained via genetic transfor-

mation. Moreover, taking into account the scant number of tomato genes identified to date in relation to salinity and, especially, water deficit stress, the identification of new genes playing a significant role in the response mechanisms to drought and/or salinity is a priority objective. To fulfill the expectations created in this field, it would be necessary to advance not only in the identification of new genes playing pivotal roles in tolerance but also in the identification of regulatory elements modulating the expression level of the transgenes spatially and temporally.

Transcriptomic analysis can be useful to identity new stress-related pathways and genes regulated by stress encoding unknown proteins (and putatively new functions) and to infer the main mechanisms responsible for stress tolerance. After the identification through microarray analysis of the hundreds of genes that are differentially expressed under stress conditions, the use of a PTGS-based strategy could be particularly valuable in order to discriminate the key genes for the tolerance processes. It is interesting to point out that a combination of microarray and proteomic analysis can indicate whether gene regulation is controlled at the level of transcription, translation, posttranslational modification, or protein accumulation. Furthermore, by comparing the behavior of salt-sensitive and salt-tolerant genotypes, ionomic approaches can provide new insight into the key mechanisms responsible for ion homeostasis and the underlying causes of the different abilities to use saline ions in the osmotic adjustment of halotolerant genotypes.

The identification of mutants, especially insertion mutants, altered in the level of salt or drought tolerance can be particularly useful in the identification of key or pivotal genes involved in different tolerance mechanisms. Likewise, in-depth physiological studies and the use of transcriptomic and proteomic approaches for these mutants may provide valuable information on the key physiological processes altered in these mutants. We foresee that the combined use of all these genomics tools will allow the genetic and physiological dissection of those complex traits, thus allowing the proper design of future breeding programs. In conclusion, the research opportunities in the coming years are very important, as not only are the -omic tools now available but also will the tomato genome be soon sequenced.

Potato: Improving Crop Productivity and Abiotic Stress Tolerance

Gefu Wang-Pruski and Andrew Schofield

Potato is a prestige food crop that billions of people in the world depend on as an energy source. Its widespread cultivation and adaptation have rendered it attractive for humans of all cultures and geographic locations. However, its effective production is challenged by many unfavorable environmental conditions, such as drought, heat, cold, and salinity. Recent tools developed in genomic research have advanced our understanding of the potato crop in its ability to manage these stresses. This chapter provides the latest information on our understanding of stress tolerance mechanisms in potatoes based on functional genomics, transcriptomics, proteomics, and metabolomics studies. We also recommend many choices of functional genes that can be used for improving stress tolerance in potatoes. We would like to point out that due to lack of the completion of the potato genome sequence, many research projects are not able to provide more advanced systems biology data in comparison to that available for many other agricultural species.

44.1
Introduction

The potato crop (*Solanum tuberosum* L.) is ranked as the fourth food crop in the world after rice, wheat, and maize (FAOSTAT). Its production in 2009 reached 329.6 million ton with China as the top producer with 69 million ton, followed by India with 34 million ton. A detailed, country-wise information on potato production, utilization, and trade can be found in the annually updated databases of the United Nations Food and Agriculture Organization (FAO). The potato is a starchy, tuberous crop from the Solanaceae family known as the nightshades. It originated in the region of the Andes and was introduced to the rest of the world four centuries ago. Today, potatoes have become an integral part of much of the world cuisine due to their rich content of carbohydrates, proteins, vitamin C, iron, and fiber.

Potatoes are grown in about 100 countries, occupying every continent of the world. In some parts of the world, true botanical seeds are used to produce the crop, although most of the North American and European production systems rely on tuber seeds because of their genetic uniformity for traits such as size, color, texture,

Improving Crop Resistance to Abiotic Stress, First Edition.

and biochemical contents. Potatoes are used as fresh, processed, and value-added food products, as well as a source of industrial starch. The variety requirements depend on needs, including tuber shape and size, sugar content, frying color, nutritional value, storability, and disease resistance. The issues facing the industry are high acrylamide content in processed products, obesity related to consumption, and sustainable production systems for disease and pest control.

Nitrogen source is essential for tuber production. Nitrogen available to plants in the soil and nitrogen loss in the system determine how much nitrogen is actually used by the plants. Because excess water can lead to nutrient leaching, water becomes a key factor in determining how nitrogen can be taken up by plants. Estimation of irrigation needs have been established in many countries based on the variety and climate conditions. As precision farming for crop management increased in popularity, effective nitrogen and water applications may be found in potato production systems around the world. Nevertheless, severe weather conditions and climate change will continue to challenge the potato production systems in different parts of the world. Therefore, generation of new cultivars adapted to different stress conditions will become essential for potato production in the coming years.

44.2 Potato Genomic Resources

Besides the cultivated potato (*S. tuberosum* ssp. *tuberosum*), other crops such as tomato, pepper, eggplant, and tobacco are also key members of the Solanaceae family. Their genetic information is important for understanding the genome of potatoes. For instance, tomato (*S. lycopersium*) has a similar genome size to potato and is seen as a genetic and genomic model for the Solanaceae family. Cultivated potato behaves as an autotetraploid and has $2n = 4x = 48$ chromosomes. It is generally understood that potato has a genome size of 850–1000 Mb, which is very similar to that of tomato. However, a large number of wild and hybrid diploid selections are being used for genetic mapping-related studies due to their reduced complexity of genome recombination. Nevertheless, the lack of homozygous lines in potatoes makes gene mapping and breeding a very slow and challenging process.

The potato genome sequencing was projected to be completed within 6 months by the international Potato Genome Sequencing Consortium (PGSC). The completion of the genome sequence will no doubt provide valuable information about the genome arrangement, diversity, functional genes, and gene alleles. Major potato genome databases available are PGSC (www.potatogenome.net), The Institute for Genomic Research (TIGR) Solanaceae Genomics Resource (http://jcvi.org/potato), The Canadian Potato Genome Project (www.cpgp.ca), Solanaceae Coordinated Agricultural Project (http://solcap.msu.edu), and the DFCI *Solanum tuberosum* Gene Index (StGI) (http://compbio.dfci.harvard.edu/tgi/cgi-bin/tgi/gimain.pl?gudb = potato). Many functional genomics studies have already used the sequencing information for trait analysis and marker discovery. Over the past 10 years, the potato research community around the world has also established extensive genomic

resources, including expressed sequence tag (EST) libraries, SAGE libraries, microarrays, molecular function maps, and mutant populations [1–3]. Genomic data from EST libraries, molecular linkage maps, and microarray expression analyses will help identify the genetic components underlying many of the traits, for example, yield, quality, and abiotic and biotic stress managements. In addition, natural genetic resources (wild potato varieties and germplasm collections) can be used in concert with genomic tools such as marker-assisted selection, polymorphism identification, and association mapping to improve breeding lines.

44.3
Abiotic Stresses Related to Potato Production

Potatoes grow the best under long and hot day and cool night conditions. They are very sensitive to light, water, and sources of nitrogen. Any stress condition, such as water, temperature, salinity, or mechanical damage, will significantly impact the yield, tuber quality, and marketing value. Even a short period of acute stress can cause a substantial decrease in total and marketable yield. For the North American market, 50% of the potatoes are processed during storage, so postharvest stress to tubers can further reduce the marketable quality and produce low temperature-induced cold sweetening and after-cooking darkening (ACD), disorders that are induced or exacerbated by storage conditions.

This chapter will focus on five key abiotic stress issues: drought, heat, cold and frost, salinity, and wounding. Since the molecular basis for the stress responses is the key to understanding the stress management mechanisms in potatoes, we have provided information about cellular responses and regulation of each stress, and then provided an overview on the research outcomes in molecular gene functions and omics studies. Owing to the large volume of literature for these topics in potatoes, we did not compile an exhaustive list of references, but rather included those that highlight key findings and employ an "omics" perspective to provide insight to direct future work.

44.3.1
Water and Drought Stress

Water is becoming an increasingly scarce resource on earth. Approximately, 80 countries with 40% of the world population suffer from serious water shortage. The potato produces more food energy per unit water on dry weight basis than the other food crops [4]. Thus, water productivity in potatoes is two to three times higher than that of maize, rice, and wheat [5]. Ironically, although the potato crop uses water relatively efficiently, it is also characterized as more drought sensitive than other agronomic crops. This is, in part, due to a lower root length density compared to the other crops. Therefore, in the low rainfall areas, utilization of irrigation systems is not uncommon if higher yield and quality are desired. Drought tolerance is measured by the relative ability of a variety to produce tubers from a limited amount of water [6]. However, water requirements vary for different stages of plant development (shoot

and stem growth, and tuber formation) and tuber bulking, making the entire process difficult to control and predict. Studies normally look into early drought or late drought conditions. If the drought conditions appear early in the season, the plant's survival strategy is to minimize water losses to transpiration; thus, leaf growth begins to slow down, followed by reducing areal growth and canopy size [7]. If the conditions do not improve, the plants will have a reduced capacity for light interception, resulting in lower yields [8].

In potato production, varieties are often categorized by early or late maturing. This makes the situation even more difficult to manage. Some early-maturing potato varieties escape late-season drought events, whereas late-season drought may significantly impact yield losses in late-maturing varieties [9]. There is a variety difference in drought tolerance in potatoes and the effect of drought timing also depends on genotype. For some varieties, the effect is more profound when drought occurs during tuber initiation [10–12], while in others more critical during tuber bulking period [13, 14].

44.3.1.1 Effect of Drought on Tuber Quality

Drought has significant impact on a variety of tuber qualities and defects. Drought can cause tuber cracking, secondary growth, malformations, hollow heart, and internal brown spot. Drought can adversely increase the contents of glycoalkaloids such as α-solanine and α-chaconine, compounds that are believed to cause cancer and other health problems. Drought can also cause sugar end, a disorder characterized by relatively low starch and high sugar content in the basal end of the tuber. Processing these tubers resulted in French fries with dark and discolored ends. Stressed plants accumulate large amounts of sucrose in the basal tissues of the tuber immediately following stress. This is because water deficit, as well as heat stress, induces changes in the activities of certain key carbohydrate metabolizing enzymes, shifting the tuber from a starch synthesizing function to starch mobilization. Drought-stressed plants are also more susceptible to biotic stresses; for example, drought conditions increase pest disease infestations of cyst nematodes [15, 16] and drought reduces transpiration and stomatal conductance, which increases *Verticillium*-related wilting disease.

44.3.1.2 Drought Sensing Mechanisms

Root dry mass was found to be critical for water stress conditions, as it is significantly correlated with leaf area, photosynthesis, reduction of stomatal conductance, and tuber yield [17]. If drought occurs before tuberization, the plants will lose the ability to produce a higher number of stolons per stem [18], resulting in a lower tuber yield. If it is during tuber bulking stage, it will lower both tuber number and size [19]. It is understood that plant responses to drought, including stomatal reactions, are triggered by root signals, not just leaf water potential. In this case, abscisic acid (ABA) plays an essential role in stress signaling. At least four independent regulatory systems for gene expression changes in response to water stress have been identified, two are ABA dependent and two are ABA independent [20]. When potato roots sense soil water deficits, well before leaf water potential drops, ABA is produced in root tips

and transported through the xylem to the leaves to attenuate growth and close stomata [21]. Such signal transduction pathways include a plethora of secondary messengers such as hormones, phospholipids, and calcium ions [22].

Decreased accumulation of reactive oxygen species (ROS), greater mitochondrial activity, and active chloroplast defenses all contributed to the management of drought stress in a drought-resistant cultivar. In stressed plants, the primary sources of ROS are the Mehler reaction and the antenna pigments in the chloroplasts, the photorespiratory pathway in peroxisomes, the cytochrome reactions in the endoplasmic reticulum and cytoplasm, and oxidative processes in the mitochondria. Under drought conditions, drought-tolerant potato lines upregulated members of all major ROS scavenging enzymes in the chloroplasts: superoxide dismutase (SOD), ascorbate peroxidase (APX), catalase (CAT), glutathione peroxidase, and peroxiredoxin gene families [23–26]. In addition, other genes encoding proteins that contribute to increased ROS scavenging capacity such as glutathione synthetase, glutathione-*S*-transferase, glutathione transporter, two thioredoxins, and four thioredoxin-related chloroplast-targeted genes were induced in a drought-resistant accession [24, 27]. Evidence also showed that several genes in the biosynthesis pathway of antioxidant compounds, such as flavonoids, anthocyanins, and xanthophylls, were strongly induced in tolerant cultivars. In another study, gene transcripts of three key enzymes in the biosynthesis of flavonoid and carotenoids were increased in leaves and roots under mild and moderate drought conditions [28].

Osmotic adjustment is the process by which plant cells maintain turgor during water deficit. The osmotic potential inside the cytoplasm is lowered by the accumulation of osmolytes (also called compatible solutes) such as amino acids and sugars [29]. Proline and trigonelline are two compounds that have received a lot of attention as potential compatible solutes and it has been suggested that proline could act as an antioxidant [30]. The accumulation of these compounds is often observed in response to hyperosmotic stress [31, 32] and in response to a combined treatment of heat and drought stress [33, 34]. In one study, drought caused an increase in proline, trigonelline, and proline analogues in a drought-resistant potato cultivar, whereas the drought-susceptible cultivar had an increase only in proline analogues [35]. In another study, proline increased in both drought-resistant and -susceptible potato cultivars [24]. Nevertheless, the role of proline remains controversial. Proline levels often increase earlier in drought-susceptible varieties than in more tolerant ones, which has led to the conclusion that proline is only an indicator of plant water status but not of tolerance. Others have suggested that because minor proline analogues, such as hydroxyproline, increase during drought stress, they may play a role in increased synthesis or reconstitution of cell wall components [36], and there is some evidence that free proline synthesized in other plant parts is transported to the roots to be used for cell wall synthesis in the apical region [37].

44.3.1.3 **Breeding through Omics Approaches**

Traditional breeding has made limited success in drought tolerance using existing potato germplasm. This is partly because the timing and severity of naturally occurring drought is quite erratic and so plants tend to respond differently from

year to year. As a result, the early stages of breeding programs often aim for high yield in favorable environments, but these gains are not usually maintained in environments commonly affected by severe stress. In addition, direct selection for drought tolerance under water-stressed conditions is hampered by low heritability, polygenic control, and epistasis of many drought tolerance traits [27]. Another obstacle for breeding programs is a reluctance to use unadapted parents, such as a wild potato species. It is also difficult to breed for tropical environments where high temperatures are a factor because many drought tolerance traits might not be effective when the plant experiences a combination of both drought and heat effects.

44.3.1.4 **Pathways Involved in Drought Stress**

Comparing transcriptomic and metabolomic profiles of tolerant and susceptible genotypes has led to the identification of some changes in photosynthesis and carbon and amino acid metabolism that are closely related to drought tolerance [35]. It was also found that drought stress regulates osmotic adjustment, carbohydrate metabolism, membrane modifications, strengthening of cuticle and cell rescue mechanisms, detoxification of oxygen radicals, and protein stabilization [24]. In addition, drought stress increases ethylene biosynthesis that may subsequently increase stress perception since ethylene and ABA attenuate leaf growth under water stress [24, 38]. Drought treatment also induces a number of ABA-responsive genes and leads to an accumulation of gibberellins degrading enzymes.

Stomatal closure under drought conditions prevents CO_2 supply for photosynthesis, leading to a reduction in net photosynthesis. This repression triggers regulation of genes functioning in the light reaction, Calvin cycle, and chlorophyll biosynthesis [35] and is accompanied by an increased expression of genes related to photorespiration and cyclic electron transport in photosystem I [24, 35]. Some drought-resistant genotypes, presumably under tolerable drought conditions, upregulated photosynthesis-related genes, while the same genes are downregulated in drought-susceptible genotypes [39].

Drought stress also represses transcription of genes involved in carbohydrate biosynthesis, glycolysis, and the tricarboxylic acid cycle, while sucrose metabolism is induced. These changes are required because under drought conditions, carbohydrate metabolism is redirected to reserve mobilization, as illustrated by induction of starch degrading enzymes, invertase and sucrose synthase [23, 24]. This was proved by Watkinson's study [40] in which expression profiles of genes associated with carbon metabolism contributed to differences in tuber development in phenotypes of adapted and acclimated, drought-stressed *S. tuberosum* ssp. *andigena*.

Finally, attention needs to be given to genotype differences in stress response strategies. Mane *et al.* [23] analyzed two potato landraces during drought and drought recovery. One landrace, Sullu, maintained vegetative biomass accumulation during drought while the other, Ccompis, experienced reduction in vegetative growth. Interestingly enough, both landraces maintained the same tuber yields as nonstressed controls. In Sullu, the main response that helped maintain vegetative growth

appears to be a capacity to uphold photosynthetic efficiency, minimize stomatal resistance, and activate photosynthetic genes during recovery. Other differences that are perhaps caused by the increased photosynthetic capacity include increased cell wall biosynthesis, maintenance of plastid SOD transcripts, and significant increases in sucrose, trehalose, and proline. By contrast, Ccompis differs in all of these aspects, most importantly in respect to photosynthesis. This study demonstrates that a diversity of effective strategies for dealing with abiotic stresses may exist naturally within the potato germplasm.

44.3.1.5 Genes Involved in Drought Stress Signaling

Many genes have been identified and their functional studies have shown promises with regard to drought tolerance. Transcriptomic studies found upregulation of genes for Ca^{2+} binding and GTP binding factors, kinases, and phosphatases [24]. Genes encoding several protein phosphatases 2C (PP2C), negative regulators of ABA signaling in *Arabidopsis*, are potential candidates for yield maintenance under drought conditions [41, 42]. Drought stress induced nitrite reductase and a chloroplast PII nitrogen-sensing protein, known to activate glutamine synthase [43]. Cysteine biosynthesis and sulfur uptake genes, such as adenosine phosphosulfate reductase, are upregulated at an early stage of drought condition, but reversed to repression under prolonged drought [35].

Transcription factors are actively involved in drought stress response. Both ATHB-7 and RD26 are upregulated by drought and function in one of the ABA-dependent regulatory systems, whereas a dehydration-responsive element DREB is regulated in ABA-independent regulatory systems [39]. Two other factors, ASR1 and ASR2, are strongly upregulated by drought stress [24]. ASR1, when present in the nucleus, regulates the expression of a hexose transporter, while in the cytosol, it functions as a chaperone to stabilize proteins under abiotic stress conditions [44]. Other transcriptional factors found are members of the WRKY, SCARECROW, MYB, CCR-4, TAF-3, and NAM transcription factor families. They are commonly induced by elevated H_2O_2 levels in potato leaves under drought conditions [24].

Polyols are osmotically active solutes that can effectively replace water in establishing hydrogen bonds and thereby protect enzyme activities and membranes experiencing water stress [45]. Drought-stressed cv. Sullu had both increased levels of a polyol (galactinol) and its precursors (galactose and inositol) and increased transcript levels of two genes (glucose-4-epimerase and galactinol synthase) involved in galactinol synthesis [35], whose overexpression in *Arabidopsis thaliana* has been shown to increase drought tolerance [46, 47]. Transgenic potato lines of cv. Desiree that overexpressed a dehydrin 4 (DHN4) isolated from barley, or a stress-inducible, heat-stable LEA group 3-like protein from bromegrass (ROB5), showed significant potential to enhance yield under moisture stress [48]. Interestingly, a wild tuber-bearing species, *Solanum gandarillasii* Cardenas, was found to exhibit reduced osmotic adjustment responses resulting in low transpiration rates [49].

Membranes are the main targets of degenerating processes caused by drought. During drought stress, there is a significant upregulation of nonspecific lipid transfer protein genes [50]. Other drought stress-induced gene products, such as heat shock

proteins (HSPs) and chaperones are used to protect cellular structures by maintaining the hydration of cellular compounds such as proteins and membranes. One orthologue to the *Arabidopsis* HSP At5g12030 was found to enhance drought tolerance [51]. An HSP DnaJ gene family was found to increase drought tolerance in potatoes [24, 25]. Others reported that an ATP-dependent metalloprotease and chaperone are induced in potatoes for drought tolerance [52].

44.3.1.6 Gene Testing in Transgenic Lines

Many labs have employed a transgenic approach to test candidate genes for improved drought tolerance in potatoes. Waterer *et al.* [48] tested the functions of constitutive CaMV 35S promoter or a stress-induced *Arabidopsis* COR78 promoter for the overexpression of four transgenes. The transgenic lines with the COR78 promoter produced higher yield under nonstressed conditions than the 35S promoter [48]. Interestingly enough, most of the transgenic lines demonstrated higher yields under drought stress in field trials. As plants respond to many stresses using similar mechanisms, Tian *et al.* [53] studied the potato zinc finger protein StZFP1 that is induced by salt and exogenous ABA. Findings are worth to explore further for studying stress management in plants. Transgenic potatoes expressing trehalose-6-phosphate synthase (TPS1) had a 30–40% reduction in stomatal densities. This appeared to cause lower CO_2 fixation rates under normal and drought-stressed conditions, enabling TPS1 plants to conserve water [54].

Transgenics overexpressing genes encoding antioxidant enzymes improved the drought tolerance of potatoes. Overexpression of nucleoside dikinase 2, Cu/Zn-SOD, and APX improves drought tolerance [55–57]. Transgenic potato lines of cv. Desiree that overexpressed wheat mitochondrial MnSOD3:1 under the direction of a stress-inducible COR78 promoter showed significant potential to enhance yields under moisture stress [48]. Simultaneous expression of choline oxidase, superoxide dismutase, and APX in the potato chloroplasts provides synergistically enhanced protection against salt and drought stresses at the whole-plant level [58]. Transgenic potatoes overexpressing *Arabidopsis* glutathione reductase gene (AtGR1) exhibited faster recovery from drought and with less visual injury compared to nontransformed controls [59]. Higher percentages of the reduced ascorbate were observed for transgenic potato and poplar trees with overexpressed glutathione reductase [60], which might be attributed to the higher glutathione levels in the transgenic plants [59]. Another study showed that overexpression of both Cu/Zn-SOD and APX genes in sweet potato (*Ipomoea batatas*) leaves can protect them from stress environment and enhance their drought tolerance. Finally, it was found that genes related to the accumulation of ROS could improve drought, salinity, and oxidative stress tolerance [61].

44.4 Heat Stress and Thermotolerance

Temperature during the growing season affects the dynamics of the growth and development of the potato plants, resulting in the significant effects on yield and

quality of potato tubers. For a complete coverage of the issue, read the comprehensive review given by Struik [62]. As Striuk pointed out, it is important to note the parts of the plants that are exposed to certain temperatures and the period of exposure to specific temperature treatments. In this review, estimated optimal temperatures for each stage of the plant cycle are given. Temperatures significantly higher or lower than the optimal levels will cause stress to the plants or can damage the plant or tubers during growth and storage. Heat injury and sunscald are the damages to foliage and tubers caused by high temperature ($>25\,^{\circ}C$) and/or direct sunlight. Most of the leaf injury occurs during intense dry weather and when there is a strong wind (air temperature $>30\,^{\circ}C$). Tubers lying in the collection rows after digging may be injured internally or externally when exposed to direct solar radiation and high temperatures.

Recent attention on global warming should bring some concerns on potato production. Projections indicate that global average temperatures will increase from 1.1 to $6.4\,^{\circ}C$ by the end of this century, depending upon region [63]. Generally, increasing CO_2 concentrations and air temperatures will result in lower growth and yield, reductions in the duration of the plant cycle and increase in potato diseases. Thus, the development of cultivars that are tolerant to high temperatures is critical to the strategy to minimize the global warming effects. Furthermore, the problem is compounded when other stresses, such as drought and salt, are factored in. For example, some wild *Solanum* species effectively deal with drought stress by reducing transpiration rates; however, this also reduces evaporative cooling effects that in turn require leaves to possess a higher thermal tolerance [49]. If heat stress is added to salt stress 40–60 days after emergence, the mechanisms that normally prevent salt accumulation fail and the young expanding leaves can be permanently damaged.

A number of tools including cultural practices and genetics are available to ameliorate heat stress. It appears that potato leaves grown under heat stress exhibit impaired cell expansion, but this can be overcome by increasing root zone calcium levels to promote axillary shoot growth [64]. Literature has suggested a significant amount of variation in tolerance to heat and cold stresses both among *S. tuberosum* cultivars and wild relatives [23, 49, 65–69]. These variations may provide breeding materials to develop thermotolerant varieties.

44.4.1 Effect of Heat on Tuber Quality

Heat stress and water deficit appear to induce changes in carbohydrate metabolism in the tuber, shifting from starch synthesis to starch mobilization [70]. The frequency and severity of internal heat necrosis, a disorder that manifests in the form of brown spots in the tuber flesh, affects fresh market and processing quality. Such defect occurs when the early growing season is subjected to high day and night temperatures and low rainfall [71]. The same weather conditions can also cause sugar end, which results in dark colored French fries. In addition, skin russeting occurs in potato tubers exposed to high soil temperatures, which triggers the production of thick and protective skin layers that become cracked with subsequent tuber expansion [72].

44.4.2
Cellular Response to Heat

Heat as a signal triggers several plant responses, including production of HSPs, molecular chaperones, osmoprotectants, and oxidative response pathways. These molecules protect macromolecular structures and proteins from denaturation during heat stresses. For example, stress-induced tomato ABA stress ripening 1 (SIASR1) protein has chaperone-like activity and can stabilize a number of proteins against denaturation caused by heat and freeze–thaw cycles [44]. The heat-tolerant potato cultivar Norchip, when exposed to high temperatures (40 °C), synthesized small HSPs for a longer time period than other more heat-sensitive cultivars [69]. Oxidative stress also plays a role in heat stress. For example, a sweet potato peroxidase (SWPA4) responds to several abiotic stresses and contains a *cis*-acting heat shock element in its promoter [73]. Tang *et al.* [56, 74] developed several potato lines using an oxidative stress-inducible SWPA2 promoter to express either Cu/Zn SOD and APX in the chloroplasts or *Arabidopsis* nucleoside diphosphate kinase 2 (NDPK2) in the cytosol. In both cases, the presence of the transgene greatly diminished the reduction in photosynthetic activity that was caused by high temperatures (42 °C for 20 h) [56, 74]. In another study, Waterer *et al.* [48] transformed cultivar Desiree to overexpress one of the four genes: mitochondrial MnSOD3:1 from wheat or a cold-inducible transcriptional factor DREB/CBF1 from canola, as well as the two previously mentioned genes encoding dehydrin 4 (DHN4) from barley and LEA group 3-like (ROB5) from bromegrass [48]. All of the transgenes appeared to enhance the heat stress tolerance (44 °C) of whole plants or excised leaves, with lines transformed with SOD3.1 showing the greatest effect. In low-temperature stress trials conducted under controlled environment and in the field, lines overexpressing SOD3:1 showed an enhanced capacity to grow at suboptimal temperatures (10 °C), while lines transformed with SOD3.1 or ROB5 had greater tolerance to freezing temperatures than the parental lines [48]. Therefore, there may well be similar cellular mechanisms in potatoes when dealing with high or low temperature stresses.

44.4.3
Cultivar Development through Omics Approaches

Few studies have been completed at the omics levels. Below are the three individual studies that have provided some key information about the pathways that are regulated by heat, cold, and salt. Readers should by now realize that cells use similar mechanisms to respond to different stresses, that is why often similar genes and pathways are found under different stress stimuli. Rensink *et al.* [75] generated 20 756 ESTs from a cDNA library constructed by pooling mRNA from heat, cold, salt, and drought-stressed potato leaves and roots and termed it the potato abiotic stress (POA) collection. This collection contained 1476 unique sequences, 667 contigs, and 809 singleton ESTs. In their subsequent study [76], researchers used a ~12 000 clone

potato cDNA microarray to measure the expression of seedlings grown under controlled conditions and subjected to cold (4 °C), heat (35 °C), or salt (100 mM NaCl) stress for up to 27 h. They discovered that potato gene products implicated in stress adaptation were similar to those reported in other plant species, such as molecular chaperones, HSPs, late-embryogenesis abundant proteins, and gene products with enzymatic activity, as well as several transcription factors, signal transduction proteins, and hormone signaling-related genes. In a study that focused on skin russeting induced by heat stress, Ginzberg *et al.* [72] looked into the transcriptomic profile of the periderm of tubers. Results revealed the upregulation of genes encoding heat shock proteins and regulation of transcription factors and genes related to cell proliferation and differentiation.

44.5 Cold and Frost Stresses

Potato plants can be injured by low temperature and frost in the field during the growing season. Low-temperature injury occurs when the leaf temperature drops below 0 °C, but tissues are not yet frozen. Frost damage occurs when the leaf tissues become frozen. At the end of the growing season, tubers in the ground can be injured by cold and frost. They become very sensitive to mechanical damages due to lifting, transport, and storage. Potato tubers can be damaged when the temperature is below 3 °C. The severity of the damage depends on variety, temperature, and the exposure duration. When the storage temperature is between freezing and 9 °C, tuber starch is converted into sugar, resulting in cold sweetening. Cold sweetening is a major processing defect, causing brown color after frying for French fries and chips. When the temperature is below 3 °C, tubers can be damaged internally and externally. The damaged tissues will rot by bacterial pathogens soon after.

Cold conditions that could cause damage to potatoes are temperatures below which cells can handle for normal physiological activities. For clarity in this section, we will use the terms cold tolerance and cold acclimation to refer to low temperatures above freezing, and we will use freezing tolerance to refer to temperatures below 0 °C. While cultivated potato (*S. tuberosum*) does not have the ability to cold acclimate, some wild *Solanum* species can be acclimated to cold by exposure to low temperature (~4 °C) for a period of time [77]. The degree of cold acclimation can be assessed by several methods including visual inspection or by measuring changes in electrical conductivity of the leaves and estimated by the LT50 corresponding to the temperature inducing 50% of injured cells [77]. There is a quite overlap among different stress responses. For example, microarray analysis indicates that leaves respond to cold and salt stresses very similarly at 9 and 27 h [76].

In response to low-temperature stress, plant membrane lipids have a tendency to change from gel to liquid-crystalline phase due to the increased level of lipid desaturation. Thus, fatty acid desaturases have been the focus of improving cold tolerance in plants [78]. It has been found that an increase in 18 : 2 (linoleate) in the

purified plasma membrane fraction during cold acclimation is associated with genetic variations in cold acclimation capacity [79]. This increase was found only in genotypes that are able to cold acclimate and was reversible on deacclimation, suggesting a link between the accumulation of 18 : 2 and the acquisition of freezing tolerance [80]. An accumulation of Δ9 desaturase gene transcripts during cold acclimation is confirmed to be associated with the cold acclimation response in potatoes [80]. Also, cold tolerance (long-term growing at 8 °C), as well as freezing tolerance (−7 °C for 30 min), was enhanced in transgenic lines expressing an acyl-lipid Δ12-desaturase gene from *Synechocystis* spp. PCC6803 because of an increased unsaturated fatty acid concentration in their lipids, with increased content of 18 : 2 and 18 : 3 fatty acids [81, 82].

Lipid profile is, therefore, an effective measure of the cellular responses to cold stress. One study compared the lipid profiles between a freezing-tolerant, cold-acclimating wild potato species (*S. commersonii*) and a freezing-sensitive, nonacclimating cultivated species (*S. tuberosum*). Following cold acclimation, both species had a decrease in palmitic acid, an increase in unsaturated to saturated fatty acid ratio, an increase in free sterols, an increase in sitosterol, and a slight decrease in cerebrosides. Lipid changes detected only in the acclimating species included an increase in phosphatidylethanolamine, a decrease in sterol to phospholipid ratio, an increase in linoleic acid, a decrease in linolenic acid, and an increase in acylated steryl glycoside to steryl glycoside ratio [83]. This study highlighted the importance of membrane lipid profiles in regulating frost and cold tolerance in plants. Another study [84] has shown that during low-temperature treatment, *Solanum* species that are able to acclimate to cold induced a noticeable increase in SsLTP1 (a lipid transfer protein), while species that display a low capacity for cold acclimation had no change in SsLTP1 levels.

44.5.1 Cellular Response to Cold

In response to cold stress, cells accumulate osmoprotectants, small molecules that balance the osmotic difference between the cell surroundings and the cytosol. Upon cold exposure, carbohydrates accumulated in cultivars that are cold tolerant [77]. It is worth to point out that even under nonstressed conditions, most carbohydrates (sucrose, galactose, galactinol, raffinose, and glucose) were present at higher levels in the constitutively tolerant cultivar *S. phureja*. In this plant, trehalose levels reached concentrations equal to those of other carbohydrates, giving evidence that the sugar acts as an osmoprotectant rather than merely playing a regulatory function as has been suggested in other situations [85]. Expression of carbohydrate-related genes during cold exposure matches these metabolite profiles in cultivar Desiree, showing the upregulation of sucrose synthase and galactinol synthase, leading to galactinol and eventually raffinose accumulation [77]. Free polyamine accumulation has been demonstrated to be involved in abiotic stress tolerance in other species [86, 87]. This was also detected in potatoes where free polyamine metabolism was affected by cold as shown through an upregulation of

arginine decarboxylase, *S*-adenosylmethionine decarboxylase, and spermidine synthase genes [77, 88]. Potato plants transformed with an apoplastic-localized yeast invertase had a greater invertase activity, higher content of sugar, and produced significantly less lipid peroxidation activity when exposed to low temperature (3 °C) and freezing temperatures (−1 or −9 °C) [89, 90]. The authors suggested that the improved cold tolerance was attributed to the stabilizing effect of sugar on the membranes.

Cell signaling is one of the most important cellular responses to cold treatment. Potatoes possess at least three calcium/calmodulin signaling proteins that display differential expression in response to cold stress in leaves after cold acclimation, and when combined with osmotic stresses [91]. Plant hormones, such as ABA pretreatment confers freezing tolerance to microplants transferred to soil, with no significant negative long-term effects on tuber production. Responses to ABA were found to be associated with increased antioxidant enzymatic activities of peroxidase and APX and decreased H_2O_2 content in the induction of freezing tolerance in the potato [92]. Antistress effects of salicylates can also be used in a planned manner to improve *in vitro* culture technology and hardening in potatoes for induction of tolerance to freezing in microplants after transplanting them to soil [93]. It appears that at least two mechanisms are involved in the induction of freezing tolerance in potato by salicylic acid (SA). One mechanism, exemplified in the cold-sensitive cultivar Atlantic, appears to involve induction of hydrogen peroxide (H_2O_2) accumulation leading to enhanced CAT activities, while another mechanism exemplified in the more cold-tolerant cultivar Alpha does not appear to involve H_2O_2 accumulation or enhanced CAT activities [94].

ROS generated during cold stress are involved in inducing the oxidative stress during chilling and in triggering cold-induced damage [95]. ROS can either act as signals that induce protection mechanisms or accelerate injury [96]. Freezing tolerance is attributed to the protective effect of sugars caused by their ability to scavenge ROS nonspecifically under stress conditions [97, 98].

44.5.2
Gene Functions and Omics

Protective proteins are produced under cold stress conditions. Pruvot *et al.* [99] identified CDSP34 protein that accumulates in the chloroplast in response to low temperatures. This protein plays a role in the structural mechanisms involved in the thylakoid tolerance to stress. A chaperonin protein Cpn60β involved in sustaining proper protein folding under stress was found to be constitutively expressed at a higher level in cold-tolerant potato species *S. commersonii*, but not in cold-susceptible *S. tuberosum* [100]. Dehydrins are believed to act as emulsifiers or chaperones in the cells by protecting proteins and membranes against unfavorable structural changes caused by dehydration. One of the dehydrin proteins, dhn2, was found to express at a higher level in cold-tolerant potato species [100]. Furthermore, the cold acclimation that improved the freezing tolerance in *S. commersonii* was associated with the accumulation of the transcripts of Scdhn2 [96]. A similar response to cold acclimation

was also observed for DHN24 (a SK3-type dehydrin protein) [101] and TAS14 [88]. As mentioned previously, overexpression of DHN4 in potatoes did not provide any benefit with respect to cold tolerance, although in the same trials, overexpression of mitochondrial MnSOD3:1 did confer tolerance [48].

In low-temperature stress trials conducted under controlled environment and in the field, lines overexpressing a heat-stable, LEA group 3-like protein from bromegrass (ROB5) had greater tolerance to freezing temperatures than the parental line [48]. Another class of proteins commonly studied in relation to cold and freezing tolerance are antifreeze proteins (AFPs) that inhibit ice growth and recrystallization. Expression of a synthetic AFP (similar to type 1 AFP of winter flounder) in cultivar Russet Burbank conferred freezing tolerance as assessed by electrolyte release analysis of the transgenic plant [102].

Many transcription factors regulate gene expression under cold conditions. Transgenics overexpressing several transcription factors (ERF, EREBP, DREB, and CBF) have improved freezing tolerance in potato plants. Ethylene-responsive factors (ERFs) are plant-specific transcription factors, many of which have been linked to plant defense responses. Overexpression of CaPF1, an ERF/AP2-type pepper transcription factor gene, effectively increased tolerance to freezing in potatoes [103]. In addition, StEREBP1 (ethylene-responsive element binding protein 1) is a transcription factor that responds to several environmental stresses. Overexpression of StEREBP1 enhanced tolerance to cold stress (growth at 8–10 °C for 2 months) in transgenic potato plants [104]. Overexpression of *Arabidopsis* rd29A::DREB1A also enhances freezing tolerance in transgenic potatoes [105]. Even in the absence of cold treatment, ectopic AtCBF overexpression improved the freezing tolerance of transgenic *Solanum* species [106]. In the meantime, overexpression of ectopic AtCBF1 affected many alterations associated with cold acclimation such as thickening of leaves and increase in proline and total sugar contents. The leaves of these transgenic *S. commersonii* were darker green, had higher chlorophyll and lower anthocyanin levels, had greater stomatal numbers, and displayed greater photosynthetic capacity, suggesting their higher productivity potential [107].

It is worth mentioning several other genes. For instance, potato 1-aminocyclopropane-1-carboxylate oxidase genes, ACO1 and ACO2, can be induced by cold stress (0 °C), but are differentially expressed by other stresses such as heat, wounding, and soil flooding [108]. Renaut [109] presented a series of studies on the cold response in two genotypes of *S. tuberosum*, PS3 and Desiree. Oufir *et al.* [77] focused on carbohydrates and polyamines because they are known cryoprotectants associated with cold acclimation. They used transcriptomics and metabolomics approaches to demonstrate how three genotypes of potato responded to chilling exposure: a tetraploid *S. tuberosum* (cultivar Desiree) was not able to acclimate to cold, a dihaploid *S. tuberosum* (PS3) acclimated to cold, and *S. phureja* (CHS) was more tolerant to cold on a constitutive level. Although free polyamine accumulation was not pronounced upon cold exposure, an array of genes involved in several other metabolisms, for example, amino acid, carbohydrate, energy, detoxification, and photosynthesis, were differentially expressed in these potatoes under cold exposure.

44.5.3
Cold-Induced Sweetening during Storage

Refrigeration is the most important and effective technology employed to maintain the postharvest quality of potatoes. Storage at cold temperatures prevents sprouting, minimizes disease losses, reduces shrinkage, and improves the retention of dry matter and extends the marketability, thus supplying consumers and the processing industry with high-quality tubers throughout the year. Unfortunately, when tubers are stored at temperatures between 2 and 4 °C, they undergo a phenomenon known as cold sweetening or low-temperature sweetening (LTS). At these temperatures, the rate of conversion of starch to reducing sugars (i.e., glucose and fructose) is accelerated. These potatoes are unacceptable for processing into chips or French fries because when cooked in oil at high temperatures, the accumulated reducing sugars react with free amino acids in the potato cells, forming a brown to black pigmented and bitter-tasting product via a nonenzymatic, Maillard-type reaction [110, 111]. Such products also have elevated amounts of acrylamide, a neurotoxin and potential carcinogen [111]. Therefore, LTS is a major concern since all commercial potato cultivars used for the production of potato chips and fries accumulate excess free reducing sugars when exposed to cold stress.

The mechanism of LTS is somewhat understood. Low-temperature storage of potato tubers induces amylolytic enzymes that initiate the breakdown of starch stored in the amyloplasts. The breakdown products, both hexose phosphates (hexose-P) and free sugars, are exported from the amyloplast to the cytosol where they are converted to sucrose [112]. Sucrose-phosphate synthase produces sucrose 6-phosphate (Suc6P) and UDP from UDP-glucose and D-fructose 6-phosphate. Then, Suc6P is hydrolyzed by sucrose phosphatase (SPP) to yield sucrose and inorganic phosphate (Pi) [113]. This sucrose can then be hydrolyzed into its constituent hexoses by soluble acid invertase [114].

A genomic investigation by the Canadian Potato Genome Project initiative (www.cpgp.ca) [115] sheds some light on LTS. In this study, mature, harvested tubers of cultivar Shepody were stored at 4 °C for 3 months. Normalized library was constructed and ESTs were sequenced. Among the 5000 ESTs identified, only 7 transmembrane proteins Mlo8 and putative protein transport protein SEC13 were highly regarded, while others were marked unknown. With the complete genome sequencing data like to soon become available, these genes could be revisited for their functions related to LTS.

At present, sucrose phosphatase and the vacuolar acid invertase (VInv) are targeted in order to control LTS. Chen *et al.* [116] suppressed sucrose synthesis by RNAi-mediated silencing of SPP expression, leading to an accumulation of Suc6P. Overall, SPP-silenced tubers exhibited only minor differences in total soluble carbohydrate accumulation. However, the sucrose to hexose conversion was greatly reduced because of an unexpected blocking of cold-induced expression of VInv. Bhaskar *et al.* [111] used a targeted RNAi approach to demonstrate that the potato VInv is responsible for reducing sugar accumulation in cold-stored tubers. Even when tubers

were stored at 4 °C, potato chips processed from VInv-silencing lines were light in color and showed a 15-fold reduction in acrylamide [111]. In a more traditional breeding approach, Hamernik *et al.* [117] achieved a similar goal by introgressing wild species germplasm with extreme resistance to cold sweetening at very low storage temperatures (2 °C) into the cultivated potato. Selected accessions were crossed as males to haploids of *S. tuberosum* to produce adapted hybrids, which produced good tuber type and low levels of reducing sugars under extremely low storage temperatures [117]. Interestingly, comparable low levels of VInv gene expression were observed in cold-stored tubers of VInv silencing lines and wild potato germplasm stocks that are resistant to cold-induced sweetening. These results demonstrate that both processing quality and acrylamide problems in potato can be controlled effectively by suppression of the VInv gene through biotechnology or targeted breeding.

Several other attempts had been made to control LTS, by manipulating VInv activity through the ectopic expression of an invertase inhibitor [118–120], through antisense inhibition [114], or through RNAi suppression [121, 122]. The success of these efforts was limited because invertase activity was only partially reduced. It seems a nearly complete silencing of the VInv gene is required to effectively control LTS [111].

44.6 Salt Tolerance

Soil salinity is defined as excess sodium chloride (NaCl) in soil. Plants encounter salt stress when grown in naturally occurring saline soils or when irrigated with saline water. According to the review by Donnelly *et al.* [123], most of the areas in the world under potato cultivation are in countries that are not overly affected by salinity. The exceptions, as pointed out by the authors, are countries in Southern and Southeastern Asia. Since China and India have become the top two potato producers in the world (producing over 30% of the world potatoes), the salinity problem could become a major issue for these two countries. In order to maintain production levels in these countries, potato cultivars with improved stress tolerance to heat, drought, and salinity are the top priority.

Irrigation has become an important agricultural practice, which is employed to produce up to 30% of the world's food using 15% of the cultivated land area. Salt injury occurs when high-concentration salt water comes in contact with above- or underground plant parts. This contact will lead to withdrawal of water from the plant tissues due to osmotic pressure. The injured tissue cannot resume normal functions and lead to necrosis.

Mechanisms of salinity tolerance in plants are related to a combination of plant stresses, including drought stress, ion toxicity, mineral deficiency, and oxidative stress. Because salinity affects major biochemical processes of the cell, such as protein synthesis, energy generation, photosynthesis, and lipid metabolism, plants use diversified mechanisms to counter these effects. These include limiting the

uptake and transport of selected ions, compartmentalization in cells and organs, altered cellular and organelle membrane structures, producing antioxidant compounds and enzymes, and using alternative biosynthetic pathways. Early studies showed that proline, a compatible solute as mentioned earlier, is accumulated in the saline-stressed potatoes. Potatoes were considered as moderately salt-sensitive in early studies. However, significant variations in salt tolerance among *S. tuberosum* cultivars are expected, but they have not been explored systematically. Some field, greenhouse, and *in vitro* evaluations have been completed as summarized in Donnelly *et al.* [123]. As already mentioned, plants' response to salt is also related to the responses to other stresses, as demonstrated by microarray analysis of leaf responses to cold and salt stresses [76].

44.6.1 Mechanisms of Salt Response

Major changes in potato leaves in response to salt exposure were found to be the repression of photosystems I and II and chlorophyll synthesis, according to microarray analyses [124]. This was mirrored by protein data in which the most drastically downregulated proteins were involved in photosynthesis and protein synthesis [125]. In addition, changes in gene expression of carbohydrate and amino acid metabolism suggested that salt stress caused modifications at the metabolic level.

Studies have identified cell signaling proteins from potatoes that are induced by salt stress, including a novel leucine-rich repeat receptor-like kinase, StLRPK1 [126], and calcium/calmodulin signaling components ScCaM1 and ScCaM5 [91]. Catecholamines are synthesized in response to both ABA and salt stress, and are proposed to be stress agent compounds that play an important role in the regulation of starch–sucrose conversion in plants and may be implicated in several other functions including wounding and pathogen responses [127]. Expression of StPUB17, an UND/PUB/ARM repeat E3 ubiquitin ligase, is upregulated by many abiotic stresses including salt, and StPUB17-silenced plants were more susceptible to both salt stress and *Phytophthora infestans* [128]. Nitric oxide appears to interact with salt stress signaling according to studies on *Arabidopsis*. *Arabidopsis* mutants of the AtnOA1 gene involved in nitric oxide synthesis are more sensitive to salt stress, but transgenic expression of StNOA1 from *S. tuberosum* was able to return salt sensitivity to wild-type level [129–132].

In response to salinity, cells accumulate osmoprotectants, small molecules that balance the osmotic difference between the cell's surroundings and the cytosol. Proline is a small molecule that accumulates upon salt exposure and is believed to protect cells via a mechanism similar to that proposed for drought tolerance. *N*-succynilarginine is induced under salt stress and it is involved in arginine metabolism that leads to the production of ornithine and proline [125]. Overexpression of Δ1-pyrroline-5-carboxylate synthetase increases proline production and confers salt tolerance in transgenic potato plants [133]. Lycine-betaine (GB) is a common compatible solute that accumulates in many higher plant species in response to salinity, drought, and low temperature [134], but potato is betaine deficient. It has been demonstrated in a variety of studies that GB exerts protective

effects and stabilizes macromolecules, enzyme activities, and membranes under stressful conditions [135, 136]. Transgenic plants with enhanced salt tolerance were engineered with the ability to synthesize GB in chloroplasts via the introduction of the bacterial choline oxidase (codA) gene under the control of an oxidative stress-inducible SWPA2 promoter [137]. Ning *et al.* [138] also created transgenic potato plants expressing a gene for GB synthesis that had improved tolerances to drought and salinity. Pruvot *et al.* [99] identified two proteins that accumulate in response to salt: CDSP 32 is suggested to be involved in osmoregulation in the stroma and CDSP 34 is postulated to play a role in the structural mechanisms involved in the tolerance of thylakoids to dehydration stress [99].

A cDNA microarray analysis of leaves reveals that salt stress activated several HSPs, late-embryogenesis abundant proteins, and dehydrins [124]. The accumulation of HSPs can act as chaperone to facilitate the correct folding of proteins and protect them from denaturing under stress conditions. The leaves of potatoes exposed to salt stress induced the gene expression of several HSPs [124] and salt-tolerant cultivars have a propensity to accumulate more HSPs under salt stress [125]. Cpn60b is another example of a molecular chaperone from *Solanum* that is induced by salt stress [100]. These authors first identified this gene along with several others in a functional screen for salt tolerance using a heterologous expression method in *E. coli*. Another of these candidate salt stress-related genes was dhn2, a dehydrin that shares homology with the D11 group of LEA dehydrins and is synthesized during seed desiccation and in response to salt stress.

Several hormones have been implicated in responses to salt stress. For example, calreticulin is a Ca^{2+} storage protein that appears to be involved in ABA-induced salt tolerance. Its gene expression and protein levels are induced by salt stress [139]. Furthermore, grafting experiments demonstrate that both salt stress tolerance and calreticulin expression are regulated by the roots [139]. Experiments with acetylsalicylic acid suggest that pretreatment induces preadaptive responses to salt and water stresses leading to the protection of the photosynthetic pigments and the maintenance of membrane integrity, which is ultimately reflected in improved plant growth [140].

Salt transporters/vacuolar Na^+/H^+ antiporters have been studied for salt response. Plant cells adapting to salt stress improve cellular ion homeostasis by accumulating organic solutes in the cytosol, by compartmentalizing ions in the vacuole, and by excluding extra Na^+ ions from the cells. To this end, transgenic potato plants constitutively overexpressing an *Arabidopsis* tonoplast Na^+/H^+ antiporter (AtNHX1 gene) were constructed but not analyzed for salt tolerance [141]. Another group by Bayat *et al.* [142] transformed two cultivars of potatoes (*S. tuberosum*) with a barley antiporter gene (HvNHX2) driven by the CaMV 35S promoter. Transgene expression conferred a higher NaCl tolerance to one of the cultivars.

44.6.2
Genes Related to Salt Tolerance

Altering potato metabolism through transgenic approaches has also altered salt tolerance. Besides the genes indicated above, several others have been studied.

Transgenic plants with reduced StubGAL83 expression had increased sensitivity to salt stress, as well as impaired root and tuber development [143]. This potato gene was suspected to be an important regulator of salt stress because it encodes a subunit of a protein kinase complex that is similar to the yeast SNF1 and mammalian AMPK complexes that are modulated by changes in the cellular AMP/ATP ratio and are important regulators of metabolic and stress responses. Conversely, continuous expression of a glyceraldehyde-3-phosphate dehydrogenase in transgenic potato plants resulted in improved tolerance against salt loading [144]. The importance of nitrogen status in metabolism has been highlighted in salt-stressed potato plants that had increased glutamine synthetase activity in the roots and decreased activity in the leaves [145].

Salt stress response is also related to biotic stress factors. Microarray analysis of leaves reveals that salt stress induced the expression of several pathogenesis-related proteins, as well as several transcription factors related to plant defense pathways, demonstrating a crosstalk between abiotic and biotic stress responses during salt exposure [124]. In another study, 6 of 20 proteins upregulated by salt stress were known to play a role in plant defense (i.e., osmotin-like protein, HSPs, calreticulin, and protease inhibitors) highlighting the close link between these processes [125]. For example, osmotin is a member of the pathogenesis-related family of proteins 5 (PR-5), which is induced by biotic stresses and implicated in defense against fungi [146, 147]. However, osmotin protein levels in salt-tolerant cultivars are also upregulated in response to salt. Furthermore, overexpression of osmotin has been proposed to confer salt tolerance to transgenic potato plants [148]. PR-10a is another pathogenesis-related protein with increased protein expression in potato cell cultures under salt stress. Potato cell cultures that overexpressed a PR-10a transgene were conferred increased salt and osmotic tolerance [149].

Transcription factors are involved in osmotic stress response via ABA-dependent or ABA-independent pathways. Functional studies of several transcription factors have demonstrated their effectiveness in mitigating salt stress [124]. For example, *Arabidopsis*DREB/CBF (dehydration-responsive element binding/C-repeat binding factor) proteins are key transactivational factors involved in environmental stresses such as cold, drought, and salinity [105]. Improved tolerance to salinity was conferred to potato plants transformed with *Arabidopsis* DREB1A under the control of an *Arabidopsis* stress-inducible promoter (rd29A) [150]. Ectopic expression of potato StZFP1 (a TFIIIA-type zinc finger protein), also driven by rd29A, in transgenic tobacco increased plant tolerance to salt stress [53]. StEREBP1 (ethylene-responsive element binding protein 1) is a transcription factor that binds GCC and DRE/CRT *cis*-elements and that responds to several environmental stresses including low temperature. Overexpression of StEREBP1 in potatoes enhanced their tolerance to cold and salt stress [104].

44.6.3 Omics Studies

Salinity tolerance is a multigenic trait with complex regulatory factors. Significant progress in its understanding has been made in *Arabidopsis* and tomato; however,

breeding for salinity tolerance in potato is still in its infancy. Several tolerant lines of cultivated and wild species have been identified on the basis of the Center for Genetic Resources (CGN) Genebank evaluation data, but breeding a tolerant line with growth vigor and yield is still a long process. To aid in this endeavor, several transcriptome-wide analyses have been performed in order to identify potato genes involved in salinity. As previously mentioned, Rensink *et al.* [75, 76] profiled genes in response to salt and temperature stresses. Other omics studies include a microarray study by Legay *et al.* [124] and a proteomics study by Aghaei *et al.* [125]. Both described the expression of several individual genes or proteins and several functional categories of genes that are differentially regulated under salinity.

Salt tolerance of potato cultivars and clones in general has increased activity of antioxidant enzymes, including SOD and peroxidase (POD) [151–153] as well as APX, CAT, and glutathione reductase (GR) [154]. Similarly, treatments that boost the antioxidant capacity of a plant, such as exogenous application of ascorbic acid, have also been found to ameliorate the salinity tolerance and increase the CAT and SOD activities in *S. tuberosum* [155].

Several examples of successful transgenic approaches have manipulated the antioxidant system to improve salt tolerance. For example, transgenic *in vitro* plants expressing a bacterial CAT gene had an improved multiplication rate under salt stress compared to control, while knockdown of the CAT gene reduced the multiplication rate, tuber yield, and leaf chlorophyll content [156]. Another study expressed *Arabidopsis* nucleoside diphosphate kinase 2, a known regulator of antioxidant gene expression, under the control of anoxidative stress-inducible promoter (SWPA2). The transgenic potato plants had higher APX activity and were more tolerant to high salt concentrations, presumably because of improved scavenging of ROS derived from salt stress [56]. This same research group demonstrated that transgenic potato plants expressing Cu/Zn SOD and APX genes in chloroplasts under the control of the SWPA2 promoter had increased tolerance to salt stress. Furthermore, retransformation of these same transgenic plants with a bacterial choline oxidase (coda) gene to synthesize glycine-betaine in chloroplast synergistically enhanced salt tolerance. Ectopic production of glycine-betaine in the chloroplast helped to maintain higher activities of SOD, APX, and CAT during salt stress [58]. A similar transgenic approach engineered potato plants with enhanced ascorbic acid accumulation and tolerance to salt stress by overexpression of a rat GLOase gene that is responsible for ascorbic acid production [157]. The T1 transgenic plants exposed to salt stress (100 mM NaCl) survived better with increased shoot and root length compared to untransformed plants. The elevated level of AsA accumulation in transgenics was directly correlated with their ability to withstand abiotic stresses.

44.6.4 Wounding

Tuber skin is a suberized layer of native periderm. It is often called skin-set. Tuber skin is used to protect tubers from pathogen infection, desiccation, and water loss. Tuber skins can be easily wounded by mishandling during harvest and postharvest

storage, resulting in decreased tuber quality and increased defects. The cultivars that lack an effective suberization function will be more prone to tuber defects such as bruising, crack, and skinning. In some cases, within 1 h of wounding, tuber skin tissues respond with wound-induced suberization [158]. The overall wound-healing process in potato tubers is characterized by the rapid accumulation of waxes to restrict water vapor loss [159] and the development of a suberized closing layer and associated wound periderm that resists desiccation and microbial invasion [160]. Suberization requires the biosynthesis of phenolic, aliphatic, and glycerol monomers and assembly of these monomers into polymer domains, named as suberin poly (phenolic) domain (SPPD) and suberin poly (aliphatic) domain (SPAD) [161]. Phenylalanine ammonia lyase (PAL) is a major player in the regulation of wound-healing activity because it is required for the formation of polyphenols in the SPPD [160]. In relation to this, a proteomic analysis of the wound-healing process reveals the accumulation of several peroxidases [162] that have been postulated to participate in the cross-linking of the hydroxycinamic alcohols that constitute lignin and SPPD [163].

Three hormones have been traditionally associated with wound healing because their levels dramatically increased upon wounding [164]. Most recent evidence implicates ABA in wound healing [164], but does not support a role for ethylene in this process, while the role of jasmonic acid remains speculative [164]. This is further supported by the observation that wound-healing ability declines with tuber age/storage, partly because of a reduced ability to accumulate ABA that appears to modulate PAL activity and accumulation of suberin polyphenols [160].

Chaves *et al.* [162] provide insight into the proteomics behind the wound-healing process in tuber slices. The cell differentiation processes that were triggered by slicing lead to changes in metabolism, activation of defense, and cell wall reinforcement. Proteins detected related to storage, for example, patatin, cell growth and division, cell structure, signal transduction, energy production, disease/defense mechanisms, secondary metabolism, and suberization. Even 8 days after wounding, the protein patterns of slices of wound periderm and native periderm were still quite different [162].

To further understand the metabolites associated with suberization process, a GC/MS-based metabolite profiling study was conducted, using wound-healing potato (*S. tuberosum* L.) tubers [165]. Using principal component analysis methods, the authors revealed a separation of metabolite profiles according to different suberization stages, with clear temporal differences in the nonpolar and polar profiles. These temporal differences were in keeping with earlier histochemical analyses of suberin macromolecular assembly: first, the phenolic compounds that accumulate in response to a wounding event are polymerized into the SPPD within the primary cell wall; then, this event is closely followed by the biosynthesis of SPAD components and their assembly into a multilammelar structure between the cell wall and the plasma membrane [161, 166]. Yang *et al.* [165] observed that the nonpolar metabolite profiles contained characteristic SPAD components, which appeared later than the bulk of the SPPD components apparent in the polar metabolite profiles. In the nonpolar profiles, suberin-associated aliphatics contributed the most to cluster formation, while a broader range of metabolites (including organic acids, sugars, amino acids, and phenylpropanoids) influenced cluster formation among polar profiles. The authors exploited strong

correlations between known suberin-associated compounds and several unidentified metabolites in the profiles to identify novel compounds involved in suberin biosynthesis. In addition, the results distinguished between suberin-related metabolites and metabolites associated with other wound-induced processes. For example, chlorogenic acid was clearly identified as one of the phenoic compounds induced by wounding.

In addition to suberization, wounding of potato tubers induces changes in some other metabolites, including those that function as defense compounds, for example, hydroxycinnamoyl putrescines [165, 167] and chlorogenic acid [165, 168]. Plants appear to have distinct signal transduction pathways that can distinguish between insect damage and abiotic damage based on the presence of insect-derived elicitors that function to induce plant defense against herbivory [169, 170]. For example, Turra *et al.* [171] have demonstrated differential expression patterns of potato protease inhibitors in response to wounding and nematode infection. Nevertheless, during the wound-healing process, a number of upregulated proteins result in the production of antimicrobial compounds such as phenols and pathogenesis-related (PR) peptides or the protein themselves are PR, such as beta-1,3-glucanase (PR-2), chitinases (PR-3), osmotins (PR-5), protease inhibitors (PR-6), plant peroxidases (PR-9), and PR-10 proteins [162]. The induction of multiple protease inhibitors upon wounding [162] is of particular interest because after patatin, low molecular weight proteinase inhibitors are the most abundant group of tuber storage proteins [172] and they have been implicated in the regulation of endogenous protease activity, protein stabilization, modulation of apoptosis, and protection from biotic stress [173, 174].

In addition to its function in defense [165, 168], chlorogenic acid is a major chemical involved in a nonenzymatic discoloration in potato tubers, called after-cooking darkening (ACD) [175]. This leads to another study that recently completed. Murphy *et al.* [176] used a comparative proteomics approach to identify proteins related to potato tuber ACD, a defect not welcomed by French fry industry. Clustering analysis of relative quantitative proteomics data revealed a cluster of proteins whose relative expression appeared the most positively correlated with darkening and an additional, smaller cluster of proteins, negatively correlated with darkening. Perhaps, most interestingly, they observed multiple proteins related to lipid signaling and protease inhibitor-based wound responses that are correlated with tissue darkening. The changes in relative protein abundance showed an enhanced wound response program in high ACD tissues. Among the wound-induced proteins, five were suggested by the authors for further investigation. They are polyphenol oxidase, aspartic protease inhibitor 7 precursor, 5-lipoxygenase, linoleate:oxygen oxidoreductase, and patatin T5 precursor. The authors suggest this wound response occurs in parallel to an increase in polyphenol synthesis, leading to tissue darkening [176].

44.7
Conclusions and Future Perspectives

Environmental stresses, both during growing season and during postharvest storage, can affect the marketable quality of the potato crop. Stresses during the growing

season reduce photosynthetic efficiency and function, resulting in varied metabolism changes and inhibition of the optimal growth and development of tubers. Recent efforts in genomics, transcriptomics, proteomics, and metabolomics to understand the physiology, biochemistry, and molecular genetics of stress responses have provided insight into these processes. Many promising genes have been identified and their roles and effectiveness in stress tolerance will be tested. Unfortunately, one last hurdle lies in the fact that traditional transgenic approaches have not been welcomed by consumers and agricultural policy makers of the developed world. This resistance has inhibited the introduction of many stress-tolerant transgenic cultivars into world markets thus far. Nevertheless, recent advancement in intragenic approaches, as outlined by Rommens *et al.* [177, 178], show promise in developing new cultivars while reducing concerns about the use of selection markers and genes from foreign species. It is very likely that some well-defined new generation intragenic potato cultivars will be successfully tested under field conditions.

The completion of the potato genome sequencing in the near future will boost the study of abiotic stress significantly. Many genes and markers will be identified and developed using the existing breeding lines. Because of the complexity and the heterozygosity of the cultivated potato cultivars, association mapping method will become a more effective tool to identify genes and markers with much less time. Finally, marker-assisted selection could be more successful if omics data could be integrated into breeding processes for new cultivar development.

Potato: Production Strategies under Abiotic Stress

Joginder Singh Minhas

Potato production is rapidly expanding in tropical and sub-tropical environments. The population density in these areas is high and potato with its high productivity of edible energy per unit area and time has the potential to alleviate hunger and malnutrition. However, the crop is exposed to various kinds of abiotic stresses like drought, heat, salinity etc. in these environments which are important limiting factors for potato productivity. The average tuber yield in these areas is less than half compared to temperate climates. With increased human activity impacting climate change, these stresses are likely to be experienced in higher magnitude and more areas. Genetic variability exists for tolerance to these stresses in potato and related species germplasm and can be exploited for developing abiotic stress tolerant varieties. Moreover, it is important to understand stress tolerance mechanisms operating in different plant species, and utilize our knowledge of agronomy, physiology, genetics and molecular biology to develop new genotypes capable of giving good yields under stressful environments.

45.1
Introduction

Although cultivated potatoes originated in highlands of South America, full potential of the crop was exploited in the temperate countries through organized breeding work. From these countries, potato was introduced to the tropical and subtropical areas of the world. As of now, potato is one of the most important food crops, both in developed and in developing countries. Owing to high protein–calorie ratio (17 g protein:1000 kcal) and short vegetative cycle, potato yields substantially more edible energy, protein, and dry matter per unit area and time than many other crops. In 2005, potato production by the developing countries overtook production by the developed countries. Most of these countries lie in tropical and subtropical zones of the world and are prone to various abiotic stresses such as drought, salinity, and high temperature. Abiotic stresses reduce the potential crop yields to a large extent and

present a major challenge to sustainable food production. Water is recognized as the most crucial natural resource for agricultural productivity. Water stress related problems are aggravating all over the world since droughts are becoming a common occurrence in rain-fed agriculture, more so, because of global weather changes. Scanty rainfall or inadequate irrigation creates drought-like situation resulting in reduced water availability to the crops. Loss of water due to high temperature also contributes to drought and leads to symptoms typical of dehydration or desiccation. Physiological drought is caused by high osmolarity (due to excessive salinity) of the soil because of which plants cannot utilize water even if available. Salinity directly affects ionic balance in the cells resulting in reduced growth and dry matter production. Temperature has profound effect on plant growth and development. Low temperatures lead to reduced photosynthesis and frost injury. High temperature has direct and indirect effects that reduce plant productivity. Direct effects are reduced photosynthesis and increased respiration leaving little photosynthate for growth and development. Indirectly high temperature disturbs partitioning of sugars among different organs affecting yield; for example, in potato, translocation of sugars is diverted to aboveground parts leading to severe yield reduction even at mild night temperatures.

Physiologically, stress tolerance can be defined in many ways like ability of the plant to survive under severe stress through osmotic adjustment and reduced metabolism, percentage yield reduction under stress compared to control, seed setting under stress, and so on, but from agronomic point of view, total commercial crop yield under stress is the only criterion. Therefore, the aim of the agricultural scientist is to develop stress-tolerant varieties and agrotechniques to maximize crop productivity under stressful environmental conditions.

45.2 Drought Stress

Drought is considered to be the major limiting factor for yield in the world potato production [1] influencing negatively not only yield but also tuber quality. Insufficient water supply may occur almost anywhere where potatoes are grown. In arid regions (e.g., subtropics), where potato production is possible only with irrigation, short periods of drought often arise because of inadequate irrigation techniques or shortage of water. Even with good irrigation practices, water stress may occur because of high transpiration rates, especially during mid-day, when root system cannot completely meet the water requirements of the plant, leading to increased water potential and consequent reduction in the rate of photosynthesis [2]. In the temperate climatic zones, both short and long periods of drought may occur almost every year due to irregular rainfall, particularly on soils with low water holding capacity. Taking into account production conditions and the present yield levels, it is estimated that the average potato yield in the world could be increased by at least 50% if the water supply to the crop could be optimized. Introduction of drought tolerance in potato through breeding and biotechnological means should therefore receive high priority.

45.2.1
Potato Growth and Production

Drought may affect potato growth and production in three ways: (1) by reducing the amount of productive foliage, (2) by decreasing the rate of photosynthesis per unit of leaf area, and (3) by shortening the vegetative growth period. Drought after planting may delay or even inhibit germination. Drought after planting is generally experienced by the potato crop under rain-fed conditions. Bansal and Nagarajan [3] found that water stress caused reduction in leaf growth in all the eight cultivars tested by them, although the extent of reduction varied within the varieties. Even mild water stress of −3 to −5 bars greatly reduced leaf expansion in potatoes [4]. Similar results on reduction of leaf growth under water stress were obtained by other workers [5–7]. Insufficient water supply in the period between the emergence and the beginning of tuber bulking may therefore lead to a limited growth rate of foliage and to small leaves and small plants. As a consequence, soil cover with green foliage will often be incomplete and yields will be below optimum. Decline in the rate of photosynthesis is fast and substantial even at relatively low water potentials of −3 to −5 bars [8, 9]. Even in the irrigated crop, plants experience water stress during the mid-day as the roots are not able to fully meet the transpirational demands of the plants. Mid-day depression in the rate of photosynthesis in well-irrigated crop was reported by Minhas and Sukumaran [2]. Plants respond to water stress by closing their stomata, thus shutting out the supply of CO_2. Sugar concentration within the leaf tissue increases to increase the osmotic potential of the plant, thus leading to feedback inhibition of photosynthesis [10]. Sensitivity of the potato crop to water stress varies with the developmental stage of the crop. Various authors have defined these stages as per their convenience; however, the stage between stolon initiation and early tuber development is the most sensitive, and stress at this stage causes maximum reduction in tuber yield [11–14]. Water stress during the tuber bulking stage caused a reduction in the leaf expansion rate, but to a lesser extent, compared to plants before tuber initiation. The presence of the tubers probably increased the water capacitance of the plants [10, 15] leading to reduced effect of water stress. Apart from reduction in leaf growth, water stress during tuber bulking stage accelerates plant senescence resulting in decreased LAI. At first, lower leaves start to wilt and drop off, while drought simultaneously inhibits the development of new leaves [16].

45.2.2
Drought and Tuber Quality

Drought stress also affects tuber quality characteristics such as shape, dry matter content, and reducing sugar content. Tuber shape defects such as dumbbell-shaped, knobby, or pointed end tubers are caused by short periods of drought during the tuber bulking stage. Misshapen tubers can also occur due to secondary growth, which is especially likely to occur in dry soils where temperature can go high [17]. This phenomenon may also result in poor cooking quality (glassiness) in some of the

tubers or jelly end or translucent end tubers. All these tubers have high content of reducing sugars, which makes them unfit for the processing industry. Tubers of water-stressed plants often have higher content of total sugars than well-irrigated plants [18]. Some studies have shown that the dry matter and starch content of potato tubers grown under low soil moisture was higher than the well-watered plants, thus improving the quality [19–21]. Other studies have shown that dry matter declines upon exposure to drought [22]; however, there were varietal differences for this character [18]. Tuber starch content has been reported to increase under drought stress [5].

45.2.3 Coping with Drought Stress

With the spread of potato cultivation to tropical and subtropical areas, the crop is likely to be exposed to increasing incidences of drought stress. Therefore, to cope with it, the first line of defense is the development of drought-tolerant varieties. Genetic variability exists in the potato germplasm, varieties, and wild species for tuber yield under drought stress [23–25]. Newer techniques such as heavy carbon isotope (^{13}C) discrimination based on $\Delta^{13}C$ values indicate water use efficiency of the plant. Screening of potato germplasm for $\Delta^{13}C$ showed good genetic variability for this character and can be utilized for breeding drought-tolerant varieties [26]. Screening techniques have also been developed by various workers on the basis of leaf extension after relief of stress [3], root mass in *in vitro* plantlets [27, 28], isotope discrimination ratio [29], and field screening using line source principle [30]. Using these techniques, some of the drought-tolerant varieties have already been developed/screened [18, 23, 24, 31].

Along with developing tolerant varieties, drought stress can be managed to some extent by various agronomic, chemical, and biological means. Soil water stress combined with higher atmospheric evaporative demand leads to severe stress affected yield losses [32]; therefore, crop under limited water supply can be grown when atmospheric evaporative demand is low. Mulching with agricultural waste during periods of drought helps in conservation of water, better crop stand and yields [33]. Plastic mulch on the ridges helps in rainwater harvesting and conservation between the ridges leading to better tuber yields [34]. Potassium application to the soil [35, 36] and spray of potassium humate [37] improves crop performance under drought stress. The use of gel polymers in the soil under water-limiting conditions improves water availability to the crop and tuber yield [38]. Some rhizobacteria contain the enzyme 1-aminocyclopropane-1-carboxylase (ACC) deaminase that degrades the ethylene precursor ACC and promotes plant growth, particularly under unfavorable environmental conditions such as drought. These bacteria can attenuate the growth inhibition caused by water deficit [39]. Better tuber yield can be obtained under water-limiting conditions by using drip irrigation combined with appropriate placement of drip tapes. While Onder *et al.* [40] found surface and subsurface drip equally effective, Patel and Rajput [41] reported a distinct advantage of subsurface drip irrigation at 10 cm for obtaining maximum tuber yield

at 100 and 80% irrigation levels. A combination of drought-tolerant varieties coupled with modern water saving irrigation techniques can be used to successfully produce potatoes in arid and semiarid zones of the world.

45.3 Heat Stress

Potato originated and evolved in the tropical highlands of Andes and hence prefers cool climate (17 °C) for optimum tuber yield [42]. Higher temperature may inhibit yield by overall reduction of plant development due to heat stress or by reduced partitioning of assimilates to tubers. Minimum night temperature is very important for potato crop. Whether or not potato will tuberize depends largely on the minimum night temperature and not on the average daily temperature. Tuberization is reduced at night temperatures above 18 °C and there may not be any tuberization at night temperature of 25 °C and above, even though potato plants can tolerate day temperature of about 35 °C without much deleterious effect. High temperature induces development of plants with thin stems, small leaves, and long stolons, increase in the number of internodes, inhibition of tuber development and a decrease in the ratio of tuber fresh weight to total fresh weight [43–46]. Heat stress affects many plant processes, and some of them are discussed in the following sections.

45.3.1 Photosynthesis and Respiration

Optimum temperature for dark respiration is 16–20 °C [47] and for photosynthesis it is 24–28 °C [48]. Higher temperature increases the rate of dark respiration and reduces the rate of photosynthesis in plants. Bushnell [42] measured the rate of night respiration in potato plants at different temperatures and found doubling of respiration with every 10 °C increase in temperature. So, as the temperature increases, more and more carbohydrates are used up as respiratory substrate and less and less are synthesized and are available for translocation to the tubers. At certain temperature (30 °C according to Burton [49]), there is no net assimilation. However, chlorophyll fluorescence studies showed that photosynthetic apparatus in potato is stable up to 38 °C, but beyond that there is a drastic reduction in photosynthetic efficiency [50].

45.3.2 Tuberization

The most prominent effect of high temperature is on the partitioning of assimilated carbon between leaves and tubers. The inhibition of tuberization at high temperature has often been demonstrated since the early study by Bushnell [42]. Gregory [51] found that tubers were initiated under short days over a long range of day tempera-

tures, but initiation was depressed at high night temperatures (over 26 °C). Under long days, the temperature range for tuberization was greatly restricted, with the necessity for lower night temperatures (10–17 °C). This interaction suggests that the high-temperature inhibition may operate through similar mechanism to the long-day inhibition and perhaps is subject to manipulation by the control of hormone levels [52]. Further proof of this hypothesis is provided by the increased synthesis of GA in apical buds exposed to high temperature and its transport to stolons where it inhibits tuberization [53] and that manual disbudding increased tuberization [54]. Wolf *et al.* [55] studied the partitioning of ^{14}C at 32/22, 32/12, 27/22, 27/12, and 22/12 °C day/night temperature. Neither the total plant productivity nor the export of carbon from the source leaf was affected by temperatures. More of assimilated carbon was partitioned to vegetative parts at high temperature, while at lower night temperature most of the assimilated carbon was partitioned to the tubers. They concluded that the main effect of high temperature is on assimilate partitioning and not on total plant productivity. Basu and Minhas [56] studied the partitioning of assimilated carbon within the source leaf into starch and sucrose in three heat-tolerant and three heat-susceptible varieties. They found that in heat-tolerant varieties 20–25% of the assimilates were converted to sucrose and 40–45% into starch, whereas in heat-susceptible varieties about 5% of the assimilates were converted to sucrose and 80–85% were converted to starch. Exposure of potato plants to heat stress alters the hormonal balance between roots and shoots, thus affecting tuberization and bulking. When potato plants are exposed to high temperature, gibberellin content in the leaves increases promoting haulm growth and inhibiting tuberization [53]. Basu and Minhas [57] studied gibberellins and abscisic acid concentrations in heat-tolerant and -susceptible genotypes and found that GA/ABA ratio was low in shoots of heat-tolerant genotypes and high in the shoots of heat-susceptible genotypes. GA-like substances decreased in the shoots and tended to accumulate in the roots of heat-sensitive genotypes during tuber bulking stage, whereas substantial amounts of GA-like substances remained in the shoots of heat-tolerant genotypes. They suggested that tuberization at high temperature may be related to high levels of ABA-like inhibitors in the roots during tuber induction.

45.3.3 Tuber Quality

Apart from the effects of heat stress on plant growth, development and yield, tuber quality is also affected by high temperature. Physiological disorders such as internal necrotic brown spots, chocolate spots, or internal rust spots in tuber parenchyma are linked to hot dry weather during tuber bulking [58]. Similarly, brown discoloration of the vascular ring or heat necrosis occurs at high soil temperature and varies with the severity of the stress, tuber development stage, and cultivar [59]. High temperature during harvest causes tuber rot in the irrigated soil [60]. High temperature also causes tuber shape disorders such as misshapen tubers, chain tubers, field sprouting, and reduced dry matter content [43, 61]. High temperature may cause preharvest sprouting and is linked to increased GA/ABA ratio [62].

45.3.4
Coping with Heat Stress

Potato prefers cool climate for optimum tuber yield. Therefore, the world over, the crop is grown during cool summer days in temperate zones or during short winter in subtropical zones. Most of the suitable temperature niches for potato cultivation in tropical and subtropical zones have already been occupied, leading to spatial and temporal concentration for its cultivation. To bring more area under potato, the only option available is to extend potato cultivation to less suitable areas and seasons where the crop is likely to experience high-temperature stress. Potato productivity is drastically reduced when grown under high temperatures. Therefore, development of heat-tolerant varieties is the foremost requirement for extending potato cultivation to new areas.

Genetic variability for heat tolerance exists in cultivated potato, primitive and wild species, and intergroup hybrids [63, 64]. Along with genetic variability, a good screening technique is also required for a successful breeding project. Various workers have developed screening techniques such as those based on tuberization in leaf bud cuttings, where single-node cuttings are exposed to high temperature for 3 weeks and then checked for tuberization [65] and ratio of internode length in two-node cuttings grown at high and normal temperature [66], and glasshouse screening technique for seedling populations based on their capacity to tuberize at high temperatures [67]. A combination of these screening techniques has been used by various workers for the successful development of heat-tolerant potato varieties [68, 69]. These heat-tolerant varieties have been able to extend potato cultivation to warmer nontraditional areas of Israel and India. These varieties are also a timely tool for mitigating the ill effects of global warming on potato production in the world.

Apart from heat-tolerant varieties, heat stress can also be mitigated by agronomic practices. Soil treatments like covering the soil with reflectants such as white chalk layer reduced daytime soil temperature by 7 °C, hastened emergence, foliage development, and tuber yield by more than 50% [70]. Mulch also had beneficial effects in reducing soil temperature, decreasing weed population, and increasing yield under hot dry conditions [71, 72]. Intercropping with shade crops such as maize have also shown beneficial effect; for example, shading with maize (one row of maize:three rows of potato) improved potato yield with additional maize yield coming as bonus [73, 74]. Application of calcium as fertilizer also improved the performance of potato varieties exposed to heat stress [75]. Therefore, heat stress can be successfully managed by a combination of heat-tolerant varieties and suitable agronomic practices.

45.4
Salinity Stress

Owing to an excessive use of irrigation, salinity problem in soils is increasing the world over. Moreover, vast tracts of saline soils are present in all the continents of the world. Salinity is a major cause of low crop production in many regions. Increasing

population and industrialization are taking a heavy toll on fresh water resources, and the quantity and quality of water available for agriculture are likely to decline in future. Therefore, we need to look for alternative water resources and crops that can tolerate lower quality water.

45.4.1 Ionic Imbalance in Soil

Salinity adversely affects growth and productivity of many crop plants. Soil salinity or the use of saline water results in higher osmotic potential in the soil solution, thus reducing water uptake by roots. Saline soils also have the problem of water infiltration, aeration, and root respiration [76]. Excessive concentration of certain ions such as Na, Cl, Ca, Mg, B, and SO_4 in the soil solution can cause physiological disorders in plants. In saline soils, there is an increase in adsorbed Na, a decrease in adsorbed Ca and Mg, and precipitation of Ca and Mg carbonates [77]. Saline water increases the proportion of exchangeable sodium ions in the soil solution leading to formation of sodium bicarbonate, thus raising soil pH. Resulting alkaline conditions reduce availability of nutrients such as PO_4, Fe, Mn, Zn, and so on to the plant. In calcium carbonate-rich soils, this damaging process is inhibited. This phenomenon has been exploited for saline soil reclamation by addition of gypsum. At cellular level, salinity-induced nuclear degradation in root meristematic cells was alleviated by addition of calcium to the growth medium [78].

45.4.2 Crop Growth and Yield

Affects of salinity stress are aggravated if it is combined with heat stress, water stress, high light intensity, and low humidity as encountered in natural environments [79, 80]. Crops have been rated for salt tolerance on the basis of two parameters, that is, the maximum salinity up to which there is no yield reduction and the percentage yield decrease per unit of salinity increase. According to these parameters, potato has been classified as moderately sensitive to soil salinity [81, 82]. Plant height, leaf area, and dry weight accumulation in potato are significantly reduced by salinity. Tuber yield is reduced through reduced tuber number and weight per tuber [83, 84].

Potato leaves are very sensitive to saline water and are severely damaged by sprinkler irrigation [82]. Uptake of sodium and chlorine induces toxicity as evident from leaf burn along the margins. Salinity adversely affects relative water content, stomatal conductance, and transpiration rate in potato. It also leads to changes in chloroplast ultrastructure such as thylakoid swelling and decreased grana stacking, affecting photosynthesis and reducing growth and dry matter production [85]. Irrigation with saline water during tuber germination caused greater depression in yield (59%) than when it was applied well after plant establishment (22–31%) [86]. High salinity levels (EC > 10 dS m^{-1} in the root zone) may cause coarse russetting and furrowing of tubers accompanied by severe browning of the surface, thus reducing tuber quality [87].

45.4.3
Field Selection for Salt Tolerance

Genetic variability for plant response to salinity has been found in wild potato species and potato varieties. *Solanum chacoense*, *S. kurzianum*, *S. juzepczuckii*, and *S. curtilobum* have been found to be salt tolerant in various experiments involving irrigation with saline water, glasshouse trials, and production of microtubers in the presence of NaCl in the growth medium [88, 89]. Screening for salinity tolerance has been carried out in the field by irrigation with saline water or by growing the crop in saline soils and salt-tolerant varieties such as Patrones, Norland, Red Lasoda, Cara, Serrana Alpha, Arica, and so on have been identified. These varieties fall in all maturity groups, and earliness or lateness is not related to salt tolerance [86, 90, 91]. Some of the Israeli varieties such as Almera, Hermes, and Maris Peer are not affected by moderate level of salinity, and the Peruvian variety Serrana is most salt tolerant [87].

45.4.4
Laboratory Selection for Salt Tolerance

Salt-tolerant potato lines have also been developed using recurrent *in vitro* selection of cell lines over a number of generations by exposing them to increasing salt concentration. Whole plants regenerated from salt-tolerant calli accumulated more fresh and dry weight when watered with 90 mM NaCl and also produced more tubers per plant [92]. The known salt-tolerant variety Serrana produces profuse root mass in MS medium containing 154 mM NaCl; so, plants have been screened *in vitro* by measuring root growth in culture medium containing high NaCl concentration [93, 94]. *In vitro* selection for salt tolerance has also been reported by Burgutin *et al*. [95] who identified 38 somaclones that maintained superior performance in field tests over many years.

45.4.5
Coping with Salinity

Salt-tolerant varieties have been selected using field and laboratory screening methods and are being regularly grown in many countries where good-quality water for irrigation is not available. In central Negeve desert, the underground water, too saline for irrigation, is being mixed with fresh water from the Sea of Galilee to control salinity level before applying it for irrigation to different crops [87]. This model can be easily replicated in other areas of the world facing similar problems. Sensitivity of the potato crop to salinity varies with the growth stage of the plant. Some stages are more sensitive to salinity than others [86]. Therefore, more sensitive stages can be irrigated with better quality water and the rest of the stages can be irrigated with poor-quality water to get optimum yield. In saline areas where fresh water is available, excess water can be used to leach down the salts from the top layer. In such cases, depletion of the nitrate from the root zone should be taken care of for optimum yields. Proper

fertilizer management can reduce metabolic disturbances brought about by salinity. Potassium nutrition stands out in increasing plant tolerance to salinity. It has been shown that potassium application up to 600 kg ha^{-1} increased the tuber yield of four cultivars irrigated with saline water with 9.38 dS m^{-1} electrical conductivity [96].

45.5 Reactive Oxygen Species and Abiotic Stress

Reactive oxygen species (ROS) are generated under abiotic stresses such as drought, salinity, and oxidative stress. ROS are produced in the chloroplast due to oxidative stress and is scavenged by superoxide dismutase (SOD). ROS, when produced in high amounts, cause severe damage to plant cell membranes. It has been shown that salt tolerance in potato varieties is linked to high activity of antioxidant enzymes such as peroxidase (POD) and SOD [97]. When frost-tolerant Andean potato species *S. curtilobum* and frost-sensitive *S. tuberosum* were exposed to PEG-mediated water stress, SOD activity increased by more than twofold in stress-tolerant variety and it was highly correlated with chlorophyll fluorescence parameter f_v/f_m indicating protection of PSII from ROS generated by water stress [98]. Other chemicals that scavenge ROS have also been found to enhance yield and provide protection against abiotic stresses; for example, cobalt in the culture medium provided protection to potato seedlings during osmotic stress [99]; treatment with diphenylamine, a potent antioxidant, increased potato yield by 27–47% [100]; and potato plants sprayed with antiozonant ethylenediurea (EDU) had higher amount of reduced glutathion, protected leaves against ozone damage, and increased tuber yield [101]. Treatment of plants with chlorocholine increased SOD, POD, and catalase activities, improved P, K, Ca, Mg, Fe, Mn, and Zn content, and enhanced tuber yield under suboptimal conditions [102]. Transgenic potato plants carrying bacterial catalase gene imparted salt tolerance to potato [103], proving beyond doubt the role of antioxidant enzymes in amelioration of abiotic stresses.

45.6 Conclusions

Potato produces highest amount of edible energy, protein, and dry matter per unit area and time compared to other food crops. Therefore, the crop has the potential to feed more people per unit area than any other crop. Already, more potatoes are being grown in developing countries in the tropics and subtropics than in developed countries in the temperate zones. The major limitations to potato production in tropics and subtropics are high temperatures, scarcity of water, and salinity. With increasing population and industrialization in these countries, quality and quantity of water available for agriculture are going to go down with each passing decade. These problems are likely to aggravate with impending global warming. Therefore, the study of abiotic stresses in potato crop has assumed substantial significance. It is a

challenge for scientists to use their understanding of stress tolerance mechanisms and modern technologies to develop new varieties capable of giving good yields under stressful environments. Given the genetic diversity available in potato germplasm and increased knowledge of physiology and molecular biology, the prospects are promising for our ability to improve potato yield in nontraditional environments and make more food available to millions.

Tobacco: A Model Plant for Understanding the Mechanism of Abiotic Stress Tolerance

Scott Schaeffer, Tyson Koepke, and Amit Dhingra

Agricultural productivity across the globe is threatened by environmental fluctuations. Years of human agronomic activity has further confounded the problem by increasing abiotic stress factors in the environment. There is an impending need for designer crops that can withstand an ever-increasing level and range of abiotic stresses to continue to support the food needs of a burgeoning population. Plants are also being explored as a source of fuel, which necessitates production of appropriate crops in nonarable lands. Thus, abiotic stress-resistant crops are relevant for both food and fuel needs in this century and beyond. Unlike biotic stresses, which are mostly monogenic traits and thus amenable to molecular breeding, abiotic stress resistance involves adjustments in morphological and physiological parameters. The multigenic nature of the trait makes it difficult, if not impossible, to breed crops in a timely manner that will be able to withstand the environmental fluctuations. This is particularly relevant for perennial crops. While annual crops can be bred in a matter of years, perennial crops stand to gain from directed biotechnological approaches. Several studies over the years in different plant species have identified various mechanisms and associated genes underlying abiotic stress resistance or tolerance. The scientific literature is replete with instances where these mechanisms were successfully unraveled in a heterologous host, tobacco that has long-served as surrogate for test of novel gene function. These studies underpin the fact that abiotic stress resistance mechanisms are shared within the plant kingdom. This chapter summarizes the current body of knowledge on our understanding of abiotic stress tolerance as deciphered from studies performed in tobacco.

46.1
Introduction

Environmental stress and in particular abiotic stress has never been more relevant to crop production than now when our planet faces climatic upheavals. Extreme temperatures resulting in freezing or drought-like conditions, extensive irrigation leading to increase in salinity and use of fertilizers for crop production over the years, and other soil quality issues related to heavy metal pollution threaten agricultural

Improving Crop Resistance to Abiotic Stress, First Edition.

productivity. The situation is compounded by the need to sustain a burgeoning population estimated to rise to 9.1 billion by 2050 [1]. A recent effort to utilize crops as a source of fuel has further complicated the situation as it breeds competition for arable lands [2]. It necessitates generation of food and fuel crops suited to extreme environments to meet the world's food and fuel needs in this century and beyond.

Over eons of evolution, plants have developed tolerance mechanisms so that they can withstand environmental fluctuations. These mechanisms are wired in the genetic architecture of the plant and are called adaptation. In addition, plants can acclimate to a given stress by repeated low-grade exposure and then withstand fluctuations in abiotic conditions. This narrow window of resilience to stressful conditions is termed as phenotypic plasticity that does not require any permanent physiological or metabolic alteration [3]. These mechanisms represent available examples in nature that scientists can use to generate abiotic stress resistant crops that are adapted to harsh environments and harbor a wide range of phenotypic plasticity.

Unlike biotic stress, where defined genetic mechanisms and targets can help counter a given scourge, a plant's response to abiotic stress engages a highly complex network of physiological, genomic, proteomic, and metabolomic components. The complexity in countering environmental fluctuations, moderate or extreme, might have been a trait that was developed by the plant during evolution as a consequence of being a sessile inhabitant of the planet. It is no wonder then that genetic, molecular biology, and recently the genomics approaches have unearthed multifarious mechanisms that could be targeted for equipping desired crops to withstand a given abiotic stress. Eventual goal is to arm the plant with innate physiological mechanisms that help it in maintaining cellular homeostasis in the face of transient or chronic abiotic stress.

A large body of information exists on molecular mechanisms of abiotic stress tolerance in plants that has led to the identification of several genes or genetic loci involved in the process [4]. Since the establishment of genetic transformation strategies in the early 1980s, efforts have been underway to develop abiotic stress-resistant or -tolerant agricultural crops. Abiotic stress is a multigenic trait; that is, it is regulated by multiple genes. Thus, genetic improvement of crops via molecular breeding can prove to be an uphill, if not impossible, task. Furthermore, phenotypic characterization of abiotic stress resistance or tolerance is difficult due to the variation in stress sensitivity at different developmental stages. The observed resilience to abiotic stresses is a result of adjustments at the morphological or physiological state of the whole plant, a trait difficult to track and manipulate during breeding experiments. In contrast, resistance mechanisms are mediated by genomic, proteomic, and metabolic entities that are open for biotechnological manipulations [4]. In a rapidly changing environmental context, there is a need to develop new abiotic stress-resistant crops in a timely manner. While annual crops could be bred in a matter of years, perennial crops face the impediment of juvenility in addition to the complexity of the trait to be bred.

Some of the common abiotic stresses faced by plants are high light intensity, metal toxicities, waterlogging, extremes of cold (freezing) and heat, drought, and salt [5]. When faced with these, a plant sets into motion a cascade of molecular events to adjust the cellular homeostasis in order to reduce the damaging effect of the

immediate osmotic or oxidative stress. As summarized in Figure 46.1, the message is first perceived or sensed by receptors and transduced further via calcium and MAP kinases resulting in the activation of stress-sensitive transcription factors such as CBF/DREB. As a consequence, several stress–response mechanisms are activated that may involve detoxification, a process that scavenges dangerous reactive oxygen species (ROS) species, osmoprotection, movement of ions and water, and activation

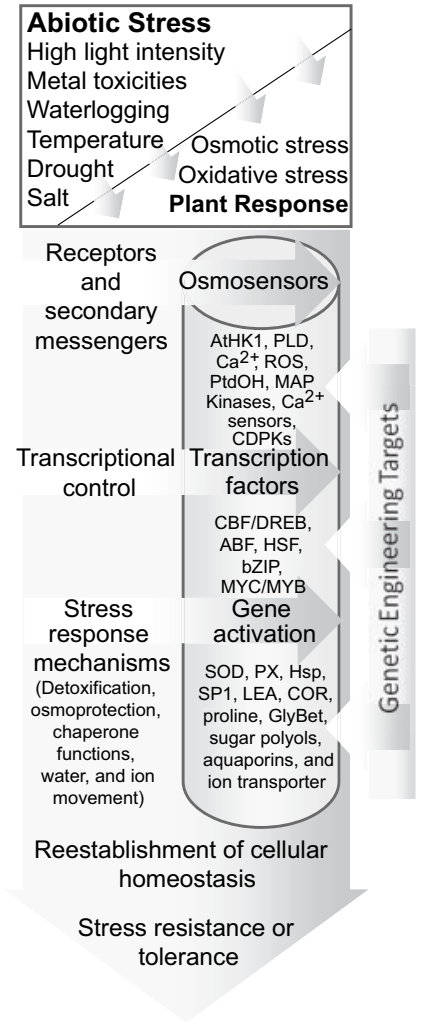

Figure 46.1 Schematic representation of the abiotic stress signal transduction pathway. Abiotic stresses trigger secondary stresses such as osmotic and oxidative stress that are sensed by receptors and transduced further via calcium and kinase cascade. Eventually activation of the involved transcriptional networks including transcription factors and associated genes engage multiple stress response mechanisms to establish cellular homeostasis. Adapted from Ref. [4].

Table 46.1 Primary affects associated with different abiotic stresses.

Primary effects	Abiotic stress
Water potential reduction	Water deficit, salinity, and freezing
Cellular dehydration	Water deficit, salinity, and freezing
Hydraulic resistance	Water deficit
Ion toxicity	Salinity
Hypoxia, anoxia	Flooding and soul compaction
Membrane destabilization	High temperature, chilling
Protein destabilization	High temperature
Symplastic ice crystal formation	Freezing
ROS production	High light intensity, trace element toxicity
Photoinhibition	High light intensity
Disturbed cofactor binding to DNA and proteins	Trace element toxicity

of chaperone function [4]. These mechanisms are facilitated by a suite of genes identified in various studies over the years.

Any imbalance in the abiotic factors manifests in a series of physiological changes termed as primary effects followed by secondary effects. Primary effects of abiotic stresses are listed in Table 46.1. Secondary effects include reduced cell/leaf expansion, reduced cellular and metabolic activities, stomatal closure, photosynthetic inhibition, leaf abscission, altered carbon partitioning, ROS production, ion cytotoxicity, cell death, fermentative metabolism, reduced CO_2 production, inadequate ATP production, and physical destruction, to name a few. Thus, any given abiotic stress never operates alone.

It is noteworthy to mention that several abiotic stress-related genes from other plant species have been successfully engineered in tobacco to obtain stress tolerance or resistance. These studies underpin the fact that abiotic stress resistance mechanisms are shared within the plant kingdom, and biotechnological manipulation may be an efficient method to ensure supply of food and fuel in the future. This chapter summarizes studies undertaken to understand the mechanism of abiotic stress resistance by testing stress-related genes in tobacco as a surrogate system that has long-served as a system of choice for testing gene function [6]. Each section is organized to provide an overview of the mechanism by which each abiotic stress condition manifests itself in a plant following which a much exhaustive list of genes is provided in a tabular format and a few relevant examples of transgenic approaches in tobacco are presented to illustrate the process.

46.2 Heat Stress

Global warming is a reality or not is a debate for another forum. Our planet is experiencing climatic change and of late extremes in weather conditions have

Table 46.2 A list of genes tested in tobacco for heat stress.

Gene	Mechanism	Gene description	References
DnaK	ROS scavenging	DnaK/HSP70	[10]

GST + GPX	ROS scavenging	Glutathione *S*-transferase	[12]
BADH	Osmoprotection	Betaine aldehyde dehydrogenase	[14]
AspDC	Osmoprotection	l-Aspartate-alpha-decarboxylase	[15], Fouad and Rathinasabapathi, 2006
AlSAP	Activation of stress-related genes	Stress-associated protein	[16]

become a norm. These fluctuations may not add to the average temperatures in a region but have a profound effect on field performance of plants. Short exposure, ranging from 5 min to 1 h, to high temperatures can lead to plant death.

Exposure of plants to high temperatures primarily leads to membrane and protein destabilization. The fluidity of membranes is increased resulting in leakage of ions culminating in cellular disruption. The 3D structure of individual proteins is disrupted, thereby leading to aberrant protein function and activity.

Plants experience an inhibition of photosynthesis and respiration primarily due to an imbalance between CO_2 fixed via the former process and released due to the latter. This usually happens when environmental temperature exceeds the internal temperature compensation point when the CO_2 budget is balanced by the two processes mentioned above. There is a simultaneous production of reactive oxygen species that in higher amounts triggers a cascade of events to self-destruction. Change in cellular homeostasis mediated by chronic heat stress results in cell death [7]. Several genes have been identified and tested for imparting heat stress tolerance (Table 46.2). Their molecular functions range from being molecular chaperones to providing osmotic resilience stressing the fact that multiple strategies could be utilized to engineer plants to withstand heat stress.

46.2.1
Heat Shock Proteins

As the name suggests, heat shock proteins are expressed when plants are exposed to elevated temperatures [8]. Several genomics and proteomics studies have focused on studying the role of HSPs in different plants [9]. Heat shock proteins are chaperones that facilitate protein folding and protein–protein interaction of other proteins. They are also involved in protein transport across membranes. Tolerance to heat stress has been obtained to varying degrees in different plant species by expression of HSPs. One such study in tobacco utilized a DnaK/HSP70 gene from a halotolerant cyanobacteria *Aphanothece halophytica*. Engineering of this gene in tobacco provided enhanced tolerance to heat and salt stress. The transgenic tobacco

plants exhibited higher levels of ascorbate peroxidase (APX) and catalase activity compared to the wild-type plants indicating that higher ROS scavenging may be the mechanism that provided the observed tolerance [10].

46.2.2 ROS Scavenging

Strategies to obtain heat-tolerant plants centered on ROS scavenging and detoxification abound. Generation of ROS is either a primary or a secondary effect of abiotic stress. During high-temperature stress, ROS is generated as a secondary effect and several genes have been engineered in plants to scavenge it and thereby obtain heat-tolerant plants. A chloroplast ascorbate peroxidase gene (TtAPX) from tomato was engineered in tobacco. Under high-temperature stress, there was improved seed germination, higher ascorbate peroxidase activity, and lower accumulation of hydrogen peroxide and malondialdehyde compared to the wild-type plant. In addition, the photosystem II exhibited higher photochemical efficiency [11]. In another study, ectopic expression of glutathione *S*-transferase with glutathione peroxidase activity resulted in enhanced growth of transgenic seedlings when exposed to multiple stressful conditions. Concomitant higher levels of monodehyroascorbate reductase correlated with higher glutathione and ascorbate levels. The authors concluded that the observed stress tolerance was due to glutathione-dependent peroxide scavenging resulting in reduced oxidative damage [12].

46.2.3 Osmoprotection

Heat stress disturbs the water and ion balance causing osmotic stress in the plant. Engineering efforts have centered on genes that participate in pathways producing compounds that may provide osmoprotection. One such compound is glycine-betaine, a quaternary amine widely distributed in the plant kingdom that provides plants protection against osmotic stress [13]. While there are several examples of engineering of the betaine aldehyde dehydrogenase (BADH) gene for tolerance to various stress types, in tobacco, expression of BADH resulted in accumulation of glycine-betaine [14]. The transgenic plants expressing BADH exhibited higher thermostability of the oxygen-evolving complex and the PSII reaction center. The level of H_2O_2 generated was lesser compared to wild-type plants. In another study, a prokaryotic gene L-aspartate-alpha-decarboxylase was expressed via integration in the nuclear genome. This gene catalyzes decarboxylation of L-aspartate to generate beta-alanine and CO_2. Transgenic plants had higher levels of beta-alanine, pantothenate, and total free amino acids and increased thermotolerance compared to controls [15]. In a related study, the same gene was engineered in tobacco via chloroplast transformation. It was found that PSII exhibited higher thermotolerance than in wild-type plants that may be due to osmotic protection of ROS scavenging [16].

46.2.4
Other Mechanisms

A close inspection of Figure 46.1 reveals that the protective mechanism to multiple stresses could be mediated by some common factors. A novel gene, AlSAP from *A. littoralis*, a halophytic grass, was engineered in tobacco resulting in tolerance to multiple abiotic stress conditions. The plants showed high level of resilience and successfully completed their life cycle to produce viable seeds under heat stress. The transgenic plants were also tolerant to salinity, drought, and freezing. Although the mechanism in which this gene operates is not clear, its overexpression resulted in enhancing the transcripts for eight other stress-related genes [17].

46.3
Cold Stress

Cold stress either manifests itself in the form of chilling or freezing that occurs when the temperature falls to a very low. Chilling results in membrane destabilization leading to secondary effects that are common to the heat stress. The difference is that membrane fluidity is reduced, thereby affecting several biochemical processes, ATPase activity, solute transport, energy transduction, and enzyme-dependent metabolism. Chilling injury results in vitrification and discoloration of leaves. On the other hand, freezing causes symplastic ice crystal formation. As water freezes, it expands and results in physical destruction of cellular structure [7]. Extracellular ice crystal formation may not have major damaging effect; however, intracellular ice crystal formation results in shearing of membranes and organelles. Several studies have been conducted in tobacco to understand the mechanism of cold tolerance or simply engineer the tolerance and/or resistance to cold (Table 46.3).

46.3.1
Osmotic Homeostasis

Osmotic adjustment is one of the ubiquitous mechanisms by which a plant is able to counter stress. There are several metabolic subroutines through which osmotic homeostasis can be reestablished within a plant exposed to stress. One such pathway is the chloroplast-localized glycine-betaine synthesis pathway that has been discussed elsewhere in this chapter in relation to other types of abiotic stress. Glycine-betaine provides osmoprotection to bacteria, plants, and animals. Several attempts at expressing eukaryotic genes for enzymes in glycine-betaine synthesis pathway and thus tolerance to cold proved futile. However, when a choline oxidase gene (*cod*A) from *Arthrobacter globiformis* was targeted to tobacco plastids, the resulting transgenic tobacco plants were able to withstand prolonged exposure to freezing [18, 19]. Perhaps, the *cod*A gene used in this study had better stability or was bereft of any feedback inhibition since the transgenic plants accumulated significant amount of glycine-betaine. Fructans, polymers of fructose, are also considered to play a role in

establishing osmotic homeostasis [20]. Tobacco was engineered with the constitutively expressed *Bacillus subtilis Sac*B gene coding for levansucrase, fused to the carboxypeptidase Y vacuolar sorting signal from yeast or a levensucrase gene from *Zymomona smobilis* [18, 21]. Transgenic tobacco plants with bacterial fructans demonstrated the capability to recover from freezing stress whereas wild-type tobacco plants perished [17]. The accumulation of fructans was observed to increase in the presence of cold stress. In the same study, constitutive expression of proline synthesis gene AtP5CS also resulted in tolerance to cold stress [18, 19].

46.3.2 ROS Scavenging

As shown in Figure 46.1, generation of reactive oxygen species is either a primary or a secondary effect of a given abiotic stress. There have been several instances where scavenging or prevention of ROS generation through transgene expression has been employed to attain cold tolerance. In one of the early examples, a chloroplast-targeted Cu/Zn superoxide dismutase was engineered in tobacco to confer resistance to low temperature [22]. The transgenic plants demonstrated enhanced levels of ascorbate peroxidase-specific activity suggesting enhancement of the ROS scavenging system.

More recently, direct overexpression of a thylakoid-targeted tomato tAPX (ascorbate peroxidase) gene in tobacco resulted in transgenic plants that were able to withstand low-temperature stress [11]. In another study, the concept of exogenous application of H_2O_2 in conferring abiotic stress tolerance was tested. The glucose oxidase (GO) gene from *Aspergillus niger* was expressed in tobacco. The GO expressing plants exhibited higher levels of H_2O_2 and electrolyte leakage was found to be the least in these plants when exposed to chilling temperature for 12 h [23]. The cold tolerance was perhaps associated with elevated levels of total antioxidant content and ascorbate peroxidase activity. Several other genes relating to ROS scavenging listed in Table 46.3 have also been successfully engineered to confer cold tolerance.

46.3.3
Increased Unsaturated Fatty Acids

The phosphatidylglycerol membranes of cold-resistant plants abound in unsaturated fatty acids. A desaturase enzyme enhances the amount of unsaturated fatty acids, thereby allowing the membranes to remain fluid during acclimation to cold temperatures [24]. A gene coding for glycerol-3-phosphate acyltransferase from chilling-sensitive squash was constitutively expressed in tobacco under control of the CaMV 35S promoter [25, 26]. With a similar goal, a broad-specificity Δ9 desaturase gene (des9) from the cyanobacterium *Anacystis nidulans* was engineered into tobacco [27]. The resulting transgenic plants showed reduced saturated fatty acid content in most membrane lipids and were able to survive prolonged chilling (11 days at 1 °C or 52 days at 10 °C). In another study, an *Arabidopsis* chloroplast ω-3 fatty acid desaturase gene (FAD7) was engineered in tobacco to produce transgenic plants with enhanced levels of trienoic (16 : 3 and 18 : 3) fatty acids [28]. Enhanced cold tolerance was observed in transgenic plants. The FAD7 gene was also engineered in tobacco expressed via a cold-inducible *Arabidopsis* cor15a promoter [29]. The resulting transgenic plants demonstrated greater degree of survival under prolonged chilling stress maintained at 0.5, 2.0, or 3.5 °C for 44 days, had higher levels of trienoic fatty acids, and enhanced chloroplast membrane ultrastructural stability.

46.3.4
Other Mechanisms

Cold tolerance has been imparted to transgenic tobacco by expression of cold acclimation or cold-regulated gene. Two cold acclimation proteins CAP160 and CAP85 were constitutively expressed in tobacco and the resulting transgenic plants were also crossed to obtain progeny harboring both proteins. A minor but significant cold tolerance was observed in the transgenic plants [30]. Similarly, constitutive expression of a citrus (*Citrus unshiu* Markov.) dehydrin, resulted in cold-tolerant transgenic plants [31]. The transgenic plants also exhibited more efficient germination at 15 °C compared to wild-type seeds. On the basis of *in vitro* data showing CuCOR19 protein prevented peroxidation of soybean liposomes, it is proposed that

this dehydrin may act as an ROS scavenging protein. Several other studies where animal cell death suppressor proteins, jasmonate- and ethylene-responsive factors (JERF), late-embryogenesis abundant protein, and so on have been expressed in tobacco to confer tolerance to cold [32–35].

46.4
Drought Stress

Drought stress is created due to water deficit that leads to a reduction in water potential and cellular dehydration, and creates hydraulic resistance. As a result of these primary effects of water deficit, multifarious processes malfunction. There is a reduction in cell/leaf expansion, stomatal closure, inhibition of photosynthesis, cell wall collapse called cytorrhysis, ion toxicity, leaf abscission, altered carbon partitioning, destabilization of membranes, and ultimately cell death. While drought stress is a major stress by itself, it is evident that many of the ill effects of drought are, in fact, caused by oxidative stress since some of the work targeting oxidative stress response pathways has shown to impart drought tolerance.

To examine plant responses to drought, two methods are typically used. The first, and most simple, is to reduce the amount of water given to the plants. The second involves adding an osmotic adjusting compound such as polyethylene glycol (PEG) to the water to reduce the ability of the plant to uptake water. This second method is also amenable to tissue culture work with both liquid and solid media. As mentioned previously, many of the genes conferring increased resistance to salt stress also impart drought tolerance (Table 46.4). Unfortunately, due to the nonuniformity of drought stress application and the various measurements used to examine tolerance levels, it is difficult to decipher patterns in which pathways have a larger overall effect on drought tolerance, though it is clear that there are many ways to impart drought tolerance in tobacco.

46.4.1
Osmotic Adjustment (Trehalose and Fructans)

As with the experimental method of adding compounds to water to modify the osmotic potential, producing similar compounds inside the plant can have similar effects. Trehalose, fructans, and D-ononitol have all been accumulated in transgenic tobacco to impart drought tolerance. The mechanism for these molecules to create drought stress tolerance is by reducing the water potential in the plant cells allowing them to uptake water from soil when a plant without the molecules would be unable to do so.

Trehalose 6-phosphate synthases (TPS1) perform the first step in trehalose production as shown in Figure 46.2a and have been used to produce trehalose in plant cells. Romero *et al.* [36] showed that TPS1-expressing tobacco accumulated trehalose and that increasing levels of trehalose correlated with increased drought tolerance when water was withheld for 15 days. Similarly, TPS1 showed a dose-

dependent maintenance of photosynthetic capabilities in wild-type ($\sim$3 μmol m^{-2}), low producing transgenic ($\sim$5 μmol m^{-2}), and high producing transgenic ($\sim$10 μmol m^{-2}) lines, showing lowest to highest photosynthesis [37]. The high producing line also had increased relative water content (RWC) compared to the low producing line

and the wild type after 21 days of drought stress. Trehalose phospholylase (TP) was also used to increase trehalose production (Figure 46.2b) in tobacco. Total trehalose production reached 6.3 μmol g^{-1} tissue in the transgenic compared to ~4 μmol g^{-1} in wild type [38]. Though this increase is small, when water was withheld the wild type plants wilted by day 2 while some TP lines did not wilt even after 10 days without water. Detached leaf water retention assays demonstrated that the best TP lines lost roughly half the water the control did. Both the water withholding and detached leaf assays showed variation among the transgenic lines that suggests a possible dose-dependent effect of trehalose accumulation on drought tolerance. The third trehalose producing enzyme used by Zhang *et al.* [39] is the trehalose synthase (TSase) that produces trehalose using the same mechanism as TP. After 10 days without water followed by restarting watering, the TSase transformants had better recovery from drought stress than the wild type. Increased leaf water content, higher chlorophyll, and increased SOD and POD activities were also observed in the TSase lines.

Fructans are fructose polymers that have also been used to improve drought tolerance in tobacco. When germinated and grown on MS [40] containing 8% PEG, levansucrase (levU) expressing tobacco transformants grew the same way as unstressed, while the wild type could not grow [21]. Similarly, fructan production through another levansucrase, SacB, showed transgenic lines grew faster than wild type in 10% PEG hydroponic solution, with 19% higher fresh weight and 32% higher dry weight [41].

Production of D-(+)-ononitol from *myo*-inositol also improved drought stress tolerance [42]. For this work, a *myo*-inositol *O*-methyltransferase was expressed in tobacco and increased the total *myo*-inositol + D-(+)-ononitol to twofold the levels in the wild type. The transgenic lines showed similar reductions in photosynthesis to the wild type but recovered more rapidly upon watering after drought stress.

46.4.2 Transcription Factors

Another class of genes used to induce drought tolerance in transgenic tobacco is that of transcription factors. Owing to their DNA binding nature, transcription factors have the ability to control expression of multitudes of genes in various pathways and likely enable the crosstalk between the abiotic stresses. Several DNA binding domains are associated with abiotic stress response though the most common to date is the AP2 domain (Apetala 2).

Several AP2 containing transcription factors have been shown to improve drought tolerance when expressed in tobacco. Ethylene-responsive factors (ERFs) and JERFs are AP2 class transcription factors. When ERF3 was expressed in tobacco and the plants unwatered for 30 days, the ERF3 lines were able to grow taller than weight and flower while the wild type was not able to complete its life cycle [43]. A second set of experiments with ERF3 showed increased free proline levels and increased soluble carbohydrate accumulation [44]. These plants were then able to maintain higher root growth rates when submerged in 2% PEG compared to the control plants. When using JERF3 transgenic plants, no major differences were seen between the wild type

and the JERF3 plants during 15 days of drought; however, after 2 days of postdrought watering, all the JERF3 plants recovered, while only 20% of the wild-type plants were able to survive the 15 day drought stress [45]. Looking at JERF3 effects on other genes, it was found to upregulate many genes across the osmotic and oxidative stress pathways. CBF/DREB domains (C-repeat binding factor/dehydration-responsive element binding factor) contain an ERF/AP2 binding domain and were also tested for their ability to improve drought tolerance. Expressing DREB1A with the stress-inducible promoter rd29A yielded better growth than DREB1A with the 35S promoter under nonstressed conditions [46]. After 2 weeks without watering, both DREB1A types outperformed the wild-type plants. This work suggests that a stress-inducible promoter may enable the benefits of overexpressing stress tolerance genes without hindering plant growth under nonstress conditions. Separately, using 200 mM mannitol drought stress in solid growth media, DREB1B expressing tobacco lines had higher germination rates, overall growth chlorophyll retention, and decreased lipid peroxidation compared to the control plants [47]. The same solid growth media with 15% PEG instead of mannitol revealed higher growth inhibition for the wild type and a reduced inhibition in DREB1B plants. After 21 days without watering, DREB1B lines had up to 135% more water retention based on fresh and dry weights. As expected, the DREB1B lines did show an increase in expression of several stress-related genes.

Another transcription factor, the ABA-responsive binding factor (ABF) has also showed improved drought tolerance in tobacco [48]. The ABF lines lost less water in a dehydration assay and had lower ion leakage than the wild type. Over 3 weeks without water, ABF lines had more growth and higher amounts of chlorophyll than the wild type. Overexpression of ABF also led to upregulation of POD, SOD, and CAT (catalase).

Asr1, a zinc-dependent DNA binding peptide of unknown function, was expressed in tobacco [49]. A leaf detachment assay showed the Asr1 plants lost less water than the wild-type leaves. They also showed increased expression of 12 genes, many of which are known to be associated with stress responses.

46.4.3
ROS Scavenging Pathways

Reactive oxygen species are a major cause of damage from drought stress as verified by expression of many ROS mitigating genes improving drought tolerance. The overexpression of one of the major ROS reducing genes seen in Figure 46.3 appears to stimulate the expression of the others to some degree so the effect of each individual gene is difficult to decipher.

Superoxide is a primary reactive oxygen species that can be reduced into hydrogen peroxide by superoxide dismutase (SOD). SOD-overexpressing tobacco showed less rapid decreases in photosynthesis during drought stress compared to wild type when plants were exposed to either lack of watering or watering with 10% PEG [50].

The second step of this pathway involves ascorbate peroxidase that reduces ascorbate into monodehydroascorbate (MDA) to reduce the hydrogren peroxide

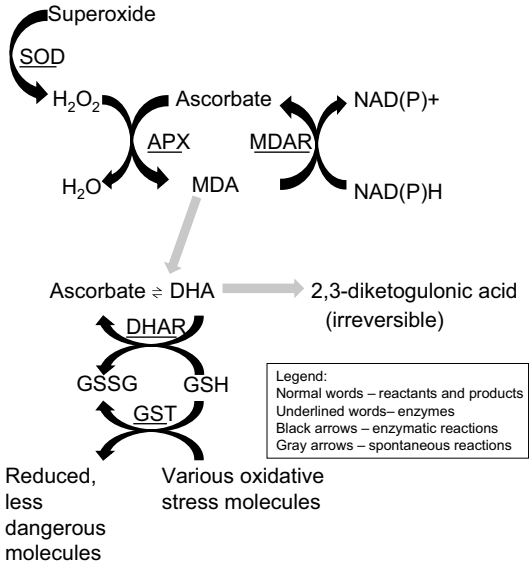

Figure 46.3 ROS generation and scavenging pathways in plants.

into water. APX-overexpressing tobacco lines showed 91–92 and 70–65% germination on 0.1 and 0.3% mannitol media, while the wild type had 70 and 24% germination [51]. This work found that hydrogen peroxide measurements were one-third to one-quarter of the wild-type levels during the stress. The authors also identified a decrease in the inhibition of PSII in the APX line. When total plant weight was measured, the APX lines showed higher growth in 300 mM mannitol, but the sample size was insufficient to find statistical significance. APX was also expressed using a glutathione reductase promoter resulting in a 3.8-fold increase in APX activity [52]. Net photosynthesis measurements showed 49.5 and 65.3% photosynthesis in transgenic and 16.2 and 58% in the wild type when comparing 10 days without water and 10% PEG treatments against normally watered control.

Once ascorbate is oxidized by APX, the MDA needs to be recycled into ascorbate or it will spontaneously disproportionate into dehydroascorbate (DHA) or ascorbate. The MDA to ascorbate reaction is carried out by MDA reductase (MDAR) and expression of MDAR has shown improved retention of starting photosynthetic rates after 8 days of 10% PEG stress [53]. Similarly, DHA reductase (DHAR) reduces DHA using glutathione (GSH) to regenerate ascorbate and if this does not occur rapidly enough, DHA can spontaneously and irreversibly degrade into 2,3-diketogulonic acid [53]. Eltayeb *et al.* [54] expressed DHAR in the cytosol and decreased the photosynthetic inhibition initiated by 8 days of either withholding water or watering with 10% PEG compared to wild type with the same treatments.

Another class of enzymes that use reduced GSH are the glutathione *S*-transferases (GSTs). These enzymes have various specificities and are involved in reducing many molecules from oxidized states. Expressing GSTs in tobacco resulted in a sixfold increase in GST activity and reduced wilting during 2 weeks without watering

compared to the wild type [55]. The GST lines also recovered from the drought stress almost immediately while the wild type did not recover and died. In tissue culture experiments, 4% mannitol hindered wild-type growth and the GST plants were phenotypically normal in up to 8% mannitol that killed all of the wild-type plants. Tissue-cultured plants on 15% PEG expressing an auxin-inducible GST from *Prosopis juliflora* (PjGSTU1), which has both GST and glutathione peroxidase (GSX) activities in *Escherichia coli*, retained turgor pressure longer than control plants [56].

Several other plant peroxidases (POD) have been used to improve drought tolerance in tobacco. Swpa4, a secratory class III peroxidase, decreased bleaching and maintained higher PSII activity following 8 days of drought stress [56]. Swpa4 plants also had an eightfold increase in H_2O_2 production leading to upregulation of many pathogen response genes. Since different levels of POD did not affect stress levels significantly, the response does not appear to be dose dependent but is rather turned on by swpa4 expression. Expression of a cell wall peroxidase (TPX2) increased the germination rate on mannitol likely due to decreased seed pore size and increased water uptake [57].

Aldose or aldehyde reductase (ALR) acts to reduce lipid peroxidation product 4-hydroxynon-2-enal. When unwatered for 35 days, ALR expressing plants were able to retain photosynthetic capabilities and recover after watering, while wild-type plants did not [58]. As expected, the transgenic lines also showed lower lipid peroxidation levels.

46.4.4 Protectants (Glycine-Betaine)

Glycine-betaine production improves overall plant health during multiple stresses including drought stress. Choline monooxygenase, CMO, is the last step in glycine-betain production and CMO transgenic plants showed 48.7% germination in 5% PEG media and 16.5% in 10% PEG media compared to 15.7 and 1.6%, respectively, for the wild type [59]. After 2 months in 10% PEG media, CMO shoot segments were still growing while the wild type had stopped growing or died. Similarly, plastid expression of CMO allowed the plants to remain unaffected after 15 days without water and the wild type completely wilted and did not recover after the end of the stress [60]. In addition, the transgenic had ~70% germination in 300 mM mannitol containing media and the wild type only had ~20% germination.

Two methyltransferases from the glycine-betain production pathway, GSMT2 and DMT2 (named T2), were expressed in tandem and produced more glycine-betain than betA lines [61]. In media with 20% PEG, T2 lines showed better germination than either betA or wild-type seeds and better than wild-type seeds in 5, 10, and 15% PEG. Through a 7 day drought period, the T2 and betA both grew more than the wild type. The relative water content and photosynthetic measurements after the 7 days of drought were highest in the T2 and lowest in the wild type. Contrarily, ion leakage and lipid peroxidation were lowest in the double transgenic and highest in the wild type. The glycine-betaine levels and their effect on drought stress demonstrate another example of dose effect of stress tolerance.

46.4.5
Other Mechanisms

While many of the genes tested in tobacco that confer drought tolerance fit into clean categories, others are not as clearly defined and are discussed in this section.

SAP8, stress-associated protein 8, showed 98 and 86% germination in 300 mM and 400 mM mannitol, respectively, while the wild type had 50 and 40% germination [62]. Overall decreases in shoot length, root length, and fresh weight were significantly higher in the wild type than in the SAP lines at each mannitol concentration as well.

Another SAP was shown to improve drought tolerance since SAP lines produced viable seeds, while wild-type plants failed to enter the reproductive phase prior to death when exposed to 25% relative soil moisture content for 30 days [17]. The role of this SAP in stress response is not yet defined.

Calcium binding annexin with many hypothesized functions was expressed in tobacco yielding transgenics that stayed green and living on 250 mM mannitol, while the wild-type tobacco became chlorotic and died [63]. During leaf disk assays in varying concentrations of mannitol, the wild type lost 70–76% of their chlorophyll and the transgenics lost only 24–34% of the chlorophyll. In addition, the wild type showed much higher rates of lipid peroxidation at all mannitol concentrations.

NtHAL3, a salt tolerance gene from *Sacchromyces cerevisiae*, yielded some lines with much higher relative growth than wild type in tissue culture media supplemented with 150 or 300 mM sorbitol after 5 days, while other lines were only slightly above wild type [64]. Plants expressing of NtHAL3 also showed increase in cellular proline.

An antiquin-like protein/aldehyde dehydrogenase, ALDH7, is involved in either general stress response or turgor pressure maintenance and its expression improved relative water content in leaves after 2 weeks without water to 52–61% from ~40% in the wild type [65].

Overall, the genes and mechanisms discussed in this section show the diversity of genes that aid in drought tolerance and provide insight into the range of genes that may be tested in the future that will have an effect on drought tolerance. Pyramiding of these genes will reveal whether the mechanisms are complementary or completely overlapping.

46.5
Salt Stress

Salt stress, specifically from sodium chloride, induces stress via several mechanisms including direct interaction of sodium ions with plant proteins and a disturbance in osmotic balance. As drought also causes stress through disruption of the osmotic balance in plant cells, factors that confer tolerance to salt stress often also confer tolerance to drought stress. These factors often relate to osmoprotectant synthesis and ROS scavenging. Damages resulting from salt-induced stresses have a severe impact on agricultural systems and are predicted to

cause the loss of up to 50% of earth's arable land by 2050 [66]. Mechanisms developed by plants to cope with living in high salt environments include salt exclusion, compartmentalization, use of osmoprotectants, and increases in protein stability [67, 68] (summarized in Table 46.5). Tobacco has been used extensively as a tool to study various mechanisms and genes involved in salt tolerance that may translate into future efforts to engineer salt tolerance or hyperaccumulation into crops (Table 46.6).

Tobacco has been engineered in numerous studies to identify the effects of the production of osmoprotectants upon increasing salt tolerance. These osmoprotectants are thought to increase stress tolerance through direct interaction and stabilization of lipids and proteins and removal of free radicals [69], in addition to the adjustment and maintenance of favorable cellular water potential [70, 71]. Overexpression of both yeast apoplastic invertase and vacuolar-targeted invertase in tobacco result in plants containing higher levels of sucrose, glucose, and fructose compared to wild-type plants in both source and sink tissues [72]. Increases in these sugars yielded plants with increased salt tolerance measured by photosynthetic activity [73].

46.5.1 Mannitol

Mannitol is a sugar alcohol that is not naturally synthesized in tobacco. Transgenic plants engineered to produce elevated levels of mannitol [74] through the overexpression of an *E. coli* gene encoding mannitol 1-phosphate dehydrogenase (*mtlD*)

Table 46.5 Salt Tolerance Osmoprotectants.

Osmoprotectant	Gene (s)	Protein	Species of origin	Reference
Mannitol	Mt1D	Mannitol 1-phosphate dehydrogenase	*Escherichia coli*	[74]
Proline	P5CS	Δ1-pyrroline-5-carboxylate synthase	*V. aconitifolia*	[77]

GmNHX1	Na^+/H^+ antiporter	[84]

displayed increased salt tolerance compared to wild-type tobacco. Transgenic lines produced concentrations of 6 μmol mannitol per gram of fresh weight in the leaves and roots of some transformed plants [75]. Under prolonged exposure to 250 mM NaCl for 30 days, tobacco expressing the *mtlD* transgene experienced an 80% increase in height, while control plants grew only by 22% [74]. Mannitol accumulation promoted the growth of new leaves and roots leading to extreme differences in biomass formation between transgenic and wild-type tobacco plants. Later studies using the overexpression of *mltD* in tobacco to study salt tolerance found that overexpression of the *mltD* transgene caused a 20–25% reduction in size without application of a salt stress [76]. Under salt stress, WT plants experienced a decrease in dry weight of 44%; however, no significant decrease in dry weight occurred in tobacco overexpressing the *mltD* gene. The significant difference in growth of *mltD* overexpressing tobacco suggests that the apparent salt tolerance conferred by the overproduction of mannitol may actually be a result from the slower growth.

46.5.2 Proline

Likewise, another osmoprotectant, proline, was produced at elevated levels through transformation of a gene encoding *Vigna aconitifolia* (mothbean) Δ1-pyrroline-5-carboxylate synthase (P5CS) [77]. Plants expressing *V. aconitifolia P5CS* gene produced 10–18 times more proline than wild-type plants. Both WT and *P5CS* transgenic tobacco plants were grown to the four-leaf stage and transferred

to 400 mM NaCl solution for 3 weeks. Transgenic plants produced double the biomass and also displayed increases in flowering. Further studies looked into increasing the production of proline in tobacco via altering the feedback inhibition of proline upon P5CS [78]. *P5CS* was mutated using site-directed mutagenesis to change ala-129 to phe-129 resulting in mutant P5CS displaying low feedback inhibition [39]. Accumulation of proline in transformants overexpressing the mutated *P5CS* was double that of transformants overexpressing the wild-type P5CS gene under salt stress conditions [78]. Generation of tobacco expressing an *Arabidopsis* antisense gene encoding for proline dehydrogenase resulted in increased proline concentrations and increased salt tolerance [79]. Increased levels of proline were also induced in tobacco cells under salt stress through overexpression of the *NtHAL3* gene encoding a protein putatively involved in the coenzyme A pathway [64].

46.5.3
Glycine-Betaine

Increases in the osmoprotectant glycine-betaine were achieved in tobacco through overexpression of the *betA* gene encoding choline dehydrogenase from *E. coli* that oxidizes choline to produce betaine aldehyde [80]. Wild-type tobacco does not accumulate glycine-betaine; however, significant amounts of glycine-betaine accumulated in tobacco expressing the *betA* transgene. Expression of *betA* appeared to confer tolerance to salt stress allowing for an 80% increase in total dry weight compared to wild-type plants. Further modification of the glycine-betaine pathway was achieved through cotransformation using both *betA* and *betB*, encoding betaine aldehyde dehydrogenase [81]. Plants expressing the two transgenes accumulated two–three times more glycine-betaine than those solely overexpressing *betA* and displayed a higher rate of photosynthesis and biomass accumulation under salt stress.

46.5.4
Inositol and D-Ononitol

Tobacco plants transformed with the *IMT1* gene from the ice plant (*Mesembryanthemum crystallinum*) were able to accumulate amounts of D-ononitol exceeding 35 μmol g^{-1} fresh weight [42]. Transgenic tobacco expressing the *IMT1* gene exhibited higher photosynthetic CO_2 fixation compared to nontransgenic control plants under salt stress. Similar results were observed through engineering tobacco to express the *PINO1* gene encoding a L-*myo*-inositol-1 phosphate synthase (MIPS) from *Porteresia coarctata* (a halotolerant species of wild rice) [67]. Overexpression of the *PINO1* gene allowed for increased accumulation of inositol. Comparison of tobacco overexpressing *RINO1*, an MIPS from *Oryza sativa*, to those overexpressing *PINO1* revealed that *PINO1* transformants accumulated higher cellular inositol concentrations and maintained higher photosynthetic activities. Further studies display that overexpression of both the *IMT1* gene and the *PINO1* gene display an increased salt tolerance compared to the transformants expressing only the *IMT1* gene or the *PINO1* gene [82].

46.5.5
Sodium Transport

Sodium transport appears to be a common mechanism used by plants to control intracellular sodium concentrations. Overexpression of genes encoding antiporters in the vacuole or plasma membrane can significantly affect the salt tolerance of transgenic tobacco plants. Overexpression of *AtNHX1*, encoding a vacuolar *Arabidopsis* Na^+/H^+ antiporter, in tobacco results in plants more tolerant to salt stress [83]. Eighty-five percent of seeds from transgenic *AtNHX1* plants were able to germinate in concentrations of salt toxic to all but 5% of wild-type tobacco seeds. Activity of the vacuolar ATPase was found to be essential in maintaining the pool of cytosolic H^+ for transport to occur. In transgenic tobacco plants overexpressing *AtNHX1* vacuolar ATPase activity increased anywhere from 119 to 130% after salt stress, while wild-type plants exhibited an increase in activity of only 7%. Neither H^+-pyrophosphatase (PPase) nor plasma membrane ATPase exhibited changes in activity in either transgenic or control plants. Tolerance to salt was also conferred in tobacco through overexpression of *GhNHX1*, encoding a cotton tonoplast Na^+/H^+ antiporter [84]. Overexpression of a vacuolar antiporter regulating protein from rice, *OsARP*, conferred increased tolerance to salt stress in tobacco [85]. While the complete function of the *OsARP* product is not known, it was shown to localize to the tobacco tonoplast membrane and allow for increased storage of sodium ions in transgenic plants compared to the wild type. Through this study, OsARP is hypothesized to interact with NHX1 to increase sodium transport from the cytosol into the tonoplast.

Overexpression of either vacuolar PPase from *Thellungiella halophila* (*TsVP*) or *Arabidopsis* (*AVP1*) into tobacco conferred increased tolerance to 300 mM NaCl [86]. Vacuolar PPases function through transporting protons into the vacuole from the cytoplasm establishing a gradient from which H^+-dependent antiporters can function. At 300 mM NaCl, transgenic tobacco expressing either *AVP1* or *TsVS* accumulated 60% more dry weight than wild-type tobacco. In addition, TsVP and AVP1 transgenic lines were able to accumulate 20–30% more sodium than wild-type plants under salt stress (300 mM NaCl) conditions. Damage to the cellular membrane was reduced in both TsVP and AVP1 overexpressing tobacco, indicating that the increased ability to compartmentalize sodium ions into the vacuole significantly reduces the effects of sodium toxicity.

46.5.6
Increased Protein Stability

Increased protein stability under high saline conditions can be achieved through both the activity of stabilizing chaperone proteins and the structural modifications of proteins that lead to increased stability. DnaK/HSP70 proteins are involved in binding to proteins that have become denatured or are in nonnative states and are involved in aiding in their refolding to functional forms. Overexpression of DnaK1 from a halotolerant cyanobacterium, *A. halophytica*, in tobacco resulted in increased tolerance to high salt conditions [68].

Increased stability under high salt conditions was observed when comparing the *PINO1* gene encoding a L-*myo*-inositol-1 phosphate synthase from *Porteresia coarctata* (a halotolerant species of wild rice) to the MIPS found in *O. sativa*, *RINO1* [67]. Overexpression of *PINO1* confers the ability in tobacco to accumulate high cellular inositol concentrations under salt stress conditions, while overexpression of *RINO1* leads to lower levels of inositol accumulation. The specific activities of extracted L-*myo*-inositol-1 phosphate synthase from both *RINO1* transformants and control plants were drastically lower than that isolated from *PINO1* transformants at all tested NaCl concentrations. This difference peaked at 500 mM NaCl with almost a 10-fold increase in specific activity in *PINO1*transformant MIPS. The amino acid sequence of the MIPS from *Porteresia coarctata* and *O. sativa* differ greatly resulting in differing hydrophobicities and surface charges, suggesting such differences are important mechanisms in developing salt-tolerant proteins.

46.5.7 Exclusion

The plant cell wall is extremely important in controlling the entrance of external molecules into a plant cell. One method plants may have developed to tolerate higher levels of environmental salt is through reducing the permeability of cell and seed cell walls. Reduction of cell wall pore size was, in fact, achieved in tobacco through overexpression of *TPX2*, a gene encoding a tomato peroxidase known to play a role in modification of the cell wall structure [57]. Seeds from resulting transformants displayed a significant increase in the rate of germination (~80%) in the presence of 250 mM NaCl compared to wild-type tobacco seeds (~30%).

46.5.8 Transcription Factors: Jasmonate/Ethylene-Responsive Factors

ERFs and JERFs have been associated with promoting responses to biotic and abiotic stresses that initiate the ethylene signaling cascade [87]. These ERFs are activated by downstream participants in the ethylene cascade such as EIN 3 and EILs. ERFs are transcription factors that bind PR genes and other genes with GCC box promoters [88]. Overexpression of tomato *JERF3*, a gene whose product has high homology to only the DNA binding domain of ERF in tobacco, yielded salt tolerance [89]. Leaf disks from plants overexpressing the *JERF3* gene retained about 80% of their original chlorophyll content when placed in 300 mM NaCl, while wild-type plants maintained less than 20%. These plants expressed genes with GCC box, CE1, and DRE (dehydration responsive element)-containing promoters such as *PR* gene, as well as genes involved in ROS scavenging and photosynthetic carbon assimilation [34, 89]. A similar protein, JERF1, was produced at high levels in transgenic tobacco and displayed similar properties to JERF3; however, tobacco overexpressing *JERF1* also produced elevated levels of abscisic acid (ABA) and displayed higher vacuolar Na^+ concentrations compared to wild-type controls [33]. Salt tolerance is also conferred through the expression of rice *OsBIERF3* that was shown to induce the expression of

PR-1a [90] and soybean *GmERF3* [44]. While exact mechanisms have not been established, salt tolerance is also established in tobacco plants overexpressing a *Camptotheca acuminate* allene oxide cyclase, a key enzyme involved in the synthesis of jasmonates [91]. This study suggests that overproduction of jasmonic acid can play a significant role in developing salt tolerance; however, future studies will need to identify the molecular basis of this tolerance.

46.5.9
Reactive Oxygen Species Scavengers

As the production of reactive oxygen species is one of the major factors caused by salt stress, much attention has been given to increasing tolerance to salt stress through genetically engineering tobacco to more efficiently scavenge ROS. Engineering plants to have enhanced scavenging of reactive oxygen species has been shown to lower the toxic effects of high salt in tobacco.

Overexpression of *swpa4*, a gene encoding a peroxidase from *Imomoea batatas* (sweet potato) in tobacco, resulted in increased salt tolerance [92]. The specific activity of isolated plant peroxidases in transgenic lines expressing *swpa4* was 50 times higher compared to control plants. In addition, *swpa4* overexpressors had elevated levels of both lignin and phenolic compounds and increased chlorophyll content under salt stress conditions at both 200 and 400 mM NaCl.

Copper/zinc superoxide dismutases (Cu/Zn SOD) convert the highly reactive superoxide radical to H_2O_2. While H_2O_2 itself is cytotoxic, this reaction is the first line of defense that plants have to protect themselves against ROS. Overexpression of a gene encoding Cu/Zn SOD from *O. sativa* in tobacco chloroplasts protected against paraquat treatment and also conferred tolerance to high salt conditions [50]. Photosynthetic activity of tobacco overexpressing *Cu/Zn SOD* was significantly higher compared to the control during salt stress, and after 10 days of a recovery period maintained 79.1% of the original photosynthetic activity compared to 37.9% observed in control plants.

Ascorbate peroxidase is one of the many enzymes responsible for the scavenging of reactive oxygen species. APX catalyzes the reduction of H_2O_2 to H_2O using ascorbate as an electron acceptor that is oxidized generating a monodehydroascorbate radical (MDA). MDA can then be reduced back to ascorbate by MDA reductase or ferrodoxin. However, if this reaction does not occur in time MDA can break up disproportionately to ascorbate and dehydroascorbate. Dehydroascorbate must then be reduced through the action of dehydroascorbate reductase (DHAR), using reduced glutathione. Oxidized glutathione can then be converted back to GSH by glutathione reductase (Figure 46.3).

Overexpression of *DHAR*, *MDA*, and *APX* can significantly reduce the toxicity of salt stress-induced ROS production. Transformed tobacco overexpressing a gene encoding a thylakoid-bound APX from tomato possessed higher germination rates, photosynthetic rates, root lengths, and fresh weight and lower levels of hydrogen peroxide compared to wild-type tobacco under salt stress [51]. Tobacco chloroplast transformation using a gene encoding cytosolic APX from *Arabidopsis* also gener-

ated tobacco more tolerant to elevated levels of salt [52]. Transgenic tobacco with chloroplasts engineered to overexpress a human *DHAR*, exhibited higher levels of ascorbate and oxidized glutathionein in comparison to wild-type plants [92] and displayed increased tolerance when grown in media containing 100, 150, and 200 mMNaCl [94]. *MDA* overexpression in tobacco also conferred salt tolerance, yielding plants with higher photosynthetic rates and lower levels of hydrogen peroxide under salt stress compared to wild-type tobacco [53]. Overexpression of multiple genes in this pathway shows great promise for further increasing the efficiency of ROS scavenging under stress conditions. This was demonstrated through the overexpression of CuZnSOD, APX, and DHAR in the chloroplasts of tobacco [94]. Control tobacco, tobacco overexpressing CuZnSOD and APX (CA), and tobacco overexpressing all three genes (CAD) were grown in media containing 100 mM NaCl for 50 days. CAD tobacco had average dry shoot weights 22.3% higher than CA tobacco and 35.0% higher than control tobacco and also displayed increased root growth.

Glutathione in the reduced state is essential for the reduction of dehydroascorbate to maintain the cellular pool of ascorbate available for ROS scavenging. In addition to this role, glutathione is also utilized by the glyoxalase pathway for glutathione-based detoxification of malondialdehyde (MD) and methylglyoxal (MG), a potent cytotoxic compound produced during lipid peroxidation. Overexpression of *glyI* from *Brassica juncea* encoding glyoxylase I in tobacco conferred tolerance to MG and high salinity in transgenic tobacco [96]. Addition of *glyII* from *O. sativa* conferred greater tolerance to high methylglyoxal and NaCl concentrations [97]. Plants expressing both *glyI* and *glyII* grew under continuous salt stress and were able to flower and produce seed. Enhancing the glyoxylase pathway through tobacco genetic engineering enabled plants to resist an increase in MG levels under salinity stress, through maintenance of higher reduced:oxidized endogenous glutathione pools [98].

46.6 Metal Toxicity

Many heavy metals are necessary for plant growth and biochemical functions such as B, Co, Mn, Cu, Zn, Fe, Mg, and Mo; however, at elevated levels heavy metals can cause severe stress and toxicity in plants. These high concentrations of heavy metals are found naturally in some areas of the world as such, but are often associated with lands containing industrial pollutants. Heavy metals cause toxicity to plants via multiple mechanisms as symptoms are highly plant, metal, and dose specific. Heavy metals have been shown to promote the formation of free radicals [99, 100], compete with metal cofactors of plant enzymes, affect enzyme activity through the binding of sulphydryl and nitrogen-containing groups [101], cause cellular leakage through interactions with phospholipid head groups [99], cause disruption of ATPases, and interrupt the synthesis of lipids. Interruption or denaturation of proteins or enzymes involved in photosynthesis and respiration have been shown to generate ROS making the mitochondria and chloroplast specifically susceptible to heavy metal stress

[102, 103]. Ultimately these effects can lead to reduction in growth, chlorosis, curling of leaves, and necrosis.

Many plants have evolved mechanisms to either avoid heavy metals or prevent the interaction of these metals with cellular components. Plants that avoid heavy metals maintain the ability to either prevent the uptake of heavy metals or actively excrete these metals. Over 400 species of plants have developed methods of metal hyperaccumulation via heavy metal chelation or compartmentalization [104]. In addition to plants, many species of fungi and bacteria have developed mechanisms to overcome heavy metal stress. In order to further study the functions of these genes, tobacco has been implemented as a model system in numerous studies partly due to the ease of both nuclear and chloroplast transformation and its susceptibility to heavy metal stress. Many studies have utilized tobacco to display that certain genes are able to confer resistance to a broad range of heavy metal stresses, while others have focused on mechanisms unique to an individual heavy metal. Some of these studies are summarized in Table 46.7 and described in subsequent sections to illustrate the diversity of heavy metal tolerance mechanisms studied in tobacco.

46.6.1 Tolerance to Multiple Heavy Metals

As many heavy metals cause toxicity to plants via similar mechanisms such as ROS production, some genes have been shown to confer tolerance to stresses of multiple heavy metals.

Phytochelatins and metallothioneins are plant peptides that bind metals creating a sort of a shield that prevents or limits the interactions of metals with cellular components [105]. Phytochelatin synthase produces phytochelatins from glutathione. When present at high levels in transgenic tobacco, pytochelatin synthase transformants produce phytochelatins at elevated levels compared to wild-type plants. Transformation of tobacco with phytochelatin synthase from *Arabidopsis thaliana* resulted in the ability to accumulate cadmium within the plant at a twofold higher concentration [149]. A similar study investigated the effects of phytochelatin synthase from the cadmium hyperaccumulator *Cynodondactylon* on cadmium tolerance in tobacco [106]. Expression of this phytochelatin allowed for a 3.4-fold increase in intracellular cadmium concentrations compared to the wild-type plant. Overexpression of phytochelatin synthase from *A. thaliana* also allowed for increased tolerance to arsenic [107]. Increasing the pool of cysteine, a precursor for glutathione, through the overexpression of spinach cysteine synthase increases tolerance to cadmium, selenium, and nickel, but not lead or copper in tobacco [108]. Increases in both cysteine and glutathione were detected in cysteine synthase transformants. The increases in available glutathione likely allowed for increased phytochelatin conjugation of free heavy metals. Other phytochelatins such as the bacterial *ppk* increase mercury accumulation and tolerance in tobacco [109]. Dehydrins, another class of metal binding proteins, have also been shown to increase tolerance in tobacco to both cadmium and zinc stress through limiting ROS production leading to lipid peroxidation [110].

Table 46.7 A list of putative tolerance mechanisms associated with metal toxicity is provided.

Putative tolerance mechanism	Metal	Gene(s)	Function	Species of origin	References
Induction of ROS scavengers	Cd, Cu	*ThCHIT 33*, *ThCHIT42*	Endochitinase	*T. harzianum*	[137]
Removal of ROS cytotoxic byproducts	Cd	*MsALS*	Aldose/aldehyde reductase	*Medicago sativa*	[113, 114]
	Cd	*TvGST*	Glutathione transferase	*T. virens*	
Removal of organic groups	Hg	*merB*	Organomercury lyase	*E. coli* plasmid NR1	[122]
Overexpression of metal-containing proteins	Fe	*MsFer*	Ferritin	*M. sativa*	[119]
Volatilization	Hg	*merA*	Mercuric ion reductase	*E. coli* plasmid NR1	[122]
Metal reduction	Cd	*ArsC*	Arsenate reductase	*E. coli* plasmid R773	[112]
Chelation	Hg	*ppk*	Polyphosphate kinase	*Klebsiella aerogenes*	[109, 149]
	Cd	*AtPCS1*	Phytochelatin synthase	*A. thaliana*	[106]
	Cd	*CdPCS1*	Phytochelatin synthase	*Cynodondactylon*	[107]
	As	*AtPCS1*	Phytochelatin synthase	*A. thaliana*	[110]
	Cd, Zn	BjDHN2/BjDHN3	Dehydrin	*B. juncea*	[108]
	Cd, Se, Ni	*SpCSase*	Cysteine synthase	*Spinacia oleracea*	

Overexpression of CHIT42 and CHIT33, two fungal endochitinases yielded significantly fewer visible effects of high salt, copper, and cadmium stresses compared to wild-type plants [111]. Induction of tobacco peroxidases occurred in plants expressing both CHIT42 and CHIT33 indicating that these genes may confer heavy metal tolerance by inducing the expression of genes involved in oxidative stresses.

46.6.2 Cadmium

Compared to many other heavy metals, a significant amount of research has been performed on utilizing tobacco to study genes involved in conferring cadmium tolerance to tobacco. Overexpression of bacterial *ArsC*, encoding arsenic reductase in tobacco, yields up to a threefold increase in biomass accumulation compared to wild-type plants in media containing 100 μm $CdCl_2$ [112]. While no concrete mechanism has been associated with Cd tolerance by *ArsC*, it is hypothesized that ArsC may participate in the reduction of Cd(II) to Cd[0], a nontoxic cadmium form that may then be safely stored within the plant cell. Removal of ROS intermediates prevents the toxic effects of these ROS induced by the presence of heavy metals.

Overexpression of alfalfa/aldehyde reductase in tobacco reduces chlorosis in high concentrations of cadmium possibly through detoxification of the product 4-hydroxynon-2-enal produced via lipid oxidation [58, 113]. A similar mechanism likely confers tolerance to cadmium-induced stress in tobacco overexpressing the glutathione transferase gene from *Trichoderma virens* [114]. Glutathione transferases are thought to allow for this tolerance by binding lipid peroxidation products to glutathione.

46.6.3 Iron

Iron represents an interesting model of heavy metal stress. Plants require iron for many biological processes; however, increased levels of iron within plant cells can induce reactive oxygen species via the Fenton reaction [100, 115]. Typically, biological systems store iron reserves conjugated with proteins known as ferritins; however, excess iron is still able to cause stress [100, 116]. Transgenic studies on tobacco display that overexpression of ferritin results in lower levels of lipid peroxidation products and higher rates of photosynthesis under conditions promoting the production of ROS due to paraquat application [117]. However, overexpression of ferritins in tobacco results in phenotypes resembling iron deficiencies, as available iron pools are likely limited in the plant [118]. Overexpression of ferritins results in a 1.3–1.5-fold increase in total iron content [119].

46.6.4 Mercury

Mercury is present in many forms within the environment including Hg^{2+}, volatile Hg^0, and organic mercury, specifically methylmercury [120, 121]. Hussein *et al.* [122]

displayed that expression of *merA* and *merB* via the chloroplast genome of tobacco provided increased tolerance to mercury. *merB* encodes for a protein that removes organic groups from organomercury, which is highly toxic to plants due to interference in electron transport and chlorophyll in the chloroplasts. *merA* encodes for a protein that reduces toxic Hg^{2+} to volatile elemental Hg^{0}. With high levels of these detoxifying enzymes in the chloroplasts, transgenic tobacco was able to accumulate high mercury levels and volatize mercury at high rates compared to tobacco not expressing these genes.

An alternative approach for mercury phytoaccumulation instead of phytovolatilization was performed in tobacco [109, 123]. Nagata *et al*. engineered tobacco to express *merT*, a mercury transport protein, and *ppk*, a bacterial polyphosphate kinase that is able to chelate mercury ions and prevent volatilization. The mercury transport protein drastically increased the uptake of mercury compared to *ppk* only plants at Hg^{2+} concentrations of 2.5 μM and below. When comparing *ppk* tobacco, *ppk*/*merT* tobacco, and wild-type plants growing in media containing Hg^{2+}, both plants containing the *ppk* transgene gained the ability to accumulate significantly higher biomasses, indicating fewer effects of the toxicity of mercury. Addition of the merB gene to tobacco containing *ppk*/*merT* transgenes further increased mercury tolerance [124].

46.7 Conclusions

The convenience of being able to genetically engineer both nuclear and plastid genomes separately or simultaneously is present only in tobacco. Despite the fact that *Arabidopsis* has emerged as the dicot model over the years, tobacco continues to be employed extensively in analysis of several plant mechanisms as is evident in this chapter.

Sunflower: Improving Crop Productivity and Abiotic Stress Tolerance

Carlos A. Sala, Mariano Bulos, Emiliano Altieri, and María Laura Ramos

Conventional breeding has been successful in constantly raising the sunflower (*Helianthus annuus* var. *macrocarpus*) yield potential and its stability. This improvement has been possible through both the direct manipulation of several genes controlling resistance to fungal diseases, pests, and parasitic weeds and the indirect selection of quantitative trait loci that control heritable variability of the traits and physiological mechanisms that determine biomass production and its partitioning. However, this approach may now be insufficient, since genetic progress has been slower in recent decades, and it is necessary to provide improvements at a rapid pace due to the redistribution of sunflower production toward marginal areas, due to the rapid changing cultural practices such as no-till planting or weed management, and due to the increases in the frequency and severity of abiotic constraints because of global climate change. Research in the last decades led to three main approaches to change the objectives and the current tools for sunflower breeding. First of all, plant physiology provided new tools and models to understand the complex network of yield- and stress-related traits in order to identify target traits useful to improve selection efficiency. Second, molecular genetics has led to the discovery of a large number of loci affecting yield under potential and stress conditions or the expression of stress tolerance-related traits. Third, molecular biology has provided genes that are useful either as candidate sequences to dissect QTL or for transgenic approaches. In this chapter, we reviewed and discussed molecular breeding strategies to improve sunflower yield potential and its tolerance to abiotic stresses and xenobiotics, emphasizing the requirement to face this task through an integrated multidisciplinary approach based on plant genetics and genomics, physiology, and modeling.

47.1
Introduction

Sunflower (*Helianthus annuus* L. var. *macrocarpus* Ckll.) is grown all over the world with three main purposes: beauty (ornamental sunflower), direct consumption of the seeds (confectionary sunflower), and oil production (oilseed sunflower). By far,

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

the last of them is the most important objective in terms of acreage and production [1] and is the subject of this chapter. Sunflower oil has been traditionally viewed as a healthy vegetable oil and it is considered a premium oil for salad, cooking, and margarine production [2] and is also being evaluated as a source of biodiesel [3].

With a cultivated acreage of over 22 million ha and an annual production of around 9 million ton, sunflower is grown on every continent, but its production is mainly concentrated in the Russian Federation, Ukraine, India, and Argentina. Sunflower oil is the fourth most important vegetable oil in world trade after soy, palm, and canola oils. Unlike soybean, sunflower is primarily an oil crop, with high protein meal being a by-product. The world production of sunflower pellets is also important, as it is the principal grinding subproduct. Argentina is the leading exporter and the European Union is the greatest importing block [4].

Morphological, geographical, molecular, and archeological evidence indicates that sunflower domestication took place in eastern North America [5–7], where it was used as a source of food, pigment, and medicine by the Native American Indians [8]. A substantial genetic bottleneck occurred during domestication, both at the nuclear [9] and at the plasmon levels [7]. In fact, the cultivated sunflower gene pool has retained only 40–50% of the nucleotide diversity that can be found in wild sunflower populations [10].

The transformation of sunflower into a major oilseed crop, however, took place only in the second half of the twentieth century due to two major breeding achievements: the drastic increase in oil percentage in sunflower achenes achieved in the former Soviet Union from 1920 to 1960 [11] and the development of a cytoplasmic male sterility system [12] combined with fertility restoration by nuclear genes [13] that enabled the commercial production of hybrid seed [14, 15]. Even though domestication and breeding create population bottlenecks and eroded genetic diversity in sunflower [6, 9, 10], diverse and complex parentage and migration have apparently partially counteracted the effects of domestication and other diversity-reducing processes in modern oilseed sunflower inbred lines [16]. Significant nucleotide diversity was discovered across inbred lines despite the effects of genetic drift and the winnowing of unfavorable alleles through intense selection and inbreeding in single-cross hybrid sunflower breeding programs. Surprisingly, nucleotide diversity was estimated to be 1.7-fold greater in elite inbred lines than primitive and early open-pollinated (OP) cultivars. In fact, nucleotide diversity in sunflower is only slightly lower than maize, two- to fivefold greater than other domesticated grasses, eight- to tenfold greater than soybean, and several-fold greater than other autogamous plant species [17].

Crop performance is the end result of the action of thousands of genes and their interactions with environmental conditions and cultural practices. Conventional breeding has been very successful in constantly raising the sunflower yield potential and its stability. This improvement has been possible through the direct manipulation of several genes controlling resistance to fungal diseases, pests, and parasitic weeds, and the indirect selection of quantitative trait loci (QTL) that control heritable

variability in the traits and physiological mechanisms that determine biomass production and its partitioning. This last approach came into being with little or no knowledge of the factors governing the genetic variability exploited by breeders for crop improvement. However, this approach may now be insufficient since it is necessary to provide improvements at a rapid pace due to the redistribution of sunflower production toward marginal areas and due to the increase in the frequency and severity of abiotic constraints because of global climate change. Cold stress, drought, and salinity will probably become more prevalent in certain areas, while there will be an increased demand for agricultural products and reduced availability of agricultural land and natural resources such as water and fertilizers. Finally, breeding also needs to exploit positive interactions with rapid changing cultural practices such as no-till planting or weed management.

We review and discuss published results about molecular breeding strategies to improve sunflower yield potential and its tolerance to abiotic stresses and xenobiotics, emphasizing the requirement to face this task through a multidisciplinary approach based on plant genetics and genomics, physiology, and modeling.

47.2 Breeding Achievements

Scientific sunflower breeding was started in 1910–1912 at Krasnodar by Vasilii Stepanovich Pustovoit, an academic, based on the varieties locally developed during the nineteenth century [18]. The efforts of breeders were initially devoted mainly to genetically control parasitic weeds (broomrape, *Orobanche cumana*) and insects (sunflower moth, *Homeosoma electellum*), but the development of varieties with high oil content by Pustovoit became a milestone in the evolution of sunflower as an oil crop throughout the world. The local varieties cultivated in Russia in 1913 contained only 30–33% of oil in dry seeds. This percentage increased up to 43% in 1935, 46% in 1953, and 51% in 1958, when the variety "Peredovik" was released [18]. This spectacular increase in oil content of the achenes did not cause any decline in the seed yield of the varieties released. The open pollinated Russian cultivar Peredovik, with high oil content, introduced during the 1960s in the Western countries (the United States, Canada, Western Europe, and Argentina), was the basis of the first sustained commercial production of oilseed sunflower in these countries [19].

The discovery of cytoplasmic male sterility, with its inherent advantages, provided a highly efficient method for commercial production of hybrid seed and was the second milestone in the development of sunflower. The first stable source of cytoplasmic male sterility was discovered by Patrice Leclercq in 1968 from an interspecific cross involving *H. petiolaris* and *H. annuus* [12]. Subsequent identification of genes for fertility restoration in wild species [13] and in certain obsolete sunflower cultivars [20] allowed an efficient and economical production of hybrid seed. The development of the first sunflower hybrids based on cytoplasmic male

sterility in the early 1970s intensified the interest of seed companies in the crop, which led to a considerable increase in sunflower production in many countries. When comparing sunflower yields in the countries that grew open-pollinated varieties before the introduction of hybrids, seed yields increases of about 20% were estimated [19].

Information regarding breeding achievements with respect to seed and oil yields after the initial introduction of hybrids is scarce. The main exceptions are the results reported for Argentina [21–25]. Taking into account that approximately 1.9 million ha of sunflower is grown in Argentina between latitudes 26° S (Chaco province) and 39° S (southern Buenos Aires province), that this area includes a wide range of environmental conditions (subtropical and temperate climates and different types of soils) and management practices, breeding achievements for sunflower in Argentina are a representative example of other regions in the world and will be considered in this chapter.

The relative contributions of plant breeding and crop management to yield improvement over time in a given cropping region can be separated (e.g., [26, 27]). Genetic gains can be estimated by comparing a historic set of cultivars with uniform management practice or the trial data collected by breeding programs. This gain in relative terms is subtracted from the total gain in farmers' fields and the residual is assumed to be due to changes in management practices [28].

Using this approach and a set of sunflower cultivars released in Argentina between 1930 and 1995, López Pereira *et al.* [21] found that both grain and oil yields were positively associated with the year of cultivar release and that there was a clear discontinuity in yield trends with a marked step around 1970, when the first hybrids were released. On average, hybrids outyielded open-pollinated cultivars by 23% for grain and 36% for oil. No improvement in yield potential, however, was apparent during long periods before and after this turning point (Figure 47.1). These authors hypothesized that the historic requirement for disease tolerance and grain quality, together with a rather narrow genetic base, has imposed restrictions on the improvement in yield potential. In further studies, focusing on the genetic gain by selection in the period between 1983 and 1998, Sadras *et al.* [24] found a positive association between oil yield and year of commercial release, which was related to both resistance to fungal diseases (specially verticillium wilt, caused by *Verticillium dahliae*, [29, 30]) and response to intraspecific competition.

Using meta-analysis of multienvironment trials [31], de la Vega *et al.* [32] quantified increases in oil yield and determined the contributions of change in both biotic stress resistance and yielding ability in favorable environments for sunflower hybrid varieties released during the period 1995–2005. Genetic gains came about due to both an increase in the number of hybrids with resistance to the major biotic stress (*V. dahliae*) and a genetic gain in oil yield of 14.4 kg ha^{-1} yr^{-1} in these resistant hybrids. It is likely that at least part of the slowdown observed in grain yield gains in the national data during 1995–2005 was a result of a breeding process that, for that period, increased oil yield mostly through an increase in grain oil concentration [32] and, also, because of the presence of large and regional genotype × environment (G × E) interactions [25].

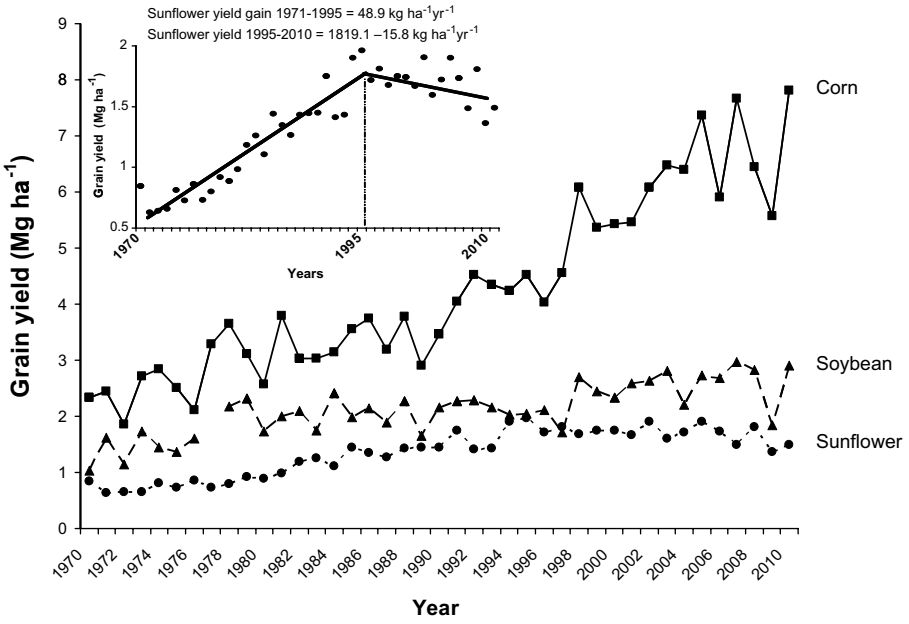

Figure 47.1 Comparison of sunflower, maize, and soybean grain yields per hectare in Argentina over the past 40 years. Two main aspects permit to explain the bilineal relationship between mean sunflower yields and year, as shown in the box: (a) national data accounts only for mean grain yield and not oil content that was a main breeding objective during the past two decades; (b) the explosive growth of soybean in Argentina, which increased from 6.0 million ha planted area in 1994 to more than 15 million ha in 2010, has pushed sunflower production to more marginal areas [32] (data obtained from [298]).

47.3
Identification of Key Traits Useful for Increasing Yield Potential and Abiotic Stress Tolerance

Conceptually, the environmental effect on a genotype depends on three main elements: soil, cultural practices, and weather. Soil and cultural practices are usually persistent from year to year and can be regarded as fixed. The weather element is more complex because it has a persistent part represented by the general climatic zone and an unpredictable part represented by time variation (year to year). Once the environmental effect has been conceptually subdivided into predictable and unpredictable components, a similar subdivision can be made for the G×E interaction [33, 34]. Understanding of the underlying physiology of the genotype-specific responses to predictable and unpredictable environmental variation would improve the efficiency of selection within a complex target population of environ-

ments [25, 35, 36]. On the other hand, it permits to identify key traits as targets for selection to cope with the predictable and unpredictable elements of the environment in a given region, namely, (i) attributes that can be selected to achieve adaptation to the target environment by emphasizing predictable interactions (e.g., phenology and photoperiodic response; duration of grain filling, a trait associated with canopy stay green; and salt and cold tolerance) and (ii) attributes that allow the unpredictable G × E interactions to be accommodated, improving yield stability in a target production environment (e.g., osmotic adjustment, leaf expansion, etc.).

Sunflower is a glycophyte species moderately tolerant to salinity and is considered in the same tolerance category as soybean [37]; therefore, it can be grown successfully on most agricultural soils [38]. However, if the competence with other crops requires the expansion of the sunflower crop to regions with saline soils, apparently there exists enough genotypic variability and medium-to-high heritabilities for salt tolerance in sunflower, in order to develop salt-tolerant sunflower hybrids by conventional breeding methods [39–41]. In addition, genetic resources from wild species [42–46] have been exploited to develop salt-tolerant lines [47, 48].

Higher yield stability in regions with marked interyear variability in rainfall, a characteristic of drought-prone areas, involves the identification, testing, and breeding for particular attributes. Identification of such attributes can be assessed by comparing a range of genotypes over several years, under both irrigated and rainfed conditions that produced terminal droughts. This approach was followed by Fereres *et al*. [49] and Giménez and Fereres [50] in an extensive comparative analysis of drought tolerance in sunflower. They showed that yield under drought was closely associated with harvest index and found intraspecific variability in root depth, which in turn was linked to cultivar maturity type. They also identified variability for both sensitivity of leaf conductance to leaf water potential and for osmotic adjustment (OA). Furthermore, they found no association between yield potential and susceptibility to drought indicating that the development of high-yield, drought-tolerant cultivar is possible [51].

As was pointed out by Connor and Hall [51], evidence suggests that it should be possible to breed for tolerance to some categories of stress in sunflower without loss of yield potential because there are firm indications of intraspecific variability in traits that confer tolerance (see Ref. [52] for a review). The likelihood of success will be increased if work is geared toward the identification of key attributes based on a good understanding of the causal relationships between the presence of a trait and the physiology of yield loss minimization under stress [53]. Further progress will depend on the introduction in high-yield genotypes of traits able to improve stress tolerance without detrimental effects on yield potential, thus reducing the gap between yield potential and yield in stress-prone environments. This goal can be achieved through the identification of stress tolerance-related traits and the subsequent manipulation of the corresponding genes using marker-assisted selection (MAS) and/or gene transformation.

47.4
Linkage Mapping

47.4.1
Genetic Linkage Maps and other Genomic Resources

Over the past decades, several genetic linkage maps differing in length and density were developed for cultivated sunflower (a paleopolyploid, [54]; with $2n = 2x = 17$ chromosomes) or for crosses between cultivated and wild sunflowers (see Refs [15, 55] for reviews). These maps are based on different molecular markers such as restriction fragment length polymorphism (RFLP) and/or random amplification of polymorphic DNA (RAPD) markers for the first reported maps [56–63]. RAPDs have been used primarily for tagging phenotypic loci in sunflower, for example, rust (*Puccinia helianthi* Schw.) and broomrape-resistance genes [64, 65]. Later on, the addition of Amplified Fragment Lenght Polymporphism (AFLPs) [66–68] and direct amplification of length polymorphism markers (DALPs) [69] allowed further saturation of genetic linkage maps. The distribution of DALPs and AFLPs revealed that both markers tagged different regions to enable covering most of the sunflower genome.

Another multipoint marker developed for sunflower and used for mapping purposes are the so-called target region amplification polymorphisms (TRAPs), using EST database information to generate polymorphic markers around targeted candidate gene sequences [70]. The TRAP technique has been employed in sunflower to construct a linkage map [71], to define the sunflower linkage group (LG) ends through the use of TRAP markers based on *Arabidopsis*-type telomere repeat sequences [72], to map several traits (e.g., *ms9*, [73]; a gene for downy mildew resistance, [74]; the chlorophyll-deficient mutation *yl*, [75]; the fertility factor *Rf1*, [76]), and to assess germplasm relationships.

Two of the RFLP maps have been used as tools for mapping phenotypic and quantitative trait loci [77–85]; however, the widespread use of RFLP markers and maps in sunflower has been restricted by lack of public RFLP probes, a consequent lack of a dense public RFLP map, and low-throughput nature of RFLP markers. The difficulties posed by the historic lack of public, single-copy DNA markers were only slightly offset by the emergence of facile, universal DNA markers, such as RAPDs, AFLPs, and TRAPs. While RAPD, AFLP, and TRAP markers have a multitude of uses, they are dominant, multicopy, and often nonspecific in nature and, as a whole, unsatisfactory for establishing a genome-wide framework of DNA markers for anchoring and cross-referencing genetic linkage maps. Single-copy, codominant DNA markers are preferred for such purposes and until 2002 were lacking in sunflower [86].

The concomitant development of a large number of simple sequence repeat (SSR) markers and the automation of mapping procedures [87–89] eliminated the long-standing bottleneck caused by the scarcity of single-copy DNA markers in the public domain and supplied the critical mass of DNA markers needed to create a public reference map, unify independently developed molecular genetic linkage maps, and establish an universal LG nomenclature. Tang *et al.* [88] constructed the first genetic

linkage map for sunflower on the basis of SSR markers and the first dense public genetic linkage map on the basis of single- or low-copy DNA markers. Since the three RFLP maps of sunflower lacked common, public domain DNA markers, QTL and other trait mapping results could not be universally exploited, compared, or validated, this resource created the basis for rapidly, efficiently, and fully integrating first-generation genetic linkage maps developed by using RFLP markers. Yu *et al.* [90] integrated and cross-referenced the Tang *et al.* [88] SSR map with the RFLP maps of Berry *et al.* [58] and Jan *et al.* [59] using the Gedil *et al.* [67] RFLP map as a bridge. Insertion–deletion (INDEL) markers were also developed from RFLP markers by sequencing the cDNA clones, aligning sunflower cDNA and *Arabidopsis* genomic DNA sequences, predicting from such an alignment intron sites in sunflower genes, and designing flanking primers to amplify the introns and flanking coding regions spanned by the primer pairs. The density and utility of the molecular genetic linkage map of cultivated sunflower was increased by adding unmapped SSR markers developed by European researchers (Cartisol, CRTx SSRs), together with those already developed by North American (ORSx SSR markers) and South American researchers (INTA Argentina, Hax markers; [87]). These efforts contributed to the availability of more than 2000 SSR markers for mapping purposes in sunflower [55]. All the reported linkage maps can be easily viewed and compared using a useful web-based application: CMap [91].

Most of the SSR markers used in sunflower mapping are neutral (usually located in intergenic genomic regions), as they were developed from genomic libraries using microsatellite motives as hybridization probes [87–89]. In recent years, due to the rapid increase in sequence information, sunflower transcript assemblies were built and mined to identify SSRs and INDELs for marker development, comparative mapping, and other genomics applications in sunflower. In fact, more than 320 000 expressed sequence tags (ESTs) have been generated and are available for sunflower and related species of the genus *Helianthus* [92]. The information can be accessed through the Compositae DataBase [93], the GenBank dbEST division [92], the Compositae Genome Project [94], and the Gene index accessible through the GenBank UniGene division [95].

To create a transcript map for sunflower, Lai *et al.* [96] identified 605 ESTs that displayed small INDEL or single-nucleotide polymorphism (SNP) variations *in silico*, had apparent tissue-specific expression patterns, and/or were ESTs with candidate functions in traits such as development, cell transport, metabolism, plant defense, and tolerance to abiotic stress. Primer pairs for 535 of the loci were designed from the ESTs and screened for polymorphism in recombinant inbred lines (RIL). In total, 273 of the loci amplified polymorphic products, of which 243 mapped to the 17 LGs of sunflower. Comparisons with previously mapped QTL revealed some cases where ESTs with putatively related functions mapped near QTLs identified in other crosses for salt tolerance and for domestication traits such as stem diameter, shattering, flowering time, and achene size. The generation of EST-SSR and SNP markers complemented existing SSR marker collections [97, 98] allowing the inclusion of functional markers in genetic maps [96, 99]. Through direct sequencing of sunflower genomic regions, belonging to a small group of inbreds and landraces, more than

1700 SNPs and 147 INDELs were obtained [10, 17, 100]. Recently, a restriction site-associated DNA sequencing technology for SNP discovery identified more than 1400 unique contigs with at least one high-quality SNP [101].

Sequencing more diverse EST libraries within cultivated sunflower or from wild sunflower species could enhance the number of polymorphisms discovered. It is questionable, however, whether all these polymorphisms would also be segregating in the available mapping populations. As shown in maize and its wild relative teosinte [102], cultivated maize harbors much less polymorphism than teosinte. A framework to integrate all the reported information concerning sunflower genomics and to generate the basis for future research is the Sunflower Genome Sequencing Project [103], which is still in progress.

47.4.2
Recombinant Inbred Lines Used for Mapping Purposes

Populations of RILs have been used for developing reference linkage maps of the sunflower genome and for QTL mapping studies. Two of them were used and reported on several occasions and for this reason both of them will be described here in some detail.

The population of RILs from the cross RHA266 × PAC2 was developed by the INRA in France. RHA266 is a restorer, unbranched, oilseed sunflower line, released in 1971 by the USDA-ARS and Texas Agricultural Experiment Station [104]. It is based on Peredovik germplasm crossed by a line with rust resistance, 953-102-1-1-41. PAC2 is a line developed by INRA and was obtained from a cross between the USDA line HA61 and a wild *H. petiolaris* population [57].

The other population of RILs was developed by US researchers from the cross RHA280 × RHA801 [88]. RHA280 is a restorer, unbranched, nonoilseed sunflower (confectionary) inbred line developed by selection from Sundak and released in 1974 by the USDA. RHA801 is a restorer, branched, oilseed sunflower line, developed and released by USDA in 1981, and derived from a restorer population with a complex pedigree after one cycle of recurrent selection for improved yield [105].

These populations represent interesting tools for mapping studies because they were used as a framework for developing linkage maps obtained with different kinds of molecular markers. However, their use as populations to identify yield or stress-related traits may be limited by the little differences between their parental lines for many of the features under study and because none of them is a high-yield modern inbred line, so the QTL obtained using these RILs may now be ubiquitous in the elite germplasm.

47.4.3
QTL Mapping

Yield and tolerance to abiotic stress are complex traits regulated by a number of factors that can be studied as component traits. The development of different

genetic maps for sunflower allowed genetic dissection of the quantitative traits controlling a wide range of physiological characteristics related to oil yield and the adaptive response of sunflower to abiotic stress. This is a prerequisite to allow cost-effective applications of genomics-based approaches to breeding programs aimed at improving the sustainability and stability of yield under adverse conditions.

47.4.3.1 Oil Yield

Most cultivated sunflower is grown as a source of vegetable oil. Thus, the principal goal of sunflower breeding programs is to develop F_1 hybrid cultivars with high oil yield. Sunflower oil yield per unit area is determined by the product of seed yield per unit area and oil percentage in the seed. Therefore, consideration of both components is important when breeding for high oil yield hybrids.

Seed oil concentration is a complex trait determined by the genotype and the environmental conditions. Search for seed oil concentration QTL using a genetic map of 205 loci defined by RFLP [81] and composite interval mapping resulted in the detection of eight QTL on seven LGs that accounted for 88% of the phenotypic variation for seed oil concentration across environments [79]. Gene action was additive for four QTL and dominant or overdominant for the others. Four of the eight QTL were detected in two or more environments, and the parental effects were the same across generations and environments. In another study, six QTL for percentage of oil in the grain were detected using a set of 244 F_3 families derived from another cross and a genetic map based on 170 AFLP and SSR markers. The percentage of phenotypic variance explained was 90.4% [106]. On 220 F_2 and 180 F_3 progenies of different genetic origin, and using a genetic map based on RFLP and SSR [107], four QTL were identified in both F_2 plants and F_3 families on four LG, which explained 68–70% of the phenotypic variance. Tang *et al.* [108] identified six QTL for seed oil content in a low- $\times$ high-oil (RHA280 $\times$ RHA801) RIL mapping population segregating for apical branching (*B*), phytomelanin pigment (*P*), and hypodermal pigment (*Hyp*) loci. The seed oil concentrations of RHA280 and RHA801 differed dramatically, from 254 to 481 g kg^{-1}, respectively. Interestingly, three of the QTL were tightly linked to *B*, *P*, and *Hyp*. The same relationship between apical branching and seed oil content was observed in other mapping populations [109, 110].

Hajduch *et al.* [111] using a proteomic approach reported 77 protein spots differentially expressed in the high oil line RHA801 versus the low oil line RHA280. Identification of 44 of these proteins indicated that the two main processes affecting low or high oil concentration in these lines were glycolysis and amino acid metabolism suggesting that seed oil content is tightly linked to carbohydrate metabolism and protein synthesis in a complex manner. Although the number of differences found by these authors should not be related only to seed oil content as they stated, since RHA801 and RHA280 are not isolines but members of rather different gene pools, their results describe the proteomic differences between confectionary and oilseed varieties.

47.4.3.2 Seed Weight

Seed weight is an important property under complex genetic and environmental control, and associated with morphological and developmental characteristics such as plant height or flowering dates. A set of 244 F_3 families was screened with AFLP and microsatellite markers and a linkage map was constructed based on 170 markers. One putative QTL for 1000-grain weight was detected explaining 5.4% of total phenotypic variance [106]. Al-Chaarani *et al.* [68] reported three QTL for this trait and one of them was a major QTL that explained 37% of the phenotypic variance for this trait.

Using a genetic map with 290 markers for a cross between two inbred sunflower lines and 2 years of observations on F_3 families, two QTL controlling seed weight were detected. Phenotypic variation explained by both QTL were 16.0 and 25.2 for F_2 an F_3 populations, respectively. Some of the QTL controlling seed weight overlapped with those controlling oil content. The QTL on the same LG as the branching gene *b1*, also reported by Mestries *et al.* [109] for another cross, was almost certainly linked to capitulum size. The second QTL for seed weight was close to the one for flowering date. The seed weight character measured is not "yield" in the agricultural sense of seed production per hectare of hybrid genotypes. It was seed weight per capitulum on selfed plants, with little involvement of heterosis [110].

In the RIL population from the cross RHA280 × RHA801 mentioned before, five QTL controlling seed weight were reported explaining 72.8% of the phenotypic variation. However, the contribution of the pleiotropic effect of the apical branching gene *B* accounted again for the bulk (52.5%) of this variation.

47.4.3.3 Days to Flowering

Sunflower can be grown under a wide variety of climatic conditions so a wide range of total crop durations are required around the world. In addition, knowledge of the relative lengths of the period from sowing to flowering, when potential seed number is determined, and of the period from flowering to maturity, when seed filling occurs, can be important in breeding for yield. Present-day sunflower varieties show wide variation in these characters.

Diversity of the production area together with the characteristic of the original germplasm base and the subsequent introduction of foreign germplasm determined the coexistence of a great variability in types of hybrids grown in Argentina. Historically, two major hybrid types of different genetic origin were grown in the Argentine sunflower production area from the 1970s to early 1990s: (i) intermediate-late to late maturity hybrids of white-striped seed, low grain oil concentration, and high relative grain yield, mostly developed from locally bred, open-pollinated varieties, and (ii) intermediate-early to early maturity hybrids of black seed, high grain oil concentration, and low relative grain yield, largely derived from Eastern European and US germplasm. Breeding and selection by recombining both types converged to a third hybrid type that combined high grain yield and high grain oil concentration with an intermediate maturity. The breeding process involved the selection of the maturities that tended to maximize yield potential and stability in each of the three megaenvironments or subregions of sunflower production in

Argentina [25]. This process reduced the original range of phenological responses within subregions, but tended to concentrate on different maturity types among megaenvironments. The modern high-yield hybrids are late, intermediate, or early compared to the mean of the old ones in the northern, central, and southern subregions of Argentina, respectively, which in turn reflects the positive, orthogonal, and negative associations between oil yield and maturity in the three subregions [25].

León *et al*. [78] mapped QTL associated with growing degree days (GDD) to flowering and photoperiod (PP) response in an elite sunflower population derived from a cross of two divergent lines representative of the two original germplasm pools: HA89 and ZENB8 [25]. HA89 exhibits an ambiphotoperiodic response (short- or long-day response depending on photoperiod); it shows its longest relative maturity when the photoperiod at emergence is about 11–13 h and a long-day response at longer day lengths. Relative to ZENB8, HA89 line types require more growing degree days to flower when the photoperiod during emergence is equal to or less than 14 h. This type of response reflects that of group II hybrids, which are relatively late in the northern subregion, where emergence and vegetative period occur under short photoperiods, and relatively early in the central and southern subregions, where later planting and higher latitudes are associated with longer photoperiods for the same crop phase. The line ZENB8 exhibits a day-neutral to short-day response, and takes more days to flower than HA89 under photoperiods longer than 14 h; this type of response being representative of that of group I hybrids.

Two hundred and thirty-five F_2-generation plants and their $F_{2:3}$ and $F_{2:4}$ progenies of a single-cross population derived from the cross HA89 × ZENB8 were evaluated in six environments (locations, years, and sowing dates) with photoperiods known to elicit a PP response between the inbred lines. Detection of QTL was facilitated with a genetic linkage map of 205 RFLP loci and composite interval mapping. Six QTL in LGs A, B, F, I, J, and L were associated with GDD to flowering and accounted for 76% of the genotypic variation in the mean environment; however, QTL in LG A and B accounted for 72% of the genetic variation and were highly dependent on PP. QTL mapping of the ratio of the GDD required by a progeny to flower at a PP of 12.1 and 15.0 h, defined as the photoperiod response (PPR), suggested that alleles at QTL in LG A and B were responsive to PP. QTL in LG F and J showed QTL × E interaction but the LOD values were not associated with PP. QTL × E interactions for additive effects were highly significant for LG A, B, and F. QTL × E interactions for QTL with dominant effects were significant for LG A, B, and J. The dominant effect of QTL in LG B increased in environments with a longer PP [78].

Given these two QTL (A and B) that are strongly associated with the photoperiod response that controls GDD to flowering, Fonts *et al*. [112] examined the phenology of near-isogenic families bearing all combinations of alleles for both of them associated with photoperiodic response when growing in controlled environment chambers under short and extended photoperiods. Plants were harvested at intervals, the apices dissected out, and apex development from the start (apex transformation) to the end of floral differentiation scored. Near-isogenic lines (NILs) exhibited significant effects of photoperiod, QTL, QTL × photoperiod, and QTL × QTL interactions for the timing of apex transformation and for the inverse of rate of development during

floral differentiation. The strong QTL A × QTL B interaction for both traits reflects a much greater delay in development under both photoperiods when QTL A was derived from HA89 and QTL B from ZENB8. Also, they found a three-factor (QTL A × QTL B × photoperiod) interaction, acting on the rate of development during the floral differentiation process [112]. Interestingly, some of the combinations of alleles at both QTL should be representatives of the type III group of high-yield hybrids grown in Argentina. These and other alleles may be used to achieve a better match between the edaphoclimatic supply and the physiological requirements during critical periods of the crop in different production areas of the world. This better adaptation to the predictable environmental variation should be complemented with a better understanding of the physiological and genetic causes underlying genotypic differences for the duration of the grain filling period.

47.4.4
Mapping QTL for Yield-Related Traits under Stress Conditions

Generally, QTL studies in sunflower have been performed under only one water regime. Such studies do not lead to separation of constitutive QTL from adaptive ones. Sorting out constitutive from adaptive QTL effects is possible by evaluation of the same mapping population under different conditions. These studies permit to investigate the genetic basis of trait association by looking for colocation of corresponding QTLs for yield-related traits on the genetic map under stress and nonstress conditions as exemplified below.

Using a set of sunflower RILs derived from the cross PAC2 × RHA266, Ebrahimi *et al.* [113] determined the effects of water stress on several seed quality traits including oil content in the seed, and mapped QTL controlling these traits under two different water treatments. Interestingly, in spite of that there were no significant differences for oil content in the seed between both parents in the four environmental conditions, significant variation among RILs was observed. Genotype × environment interaction was detected only for the RILs under greenhouse but not under field conditions. Eighteen QTL for oil content were detected under well-watered conditions and eleven under stress conditions, but only three of them were common to both treatments, although the phenotypic correlation for oil content under both water regimes was significant. Both parental lines contributed to the expression of oil content. The most important QTL for oil content was found on LG 16 and explained 16% of the phenotypic variance. The positive alleles for this QTL come from RHA266. Four other QTL for this trait under both water treatments were found on LG 16, so this region appears to be important for oil content under water-stressed and well-watered conditions. Two QTL, in LG1 and LG16, were also reported by Tang *et al.* [108] for oil content in sunflower recombinant inbred lines.

QTL controlling four chlorophyll fluorescence parameters were analyzed in the same population of RILs under well-watered and water-stressed conditions in 45 day-old plants at stage near flower bud formation. A large genetic variation and transgressive segregation were observed for the traits studied under two water

treatments. Results showed that the progressive water stress did not cause long-term downregulation of photosynthesis apparatus, but it reduced actual efficiency of PSII electron transport. QTL analysis showed that several putative genomic regions were involved in the total variation of chlorophyll fluorescence parameters under two water treatments. Among the 26 QTL detected under well-watered conditions, 5 were shown to be constitutive by QTL-by-water treatment (environment) interaction. Most of the QTL were specific for one condition, demonstrating that the genetic control of the expression of the traits related to photosynthesis differed under different water conditions. In several cases, one QTL was found to be associated with more than one trait. The results also showed overlapping QTL for some of the chlorophyll fluorescence parameters and plant water status traits described above, mainly on LGs 7 and 16 [114].

The same population of RILs was used to study agronomical traits under greenhouse and field conditions, each with two water treatments. The difference among RILs was significant for all the traits studied under all conditions; and water treatment × RIL interaction was also observed for most of the traits under both field and greenhouse conditions. Several QTL were identified for yield-related traits with the percentage of phenotypic variance explained by QTL (R^2) ranging from 4 to 40%. QTL for grain yield per plant under four water treatments were identified on different LGs, among which two were specific to a single treatment. Three QTL for grain yield per plant were overlapped with several QTL for some of the drought-adaptive traits described before [115].

Differential display analysis was used to compare overall differences in gene expression between drought- or salinity-stressed and unstressed (control) plants of sunflower. Five drought-regulated cDNAs and twelve salinity-regulated cDNAs were cloned and sequenced. Thirteen of these cDNAs were confirmed to be expressed differentially in response to drought or salinity stress by quantitative reverse transcriptase polymerase chain reaction (RT-PCR). Regulation of the expression of these 13 genes was analyzed in leaves of drought-stressed plants and in roots and shoots of drought- and salinity-stressed seedlings. Results showed that certain genes respond to both stresses, while others are uniquely regulated either in terms of the stress stimulus or in terms of the plant tissue [116]. In this context, results of QTL analysis for different traits under stress and nonstress conditions confirm the differential display results and highlight the existence of adaptive QTL (or genes) that are detected (expressed) only under specific environmental conditions or modify its expression with the level of an environmental factor, and QTL (genes) consistently detected (expressed) across most environments.

Selecting which QTL/traits follow with MAS is crucial. The improvement of drought tolerance should not be achieved with a parallel limitation of yield potential. Hence, drought-tolerance traits should be tested in both stressed and nonstressed environments before being introduced in an MAS breeding program. QTL for drought-related traits coincident with QTL for yield potential should be considered as priority targets for MAS. However, confirmation and validation of the reported QTL in different genetic backgrounds should be performed prior to their utilization in breeding.

47.4.5
Mapping QTL for Stress-Related Traits

Genetic mapping with dense marker maps can be used to identify the number and genetic positions of QTL associated with specific traits that confer yield advantages under stress conditions. In addition, this process can be used both to estimate effects of the segregating QTL and their contributions to trait variation (individually and in combined QTL models) and to obtain estimates of their stability across environments and across genetic backgrounds. Trait-based physiological approach has been used successfully in other crops to improve performance in drought-prone environments [117] and it can be used in sunflower, integrated with an MAS approach, to improve yield and yield stability efficiently.

Three target traits in sunflower that can confer yield advantages in stress-prone environments and for which QTL analyses were reported are osmotic adjustment, leaf expansion, and cold tolerance during initial stages of development, and will be reviewed below.

47.4.5.1 Osmotic Adjustment

Osmotic adjustment refers to the lowering of osmotic potential due to the net accumulation of solutes in response to water deficits [118]. Since OA helps to maintain higher leaf relative water content (RWC) at low leaf water potential (LWP), it is evident that OA helps to sustain turgor maintenance and hence growth, while the plant is meeting transpirational demand by reducing its LWP [119, 120].

Chimenti and Hall [121] examined intraspecific variation in osmotic adjustment in sunflower using a collection of 33 genotypes of different origin, which were exposed to water stress at the 8-leaf stage. Changes in osmotic adjustment with ontogeny were also evaluated in the pre- and postanthesis phases using seven genotypes drawn from this collection. Estimates of OA were derived from measurements of leaf RWC and osmotic potential during a period in which the soil was allowed to dry gradually. All genotypes at the 8-leaf stage showed some degree of OA and significant differences in RWC were found between extreme genotypes in all three ontogenetic phases. The value of OA as a trait that can contribute effectively to yield maintenance under drought in sunflower was later examined by Chimenti *et al.* [122]. They screened a set of 25 inbred lines reputed to differ for drought tolerance for OA expressed in the 8-leaf stage. They crossed the extreme lines (high and low OA) and selected four individuals (two high OA, two low OA) from the F_2 population derived from this cross. Crops of F_3 families obtained by self-pollination of these individuals were grown under a rainout shelter and subjected to a 30 day drought ending at anthesis. High OA families expressed greater OA at full turgor, estimated as the difference in osmotic potential between drought and control treatments, than the low OA families at the end of the drought period. Crops of high OA families extracted more water from the profile during the stress period, had greater shoot biomass and harvest index at physiological maturity, and greater grain yield (~30%). There was no effect of OA on these variables in the irrigated controls [122].

The significant value of OA as a key trait contributing to drought tolerance in sunflower prompted the analysis of QTL and the development of markers for this

trait. Jamaux *et al*. [123] identified both physiological and molecular markers of OA based on two pools of genotypes differing for the trait. Two families of sunflower lines with contrasting OA, T− (low desiccation rate) and T+ (high desiccation rate), differed significantly in relative water loss (RWL) of excised leaves under watered and dry conditions. Since the T−/T+ lines had contrasting OA, the RWL criterion could be considered a marker of OA, at least in the T−/T+ genetic background. The higher the values of OA, the lower were the RWL values. Differential screening of two cDNA libraries, one obtained from a T− and the other from a T+ nonstressed sunflower plant, led to the isolation of three constitutive clones, DRS12, DRS14, and DRS26. Although no DRS12- and DRS14-related protein was found in databases, the DRS26 cDNA showed a high sequence homology and identity with a mammalian amino acid transporter, suggesting that the DRS26 polypeptide could be involved in vacuolar transport of osmolytes such as amino acids. RFLP analysis with the restriction enzyme *Bam*HI and the DRS26 cDNA probe differentiated the two families of sunflower and suggested a role for DRS26/*Bam*HI as a marker of T− genotypes. When bulk analysis with RAPDs was conducted, a primer was found that easily differentiated T− and T+ individuals [123]. Using an integrated and high-density linkage map based on SSR and AFLPs, Poormohammad Kiani *et al*. [124] localized 8 QTLs for OA on a population of 129 RILs. Four of them were colocated with QTL for other plant water status variables. A major QTL for OA on LG 5 accounted for 29% of the phenotypic variation. These exciting results indicate not only that OA is a key trait for developing sunflower genotypes with increased tolerance to water deficits but also that this complex and technically difficult-to-assess trait can be approached by MAS. However, more research is needed for QTL confirmation and validation before its practical implementation in sunflower breeding programs.

47.4.5.2 **Leaf Expansion**

During the vegetative phase, and to maintain plant water status within tolerable limits, the sunflower crop relies more on restricting interception of radiation and hence evaporative demand than it does on stomatal closure, due to its explorative root system. The sensitivity of leaf expansion to water deficit has been demonstrated in a number of studies. The results showed that crops subjected to water deficits before anthesis develop small leaf area index (LAI), but maintain activity per unit leaf area [125–129]. Even in crops that are visibly wilted, stomata do not close completely and photosynthesis continues [130]. The effects of water stress on leaf expansion are mediated by changes in both cell number and cell size. The latter effect predominates in leaves unfolding early during stress episodes and the former in later stages of exposure to stress, consistent with the partial temporal separation of the processes of cell division and expansion [131].

The extent of leaf growth reduction caused by water deficit is very important in determining the adaptation of a certain crop variety to a climate scenario. In a scenario where long-term droughts are expected, a genotype that reduces its leaf growth is more likely to reach maturity with a certain amount of available water. On the other hand, in a scenario where short-term water deficits are expected, a genotype that maintains leaf growth is likely to have higher yields [132]. It has been shown that a

genotype can maintain its leaf area by maintaining growth rate [132] or by increasing the duration of leaf growth [133]. Moreover, an increased duration of growth could have the benefit of increasing the opportunity for recovery after rainfall [134]. The natural genetic variability for these traits could be used to develop crop varieties adapted to specific scenarios. Despite this, breeding for these traits is not a common approach for obtaining drought resistance in crop species, probably because of a lack of well-characterized sources of genetic variability. In this sense, the work reported by Pereyra-Irujo *et al.* [135] is an important first step to determine the feasibility of this approach in sunflower breeding. Eighteen nonbranching sunflower inbred lines, comprising most of the genetic variability of cultivated sunflower, were selected by these authors to analyze the response of leaf growth to water deficit in order to identify and quantitatively describe sources of genetic variability for this trait that could be used to develop sunflower varieties adapted to specific scenarios. Plants were subjected to long-term, constant-level, water deficit treatments [136] and the response to water deficit quantified by means of growth models at cell, leaf, and plant scale [137, 138]. Significant variation among lines was found for the response of leaf expansion rate and of leaf growth duration, with an equal contribution of these responses to the variability in the reduction of leaf area. Intrinsic genotypic responses of rate and duration at a cellular scale were linked to genotypic differences in whole-plant leaf area profile to water deficit. The results reported suggested that genetic differences in leaf growth rate under water deficit could be determined by cell wall properties, while increased duration of leaf growth is partly due to a prolonged phase of epidermal cell division. This implies that rate and duration responses could be the result of different physiological mechanisms and are therefore capable of being combined to increase the variability in leaf area response to water deficit in sunflower [135]. Identifying the mechanisms underlying genetic differences in the response of leaf growth to water deficit and exploring the genetic base of the crop for these mechanisms are of paramount importance as initial steps toward marker dissection of the relevant traits and their validation in different genetic backgrounds that, ultimately, will allow the implementation of this novel strategy in sunflower improvement for drought tolerance.

47.4.5.3 Cold Tolerance during Germination and Emergence

The anticipation of planting dates as a strategy to maximize the growing season and to escape drought stress during flowering or grain filling has increased the importance of low-temperature stress tolerance in sunflower during germination and early growth to increase yield potential and its stability [139, 140].

Even though it has been reported that growth of sunflower seedlings was inhibited to some degree when they were subjected to suboptimal temperatures [141], there exists genetic variability for cold tolerance during initial growth stages. Genotypic variability for emergence rate under field conditions during early planting and for germination rate at low temperatures under controlled conditions has been reported for a set of 13 commercial hybrids and 26 inbred lines [139]. Also, it has been shown that there exists variability in the cultivated gene pool for the relative crop growth rates under low-temperature conditions by

screening a group of 21 inbred lines under field conditions [140]. More recently, a study was conducted to identify physiological traits associated with cold tolerance in sunflower and to identify the genomic regions involved in their variation [142]. A population of 98 RILs and their two parents were sown in the field under the conventional sowing date (control) and 1 or 2 months earlier (long-term low-temperature treatments). Several traits putatively associated with cold tolerance and acclimation mechanisms to stress conditions have been investigated at early development stages. Significant differences were observed among the three sowing dates for all traits. Chlorophyll content and specific leaf area were genetically associated with cold tolerance, which suggests that they could be used as selection criteria in conventional breeding programs. QTL analyses show that several putative genomic regions are involved in the variation in the physiological traits studied under low-temperature conditions [142].

All these results indicated that there exist enough variability and phenotypic and molecular tools to breed sunflower for cold tolerance during initial stages of growth.

47.4.6 Traits that are Awaiting More Research

47.4.6.1 Stay Green

Delayed leaf senescence during the grain-filling phase of grain crops, or stay green (SG), may be functional, when the loss of canopy capacity for carbon fixation is delayed or occurs at a slower rate, or is cosmetic, when maintenance of leaf chlorophyll is combined with the disassembly of the photosynthetic apparatus [143, 144]. Functional SG has been recently demonstrated in sunflower and is considered a valuable trait in sunflower breeding since it may contribute positively to increases in yield potential through increments in biomass production or yield stability under conditions of water shortage, late sowings, or high plant population density [145]. Functional SG can also increase resistance to stalk breakage (stem lodging) by preventing (or minimizing) remobilization of carbohydrates from the stem during grain filling by maintaining crop photosynthesis [146]. Susceptibility to stem and root lodging in sunflower increases with crop population density suggesting that SG could be a valuable secondary trait in selection for higher and more stable yields in this crop species [147, 148].

Studies on variability and inheritance of the stay-green trait in sunflower using two crosses indicated that additive effects were the main source of genetic variation and the authors concluded that selection for this trait could be made in early-generation segregating populations [149]. However, the trait studied by them was stem color at maturity and not delayed leaf senescence.

Identification of sources for the functional SG trait in sunflower by exploring the genetic base of this crop will lead to a significant advance in breeding for yield potential and stability and greater adaptation to drought conditions. Also, it will allow the discovery of stay-green drought tolerance QTL or genes to speed up their introduction into elite genotypes, as was the approach in other crops [150–152].

47.4.6.2 Tolerance to Stem Lodging

Root and stem lodging, defined as the permanent displacement of the stem from its vertical position, causes important yield losses in sunflower. The prostrate head of lodged plants is not retrieved during mechanical harvesting causing significant losses. Also, lodging may contribute to fixing the upper limit to commercially viable crop population density since yield is known to increase up to densities higher than those used at present [148]. Sunflower lodging has been observed to result from failure of the root anchorage system or from tensile failure of the stems. The susceptibility to lodging and its occurrence in stems or roots of crops exposed to high winds depend on complex interactions between the mechanical properties of the stems and the soil–root system that anchors the plants, the shape of the upper sections of the plant that capture wind gusts, and rain. The values of these variables vary throughout crop development and can change with cultural practices, genotype, and soil properties. Stem lodging can occur in well-anchored crops when the force applied to the lower portion of the stem exceeds the stem failure moment. Root lodging is usually associated with rain that weakens the anchorage (i.e., the soil–root system) via a reduction in soil strength [147, 153]. Crops are particularly susceptible to stem lodging during grain filling and at harvest maturity, but the temporal and spatial unpredictability of lodging events under field conditions has hampered systematic research on this issue [148].

Sposaro *et al*. [154] have successfully adapted previous models for lodging in cereals to the sunflower crop, and this model has been shown to perform well under field conditions [148, 154]. It provides a systemic framework that can handle the multiple determinants of lodging and can serve to establish the relative importance of several plant variables critical to the determination of root and stem lodging susceptibility, providing useful guidelines for conventional breeding and for the dissection of this complex trait by molecular markers. The demonstration of the existence of genotypic differences in tolerance to root [147] and stem lodging [148] should encourage the exploration of the sunflower genetic base in order to identify sources of tolerance at high crop population densities in sunflower.

47.4.6.3 Reduced Height

Progress in improving the standability of conventional height sunflower has been slow [1]. Present hybrids, when protected from lodging and disease, show increase in yield potential with crop population densities almost three times the commercial density of 5 plants m^{-2} [155]; it seems very likely that propensity to lodge at high crop population densities also plays a part in reducing realizable yield potential in this crop [148]. Therefore, reduced height germplasm has the potential to increase both stem strength and yield potential of the sunflower crop.

Reduced height controlled by recessive genes in lines with a reduced number of leaves has been reported on several occasions [156–161]. However, none of them has been used to improve yield as yet because of the excessively severe phenotypes of these mutants. On the other hand, three sources of reduced height ("DDR", "Donsky," and "Donskoi 47") with an equal or similar number of leaves as conventional-height sunflowers were reported [162, 163]. DDR and Donsky were used to

develop several restorer and maintainer lines [164–166]. The inheritance of reduced plant height in the sunflower line Dw89, which traces back to "Donsky," was determined to be controlled by alleles at two loci, designated *dw1* and *dw2* [166]. Reduced height in Donskoi 47, on the other hand, is controlled by a single dominant gene, *Dw* [163]. The inheritance of dwarfism in the source DDR has not been determined. The utilization of traits for reduced plant height to maximize yield potential and reducing stem lodging in other crops [167, 168] is a strategy that deserves to be fully explored in sunflower.

47.5
Tolerance to Herbicides

Weeds compete with sunflower for moisture and nutrients, and depend on species for light and space. Weed competition causes substantial yield losses in sunflower, ranging from 20 to 70% [169–173]. The amount of yield reduction varies depending on the weed species, weed density, time of weed and crop emergence, climatic conditions, and type of soil. Competition can occur from early germinating weeds, such as species of winter annuals that germinate early in the spring and develop a competitive advantage if they emerge before the sunflower. Competition can be a serious problem under drought conditions, since several weeds have tolerance to limited moisture (e.g., *Kochia scoparia*), and even under cool temperature conditions following planting since sunflower emergence and initial growth are reduced, but these variables remain unaffected for many weed species [174].

Herbicides are the most desirable method for weed control; however, the availability of selective herbicides for the sunflower crop is quite limited and due to the high cost of herbicide registration, new molecules of herbicides are unlikely to be specifically developed for weed control in sunflower. For this reason, gene discovery and trait development for herbicide resistance in sunflower is one of the most important issues in raising the productivity and the competitive ability of this crop in the near future.

47.5.1
Nontarget-Site Herbicide Resistance

Herbicides can cause several injury problems to the sunflower crop (see, for example, Blamey *et al*. [174], Table 12–13, pp. 642–644). As a matter of fact, sunflower genotypes varied widely in their response to soil-applied and to postemergence herbicides [175]. For diclofop {2-[4-(2,4-dichlorophenoxy)phenoxy] propanoic acid), for example, genotypic response can range from susceptibility to tolerance and the tolerance level also varies according to growth stage of the plants, herbicide rate, and environmental conditions, such as temperature and relative humidity [176]. Natural variation in tolerance was recently investigated by screening 97 inbred lines with a combination of the herbicide imazamox and the insecticide Malathion, an inhibitor of cytochrome P450 monooxygenases (P450s). One tolerant line, named TolP450-1,

was selected and characterized in the field and in the greenhouse to evaluate its response to the herbicides imazamox, prosulfuron, and atrazine at different plant development stages (germination, VE, and V3) with and without Malathion. For all herbicides and all development stages analyzed, TolP450-1 showed significantly higher tolerance compared to the susceptible line RHA266, and in all cases the tolerance was reversed by Malathion [177]. The P450 gene family in plants encodes the most versatile class of enzymes involved in the metabolic detoxification of xenobiotics and in nontarget-site herbicide resistance in plants [178]. One of the first P450 genes identified for herbicide resistance, CYP76B1, was cloned from a sunflower relative, the Jerusalem artichoke, *H. tuberosus* [179, 180]. CYP76B1 metabolizes with high efficiency a wide range of xenobiotics, including alkoxycoumarins, alkoxyresorufins, and several herbicides of the class of phenylureas [181]. These observations indicate that there exists natural variation for P450s genes in the cultivated and wild sunflower germplasm to be used in developing new traits for nontarget herbicide tolerance for the sunflower crop.

47.5.2 Target-Site Herbicide Resistance

Imidazolinone and sulfonylurea herbicides have been demonstrated to have a broad spectrum of weed control activity, flexibility in timing of application, low usage rates, and low mammalian toxicity [182, 183]. These herbicides inhibit the enzymatic activity of acetohydroxyacid synthase (AHAS, EC 4.1.3.18, also known as acetolactate synthase, ALS [184, 185]), the first enzyme in the pathway for the synthesis of the branched chain amino acids valine, leucine, and isoleucine [186]. The same enzyme has been shown to be the site of action for the triazolopyrimidines [187], pyrimidyloxybenzoates [188], and sulfonylaminocarbonyl-triazolinones [189].

Imidazolinone- and/or sulfonilurea-tolerant plants with altered AHAS genes and enzymes have been discovered in many species, which permitted the development and commercialization of several herbicide-tolerant crops [183]. Resistance in most of these cases is due to a form of the AHAS large subunit enzyme (AHASL) that is less sensitive to herbicide inhibition and is conferred by a single, partially dominant nuclear gene [183, 190]. This reduction in herbicide binding is caused by mutations at key sites in the genes coding for the catalytic subunit of AHAS. Several authors have reviewed known mutations of the AHAS genes that confer tolerance to AHAS-inhibiting herbicides in plants [191, 192].

On the basis of molecular studies, Kolkman *et al.* [193] identified and characterized three genes coding for the AHAS catalytic subunits in sunflower (*Ahasl1*, *Ahasl2*, and *Ahasl3*). *Ahasl1* is a multiallelic locus and the only member of this small family where all the induced and natural mutations for herbicide resistance have been described thus far in sunflower. *Ahasl1-1* (also known as *Imr1* or Ar_{pur} [193, 194]) harbors a C-to-T mutation in codon 205 (*Arabidopsis thaliana* nomenclature) that confers a moderate resistance to imidazolinones, *Ahasl1-2* (also known as Ar_{kan}) shows a C-to-T mutation in codon 197 conferring high levels of sulfonylurea resistance [193], and *Ahasl1-3* presents a G-to-A mutation in codon 122 that confers high levels of imidazolinone resistance [195].

All these alleles are being used for the production of sunflower hybrids resistant to herbicides. The first commercial herbicide tolerance trait in sunflowers is known as "Imisun" and its development started in 1996, when imidazolinone-tolerant wild sunflowers were discovered in a field in Kansas, USA. Subsequent crossing of these plants with cultivated sunflower lines gave rise to imidazolinone-tolerant populations and lines [196] that were released as donor materials for developing hybrid varieties commercially launched in the United States, Argentina, and Turkey in 2004. The inheritance of Imisun is additively controlled by two genes, where one of them is the partially dominant allele *Ahasl1-1* and the other (Imr_2) is a modifier or enhancer factor [194, 197]. Synergistic effects of imidazolinones and Malathion on tolerance in Imisun genotypes suggest that *Imr2* is a member of the P450 gene family (Bulos and Sala, unpublished). To produce Imisun sunflower hybrids that express commercial tolerance levels to imidazolinone herbicides, both components need to be homozygous in the final variety. The second imidazolinone tolerance trait in sunflowers, known as CLPlus, is controlled by the expression of the partially dominant nuclear allele *Ahasl1-3* that was developed by seed mutagenesis and selection with imazapyr [198]. Biochemical studies together with the results of several years of evaluation under field conditions in many countries permit to conclude that CLPlus provides a better level of tolerance to imidazolinones than Imisun [199]. Owing to the high levels of tolerance, only one homozygous component, namely, *Ahasl1-3*, or the combination of both *Ahasl1-1* and *Ahasl1-3* alleles in the final hybrid variety, is required to achieve commercial tolerance levels [199, 200].

Sulfonylurea-tolerant sunflowers were developed from wild sunflower populations discovered in the United States [201]. The tolerance allele *Ahasl1-2* was introgressed into cultivated sunflower by forward crossing and selection with the herbicide tribenuron, and gave rise to the trait known as "Sures" [202]. The same type of tolerance was obtained by EMS mutagenesis [203] and was developed and commercialized under the name "ExpressSun" [204].

Introgression of genes for herbicide resistance into high-yield sunflower germplasm is being facilitated by MAS with diagnostic markers for each one of the resistance alleles [193, 205]. Selection of cultivated germplasm, wild *Helianthus* species, and mutagenized libraries will allow the discovery of new sources of herbicide resistance (e.g., [206]), especially other modes of action apart from the inhibition of AHAS in order to complement the current technologies.

47.6
Candidate Gene Approach

A large number of abiotic stress-induced genes have been identified in a wide range of plant species although a molecular basis for plant tolerance to these stresses remains far from being completely understood. Some examples of candidate genes obtained as a result of transcriptomic analysis and that plausibly play a relevant role in stress tolerance in sunflower have been reported, and they are described below.

47.6.1 Dehydrins

Late embryogenesis-abundant proteins are extremely hydrophilic proteins that were first identified in land plants. Intracellular accumulation is tightly correlated with acquisition of desiccation tolerance, and data support their capacity to stabilize other proteins and membranes during drying, especially in the presence of sugars such as trehalose. Among the water stress-induced proteins so far identified, dehydrins, the D-11 subgroup of late-embryogenesis abundant proteins [207], are frequently observed. Dehydrins are highly abundant in desiccation-tolerant seed embryos and accumulate during periods of water deficit in vegetative tissues. These proteins display particular structural features such as the highly conserved Lys-rich domain predicted to be involved in hydrophobic interaction leading to macromolecule stabilization [208, 209]. These drought-induced proteins lack a fixed three-dimensional structure. Their specific molecular action, as well as the reason for their disordered character, is as yet poorly understood. It has been speculated, however, that dehydrins are tuned to acquire a biologically active structure only under the conditions in which they normally function (i.e., upon dehydration) [210]. Very little is known about dehydrin functions *in planta*. Studies have established correlations between drought adaptation and dehydrin accumulation in several species. Positive correlations were also reported for species tolerant to stresses that have a dehydrative component such as salt stress [211, 212] and freezing and cold stress [209, 213–215].

To investigate correlations between phenotypic adaptation to water limitation and drought-induced gene expression, Cellier *et al.* [216] studied a model system consisting of a drought-tolerant line (R1) and a drought-sensitive line (S1) of sunflower subjected to progressive drought. R1 tolerance is characterized by the maintenance of shoot cellular turgor. Drought-induced genes (*HaElip1*, *HaDhn1*, and *HaDhn2*) were previously identified in the tolerant line. *HaDhn1*- and *HaDhn2*-deduced proteins belong to the dehydrin family, and *HaElip1* is a related homologue of early light-induced protein (ELIP) [217]. The accumulation of the corresponding transcripts was compared as a function of soil and leaf water status in R1 and S1 plants during progressive drought. In leaves of R1 plants, the accumulation of *HaDhn1* and *HaDhn2* transcripts, but not *HaElip1* transcripts, was correlated with the drought-adaptive response. Drought-induced abscisic acid (ABA) concentration was not associated with the varietal difference in drought tolerance. Stomata of both lines displayed similar sensitivity to ABA. ABA-induced accumulation of *HaDhn2* transcripts was higher in the tolerant than in the sensitive genotype. *HaDhn1* transcripts were similarly accumulated in the tolerant and in the sensitive plants in response to ABA, suggesting that additional factors involved in drought regulation of *HaDhn1* expression might exist in tolerant plants. In leaves of R1 plants, the steady-state level of each transcript increased gradually as the water potential declined. In the S1 plants, the fluctuations of the steady-state level of *HaElip1* transcripts were not correlated with the decreases in leaf water potential. Similar levels of *HaElip1* transcripts were accumulated in S1 and R1 plants except in leaves with water potentials between 20.9 and 21.2 MPa. Steady-state levels of *HaDhn1* and

HaDhn2 transcripts in S1 plants remained low and constant in leaves with a water potential of less than 20.6 MPa. At an equivalent water potential, they accumulated at a higher level in R1 than in S1 leaves. At low leaf water potential, steady-state levels of *HaDhn1* and *HaDhn2* transcripts were nine- and fivefold higher, respectively, in leaves of R1 compared to S1 plants [216]. Sequence analysis of the deduced dehydrin (Dhn1) proteins showed diversity in cultivated and wild sunflower accessions, the latter being more variable [218, 219]. Despite these exciting findings, no other study concerning mapping or validation of these genes for their role in drought tolerance was reported.

47.6.2 Tanscription Factors

As was described in Section 47.4.5, a large array of genes are activated by stress conditions, meaning several proteins are produced to join the pathways that subsequently lead to synergistic enhancement of stress tolerance [220–228]. These genes are classified into two groups: regulatory genes and functional genes. The regulatory group includes genes encoding various transcription factors (TFs), which can regulate various stress-inducible genes cooperatively or separately and may constitute gene networks. The functional group contains genes encoding metabolic components such as sugar, sugar alcohols, and amines, which play an important role in stress tolerance. Gaining an understanding of the mechanisms that regulate the expression of these genes is a fundamental issue in plant biology and will be necessary for the genetic improvement of plants for abiotic stress tolerance.

Stress tolerance seems to be controlled mostly at the transcriptional level [229], where the main players are proteins called transcription factors or *trans*-acting elements. Transcription factors are able to enhance or reduce the rate of transcription of their target genes. They specifically recognize and interact with DNA sequences (*cis*-acting elements) located in the regulatory regions of their targets. These TFs and *cis*-motifs function not only as molecular switches for gene expression but also as terminal points of signal transduction in the signaling processes. Typically, the TFs contain a distinct type of DNA binding domain and transcriptional regulation region, and are capable of activating or repressing transcription of multiple target genes [230, 231]. In plants, approximately 7% of the genome encodes for putative TFs [232]. It has been estimated that *Arabidopsis* and rice have between 1300 and 1500 transcription factor encoding genes [233, 234]. Some of them have been identified as stress responsive. Each of these stress-related transcription factor families exhibit a distinctive DNA binding domain [235].

Hahb-4 is a member of sunflower subfamily I of homeodomain-leucine zipper proteins, which constitutes a family of transcription factors found only in plants. *Hahb-4* was found to be regulated at the transcriptional level by water availability and abscisic acid [236]. Transgenic *A. thaliana* plants that constitutively overexpress *Hahb-4* developed shorter stems and internodes, rounder leaves, and more compact inflorescences than their nontransformed counterparts. Transgenic plants were more tolerant to water stress conditions, showing improved

development, a healthier appearance, and higher survival rates than wild-type plants [237]. Indeed, either under normal or drought conditions, they produce approximately the same seed weight per plant as wild-type plants under normal growth conditions. It has been proposed that Hahb-4 may participate in the regulation of the expression of genes involved in developmental responses of plants to desiccation and that it is a component of ethylene signaling pathways inducing a marked delay in senescence [238]. Furthermore, transgenic plants expressing this gene under the control of its own inducible promoter showed that the expression of this TF is regulated by external factors such as drought, extreme temperatures, osmotic stresses, and illumination conditions, and is specific to different tissues and organs of the plant. Their role as transcription factors is related to developmental events in response to such environmental conditions, particularly those in which abiotic factors generate stress [239–244]. Interestingly, this family of TFs was found only in sunflower and for this reason, it can be a useful candidate for obtaining transgenics with enhanced resistance to abiotic stress in other crops (see Section 47.8).

Another TF from sunflower is *HAhb-10*, a member of subfamily II homeodomain-leucine zipper proteins, whose expression is regulated by illumination conditions in photosynthetic tissues, and their function in plant development is associated with this environmental factor, particularly in the case of the shade avoidance response [245–247]. Transformed plants of *Arabidopsis* overexpressing HAhb-10 have a shorter time to maturity maintaining their seed yield [248], and also showed increased tolerance to oxidative stress produced by paraquat [248, 249].

47.6.3
Other Genes

A cDNA microarray containing about 800 clones covering major metabolic and signal transduction pathways allowed to identify many differentially expressed genes in leaves and embryos of drought-tolerant and -sensitive genotypes of sunflower subjected to water-deficit under field conditions [250]. The majority of the cDNA clones differentially expressed under water stress was found to display opposite gene expression profiles in a drought-tolerant genotype when compared to a drought-sensitive one. These dissimilarities suggest that the difference between tolerant and nontolerant plants is mainly associated with changes in mRNA expression. However, phenotypic variation resides also in changes in allelic sequences that can affect the efficiency of the encoded proteins. Hence, sequence variability of stress-related genes can modulate the stress response within a species.

Differential expression of four water stress-associated genes, aquaporin, dehydrin, leafy cotyledon1-like protein, and fructose-1,6 bisphosphatase, was examined using four RILs and parental lines presenting contrasting responses to dehydration and rehydration [114]. Water stress revealed a high genetic variability for water status and gas exchange parameters compared to well-watered genotypes. QTL mapping showed that RILs carrying different genomic regions for some QTL also presented physiologically different characteristics and gene expression patterns. The expres-

sion level of aquaporin genes in leaves of four RILs and their parents was downregulated by water stress and was associated with relative water content. Downregulation was also associated with genomic regions having alleles with negative effects on plant water status. The level of dehydrin transcripts, on the other hand, increased in leaves of all studied RILs in response to water stress. Transcript accumulations of dehydrin and leafy cotyledon1-like genes, likely involved in protective tolerance processes, were not correlated directly with plant water status or QTL effects. Downregulation of fructose-1,6 bisphosphatase was observed under water stress. Net photosynthesis rate and the fructose-1,6 bisphosphatase gene expression levels were associated mainly after rehydration [114]. These results indicate that there exists an association between physiological response to water stress and differential expression of water stress-related genes.

Sequence polymorphisms of eight unique genes putatively involved in drought response in eight inbred lines of sunflower of different origin and phenotypic characters and showing different drought response in terms of leaf RWC were analyzed. The selected genes encode a dehydrin, a heat shock protein, a nonspecific lipid transfer protein, a z-carotene desaturase, a drought-responsive element binding protein, a NAC-domain transcription regulator, an auxin binding protein, and an ABA-responsive C5 protein. A pairwise comparison between genetic distances calculated on the eight genes and the difference in RWC showed a significant correlation in the first phases of drought stress [219].

These initial results concerning sequence variability for putative stress-related sequences encourage more research in this area, using a broader and diverse set of lines, coupled with association mapping and extensive phenotyping. The likelihood of this approach for MAS will depend on the confirmation and validation of the selected candidate genes in modifying the stress response on different genetic backgrounds.

47.7 Marker-Assisted Selection

The fundamental advantages of MAS over conventional phenotypic selection that can be exploited by breeders to accelerate the breeding process are as follows: (a) MAS may be simpler than phenotypic screening, which can save time, resources, and effort; (b) selection can be carried out at the seedling stage; and (c) single plants can be selected [251, 252].

In previous sections, we described numerous studies on DNA markers linked to genes or QTL for different traits related to yield potential or tolerance to abiotic stresses. In contrast, literature on practical application of these markers in sunflower breeding programs remains very limited. Even though it was assumed that most markers associated with QTL from preliminary mapping studies were directly useful in MAS, it has become widely accepted that QTL confirmation, QTL validation, and/or fine (or high resolution) QTL mapping may be required. Although there are examples of highly accurate preliminary QTL mapping data as determined by

subsequent QTL mapping research [253], ideally a confirmation step is required because QTL positions and effects can be inaccurate due to factors such as sampling bias [254]. QTL validation refers to the verification that a QTL is effective in different genetic backgrounds [255]. Additional marker-testing steps may involve identifying markers within a 10 cM "window" spanning and flanking a QTL and converting markers into a form that requires simpler methods of detection [251, 256].

Ideal markers for MAS are those based on gene mutations underlying the trait of interest. This kind of markers has been developed in sunflower for oil quality traits (e.g., [108]) and resistance to herbicides [193, 205]. For traits related to yield, yield components, or tolerance to abiotic stresses, the situation is more complex. Factors such as population structure and size, parental selection and genetic background effects, epistasis, inaccurate phenotyping, or QTL × environment interactions contribute to bias the estimation of QTL effects, thus reducing the likelihood of successful use of these QTL in MAS programs [15, 257, 258].

QTL validation in independent samples and in different genetic backgrounds and environments is, therefore, necessary before using them in MAS breeding programs. A major challenge that remains is to confirm that QTL discovered in a given mapping population will improve yield potential or drought tolerance when introduced into high-yield elite genotypes. This is particularly difficult when the traits are governed by "context-dependent" gene effects (i.e., interaction with other genes and/or environment). In these cases, the value of the QTL alleles can differ depending on the genetic structure of the current germplasm set in the breeding program [259]. Also, a desirable QTL allele discovered in nonelite genetic material may not offer any improvement because the allele may already be ubiquitous in present varieties. In addition, the effects of the positive allele may not be transferable to elite backgrounds due to unfavorable epistatic interactions [260].

Taking into account all these considerations, there exist examples of successful implementation of MAS for yield-related traits in sunflower. QTL for oil content, for example, have been validated across generations, environments, and mapping populations [77, 108] and some of the QTL underlying differences between genotypes have been associated with phenotypic markers (*Hyp*, hypodermal pigment [77, 80, 108]), which allowed León *et al*. [261] to establish combined marker and phenotypic-assisted selection for high oil content during the backcross process.

47.8
Transgenic Breeding

Tissue culture and plant regeneration are key steps of the transformation process. Therefore, sunflower biotechnologists invest considerable effort in this area. Based on the tissue type for regeneration, sunflower culture systems include somatic and zygotic embryos, hypocotyls, mature cotyledons, and protoplasts (see Ref. [262] for review). The regeneration rate of whole sunflower plants is variable and depends on genotypes used, explant type, and development stage, and culture media and conditions [263]. Genetic variation is closely associated with regeneration ability.

Organogenetic traits were mapped to QTL by Deglene *et al.* [264] and Flores Berrios *et al.* [265]. Some segments of the LG 1, 15, and 17 are likely to contain genes important for organogenesis, somatic embryogenesis, and protoplast division. The QTL identified in these three LGs should be involved in cell division in early events associated with cell differentiation [266].

Sunflower genetic transformation was achieved by *Agrobacterium tumefaciens*-mediated protocols [267–269] and by combining this technique with particle bombardment [270], sonication [271], wounding with glass beads [272], or enzymatic treatments [271, 273]. Most of the published protocols of sunflower transformation showed a low efficiency [268, 270, 273–279]. Efficient transformation protocols with high reproducibility and high transformation frequency have been reported [280, 281] together with techniques to enhance the selection of transformed explants [279]. The usefulness of these methodologies remains to be assessed. On the other hand, an optimized protocol for *Agrobacterium*-mediated transient transformation of sunflower leaf disks was developed with the aim of quickly overexpressing or silencing a given gene, enabling the study of several biochemical processes and the characterization of sunflower regulatory sequences [282].

Most of the transgenic traits in sunflower under field trials at present are focused on biotic stress and herbicide resistances. Cantamutto and Poverene [283] mentioned several examples of them, including tolerance to glyphosate and glufosinate ammonium and resistance to insects, fungal diseases, and broomrape, and quality traits such as enhanced protein quality and modified stereate content. They were developed mainly by private companies, but some of them were obtained also from public institutes [278, 284, 285]. Traits related to abiotic stresses in sunflower using the transgenic approach remain to be developed.

Although transgenic sunflower varieties have already been obtained, and they remain the subject of ongoing research in both the United States and Argentina, the interest in GM sunflower research has decreased in the twenty-first century, mainly because official control bureaus have imposed restrictions in the face of ecological concerns [283]. These concerns are related to the risks associated with the gene flow from transgenic cultivars to the wild flora and are a matter of general controversy not only in the United States but also in other parts of the world [286]. Gene flow from domesticated, transgenic, or mutant sunflower plants to wild species is well documented [287–290]. This potential gene containment is discouraging the advancement and realization of transgenics' full development in sunflower.

In spite of the low transformation efficiency and biosafety concerns related to transgenic sunflower, the use of sunflower genes to mitigate abiotic stresses in other crops has been described. A xenobiotic-inducible cytochrome P450 gene, CYP76B1, obtained from *H. tuberosus* was constitutively expressed in tobacco and *Arabidopsis* conferring to the transformed plants an enhanced resistance to several herbicides and xenobiotics. Beside increased herbicide tolerance, expression of CYP76B1 has no other visible phenotype in the transgenic plants and can be a potential tool for phytoremediation of contaminated soils [291]. Sunflower transcription factors, like those described in Section 47.6, have been proposed as candidates for genetic

transformation of different crops in order to enhance the tolerance not only to abiotic stresses but also to modify the growth cycle and the tolerance to xenobiotics in transgenic plants [248, 249].

47.9 Prospects

Improvements in sunflower yield potential and stability during the last decades have been slow and mainly based on the unconscious pyramiding of yield associated characters with biotic and abiotic stress-related traits. Research has led to three main approaches to change the objectives and the current tools for sunflower breeding. First of all, plant physiology provided new tools and models to understand the complex network of yield and stress-related traits in order to identify target traits useful for improving selection efficiency. Second, molecular genetics has led to the discovery of a large number of loci affecting yield under stress conditions or the expression of stress tolerance-related traits. Third, molecular biology has provided genes that are useful as candidate sequences to dissect QTL or are useful for transgenic approaches.

Even though there exist some successful results of synergistic interactions among these three approaches, the great challenge in the near future is to formalize the integration of molecular genetics with physiology and breeding in order to (a) identify the most relevant traits as targets for research, (b) screen the genetic base of the sunflower crop to detect the most promising genotypes as putative sources for these traits, (c) establish and screen introgression libraries from wild species of *Helianthus* that are reservoirs of potential useful genes for stress tolerance [292], and (d) dissect yield and other integrative traits that influence stress tolerance into heritable traits by using phenotyping platforms with model-assisted methods [293–296]. Routine cloning of the genes underlying the QTL is still a long way off, but it will, ultimately, provide simple markers for an effective MAS.

To date most plant QTL have been cloned by the positional cloning approach, although alternative strategies based on candidate genes and linkage disequilibrium may represent an interesting shortcut to QTL cloning [258, 297]. Cloning genes for stress-related traits offers the opportunity to approach stress tolerance by means of reverse genetics. So far, the utilization of mutagenesis as a source of new traits for increasing stress tolerance has been unaffordable. However, reverse genetics coupled with a tilling strategy and an efficient phenotyping platform could be a virtual inexhaustible source of new useful allelic variants for increasing stress tolerance.

Ultimately, as was pointed out by Collins *et al.* [258], integration of QTL information into a breeding pipeline aimed at improving tolerance to abiotic stresses will best be achieved within a multidisciplinary context able to provide the operational framework required to correctly link the stress-responsive mechanisms of crops with the functional variation of the relevant networks at the cellular and molecular levels.

Sesame: Overcoming the Abiotic Stresses in the Queen of Oilseed Crops

Suman Lakhanpaul, Vibhuti Singh, Sachin Kumar, Deepak Bhardwaj, and Kangila Venkataramana Bhat

Sesame, one of the important oilseed crops, is valued for its high quality oil rich in polyunsaturated fatty acids (PUFA) and thus offers excellent health benefits. The oil also has unique antioxidative property that increases its keeping quality by preventing oxidative rancidity. However, the research efforts for developing improved sesame cultivars having tolerance to biotic and abiotic stresses have been rather meager so far. Sesame is largely cultivated in marginal lands by resource-poor farmers and is thereby prone to several abiotic stresses. The crop possesses effective tolerance to drought due to its extensive root system. Preliminary studies have been carried out in sesame regarding salt, drought, and heavy metal stress. Parameters such as root and shoot morphology, cuticle thickness, antioxidative enzymes, malondialdehyde, proline content, and so on have been assessed under stressed and control conditions. Role of stress-associated genes and their products such as lipid transfer proteins, caleosins, steroid dehydrogenase, phytostatins, γ-aminobutyric acid, metallothioneins involved in diverse stresses are under investigation. The presence of phenylpropanoid compounds, namely, lignans, an innate nonenzymatic antioxidant defense mechanism against reactive oxygen species in sesame, is a special area being researched. However, the areas that still remain untouched include waterlogging and chilling stress, both of which are highly detrimental to the crop survival. Inspite of huge repertoire of germplasm collection, limited research efforts on the use of conventional and biotechnological methodologies have resulted in minimal success in developing abiotic stress-tolerant cultivars. The absence of efficient *in vitro* regeneration protocols further compounds challenges for development of desired novel genotypes. The possible strategies that could be helpful in incorporating abiotic stress tolerance in plants have been discussed here along with the fundamental studies dealing with different stresses and their effects on sesame, followed by information on stress-related genes under focus in sesame.

Improving Crop Resistance to Abiotic Stress, First Edition.

48.1
Introduction

Global population has increased with the unprecedented rate over the past few decades resulting in shortage of resources at all fronts. However, the biggest problem is the shortage of food particularly in the underdeveloped parts of the world. Providing additional land for cultivation is already becoming unrealistic due to increasing demands of urbanization on the one hand and the need to maintain and restore the much reduced forest cover on the other hand. In addition, a series of natural calamities and global environmental changes have compounded the abiotic and biotic stresses that adversely affect the productivity of the crop plants. Abiotic stress is, in fact, a general term referring to physical stresses experienced by the plant vis-a-vis the unfavorable conditions posed by the environmental factors or the substratum where the plant is growing. The negative influences of abiotic stresses such as drought, salinity, cold, chilling, flooding, and so on affect survival, biomass production and accumulation, and grain yield in most crops [1]. About 85% of crop productivity losses are due to different kinds of abiotic stresses [2], which is much more significant in comparison to the losses that occur due to insects/pests, weeds, and diseases [3].

Plants have evolved several adaptations to survive the harsh environmental conditions due to innate plasticity in their physiological and metabolic processes. The conquest of nearly the entire planet with the living organisms spanning extreme conditions on both sides of all the physical parameters provides evidence for the range of functional capability of the biological machinery and hope for the incorporation of such traits in the desired taxa. The need for the addition of traits imparting tolerance to abiotic stresses cannot be overemphasized. Both conventional breeding and biotechnological tools, individually or in combination, have yielded superior genotypes in major crop plants. However, several other crop plants that not only contribute significantly to the food and nutritional requirement but also play an important role in diversification of the crops are far from researched. Sesame (*Sesamum indicum* L.) is one such crop that deserves urgent and immediate attention of the scientific community.

48.2
Sesame: an Oilseed Crop

Sesame, an important oil yielding plant, is one of the most ancient crops known and used as oilseed. The high regard it enjoys among the users has earned it the poetic label "queen of oilseeds" [4]. Ironically, it has also been considered an "orphan crop" due to lack of research efforts ascribed to the fact that it is not a mandate crop for any international crop research institute [5]. Though sesame is cultivated on a worldwide basis for its seeds, oil, and protein, it is predominantly an annual crop of warmer areas, particularly Asia and Africa [6] where it is used both as a leafy vegetable and an oilseed crop. The presence of unique antioxidant compounds such as sesamin,

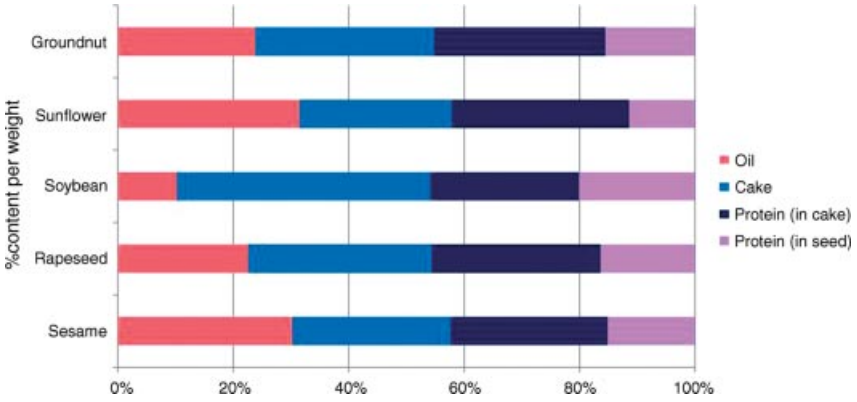

Figure 48.1 Oil and protein content of selected oilseeds (% content per weight basis) (http://www.fao.org/inpho/content/compend/text/ch05-01.htm).

sesamolin, and sesaminol makes the sesame oil one of the most stable vegetable oils in the world. The oil content ranges from 32.5 to 58.8%, which is generally greater in white than black seeds [7]. In general, the oil content compares well with other oilseed crops (Figure 48.1). The oil is rich in linoleic acid (LA) (Figure 48.2) and has been recommended for healthy diets with low LA and high alpha linoleic acid in combination with canola or mustard oil [8]. Seeds as a whole serve as nutritious food for humans and are widely used in bakery and confectionery products [9]. Sesame meal contains 35–50% protein, which is rich in tryptophan and methionine, and is used as poultry feed. Its leaves used as a vegetable are a rich source of carotene, ascorbic acid, iron, and calcium along with adequate quantities of protein [10].

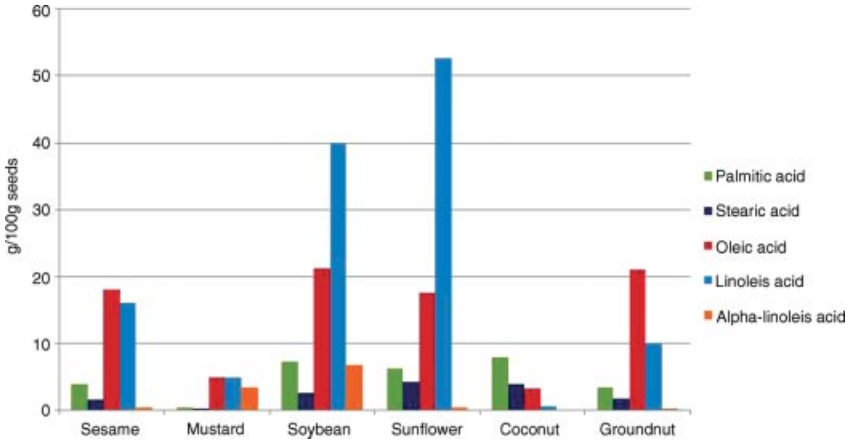

Figure 48.2 Fatty acid composition of common oilseeds. Adapted from [11, 12].

Sesame cultivation has many advantages as the seed set and yields are relatively well under high temperature and the crop can be grown even on residual moisture without any extra rainfall. Sesame crop also improves water percolation of the soil as its extensive branching system of feeder roots penetrates very deep into the soil. It can be grown in pure stands and also as a companion crop [5]. Furthermore, it responds well to additional inputs in terms of irrigation and fertilization (by at least doubling the yield capacity), and thus has an important role in intensive management systems, including sequential multiple cropping [13].

Sesame is grown in the tropical to temperate zones from about 40°N latitude to 40°S latitude [14]. The plant is adapted to many soil types, but it thrives best on well-drained, fertile soils of medium texture (typical sandy loams) and at neutral pH. In India, sesame as a sole crop is mainly cultivated in drier parts of Maharashtra, Madhya Pradesh, Rajasthan, Gujarat, Andhra Pradesh, Uttar Pradesh, and Karnataka. However, it is grown in almost all states of India either as a mixed crop or in other forms of small-scale cultivation [15]. In Northern India, the crop is taken as rain-fed *kharif* crop and in Central India as a semi-*rabi* crop. However, in the South the crop is taken in both the seasons and in the Northeast the crop is taken three times in a year.

According to the Food and Agriculture Organization of the United Nations (FAO, 2002), sesame ranks 6th in the world production as an edible oil seed (2 893 114 million ton) and 12th in the overall world production of vegetable oil (754 159 million ton). The world production of sesame seed and seed oil is 3.2 million ton and 0.8 million ton, respectively (http://www.agmrc.org/agmrc/commodity/grainoilseeds/sesame/sesameprofile.htm). However, the world production fluctuates due to local economic crop production pressures and weather conditions. India accounted for 7.4% of the world's edible oil consumption with an estimated production of 28.21 million ton of nine cultivated oilseeds in 2007–2008 (http://fcamin.nic.in/dfpd/EventDetails.asp?EventId=561&Section=Edible + Oil&ParentID=0&Parent=1&check=0). The major oilseeds responsible are groundnut, soybean, and rape/mustard seeds covering 80% of the total oilseeds grown in India. The consumption of edible oils in India reached 142.62 lakh ton that exceeded from their net availability of 86.54 lakh ton from all domestic sources. This gap bridged by import of mainly soybean and sunflower oil, takes them away from the reach of majority population due to their high costs. Inspite of this lacuna, export of oilmeals, oilseeds, and minor oils from India has increased from 5.06 million ton in the financial year 2005–2006 to 7.3 million ton in 2006–2007 in order to hold the agricultural economy. In year 2009, of the 0.6 million ton of sesame seed production, 0.194 million ton was exported (http://fcamin.nic.in/dfpd/EventDetails.asp ?EventId=561&Section=Edible + Oil&ParentID =0&Parent=1&che ck=0). High prices of both soybean and sunflower oil are still a major concern. In light of these aspects from both Indian and global perspective, sesame oil needs to find a strong foothold to meet the demands of a healthy diet. In this constrained scenario, increasing the production of sesame offers some kind of hope, which can be achieved only by overcoming various hurdles limiting the crop yield.

48.3
Constraints on Sesame Productivity

The plant architecture of sesame is poorly adapted to modern farming systems because of its indeterminate growth habit causing nonuniform ripening of capsules, sensitivity to wilting under intensive management, and absence of nonshattering cultivars suited for mechanical harvest [16]. Other physiological and biotic aspects include low yielding varieties and yield losses due to pests. These along with abiotic stresses are responsible for the reduced output, making it a small holder's crop. More importantly, sesame seedlings apparently show slow growth to develop root mass for soil penetration, the duration in which it is susceptible to various pest infestations and fluctuations of soil environments.

48.4
Abiotic Stress and Sesame

Incorporating abiotic stress tolerance in sesame necessitates first and foremost the identification of the important stresses that delimit its productivity. Baseline studies regarding effects of various abiotic stresses have been carried out on sesame, mostly concerned with breeding aspects. Of all the abiotic stresses such as drought, salinity, extremes of temperature, and so on, waterlogging and chilling sensitivity are the two specific abiotic stresses encountered by the cultivated sesame. It does not in any way undermine the need to address other stresses. Although, it is important to note that sesame crop is specifically prone to suffer significant losses if faced with water logging and its cultivation is restricted to areas and duration that are not subjected to low temperatures. However, due to its locally adapted drought tolerance the crop is valuable in many semiarid regions.

48.4.1
Waterlogging Stress

Sesame crop is highly susceptible to waterlogging, as the crop undergoes immediate senescence and declines within 2–3 days of exposure to flooding stress. This causes excessive devastation in fields (Figure 48.3) where accumulated water needs to be regularly drained out. Increased irrigation has shown to significantly reduce the sesame yield [17]. Even drought-tolerant sesame accessions are very susceptible to high moisture [18]. Hence, waterlogging is an important abiotic stress on this crop and there is a need to develop improved genotypes that could survive the flooding stress.

Studies on any aspect of water logging stress on sesame are entirely lacking. However, other crops showing waterlogging susceptibility such as cotton display significant reductions in stem elongation, shoot mass, root mass, and leaf number along with altered expression of 1012 genes (4% of genes assayed) in root tissue 4 h

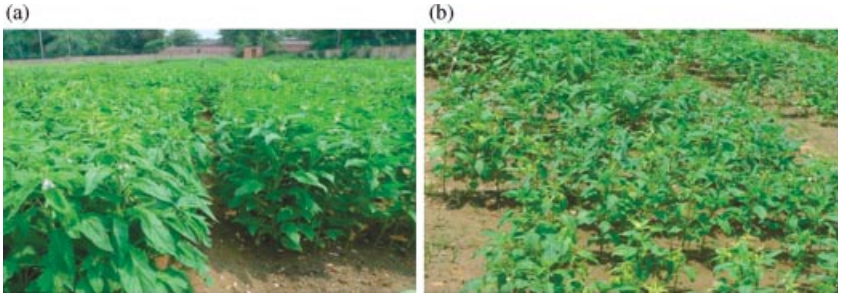

Figure 48.3 Field photograph depicting extreme susceptibility of sesame to waterlogging during *kharif* crop. (a) Well-drained plot (after regular pumping out of stagnant water) showing normal plant growth. (b) Plots left with stagnant rainwater for more than 12 h showing growth retardation, senescence, and plant mortality.

after flooding [19]. Many of these genes were associated with cell wall modification and growth pathways, glycolysis, fermentation, mitochondrial electron transport and nitrogen metabolism. Altered global gene expression was also observed in leaf tissues in response to waterlogging changing 1305 gene expression profiles (5% genes assayed) after 24 h of flooding, mainly involving genes for cell wall growth and modification, tetrapyrrole synthesis, hormone response, starch metabolism, and nitrogen metabolism [19]. Interestingly, in case of rice cultivars, wide variation exhibited for the ability to tolerate complete water submergence was found to be associated with just one locus (Sub 1) on chromosome 9. A transcriptional factor of the B-2 subgroup comprising ethylene-responsive element binding proteins (EREBP) located in the Sub 1 locus could explain the physiological and developmental processes associated with submergence tolerance in rice [20].

Therefore, recent approaches used to develop flooding-tolerant plants are concentrating first on the fermentation pathway. The second focus is specifically on modifying the transcriptional factor gene, AtMYB2, to finally enhance the expression of fermentation pathway genes [21]. However, none of the developed transgenic lines in rice or cotton using this approach has yielded significant tolerance to hypoxic stress. The identification of novel genes from cDNA library of anaerobically induced *Arabidopsis* root [22] that also would be helpful in developing flooding-tolerant sesame genotypes.

48.4.2
Chilling Stress

Sesame comes under the category of chilling (0–15 °C) sensitive plants that include crops such as rice, maize, soybean, cotton, and tomato, where the plants are incapable of cold acclimation, that is, are unable to increase their freezing tolerance when exposed to low temperatures [23]. There is a spontaneous retardation in sesame plant growth observed as drying off of axillary buds and restricted growth of plant organs, namely, leaves, floral buds, and fruits, finally leading to plant death.

Oplinger *et al.* [24] have reported that the absence of 90–120 frost-free days are required for commercial cultivars of sesame where day temperature between 25 and 26.7 °C is favorable. The plant shows significant reduction in growth below 20 °C and growth and germination are totally inhibited below 10 °C. Sesame seed shows marked reduction in content of lignans (sesamin and sesamolin) in the oil [25] during frost damage. This reduced strength of the reactive oxygen species (ROS) scavenging machinery that prevents the system from oxidative stress, generated due to chilling reveals the seriousness of the situation and could be one of the factors responsible for the cellular injury and senescence of the sesame plant.

The mechanism of chilling tolerance, although less worked out, is finding way by the pathways deciphered for cold acclimation as the molecular changes that occur during latter are also found to play a role in chilling tolerance [26, 27]. The few characterized genes basically include the transcription factors that act upstream in cold acclimation or as effector molecules that act to counter the potential damaging effects of cold stress [28]. These cold-responsive genes are members of different low-temperature regulons, as some are regulated by the C-repeat binding (CBF) transcription factor while the others are not [29].

Exogenous application of chemicals such as glycine-betaine has proved fruitful in improvement of tolerance in chilling-sensitive tomato plants [30]. In another approach, chilling-tolerant plants were obtained by increasing levels of trienoic fatty acids [31] or the accumulation of cold-responsive proteins (*COR*) by increased expression of the genes positively regulating their expression such as SCOF-1 from soybean [32], CBF-1 [33], and ABI3 [34]. CBF3 is known to integrate various components of the cold response and its overexpression, in addition to increasing the tolerance of cold-induced accumulation of proline and soluble sugars (reviewed by Yuanyuan *et al.* [35]) [36]. Activation of stress-inducible genes by binding of factors such as DREB1A on the upstream regulatory elements (DRE, dehydration-responsive element) has also led to substantial increase in stress tolerance, including cold stress [37]. Other important category of genes involved in providing cold stress tolerance includes *KIN* (cold-induced), *LTI* (low-temperature-induced), and *RD* (responsive to dehydration) genes. The proteins with multiple hydrophilic ice binding domains termed antifreezing proteins (AFPs), having the ability to inhibit the growth and recrystallization of ice in intercellular spaces [38], are being worked out. The heterologous overexpression of genes encoding AFPs in freezing-sensitive plants enhanced the freezing tolerance of host plants as observed in case of transgenic tobacco plants (made of AFPs of carrot) that survived subfreezing temperature of −2 °C [39].

The role of cellular metabolic signals and RNA splicing, their export, and secondary structure unwinding has emerged out to be of central importance in regulating cold-responsive gene expression and chilling tolerance. One of the key players is ubiquitination-mediated proteasomal protein degradation that has a crucial role in regulating one of the upstream transcription factors, INDUCER OF CBF EXPRESSION 1 (ICE1), and thus in controlling the cold-responsive transcriptome [40]. The knowledge of such key players in plants under cold stress is paving the way for more efficient tools to make them chilling tolerant.

48.4.3 Salt Stress

High salt concentrations limit sesame cultivation especially in arid and semiarid regions. Sesame cultivars show a considerable variation in the degree of salt tolerance [41]. In response to high NaCl treatments (50 and 100 mM), two sesame cultivars Orhangazi and Cumhuriyet showed reduction in root and shoot length, increased lipid peroxidation while dry weights were affected minimally [42]. These affects were more pronounced in the cv. Orhangazi than in cv. Cumhuriyet. Similar studies have shown that dry weight was less affected in salt-tolerant sugar beet and moderately tolerant cotton [43]. Change in free proline levels in relation to salinity have figured out its roles such as balancing capacity as an osmolyte, stabilizing proteins, regulating cytosolic pH, and scavenging hydroxyl radicals [44]. Cultivar Cumhuriyet was superior to the other one in proline content, which increased with time and concentration of NaCl treatment as observed in relatively salt-tolerant plants such as *Beta vulgaris* [45], *Brassica juncea* [46], and alfalfa [47]. Increase in the activities of ROS scavenging enzymes has been found closely related to salt tolerance in case of many plants [48–52]. Constitutive and induced levels of superoxide dismutase (SOD) activity was observed for cv. Cumhuriyet compared to cv. Orhangazi that was accompanied by an increase in the activity of major H_2O_2 scavenging enzymes such as ascorbate peroxidase (APX), catalase (CAT), and peroxidase (POX). This activity declined after 2 weeks that was suggested to be taken care of by lignans (nonenzymatic antioxidative processes in sesame) that also showed increased level of accumulation under stress.

Germinated seedlings of different sesame cultivars grown in the presence of varying concentrations of NaCl (30, 50, and 70 mM) showed alterations in electrophoretic patterns of proteins and other metabolites. Analyses revealed cv. RT-46, RT-54, and RT-127 to be salt tolerant, while cv. RT-125 to be sensitive as it showed retarded seedling growth along with low levels of total soluble sugars, sucrose, SOD activity, and higher malondialdehyde (MDA) and proline content in the presence of more than 30 mM NaCl [53].

During seed germination in sesame, expression of *SeMIPS* (*myo*-inositol 1-phosphate synthase) showed downregulation with increase in concentration and duration of exposure to the saline environment. The protein catalyzes glucose-6-phosphate to *myo*-inositol 1-phosphate, which is the first product in the biosynthetic pathways of myoinositol, phytic acid, and other essential cellular components [54–56]. The *SeMIPS* protein was highly homologous with those from other plant species (88–94%). It was present in several copies and expressed in an organ-specific manner. In case of *Arabidopsis*, Nelson *et al.* [57, 58] have also shown salinity to affect transcription of the *MIPS* gene during biosynthesis of *myo*-inositol and its derivatives. Similar salinity stress studies on *Arabidopsis thaliana* showed its upregulation in salt-tolerant plants and its reduction in the salt-sensitive ones [59]. Downregulation of EST coding for *MIPS* was also observed in sunflower (a salt-sensitive crop), under salt stress [60]. Genes responding to salinity have been reported from rice [61], common ice plant (*Mesembryanthemum crystallinum*) [62–64], and tomato [65], which could be implemented in achieving salt tolerance.

48.4.4 Drought Stress

Sesame is known to be endowed with the property of drought tolerance due to its extensive root system. However, drought severely limits sesame production in marginal and low rain-fed areas. In addition, accessions from wet areas such as Korea and Bangladesh are very susceptible to drought [18]. Assessment of drought tolerance as a ratio of yield under water stress to that under normal irrigation carried out for 17 sesame genotypes showed that the seed yield was sensitive to water shortage more than the morphological characters [66], while the mean weight of individual seeds escaped such effects. This depicts that postflowering response of drought in sesame is production of less seeds, instead of compromising on the seed size [67]. A survey of 27 sesame genotypes in Moghan region for tolerance to drought revealed Karaj1, Naz takshakhen, Varamin237, and Varamin2822 genotypes to be mid-resistant and suitable for cropping under drought stress on the basis of six drought tolerance indices [68].

Assessment of enzymes involved in prevention of ROS generated as an outcome of drought stress revealed increased activities for SOD, POX, CAT, and polyphenoloxidase (PPO) both in leaves and roots of sesame [69]. On the other hand, fresh and dry mass and total protein content of leaves showed a decreasing trend. Assay for MDA content was indicative of reduced lipid peroxidation. Yekta cultivar of sesame was found to be more resistant than the cultivar Darab14 [69].

Improved tolerance against drought is reported to have an association with increased content of cuticular waxes per unit leaf surface area in oats, rice, sorghum, alfalfa, and crested wheat grass [70]. However, the increased wax deposition does not always correlate inversely with transpiration rate. Imposition of water deficit on sesame cultivars caused an increase in wax amount by 30%, with 34% increase in alkanes, 13% in aldehydes, and 28% of the unknown ones [67]. An increase of 49% in cuticle thickness due to monomers of alkanes has also been observed in *Arabidopsis* plants on subjection to water deficit. Under such conditions, the gene ECERIFERUM1 having role in alkane metabolism showed upregulation [70]. Transcriptional factors such as WAX INDUCER 1 (WIN 1) in *Arabidopsis* have also been implicated in increasing wax deposition [71]. Deciphering of drought induction of alkane metabolic pathway, role of cuticle, and the actual mechanism behind slowing down of transpiration rate in drought tolerance, which regulates survival of sesame plant, is still awaited.

48.4.5 Heavy Metal Stress

Previous investigations have found oil-yielding plants, namely, mustard and sunflower, to be suitable for rhizoextraction as they accumulated more Cr from the soil in comparison to 36 other agricultural plant species [72]. Within oilseeds the pattern of heavy metal accumulation showed sesame to stand third after peanuts and rapeseed with sunflower being the last. The distribution pattern in the plant organs of sesame

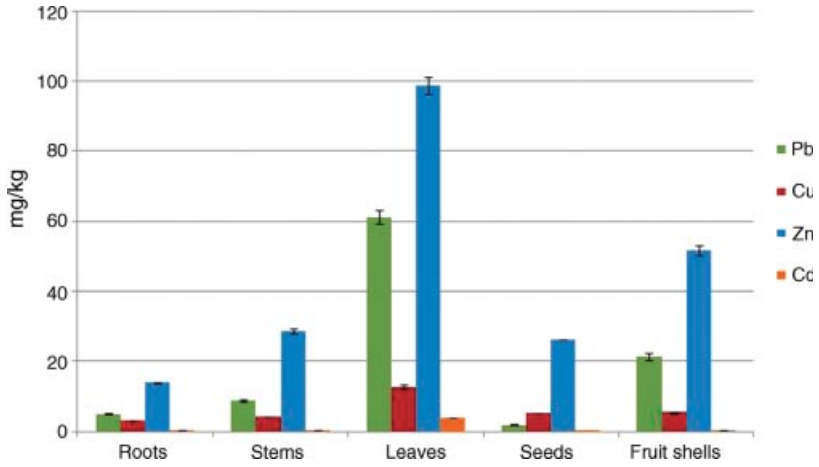

Figure 48.4 Organ-wise distribution of heavy metals in sesame at commercial ripeness stage (adapted from Angelova *et al.* [73]). Error bars represent the standard deviation.

showed an order of leaves > stem > roots > fruit shell > seeds [73] (Figure 48.4), revealing that the content was very less in the economically important edible organ, the seeds. The respective accumulation of heavy metals after 60 days of growth period in sesame followed an order of K > Na > Fe > Zn > Cr > Mn > Cu > Pb > Ni > Cd as determined by the technique of sequential extraction using EDTA [7]. In addition, the translocation of these metals was found less in upper parts. The potential of sesame to extract heavy metals from contaminated soils has also been determined by chemical fractionation analysis of *S. indicum* var. T55, which depicted an increased accumulation of toxic metals (Cr, Ni, and Cd) with increase in sludge ratio. The tannery sludge favored plant growth at lower amendment rates (25%) as depicted by increased fresh weight and number of leaves [74].

Increased affinity of sesame seeds toward accumulation of trace elements has also been reported in comparison to corn grains (0.54–1.94 ppm). Range of Cr content in sesame seeds was 0.77–2.14 ppm, with recommended daily allowances being 0.05–9.2 ppm [75]. Application of organic waste compost including municipal waste (MW) had no effect on the chemical constituents (oil, carbohydrates, and total protein) of sesame seeds. With treatment of MW, lead and cadmium concentrations increased in the plant; however, the amount of metals tested did not exceed the phytotoxic level [76]. Seeds of the high-yield sesame cultivar PB-1 showed significant tolerance to lead as shown by accumulation of more dry mass during early growth phase, although fresh weight showed slight inhibition at higher levels (2 mM of Pb^{2+}). On the other hand, cultivar HT-1 was shown to be Pb^{2+} sensitive [77]. Accumulation of Pb^{2+} increased with increasing concentration of the heavy metal in root, stem, and leaves. Estimation of *in vivo* nitrate reductase activity showed inhibition in roots and leaves with less effect on the latter, correlating with the respective accumulation of Pb^{2+} in the organs. However, *in vitro* nitrate reductase activity was not inhibited by

the metal. Total organic nitrogen was higher in young roots proposed due to increased N translocation from seeds to roots [77]. All these studies suggest that sesame shows tolerance to the presence of heavy metals in the soil and in fact shows significant ability to accumulate such elements. Therefore, sesame plant provides an interesting research system to understand the mechanisms involved in heavy metal accumulation, an area that is gaining importance for dealing with the management of degraded ecosystems due to contamination by undesirable concentration of toxic metals. However, it is of utmost importance to ensure the complete absence of these harmful moieties in the seed and seed oil for the safe edible consumption.

48.5
Abiotic Stress and Areas of Special Focus in Sesame

Out of the vast repertoire of genes governing abiotic stress tolerance in plants, few genes and gene products have gained special focus in sesame.

48.5.1
Lipid Transfer Proteins

The transfer of phospholipids between membranes is facilitated by group of proteins called lipid transfer proteins (LTPs) [78]. These are small (7–10 kDa), abundant, basic proteins containing eight conserved cysteine residues involved in four disulfide bridges. On the basis of the number of amino acids between the fourth and fifth cysteine residues in the motif's core, plant LTPs have been categorized into eight groups (LTP1–LTP8) [79]. Initially observed in spinach leaves, maize coleoptiles, and barley aleurone layers, they show ubiquitous expression in seedlings, leaves, stamen, tapetum, and microspores, as well as in somatic and zygotic embryos [78]. LTP genes are shown to be responsive to environmental changes such as salt, drought, abscisic acid (ABA) or cold treatment [80–84]. A nonspecific LTP gene isolated by subtractive hybridization between drought-tolerant and -sensitive sunflowers showed transcript induction by water stress and ABA [85]. cDNA microarray analysis in sunflower revealed upregulation of an LTP under chilling stress. However, downregulation of LTP was exhibited in saline environment as earlier shown in case of *Arabidopsis* [86]. LTPs are proposed to have a function in repairing stress-induced damage in membranes or changes in their lipid composition, perhaps to regulate their permeability to toxic ions and the fluidity [87, 88]. LTPs have also been shown to be secreted in response to NaCl stress and even affect cell wall extensibility [89]. Periodic dehydration stress in tree tobacco (*Nicotiana glauca*) leaves increased LTP mRNA expression and cuticular wax deposition. In addition, immunolocalization and LTP:: GFP fusion studies have localized LTPs to the cell wall and predominant expression in the epidermis [90, 91] suggesting their role in cutin and wax assembly [92]. Most plant LTPs are secreted to the cell wall by unidentified pathways. Although some intracellular LTPs have been observed in glyoxysome matrix of castor (*Ricinus comunis*) seed and protein storage vacuoles of cowpea (*Vigna unguiculata*) [93, 94].

These LTPs are present in multiple isoforms as detected in *Arabidopsis* and rice genome, showing differential expression pattern, whose functions are yet to be discovered [79, 83].

It is important and pertinent to point out that LTPs constitute one of the most abundant ESTs of immature sesame seeds of which 21 isoforms were identified [95]. Partially purified LTP isoforms of sesame (*SiLTP*) showed the ability to bind fluorescent fatty acids and transfer fluorescent phospholipids. Five *SiLTP* isoforms were most abundantly expressed in developing seeds, but also detected in flower tissues. *SiLTP3* and *SiLTP4* transcripts were also expressed in leaves and seed walls, respectively. *SiLTP2* and *SiLTP4* isoforms exhibited significantly inducible expression patterns with exogenous application of 300 mM NaCl and 300 mM mannitol. Exogenous ABA, which has been shown to mediate plant tolerance to water or cold stresses, also significantly induced the *SiLTP2* and *SiLTP4* isoforms. These were localized to plant cell membranes as seen by transient expression in *Arabidopsis* and were found to be associated with large organelles such as ER, probably being secreted from the cells via the classical secretory pathway. However, the biological roles of *SiLTPs* in response to salt and osmotic stresses remain to be elucidated, which might play an important role in plant acclimation to water stress during seed development.

48.5.2 Caleosins

Caleosins are calcium binding proteins of 27 kDa, ubiquitous among higher plants with similar candidates in algae and fungi [96]. These were identified in sesame seeds as minor proteins (Sop1) of oil bodies (OB) by immunolabeling [97]. Sop1 was found to be homologous to a rice protein (*OsClo*) that expresses abundantly in late embryogenesis and is responsive to ABA and osmotic stress (dehydration and NaCl) in seedlings and in vegetative tissues [98]. Similarly, mRNA of an *Arabidopsis* caleosin homologue (*AtClo1*) was detected in response to ABA during dehydration [99]. Sesame caleosin (*SiClo1*) mRNA accumulates in OBs, with maximal expression seen 2 weeks after flowering, thereafter undetectable in mature seeds [100]. In contrast to *OsClo*, *SiClo1* is therefore apparently seed specific. Recent analyses indicate that *Arabidopsis* contains at least five caleosin-like genes situated on four of the five chromosomes (*AtClo1–5*, [96]). *AtClo2–4* are expressed at low levels in various tissues, including nonoil storage tissues, while *At-Clo1* expression is seed specific. Interestingly, *AtClo1–4* expression is not responsive to ABA or osmotic stress in vegetative tissues, as in case of rice *OsClo*. Carrot oleosin is responsive only to ABA in embryonic tissue, and not in adult tissue [101]. A better understanding of this expression pattern in plant stress responses would be beneficial.

Caleosins have been located on the surface of OBs or associated with an endoplasmic reticulum (ER) subdomain [96]. Caleosin comprises three distinct structural domains: a unique N-terminal hydrophilic domain (containing a single Ca^{2+} binding EF hand), a central hydrophobic anchoring domain, and a C-terminal hydrophilic domain containing four possible phosphorylation sites [98, 100]. The central hydrophobic domain of *SiClo1* is proposed to consist of an amphipathic

α-helix followed by a short anchoring region formed by a pair of antiparallel β-strands connected by a proline knot-like motif [100]. The EF hand of *OsClo* is known to bind calcium *in vitro* [98]. Similar probability exists for *SiClo1* to bind calcium as *SiCLO1* purified from oil bodies or heterologously expressed exhibits EGTA-retarded and calcium-rescued migration in SDS-PAGE [100].

An *Arabidopsis* caleosin, *RD20* (responsive to dehydration 20) is reported to show enhanced expression by ABA, salt, dehydration, and osmotic stresses [99, 102]. It is among the early induced genes, one of the most highly expressed and often used as a stress marker gene [103, 104]. *RD20* is located at the bottom of chromosome 2, a region that appears to be important in the regulation of plant transpiration efficiency in *Arabidopsis*. It is expressed in particular tissues or organs during plant development. In contrast to other *Arabidopsis* caleosin genes *RD20* promoter sequence is enriched with AtMYC2 binding sites such as the ABRE (ABA-responsive element), ABRE-like, and DRE. Interestingly, AtMYC2 acts as a positive regulator of ABA signaling under drought stress [105]. *RD20* is able to bind calcium and also support a putative peroxygenase activity as in case of *OsClo* and *AtClo1* [99, 106]. Such peroxygenase activity in maize is involved in cuticle and wax synthesis [107], the latter is enhanced under water deficit conditions and ABA, to prevent water losses [70]. Recently, *RD20* was shown to be one of the components involved in enhancing tolerance to water deficit mechanisms through the regulation of stomatal aperture, plant growth, and water use efficiency [108] and in salt stress response, thus, hypothesized to act as a stress signaling hub that sets up multiple abiotic responses. The ability of sesame caleosins to undergo ubiquitination at two sites in the lysine residues in the C-terminal domain has been reported [109]. As ubiquitination of proteins has also been observed in stress responses [110], it would be interesting to establish such a role, if any, for *SiClo*.

48.5.3 Steroid Dehydrogenase

Sesame steroleosin (Sop 2), a 39 kDa protein comprising 348 amino acid residues, is a minor protein of OBs [111]. The Sop2 gene was obtained by immunoscreening that showed transcription in the maturing seeds. The protein possesses a hydrophobic anchoring segment preceding a soluble domain homologous to sterol binding dehydrogenases/reductases known to be involved in signal transduction in diverse organisms. Structure of the soluble domain consists of a seven-stranded parallel β-sheet with the active site, S-(12X)-Y-(3X)-K, between an NADPH and a sterol binding subdomain. Its sterol-coupling dehydrogenase activity has been demonstrated both in the overexpressed soluble domain of steroleosin and in purified oil bodies. Southern hybridization suggests the presence of one steroleosin gene and certain homologous genes in the sesame genome [111]. In contrast, eight hypothetical steroleosin-like proteins are present in the *Arabidopsis* genome with a conserved NADPH binding subdomain, but a divergent sterol binding subdomain. Steroid dehydrogenase-like protein (SDs) has been found to be induced by drought stress [112] and in response to high light stress and ascorbate deficiency in

Arabidopsis [113]. This indicates role of SDs in protecting against ROS produced by high light and in the absence of ascorbate (vitamin C), one of the major antioxidant species of chloroplasts that is a cofactor of thylakoid-bound and stromal ascorbate peroxidases that detoxify H_2O_2 produced by SODs. Transgenic *Arabidopsis* plants overexpressing hydroxylsteroid dehydrogenases (AtHSD1) also provide increased tolerance to salinity stress [114]. Whether this tolerance is mediated by brassinosteroid signaling or increased ABA catabolism remains to be elucidated, before getting utilized in other crops such as sesame.

48.5.4 Phytostatins

Phytocystatins, homologues of cystatins of animals, are a small family of plant proteins commonly ranging from 12 to 16 kDa, consisting of more than 80 members [115]. In general, they possess three conserved residues, a G residue in the vicinity of the N-terminal end, a highly conserved QVVAG motif in a central loop segment, and a PW dipeptide motif closer to the C-terminal end of the protein, which are known to interact with the active site cleft of cysteine proteinases belonging to the papain family, causing their reversible inhibition [116]. In addition, plant cystatins possess a unique and conserved LARFAVDEHN sequence at the N-terminal end of an α-helix segment [117]. Apart from their participation in biotic stresses and seed germination, their role in abiotic stresses has been proposed. Accumulation of phytocystatin mRNA (AtCYS1) has been observed in *Arabidopsis* under high-temperature stress [118], in the vegetative tissues of barley plants subjected to anaerobiosis, darkness, and cold shock [119], and in the leaves and roots of chestnut plantlets exposed to cold, saline- or heat-stress [120]. Similarly, in grain amaranth, increased expression of cystatins (AhCPI) was seen in roots and stems substantially in response to water deficit, salinity, cold, and heat stress, whereas heat stress induced a rapid and transient accumulation in leaves [117].

Low-abundant endogenous cystatin (22 kDa) has been purified to homogeneity via a papain-coupling affinity column from mature sesame seeds. These were shown to express in germinating seeds; however, their ability to inhibit endogenous cysteine proteases was not revealed [121]. These proteins from sesame have been expressed and purified via artificial oil bodies for final biotechnological application in protection of plants and other industrial uses [122]. The role of sesame phytocystatins in abiotic stresses requires further research efforts.

48.5.5 Lignans

Stresses such as drought, salt, UV radiation, ozone, chilling, heat shock, pathogen attack, and so on increase the production of ROS in plants leading to development of several enzymatic and nonenzymatic defense systems against ROS. Under such oxidative stress conditions, plants with high constitutive and induced antioxidant levels are known to have better resistance to damage [123–125].

In contrast to the meager knowledge on enzymatic antioxidative defense system operating in sesame, the nonenzymatic antioxidant substances termed lignans effective in oxidative defense system are well studied. Widely distributed in vascular plants, lignans comprise a large group of natural products characterized by coupling of two *p*-hydroxyphenylpropane (C_6C_3) units and possessing a β,β′-linkage. These are represented by about 20 compounds in sesame, basically in the form of oil-soluble and glycosylated lignans [126]. Among the oil-soluble ones, the most predominant are sesamin and sesamolin, accompanied by traces of others. Interestingly, the two lignans, sesamolin and sesamolinol, possess an oxygen bridge between their benzene and furofuran rings, the feature unique to the genus *Sesamum* [127]. Sesame seeds have on average 0.63% lignans with sesamin and sesamolin contents ranging from 0.07 to 0.61% (mean ± SD, 163 ± 141 mg/100 g) and from 0.02 to 0.48% (101 ± 58 mg/100 g), respectively [7, 128]. Among sesame cultivars of India, those collected from the Northeastern states are found to be higher in lignan content (18 g sesamin/kg, 10 g sesamolin/kg) [129]. The most frequent technique used for lignan-type detection and quantification in sesame is high-performance liquid chromatography [130–132] that has now been subsequently simplified [133]. LC-NMR-MS has also emerged as the fast screening device for the characterization of sesame lignans from various sesame oil-based sources, for assessing the antioxidant activity of the extracts, and especially for modifying the lignan profile of the conventional sesame oil extract to get a sesaminol-enriched extract [134].

Studies on these lignans with respect to stress have displayed their stress combating ability. Under *in vitro* experimentation, sesaminol was shown to inhibit Cu^{2+}-induced lipid peroxidation in low-density lipoprotein and was found to be more effective scavenger than either α-tocopherol or probucol in reducing the peroxyl radicals in aqueous solution [135]. The analysis of sesame oil extracts for antioxidant activity has revealed the following order: sesamin < sesame oil extract < sesaminol-enriched sesame oil extract < sesamol. The combination of sesaminol and γ-tocopherol has been proposed to be synergistically responsible for the actual oxidative stability of sesame oil [134].

Sesamin, one of the major furofuran lignan in sesame seeds, has been extensively studied by Ono *et al*. [136]. The gene responsible for the catalysis of sesamin biosynthesis from pinoresinol (the first lignan in the pathway) is deciphered out to be a cytochrome SiP450, CYP8101. The protein requires NADPH for its activity and is unique due to its dual catalyzing ability leading to the formation of two methylenedioxy bridges (producing sesamin via piperitol), which is restricted to only one such bridge in all known P450 proteins. This biosynthesis has been localized to the cytoplasmic surface of endoplasmic reticulum as revealed by the expression of CYP81Q1-GFP protein in onion epidermal peel via transient system. The gene is present singly and its functional validation has been obtained by the observation of a functional homologue isolated from *S. radiatum* (having sesamin in seeds) and the presence of a nonfunctional P450 homologue from *S. alatum* that lacks sesamin. The P450 proteins are shown to have evolved independently as the CYP81Q1 shows only 24% sequence identity with the Ranunculaceae member, *Coptis* CYP719A1. The mode of action of CYP81Q proteins has also been proposed, the diagrammatic

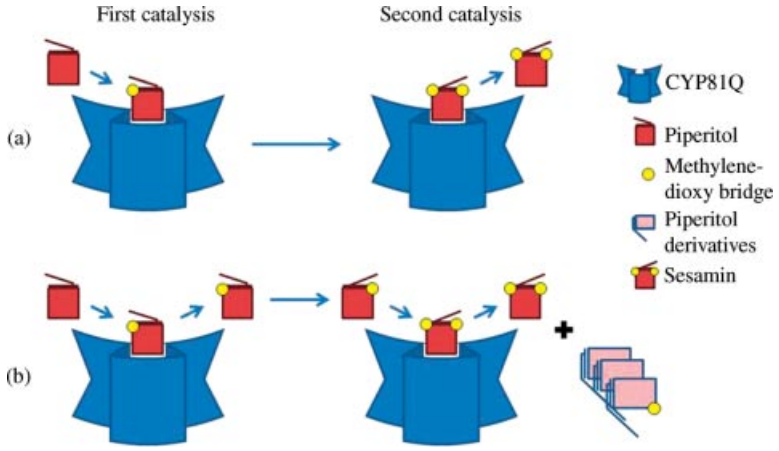

Figure 48.5 Diagrammatic representation of the two alternative models proposed for the mode of action of cytochrome P450 of sesame, CYP81Q (adapted from Ono *et al.* [136]). (a) Sequential methylenedioxy bridge formation. Piperitol reverses in the active site after the first catalysis for formation of second methylenedioxy bridge at the opposite end. (b) Piperitol is released after first catalysis and then recaptured for second one, a part of it being converted to its derivatives.

representation of which is given in Figure 48.5. Genes involved in biosynthesis of antioxidant lignans and accumulation of storage products have been identified in the form of 3328 ESTs from a cDNA library of immature seeds [137]. When compared to the model plant *Arabidopsis* proteome, a total of 62 ESTs from sesame were proposed to be involved in lignan biosynthesis (Figure 48.6).

Apart from being beneficial to human health as anticancerous and anticholestrol agents, studies on rats showed lignans to increase the expression of β-oxidation-associated enzymes in peroxisomes (upregulation of 38 genes, 16 of which are involved in lipid metabolizing function) [138]. Several mechanisms of action have been proposed to explain the potential physiological role of sesame lignans. Especially in animal systems, namely, cultured liver cells. The role of sesamin on the lipid metabolism has been studied extensively and the following mechanisms of actions have been proposed: inhibition of Δ5-desaturase activity [139], inhibition of HMG-CoA reductase activity [140], and inhibition of acyl-CoA cholesterol acyltransferase (ACAT) activity [141]. However, such gene profiling studies and their potential status associating lignans with different stresses are lacking with respect to plants as a system. Overall, this area needs further attention to decipher the actual mechanism behind the combating of stress in plants in general and sesame in particular.

48.5.6
Geranylgeranyl Reductase

Tocopherols are lipid-soluble antioxidants known collectively as vitamin E. These compounds are the major line of defense against ROS generated during various

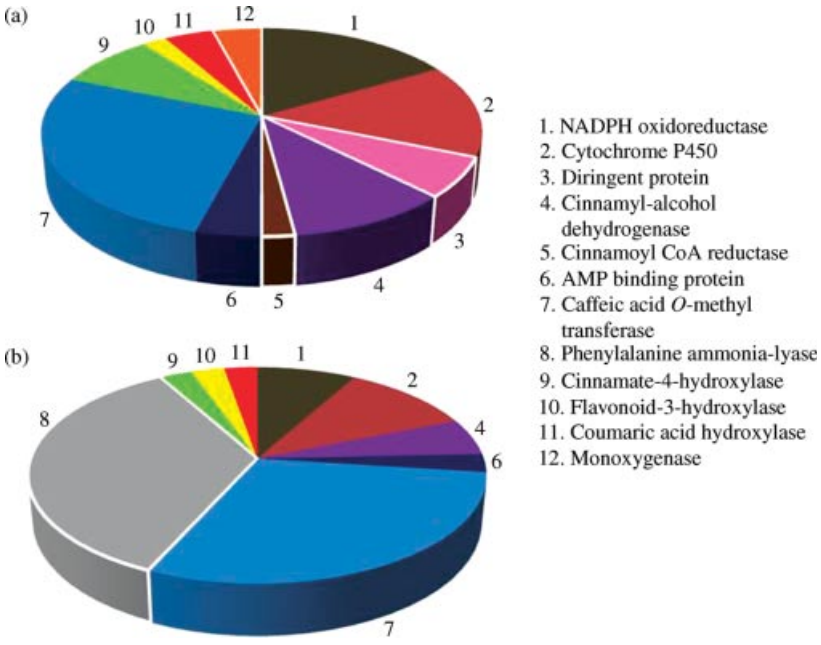

Figure 48.6 Putative ESTs involved in synthesis of lignan, an innate antioxidant defense system in plants (a) sesame and (b) *Arabidopsis* (adapted from Suh *et al.* [137]). Sectors unique to the respective plant are highlighted with white borders.

abiotic stresses. Plants synthesize four isoforms of tocopherols, α-, β-, γ-, and δ-tocopherol, which differ by the numbers and positions of methyl substituents on the aromatic rings of the molecules [142]. The highly efficient antioxidant sesame oil contains about 528 μg/g of total tocopherols [143]. Formation of the first tocopherol intermediate requires reduction of geranylgeranyl diphosphate (GGPP) to phytyl diphosphate [144] that is catalyzed by the enzyme GGPP reductase (*Chl P*) [145]. Sesame GGPP reductase (*SiChl P*) encoded as a 465 amino acid polypeptide shows high degree of similarity to the plant *Chl P*s with the closest evolutionary relationship to tobacco *Chl P* [146]. In contrast to the bacterial *Chl P*s, the *SiChl P* contains an aminoterminal extension that resembles a plastid transit peptide sequence, indicating the possible localization of the enzyme in chloroplasts as known for plant *Chl P*s [147]. The sequence consists of 55 amino acids with the cleavage site located between A55 and A56 in the sequence NLR → VAV. This transit peptide predicted from *SiChl P* is rich in serine and threonine but deficient in acidic amino acids [148]. GGPP belongs to the family of oxidoreductases that contain a nucleotide cofactor-binding domain for stabilization of the β-strand and α-helix interaction, connected by a short loop in which the ligand binding domain is located [149]. The presence of typical motif commonly found in oxidoreductases, V/IXGX1- 2GXXGXXXG/A, in the N-terminus of the mature *SiChl P* polypeptide clearly indicates its function [146]. *SiChl P* is present as a single gene with its high expressions observed in developing

seeds and leaves supporting its role in tocopherol biosynthesis in sesame. In addition to factors such as dark and ethylene, *SiChl P* was shown to be repressed by ABA, which is generally produced upon drought and cold stress with subsequent induction of expressions of various subsets of downstream genes [150, 151]. Similar diminished expression was seen for *PpChl P* in peach leaves in response to cold stress and wounding [152]. *Chl P* has been identified from soybean, ice plant, and several photosynthetic bacteria, although detailed investigations have been performed only in a few plant species such as tobacco [145] and *Arabidopsis* [153].

48.5.7 γ-Aminobutyric Acid

γ-Aminobutryric acid (GABA) is a four carbon nonprotein amino acid found in all prokaryotic and eukaryotic organisms. The metabolic pathway involving synthesis and catabolism of GABA is known as "GABA shunt," as it bypasses two steps of tricarboxylic acid cycle. It rapidly accumulates in responses to heat, drought, salt and low-temperature stresses [154–157]. GABA is proposed to be involved in stress perception in sesame, as application of stresses such as drought, salt, heavy metal, and high temperature showed increment in GABA levels, but it was not able to sustain normal plant growth [158]. Highest increment of GABA was in case of heavy metal treatment, followed by drought, while accumulation rates under salt and high-temperature treatments were almost the same. Differential ability of the sesame plant in coping with these stresses was proposed to be the reason behind variation in the rate of GABA synthesis [158]. Upregulation of a GABA receptor has been observed in two tolerant genotypes of barley [159] and increased expression of genes for GABA shunt in response to drought [160]. GABA has been shown to reduce accumulation of ROS in aluminum and proton-stressed barley [161]. Its other proposed roles under different stresses include maintenance of C:N balance, regulation of cytosolic pH, and osmoregulation and as a signaling molecule [162]. Furthermore, the role of Ca^{2+}/CaM in GABA-mediated tolerance to oxidative stress, heat shock, and osmotic and salt tolerance through effector molecules has also been suggested [163].

48.5.8 Metallothioneins

Metallothioneins (MTs) are ubiquitous low-molecular weight, cysteine-rich cytoplasmic proteins that can bind metals via mercaptide bonds. On the basis of the number and arrangement of cysteine residues, all the plant MTs belong to class II (in contrast to the vertebrate class I) and can be further subdivided into four types according to the distribution pattern of Cys residues [164, 165]. Expression analysis has shown type 1 MTs to express preferentially in roots [166], type 2 mainly in leaves [167, 168], type 3 in ripe fruits and leaves [169], and type 4 in developing seeds [170–172]. In plants, MTs are known to participate in maintaining the homeostasis of essential copper (Cu) and zinc (Zn) at micronutrient levels and in heavy metal stress for detoxification of nonessential toxic metals such as cadmium

(Cd) and arsenic (As) [173–176]. The expression of MT genes is affected by oxidative stress, and other abiotic stresses, such as drought and salt [177, 178], hence their role as protectants from oxidative damages has been proposed [179–182]. MTs from *Tamarix hispida* (*ThMT3*) was upregulated by high salinity and heavy metal ions, with predominant expression in the leaf [183]. Transgenics for MTs in rice (*OsMT1a*) enhanced its drought tolerance and increased activity of ROS scavenging enzymes [184] showing expression in roots. Tobacco plants overexpressing *GhMT3a*, a type 3 MT isolated from cotton (*Gossypium hirsutum*), were shown to have reported only half of H_2O_2 levels in transgenic than those in wild-type plants under salt, drought, and low-temperature stresses, suggesting that changes in ROS signaling might be the reason for higher stress tolerance [185]. It has been hypothesized that MTs scavenge the superoxide radicals either independent of SOD or act as an activator of SOD by supplying metals such as Cu or Zn to apo-SOD [186]. Transcriptome analysis of mature sesame seeds has revealed the presence of abundant transcripts for metallothioneins [171] indicating the presence of a conserved metal toxicity combating mechanism in sesame. Further research on overcoming the limitations regarding *in vivo* protein expression studies would be beneficial in dissection of the actual process of scavenging performed by the MTs.

48.6
Approaches for Incorporation of Abiotic Tolerance

The process of incorporation of genes imparting tolerance to abiotic stresses would involve either avoiding the stress or combating the stress by inducing expression of genes that directly or indirectly are responsible for the synthesis of required metabolites. The basic strategies initiating synthesis of these metabolites can be targeted either at the functional genes or regulatory genes. Advances in high-throughput techniques have enabled identification of large number of genes that are differentially regulated in response to a specific environmental stress. Both conventional and nonconventional methodologies await their utilization for incorporating abiotic stress tolerance in sesame. The final goal of developing stress-tolerant genotypes can be achieved by different approaches, but the key steps that need to be undertaken (Figure 48.7) are as follows:

- Search for useful traits/genotypes.
- Identifying and understanding the precise mechanism and genes responsible for the stress tolerance.
- Transfer of the trait using conventional or biotechnological tools.
- Screening of the target genotypes for successful transfer of the desired trait.
- Acceptance of the farmers for growing the novel genotypes.

Therefore, irrespective of the approach used for incorporation, the first and foremost requirement is the search of the donor of the desired trait. Conventional approaches can be applied only if taxa having the desired trait constitute the primary, secondary, or even tertiary gene pool of the crop plant. In the absence of desired trait

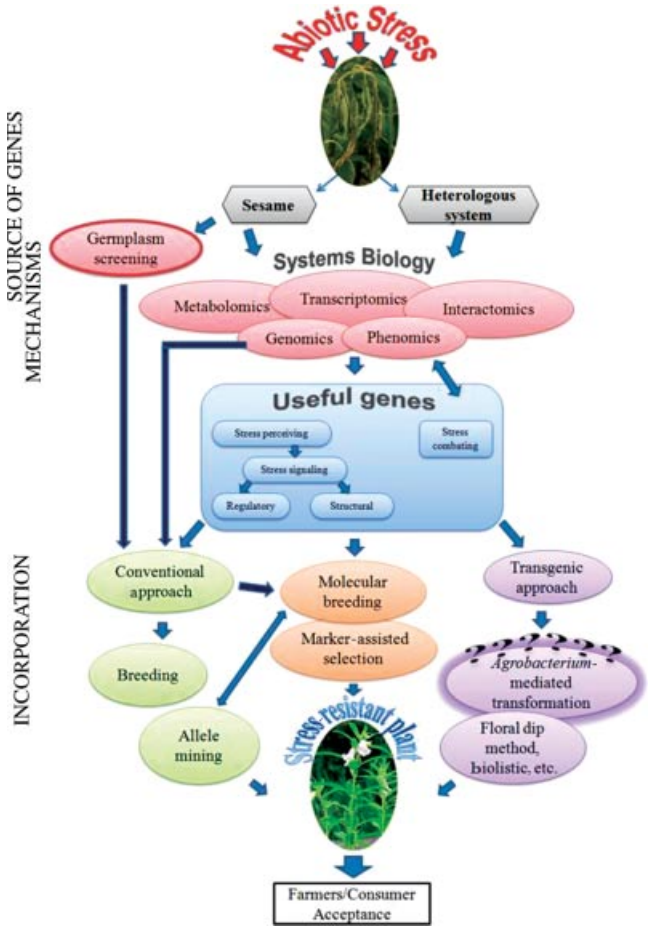

Figure 48.7 Schematic representation of the fundamental steps involved in development of abiotic stress-resistant plants using different approaches.

within the conventional gene pool, the biotechnological approaches provide the required tools for the transfer of the traits from the donor taxa to the desired background. Once the transfer has taken place, the screening methodologies would remain the same in both the approaches. However, the acceptance of the improved cultivar by the farmer and the consumer can again have different reactions depending upon the approach used.

48.6.1 Search for Useful Genes in the Sesame Germplasm

Natural genetic diversity is a sustainable resource that can enrich the genetic basis of cultivated genepool with novel alleles that improve productivity and adaptation.

Substantial genetic variation existing in the cultivated genepool of sesame can be exploited in breeding programs addressing abiotic stress tolerance. Furthermore, the wild species of *Sesamum* have been reported to possess desirable genes for the characters of major importance in sesame breeding including drought resistance and tolerance to heavy rainfall [187]. Desirable characters have been identified for the sesame improvement with aims to maintain and enhance sesame production in addition to high yield potential coupled with harvest index, seed retention, uniform maturation through determinate habit, and tolerance to biotic and abiotic stresses. A list of major characters identified [6, 188–192] with an emphasis on overcoming abiotic stresses are listed below.

Seedling characters: Fast vigorous germination and emergence with strong hypocotylar elongation, rapid growth in early stages, and ability to germinate and withstand lower temperatures.
Plant characters: Rapid root growth, deep taproot penetration with well-distributed secondary root system; leaves with medium to broad base, narrow lanceolate toward apex, short petioles, higher photosynthetic efficiency, and early abscission.
Physiological characters: Photo- and thermoinsensitivity, early maturity, and higher nutrient uptake under low fertility; tolerance to water logging, drought, salinity; nonlodging under high fertility; and uniform ripening.
Yields: High and stable under a wide range of environmental conditions.

Significantly large germplasm collections have been made for sesame by different sesame growing countries and have been characterized for morphoagronomic traits following the IBPGR (now Biodiversity International) descriptors.

Being the center of origin and diversity for sesame [4], India has particularly rich diversity for economically important traits that are largely underexplored for use in crop improvement programs [5, 193]. However, a systematic screening of the germplasm or even the core collections identified is entirely lacking. Few fragmented studies using limited collections have been attempted for tolerance to different abiotic stresses. Therefore, there is need to undertake systematic and comprehensive screening of sesame germplasm for tolerance to individual abiotic stresses giving suitable environment. The specific trait-based core collections can be identified and used as reference collections for individual stresses. The promising germplasm accessions identified can be directly used as the donor in the conventional breeding programs and also subjected to detailed investigations for gene prospecting.

The major challenges in successful incorporation of abiotic stress tolerance in the desired taxa or genotypes are the gaps in the understanding of the mechanisms responsible for their expression. First, the precise metabolic and structural attributes that impart such valuable adaptations in the plants are far from understood. Next major challenge is the transfer of these traits to the genotypes of our choice. A synergy between traditional breeding and genomic approach is the need of the hour in meeting these challenges. Characterization of sesame genetic diversity should employ the tools of functional genomic approaches. Therefore, discovery of gene trait from the diverse genetic resources available coupled with phenotyping and

bioinformatics followed by proof of the candidate gene function *in planta* leading to successful expression of the trait in the desired background is being advocated [194]. Growth or yield penalty in the stress-resistant plants under the unstressed conditions is yet another challenge that can be addressed by driving expression of genes in response to stress by an inducible promoter [195].

48.7 Conventional Approach

The conventional approaches to develop the genotypes of interest involve creation of new gene combinations by either crossing the genotypes having the desired traits individually or by introducing new germplasm. The desired variability thus obtained needs to be narrowed down to few genotypes. The success of the effort necessitates exercising high selection intensity (i.e., selection of few genotypes) on genotypes having large differences (i.e., having high genetic variance) using accurate methods to assess characters that are transmitted to subsequent generations (i.e., having high heritability).

Conventional breeding approaches for incorporation of the desired trait have always been the first choice of the breeders provided the source of the desired gene and the target genotypes do not pose uncircumventable crossability barriers. This approach essentially requires identification of stress-resistant genotype within the gene pool, followed by their crossing with agronomically superior cultivar and repeated backcrosses and selection of the desired phenotypes in each generation. Although attempts are being made to develop drought-tolerant sesame cultivars through breeding approach [66], the process is challenging because of gaps in understanding/information on precise phenotypic traits to be selected in the segregating generation. This process can be made more specific and targeted by marker-assisted breeding. However, there are still no such usable validated markers available in sesame. Furthermore, the very basic requirement of MAS, that is, a saturated linkage map based on molecular marker, is still lacking and is a prerequisite for background selection for recipient's genotypes.

48.7.1 Recent Approaches in Utilization of Genetic Variation

48.7.1.1 Association Genetics

Association mapping, a high-resolution method for mapping quantitative trait loci, based on linkage disequilibrium, holds great promise for the dissection of complex genetic traits. Most traits related to abiotic stress tolerance are controlled by multiple quantitative trait loci. Genetic mapping and molecular characterization of these functional loci would facilitate genome-aided breeding for stress tolerance. Two of the most commonly used tools for dissecting complex traits are linkage analysis and association mapping. Linkage analysis exploits the shared inheritance of functional polymorphisms and adjacent markers within families or pedigrees of known

ancestry. Linkage analysis in plants has been typically conducted with experimental populations that are derived from a biparental cross. Although based on the same fundamental principles of genetic recombination as linkage analysis, association mapping examines this shared inheritance for a collection of individuals often with unobserved ancestry. As the unobserved ancestry can extend thousands of generations, the shared inheritance will persist only for adjacent loci after these many generations of recombination. Essentially, association mapping exploits historical and evolutionary recombination at the population level [196]. By exploring deeper population genealogy rather than family pedigree, association mapping offers several advantages over linkage analysis such as much higher mapping resolution, greater allele number, broader reference population, and less research time in establishing an association. Linkage analysis and association mapping, however, are complementary to each other in terms of providing prior knowledge, cross-validation, and statistical power.

The linkage disequilibrium approach that forms the basis for association mapping is useful in identifying the genetic mechanisms responsible for abiotic stress tolerance and their fine dissection. Linkage disequilibrium (LD) refers to the nonrandom association of alleles between genetic loci. The core collection of sesame representing the genetic variation in cultivated sesames [197] is a good source for identifying the basic mechanisms contributing to abiotic stress tolerance in sesame. The process is also useful in detection of molecular markers closely linked to the genes of interest, thereby providing a mechanism to transfer the genes identified from donors to recipients through marker-assisted breeding programs.

48.7.1.2 **Phenomics**

Precision of association analysis depends to a large extent on the accuracy of phenotyping. Although enhanced yield of economically important product of a crop is the ultimate target in crop breeding, yield as a trait is highly complex to be deciphered in terms of effects of a gene or its allelic forms. Furthermore, association analysis attempts to relate a product of expression to an allele. Therefore, accurate estimation of gene effects is basic to the success of the approach. Association analysis requires accurate "phenotyping" of genotypes on a scale larger than any breeding-related analysis; hence, an approach such as "phenomics" is essential for unbiased estimation of effects of genes [198]. State-of-the-art phenomics facilities such as the Australian Plant Phenomics Facility with the Plant Accelerator involving the Waite Campus of the University of Adelaide and the High Resolution Plant Phenomics Centre involving CSIRO Plant Industry and the Australian National University in Canberra have highlighted the scientific advantages of automation in large-scale phenotyping in crop modeling. Such facilities include infrared and RGB imaging and other facilities to estimate total biomass, canopy temperature, and other features that are useful in evaluating a plant response to environmental stress and impulses. Since the procedures involved are nondestructive in nature, there is an added advantage for carrying forward the genotypes selected.

Besides, molecular dissection of tolerance mechanisms in heterologous systems that is an integral part of such approaches may lead to isolation of novel genes and

promoters. These genes can be used to improve tolerance in cultivated species or agronomically superior cultivars of sesame. Several genes for abiotic stress tolerance such as *codA*, *metD*, *tps1*, *mdh*, *hsp*(*s*), *acdS*, and sigma factors and antioxidant enzymes have been identified and utilized for development of transgenic crop plants. Isolation of such genes and alleles from indigenous resources will enrich the gene pool, which can further enhance both the transgenic and the conventional crop breeding programs. Phenomics approach also enables us to understand the precise molecular mechanism involved in conferring tolerance against different kinds of abiotic stresses.

Breeders conventionally go for early selection for characters such as biotic stresses, desirable plant type, and other yield-related traits. It is only at the advanced testing stages that the entries are tested for abiotic stresses when their numbers have been significantly reduced and are far from a complete representation of the initial material. Therefore, the success for breeding abiotic stress-resistant genotypes has been poor due to low selection intensity at this stage. The various reasons for having apprehensions on selection at early stages range from the presence of fewer differences between entries leading to reduction in the selection gain due to low heritabilities and variance for yield traits under abiotic stresses as the yields fall. Also, there are practical problems in selecting the best germplasm due to experiment-to-experiment variation because of high genotype × environment interaction in stress experiments. In addition, a general assumption that the high-yield entries in the stress-free environments will have the increased grain yield potential under the abiotic stress condition prevails. Finally but perhaps most importantly, lack of interest on the part of private seed sector for the resource-poor farmers due to their commercial interest in favor of rich farmers prevails that in turn unfortunately influences the public sector scientists also.

In addition to the constraints due to conventional breeding practices, the genetic considerations for the lack of abiotic stress tolerance in the cultivated gene pool cannot be ignored. Foremost among the genetic reasons is the founder effect that results in the genetic bottleneck during domestication of the crop plants. Occurrence of wild relatives as natural populations under the harsh environmental conditions in case of most of the crop plants confirms the loss of useful alleles during domestication.

Though the traditional/conventional approaches of plant breeding have contributed significantly to the increase in the crop productivity resulting in cultivars having higher tolerance to biotic stresses and better plant types, there is need to adopt modern biotechnological approaches for dealing with abiotic stresses as the success stories in this aspect are rather few. The basic causes responsible for this shift are [195] as follows:

1) Focus has been on yield rather than on specific traits.
2) Difficulties in breeding for tolerance traits as they are subjected to GXE interactions.
3) Relatively infrequent use of simple physiological traits as measures of tolerance.
4) Desired traits can be used only from closely related taxa.

48.8 Transgenic Approach

Transgenic approaches being employed for the transfer of abiotic stress tolerance to other crops could be helpful in sesame. The use of transgenic approaches for incorporation of useful genes often depends upon the efficient *in vitro* regeneration protocols. However, a highly efficient regeneration protocol for sesame has yet to be optimized. Several attempts have been made to develop efficient *in vitro* regeneration and transformation protocols for sesame in the past decades. The first initiative was taken by Govil and Singh [199] for haploid production using anthers. Whole plants were obtained by shoot tip culture by Lee *et al.* [200]. Further studies using shoot tip as explants resulted in callus [201], while multiple shoot buds to single plantlet were obtained when shoot tips used were pretreated [202] or were supplemented with kinetin in addition to BA [203]. Leaf segments as explants showed responses such as adventitious shoot formation and rooting of shoots [204]. Using anther as explant caused callus generation in most cases [205]. The use of hypocotyls and cotyledon gave no callus even under various combinations of media [201], while Lee *et al.* [206] were successful in attaining the callus stage. A different attempt via protoplast culture of hypocotyls also resulted in callus production [207]. Although, embryo-like structures and adventitious shoots were observed when reducing the concentration of both NAA and BA from the earlier adopted ones [208, 209]. In addition, direct usage of callus in protoplast culture also failed to generate plantlets and terminated at callusing [210]. Rooting of the regenerated shoots also poses problem. Some success was achieved by Takebayashi *et al.* [211], but the use of seedling or seed resulted only in callus formation [212] and subsequent variations of explants as wounded cotyledon lamina or deembryonate cotyledon as a whole ended up with multiple shoots [213, 214]. There is no report of standardized protocol for indirect regeneration of plants from callus. Xu *et al.* [215] reported a low plant conversion rate from somatic embyos that was followed by the report of induction of multiple shoots from nodal segments with axillary buds [216]. Further progress in shoot regeneration has been achieved at a maximum frequency of 63% and 4.4 shoots per regenerating explants [213]. Only recently, internodal thin-cell layer culture was reported to produce efficient shoots with rooting and establishment of 80% plantlets [217].

Success stories of *Agrobacterium*-mediated genetic transformation in sesame are few. Ogasawara *et al.* [218] transformed sesame for increasing the yield of naphthoquinone by the means of *Agrobacterium rhizogens* ATCC 15834 mediated hairy root culture. The use of *A. tumefaciens* by Taskin *et al.* [219] for expression of carrot calmodulin gene in another species of sesame (*S. schinzianum*) has been reported [220]. Production of recombinant proteins (a fungal protein, phytase) has been achieved by sesame hairy root cultures [221]. Recently, successful recovery of fertile transgenic plants was achieved using *A. tumaefaciens* strain with cotyledon explants that displayed a transformation efficiency of 1.01% [222]. In view of the above, any attempt to use transgenic technologies for incorporating abiotic stress in sesame should prefer methods where the *in vitro* regeneration step is not needed. This includes floral dip method where flowering shoots are swirled in a solution of

Agrobacterium, resulting in the formation of transgenic seeds [223, 224]. Of the various biolistic methods that involve physical DNA delivery, microprojectile bombardment of tissues has also proven useful for transforming plants that lack good regeneration systems [225]. Another method involving infection of apical meristem of the differentiated embryo of the germinating seedling with *Agrobacterium* has worked well in the recalcitrant cotton resulting in transgenic T1 plants [226]. However, in groundnuts infection of *Agrobacterium* after pricking of embryo axes of mature seeds with one excised cotyledon directly gave transformed seedlings [227]. Nevertheless, lack of protocols necessary for transgenic development in sesame may get compensated with extremely high genetic variability present in the cultivated gene pool of sesame and its wild allies [5].

High-throughput technologies along with powerful bioinformatics tools are proving useful to meet the challenges in understanding the abiotic stress tolerance in more than one way. The "omics" approaches have opened up the genome, its transcriptional products, regulatory networks, signaling pathways and their interactions, and the metabolites involved in the entire gamut of stress tolerance spanning from its perception, differential gene expression, and imparting protection from damage caused due to abiotic stress. Therefore, the functional genomics approaches involving transcriptome, interactome, and metabolome profiling of the plant subjected to specific stress environment are required in sesame (Table 48.1).

Table 48.1 The generalized key steps, activities, and expected outputs involved during incorporation of abiotic stress tolerance.

Key steps	What needs to be done	Output
Identification of trait donor	Large-scale germplasm screening including wild relatives	Core/reference collection for fine scale analysis
	Phenomics for fine dissection of underlying mechanism	Donors for specific mechanisms of tolerance
	Functional genomics	Understanding the natural mechanisms and pathways
	Association genetics	SNPs for specific traits
	Genome-wide approach	Allelic variations for specific mechanisms
	Candidate gene approach	Marker tags for specific traits
	Allele mining	Superior/elite germplasm for direct utilization
	Gene mapping and marker tagging	
Understanding the mechanism of tolerance	Functional genomics	Identification of genes/pathways/networks for tolerance
	Systems biology approach	
Incorporation of the stress tolerance	Conventional back cross breeding	Abiotic stress resistant varieties
	Marker assisted breeding	
	Transgenic approach	

Research efforts on incorporation of abiotic tolerance in sesame can greatly benefit from the lessons learnt from other crops where considerable progress has already been made. The studies on large number of crops indicate that pathways and gene networks between different abiotic stresses overlap significantly. On the other hand, managing tolerance to one type of stress can result in making the plants susceptible to other type of stress due to opposing physiological and molecular processes. Thorough investigations into the individual stress response may contribute to the understanding of the basic mechanisms involved, but would be largely unsuccessful in translating this knowledge for developing genotypes that exhibit superior performance in the field. Therefore, there is need to study the multiple stresses simultaneously in various combinations. In addition, due consideration needs to be given to the phenology-related parameters of the plant also as similar stresses are known to affect plants with different life cycle differently.

Research efforts and funds to "orphan" crops such as sesame that go beyond the mere increase in crop yields deserve special emphasis as they are crucial for food and nutritional security on a regional or local basis. Though gross economic and welfare impacts of investments made in crops such as sesame may appear to give low returns, the alternative indicators such as promotion of crop and genetic diversity leading to overall agricultural stability highlight the urgent need to pay attention to these crops [228]. In addition, an understanding of the basic mechanisms of the unique traits lacking in major plants and model systems such as extraordinary antioxidative ability of sesame seed oil, drought tolerance, ability to accumulate heavy metals, and so on can be utilized for the improvement of major cops subsequently.

Jatropha curcas: Approaches to Engineer Fatty Acid Synthesis and Abiotic Stress Tolerance

Nalini Eswaran and Tangirala Sudhakar Johnson

Owing to volatile crude oil prices, increased demand for transportation fuel in emerging economies, and changes in global climatic conditions, it is widely agreed that more sustainable alternative energy sources need to be developed in the near future. *Jatropha curcas*, a member of Euphorbiaceae, is emerging as the most promising tree-borne oil seed as a source of biodiesel as it does not compete with conventional food crops and has a lipid composition similar to that of fossil fuel. However, nonavailability of improved varieties and production under semiarid conditions marred the prospects of being a successful energy crop. In this review, we present the progress and genetic engineering approaches toward the improvement of two important traits, namely, fatty acid synthesis and abiotic stress tolerance. Integration of "omics" approach for identifying key regulatory elements, genes, with metabolic engineering is essential to realize the full potential of *Jatropha curcas* as an energy crop.

49.1
Introduction

Increase in crude oil prices, global warming, and limited reserves of fossil fuels underlined the importance of renewable and alternative energy sources such as biofuel. Among biofuels, bioethanol and biodiesel are considered the first-generation fuels, which are progressively contributing to the decrease in dependency on fossil fuel. The keen interest in biofuels is mainly driven both by climate change issues, aiming to reduce carbon emissions, and by geopolitical issues, aiming to reduce nations' dependence on fossil fuels. Biofuel production holds significant economic, social (food security and local empowerment), and environmental risks (such as loss of biodiversity and water shortage). Research on the use of vegetable oils as a diesel fuel has been intense during periods of petroleum shortages such as World Wars I and II and the energy crisis of the 1970s [1]. Many countries are using edible oil-seed crops such as soybean, groundnut, sunflower, and oil palm for producing biodiesel.

Improving Crop Resistance to Abiotic Stress, First Edition.

Table 49.1 Characteristics of the main oil crops for biodiesel production (*adapted from Ref. [3]*, reprinted with kind permission from ASA, CSSA, and SSSA Book Publishing).

Plant species	Source of oil	Oil content (%)
Aconitum flavum	Seed	46.9
Arachis hypogaea (peanut)	Kernel	40–43
Attalea speciosa	Seed	66.0
A. indica (neem)	Kernel	25–45
Brassica spp. (canola)	Seed	40–48
Calophyllum inophyllum	Kernel	75
Carthamus tinctorius (safflower)	Seed	32–40
Cocos nucifera (coconut)	Fruit	55–60
Elaeis guineensis	Kernel	45–55
Garcinia indica	Kernel	41
Glycine max (soybean)	Seed	20
Helianthus annus (Sunflower)	Seed	38–48
Hevea brasiliensis	Seed	40
J. curcas	Seed	25–40
Madhuca pasquieri	Kernel	46.6
M. phillippinensis	Seed	60
Mesua ferra	Seed	70
Persea americana (avocado)	Fruit	7–35
P. pinanta	Seed	25–40
R. communis (castor)	Seed	45-48
S. album (sandalwood)	Kernel	62.6
Salvadora	Seed	40
Sesamum indicum	Seed	51
Shorea robusta	Kernel	18
Simarouba glauca	seed	65
Simmondsia chinensis (Jojoba)	seed	54
Terminalia catappa	Kernel	59
Thevetia peruviana	Kernel	72.4
Vernicia montana	Kernel	52.5

Table 49.1 summarizes woody oil plant resources for biodiesel production. The European Union is the global leader in biodiesel production and use, with Germany and France accounting for 88% of world production, followed by the United States, which produces 8% of global production [2, 3]. As a feedstock, about 84% of the world's biodiesel production comes from rapeseed oil. However, a prolonged use of such edible oil in many developing countries will lead to shortage of food, especially to the poor, by adversely affecting food supplies and prices. Moreover, agricultural land or lands that are valuable for biodiversity may also be used for cultivating biofuel crops creating a severe competition with food crops [3].

In this context, primary thrust is on exploitation of underutilized nonedible oil crops as a feedstock for biodiesel production. There are many such nonedible oleaginous plants such as neem (*Azadirachta indica* A.), karanja (*Pongamia pinnata*

L.), mahua (*Madhuca* spp.), castor bean (*Ricinus communis* L.), simarouba (*Simarouba glauca* DC.), physic nut (*Jatropha curcas* L.), and so on [4]. Among these crops, *J. curcas* has gained importance since it is a nonfood plant, it does not put any pressure on food supply, and it can be cultivated on wasteland instead of agricultural land.

J. curcas, a perennial shrub, belonging to the Euphorbiaceae family is one of the 170 known species of the genus *Jatropha*. *J. curcas* thought to have been native of South America is widely distributed in the wild or semicultivated areas in Africa, Asia, and parts of Europe. *J. curcas* is a shrub that can reach a height of 8–10 m. The plant root system proceeds through the development of a main taproot and four shallow lateral roots. It typically grows between a temperature range of 15–40 °C with a rainfall between 250 and 3000 mm. However, it is an open field plant species that requires intense sunshine. *J. curcas* is well adapted to arid and semiarid climates with a demonstrated ability to drought tolerance. It can also grow on a wide range of soils provided they are well drained and aerated. Seeds contain 30–35% nonedible oil that can be easily converted to biodiesel that meets the American and European standards. The profile of fatty acid composition is C14:0 (1.4%), C16:0 (15.6%), C18:0 (9.7%), C18:1 (40.8%), C18:2 (32.1%), and C20:0 (0.4%). The seeds can also be used for manufacturing other useful products such as candles, high-quality soaps, and cosmetics as well as for healing several skin disorders. Because of its several industrial and medicinal uses, initial investments toward commercial-scale plantations of this plant are under process. As per the Indian planting system, tree density for commercial cultivation is 2500 ha^{-1}. The total seed production ranges from 2000 to 4000 kg ha^{-1} depending on the genotype.

49.2
Industry Participation in Basic Research and Cultivation of *Jatropha*

Considering its importance, several companies from many countries all over the world have been involved in the development and propagation of *J. curcas* large-scale plantation ventures and basic research. In India, DaimlerChrysler AG has been involved in *Jatropha* research since 2003 in collaboration with an Indian research institution on *J. curcas* cultivation along 2500 km of Indian railroads. Experiments have been conducted along with Central Salt and Marine Chemicals Research Institute (CSMCRI) located in Gujarat in India and University of Hohenheim, Germany. Many companies such as Australia's Mission New Energy Ltd. have invested in India and have taken the initiative for feedstock procurement. The Chinese government is also playing an active role in the development of these biofuels. Chinese oil companies such as China National Petroleum Corporation (CNPC), China Petroleum and Chemical Corporation (SINOPEC), and China National Offshore Oil Corporation (CNOOC) are involved in large-scale investments for plantations of *J. curcas* in provinces of Sichuan, Yunnan, Guizhou, Guangxi, Guangdong, and Hainan. Major commercial airlines are also joining in to boost the biofuel market. Air New Zealand, British Airways, Virgin Atlantic Airways, Japan

Airlines, Boeing Company, and Pratt &Whitney are some of the companies that are planning and conducting test flights using biofuels made of *J. curcas*. There are also a number of *J. curcas* plantation development programs being run by Japanese companies such as Nippon Biodiesel Fuel Co. Ltd., IS Corporation Ltd., and Japanese Bioenergy Development Corporation [5]. Toyota Tsusho Corporation, the parent company of Toyota Motor Corporation, is investing in the cultivation of *Jatropha*, which Toyota intends to refine into biodiesel. Carbon Credited Farming (CCF) joined hands with Crest Global Green Energy to develop *Jatropha* plantations in Mali and Senegal. NASA recently experimented with accelerating the production and breeding process of *Jatropha* by sending *Jatropha* cells and cultures to space in Endeavor Space Shuttle. NASA's decision to experiment with accelerating the production process of *Jatropha*-based biofuels underscores the validity and urgent need for the production and mass implementation of biofuels in the marketplace.

In India, Indian Oil Corporation and Ruchi Soya Industries have forged a partnership to establish 50 000 ha of *Jatropha* plantations and a 31.5 Mgy (119 million L) biodiesel plant. General Motors and the US Department of Energy (DOE) have formalized a 5 year partnership with India's CSMCRI to develop *Jatropha* as a sustainable biofuel energy crop. The goal of the project is to explore the development of new varieties of the plant that have high yields and can withstand adverse environmental conditions.

Tata Chemicals Ltd. partnered with JOil, a Singapore-based *Jatropha* seedling company, to invest US$ 25 million for the production of quality seedlings for its own cultivation in India and East Africa. JOil has been set up by the Temasek Life Sciences Laboratory in Singapore. The other companies involved in *J. curcas* cultivation are Viridas plc. (www.viridasplc.com), Energem Resources Inc. (www.energem.com), and Genetwister (http://www.Genetwister.com).

S.G. Biofuels, a California-based company, has invested in *J. curcas* plantations in Latin and Central America. In 2010, they launched JMax 100 cultivar optimized for growing conditions in Guatemala with yields 100% greater than existing varieties. S.G. Biofuels is applying 1.6 million SNP markers for *J. curcas* toward the development of marker-assisted selection (MAS) methods to produce elite, high-performing cultivars. The company claims to have more than 12 000 unique genotypes of *Jatropha*, the largest and most diverse library of *Jatropha* genotypes in the world.

In Indonesia, the cultivation of *J. curcas* as a biodiesel crop was started by a company called P.T. Agrila in 2003 on the island of Lombok. It experienced a boom in cultivation when the crude oil prices went up in 2006. In 2006, the Indonesian government announced the "Blueprint: Biofuel development" as a measure against poverty and unemployment. Under the program, it was planned that 500 000 people would be employed and 7.5 million ton of *J. curcas* oil would be produced in 2010 and 1 million people would be employed and 15 000 000 ton of crude *Jatropha* oil would be produced by 2015. Myanmar is also emphasizing the development of *J. curcas* as a biodiesel crop and had planned to cultivate 2.3 million ha by 2010 [5].

The present interest by various public and private sector companies highlights the importance of *Jatropha* biodiesel as a source of alternative energy source.

49.3
Projections of *Jatropha* Cultivation

The International Jatropha Organization has announced cultivation plans and projections for different countries in each part of the world over the next 10 years. It claims that by 2017 there will be 32.72 million ha of land cultivated with *J. curcas* worldwide producing 160 million ton of seeds. According to this organization's projections for Asia, the cultivation plans of China, India, Indonesia, and Myanmar are the most prominent [5]. The cultivation in Asia is the highest at 31.2 million ha, followed by Africa at 1.36 million ha, Middle East at 0.1 million ha, and Latin and Oceania with 1000 ha each.

49.4
Challenges for Commercial-Level Success

According to an analysis by Weyerhaeuser *et al.* [6] the challenges for developing viable markets for *Jatropha* oil are considerable. The highlights are as follows:

- Ensuring sufficient quantity and quality of available, nonagricultural and non-forest land to meet a reasonable scale of feedstock demand;
- Building institutions that facilitate between smallholder farmers upstream and the oil and biodiesel processing industries downstream;
- Determining minimum efficient scales for *Jatropha* growing and processing;
- Coordinating the timing of government investments in *Jatropha* research with the speed of the *Jatropha* biodiesel industry's development, and ensuring that the scale of implementation matches the appropriate scale suggested by research results.

49.5
Target Traits for *J. Curcas* Crop Improvement

J. curcas chromosomes are very small in size with most species having 22 chromosomes. It has been an attractive crop for whole-genome sequencing due to its modest genome size of 416 Mbp [7]. Synthetic Genomics Inc. (SGI) and Asiatic Center for Genome Technology (ACGT) have announced the completion of the first draft of sequencing project. Sequencing revealed that *J. curcas* has 400 million bp, which is similar to rice. Almost at the same time, Sato *et al.* [8] reported whole-genome sequencing by a combination of Sanger method and 454 next-generation sequencing. Sequencing the genome of *J. curcas* will be useful in identifying genes of interest and provide information on factors controlling oil synthesis, maximizing yield, biotic and abiotic stress tolerance, and different toxins [8].

Genetic transformation studies using *Agrobacterium* [9, 10] and particle bombardment [11] have been reported. A number of traits have been identified for *J. curcas*

crop improvement; the traits such as seed yield, oil content, seed toxicity, female to male flower ratio, increase in branching, early flowering, synchronous maturity, and adaptation to abiotic stresses are considered relevant for the success of the commercial-scale plantations [12]. Improvement in seed yield could be achieved by increasing the ratio of female flowers [12]. Increased seed yield was achieved by increasing the ratio of lateral branches [13] and by application of paclobutrazol, a growth regulator [14]. Yield loss due to pests such as *Scutellera nobilis* and *Pempelia morosalis* has also been observed in some *Jatropha* monocultures. Pest- and pathogen-resistant varieties can considerably increase yields.

49.6
Fatty Acid Biosynthesis and Abiotic Stress Tolerance in *J. Curcas*

49.6.1
Fatty Acid Biosynthesis Genes

Identification of cDNAs involved in fatty acid biosynthesis and biotic/abiotic stresses through EST profiling is becoming popular and has gained importance. Costa *et al.* [15] generated 13 249 ESTs from developing and germinating *J. curcas* seeds. This enabled them to detect major key genes involved in lipid synthesis and degradation. Among the most abundantly expressed transcripts they found transcripts related to breakdown of the oil and carbohydrate reserves such as acetyl-CoA C-acyltransferase. Most ESTs coding for fatty acid biosynthesis enzymes, for example, *FatA*, *FatB*, *ACC*, *FAD2*, *KAS I*, *KAS II*, and so on (acyl-ACP thioesterase A, acyl-ACP thioesterase B, acetyl-CoA carboxylase, oleoyl-ACP desaturase, ketoacyl-ACP synthase I, and ketoacyl-ACP synthase II, respectively) were found in developing seeds and for fatty acid degradation pathway, *FADA*, *ATOB*, *ADH*, *ACADM*, and so on (aceyl-CoA acyltransferase, acetyl-CoA C-acetyl transferase, alcohol dehydrogenase, and acyl-CoA dehrdogenase, respectively) were found in germinating seeds of *J. curcas*. The most important enzyme was found to be oleoyl-ACP desaturase (*FAD*) that catalyzes the polyunsaturation of oleoyl-ACP (18: 1) to linoleoyl-ACP (18: 2). Since oleic and linoleic acids are the major constituents of *J. curcas* oil, this enzyme can be used for modulation of oil composition [15].

On similar lines, Gomes *et al.* [16] studied the expression levels of four genes (palmitoyl-acyl carrier protein thioesterase, 3-ketoacyl-CoA thiolase B, lysophosphatidic acid acyl transferase, and geranyl pyrophosphate synthase) involved in pathways of biosynthesis of fatty acids, biosynthesis of unsaturated fatty acid, glycerolipid metabolism, and biosynthesis of terpenoid backbones, respectively. The genes were more expressed in fruits than in leaves. This information can be useful for selective breeding for traits in relation to biodiesel production and low-phorbol varieties [16]. Knowledge of expression overview of multiple genes involved in oil biosynthesis from different stages and tissues of *J. curcas* is the approach adopted by Xu *et al.* [17]. In their study, they analyzed the expression profiles of 21 genes involved in different steps of the pathway leading to fatty acid and TAG synthesis at different time points of

seed development and compared it with leaf. They found the expression levels of 17 genes significantly higher in seeds compared to leaves. In a very recent study, Popluechai *et al.* [18] studied the proteome composition of oil bodies in the seed of *J. curcas*. The study revealed oleosins as the major component and additional proteins similar to those in other oil seed.

Several reports have been published to identify genes involved in the fatty acid biosynthesis pathway and that can be used to produce transgenic *Jatropha* plants to obtain new improved varieties with increased oil content. Increasing the oil content in seeds can be achieved by altering the expression levels of enzymes in the triacylglycerol (TAG) biosynthetic (Kennedy) pathway. Overexpression of diacylglycerol acyl transferases has been shown to increase oil content in *Arabidopsis* [19] and soybean [20]. The regulation of seed development and TAG biosynthesis in seeds has been studied in some depth [21]. Stearoyl-acyl carrier protein desaturase is an important enzyme for fatty acid biosynthesis in higher plants, which determines the ratio of saturated to unsaturated fatty acids. Tong *et al.* cloned the above gene from developing seeds of *J. curcas* and functionally expressed it in *Eshcerichia coli* [22]. Furthermore, β-ketoacyl-acyl carrier protein (ACP) synthase III (*KAS III*) is believed to be involved in carbon chain elongation. Li *et al.* cloned *KAS III* from *J. curcas*, which they termed *JcKASIII* [23]. The authors concluded that the study might help in understanding fatty acid biosynthesis in *J. curcas*. Likewise, gene involved in termination of carbon chain elongation was studied. Wu *et al.* cloned *JcFATB1* from *J. curcas*, which encodes a putative acyl-ACP TE (involved in termination of carbon chain). When *JcFATB1* was cloned in *Arabidopsis thaliana*, the saturated fatty acid content increased [24]. These results indicate that *JcFATB1* might have a role in altering the fatty acid composition.

Lipid profiling of developing seeds of *J. curcas* was carried out using ^{1}H NMR spectroscopy [25]. The oil content in seed samples ranged from 0.3 to 24.9%, lowest being at stage I (7 days after pollination) and highest at stage IV (32 days after pollination). It was concluded that free fatty acids (FFA) contributed predominantly to the total lipids in early stages of development, whereas these were replaced by triglycerol esters at the maturing stages.

Acetyl CoA carboxylase (ACCase) is biotinylated enzyme that catalyzes the ATP-dependent carboxylation of acetyl CoA to form malonyl CoA. This is the first committed step in the biosynthesis of fatty acids. A full-length cDNA of the carboxyl transferase (*accA*) gene of *ACCase* from *J. curcas* was cloned by Xie *et al.* [26]. Fluorogenic real-time polymerase chain reaction (RT-PCR) studies on fruits showed a significant increase in *accA* activities under dark condition compared to the control. The findings suggested that the expression levels of the *accA* gene are closely related to the growth conditions and developmental stages in the leaves and fruits of *J. curcas*.

Seed oil of *J. curcas* is also a source of toxins such as phorbol esters and curcin [27]. Phorbol esters have certain beneficial effects as well. Reports indicated that phorbol esters exhibit insecticidal and molluscicidal activities [27]. Lin *et al.* characterized gene 3-hydroxy-3-methylglutaryl coenzyme A reductase (*JcHMGR*) from *J. curcas*. *JcHMGR* acts as one of the key regulatory enzymes for phorbol esters biosynthesis in the cytosolic mevalonic acid pathway. Therefore, *JcHMGR* may be a target gene

Table 49.2 Partial list of genes cloned and characterized in *J. curcas*. Some of the genes have role in fatty acid synthesis.

in metabolic engineering to alter the content of phorbol estrers [27]. On similar lines, another gene encoding geranylgeranyl diphosphate synthase (*Jc-GGPPS*) was also cloned and characterized [28]. The gene was involved in mediating the biosynthesis of carotenoid and general precursor for diterpenes' biosynthesis. The results provide insight into regulation of phorbol ester biosynthesis in *J. curcas*. A number of studies have indicated that it is possible to increase the oil content of seeds by manipulating of the expression levels of key regulators of seed oil accumulation. For example, disruption of the homeobox gene *GLABRA2* led to increased oil content in *Arabidopsis* [29] and overexpression of soybean transcription factor *GmDOF4* and *GmDOF11* in *Arabidopsis* has also been shown to result in increased oil content [30]. The partial lists of genes cloned that are involved in fatty acid biosynthesis have been summarized in Table 49.2.

49.6.2
Genes Associated with Abiotic Stress Tolerance

J. curcas is capable of growing under arid and semiarid regions on marginal lands. However, under these conditions, it is known to complete its life cycle without commercially acceptable yields. To understand and characterize the genes involved during abiotic stress conditions, Eswaran *et al.* [31] developed functional genetic screen using *shs* (salt hypersensitive) mutant of yeast. Initially, three *shs* mutants have been generated by random mutagenesis that exhibited growth retardation beyond

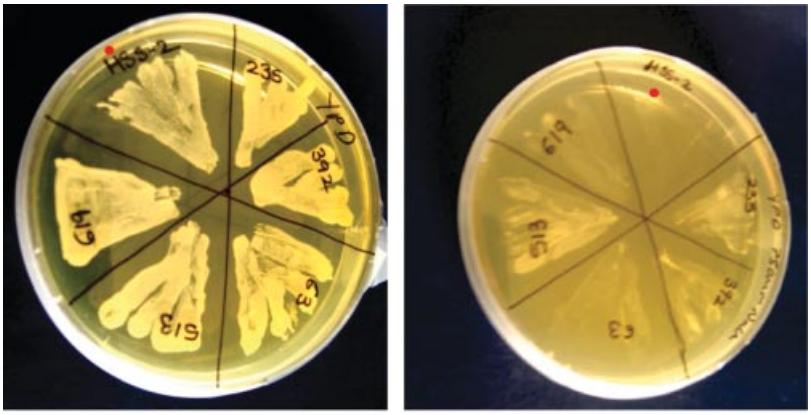

Figure 49.1 Screening and functional evaluation of *J. curcas* genes in salt-hypersensitive (*shs-2*) yeast mutant. *shs-2* mutants were selected by random mutagenesis that has salt sensitivity beyond 500 mM NaCl, whereas plasmids containing stress-tolerant genes can grow under high salt (750 mM NaCl) in synthetic media. (a) Growth of *shs-2* mutant (filled circle) at 0 mM NaCl. (b) Arrest of the *shs-2* mutant growth was seen at high salt level (filled circle), whereas plasmids containing late-embryogenesis abundant protein-5 (235), cytosolic ascorbate peroxidase-1 (392), and metallothionein (513) were found growing under high salt conditions. This screen provides evidence for rapid screening of cDNA library of *J. curcas* for abiotic stress-tolerant genes using yeast mutants (adapted from Ref. [31]).

500 mM NaCl. These mutants have been used to screen cDNA library generated from salt stressed roots of *J. curcas* (Figure 49.1). The authors obtained several full-length functional genes expressed in response to abiotic stress conditions (Table 49.3). Gene expression analysis of five selected genes in leaf and root tissues of *J. curcas* was studied in order to correlate gene expression pattern under imposed stress conditions [31]. The selected genes were late-embryogenesis abundant protein-5 (*LEA-5*), cytosolic ascorbate peroxidase (*Apx-1*), metallothionein, profilin, and annexin. Analysis of the gene expression data suggests dynamic changes in the transcript abundance of these genes, with changes in transcript level being apparent from 2 h time point, indicating an early regulation of the genes in response to salt stress. Gene expression of the normalized transcripts suggests both upregulation and repression of these transcripts. Increased expression of profilin was noted in root tissue between 2 and 8 h time points of exposure to 150 mM salt stress, whereas in leaves profilin transcript was repressed (Figure 49.2a and b), consistent with previously reported function during salt stress [32]. Furthermore, in contrast, an initial repression was observed in the expression of annexin that was subsequently induced in the root tissue, while the expression was downregulated upon salt stress in the leaves (Figure 49.2a and b). Transcript abundance in the levels of *Apx-1* and metallothionein were downregulated in roots, while a more dynamic expression pattern was observed in the leaf tissues, implicating a role in stress-adaptive

responses. Among the transcripts profiled in this study, only *LEA-5* was upregulated in leaves at the 8 h time interval, after initial downregulation at the 2 h time point, while in roots *LEA-5* expression was unaffected under salt stress. Such an induction of *LEA-5* in leaf tissue demonstrated either a longer-range signal or the terminal effects of long exposure to ions taken by the roots. Further experiments are required to delineate these effects. The limited gene expression data, indirectly suggests varied modes of gene regulation between the root and the leaf tissue in *J. curcas* (Figure 49.2a and b). The data indicates a complex framework for gene regulation during adaptation to salt stress in different tissues.

Aquaporins are membrane proteins or major intrinsic proteins (MIPs) that form water channels or pores in biological cell membranes, controlling the water content of the cells. These channels are widely distributed in all kingdoms of life including

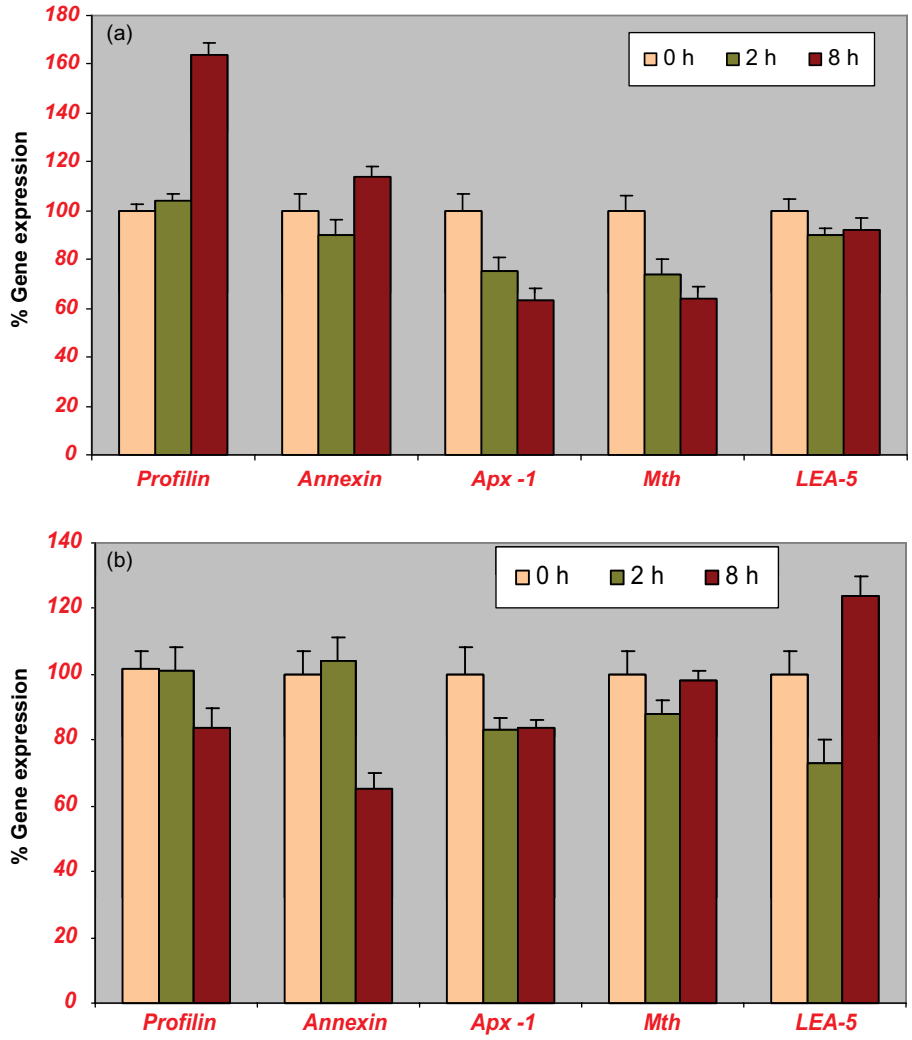

Figure 49.2 (a) Semiquantitative RT-PCR expression analysis of five different genes of *J. curcas* in root tissue after treating *J. curcas* seedlings with 150 mM NaCl. Semiquantitative RT-PCR was performed at 0 h, 2 h, and 8 h of exposure to NaCl. *Apx-1*, cytosolic ascorbate peroxidase-1; *Mth*, metallothionein; *LEA-5*, late-embryogenesis abundant protein-5. Bars represent SE of mean (adapted from Ref. [31]). (b) Semiquantitative RT-PCR expression analysis of five different genes of *J. curcas* in leaf tissue after treating *J. curcas* seedlings with 150 mM NaCl. Bars represent SE of mean (adapted from Ref. [31]).

bacteria, plants, and mammals [33]. In plants, aquaporins are present in multiple isoforms. Aquaporins are thought to be involved in plant adaptation to drought stress, controlling transmembrane water movement in plants. In order to study the role of aquaporin in drought stress, a full-length cDNA encoding aquaporin (*JcPIP2*) was isolated from seedlings of *J. curcas*. Heavy drought conditions were induced by PEG6000 to study its role. It was observed that with increasing levels of drought stress *JcPIP2* level increased indicating its role in drought resistance [34]. The presence of aquaporins is considered to play an important role in the rapid growth of *J. curcas* under dry weather conditions. In another study, betaine aldehyde dehydrogenase (BADH) gene called *JcBD1* (cloned by RT-PCR and RACE techniques) has been isolated from *J. curcas* [35]. It was observed that *JcBD1* gene transcript levels were 79% higher in case of plants exposed to drought, salt, and heat stress compared to control plants, indicating its role in all three abiotic stress tolerance. Functional expression of *JcBD1* in *E. coli* conferred resistance to salt stress [35].

J. curcas is known to be a toxic plant. Curcin, a ribosome inactivating protein (RIP), was found in the seeds of this plant. The full-length *curcin* gene has been cloned and sequenced [36]. In one study, curcin-L, a type I RIP, was isolated from *J. curcas*. Its expression could be induced in leaves by administering treatments with abscisic acid, salicylic acid, PEG, temperature (45 °C), and ultraviolet radiation. The gene transcripts were not detected in stem, roots, and seeds. A 654 bp fragment of a 5′ flanking region preceding the *curcin-L* gene, designated *CP2*, was cloned from *J. curcas* and its expression was studied in transgenic tobacco via the expression of β-glucuronidase (*GUS*) gene. It was found that CP2 was leaf specific and could induce the expression of the reporter gene under stress conditions [37].

In another study recently conducted on seedlings of *J. curcas* treated with increasing concentrations of NaCl, it was found that superoxide dismutase (SOD) activity in the cotyledons, hypocotyls, and radicles increased gradually up to NaCl concentrations of 150, 200, and 150 mmol by 70.8%, 86.8%, and 72.8%, respectively, compared to controls [38]. SOD is one of the several important antioxidant enzymes with the ability to repair oxidative damage caused by reactive oxyzen species (ROS). Similarly, peroxidase (POD) activity in the cotyledons, hypocotyls, and radicles was highest at NaCl concentrations of 150, 200, and 150 mmol by 52, 122.2, and 62.2%, respectively, compared to controls. POD is involved in various processes including lignification, auxin metabolism, salt tolerance, and heavy metal stress. Catalase (CAT) activity in cotyledons, hypocotyls, and radicles increased gradually up to NaCl concentrations of 100, 200, and 150 mmol by 75.4, 246.9, and 588.1%, respectively, compared to controls. CAT, which is involved in the degradation of hydrogen peroxide into water and oxyzen, is the most effective antioxidant enzyme against oxidative damage. Therefore, increased activity of CAT along with SOD and POD plays an important role in ROS scavenging process and salt-induced oxidative stress tolerance. Another enzyme phenyalanine ammonia-lyase (PAL), a marker in environmental stress also showed increased activity in cotyledons, hypocotyls, and radicles at NaCl concentrations of 150, 200, and 150 mmol, respectively, compared to controls [38].

Effect of high concentrations of metals such as nickel, zinc, and lead was studied. Reports indicate high concentration of nickel (100, 200, 400, and 800 μmol) (heavy

metal stress) on *J. curcas* seedlings is correlated with the activity levels of SOD, POD, CAT, and PAL antioxidant enzymes. It was found that the activity of SOD, POD, and CAT had a negative correlation with nickel concentrations with the activity highest at 400, 200, and 200 μmol of nickel. PAL had a positive correlation with the highest activity at 400 μmol of nickel. Hence, the lower nickel concentrations and higher SOD, POD, CAT, and PAL activities suggest the tolerance capacity to protect the plant from oxidative damage due to heavy metal stress [39]. Effect of different zinc concentrations on *J. curcas* seedlings and its influence on antioxidant enzymes such as SOD, POD, CAT, and PAL have also been reported [40]. Authors found that the biomass of cotyledons, hypocotyls, and radicles was increased with increasing concentrations of zinc. SOD and POD activity was increased gradually with the increase in zinc concentrations. CAT activity in cotyledons, hypocotyls, and radicles reached the largest increments at the zinc concentrations of 0.5, 2, and 0.5 mM, respectively. A similar trend was observed in case of PAL activity when compared to CAT. Hence, it is seen that SOD, POD, CAT, and PAL may also play an important role in the defense mechanisms of *J. curcas* exposed to excess metal [40]. In another similar finding, it was reported that increased SOD, POD, and PAL activity is involved in the defense mechanism of *J. curcas* radicles against lead toxicity [41]. Changes in protein content, SOD, CAT, POD, and PAL in *J. curcas* seedlings showed a clear correlation with copper concentrations. The results of this study also show that the ability of *J. curcas* to cope with metal stress depends on oxidative stress defense mechanisms [42].

Transcription factors and regulatory elements have a major role in manipulation of the expression of key genes during abiotic stress tolerance and has been a major focus of study. Tang *et al.* [43] characterized *JcERF* gene, a putative AP2/EREBP domain containing transcription factor, from *J. curcas*. The AP2/EREBP proteins in plants are the largest transcription factor family having a role in plant development and responses to ethylene, disease, and other biotic and abiotic stresses. In *J. curcas*, it was noticed that expression of the *JcERF* gene was rapidly induced upon salinity, drought, ethylene, and mechanical wounding proving that in *J. curcas* the gene has a role in tolerance to abiotic stresses. Photosynthetic characteristics and chlorophyll fluorescence parameters have also been studied in *J. curcas* under drought stress [44] and cold stress [45]. Under drought stress, it was observed that when treated with lower concentrations ($\leq$15%) of PEG, the photosynthetic rate (P_n), stomatal conductance (G_s), and intercellular carbon dioxide concentration (C_i) of the seedlings decreased with increasing PEG concentration, while the chlorophyll fluorescence parameters did not change. There was a drop in PSII activity. When drought stress was removed, there was recovery of PSII activity. The results demonstrated that *J. curcas* has strong tolerance to drought stress [44]. Similarly, under cold stress (4 °C) eight photosynthesis-related proteins significantly changed. The chlorophyll fluorescence parameters were also sensitive to cold stress. There was a correlation between photosynthesis-related proteins and chlorophyll fluorescence parameters indicating that the early-stage (0–12 h) acclimation of PSII and the late-stage (after 24 h) H_2O_2 scavenging might be involved in cold response mechanisms in *J. curcas* [45].

Guo *et al.* [46] cloned a plastidal ω3 fatty acid desaturase gene from leaves of *J. curcas*, which is involved in the synthesis of trienoic fatty acids. It is known that high ω3 fatty acid content in leaves can increase the plant's tolerance to cold stress. Hence, by identifying this gene in *J. curcas* it will be useful to understand the molecular mechanism of cold tolerance in *J. curcas* and will help in future to improve its tolerance to cold stress. It is known that soil alkalinity can also be a stress to plants. When the effect of alkalinity (Na_2CO_3 0.1, 0.2, 0.3, 0.4, and 0.5%) was studied on *J. curcas* seedlings, it was observed that increase in alkalinity caused reduction in growth. But when some beneficial microbes (*Azotobacter microfoss* and arbuscular mycorrhizal fungi (AMF)) were added in combinations, it was observed that different combinations of these microbes with 0.4% sodium carbonate increased the survival percentages compared to control plants. The combination of AM fungi and *Azotobacter* increased plant height, shoot diameter, shoot dry weight, leaf relative water content, and soluble sugar content and decreased level of soluble protein at 0.4% of Na_2CO_3 compared to other treatments [47].

Allene oxide cyclase (AOC) is a key enzyme in jasmonates biosynthesis pathway. A cDNA encoding AOC, from *J. curcas* named *JcAOC* has been cloned [48]. Semiquantitative RT-PCR analysis revealed that *JcAOC* mRNA was expressed in roots, stems, leaves, young seeds, endosperms, and flowers, but that the expression level was highest in leaves and lowest in seeds, and mRNA expression of *JcAOC* could be induced by salt stress (300 mM NaCl) and low temperature (4 °C) [48]. Phospholipase D (PLD) is a key enzyme in plants involved in phospholipid catabolism, initiating a lipolytic cascade in membrane deterioration during senescence and stress. Liu *et al.* [49] cloned 2886 bp full-length phospolipase D cDNA from *J. curcas*. Phylogenetic analysis indicated that the *J. curcas* PLD alpha (*JcPLDα*) showed a high similarity to PLD alpha from other plants. Semiquantitative RT-PCR analysis revealed that it was especially abundant in root, stem, leaf, endosperm, and flower and weakly in seed. And the *JcPLDα* was increasingly expressed in leaf undergoing environmental stress such as salt (300 mM NaCl), drought (30% PEG), cold (4 °C), and heat (50 °C). The *JcPLDα* protein was successfully expressed in *E. coli* and showed high enzymatic activities.

49.7 Future Perspectives and Conclusions

Nonedible oil crops, especially, *J. curcas* hold promise as a substitute for fossil fuel and has a prominent future. However, large-scale production without the application of improved farming techniques and elite breeds has diverse problems. With the availability of genome sequence, molecular breeding programs can be accelerated to improve yields.

A recent study to understand oil mobilization in germinating seeds, proteomic analysis of endosperm clearly showed that oil mobilization that was initiated during germination was used up for early seedling development [50]. Several pathways including β-oxidation, glyoxylate cycle, glycolysis, citric acid cycle, gluconeogenesis,

and pentose phosphate pathway were involved in the oil mobilization. These results would benefit to further understand the mobilization and control of oil in the seed.

The future of *J. curcas* as a sustainable energy crop will largely depend on successful integration of "omics" approach with metabolic engineering. The efforts at the authors' lab as detailed in Table 49.3 in identifying abiotic stress tolerance-governing factors have led to major discovery of transcriptional elements and genes in the stress tolerance pathway. The genes and outcome of the results can be successfully utilized to molecular breeding of stress-resistant *J. curcas* in particular and other biofuel crops in general.

Brassica Crop Species: Improving Water Use Efficiency: Challenges and Opportunities

Constantine Don Palmer, Wilf Keller, Jas Singh, and Raju Datla

The *Brassica* species occupies a large portion of the world's economically important cultivated crops. These include vegetables, oilseeds, condiments, and forages. These crops are grown globally under a wide range of climatic conditions. With current concerns for food and energy security, expanded use of crop products, and environmental stewardship, there is a pressing need to improve yield through greater efficiency of resource utilization. Water availability is the most limiting factor to crop productivity and with the predicted scarcity, due to climate change and increased nonagricultural demand, improving water use efficiency (WUE) in crop production is an imperative. Consequently, increased carbon assimilation per unit of water used by *Brassica* crops must not only be realized but this carbon must also be efficiently partitioned into the harvested product. Thus, these plants need to be equipped with the genetic capacity to extract more water from the soil under water-limited conditions, fix more carbon, and transpire less water. There is natural genetic variability for WUE and this can be used for screening germplasm to identify better genotypes. Evaporative demand is the driving force for water loss and WUE can be improved by increasing transpiration efficiency (TE), alteration in crop phenology, increased carbon fixation, and increased harvest index (HI) by greater partitioning of assimilates into harvestable product. Modification of root architecture, leaf morphology, and stomata conductance are important targets for developing cultivars with improved WUE. Drought tolerance is closely associated with WUE and factors contributing to maintenance of metabolic function under water-limited conditions contribute to improved WUE. Studies on *Arabidopsis* have contributed to significant advances in our understanding of WUE and drought tolerance. The use of genetic engineering and genomic tools has allowed for the incorporation of identified genetic factors for improving WUE and drought tolerance traits and will be vital to the development of new *Brassica* cultivars. The carbon fixation machinery, a vital component in yield, will require adjustments to deal with anticipated water deficits in order to take advantage of increases in atmospheric carbon dioxide as a result of climate change. Manipulation of assimilate partitioning and selection of genotypes

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

with capacity to store water-soluble carbohydrates in stems that can be remobilized to harvestable structures are targets for improving WUE. To maintain high yields of *Brassica* crops with economic use of water will require substantial increases in our understanding of the biological processes associated with growth under water-limited conditions. The availability of potential gene targets from the present and future discoveries including rapid advances coming from application of genomic technologies may provide a valuable resource base for development of superior WUE *Brassica* crops in the coming years.

50.1 Introduction

The genus *Brassica* contains a number of species of agricultural importance that are widely grown as oilseeds, vegetables, and forages and that are well adapted to a range of climatic conditions. *Brassica* oilseed crops are an important component of the global vegetable oil market and are valuable sources of condiments and vegetable protein. At present, canola quality *Brassica* oilseed crops are grown on over 25 million ha worldwide [1] with *Brassica napus* having the largest area. *B. oleracea* L. contains a number of varieties that are grown for consumption as vegetables [2]. In addition to use as a food, there are a number of secondary metabolites that are of medicinal and nutraceutical importance [3]. A number of *Brassica* species, including *B. napus* spp. *biennis* L. (forage rape) and *B. rapa* L. (turnip) are of importance as forages [4]. Increased yield is generally the main focus of improvement of agricultural crops and with the projected increase in demand for food and the use of food crops for energy and industrial feedstock, increased yield is now an imperative. *Brassica* crops can be a vital component of any strategy aimed at ensuring food and energy security. Consequently, there must be efficient use of input resources and maximization of yield. In other words, over all plant performance must be improved. While yield is a function of the genetic component of the plant, there are a number of environmental constraints including biotic and abiotic stress, which affect the final outcome. For any biological system, water is a vital component and in the case of agriculture, about 70% of the available freshwater is used in crop production [5–7]. It is now recognized that increased urbanization and the impact of climate change on water use and precipitation, will likely reduce the amount of water available for agriculture [8, 9]. A significant portion of agricultural water use is in crop production [10], and to increase yield, plants must be more efficient in water use. In this chapter, the focus will be on the status of water use efficiency in *Brassica* crop species and ways to enhance this efficiency without compromising yield. We will draw liberally from published work on water use efficiency (WUE) in other crop species such as cereals. Water use efficiency is interrelated to plant performance under water-limited conditions and this necessitates discussion of this topic in the context of drought tolerance and plant growth under water-limited conditions.

50.2 Yield

There is now the realization that yield of all crops must be increased to meet growing demand and this must be achieved in an environmentally sustainable manner. In the case of *Brassica* crops, like other crop plants, yield is the portion of biomass that is partitioned into seed, leaf, stem, root, or floral buds. To realize the genetic potential of a crop, as reflected in yield, environmental factors that negatively affect yield must be controlled. The major limitation to crop yield is water availability or drought [11]. To improve yield, with anticipated decline in water availability for agriculture, plants must be equipped with built-in genetic capacity to use water more efficiently. In cases where water is the limiting factor to plant growth, crop yield (CY) is a function of WU × WUE × HI (WU = total water use, WUE = water use efficiency, and HI = harvest index (harvestable biomass/total biomass)) [12]. Assuming these three terms are independent, an increase in any one is reflected in CY increase [13, 14].

50.3 Water Use Efficiency

The term water use efficiency is used to detail the amount of water per unit of biomass produced. This ratio of biomass to evapotranspiration is generally expressed as WUE (biomass) = (TE/1) + (E_s/T). TE is transpiration efficiency, which is the dry matter/transpiration, E_s is the water lost to evaporation from the soil, and T is transpiration by the crop [15]. This means that to increase WUE, TE must be increased or E_s reduced. In general, there are several management strategies to reduce soil water evaporation such as increasing ground cover, improving plant vigor, and optimizing nutrient status of the plant [15]. Improving transpiration efficiency, TE, can also be achieved through management, as less water will be transpired by crops that accumulate maximum biomass under cooler conditions. This is the case as the main driver for transpirational water loss is the saturated water vapor deficit. Breeding for plants with increased transpiration efficiency is desirable as this trait is under genetic control [16–18]. Plants with pubescent leaves are likely to transpire less water. Also plants with thick cuticles generally have reduced leaf water loss. Genetic variation in cuticular water loss has been reported [18, 19], and selection for genotypes with reduced water loss by this route may improve overall TE. Selection for improved TE may be hampered by the accuracy with which this can be measured efficiently and conveniently. The close relationship between $C^{13}O_2$ and $C^{12}O_2$ discrimination during photosynthetic carbon assimilation and TE was established and is considered a reliable breeding tool for selecting genotypes with high TE, at least in C3 plants [20, 21]. This technique has been used effectively in selecting wheat genotypes with high TE [22]. The advantages and limitations of this technique have been discussed [22, 23].

50.4
Drought Tolerance and WUE

Water availability is perhaps the most important factor limiting plant growth and crop yield. Given the prospect of future drought and water scarcity for crop production, as a consequence of climate change, the crop plant growth will likely occur under suboptimal water condition. Compared to other abiotic stresses affecting plant growth, drought is the one with the most far-reaching negative consequences [23]. Thus, a fundamental knowledge of how plants sense and develop mechanisms to adapt to water-limiting conditions is an imperative. Although WUE in crop production has received considerable attention, there is a widely held view that it is effective use of water, EUW, and not WUE, which is important in over all water conservation [24–26]. This concept is regarded as the important aspect of achieving drought tolerance. This involves assessment of critical periods of crop growth that are sensitive to water stress. Although modification of agronomic practices such as a modification of crop phenology and deficit irrigation through partial root zone drying, PRD, among others, genetic manipulation using transgenics may be required to address the maintenance of crop yield under water-limited conditions. Partial root zone drying may be useful in improving WUE as it probably maintains plant water status through hormonal signals that regulate stomatal function [27]. Two recent publications have highlighted the importance of farming system management in association with plant genotype to improved productivity in water-limited environments [26, 28]. Under conditions of water limitation, the main concern for improved crop yield will be maintenance of growth and biomass accumulation and effective strategies must be directed to this end. Modification in root and shoot traits may be essential for maintaining plant water status under drought conditions. For example, deep root system with increased lateral branching will be able to tap soil water at greater depths. This deep root system may also contribute to increased nutrient uptake resulting in more growth and biomass accumulation and consequently increased WUE. Breeding for drought tolerance through modification of root traits is desirable, but there are technical difficulties in accurately defining the phenotypes, as roots of crop plants are largely inaccessible for convenient observations. The use of closely or tightly linked molecular markers may assist in introgression of desirable WUE traits from wide germplasm [29]. Stomatal and epidermal conductances are important shoot traits relevant to drought tolerance and WUE as about 90% of water uptake is lost by transpiration [30]. Therefore, minimizing this loss is vital. However, gas exchange must be optimized to allow carbon assimilation without excessive water loss. Breeding for leaf pubescence density will likely increase leaf reflectance causing lower leaf temperature and lower water loss at high irradiance [30]. This may also increase leaf boundary layer resistance and enhance photosynthesis [31] contributing to increased WUE. Under conditions of drought, plant cells may maintain turgor and growth by active accumulation of solutes, a process called osmotic adjustment (OA). These solutes can be carbohydrates, amino acids, or sugar acids [32]. In soybean, a positive correlation was

found between the rate of decline in relative water content and relative OA [33]. The effect of OA on yield is debatable [34–36], but it may allow maintenance of metabolic machinery for growth resumption under favorable water conditions. However, a positive correlation between seed yield and OA was observed in *Brassica* species [37, 38]. There was also a close association between stomatal conductance, canopy temperature, and OA in the same species [39, 40]. These findings suggest that species differences or the type of osmolyte may affect physiological and biochemical responses to OA. As a strategy for maintaining turgor under conditions of water deficit by using OA, there may be a reduction in biomass as significant amount of energy can be expended in the production of osmolytes.

50.5 Stomatal Water Loss

Stomata are vital to carbon assimilation, and because CO_2 uptake is tied to water vapor loss an important aspect of WUE is to strike a balance between minimizing water loss while maximizing CO_2 assimilation. Therefore, there must a deeper understanding of the regulatory factors that control transpiration efficiency (the ratio of CO_2 assimilated to water transpired). ABA is well known to function in the regulation of stomatal aperture [41], and while this hormone is a factor in transpiration efficiency, there are several others such as cell wall composition, G protein, GPA1, RD20, a stress-inducible Caleosin, and the ERECTA gene product that are reported to be involved in the regulation of transpiration efficiency [15, 42–45]. The discovery and characterization of the ERECTA gene has potential benefits for transpiration efficiency improvement in crop plants as it affects both photosynthesis and transpiration [15]. Similarly, expression of the gene HARDY in rice significantly improved WUE through root and shoot modification [46]. There is natural genetic variation in transpiration efficiency in several plant species including Brassicas and this could be exploited to improve WUE in *Brassica* crops. There are other factors such as hydrogen sulfide and the enzyme myrosinase, which appear to be involved as signaling components in hormone-induced stomatal closure and may be important to TE [47, 48]. Stomatal density regulation is also a factor in TE as there may be an optimum density for improved WUE [49]. There is also evidence indicating an ABA-independent stomatal aperture regulatory pathway [50], which underscores the complexity of the stomatal regulatory process. Understanding the factors controlling stomatal density will also be vital to identifying genotypes with improved transpiration efficiency [51, 52].

In addition to stomatal water loss, epidermal water loss through the cuticle can be significant to overall TE, and in cotton WUE was negatively correlated with leaf epidermal conductance [18]. Also, cuticular wax composition may influence the transpiration barrier properties of the cuticle [53]. Consequently, screening *Brassica* genotypes for variation in cuticular wax composition and epidermal water loss should be considered while breeding for improved WUE.

50.6
Water Acquisition

Root characteristics will largely determine the efficiency of water uptake under water-limited conditions and root size influences both yield and WUE [54]. Plants with deep root system will be able to tap water from deeper soil layers, compared to those with shallow root system. Root length and degree of branching are characteristics that should be considered and examined in breeding for water acquisition traits. As outlined in Section 50.4, it is technically difficult to phenotype roots for selection purposes, and the use of molecular tagging and measurement of canopy temperature are suggested as alternatives for selecting root-related traits [55, 56]. The development of a phenotyping platform for root systems should advance selection for root traits [57]. Water uptake can also be enhanced by breeding for preferential root OA to sustain growth and water uptake under deficit conditions. An important aspect of root function in WUE is root–shoot signaling under water deficit conditions. ABA appears to play a role in this process and WUE can be improved by such techniques as root-deficit irrigation (RDI) or partial root drying (PRD) [58]. However, other factors such as hydraulic and pH signaling may be involved [59]. These methods are designed to increase stomatal sensitivity to ABA to effect partial closure and reduced water loss while CO_2 assimilation is maintained. The process is complicated by the influence of other hormones such as ethylene that counteracts the ABA response [58].

50.7
Carbon Assimilation

Improvement in WUE will ultimately depend on net carbon gain through photosynthetic carbon fixation. This means that factors such as internal CO_2 concentration, activity of the main CO_2 fixation enzyme Rubisco, and photorespiratory carbon loss must be optimized [60]. It is generally accepted that C4 plants maintain higher WUE, compared to C3 plants, such as *Brassica* species, as a consequence of the ability to concentrate CO_2 at the site of fixation. As a result, there is interest in expressing C4 carbon fixation pathways in C3 crop plants [61]. Modification of the catalytic activity and specificity of Rubisco have also been suggested [61–64]. While this is a potential target for improving net carbon gain in *Brassica* crop species, due consideration should be given to carbon partitioning into harvestable products as this has a significant impact on photosynthetic efficiency. There is evidence indicating the importance of sucrose transporters, SUTs, in carbon partitioning [65]. These transporters could be manipulated in *Brassica* crop species for enhanced carbon gain. Stem storage and remobilization of water-soluble carbohydrates (WSCs) to reproductive structures during grain filling increased harvest index [66]. *Brassica* genotypes with this characteristic could make a significant contribution to WUE and increased yield. Improving carbon fixation efficiency in *Brassica* oilseed species is vital as these species generally require greater biomass to produce the same amount of storage products as do carbohydrate storage crops. For increased biomass,

consideration must be given to factors contributing to high-yield potential under water-limited conditions. Increased understanding of how plants reorder metabolism to maintain growth under water deficit conditions will be vital to development of drought-tolerant and high-yield cultivars capable of improved efficiency in the use of water. For example, invertases have been shown to play a vital role in carbohydrate metabolism and yield under conditions of stress [42, 67]. This suggests that knowledge of how plants adapt various metabolic processes to maintain growth under unfavorable conditions will be vital to the development of genotypes for efficient use of input resources.

50.8
Importance of other Growth-Limiting Factors to WUE

There are many factors such as adequate supply of nutrients, pests and diseases, soil conditions, temperature, and abiotic stresses that may influence crop performance and WUE. Consequently, the impact of these conditions on the performance of *Brassica* crops must be taken into account in the development of cultivars with improved WUE. Improvement in nitrogen nutrition increased WUE through increased photosynthesis [68, 69]. Improved nitrogen nutrition may also be involved in ABA-induced root–shoot signaling and stomatal regulation [70]. Soil microflora may have a positive effect on WUE by both improving nutrient acquisition and providing signal molecules for stomatal regulation [58]. It is likely that soil mycorrhizae may contribute to WUE and this is an area that should be explored as it may offer complimentary and synergistic improvements.

When the potential consequences of climate change to crop productivity and agriculture in general are taken into account, it is clear that the sustainability will depend on the use of advance technologies to increase productivity. Breeding for increased productivity must include consideration of efficient use of all input resources [71]. There is little debate that the significant advances in our knowledge of biology in general, but specifically microbial and plant biology, should be the platform for addressing sustainability of agricultural systems. To improve WUE in *Brassica* crop species will require sustained advances in our knowledge of how these plants function under water-limited conditions and their interaction with other environmental stresses. The status of our knowledge of plant biology has improved our understanding of gene expression and genetic networks responsive to drought tolerance and water deficit [72–75]. There is a significant body of knowledge available on the physiological and biochemical aspects of plant response to drought, and the role of ABA in these processes has been advanced [76–78]. However, the mechanisms of action of these gene products remain to be established [79]. The application of genetic engineering tools has resulted in the development of transgenic crop plants expressing genes conferring tolerance to drought and increased WUE [76]. Some of these genes exhibit undesirable side effects, which may limit broader usage. However, regulated expression may circumvent these negative outcomes. Wild *Brassica* species may contain genes conferring improved WUE and drought toler-

ance. These can be introgressed into crop species by conventional breeding. However, genetic engineering offers a better option for the development of crops with such traits as access for desirable genes is potentially unlimited. This also offers an excellent platform for increasing our knowledge of gene function in a variety of genetic backgrounds. The overall aim of drought tolerance and efficiency of water use should be to maximize yield under water limited conditions. To this end, it is important to know how plants maintain homeostasis and metabolic activity under such conditions. To gain this knowledge, gene function cannot be viewed in isolation but must be viewed in the context of interacting genetic and metabolic networks in a well-integrated comprehensive systems approach [80, 81].

50.9
Water Use Efficiency in *Brassica* Species

Brassica crop species are adapted to a range of environments and like in other crop species yield is heavily influenced by water availability. Many areas of *Brassica* crop cultivation are drought prone and to meet increasing demand for *Brassica* products, it will be necessary to expand cultivation into less favorable areas. Therefore, effective water use for yield maintenance is vitally important. In spite of the importance of these species, there are not many reported studies of WUE. In a comparison of WUE and stomatal conductance in *Moricandia* and *Brassica* species, McVetty *et al.* [82] attributed lower WUE in the latter species to higher stomatal conductance. Studies with *B. oleracea* revealed a number of quantitative trait loci (QTL) for variation in leaf conductance and photosynthetic assimilation rate [83]. These findings may be useful in breeding for improved WUE [82]. Variation in tolerance to drought, attributable to differential osmotic adjustment, among *Brassica* species has been reported [84]. There are genotypic differences in response to drought stress, which may be related to OA [84–86]. These studies indicate availability of a rich source of genetic variation for drought tolerance and WUE in *Brassica* species that can be exploited in breeding for both drought tolerance and WUE.

50.10
Conventional Breeding for WUE in *Brassica* Crop Species

This invariably involves breeding for drought tolerance and growth under water-limiting conditions. With the availability of germplasm, conventional breeding can make a significant contribution to improvement in WUE and drought tolerance. Physiological and morphological traits related to WUE can be identified and their inheritance determined. Carbon isotope discrimination (CID), which measures the ratio of $^{13}C/^{12}C$ in the plant tissues compared to the air, is an indirect measure of WUE and can be used to detect genetic variation for TE in plants. This could provide an effective tool for screening the germplasm. Screening can also be done by measuring leaf ash content, LASH, and K content [87, 88]. Ash content is generally

negatively associated with WUE if a constant concentration of minerals in the transpiration stream is maintained. Since this is likely to be affected by environmental conditions, the accuracy of genotypic comparison, they should be grown in the same environment. This method has been used to identify QTL for WUE in soybean [87]. A potentially promising area of study is to screen the germplasm for differences in root architecture in relation to WUE. This is an often underexplored area of research that could improve both yield and WUE [88–90]. Improving root architecture and size will be essential to ensuring adequate transpiration during water deficit, which will have a positive influence on productivity [91–93]. QTL for root architecture in rice have been identified and their effect on yield determined [88]. Application of similar approaches in Brassicas may contribute to new potential gene targets for WUE traits in *Brassica* species.

50.11
Unique Challenges to Breeding for WUE in *Brassica* Crop Species

As a consequence of the diversity of *Brassica* crop species, where the harvestable products include oilseeds, leaves, stems, florets, flower buds, axillary buds, and tubers, breeding for WUE is naturally challenging. This is in contrast to major grain crops such as rice, wheat, and maize where the grain is generally the product at harvest. Therefore, WUE strategies such as increasing sensitivity of stomates to ABA may be unsuitable for leafy *Brassica* crops as leaf growth may be compromised [58]. Larger leaves will usually transpire more water, which means that for leafy *Brassica* crops increased WUE should be by means that do not compromise leaf growth. Increasing photosynthetic efficiency and enhancing crop development under conditions where evaporative demands are lower should improve WUE in these crops.

50.12
Engineering Drought Tolerance and WUE in *Brassica* Crops

Although conventional breeding will undoubtedly contribute to improvement in WUE, there are substantial benefits to be derived from the application of a biotechnological approach. By this approach, there is no limitation to the source of genes that can be evaluated. In contrast, conventional breeding is limited by the compatibility of germplasm with the genotype under improvement. This, in effect, widens the gene pool for improvement in WUE and drought tolerance. Another benefit of this approach is the potential to gain valuable information on gene function after expression in the desired background. Given the importance of abiotic stress to plant growth, the literature on attempts to engineer stress tolerance in plants is voluminous and there are a number of approaches for the identification of genes involved in abiotic stress [94, 95]. The model plant *Arabidopsis* has been an invaluable tool in advancing our knowledge of plant biology in general and specifically some fundamental aspects of abiotic stress responses. This topic has been reviewed

recently [94] and will not be further discussed here. The ability to identify genes for specific functions and to express them in heterologous systems through genetic engineering technology has revolutionized plant biology. Genes conferring tolerance to abiotic stresses have been evaluated in the model species *Arabidopsis* and in other plants [96–100]. The attractiveness of this technology is that we can introduce only the genes for specific traits into an elite variety without carrying along other potential undesirable genes, as is the case with conventional breeding. In that case, several rounds of backcrossing are normally required to remove the unwanted genes. An excellent example is the identification and introduction of the transcription factor NFYB2 into maize [101]. This conferred drought tolerance, WUE, and increased yield when tested under water-limited field conditions. There are a number of cases where drought tolerance, WUE, have been achieved by genetic approaches including engineering of functional and regulatory proteins, and enzymes for production of osmolytes and osmoprotectants [76, 79]. Many of these, though at the proof-of-concept stage, still show promise for incorporation into crop species to develop superior WUE traits.

In many environments where *Brassica* crop species are grown yield will be heavily influenced by water availability. Therefore, effective water use to sustain yield is vitally important. In spite of the importance of these species, there are not many studies on WUE.

Success in improving WUE and growth under water-limited conditions depends on an understanding of plant physiology and metabolism under conditions of water limitation [102]. Since the economics of water use is a function of carbon assimilation per unit of water used, efficiency can be obtained by addressing factors limiting carbon assimilation along with those controlling water losses. It is well established that a major consequence of reduced plant water status is impairment in the photosynthetic machinery [79, 102]. This is the result of reduction in internal CO_2 levels as stomates close in response not only to water deficit but also to disruption in oxidative homeostasis alterations in cellular metabolism. To maintain photosynthetic carbon assimilation, plants must be equipped with enzymes to alleviate oxidative stress. About 90% of the water absorbed by plants is lost in transpiration. This means that WUE can be improved by regulating stomatal water loss. The plant hormone ABA is a major factor in the regulation of stomatal aperture and reduction in transpirational water loss [41]. By uncovering the molecular components regulating this ABA response, it was possible to engineer drought tolerance in canola (*B. napus* L.) [103–105]. Negative regulation of ABA via downregulation of ERA1 has been reported to both enhance drought tolerance and maintain productivity in *Brassica* [104, 105]. Drought tolerance and improved WUE was also reported for canola plants expressing a gene for lipid metabolism, PtdIns-PLC2, [106]. In another study, transgenic canola plants expressing poly (ADP-ribose) polymerase exhibited lower reactive oxygen species (ROS) and displayed drought tolerance [107]. Transgenic canola plants with wheat mitochondrial Mn superoxide dismutase (Mn SOD3.1) exhibited increased vigor and tolerance to abiotic stress, including drought [108]. Similarly, the overexpression of LEA proteins has been shown to impart drought tolerance to *Brassica* seedlings [109]. However, the *caveat* is that it has yet to be

determined that the overexpression of abiotic stress-tolerant genes or transcription factors regulating these genes does not have a negative overall yield crop productivity under field conditions.

50.13
Prospects of Improving WUE in *Brassica* Crops

There is general agreement that crop productivity must be increased to meet increasing global demand [110]. It is clear that this must be achieved by a more efficient use of input resources. This requires development of crop cultivars with enough genetic capacity for high yields with minimum input. Access to desirable genes from natural variation in wild relatives of *Brassica* species will enhance development of cultivars with improved WUE. However, the application of genomics and tools of biotechnology will be vital to this activity [111]. Consideration must also be given to crop interaction with biotic and abiotic stresses that impact yield in the sense of acquiring fundamental knowledge of physiological and biochemical mechanisms underlying adaptation to stress [112, 113]. Climate change is predicted to drastically alter crop growth environment in a largely unpredictable manner, which is a major challenge to future crop yields [62, 63]. Water availability is perhaps the most limiting factor to crop growth and yield and with the prospect of further decline in this resource, as a consequence of climate change, its efficient use is paramount. For *Brassica* crops to continue to play a significant role in future food, feed, and energy security, there is need to improve WUE and drought tolerance in these species and to extract higher yields per unit of water used. While there are a number of measures proposed to conserve soil water [24, 58, 66, 113], significant research emphasis should be on the efficiency with which water is used for biomass generation in *Brassica* crops. The identification and characterization of two genes, ERECTA and HARDY [15, 46] that enhanced WUE through multiple effects on plant morphology, should be useful in the development of WUE *Brassica* cultivars. Root–shoot signaling is emerging as an important aspect of stomatal aperture regulation [114, 115], and further advances in this area should benefit plant breeding efforts aimed at the development of WUE genotypes. Regulation of stomatal water loss, improved root water acquisition, and finding ways to effect greater efficiency of carbon assimilation and partitioning into harvestable products under water-limited conditions, are likely to be keys to WUE in *Brassica* species.

Though significant progress has been made in the identification of several genetic factors implicated in WUE in plants, it is likely that many others involved remain to be identified. Rapid advances in genomic technologies offer complementary approaches for performing global gene expression analyses to identify new factors associated with WUE in model plants such as *Arabidopsis* and closely related *Brassica* crop species. New gene discoveries coupled with insights into their function and regulation will expand potential new targets for improvement of WUE in *Brassica* species.

Acknowledgments

The *Brassica* research activities in genomics and abiotic stress are supported by NRC GHI program funding to RD and AAFC/CCGI program funding to JS. This is publication # 50183 from the National Research Council of Canada.

Brassica Crops: Improving Abiotic Stress Tolerance – Current Status and Prospects

Stephen J. Robinson and Isobel A.P. Parkin

A growing awareness of the need to ensure global food security in the face of an expanding population and the uncertainties of a changing climate is driving the demand for enhanced agricultural productivity. Environmental stresses have a significant impact on harvestable yield and alleviating their toll offers opportunities to stabilize and improve crop yields. However, the physiological and genetic responses of plants grown under adverse environments are highly complex and have thwarted improvement strategies. Here, we review our understanding of abiotic stresses and the plant's response to such stresses. We focus on the improvement strategies that have been tested and on the developments in genomics technologies that could facilitate the improvement of stress tolerance in the *Brassica* oilseeds species, which are responsible for generating a large proportion of the world's edible oil.

51.1
Introduction

Humans have been remarkably successful at colonizing the globe with permanent dwellings on every continent. The population is now so numerous that our combined actions can affect Earth's climate. The dramatic explosion of human population is a recent event rising from ~1 billion in 1750 to 3 billion in 1960 and 6 billion by 1999. This exponential growth is anticipated to continue before slowing by ~2050 [1]. This population expansion has been fueled by tremendous increases in agricultural production and productivity along with advances in medical and sanitation practices. Until the beginning of the last century, the energy that sustained human life was obtained solely by photosynthesis capturing energy derived from the sun. This energy was utilized directly through the consumption of crop plants or indirectly from the consumption of animals raised on plant feed. In this way, photosynthesis set

Improving Crop Resistance to Abiotic Stress, First Edition.

a limit on the amount of food that could be generated, effectively placing a limit upon population growth.

Technological advances, improvements in agricultural practices, and mechanization improved yields and reduced the labor required for land management, furthering population growth. Agriculture was dramatically transformed during the 1950s, commonly referred to as the Green Revolution, when the provision of optimal growth environments and adapted varieties increased grain yields by 250% [2]. This was the beginning of the industrialization of agriculture with yield increases obtained from the expenditure of fossil fuel-derived energy in the form of fertilizers, pesticides, and hydrocarbon-fueled irrigation. However, as the availability of cheap fossil fuels becomes limited [3, 4] the impact of adverse environmental conditions will be a significant problem to ensuring the sustainability of adequate agricultural output. The development of crops that are better able to tolerate suboptimal growth conditions is essential if the challenges of satisfying the increased food demand are to be addressed.

51.1.1 Introducing the Brassicaceae

The Brassicaceae contains more than 3500 species classified in 350 genera and is one of the ten most economically important plant families. There is enormous variation within the *Brassica* species, and through selective breeding they have been developed as sources of oil, vegetables, mustard condiments, and fodder. Species of particular importance include *Brassica napus* (var. *oleifera*), *B. rapa* (var. *oleifera*), and *B. juncea* as sources of canola and industrial oils. The vegetable crops include broccoli, cauliflower, Brussels sprouts, cabbage, kale (*B. oleracea*), swede or rutabaga (*B. napus*), Chinese cabbage or turnip (*B. rapa*), and radish (*Raphanus sativus*). These are complemented by species grown as condiments that include Indian mustard (*B. juncea*), white mustard (*Sinapis alba*), and horseradish (*Armoracia rusticana*). The cytogenetic relationships among the *Brassica* crop species consist of combinations of three basic genomes aptly described by the triangle of U [5]. The nodes of the triangle are formed by the diploid species *B. rapa* ($2n = 20$, AA), *B. nigra* ($2n = 16$, BB), and *B. oleracea* ($2n = 18$, CC). The amphidipliod species *B. carinata* ($2n = 34$, BBCC), *B. juncea* ($2n = 36$, AABB), and *B. napus* ($2n = 38$, AACC) were each formed by pairwise hybridization among the diploid species (Figure 51.1). Research in the *Brassica* crops has benefited from advances in knowledge and the development of resources for their close relative *Arabidopsis thaliana*, the first plant genome to be fully sequenced [6].

Oilseeds and their products are among the most valuable agricultural commodities in world trade and *Brassica* oilseed species are the most important world sources of vegetable oil after palm and soybean oil. The oilseed *Brassica* crops have undergone a rapid transformation from a marginal break crop 60 years ago to become a major cash crop subsequent to the reduction of both erucic acid and glucosinolate concentration in the seed, now synonymous with canola [7]. Although the dominant *Brassica* oilseed

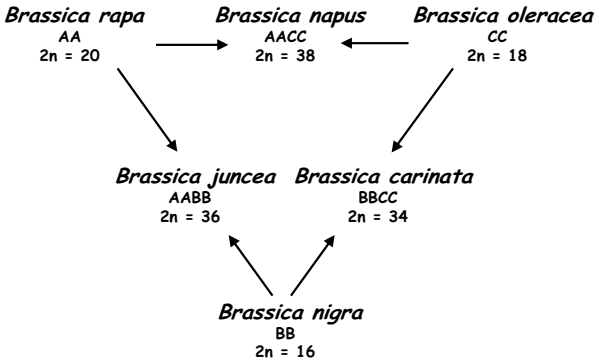

Figure 51.1 Representation of the genetic relationship among the six *Brassica* crop species as suggested by U [5].

is canola, other edible Brassicaceae oilseeds such as mustards, *Crambe*, and *Camelina sativa* constitute important variants. When considering *Brassica* oilseeds alone, an average of 50.8 million tons are produced worldwide each year (2004–2008) and average yields have increased more than twofold over the past 60 years [8]. The countries producing the largest acreages of *Brassica* oilseeds are China, Canada, and India. However, higher yields are obtained from European countries, exceeding twice those obtained in Canada as the more productive biennial varieties can be grown under the favorable European conditions as opposed to the annual varieties adapted to Canadian climates [9].

51.1.2
The Impact of Stress on *Brassica* Yield Factors

The constraint on plant distribution is primarily determined by the combined effects of temperature (Figure 51.2a) and water availability (Figure 51.2b and c) and crop plants tend to be more susceptible to extremes of these conditions. Any factor that results in a decrease in plant growth and yield beneath that predicted by the plant's genotypic potential can be considered a physiological stress. The maximum harvestable yield can be considered the upper limit of a yield potential and the difference between this and the mean harvestable yield represents the losses due to environmental stress. Losses due to abiotic stress are considerable, with estimates exceeding 60% of the yield potential being observed [10]. The local climatic conditions determine the major stresses that have an impact on *Brassica* crops, but the effects of an insufficient water supply, adverse temperatures (including both excessive heat and freezing temperatures), and salinity are frequently responsible for large annual yield losses [10, 11].

The impact of abiotic stresses on *Brassica* crops depends on a number of factors that include type, intensity, and duration of the stress along with the developmental

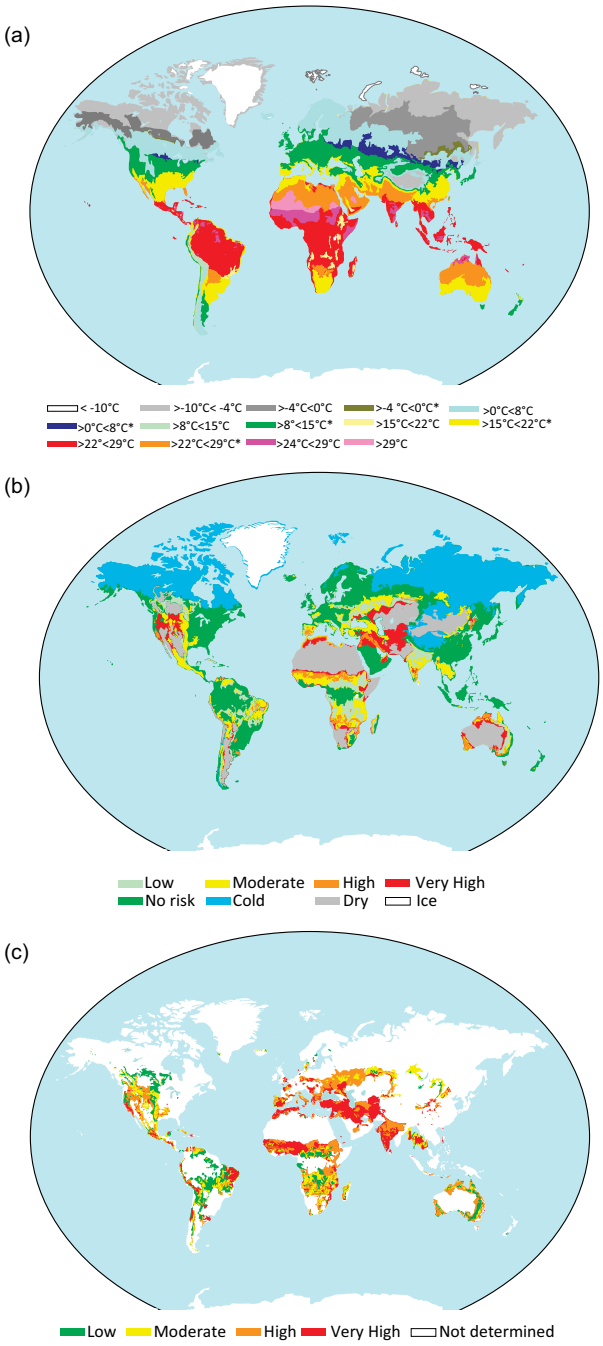

Figure 51.2 Global soil temperature and water availability limit the distribution of plant species and agricultural productivity. Average global soil temperature is presented in (a), the colored key indicates the temperature range; an asterisk denotes a temperature variance in excess of 5 °C. (b) The global soils at risk from desertification. (c) The risk of human-induced desertification. All the data presented are a summary of those produced by the United States Department of Agriculture (http://soils.usda.gov/.)

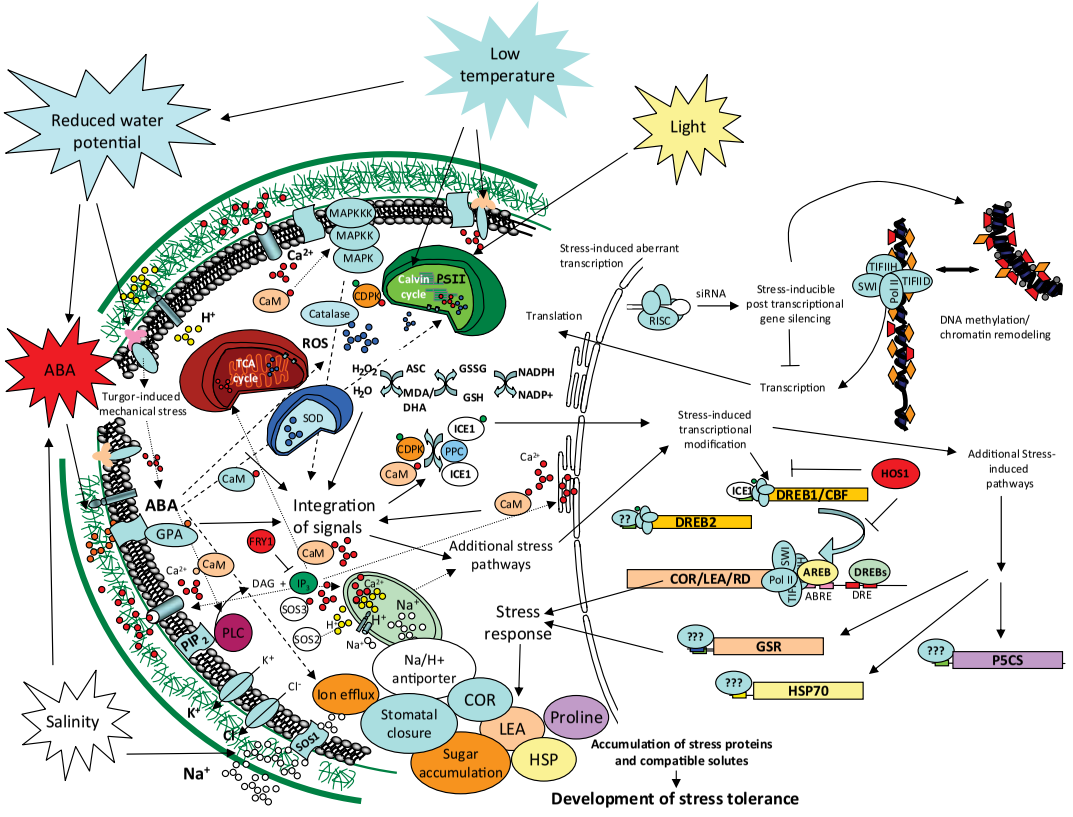

Figure 51.3 Signal transduction pathways involved in abiotic stress within the plant cell. The various abiotic stresses result in changes in membrane fluidity, mechanical perturbations caused by changes in turgor pressure, imbalances in redox potential, and the production of ABA and ROS. Upon stress perception, signals mediated through the action of hormones and secondary messengers (Ca^{2+}, IP_3) result in the activation of phosphorylation/dephosphorylation cascades that result in specific changes to regulatory proteins that activate stress-specific gene expression. Additional transcriptional regulation of abiotic stress can result from changes in DNA methylation patterns along with histone modifications that can be mediated through the action of siRNA. The solid green lines represent the cell wall matrix that sits above the plasma membrane. Integral and peripheral membrane proteins are depicted in blue. The circles represent Ca^{2+} ions (red), H^+ ions (yellow), phosphate groups (green), ROS (blue), Na^+ (white), and methyl groups (gray). Abbreviations: CaM, calmodulin; CDPK, calcium-dependent protein kinase; ASC, ascorbic acid; MDA, monodehydroascorbate; DHA, dehydroascorbate; GSSG, glutathione disulfide; GSH, glutathione; MAPK, MAPKK, and MAPKKK, mitogen-activated protein kinase cascade; PLC, phospholipase C.

stage of the crop exposed to the insult [12]. Among the *Brassica* oilseeds, environmental stresses have the greatest impact on yield during silique formation with the 2 week period post-anthesis being critical for determining the yield obtained [13–15]. During this developmental stage, oilseeds are generally most at risk of being exposed to drought and excess heat stress. Although, for annual crop types, low-temperature stress at the extremes of the growing season, with the occurrence of late-spring or early-autumn frost, can affect yield by reducing plant establishment or the quality and number of seeds per silique, respectively [16]. Arguably, the greatest agronomic impact of frost to oilseed brassicas is the reduction in yield quality resulting from early autumn frosts that damage the developing embryos resulting in chlorophyll retention in the harvested seed [17].

These critical growth stages provide the best targets to increase the stress hardiness of *Brassica* crop plants. The development of crops with targeted stress tolerance in addition to the application of good agricultural practices promises yield stabilization.

51.2
Plants' Response to Abiotic Stress

Many of the physiological adjustments that are utilized by plants to increase their ability to tolerate abiotic stresses have been described in detail for many crop species [12, 18–23] including the *Brassica* crops [24–29]. Although the relationship between many of these physiological adjustments at the cellular level and the stress tolerance in the field are difficult to establish, understanding these processes may yet determine key targets for stress improvement.

51.2.1
Metabolic Adjustments to Stressful Environments

Unique challenges are imposed by each abiotic stress. Perhaps with the exception of flooding, many of the physiological responses induced by such stresses and their cellular targets are similar, with the common motif being cellular dehydration. The unifying feature among abiotic stresses is the generation of reactive oxygen species (ROS). High levels of ROS are generated through the impairment of photosynthetic biochemical reactions, while the rates of physiochemical light harvesting are unaffected and ROS production is acentuated by adjustments to the metabolism of respiratory and photorespiratory pathways. Generated ROS include singlet oxygen, superoxide, hydroxyl radical, and hydrogen peroxide, and their presence can cause the oxidation of lipids, nucleic acids, and proteins resulting in cellular damage [30]. The cellular membrane systems and enzyme catalysts are thought to be the primary targets of oxidative stress damage [31]. Cellular membranes are responsible for regulating the passage of solutes in and out of the cell and the cellular compartments. Adverse environmental stress affects both the fluidity of the lipid bilayer and the actions of integral and peripheral membrane-associated proteins. In addition, abiotic

stresses can alter the conformation of protein structures through the disruption of chemical bonds and allosteric modifications of key regulatory enzymes [32, 33].

Natural selection has developed several solutions to protect cellular structures from the adverse effects of abiotic stress. These include the induction of ROS scavanging systems, polyamines, and heat shock proteins. In an effort to negate the toxic effects of ROS, enzymatic and nonenzymatic antioxidant compounds are produced [30, 31]. Some of these compounds are compartmentalized in specific organelles, while others are active throughout the cell. The major antioxidative enzymes include superoxide dismutase (SOD), catalase, peroxidases, ascorbate peroxidase, dehydroascorbate reductase, monodehydroascorbate reductase, and glutathione reductase, and these systems work in concert with metabolites including ascorbic acid, glutathione, α-tocopherol, and β-carotene [30].

Numerous plant studies have demonstrated a strong correlation between the accumulation of compatible osmolytes and an increase in stress tolerance. These organic compounds possess a low molecular weight, are highly soluble, and are nontoxic at high cellular concentrations [34]. It has been hypothesized that these compatible solutes function to adjust the osmotic potential of the cell, to protect against damage from ROS, to stabilize the structure of macromolecules, and to protect membrane integrity, although direct evidence for these functions awaits confirmation [35]. Proline, sucrose, trehalose, polyols, and glycine-betaine form the major compatible osmolytes identified in plants [36]. However, compatible solute accumulation is species specific where different compounds have been chosen by natural selection to accumulate to high cellular concentrations. *Brassica* species appear to accumulate proline and some simple sugars to high concentrations, but not glycine-betaine [37].

In addition to these metabolites, numerous classes of protein demonstrate a positive correlation between their cellular concentration and abiotic stress tolerance. These include the heat shock proteins [38], late-embryogeneis accumulating (LEA) [39], and the cold-responsive proteins (COR) [40]. Numerous studies have focused on the relationship between stress tolerance and the accumulation of these proteins and have revealed an integrated network of genetic pathways that respond to various abiotic stress stimuli and ultimately result in an acclimated cellular state [41, 42].

51.2.2
Hormonal Responses to Abiotic Stress

The interaction and perception of plant hormones is largely responsible for the coordination of plant growth and development [43]. Among these, the phytohormone ABA has often been referred to as a stress hormone due to the substantial number of physiological effects that stress and ABA exposure have in common [44]. A reduction in transpirational water loss through restriction of stomatal aperture, germination inhibition, and reduced leaf expansion are perhaps among the most recognizable effects of ABA [45]. However, ABA also functions to fine-tune plant growth and development under nonstress

conditions by regulating hydraulic conductivity, embryo development, and seed dormancy [45, 46].

The association between ABA and stomatal drought responses was confirmed through ABA-deficient mutant analysis, where the stomata of plants unable to synthesize ABA remained open during dehydration [47–49]. Although increases in ABA concentration are correlated with stress tolerance, the ratio among the phytohormones is important as ABA acts in concert with other phytohormones to elicit the observed physiological responses [50, 51].

ABA signal perception is beginning to be elucidated and uncovering the mechanism involved is an area of intense research [52, 53]. The control of guard cell turgor pressure and thus stomatal aperture is among the best characterized plant cell signaling pathways and involves Ca^{2+} fluxes, G-protein, and F-box protein signaling events, which regulate the efflux of K^{+} cations, anions, and charged metabolites [45, 54–59]. The physiological effects, synthesis, and catabolism of ABA have been extensively covered in a number of additional reviews [43, 60–63]. Stress-induced changes in ABA concentration are rapid and the signals originate in the root before being transmitted systemically throughout the plant. Severe dehydration causes the additional synthesis of ABA in leaf tissues, dramatically increasing ABA concentration resulting in further guard cell turgor pressure changes, adjustments to plant metabolism, and gene expression [64–67]. Ultimately, these genetic and metabolic adjustments allow the plant to acclimate to abiotic stress providing it with enhanced stress tolerance [68, 69]. The profound control that phytohormones hold over plant metabolism [70] and their proximity to stress perception make modification of ABA biochemistry an attractive if daunting target with which to modify stress responses. An improved understanding of ABA physiology and its coordination with additional phytohormones could lead to targeted strategies for improved stress tolerance in plants.

51.2.3
Brassica Stress-Responsive Genes and their Regulatory Pathways

Plants being sessile organisms must respond rapidly to environmental challenges that involve the perception and relay of the stress signal through a multitude of integrated signaling pathways, which ultimately results in changes in the cellular physiology [71, 72]. The mechanisms by which plants perceive the abiotic stress remain unknown although it has been speculated that changes in membrane fluidity, redox potential, cytoskeletal rearrangements, and turgor pressure may each play a role in triggering stress signaling cascades [73–76]. Phytohormones and secondary messengers, including Ca^{2+}, inositol phosphates, and ROS, transmit the primary signal often through multiple phosphorylation cascades, which target regulatory proteins that control stress-related gene expression (Figure 51.3).

The majority of research studing stress signaling in the Brassicas has focused on response to low temperature. The expression levels of numerous genes encoding LEA/COR proteins are induced in response to low-temperature exposure in the Brassicaceae model *A. thaliana* [77] facilitating their identification. Similarly, *Brassica*

transcripts encoding proteins orthologous to the *Arabidopsis* COR proteins accumulate rapidly in response to stress. This is highlighted by the stress response of Bn115, Bn26, and Bn19 from *B. napus*, which are homologous to the *Arabidopsis* COR15a and COR15b proteins [78]. Similarly, *Brassica* homologues of the *Arabidopsis* dehydrins *COR47* and *ERD10* and the low-temperature-inducible *Arabidopsis COR6.6* gene demonstrate analagous expression patterns in response to stress. The low-temperature response of COR/LEA proteins conserved between these species appears to be the first line of cellular defense against the effects of freezing and dehydration in the Brassicaceae with the strongest response observed for COR15. The effect of *Arabidopsis* COR15 on freezing tolerance has been assessed *in planta* [79] and *in vitro* assays [80–82], but no functional analyses of *Brassica* COR15 orthologues have been reported. However, both the solubility of recalcitrant proteins and their protection from denaturation in response to temperature stress were enhanced by the addition of the recombinant *Brassica* LEA proteins BnECP63 and Bn115 [83] suggesting that the function of these *Brassica* homologues and their *Arabidopsis* counterpart COR15 is conserved. Genetic manipulation to induce a suite of appropriate LEA proteins could hold promise for increasing the freezing and dehydrative stress tolerance in *Brassica* species.

Analysis of the promoter region of the *Arabidopsis COR* genes led to the identification of regulatory *cis*-elements named DRE/CRT (drought-responsive elements/C-repeats) [84] and subsequently the transcription factor DREB/CBF (DRE binding factor/C-repeat binding factor) that controlled the low-temperature expression of the *COR* genes [85, 86]. The core sequence (CCGAC) from the DRE/CRT *cis*-element of the *Arabidopsis COR* genes is also found in the promoter sequences of the *Brassica COR* genes and have been demonstrated to be necessary for their low-temperature response [87, 88]. The sequence similarity between the promoters of *Brassica* and *Arabidopsis COR* genes is further conserved with regulatory elements enabling their response to abscisic acid (ABA) found among these orthologues [80–91].

The *DREB1/CBF* transcription factors form a small gene family belonging to the plant-specific AP2 family. They are located as three tightly linked genes on chromosome four of the *Arabidopsis* genome and there is a high degree of conservation between the members of the *DREB1/CBF* family. Furthermore, each member of the *DREB1/CBF* gene family has been demonstrated to induce *COR* gene expression [92, 93]. The *Brassica* orthologues (*BnDREB1/CBF*) are highly homologous to their *Arabidopsis* counterparts [94, 96]. The use of protein sequence alignments of four *B. napus BnDREB1/CBF* transcripts suggested that they separate into two distinct classes represented by *BnCBF17* and *BnCBF16*, *5*, and *7* [95]. This distinction was further highlighted by the differences in binding affinity and specificity observed between BnCBF17 and BnCBF5 [95]. Examination of the expression profiles of *B. napus* DREBs generated in response to low temperature suggested differences between these two classes with induction of one class proceeding those from the second and while the members from both groups were able to bind to DRE/CRT *cis*-elements, only the class I was able to activate downstream gene expression in yeast assays [96]. These observations led to the suggestion that both temporal expression differences and competitive binding between DREB transcription factors played a

role in controlling *COR* gene expression in *B. napus* [96]. However, these functional differences have not been demonstrated *in planta* and analogous studies using class II *DREB* genes from *B. juncea* and *B. napus* indicated they could functionally activate downstream genes in assays involving both yeast and plants [97, 98]. The disagreement on the functionality of class II BnDREBs among these studies may stem from the systems in which the assays were performed (yeast versus *in planta*) and/or difference in expression level of the *BnDREB* constructs.

51.3 Enhancing Environmental Stress Tolerance

Although the physiological responses to different abiotic stresses are related, their duration and the developmental stage most affected by each stress may differ. When grown on saline soils, the plant must tolerate reduced water potential and the presence of toxic ions throughout its life cycle. While drought can occur at any stage throughout a plant's life cycle with the risk of drought increasing over the growing season, for *Brassica* crops anthesis is the most susceptible stage. The risk from freezing stress occurs at the limits of the growing season affecting seedling development and embryo maturity. These differences necessitate stress improvement strategies targeted at particular growth stages to achieve the desired yield protection.

Improvement of crop stress tolerance can by achieved through the direct insertion of small number(s) of carefully selected alleles. A number of promising strategies have been employed to engineer stress-tolerant genotypes in crop plants, and although this technology remains in its infancy, the potential of these improvements is clear. However, for these approaches to be deemed successful, the stress-tolerant germplasm must perform as well as elite lines when grown under normal non-stressed growth conditions and be able to outperform elite lines when grown in a stressful environment, which further complicates the final objective.

51.3.1 Targeted Strategies for Abiotic Stress Improvement in Brassicas

51.3.1.1 Improvement of Freezing Tolerance in Brassicas

The overexpression of *AtDREB1b/CBF1* or *AtDREB1a/CBF3* in transgenic *Arabidopsis* conferred constitutive expression of the *COR* genes, along with a constitutive and enhanced freezing tolerance phenotype [85, 99]. These observations inspired the development of *B. napus* lines overexpressing copies of the *BnDREB* genes. Similar to the results for *Arabidopsis*, overexpression of a class I *BnDREB* gene conferred a significant increase in the level of freezing tolerance, beyond that observed for wild-type controls under nonacclimating conditions, whereas lines overexpressing a class II type demonstrated a smaller increase in freezing tolerance [97]. The importance of the *COR* genes in *Brassica* species was further demonstrated in this study since the difference in freezing tolerance between the transgenic lines was correlated with the

accumulation of the *COR* genes. Preparation to withstand the onset of freezing winter temperatures involves the restructuring of metabolism during a period of acclimation to low but nonfreezing temperatures, and maintenance of photosynthetic capacity is crucial to sustain growth rates to ensure winter survival. The transgenic *BnDREB B. napus* plants constitutively expressing the class I transcription factor presented thickened dark green leaves in addition to the enhanced freezing tolerance, which was accompanied by an increase in photosynthetic capacity and efficiency normally observed in cold-acclimated tissues [97]. Similar adjustments to photosynthetic capacity have been observed in other studies investigating the overexpression of *AtDREB/CBF1* in potato [100] and *AtDREB1a/CBF3* in chrysanthemum [101].

Increases in the level of freezing tolerance can be engineered in *Brassica* species through the constitutive expression of *DREB1/CBF* alleles, although questions remain as to how this can be practically achieved since the increased freezing tolerance was associated with pleiotropic effects including late flowering and dwarfism [97]. The use of such gain-of-function alleles has to occur in combination with tightly regulated promoter sequences that are triggered by specific environmental cues to limit the negative agronomic performance associated with the pleiotropic effects of the gene expression under non-stressed growth conditions [99].

51.3.1.2 Improvement of Drought Tolerance

The water status of a plant depends on balancing the rate of water uptake and the rate of transpiration and it has been estimated that dicotyledonous plant are able to move 90% of the available soil water through transpiration [102]. The rate of water loss from leaves is a function of the size of stomatal aperture, which is highly regulated and under the control of the phytohormone ABA that responds to changes in osmotic homeostasis. A number of genes have been identified that are involved in the synthesis (*era1*) and perception (*abi1, abi2*, and *abi3*) of ABA [46, 103–105]. Attention has focused on ERA1 and ABI1 as targets for the manipulation of stress tolerance as *era1* and *abi1* alleles result in guard cell phenotypes with a greater sensitivity to ABA [54, 105, 106]. Characterization of the *era1* gene led to its identification as a farnesyltransferase, a member of the prenyltransferase proteins. Farnesyltransferases exist as heterodimers consisting of α- and β-subunits that function to modify protein targets possessing the CaaX amino acid motif with the addition of a farnesyl group [107]. *ERA1* encodes for the ~46 kDa β-subunit of farnesyltransferase (FTB), while the ~48 kDa α-subunit is encoded by FTA. In *Arabidopsis*, the deletion of either FTB or inhibition of its farnesylation capacity induces stomatal closure over a wider range of ABA concentrations than ordinarily observed [54, 108]. This altered response reduces water loss at higher soil water potentials and is an attractive target for manipulation to engineer improved stress resistance. The *Arabidopsis era1* mutant possesses a number of pleiotropic effects including delayed growth and development, increased floral organ numbers, and enlarged meristems impeding the realization of its full potential [109, 110]. A number of independent lines were developed by transforming *Arabidopsis* with an *anti-FTA/B* construct under the control of the 35S CaMV constitutive promoter [111]. Germination assays in the

presence of ABA demonstrated that the knock-down alleles possessed intermediate phenotypes compared to wild-type and the *era1* genotypes. The *anti-FTA/B* lines were able to maintain greater hydration levels than the wild-type throughout the period of dehydration and other than showing a short delay in flowering time the *anti-FTA/B* lines resembled a wild-type phenotype [111]. The use of a novel promoter to control the timing of knockdown AtFTA/B alleles has the potential to break the remaining linkage with the pleiotropic effects.

Transferring the phenotype into *Brassica* species is complicated by the additional genome duplication and the lack of a highly efficient transformation strategy. However, a knock-down phenotype for FTB was developed in canola using an *anti-FTB* construct under the control of the *RD29a* promoter [111]. The level of stomatal conductance was assessed in the transgenic lines using gas exchange analyses in both ideal and dehydrated environments. These data indicated that there was no difference in photosynthesis and transpiration rates between control and transgenic plants under adequate water conditions. However, when the plants were allowed to dehydrate, the transgenic lines exhibited an additional 10% reduction in stomatal conductance beyond that observed among control plants [111]. Similar protection from hydration stress was observed when the stress occurred at anthesis where the *anti-FTB* transgenic lines recovered from dehydration faster than their control plants resulting in a reduction in the number of aborted embryos [111].

The promising effects on drought tolerance seen for the *anti-FTB* transgenic canola lines warranted their assessment in randomized field trials. The data from these field experiments replicated those observed under controlled environmental conditions where it was demonstrated that there was no significant difference in yield between the *anti-FTB* lines and the control plants when adequate water was provided. When water was restricted, the transgenic lines were able to produce an additional 10–15% yield beyond that observed in control plants [111]. Further refinement of this technology to reduce the potential for negative pleiotropic effects employed the hydroxypyruvate reductase (*HPR*) gene promoter [102]. HPR is an enzyme that catalyzes the conversion of hydroxypyruvate to glycerate as part of the photorespiratory cycle and the expression of this gene is limited to photosynthetic tissue and is low under ideal conditions but is rapidly induced upon exposure to abiotic stress or high light intensity [102]. Similar levels of yield protection were observed using the *HPR* and *RD29a* promoter sequences in response to hydration [102].

Additional strategies designed to improve drought tolerance originate from genomics studies using canola. *Arabidopsis* microarrays were used to assay heterologous gene expression among imbibed canola seeds and seeds treated with ABA or osmotic stress. It was observed that the expression of 40 genes was induced among these treatments when compared to control seedlings [112]. One of these genes encoded a protein with homology to 11-β-hydroxysteriod dehydrogenase (HSD), an enzyme involved in animal steroid synthesis [113]. Transgenic *Arabidopsis* plants expressing an *Arabidopsis* homologue of the *HSD* gene under the control of the *CaMV 35S* promoter were 20% larger than wild-type controls, with an increase in branch and silique number and in stem diameter. In addition, the transgenic *Arabidopsis* plants tolerated high-salinity concentrations better than their wild-type controls. Similar phenotypic

observations were made when this construct was introduced into canola plants offering great promise as a strategy to modify stress tolerance in *Brassica* [114].

51.3.1.3 Improvement of Salt Tolerance

The vast majority of crop plants including the Brassicas are considered glycophytes, and when grown in saline soils they are subject to both dehydration and ionic stresses. Soil salinity rarely fluctuates and in the majority of cases crops exposed to saline soils will have to endure these stresses throughout their entire life cycle. To tolerate a moderate Na^+ stress it is critical for the plant to maintain a low cytosolic sodium ion concentration. This can be achieved by excluding entry of the ions into the cytosol and removal, sequestration, or secretion of Na^+ ions able to gain entry into the cytosol. Sodium ions are able to gain entry into the cytosol via the potassium ion transporters and can be removed from the cell or sequestered into vacuoles through the action of Na^+/H^+ antiporters. Evidence for the existence of plant antiporters was established through the complementation of Na^+/H^+ antiport mutations in fungi and the characterization of the *SOS1* mutant that identified a plasma membrane antiporter [115, 116].

The difficulties associated with manipulating stress tolerance phenotypes are highlighted in studies overexpressing Na^+ antiporter proteins. The *Arabidopsis* Na^+/H^+ vacuolar antiporter (*AtNHX1*) was isolated by exploiting the homology it shares with its fungal orthologue and its function was confirmed through the rescue of a yeast strain deficient in Na^+ exclusion [117]. The potential of manipulating salt tolerance in plants through the overexpression of the AtNHX1 protein was demonstrated in *Arabidopsis* where transgenic lines exhibiting increased antiporter activity were able to grow under a Na^+ concentration (200 mM) toxic to their wild-type counterparts [115]. These results were replicated in crop species with the introduction of the *AtNHX1* gene into both canola and tomato [118]. The transgenic canola lines overexpressing the *AtNHX1* (*35S::NHX1*) gene produced seed yields comparable to that of the wild-type under control conditions and exceeded wild-type yields exposed to 200 mM NaCl [119]. When these lines were grown under high sodium ion concentrations, the *35S::NHX1* lines accumulated NaCl up to 6% of the dry matter, as the increased antiporter activity sequestered these ions in vacuoles. In these studies, the transgenic plants were found to be substantially equivalent to the wild-type, with minimal changes in fatty acid composition and lipid content of the harvested oil [119].

However, in a recent study assaying the potential additive effects of combining a number of genes proposed to confer salt tolerance, the result observed by Apse *et al.* [115] could not be replicated [120]. Furthermore, this new study demonstrated that there were no improvements observed by combining additional salt tolerance alleles compared to overexpression of an antiporter alone [120]. The discrepancies between these studies might result from the use of different methodologies for measuring salt tolerance. Additional strategies to improve salinity tolerance have involved proteins with less well-defined functions. The ability to improve salinity tolerance through the overexpression of LEA proteins was demonstrated in *Arabidopsis* using the *DNH-5* gene from wheat [121]. This followed similar work using the barley *HVA1* gene whose overexpression was able to improve the salt tolerance of rice

protoplasts [122]. In both these instances, the improvements in salinity tolerance were accompanied by enhanced drought resistance, although the mechanisms causing these phenomena await determination [121, 122].

51.3.2 Nonspecific Approaches to Enhance Abiotic Stress Tolerance

51.3.2.1 Overproduction of Compatible Osmolytes

The correlation of compatible osmolyte accumulation in tissues exhibiting an increased level of stress tolerance was among the first observations made in comparisons between stressed and non-stressed plants. These observations have led to crop improvement strategies focusing on their overproduction to improve stresses including freezing, drought, and excess salinity, where dehydration is a common feature. Compatible solutes can accumulate to high concentrations within the cell without toxic effects and there are many solutes able to act in such a way.

The quaternary ammonium ion glycine-betaine is induced by many plant species under stress and can accumulate in the cell through either metabolic processes or exogenous application [123]. The exogenous application of glycine-betaine to leaves of *B. rapa* resulted in its translocation throughout the entire plant within 24 h [124]. Accumulation of glycine-betaine has been correlated with a stress-tolerant phenotype able to protect against exposure to temperature extremes and an increased salt concentration [125–127]. However, *Brassica* species lack the metabolic pathways necessary to accumulate glycine-betine to high concentrations [128]. Two metabolic pathways have been identified that lead to the synthesis of glycine-betaine that proceeds either through the oxidation of choline or through the methylation of glycine, and the genes encoding the enzymes catalyzing these reactions have been identified and cloned [129–132]. Strategies for stress improvement in *A. thaliana*, *B. napus*, and *B. juncea* have been designed using the overexpression of the choline oxidase gene (*CodA*) to increase the concentration of glycine-betaine in these species [131, 133–135]. Transgenic *B. napus* plants generated in these studies accumulated glycine-betaine to concentrations around 1 μmol g^{-1} FW (fresh weight) and were used in stress tolerance assays examining their response to drought, freezing tolerance, and excess salinity [136]. The transgenic material exhibited greater stress tolerance than their control counterparts leading to the conclusion that increasing the concentration of glycine-betaine was a viable strategy for enhancing stress tolerance in non-accumulating species. However, similar studies also using the *CodA* gene indicated that the glycine-betaine levels were limited by choline availability such that the resultant concentration of glycine-betaine achieved was physiologically insignificant [136]. The subcellular location of glycine-betaine may be an important factor in the efficacy of using this compatible solute since stress tolerance was observed when glycine-betaine accumulated in the chloroplasts [136]. This may explain some of the variation in stress tolerance observed in these studies and suggests that glycine-betaine acts to primarily protect the photosynthetic machinery and thylakoid membranes [135, 137, 138].

Exposure to abiotic stress leads to the accumulation of amino acids in many plant species and proline is by far the most prominent amino acid to accumulate in the *Brassica* species, with higher levels of proline observed in stress-tolerant than stress-sensitive plants [139]. It has been proposed that the accumulation of proline acts in a similar manner to glycine-betaine and functions as a cryo-protectant, a store of nitrogen, an antioxidant, and a compatible osmolyte [140, 141]. Proline is synthesized from glutamine by pyrroline-5-carboxylate synthase (P5CS) and pyyroline-5-caroxylate reductase (P5CR) or from ornithine by ornithine δ-aminotransferase, with glutamate being the major substrate under stressful conditions. The manipulation of cellular proline concentration has been hypothesized to result in an increase in stress tolerance and the efficacy of this was first demonstrated in tobacco where overexpression of *P5CS* resulted in an 18-fold increase in proline concentration and was correlated with increased tolerance to dehydration [142]. However, high proline concentrations are not always associated with an increase in stress tolerance [143]; differences in the methodologies for assessing the stress may once again explain these conflicting observations, but these data suggest that our understanding of proline accumulation is incomplete and this impedes strategies targeting its simple manipulation.

51.3.2.2 **Oxidative Stress Tolerance**

Abiotic stress causes an alteration in metabolic homeostasis and results in an increase in the production of reactive oxygen species particularly in the chloroplast. Accumulation of ROS represents a potent hazard to the cell and pathways have evolved to rapidly metabolize ROS [74, 144], limiting the damage they cause. In addition, at lower concentrations the accumulation of particular ROS (H_2O_2) has been proposed as part of the stress signal transduction network [144, 145]. The manipulation of genes that function in the metabolism of ROS offers another promising strategy to improve tolerance to stress in crop plants. Targets utilized for this strategy have included glutathione S-transferase (GST) [144, 146], peroxidase, super oxide dismutase (SOD) [144, 147–149], asorbate peroxidase, glutathione reductase, or spermine synthase [144, 150].

Improvements in oxidative stress resistance were observed in cold-treated tobacco cells that expressed a pea Cu^{2+}/Zn^{2+} SOD in the chloroplast. It was determined that the transgenic tobacco cells were able to maintain higher levels of photosynthesis than equivalent control cells when subjected to low temperatures [151]. Similar results were obtained in transgenic tobacco lines overexpressing GST or glutathione peroxidase constructs [146]. Further improvements in salinity tolerance were reported by coexpressing catalase with SOD in *B. rapa* suggesting that these effects are additive [152].

51.3.2.3 **Manipulation of Stress Signaling**

In addition to functioning as selective cellular barriers, the phospholipid membranes act as a substrate for the generation of secondary messengers in cell signaling. Phospholipase C (PLC) catalyzes the conversion of phosphotidylinositol 4,5-bisphosphate (PIP_2) to diacylglycerol and inositol 1,4,5-trisphosphate (IP_3). Although

not specific to abiotic stress, transient increases in IP_3 concentrations have been associated with exposure to these stimuli [153]. IP_3 is proposed to function as a cellular messenger causing the release of Ca^{2+} ions from internal cellular stores [55], and given this role cellular IP_3 levels must be tightly regulated, which is achieved through the action of inositol polyphosphate kinases and phosphatases. The application of strategies designed to manipulate intercellular signaling has been attempted using a homologue of an inositol polyphosphate kinase obtained from the halophyte *Thellungiella halophila* (*ThIPK2*) [154] and a *B. napus* homologue of *PLC* [155]. Subsequent to promising results observed from initial stress assays in yeast, the consituative expression of *ThIPK2* in transgenic *B. napus* lines resulted in phenotypes with increased tolerance to salinity, drought, and oxidative stress damage [154]. Furthermore, analysis of well-characterized genes involved in abiotic stress tolerance revealed an induction in their expression within the transgenic plants. The overexpression of *PLC* in *B. napus* led to increased photosynthetic capacity and a reduction in stomatal conductance, which indicates a propensity for improved drought tolerance. These results suggest the involvement of inositol polyphosphate kinase in multiple signaling pathways affecting the stress response of *Brassica* species and that engineering of improved stress tolerance can be achieved by direct manipulation of these signaling mechanisms.

51.4
Prospects for Genetic Improvement of Abiotic Stress Tolerance

Abiotic stress tolerance phenotypes are under highly complex genetic and physiological control. This has been highlighted at the molecular level by the interconnected network of interactions that induce the *COR/LEA* gene pathways [156, 157]. The use of molecular techniques and the application of genomics technologies developed for model species have revealed numerous candidate genes for stress improvement [158–160] and have resulted in a number of strategies using single genes to manipulate tolerance to particular stresses or a range of abiotic stresses.

Alternative approaches for stress improvement involve the manipulation of entire plant genomes to combine specific favorable genotypes through recombination. These strategies have accompanied human evolution over the past 10 000 years, achieved initially through fortuitous selection and more recently through targeted breeding programs. The efficiency of these programs has been enhanced by the advent of molecular genetics with the development of high-quality linkage maps that can be used to resolve complex traits by mapping the underlying quantitative trait loci (QTL) that contribute to their variation. This type of analysis is increasing in resolution with the generation of high-density single-nucleotide polymorphism (SNP) arrays [161] that will allow traits with lower heritability to be dissected. These strategies are now being combined with the analysis of genome-wide transcription profiles to identify expression QTL (eQTL) associated with traits of interest [162] that might be incorporated in breeding strategies. The high-density marker and expression platforms also offer the promise of genome-wide association (GWA)

studies that have been successfully exploited in the study of human disease [163]. However, the application of genomics technologies in plant breeding is still in its infancy and while GWA studies are becoming feasible in crops [164], the practical application of such methods will not be realized for sometime.

51.4.1 Traditional Breeding and QTL Mapping

The selection of key agronomic traits over the thousands of years of crop domestication made dramatic advances in crop improvement. The philosophy behind the Green Revolution was to provide optimal growth environments for elite genotypes that are able to outperform and ultimately replace local landraces [2, 165, 166]. The major breeding objectives for elite genotype development of the *Brassica*s have been directed toward yield improvement and hybrid production, quality enhancement, [167, 168], pod-shattering and lodging resistance [169–172], early maturation, and disease resistance [173–175], with little resources targeted at environmental stress tolerance.

Tolerance to abiotic stress is controlled by genes at multiple loci, which often possess pleiotropic interactions with loci controlling yield characteristics, which complicates breeding strategies. These difficulties are compounded as selection for stress tolerance under field conditions is problematic due to the inability to consistently apply a specific stress and adequately monitor subtle quantitative phenotypes. Furthermore, since the underlying physiological mechanisms controlling stress tolerance are poorly understood, pertinent selections for material with increased stress tolerance is challenging [176–178]. These problems can be circumvented through the use of physiological assays made in artificial laboratory environments to direct selection. Numerous such assays have been utilized to monitor stress tolerance including ion leakage [179, 180], tissue water content [181], meristem regrowth after freezing [182], ABA concentration [183], and chloroplast function [184, 185]. Reproducible data generated from these assays facilitate reliable quantitative assessments of stress tolerance and the dissection of these complex traits. The association of a few loci with large effects with robust molecular markers will enhance crop improvement and allow the manipulation of complex traits without the requirement for specific controlled environmental conditions for phenotypic assessment. The cost and time required for conventional breeding programs can be reduced considerably through the adoption of such approaches as has been demonstrated by the improvement of drought tolerance in maize [186].

The application of molecular genetic technologies has identified the linkage groups of the six *Brassica* species confirming the cytogenetic relationships first described in the triangle of U [5, 186–194] along with those to more distantly related species [195]. The density of the molecular markers describing these linkage groups allows the dissection of complex traits such as abiotic stress tolerance into individual QTL facilitating the identification of the underlying chromosomal regions controlling stress tolerance. Largely QTL mapping in Brassicas has focused on easily

measured traits; however, a large number of QTL, many with small effects, were identified in *B. rapa* and *B. napus*, highlighting the polygenic nature, and revealing the complex genetic interactions contributing to winter survival, vernalization, and freezing tolerance in these species [26, 196, 197]. However, these QTL were responsible for a small fraction of variability identified within each population compromising their use in a marker-assisted breeding strategy.

51.4.2 Promise of Genomics Technologies to Elucidate Stress Tolerance

The *Brassica* species and the model plant *A. thaliana* share a close phylogenetic relationship, which allows the results from research focused on stress physiology in *Arabidopsis* to be directly exploited in *Brassica* crop improvement. Genomics strategies have been extensively applied in *Arabidopsis* to study abiotic stress tolerance since such complex traits with their multifaceted plant response can benefit from the application of robust but wide-ranging analyses. Such analyses have been gaining traction in other crops and research in *Brassica* species is beginning to take advantage of the new opportunities that are likely to gain in momentum over the next few years.

51.4.2.1 Genetic Screens to Elucidate Plant Stress Responses

Forward genetic screening of plant populations enriched with mutations induced through the use of chemical, physical, or genetic perturbations can not only identify improved phenotypes but can also facilitate gene discovery for loci controlling stress responses. Such screening strategies have been applied successfully to identify *Arabidopsis* lines with enhanced [198, 199] or reduced [200, 201] freezing tolerance. Furthermore, the use of genetic screens assaying for changes in the activity of a reporter gene under the control of the *RD29a* promoter revealed the complex network of interactions underlying the expression of the *COR/ERD/RD* genes [202]. The expression of *RD29a* is induced by dehydration, ABA, salinity, and low-temperature exposure. Analysis of the mutants obtained through the *RD29a* reporter gene screen revealed salt overly sensitive (SOS), constitutive (COS), high (HOS) and low (LOS) expression of osmotic response mutants [32, 203–205]. The identification and characterization of these mutants has enabled the genetic dissection of many of the components involved in stress signal transduction [206–208]. The success of these screens has led to a similar strategy being employed focusing on HSP70, a heat shock protein involved in the unfolded protein response. This screen has identified a potential sensor for temperature as a protein component of the nucleosome [209]. The increasing knowledge gained from studies conducted in model organisms has and will continue to provide additional targets for improvement in *Brassica* species and allow for the refinement of current strategies [210].

51.4.2.2 Global Transcriptome Analyses

The application of high-throughput genomics technologies to stress gene discovery has led to the promise of easy gene identification. The use of differential cDNA

expression [77, 211], microarray [212–216], and serial analysis of gene expression [159, 217] has revealed sets of differentially expressed stress-responsive genes. The majority of exploratory genomics research utilizes resources developed for *Arabidopsis* due to their availability and comparatively low cost, but the development of high-throughput technology platforms designed specifically for *Brassica* species will allow more comprehensive assessments of *Brassica* transcriptomes [215, 216, 218]. These technologies have the potential to identify pathways and candidate genes for stress tolerance that can be used in similar targeted strategies as those described in Section 51.3.

51.4.2.3 The Allure of Whole-Genome Sequences

Sequencing of the *Arabidopsis* genome has identified ~30 000 genes and determining their function is an ongoing enterprise [6]. At present, there are 1876 genes annotated as being involved in abiotic stress, 1778 genes in transport, and 724 genes in intracellular signaling. Multiple rounds of whole-genome duplication have occurred throughout the natural history of the Brassicaceae and it has been proposed that the genomes of the diploid *Brassica* were triplicated relative to *Arabidopsis* [219, 220]. The resulting genome complexity present among the *Brassica* species provides additional material for evolutionary adaptations and might explain why these species exhibit an increased capacity to withstand stressful environments beyond that of *Arabidopsis*. There are projects that have been launched to assemble the genome sequences for all the *Brassica* diploids [221] (http://canseq.ca). Such studies have already uncovered significant expansion of gene families related to hormone biosynthesis within the *B. rapa* genome compared to *Arabidopsis* [222], which suggest that understanding the impact of genome evolution within the *Brassica* species might provide insight into the phenotypic variance observed within this genus.

The availability of *Brassica* genome sequences will quickly facilitate genetic studies with the development of dense genome-wide marker sets. Genome-wide association (GWA) is a powerful technique that unlike QTL mapping does not require the development of large segregating mapping populations, but utilizes the ancient recombination events that are inherited within diverse collections to resolve loci controlling observable phenotypes. Association mapping requires the ability to query genome-wide SNPs to uncover those closely associated through linkage disequilibrium with QTL and has great potential to become a gene-tagging tool in crop plants [164]. The power of this approach has been demonstrated in the crucifer *Arabidopsis* for flowering time [223] and pathogen resistance [224]. Although this technology awaits exploitation in Brassicas, it has been successfully applied to other crop species [225]. With the development of fixed foundation diversity sets (www.brassica.info) for different species and the characterization of large SNP collections [226], the tools to realize this powerful strategy in Brassicas will be available.

The availability of whole-genome sequences for the *Brassica* species will bring together linkage analysis, positional cloning, and gene expression data that will reveal the link between genes and the phenotypes they control. Transcript levels when measured in defined mapping populations can be considered as quantitative traits

and the variation observed among the progeny used to map eQTL [227]. The transcript level is determined by many factors; in some instances, the eQTL can be used as a marker for a particular phenotype and the gene underlying the eQTL might provide a good candidate for a phenotypic QTL. Expression of QTL can be classified as either *cis* or *trans*, with eQTL colocated at their target gene thought to be *cis*-acting, whereas eQTL found to be unlinked to their target gene inferred to have a *trans*-acting function. These latter eQTL have the potential to resolve major regulators of gene expression where an eQTL has an effect on the expression of groups of genes. Global eQTL mapping has been applied in *Arabidopsis* [228] and more recently in crops such as maize and barley [229]. For the interpretation of complex traits such as abiotic stress tolerance, the ability to apply these types of systems-based analyses is probably the most promising [230].

51.4.2.4 The Added Complexity that Epigenetic Changes Impact on Abiotic Stress Tolerance

Genomic DNA is organized into chromatin through the action of histone proteins with the basic unit being the nucleosome. Chromatin structure is dynamic and is modified during various physiological processes by specific and highly regulated epigenetic factors that adjust the affinity of histone–DNA interactions. Epigenetic factors increase the diversity and complexity present among organisms, and within an organism, as a single embryonic genome gives rise to a multitude of epigenomes that result in differential cell fate and tissue differentiation. The processes underlying these epigenetic changes include DNA methylation, histone modifications (e.g., methylation, acetylation, phosphorylation, ubiquitination, sumoylation, and ADP ribosylation), and the action of small RNAs and transposon elements, which affect the expression rather than the transmission of particular alleles.

The action of small RNAs results in post-transcriptional gene silencing in complementary target mRNAs. There have been several small RNAs identified from *Arabidopsis* that are implicated in abiotic stress regulation. These include elements complementary to *AAO3*, a drought-responsive enzyme involved in ABA biosynthesis, a lypoxygenase, and small RNAs created by the 3′end overlap between *SRO5* and pyrroline-5-carboxylate dehydrogenase (*P5CDH*) [231]. *P5CDH* is a single gene that is ubiquitously expressed and is involved in proline catabolism and *SRO5* is responsive to salt stress [231, 232]. It has been demonstrated that in response to salt stress the complimentary base pairing between *SRO5* and *P5CDH* transcripts activates the siRNA pathway resulting in a reduction of *P5CDH* transcript accumulation and a subsequent increase in proline accumulation [231, 232]. Such epigenetic mechanisms add an additional layer of complexity to stress-inducible gene regulation, and with the identification 30 families of miRNA and siRNA with many possessing stress-dependant expression, it is likely this phenomenon forms an integral part of abiotic stress gene regulation and that it affects a wide range of gene functions [231].

In plants, cytosine methylation of DNA occurs both at the symmetrical CpG and CpNpG loci and at the asymmetrical CpHpH loci; the symmetrical patterns are transmitted through meiosis, whereas asymmetrical patterns must be reestablished

at each generation. Genome-wide methylation patterns in *Arabidopsis* revealed that the heterochromatin rich in repetitive and transposable elements in pericentric chromosomal regions were heavily methylated. Genes possessing methylated promoter regions were more likely to be expressed in tissue-specific fashion, whereas genes methylated along coding regions were constitutively expressed [233]. Evidence indicates that abiotic stresses including low temperature and salinity cause hypomethylation of targeted loci which coincides with increased gene expression in these hypomethylated regions.

The components involved and the extent to which epigenetic changes effect gene expression, particularly how a stress memory might be stored, are only now being realized [234]. A more complete understanding of the regulation of these phenomena offers additional techniques with which to manipulate stress tolerance along with perhaps providing strategies for fine-tuning present transgenic approaches [235].

51.5
Alternative Sources of Stress-Tolerant Alleles

The identification of desirable characteristics from genetic variation found within species has led over generations to the development of adapted crop varieties. The continued improvement and expanded use of elite breeding lines has improved yield potential, but ultimately it has effectively limited the available gene pool [236]. The elite cultivars are often grown under ideal environments and are developed under intense selection pressure for improvements in yield, quality, and ease of harvesting [237, 238]. Alleles that provide additional protection against the effects of abiotic stresses often have negative net effects on yield components and have been discarded during the development of such lines. Limited genetic resources among *Brassica* crop species have led to more creative strategies for identifying potential genetic variation, with the development of resynthesized lines [239], induced mutagenized lines [240], somaclonal variants [241], induced epialleles [235], and interspecific hybridizations [242], often achieved only after embryo rescue [243].

However, extensive genetic variation exists among noncultivated *Brassica* species, landraces, and more distantly related species within the Brassicaceae. Assessment of such germplasm offers great potential for crop improvement. Although the prospect of introducing traits into *Brassica* crops from species beyond the *Brassica* genus through sexual reproduction is limited, unless a successful bridging species can be identified, analysis of exotic species will offer valuable insight, into the natural history of stress tolerance and genome evolution. The investigation of stress-tolerant species belonging to the Brassicaceae has begun with the development of EST libraries and T-DNA mutagenized populations of *T. halophila* [244–247]. *Thlaspi arvense*, a plant able to withstand the extremely harsh winters on the Canadian Prairies, has been investigated revealing its genetic architecture in relation to stress tolerance genes and how its transcriptome responds to low temperature [248–250]. It is anticipated that genetic and physiological investigation of these hardy species will reveal novel

genes and alleles that confer stress tolerance that can be captured and employed in *Brassica* crop improvement strategies.

51.6 Conclusions

In the face of a growing and discerning population, the provision of a plentiful affordable food supply requires further increases in agricultural production. This necessitates the expansion of agriculture to marginal lands that will entail the development of crop varieties adapted to harsher environments. All sessile organisms require tolerance to abiotic stress; however, the improvement of abiotic stress tolerance has received little attention in modern crop development, which has primarily focused on harvest index, quality parameters, and disease resistance. Tolerance to abiotic stress must become a priority in breeding programs, utilizing both traditional and transgenic approaches. The use of transgenic strategies for crop improvement holds great promise; however, to be considered successful, the genetic manipulation must provide enhanced yields under stressful environments while not negatively affecting yield under ideal environments. Seed yield is a complex trait, which is affected by a large number of factors throughout plant growth and development. The induction of enhanced stress tolerance must be targeted to specific growth stages, particular organs, or environmental cues. This requires the identification and characterization of highly regulated and specific promoter sequences to be ultimately successful. Owing to the genetic complexities of abiotic stress tolerance and the interaction with yield factors, it is unlikely that a single strategy will offer a panacea for abiotic stress in *Brassica* species. Fortunately, the rapid development of genomics tools for the *Brassica* oilseeds promises avenues for resolving the complexities and harnessing this knowledge to develop superior crop varieties.

Mustard: Approaches for Crop Improvement and Abiotic Stress Tolerance

Sarvajeet Singh Gill, Ritu Gill, Gautam Kumar, Ashwani Pareek, Prabodh C. Sharma, Naser A. Anjum, and Narendra Tuteja

Adverse environmental conditions seriously affect crop growth, productivity, and genome stability. These adverse environmental factors are a menace for plants that prevent them from reaching their full genetic potential and therefore limit the crop productivity worldwide. Stress conditions, such as extreme temperatures, water availability, and ion toxicity, represent abiotic stresses, which cause massive loss of crop yield. Global climatic pattern is also becoming more unpredictable with increased occurrence of drought, flood, storms, heat waves, and seawater intrusion. The oleiferous *Brassica* is the third most important source of vegetable oil in the world after palm and soybean oil and grown as an edible or an industrial oil crop that is used as a source of edible protein, in much the same way as soybean protein. According to a report of the United States Department of Agriculture (USDA), the world oilseed production was 397 metric ton in 2006–2007 and Indian agriculture contributed about 15 and 8% to the world total acreage under oilseed cultivation and production, respectively. However, the average productivity in India is only 791 kg ha^{-1} compared to the world average of 1718 kg ha^{-1}. Despite a large area under cultivation of mustard, the productivity of the crop has dropped in recent years because plant growth and development are affected by various abiotic stress factors. Protecting crop productivity under unfavorable environmental conditions is a major challenge for modern agriculture. In this review, we have attempted to provide an overview of success obtained in raising germplasm with improved salinity tolerance through breeding methods. The recent "Omics" approaches and their applications in abiotic stress research on mustard crop are also presented.

52.1
Introduction

Environmental stress is referred to the extreme environmental conditions that lead to alterations in plant metabolism resulting in decreased rate of plant's growth

Improving Crop Resistance to Abiotic Stress, First Edition.

processes, loss in productivity, or inducing damaging effect on any of plant organs/parts besides alteration in anatomical, biochemical, or molecular regulation. Abiotic stresses such as extreme temperatures (freezing, cold, and heat), water availability (drought and flooding), and ion toxicity (salinity, alkalinity, and heavy metals) are the major causes that adversely affect the plant growth and productivity worldwide [1–5]. It has been found that the relative decreases in potential yields associated with abiotic stress factors vary between 54 and 82% [2, 6]. It is estimated from the comparison of record yields and average yields for various crop plants that crops mainly attain only 20% of their genetic potential for yield due to various biotic and abiotic stress factors. Therefore, it is clear that there is an urgent need to increase abiotic stress tolerance in plants. Increasing crop production is now the highest agricultural priority worldwide because of increasing world population. According to the United Nation's World Population Prospects Report, the world population is increasing at an alarming rate of approximately 74 million people per year and is expected to reach more than 9 billion by 2050 (http://www.un.org/esa/population/unpop.htm), whereas global food productivity is declining due to the negative effects of various environmental stress factors.

Plants respond to various stress factors such as salinity, heat, cold, drought, excess water, heavy metal toxicity, wounding, excess light, nutrient loss, anaerobic conditions, and radiations through multifaceted molecular signaling pathways by perceiving and transducing the stress signal(s) through a cascade of molecular networks eventually leading to the expression of stress-related genes. These responses at the molecular, cellular, physiological and biochemical levels enable the plants to survive [7, 8]. These responses include effects of abiotic stresses on overall growth and development, electrolyte leakage, osmolyte accumulation, and the ion homeostasis [8]. The new molecular "omics" tools have opened up new perspectives in stress biology. The "omics" approaches such as genomics, proteomics, metabolomics, and transcriptomics have direct potential for improving abiotic stress tolerance in crop plants that require knowledge of stress response at molecular level, which includes gene expression to protein or metabolite and its phenotypic effects. Integration of phenotypic, genomic, transcriptomic, proteomic, and metabolomic data will enable accurate and detailed gene network reconstruction.

The oleiferous *Brassica* play an important role in global agriculture and horticulture. These crops contribute both to the economy and to the health of populations around the world. *Brassica* is the third most important source of vegetable oil in the world after palm and soybean oil and is grown as an edible or an industrial oil crop that is used as a source of edible protein, in much the same way as soybean protein [9]. *Brassica* is the Latin name of a genus that is taxonomically placed within the Brassicaceae (Cruciferae), which is one of the 10th most economically important plant families in the world. The major mustard oil-producing countries include Canada, China, France, Germany, India, and the United Kingdom. According to a report of the United States Department of Agriculture (USDA), the world oilseed production was 397 metric ton in 2006–2007. Indian agriculture

contributes about 15 and 8% to the world's total acreage under oilseed cultivation and production, respectively. However, the productivity in India is only 791 kg ha^{-1} compared to the world average of 1718 kg ha^{-1} [10]. About 90% of the total land under oilseed cultivation in India is occupied by *Brassica juncea* [11]. Indian mustard (*B. juncea* L. Czern & Coss.), belonging to the same genus *Brassica* in the Cruciferae family, is an agriculturally and economically important crop widely cultivated in Asia and Europe, and abiotic stress is a major constraint to its productivity. *B. juncea* is a dominant crop grown for human consumption as condiments, fodder, and seed. The *Brassica* plant is characterized by a large number of broad, oblong-shaped leaves present in the lower layers of the plant axis [12]. *B. juncea* is a more productive oilseed than *B. napus* in hot regions of Russia, India, China, and Canada with somewhat unreliable rainfalls, whereas *B. napus* is the higher yielding species in more temperate, wetter regions. Oil of *B. juncea* is consumed in large quantity and the production ranks second among all oilseeds in India [13]. In India, *B. juncea* is used as oil-bearing crop and has been studied extensively [14, 15]. However, due to the presence of undesirable long-chain fatty acids such as ecosenoic acid (10%) and erucic acid (50%) in the seed oil, it becomes detrimental to human health. Erucic acid increases blood cholesterol, interferes with myocardial conductance, and shortens coagulation time [16]. European Economic Commission has restricted cultivation of *Brassica* crop that contains more than 10% erucic acid content in their oil [17]. The discovery of the genes for low erucic acid oil production in the seeds of Indian mustard began the conversion of this ancient crop to a canola-type oilseed for dry areas.

52.1.1
Description of Indian Mustard

B. juncea (Indian mustard) belongs to the family Cruciferae. There are nearly 40 different varieties of this yellow flowering plant that are classified by the botanists into the genus *Brassica* of which *B. juncea* is one of the major oilseed crops of India. The oil content varies between 35 and 45% and the protein content is between 20 and 24%. The seed residue is used as cattle feed and in fertilizers. It is a high biomass crop characterized by oblong-shaped leaves.

52.1.2
Origin of Indian Mustard

Studies suggest that *Brassica* evolved from the genus *Sinapidendron* of the Miocene age through *Diplotaxis–Erucastrum* complex [18]. *B. juncea* is generally thought to have originated in the Middle East, whereas *B. rapa* and *B. nigra* species overlapped in the wild, but Central Asia and China are suggested as the sites of primary origin [19]. Hemingway [20], however, considers that *B. juncea* (L.) may also have arisen by independent hybridization at secondary centers in India, China, and Caucasus, as *B. nigra* was widely used as the commercial spice from early times.

52.1.3 Nomenclature

The oleiferous *Brassica* grown in India are divided into the following four groups:

1) Brown mustard: Commonly known as rai, raya, or laha (*B. juncea* L. Czern & Coss.)
2) Sarson
   a) Yellow sarson: *B. campestris* L. var. Sarson Prain
   b) Brown sarson: *B. campestris* L. var. Dichotoma Watt
3) Toria: lahi or maghi lahi (*B. campestris* L. var. Toria Duth)
4) Taramira or Tara (*Eruca sativa* Mill.)

In addition, there are two other species, namely, *B. nigra* Koch. (Banarasi rai) and *B. juncea* var. Rugosa (Pahadi rai). These two species do not fall under any of the four groups. These are, moreover, grown to a limited extent. Mustard (*B. juncea* L. Czern & Coss.) is the dominant species grown in India [19].

52.1.4 Botanical Description

Rape and mustard include annual herbs. Roots, in general, are long and tapering. Toria is more or less a surface feeder but Brown sarson bears long roots with limited lateral spread enabling its successful cultivation under drier conditions. The height of the stem varies from 45 cm (in some varieties of Toria) to 190 cm (in Yellow sarson). In Toria and Brown sarson, the branches arise at an angle of 30–40°. In Yellow sarson, the branches arise laterally at an angle of about 10–20° giving the plant a narrow and pyramidal shape. The inflorescence is a corymbose raceme. In the case of yellow sarson, the four petals are spread apart, whereas, in brown sarson and Toria, the petals overlap or may be placed apart, depending upon the cultivar. The flowers bear a hypogynous ovary. In Brown sarson and Toria, the ovary is bicarpellary, whereas in Yellow sarson, it may also be tri- or tetracarpellary. The fruit is sliliqua. The sliliqua are two-valved, three-valved, or four-valved, depending upon the number of carpels in the ovary. The flowers begin to open from 8:00 h and continue up to 12:00 h noon.

52.1.5 Genomic Relationships of *B. juncea*

The relationships among the cultivated *Brassica* species were largely clarified by cytological work. There are six species of *Brassica* that merit attention for their economic importance. Among the six species, three are diploid, *B. campestris* ($2n = 20$, AA), *B. nigra* ($2n = 16$, BB), and *B. oleraceae* ($2n = 18$, CC), and the other three are amphidiploids, *B. juncea* ($2n = 36$, AABB), *B. napus* ($2n = 38$, AACC), and *B. carinata* ($2n = 34$, BBCC). The botanical and genomic relationships between these six species may be represented in the form of a triangle usually known as triangle of U [21] (Figure 52.1).

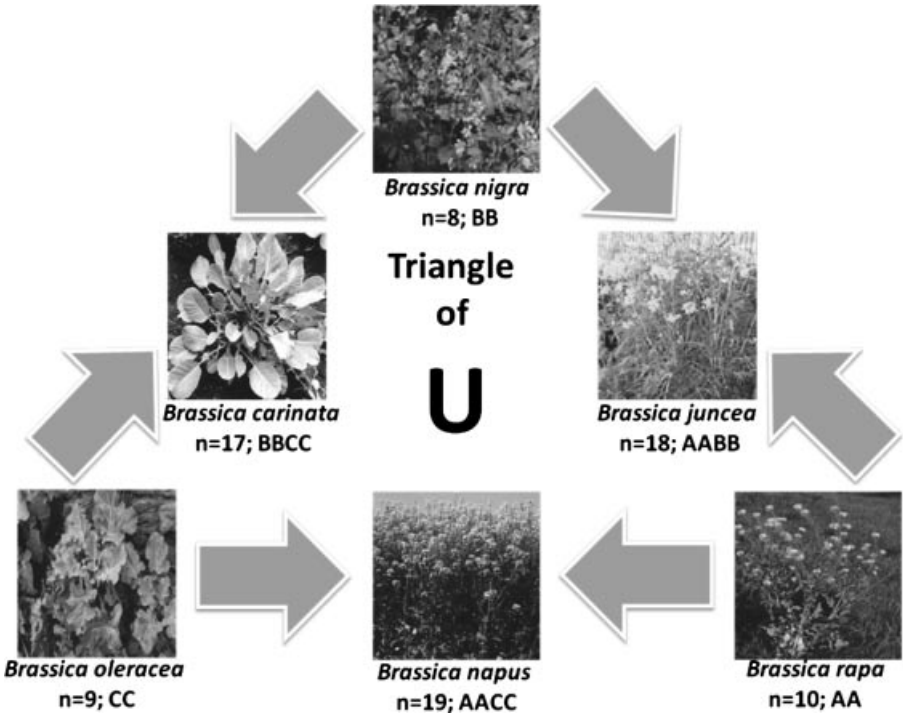

Figure 52.1 "Triangle of U" representing the genomic relationships among six crop species of *Brassica*. Three diploid species are shown (*B. rapa*, *B. nigra*, and *B. oleracea*), which represent the AA, BB, and CC genomes, respectively. Also shown are three tetraploid species (*B. carinata*, *B. juncea*, and *B. napus*), which are hybrid combinations of the basic genomes.

In this chapter, we have tried to explore the available literature on "omics" approaches such as genomics, transcriptomics, proteomics, and metabolomics in *Brassica*, the most important oilseed crop, for possible crop improvement and abiotic stress tolerance. We also present the success obtained so far in improving the salinity tolerance in brassicas employing the traditional breeding approaches.

52.2
Indian Mustard: Breeding Aspects under Salinity Stress

Limited efforts have been made for improving crop varieties for various abiotic stresses following conventional selection and breeding programs. The complex mechanisms of abiotic stress tolerance, characterized by the expression of several minor genes limit the rate and extent of progress in improving stress tolerance in crops through conventional breeding program. Furthermore, techniques employed for selecting tolerant plants are time consumable and consequently expensive. Drought and salinity are the serious impediments in decreasing the growth and yield performance of different crop varieties. The availability of genetic resources

besides the creation and exploitation of novel variability forms the basis of conventional breeding approaches. Cultivars with improved performance under different abiotic stresses have been developed through selection and evaluation in the targeted drought-and salinity-affected areas. Concerted breeding efforts at Central Soil Salinity Research Institute have resulted in the development and release of salinity tolerant cultivars such as CS52, CS54, and CS56. These varieties have consistently performed better in the salt-affected soils than the national checks, Varuna and Kranti. Further studies have shown that amphipolyploid species, namely, *B. napus*, *B. carinata*, and *B. juncea* are more tolerant toward salinity than the diploid brassicas. *B. napus* followed by *B. carinata* have been characterized as more salt tolerant, particularly in climatic zones with long cool periods. *B. juncea*, probably due to its shorter growth period compared to *B. napus* and *B. carinata*, has proved more promising in semiarid and arid climates with short winters. Brassicas are by and large more vulnerable to alkalinity than to salinity. Mustard genotypes have shown tremendous variability in plant types. Vigorous growth during vegetative stage, medium plant height, early maturity, and better response to added inputs are some of the desired characteristics, which are associated with consistent yield performance over an array of environments. Genotypes with medium plant height appear to be more stable in varied environments. The exploitation of hybrid vigor, through the use of CMS and appropriate restorer, will go a long way in raising the production potential of rapeseed and mustard in India.

Besides the yield potential and stability, germplasm is improved for traits contributing to increased productivity. Physiological characters such as nutrient use efficiency and harvest index need attention. The rapeseed–mustard crops produce large biomass but fail to translocate it to the sink, resulting in low harvest index. Attempts should also be made to breed varieties for better response to low nitrogen application, which needs tailoring of the new plant type having less secondary and tertiary branching, reduced height, longer main shoot, more siliqua on main shoot, more number of seeds/siliqua, and higher 1000-seed weight with better nutrient use efficiency and capacity to transport assimilate to seeds.

Salinity stress causes yield decline in all the species and the genotypes. The challenge is to improve the genotypes with salt tolerance characteristics retaining the economic potential of the particular genotype. Stressful environments are often said to increase the expansion of inbreeding depression. Plant's behavior also varies with intensity of stress. Inbreeding depression occurs for survival under high stress conditions and for growth under lower stress levels. The workable strategy lies in selection for tolerant genotypes paying lesser penalty in terms of yield decline. A large number of germplasm needs to be evaluated under target environments to identify the breeding material.

52.2.1 Screening Methodology for Seedling Emergence

Under field salinity conditions, it has been observed that once a seedling emerges, it continues to grow with relatively lesser reductions in growth and yield. Accordingly, it

is imperative to know the salt tolerance potential of different Indian mustard genotypes for seedling emergence by some rapid screening methodology under laboratory conditions. For this, different genotypes have been evaluated under solution culture in laboratory, sand culture, and soil culture in pots to know their interrelationships. Variability in different genotypes with respect to their behavior under salinity stress may be attributed to the differences in uptake of toxic ions along with the absorption of water by the seeds. Increase in Na^+ uptake along with the decline in K^+ uptake under salinity stress during germination has been reported by Sharma [22]. Furthermore, seedling emergence under solution culture and sand culture declined only due to the ionic stress caused by salinity of the soil solution, whereas in soil culture, osmotic effects play an associative role along with ionic effects. Accordingly, the higher decline in seedling emergence under soil culture may be associated with aggravation in ionic accumulation caused by the increasing osmotic stress along with matric stress. Seedling emergence under soil culture was also observed to decline through post-germination salt injuries to hypocotyls at the time of their protruding through soil.

Application of piece-wise linear response model to the pooled data of seven genotypes in different types of growing medium showed that threshold salinity level was highest in solution culture experiments ($C_t = 14.15$). It declined to 7.84 in sand culture and further to 5.96 in soil culture experiments [23]. Similarly, the salinity level at which 50% reduction in seedling emergence occurred was also highest in solution culture ($C_{50} = 21.06$), which declined to 15.96 in sand culture and to 12.31 in soil culture experiments. Along with the decline in C_t and C_{50} upon shifting from solution to sand and soil culture, the slope values increased from 7.25 in solution culture to 9.30 in soil culture experiments. The regression equation for the pooled data in three types of growing medium was computed to be $Y = -3.8789\ X + 111.417$ ($r^2 = 0.69$). Furthermore, the regression equation for seedling emergence under different salinity levels in solution culture was $Y = -2.1712\ (X) + 104.1922$ ($r^2 = 0.38$), while in sand culture, it was $Y = -4.2505\ (X) + 114.4129$ ($r^2 = 0.87$) and in soil culture the equation was $Y = -4.6805\ (X) + 106.7743$ ($r^2 = 0.86$), where X is salinity level and Y is seedling emergence.

Salinity levels in which the results for seedling emergence under solution or sand culture are typical representative of the results under soil culture were calculated. These values were computed where the two types of growing media recorded around 50% of seedling emergence (C_{50}). A significant positive correlation ($r = 0.81$) was observed between seedling emergence at EC_{iw} 22 dS m^{-1} in solution culture and EC_e 12.8 dS m^{-1} in soil culture. Similar correlation between seedling emergence at EC_{iw} 26 dS m^{-1} in solution culture with EC_e 12.8 dS m^{-1} in soil culture was recorded to be $r = 0.92$. Thus, using this method, a large number of genotypes can be tested for salinity tolerance in a short period of time.

52.2.2 Genetic Studies under Salt Stress

Genetic variability is the key to any crop improvement program, and the extent to which the desirable characters are heritable is also important. For improving yield

and yield component characters, information on their genetic variability and their interrelationships in different characters is necessary. Partitioning the genotypic correlation coefficients of yield components into direct and indirect effects may help estimate the actual contribution of an attribute and its influence through other characters. Sixty genotypes were evaluated for their adaptation under semiarid saline soil conditions [24]. High variability was recorded for secondary branches/plant, siliqua/plant, 1000-seed weight, seed yield/plant, and seed yield/siliqua. Further low variability was recorded for seeds/siliqua and primary branches per plant. Seeds/plant were least affected by salinity. Seeds bearing siliqua/plant and seed yield per plot showed high genetic coefficients of variation (GCV). Heritability was very high for the number of seeds/siliqua (99.74) and 1000-seed weight (61.44) and moderate for siliqua length (39.72). Genetic advance was high for seed-bearing siliqua/plant (15.02) and plant height (11.89), followed by seeds/siliqua (5.69) and sterile siliqua/plant (8.33). Genetic advance as percent of mean was high for seeds/siliqua (45.73) and 1000-seed weight (42.91), followed by seed yield per plant. High heritability associated with increased genetic advance indicated additive gene effects and greater possibility for improvement. Variability studies in 30 genotypes of Indian mustard indicated higher estimates of genetic and phenotypic coefficient of variation (PCV), heritability, and genetic advance for the number of primary branches and siliquae/plant on normal soil; and for seedling emergence, the number of siliquae on main shoot, the number of secondary branches/plant, and seed yield on saline soil. The number of siliquae/plant on normal soil and seedling emergence and plant height on saline soil had significant positive association with seed yield. Seedling emergence and plant height exhibited maximum direct, positive effects on seed yield on saline soil.

Furthermore, genetic parameters for variability were also studied under alkali stress conditions in 19 genotypes of Indian mustard [25]. The GCV, PCV, heritability, and genetic advance as percent of mean were high for 1000-seed weight on normal soil and for plant height, secondary branches per plant, the number of siliqua per main shoot length, and seed yield per plant on alkali soils. Correlation analysis revealed that seed yield per plant has positive and significant association for primary branches per plant and main shoot length on normal soil, and for plant height, secondary branches per plant and number of siliqua per main shoot length in alkali stress conditions. The path analysis showed that secondary branches per plant had maximum direct effect on seed yield under alkali stress conditions. These studies point out that the framing of selection criteria could be based on the number of primary branches per plant, main shoot length, and 1000-seed weight for normal conditions and secondary branches per plant, number of siliqua per main shoot length, and seed yield per plant under alkali stress conditions.

52.2.3 Salt-Tolerant Varieties

Among different *Brassica* species, Indian mustard (raya) showed higher tolerance to salinity/alkalinity stresses compared to *Gobhi sarson*, *Karan rai*, and yellow and brown

Table 52.1 Characteristics of Indian mustard varieties CS52, CS54, and CS56 released by CVRC for salt-affected soils of India.

Variety	CS52	CS54	CS56
Year of release	1997	2005	2008
Plant height	170 cm	160 cm	202 cm
Maturity duration	135 days	121 days	132 days
Grain type	Medium	Bold	Medium
1000-seed weight	4.0 g	5.3 g	4.4 g
Salinity tolerance	EC_e 6–9 dS m^{-1}	EC_e 6–9 dS m^{-1}	ECe 6–9 dS m^{-1}
Alkali tolerance	Upto pH 9.3	Upto pH 9.3	Upto pH 9.3
Average seed yield	15–16 q ha^{-1}	16–19 q ha^{-1}	16–18 q ha^{-1}
Recommended date of sowing	First fortnight of October	First fortnight of October	First fortnight of October (normal conditions) and upto 10th November (late sown)
Recommended for	Punjab, Haryana, and Rajasthan	Punjab, Haryana, and Rajasthan	Late-sown areas of the country (Punjab, Haryana, and Rajasthan)

sarson. Different genotypes of Indian mustard also showed differential tolerance to saline and alkali stresses. Breeding efforts following conventional breeding appraoches at CSSRI, Karnal, led to the development of high-yield salt-tolerant genotypes of Indian mustard, namely, CS52 in 1997, CS54 in 2005, and CS56 in 2008. These varieties were released by the Central Varietal Release Committee (CVRC), Government of India, for their cultivation in Punjab, Haryana, Rajasthan, and Gujarat States of India (Table 52.1).

The salt-tolerant variety CS52 yields 20% higher in salt-affected soils compared to the high-yield released varieties of Indian mustard at the national level. However, its maturity is longer by 1 week compared to the well-known high-yield released varieties of Indian mustard, that is, Varuna, Kranti, and Pusa Bold. Plant height of CS52 is around 170–180 cm. This variety is more tolerant to insects and pests' attack compared to other released varieties of Indian mustard. This variety accumulates and compartmentalizes the toxic ions in the root part, hence restricting the concentration of toxic ions in leaves and stem. Further, the toxic ions get accumulated in lower leaves, which are shed ultimately reducing the effects of toxic ions on the plant. These processes help the plant to survive better under salt stress conditions. Another characteristic of this variety is better adaptability under high temperature conditions during germination and seedling emergence stages.

These varieties can grow economically in saline soils up to a soil salinity level of EC_e 9 dS m^{-1} and in alkali soils up to pH 9.3. Within the salt-tolerant limits of this variety, CS52 and CS56 yield more than 1.6 ton ha^{-1}, whereas CS54 can yield upto 1.9 ton ha^{-1}. By growing in saline soils and even irrigating with saline waters, 39% oil content has been determined from the seeds of these varieties. The latest released variety CS56 has the additional advantage of delayed sowing upto 10th November without significant reduction in seed yield besides the salt tolerance characteristics.

52.3
"Omics" Approaches for Abiotic Stress Tolerance

Plant research has the potential to contribute significantly to solve several of the most daunting problems that our planet and we face in the twenty-first century. Developing crop plants with ability to tolerate abiotic stresses is need of the day that demands modern, novel strategies for a thorough understanding of plant's response to abiotic stresses. In particular, an array of innovative "omics" approaches such as genomics, proteomics, transcriptomics, and metabolomics are evolving at rapid pace, which is empowering the scientists to systematically analyze the genome at various levels and their effect on phenotypic variability. In contrast to the traditional approaches that mostly focus on one or a few genes at a time, omics tools particularly genomics allowed the use of important strategies such as genome-wide expression profiling that is useful to identify genes associated with stress response. Furthermore, proteomics helped a lot to analyze the relationship between gene expression (transcriptomics) and metabolism (metabolomics). Metabolomic studies, thus along with transcriptomics and proteomics, and their integration with systems biology, will lead to strategies to alter cellular metabolism for adaptation to abiotic stress conditions. Overall, the "omics" research approaches have produced copious data for living systems, which have necessitated the development of systems biology to integrate multidimensional biological information into networks and models. Applications of systems biology to plant science have been rapid and have increased our knowledge about circadian rhythms, multigenic traits, stress responses, and plant defenses, and have advanced the virtual plant project. In the proceeding pages we will discuss in detail the "omics" approaches such as genomics, proteomics, and metabolomics for abiotic stress tolerance in mustard.

52.3.1
Genomics Approaches and Abiotic Stress Tolerance in *B. juncea*

The application of genomics-type technologies is beginning to have an impact, enhancing our understanding of plant responses to abiotic stresses that interfere with the normal growth and metabolism of plants. The ongoing genome-sequencing project will give access to the required genes and will facilitate the analysis of their expression.

Abiotic stresses such as low temperature and high salinity adversely affect the seedling vigor and fertility of *B. juncea* and consequent reduction in yield [26]. Studies on *B. juncea* [27, 28] have demonstrated the coordinated transcriptional regulation of genes involved in sulfur transport and assimilation and in GSH biosynthesis. The Cd exposure, consequently, induces phytochelatin synthesis from glutathione (GSH). Zhu *et al.* [29, 30] overexpressed the γ-glutamylcysteine synthetase gene from *Escherichia coli* in *B. juncea*, resulting in increased biosynthesis of GSH and PCs and an increased tolerance to cadmium (Cd). A similar approach was taken with *Arabidopsis*; γ-glutamylcysteine synthetase was expressed in both sense and antisense orientations, resulting in plants with a wide range of GSH levels [31]. Flocco *et al.* [32]

tested the hypothesis that transgenic Indian mustard plants overexpressing ECS or GS, which have twofold levels of GSH and total nonprotein thiols, would have enhanced tolerance to organic pollutants, including the PAH phenanthrene. Exposure of plants to organic pollutants significantly enhanced total nonprotein thiol levels in both wild-type and transgenic plants [32]. Flocco *et al*. [32] concluded that GSH could be important for detoxification via conjugation to GSH, of many organic xenobiotics including phenanthrene, and that overexpression of enzymes involved in GSH biosynthesis offers a promising approach to create plants with the enhanced capacity to tolerate not only heavy metals but also certain organic pollutants. Besides the genes mentioned above, a range of other stress-related proteins have been employed in raising transgenic plants with improved tolerance toward various abiotic stresses as mentioned in Table 52.2.

52.3.2
Proteomic Approaches and Abiotic Stress Tolerance in *B. juncea*

The simple paradigm, gene to mRNA to protein, belies the complexity of the relationship between a stretch of genomic DNA and its cognate protein products. The transcriptome analyses of gene expression at the mRNA level have contributed greatly to our understanding of abiotic stress tolerance in plants. However, the level of mRNA does not always correlate well with the level of protein, the key player in the cell [33]. Therefore, it is insufficient to predict protein expression level from quantitative mRNA data. This is mainly due to posttranscriptional regulation mechanisms such as nuclear export and mRNA localization, transcript stability, translational regulation, and protein degradation. Proteome studies aim at the complete set of proteins encoded by the genome and thus complement the transcriptome studies. A proteome constitutes all different proteins in a particular "body." The body may be an organism, as in yeast proteomics [34], and can also be a subcellular particle such as an organelle [35, 36] or a protein complex [37].

52.3.3
Metabolomics Approaches and Abiotic Stress Tolerance in *B. juncea*

Undoubtedly, transcriptomic and proteomic data are important steps in deciphering a complex biological process, but they are still insufficient since most biological processes are ultimately mediated by cell metabolites. Metabolomics is considered to provide a direct "functional readout of the physiological state" of an organism. Besides, alternative mRNA splicing, protein turnover rates, and posttranslational modifications that modulate protein activity imply that changes in the transcriptome or proteome do not always correspond to alterations in the cell metabolome [38]. Target analysis, metabolite profiling, and metabolic fingerprinting are different conceptual approaches in metabolomics that can be used for a large range of applications, including phenotyping of genetically modified plants, substantial equivalence testing, determination of gene function, and monitoring responses to biotic and abiotic stress. Metabolomics can therefore be seen as bridging the gap

Table 52.2 Transgenic *Brassica* plants overexpressing genes of various pathways for stress tolerance.

Gene	Gene function	Gene source	Target *Brassica*	Phenotype	Reference
APS1	Plastidic ATP sulfurylase	*Arabidopsis thaliana*	*B. juncea*	Se tolerance	[40]
codA	Choline oxidase (glycine-betaine synthesis)	*Arthrobacter globiformis*	*B. juncea* cv. Pusa Jai Kisan	Choline tolerance	[41]
codA	Choline oxidase (glycine-betaine synthesis)	*A. globiformis*	*B. napus*	Salinity tolerance and enhance shoot growth	[42]
Gor	Glutathione reductase	*E. coli*	*B. juncea*	Increased GR activity	[43]
AtNHX1	Vacuolar Na^+/H^+ antiporter	*B. napus*	*B. napus*	Salt tolerance, growth, seed yield, and seed oil quality	[44]
SOD	Mn superoxide dismutase	*Triticum aestivum*	*B. napus*	Aluminum tolerance	[45]
WGA	Wheat germ agglutinin	*T. aestivum*	*B. juncea* cv. RLM-198	Resistance to *Lipaphis erysimi* Kalt.	[46]
CGS	Cystathionine synthase	*A. thaliana* (L.) Heynh	*B. juncea*	Selenium tolerance due to enhanced Se volatilization	[47]
CIT1	Mitochondrial citrate synthase	*A. thaliana*	*B. napus* cv. Westar	Increased root citrate exudation and Al tolerance	[48]
cpSL	Selenocysteine lyase	Mouse	*B. juncea*	Selenium tolerance	[49]
Parp1; Parp2	Poly(ADP-ribose) polymerase	*A. thaliana*	*B. juncea*	Silencing induces drought and heat tolerance	[50]
SMT	Selenocysteine methyltransferase	*Astragalus bisulcatus*	*B. juncea*	Selenium tolerance and accumulation	[51]
codA	Choline oxidase (glycine-betaine synthesis)	*A. globiformis*	*B. juncea*	Tolerance to stress-induced photoinhibition	[52]
SMT	Selenocysteine methyltransferase	*A. bisulcatus*	*B. juncea*	Selenium hyperaccumulation tolerance	[53]
PR10	Pathogenesis related	*Pisum sativum*	*B. napus*	Enhance germination and growth in the presence of NaCl	[54]
betA	Betaine aldehyde	*E. coli*	*B. oleracea*	Salinity tolerance	[55]

rolD	ACC deaminase	*Pseudomonas putida UW4*	*B. napus* var. *Westar*	Lower ethylene and nickel tolerance	[56]
ERA1	Farnesyltransferase	*A. thaliana*	*B. napus*	Antisense; promote drought resistance in the field	[57]
BNCBF5- and *17*	CBF/DREB1-like transcription factors	*B. napus* cv. *Jet neuf*	*B. napus*	Freezing tolerance and photosynthetic capacity	[58]
Lea	Group 3 late-embryogenesis abundant	*B. napus*	*B. campestris*	Salinity and drought tolerance	[59]
APS + SMT	ATP sulfurylase, selenocysteine methyltransferase	*A. bisulcatus*	*B. juncea*	Selenium tolerance and accumulation from selenate	[60]
Class I basic glucanase	Class I basic glucanase	Tomato	*B. juncea*	Resistance to *Alternaria brassicae*	[61]
PgNHX1	Na^+/H^+ antiporter	*Pennisetum glaucum*	*B. juncea*	Tolerance to high salinity	[62]
AtPCS1	Phytochelatin synthesis	*A. thaliana*	*B. juncea*	As and Cd tolerance	[63]
AtPCS1	Phytochelatin synthesis	*A. thaliana*	*B. juncea*	Cd and Zn tolerance	[64]
cpSL and SMT	Selenocysteine lyase and selenocysteine methyltransferase	*A. bisulcatus*	*B. juncea*	Enhanced potential for selenium phytoremediation under field conditions	[65]
BnPtdIns-PLC2	Phosphatidylinositol-specific phospholipase C	*B. napus*	*Canola*	Drought resistance, early flowering	[66]
ERA1	Farnesyltransferase	*A. thaliana*	*B. napus*	When downregulated promotes drought resistance	[67]
Th1PK2	Inositol polyphosphate kinase	*Thellungiella halophila*	*B. juncea*	Salt and drought resistance	[68]

between genotype and phenotype. Metabolic changes underpin plant development and responses to applied stresses, and that metabolic information reflects biological endpoints more accurately than transcript or protein analysis. Hence, the only way to the complete understanding of both gene function and molecular events controlling complex plant processes is to analyze the transcriptome, the proteome, and the metabolome in an integrative manner [39].

Acknowledgment

AP would like to thank the support of DBT, Govt. of India, for funding Brassica research in his laboratory.

Cotton: Genetic Improvement for Drought Stress Tolerance – Current Status and Research Needs

E. AbouKheir, M.S. Sheshshayee, T.G. Prasad, and Makarala Udayakumar

A significant part of cotton production comes from water-limited rain-fed areas. Being a commercially important crop, improvement of drought tolerance has received increasing attention in crop improvement programs. The marked genetic variability in desirable traits among cotton germplasm has great potential for exploitation through conventional and/or molecular breeding approaches. While most research activities targeted the cotton species *Gossypium hirsutum*, very limited physiological information is available in other cotton species. At present, the emphasis is to identify and assess variability in specific traits that have relevance in enhancing drought stress tolerance. Ensuing global research has enumerated a few traits such as roots, water use efficiency, and cellular-level tolerance as the most important besides several other physiological traits. Being quantitatively inherited, numerous research attempts have been initiated to identify the relevant QTL and to pyramid them on to superior genetic backgrounds. Likewise, phenomenal progress has also been made in understanding the molecular regulation of drought tolerance, and to identify the functional/regulatory genes for development of drought-tolerant transgenics in various crops. Such approaches are minimal in cotton and it is imperative that such approaches have great promise to develop genotypes with agronomically desirable traits through molecular breeding and/or transgenics to improve cotton yield and fiber quality. Hence, research priority should be laid on utilization of the available genomic resources through effective integration of conventional breeding with molecular breeding tools. Furthermore, cotton species, namely, *G. arboreum* and *G. herbaceum* need to be explored to assess the variability in stress-adaptive traits. This chapter examines the cotton drought response and provides an insight into the relevant traits that have a role in enhancing drought tolerance. In addition, the prospects of conventional crop improvement approaches vis-a-vis molecular breeding and transgenic approaches that have relevance to achieving crop drought adaptation without sacrificing the yield and quality. It also provides insight into the research needs on the quantitative and association genetics with an ecophysiological understanding of the cotton genomic resources and to better inform crop improvement program.

53.1 Introduction

Cotton belongs to Malvaceae family and tribe *Gossypieae* that includes eight genera [1, 2] with four of these genera (*Lebronnecia*, *Cephalohibiscus*, *Gossypioides*, and *Kokia*) having restricted geographic distributions [1, 2]. The genera *Hampea*, *Cienfuegosia*, *Thespesia*, and *Gossypium* are moderately larger genera with broader geographic range. Fiber cotton belongs to *Gossypium*, which is the largest and most widely distributed genus in *Gossypieae* tribe with approximately 50 species [3] grown in arid to semiarid regions of the tropic and subtropic regions [3–5]. Of them, only two species, *Gossypium arboreum* and *G. herbaceum*, are commercially cultivated and known collectively as "Desi" cottons, and are the Asiatic or Old World short-staple cotton. Owing to their ability to withstand drought stress, these diploid species are generally cultivated in marginal, drought-prone environments of Asia. These diploid Desi cottons are also known for their ability to resist sucking pests such as hoppers, white flies, thrips, and aphids, and leaf curl virus. However, owing to their short, coarse, and weak fiber and undesirable boll and plant features, the Desi cottons were gradually displaced by *G. hirsutum* in Asia.

Evolutionarily, *G. hirsutum* has seven landraces, namely, *palmeri*, *morilli*, *richmondii*, *yucatenanse*, *punctatum*, *marie galante*, and *latifolium*. The race *latifolium* is widely cultivated in the world and *yucatannse* appears to be the wild progenitor of upland cotton [6]. *G. barbadense* is the other domesticated allotetraploid that yields extralong staples or extrafine quality cotton fiber. This species shares about 3% of the total world cotton market [7]. The exploitation of the genetic variability of these species is yet to be realized using modern biological tools in conjunction with conventional approaches.

Most cotton fiber production comes from species *G. hirsutum* and *G. barbadense*, with a minor contribution from *G. arboreum* and *G. herbaceum*. Although cotton is cultivated in more than 70 countries [8] ranging from tropical to subtropical regions with more than 350 million ha [9], almost 65% of global area is in four countries India, China, the United States of America, and Pakistan (Table 53.1). India ranks first in terms of cultivation area, occupying 26% of the world cotton area, followed by China, the United States, and Pakistan. Globally, 115 million bales were produced during 2006–2007 season. China contributes 24% of total production followed by India, the United States, and Pakistan. Although Australia ranks first in productivity (1887 kg ha^{-1}), it contributes to only 2% of total cotton production with less than 1% of global cotton area (Table 53.1). However, among the major cotton growing countries, China holds the highest productivity (1130 kg ha^{-1}) followed by the United States and Pakistan with productivity of 858 and 703 kg ha^{-1}, respectively. India with a yield of 494 kg ha^{-1} is the lowest.

Major area of cotton cultivation in India is under rain-fed conditions, which occupy about 50%. The cultivated area is concentrated in the central part of India occupying about 66.66%, with only 23% under irrigated conditions followed by Southern India (40%) [10]. Several abiotic stresses such as temperature, soil ion concentrations,

Table 53.1 Major cotton-growing countries of the world.

Country	Area ('000 ha)	Production ('000 bales)	Yield (kg ha^{-1})
USA	5186	20 431	858
China	5300	27 500	1130
India	9250	21 000	494
Pakistan	3250	10 500	703
Australia	300	2600	1887
World	35175	115 590	715

Source: FAO [11].

light, and so on adversely affect cotton growth and development. However, the most devastating abiotic stress is soil moisture deficit and about 45% of the world's arable land suffers from chronically inadequate supplies of water for agriculture [12] including cotton [13]. It is projected that burgeoning human population and urbanization will further aggravate the increasing demand for fresh water both for human consumption and for agriculture. Furthermore, erratic and often insufficient rainfall witnessed in the recent past due to anthropogenic changes in the climate might further reduce the availability of fresh water. Although water and soil management practices have a significant role in sustaining productivity under water-limited conditions, a genetic enhancement of cotton genotypes with increased water use efficiency (WUE) as a seed-based technology has greater acceptability.

Despite increased interest to exploit the genomic resources for the development of drought-tolerant crops, it has been hindered by lack of knowledge of precise physiological characteristics that form the index diagnostic parameter of genetic variability and potential for improved productivity and quality under water-limited conditions. Using genetic mapping to dissect the inheritance of different complex traits is a powerful tool to distinguish heritability from casual associations between such traits [14]. In principle, it permits a direct analysis of the role of specific physiological traits in determining genetic variability and potential for productivity and quality parameters under abiotic stress conditions.

Cotton (*Gossypium* spp.) is a potential taxon to study the variability in genomic resources with potential for adaptation to water-limited conditions. Cotton originates from wild perennial plants adapted to semiarid, subtropical environments that experience periodic drought stress conditions. However, the modern cotton cultivars are the result of intensive selection to improve the yield of lint and its quality. Such a traditional selection with emphasis on maximal productivity under high-input and irrigated conditions has inadvertently eroded the genetic variability in drought tolerance [15]. However, considerable variation persists within and between the two cultivated tetraploid cotton species, *G. hirsutum* and *G. barbadense*, in physiological traits, which can be still exploitable.

53.2
Response of Cotton to Drought Stress

Water deficit stress has profound effects on plant growth, development, and quality. The first effect of the moisture stress may well be loss of turgor that affects the rate of cell expansion and ultimate cell size. The result is a decrease in growth rate, stem elongation, leaf expansion, and stomatal aperture with an overall decrease in the performance of the plant.

Such reduction in leaf area index (LAI) results in a reduced crop growth rate (CGR) under conditions of lower water supply [16–18]. Similar inferences where moisture stress during vegetative stage causes reduced leaf growth and leaf area have also been reported [19]. Smaller leaves, increased leaf senescence and abscission [20–22], lesser leaf numbers [23], reduced leaf area index at maturity and interception of less light by the crop, lesser plant height [19], and lower shoot-to-root ratio [19, 24] eventually decrease total dry matter produced by plant.

In one of our experiments [25], three upland cotton genotypes grown in two different water regimes (100 and 55% field capacity) showed significant reduction in leaf area (Figure 53.1a) and total dry matter (Figure 53.1b). This reduction in growth rates often corresponds linearly with water used by the crop [26]. A linear decrease in stem elongation has been reported as leaf water potential (LWP) declined and no further growth was observed when LWP was as low as −2.5 MPa [27–29].

These results clearly indicate that maintenance of leaf tissue water relations is most crucial to sustain growth rates under water-limited conditions. Therefore, greater emphasis needs to be laid on assessing the variability in root traits and the root growth response to drought stress. Significant changes in root growth patterns have been noticed during a drying cycle [30]. Stimulation of root proliferation is significantly greater as soil drying continues, a trend not observed in well-watered plants. Furthermore, during drying cycles, root growth appears closely associated with shoot growth, with elongation ceasing concurrently with cessation of growth in the shoot [31] and root elongation ceased when the soil water potential declined to less

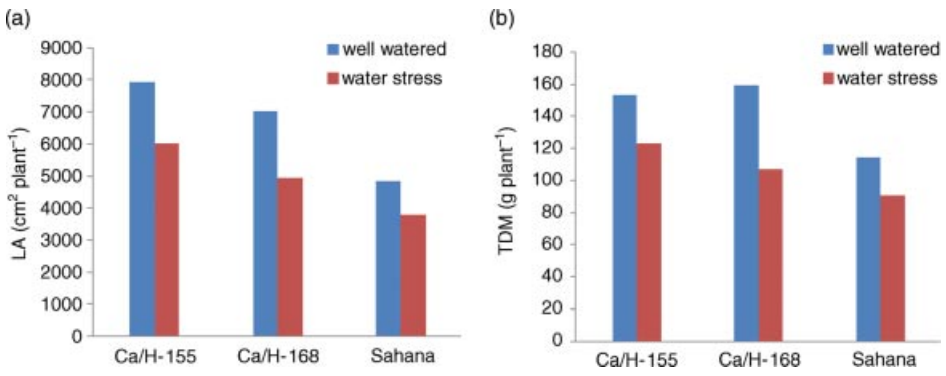

Figure 53.1 Effect of moisture stress on (a) leaf area and (b) total dry matter among three upland cotton genotypes grown into two different water regimes [25].

than −0.1 MPa. The taproot length was greater but not the root dry weight under moisture stress compared to control condition [19]. The leaf expansion was more sensitive to water stress than root elongation [32, 33].

Water deficit stress also affects boll production and thus cotton yield [34–36]. The abrupt cessation in boll formation depends on imbalance between plants photosynthetic capacity and assimilate demand [37, 38]. Moisture stress occurrence during the first 14 days after anthesis leads to boll abscission [39], but occurrence of stress after that period generally does not cause abscission [40]. However, stress later during boll formation adversely affects fiber quality. Fiber elongation was decreased when drought stress occurred during the fiber elongation stage [41–43] and if stress severity increased beyond the fiber elongation period, led to fiber immaturity and low micronaire [44]. On the contrary, mild drought stress can be beneficial due to increase in lint percentage over irrigated cotton [45] and occasionally increased micronaire [46]. Krieg [23] summarized the drought stress effects on cotton growth and productivity and demonstrated that the timing and severity of water deficit stress has a large effect on yield. Levi *et al.* [47] showed 31% reduction in seed cotton yield under moisture stress.

Soil water deficit causes a progressive and significant reduction in evapotranspiration (ET) with the extent of reduction dependant on the severity and duration of stress [27]. This reduced transpiration would lead to an increase in the canopy temperature predominantly due to a stress-induced stomatal closure [22]. The reduction in transpiration can also be attributed to a stress-induced reduction in leaf expansion [48–50], stomatal closure [51–53], and reduction in leaf metabolic activities leading to increased senescence. In cotton, photosynthesis is more sensitive to low water potential than the stomatal conductance [54, 55] mainly due to decrease in the synthesis and activity of photosynthetic enzymes under moisture stress conditions [56].

53.3
Trait-Based Breeding to Improve Tolerance to Abiotic Stress

Considering the economic importance of cotton and that a significant area of cotton production comes from water-limited rain-fed conditions, attempts to sustain or even increase yield potentials under stress is a major challenge. Through crop improvement efforts for higher absolute yields, further success in such conventional breeding may not provide the requisite yield advantage because of a narrow variability in yield among the improved cultivars [57, 58]. Therefore, understanding the plant physiological characteristics underlying yield formation can direct breeding both for specific integral traits and for crop response to stress leading to increased yield and cotton fiber quality.

Drought stress is a very complex stress, and both stress response and crop adaptation to stress are equally complicated. For achieving a comprehensive improvement in drought tolerance coupled with improved productivity under water-limited conditions, it appears that several diverse traits need to be introgressed into a single elite genetic background. Among a large number of adaptive and constitutive traits

that have been identified, traits associated with tissue–water relations need to be improved [59–61]. Traits associated with mining water from deeper soil layers (roots), water use efficiency [62, 63], and high-degree of cellular level tolerance [64] deserve greatest emphasis. Toward a trait-based breeding strategy, the first step is to systematically characterize the available cotton germplasm accessions for the variability in these traits and identify superior trait donor lines. In addition, it is also extremely important to assess variability in several morphophysiological traits such as the canopy architecture and leaf expansion traits.

53.3.1 Canopy Characters

Manipulating the canopy architecture through leaf characters can be a useful strategy in breeding for drought tolerance. Other traits such as early maturity [65, 66], reduced leaf area index, and higher canopy CO_2 uptake [67], high light-saturated single-leaf photosynthetic rates [68], a shorter sympodial plastochron [69], and increased numbers of flowers per season [70] also deserve exploitation. Meredith [71] found that a copy with subokra-type leaves yielded greater than okra, superokra, and normal leaf types. Stiller *et al.* [72] confirmed that cotton with the okra leaf morphology was more suitable for improved yield under dry land conditions.

53.3.2 Root Traits

Cotton root consists of a primary or "tap" root from which branch the secondary and tertiary roots [73]. The cotton root, whether primary or branch root, has a single layer of epidermal cells surrounding the root cortex. The endodermis, single-cell layer, surrounds the stele that contains the xylem and phloem vascular elements and a cell layer called the pericycle. The xylem elements are arranged either in a tetrarch (four distinct xylem bundles, the most common) or in a greater bundle arrangement [74]. The difference in arrangement is apparently genetically controlled and may result in significant genetic diversity in root characteristics.

The depth of root penetration depends on a number of factors such as soil moisture, structure, pH, temperature, and so on, but in general the taproot can reach depths of over 3 m and can elongate at a rate from less than 1 to over 6 cm per day. The elongation rate of the lateral or secondary roots would generally fall within the same range [75]. In general, the root system continues to grow and increase in length until young bolls begin to form [31] at which time root length declines as older roots die. New roots continue to be formed past this point, but the net result is a decline in total length [76].

A number of different root traits and morphophysiological traits have been implicated as important mechanisms that impart drought tolerance in cotton. These include distance from transition zone to the first main lateral root, taproot weight, number of lateral roots, seedling vigor, rapidity of root system development, and root-to-shoot ratio [24] and longer taproot length [19].

Several of the root-related traits show significant response to stress. An increase in root density in the soil layer between 70 and 180 cm was reported in cotton in dry soil profile compared to well-watered condition [30]. Pace *et al.* [19] found that under drought stress, there was increase in taproot length without any change in cotton taproot dry weight. Detrimental effects of drought on root growth were observed only after recovery where both taproot' and secondary roots' dry weight decreased [19, 33, 77]. Thus, increase in taproot length, at the expense of thickening, in response to drought may be a common response in cotton. Such a response may have evolved to permit cotton plants to survive drought by accessing water from deeper soil profiles [78]. Contrasting evidence exists that drought stress reduces cotton root growth, root elongation, root length density, and root distribution [32, 79, 80]. However, such root growth reductions are normally noticed when the stress is severe or when it is prolonged.

Although superior drought tolerance is associated with enhanced root growth, rapid root water uptake, maintenance of root viability at the soil surface, and rapid root regeneration after rewatering [81], no serious breeding efforts have been initiated till date to improve root traits [82]. Lack of appropriate phenotyping strategy for root traits is perhaps the most important constraint. Several techniques have been developed to study root parameters such as hydroponics [83, 84], minirhizotrons [85], minilysimeters [86], and tubes [87]. More recently, sophisticated imaging techniques have been developed for assessing root growth and development. Although these techniques have been used widely to measure root parameters, they suffer either from cumbersomeness of procedure or inability to screen large number of accessions. In addition, some of the techniques such as tubes, minilysimeters, and so on do not represent the correct phenotypic expression of roots, as they do not experience interplant competitions [88]. Similarly, hydroponic techniques also cannot be adopted to assess root growth variations over extended crop growth periods.

Most of these disadvantages can be overcome by growing plants in specially constructed "field root phenotyping structures" [88]. Briefly, these root structures are constructed using bricks and are raised beds 5 feet above ground and are 10 feet wide. The length of the structures can be varied based on the crop species and the number of accessions to be studied (Figure 53.2). Soil of the required type can be filled in these structures and plants are raised with the recommended spacing between plants. Thus, in such field root phenotyping structures plants are raised under near-natural conditions that experience interplant competition and hence would represent the best phenotypic assessment while determining the genetic variability [64, 88].

In a field study done at our center, 158 upland cotton germplasm accessions were screened for variability in root traits by raising plants in field root phenotyping structures (Figure 53.2). A significant genotypic variability in root length, root dry weight, root volume, and root-to-shoot ratio was observed [64]. Each of these parameters displayed a normal distribution illustrating the polygenic regulation of root traits (Figure 53.3).

Similarly, Basal *et al.* [89] reported a considerable genetic variation in root length, lateral root number, root fresh weight, lateral root dry weight, and total root dry weight of 68 cotton landraces. On the contrary, Roark and Quisenberry [90] observed low genetic variability in cotton cultivars. As most of the cultivars examined by them were

Figure 53.2 Specially constructed field root phenotyping structure to assess genetic variability in root traits in a large number of accessions [64].

selected from humid and high-rainfall conditions, the genotypes did not exhibit greater variability in root traits [90, 91].

Considering the importance of root traits for drought tolerance, scientists have constantly been looking toward evolving newer and more robust strategies for the assessment of genetic variability in root traits.

53.3.3
Oxygen Isotope Ratio as a Surrogate for Root Traits

Although the theory explaining the phenomenon of oxygen isotopic enrichment during evaporation of water from ocean surface is well known for almost four

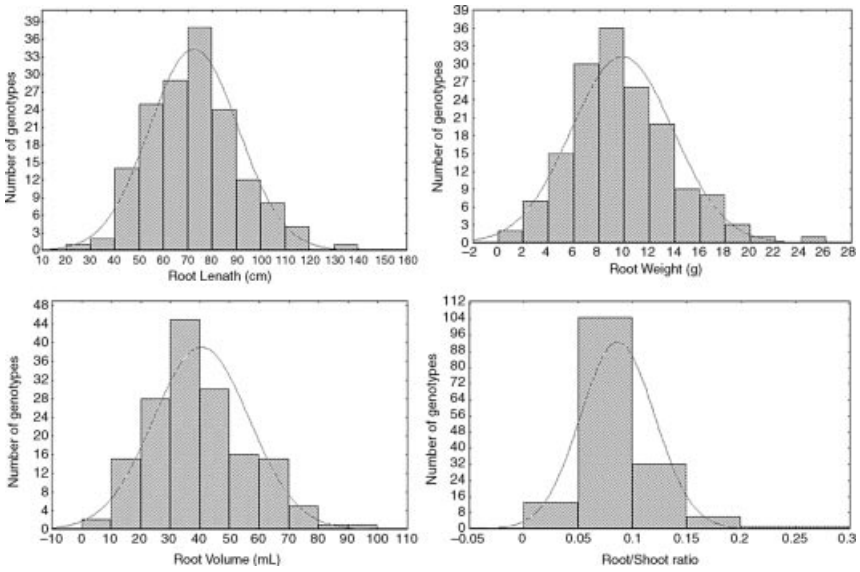

Figure 53.3 Significant genotypic variability observed for various root traits among cotton germplasm accessions [64].

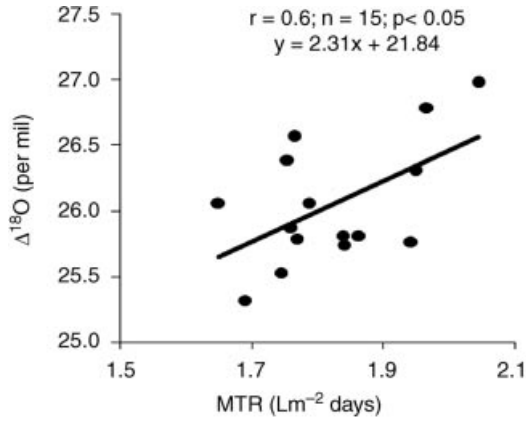

Figure 53.4 Relationship between oxygen isotope enrichment ($\Delta^{18}O$) and mean transpiration rate (MTR) among 15 cotton lines (*G. hirsutum*).

decades [92], the application of this theory to predict differences in transpiration rate has been fairly recent [93–95]. Furthermore, the relationship between stomatal conductance and leaf water ^{18}O enrichment has remained equivocal [96], though increased transpiration has been clearly shown to enrich leaf water ^{18}O [97, 98]. Sheshshayee *et al.* [99] and AbouKheir *et al.* [100] have provided experimental evidences and demonstrated that oxygen isotope enrichment is a powerful time-averaged surrogate for transpiration rate (Figure 53.4). Total transpiration is a function of canopy leaf area and the transpiration rate per unit leaf area. Accordingly, a strong positive relationship between the measured total transpiration and the predicted transpiration based on oxygen isotope enrichment was noticed among the 15 contrasting cotton lines (Figure 53.5a). Furthermore, total transpiration at a given leaf area depends on the ability of the root system in meeting the evaporative demand of the canopy. We observed a strong correlation between root biomass and the total transpiration predicted using oxygen isotope ratio (Figure 53.5b). These results clearly demonstrate the relevance of oxygen isotope enrichment as a surrogate for root traits.

53.3.4
Water Use Efficiency

Water use efficiency, the amount of biomass produced for unit volume of water transpired, is a key parameter that needs to be improved to produce better yield for a given amount of water or for having a stable yield with less water used. WUE can be considered part of resource management under moderate drought stress. Several researchers are of the opinion that there is only a small exploitable variability in WUE [100–102]. However, more recent studies have clearly demonstrated a significant genetic variability in WUE in several crop species [103–110] including cotton [100, 111–113].

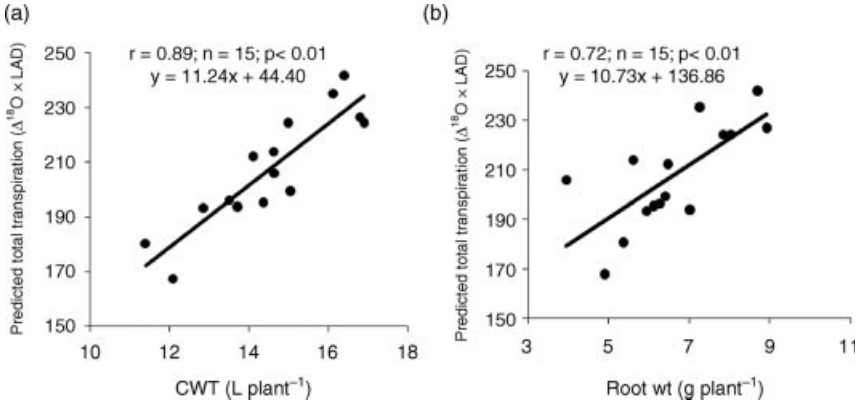

Figure 53.5 Relationship between predicted total water transpired ($\Delta^{18}O \times LAD$) with cumulative water transpired (a) and root biomass (g Plant^{-1}) (b) among 15 cotton lines (*G. hirsutum*) [100].

WUE can be measured at single-leaf level, as a ratio between the rate of carbon fixation by photosynthesis and the rate of transpiration, as a ratio of the photosynthesis rate and stomatal conductance since major water loss through the stomata [114–116]. WUE can also be measured at whole-plant level, the ratio between total dry matter accumulated during a season and amount of water transpired by plant [86]. Precise and reliable evaluation of WUE either at whole-plant level or at single-leaf level are complex, difficult to achieve, and expensive. A large drawback of WUE measured at whole-plant level is that it is cumbersome and hence cannot be used for large-scale screening. On the other hand, WUE measurement at single-leaf level is an instantaneous measurement, which fails to incorporate seasonal effects of WUE [113]. Measures of WUE that represent a single plant over an entire growing season are essential for robust breeding program. At present, neither of WUE measurements is directly suitable for selecting plants from segregating populations. Plants discriminate against the heavy isotope of carbon during photosynthesis. Theory has been well developed that links the variability in WUE with carbon isotope discrimination ($\Delta^{13}C$) [117]. The application of $\Delta^{13}C$ as a surrogate for WUE has been verified in several container and field experiments. This technique is being widely adopted as a surrogate for determining the genetic variability in WUE in several crops such as wheat [118–120], groundnut [105, 121–123], rice [124, 125], cowpea [108, 126, 127], and cotton [100, 111, 113, 128].

As expected by theory, several workers found a negative relationship between $\Delta^{13}C$ and WUE among cotton lines *G. Barbadense* [128], *G. hirsutum*, and an interspecific hybrid [100, 111, 129]. However, a positive correlation of $\Delta^{13}C$ with yield and stomatal conductance at single-leaf level was often noticed [100, 129] (Figure 53.6).

Assessment of genetic variability in WUE using $\Delta^{13}C$ revealed significant variability in many crop species [110, 120, 123, 125]. Similarly, a significant genotypic variability in $\Delta^{13}C$ among 158 upland cotton accessions was observed in our center (Figure 53.7) [64].

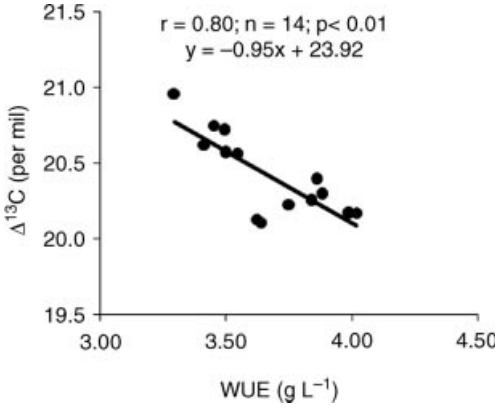

Figure 53.6 Relationship between carbon isotope discrimination ($\Delta^{13}C$) with water use efficiency among 15 cotton lines (*G. hirsutum*) [100].

Besides, the large genetic variability and a low genotype interaction with its environment and a moderate-to-high broad-sense heritability for WUE trait [113, 120, 124, 130, 131] suggest that breeding efforts could be attempted to improve productivity through selection for WUE. For instance, in a wheat breeding program, Richards *et al.* [131] and Condon *et al.* [120, 132] developed varieties with a high WUE to improve productivity under water-limited conditions. However, the yield advantage was shown to decrease when water availability during the cropping season increased [120, 131]. In many species and genotypes, moisture stress induced stomatal closure affecting not only transpiration but also photosynthesis, resulting in significant reduction in total biomass production although there is increase in WUE [61, 133]. Crop lines with such characteristics are often referred to as

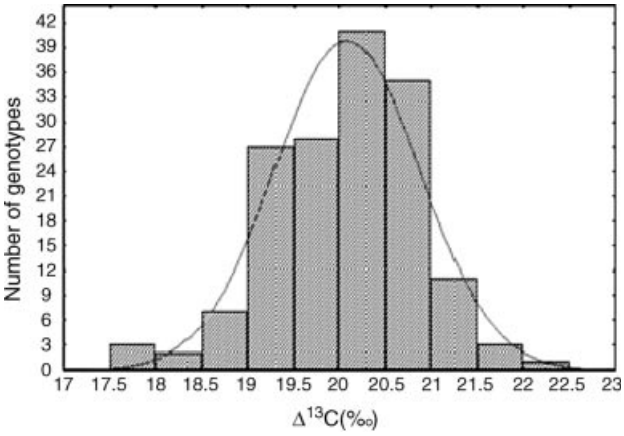

Figure 53.7 Significant genotypic variability observed for $\Delta^{13}C$ among cotton germplasm accessions [64].

Table 53.2 Classification of some crop species as capacity and conductance types.

Capacity (g_m) types		Conductance (g_s) type	
Crop	**Reference**	**Crop**	**Reference**
Groundnut	[104]	Wheat	[141]
Wheat	[119]	Wheat	[142]
Groundnut	[135]	Barley	[143]
Groundnut	[103]	Wheat	[144]
Groundnut	[121]	Wheat	[145]
Groundnut	[136]	Coffee	[146]
Beans	[137]	Cotton	[128]
Grasses	[138]	Cotton	[64]
Canola	[139]	Rice	[124]
Spruce	[140]	Cowpea	[108]

"conductance types" [95, 108, 110]. On the other hand, increase in WUE arises predominantly by maintaining high photosynthetic capacity in a few species and genotypes; selection in such types for higher WUE will not affect the plant biomass and yield that are called "capacity types" [106, 110, 134]. The classification of some crops into capacity and conductance types is provided in Table 53.2.

Cotton is classified as conductance types (Table 53.2), where WUE increases by reducing transpiration through stomatal closure, thus associated with reduction in the biomass produced [132, 147]. Recently, AbouKheir *et al.* [100] demonstrated stable isotopes (^{13}C and ^{18}O) as high-throughput technique for accurate identification of capacity type among cotton genotypes. The carbon and oxygen isotope ratios of plant organic matter integrate the diurnal and seasonal variations in C_i and g_s, respectively [110, 135]. Therefore, demonstration of carbon- and oxygen-stable isotope ratio ($\Delta^{13}C/\Delta^{18}O$) is a good time-averaged estimate of *in vivo* photosynthetic capacity and thus to identify capacity type genotypes.

53.4 Water Conservation Mechanisms

53.4.1 Epicuticular Wax

A variety of functions have been attributed to these waxes related to their involvement in physical and physiological processes, including the reduction of transpiration and gas exchange. Commonly, drought-stressed cotton leaves exhibit an increase in the waxy cuticular layer of the leaf [148, 149] for water conservation. Bondada *et al.* [150] showed that water stress increased total wax concentration in cotton and induced the production of long-chain alkanes whose number and levels were higher in the total wax of the leaf, bract, and boll compared to the corresponding well-watered cotton

plants. It has been reported that cuticular thickness and waxiness of leaf surface are genetically controlled by a large number of genes affecting the transpiration [151].

53.4.2 Cuticular/Nonstomatal Water Loss

Most of the nonstomatal water loss from the leaf would be from the epidermis due to differences in cuticular thickness. It is predominantly influenced by cuticular waxes, which is an intrinsic drought-tolerant character affecting water retention in leaves. The trait has great relevance in water conservation under drought conditions. The genetic variation in cuticular water loss has been reported in crop species and used as selection criterion for drought resistance [152–155]. Genotypic variation in cuticular water loss was assessed among the 158 cotton germplasm accessions in our center by measuring the rate of water loss from excised leaves. Results revealed a considerable genotypic variation among cotton accessions tested in moisture retention capacity at 5 h that ranged from 40.04 to 83.27% (Figure 53.9) [25].

53.5 Cellular-Level Tolerance

53.5.1 Intrinsic Tolerance

Under natural conditions, development of abiotic stress levels is a progressive phenomenon. Accordingly, plants initially experience a milder stress level before being exposed to severe stress. In response to milder stress, several genes have been shown to be either upregulated or downregulated, which leads to the development of a considerable degree of tolerance in plants when stress becomes severe. Such an acclimatization response of plants is termed "acquired tolerance" and it has been demonstrated in several species [156–160] including cotton [161].

The induction of stress triggers several signaling pathways, resulting in the expression of an array of stress-responsive genes and the gene products may alter the physiological and biochemical processes relevant to stress tolerance. While several genes are suppressed, a large number of genes are upregulated in response to stress [162–165]. Drought stress-responsive genes have their own cognate receptors, which operate independently or cooperatively to initiate downstream signaling events. Regulation of both upstream and downstream components such as heat shock protein, protein kinases, secondary messengers (reactive oxygen species (ROS), calcium, etc.), and transcription factors is directly or indirectly involved in establishing the required responses that are well studied [166–168].

On the basis of the concept that seedlings acquire a certain degree of stress tolerance when exposed to milder stress levels, the novel and high-throughput "temperature induction response" (TIR) technique has been developed and validated in many crop species [162, 164, 165] including cotton [161]. The technique involves

Table 53.3 Genetic variability in thermotolerance among 36 *G. hirsutum* genotypes [161].

	Seedling mortality (%)		Reduction in recovery growth (%)	
	Induced	**Noninduced**	**Induced**	**Noninduced**
Mean	49.77 ± 4.2	88.61 ± 2.2	80.54 ± 2.4	96.94 ± 0.6
Minimum	10.00	50.00	43.59	87.22
Maximum	93.30	100.00	96.56	100.00
CD @ 5%	24.63		16.20	

subjecting young seedlings to a mild induction temperature before exposing them to a potentially lethal temperature level. Using the TIR technique, AbouKheir *et al.* [161] observed significant difference in heat stress response among cotton species. Old World cotton (*G. arboreum* and *G. herbaceum*) species showed higher survival percentage and better recovery growth compared to New World cotton (*G. hirsutum and G. barbadense*). Plausibly, it may provide an explanation why diploid cotton types are preferred by farmers in India for cultivation in marginal and drought-prone environments. Many studies have shown that genetic variability is seen only upon stress acclimation treatment prior to severe stress [162, 164, 169–172]. It corroborates the observations of AbouKheir *et al.* [161], who reported a significant genetic variability among 36 upland cotton cultivars screened using TIR technique (Table 53.3), and on the basis of seedling survival and growth after recovery genotypes can be classified into thermotolerant, moderately tolerant, and susceptible (Figure 53.8).

In addition, seedlings exposed to induction treatment before being exposed to severe temperature have higher growth recovery than those seedlings subjected directly to severe temperature stress and also accumulated higher levels of low and high molecular weight HSPs such as HSP18.1, HSP90, and HSP104 [162, 164]. A number of earlier studies have clearly demonstrated that thermotolerance genotypes selected

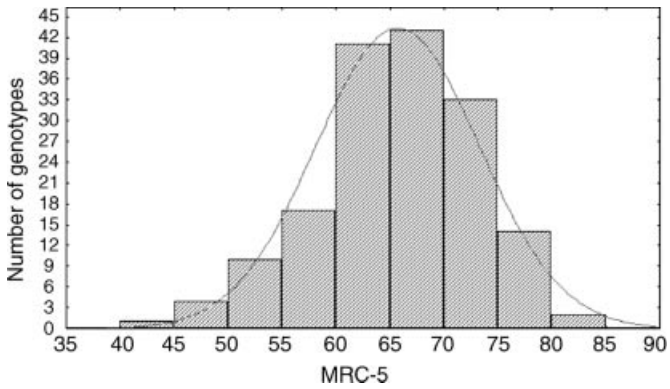

Figure 53.8 Significant genotypic variability in moisture retention capacity at 5 h (MRC-5) among 158 upland cotton accessions [25].

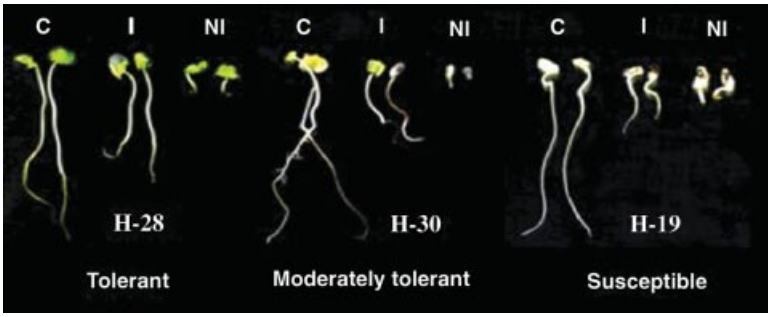

Figure 53.9 Variation in root and shoot growth in tolerant (H-28), moderately tolerant (H-30), and susceptible (H-19) lines after recovery from high-temperature stress.

with TIR technique showed better leaf area, membrane integrity, and thus better recovery growth after exposure to heat stress at whole-plant level. It suggests that the thermotolerance of genotypes analyzed using TIR technique at seedling level may also provide insight into intrinsic tolerance at plant level [162, 164, 165] (Figure 53.9).

53.5.2 Osmotic Adjustment

Osmotic adjustment helps in maintaining turgor and thus tissue metabolism under drought stress conditions [173]. Hare *et al*. [174] reported accumulation of many compatible solutes (i.e., proline, trehalose, and glycine betaine) useful in osmotic adjustment, which also protect plants against water deficit stress by buffering redox reactions by scavenging free radicals, preventing protein degradation, maintaining membrane stability, and mediating signal transduction. Boyer [175] suggested that certain sugars and their derivatives with structures similar to water (e.g., sucrose and trehalose) may hydrogen bond with cell membranes, thus stabilizing the system when water deficits occur. Oosterhuis and Wullschleger [176] found that cotton has more osmotic adjustment capabilities than other major crops and the most important solutes found in cotton leaves are potassium, nitrate, citrate, malate, and sugars, and the last two account for 10–40% of osmotic potential [177].

Eaton and Ergle [178] reported increase in hexose sugars in cotton leaves under moisture-stressed conditions. A decrease in sucrose concentration with concomitant increase in raffinose concentration is known to maximize the secondary wall synthesis in cotton fiber [179]. Cotton has been shown to accumulate an extremely high amount of glycine-betaine compared to other taxa [180]. Trehalose production is induced by a number of stresses including water deficit and salinity in cotton [181]. Trehalose-6-phosphate synthase RNA was found in all tissues tested in both water-stressed and well-watered plants with increased levels of expression in stressed leaves and roots compared to the well-watered controls. Similarly, reduction in osmotic potential was recorded under moisture stress conditions [182]. Singh *et al*. [183] showed an increase in P uptake from a drying soil leads to an increased supply of

osmotically active inorganic solutes for the cells in the growing cotton leaves. As a consequence, plants accumulate both free and bound water, ultimately leading to increased leaf expansion rate. Thus, root traits that enhance the P uptake could be a beneficial mechanism to alleviate drought stress.

Quisenberry *et al.* [184] reported significant differences among cotton cultivars for osmotic potential at zero turgor, further suggesting genotypic variation in osmoregulation in cotton. However, a significant negative correlation between shoot dry weight and increased osmoregulation was reported from the same group, implying that if cotton genotypes are selected on the basis of the degree of osmotic adjustment under water deficit stress alone, a decrease in potential growth could be a possibility in selected species. Evidently, documented reports suggest that relationship between osmotic adjustment and yield were inconsistent, which can be positive [82], negative [184, 185], or no association [186, 187].

53.5.3
Chlorophyll Fluorescence

F_v/F_m is often used as an early indicator of photosynthetic damage caused by abiotic stress in many crops [188–191]. Burke [192] developed a novel bioassay for the identification of drought stress in cotton that utilizes chlorophyll fluorescence to monitor cell viability under high-temperature dark incubation. Differences between well-watered and drought-stressed plants can be established since, under stress, plants will not mobilize carbohydrate reserves overnight and will therefore maintain higher fluorescence values during high-temperature dark incubation, with the opposite being true for well-watered plants. Normal metabolic processes have been shown to be disrupted by drought leading to a reduction in the translocation of photosynthate from leaves to other plant tissues [193]. The okra leaf genotypes did have 14% greater F'_v/F'_m across treatments compared to the normal leaf cottons. Higher photosynthetic rates per unit leaf area have been observed in okra leaf genotypes [194]. Higher chlorophyll fluorescence values in drought-stressed plants were observed in 20 genotype of diverse germplasm evaluated in a 2 year field evaluation under two water regimes [195], indicating the importance of using this bioassay to evaluate and identify the drought tolerance cotton genotypes.

53.6
Conceptual Approach to Cotton Improvement for Abiotic Stress

A variety of approaches have been used to alleviate the problem of drought stress through the enhancement of adaptive mechanisms of plants. It appears to be a formidable task as drought is a complex abiotic stress controlled by many physiological and biochemical characteristics, besides phenotypic characteristics of plants. Plant breeding, either conventional or molecular breeding, is being extensively used to tailor and develop genotypes with genetically superior traits to enable them to adapt to drought-stress environments. There has been commendable progress made

during the last century by plant breeders in developing drought-tolerant lines/varieties/cultivars of some crops through conventional breeding. However, the approach is highly time consuming and labor and cost intensive. Alternatively, marker-assisted selection (MAS) [196] has been realized to be a more efficient approach, which identifies the usefulness of thousands of genomic regions of a crop under stress conditions. Quantitative trait loci (QTL) for drought tolerance have been identified for a variety of traits in different crops. The development of comprehensive molecular linkage maps and marker-assisted selection has opened up options to pyramid desirable traits to achieve crop drought tolerance. To date, such crop improvement programs have been hampered by significant genetic × environment interaction, large number of genes encoding yield and use an inappropriate mapping population involved in mapping of QTL for better growth and yield under water deficit conditions. Advancement of scientific knowledge on genomics and proteomics has been increasingly beneficial for precise molecular breeding and transformation approaches in crop improvement. With the available tools and techniques, the realization of trait pyramiding poses a daunting challenge. Therefore, the emphasis must be placed to devising appropriate strategies and tools for precise trait pyramiding to improve drought tolerance.

The first step in this direction would be to identify genes and QTL that control the specific traits of relevance to drought tolerance and such desirable traits' variability among the genotypes. Hence, precise identification of trait donor parents/lines/genotypes is critical. It forms the basis for the development of genetic and genomic resources for focused molecular breeding and transgenic program. Despite the realized potential of molecular breeding strategy, the success has not been encouraging. It is mainly attributed to the inability to identify robust QTL due to the nonavailability of large number of codominant marker systems such as SSR. Therefore, emphasis has to be on generation of large genomic resources of marker systems (SNP and SSR) followed by devising robust and high-throughout phenotyping techniques.

Transgenics is yet another potential option to introduce novel alleles for improving drought tolerance of crop. In recent years, several transgenic programs have provided leads in improving crop adaptations, even at field level, suggesting the potentials and prospects of trait pyramiding by introducing regulatory genes with abilities to upregulate the several downstream functional genes. Suggestively, choice of regulatory genes and development of multigene cassettes with pathway-engineered genes appear to be an effective drought-tolerant trait pyramiding strategy by transgenic approach.

53.7
Potential of Genomic Resources for the Enhancement of Drought Tolerance

In the last decade, extensive research in genetics and genomics has improved our understanding of structure and function of plant genomes and has integrated basic knowledge to enhance drought stress tolerance through molecular and transgenic approaches. Cotton genetic maps have been developed for various *Gossypium* crosses, mostly between *G. barbadense* species and *G. hirsutum*. These maps collectively

include more than 5000 public DNA markers (~3300 RFLPs, 700 AFLPs, more than 2000 SSRs, and 100 SNPs). Many thousands of additional SSRs have been described [197], but only subsets of these have been mapped [198–200]. The other aspect of genomic resources is transcriptome, a cDNA sequence, which is beginning to receive wide attention. However, available knowledge of the *Gossypium* spp. transcriptome is heavily biased toward genes expressed in fibers. The total number of *Gossypium* ESTs available is 378 184 in different cotton species. On the basis of the current knowledge on cotton genomic resources, Gene Chip (Affymetrix) has been constructed with 23 977 probe sets representing 21 854 cotton transcripts.

Over the past two decades, whole-genome sequencing has been achieved in several organisms including plant species, and it is clear that most of the major crop species will also be sequenced in near future including cotton genome. In cotton, however, there is need to sequence not only cultivated (tetraploid) genotypes but also their diploid progenitors, to understand how tetraploid cottons have come to "transgress" the productivity and quality of their progenitors. As a long-term goal of characterizing the spectrum of diversity among eight genome types, the first genetically anchored whole-genome physical map of a cotton species (*G. raimondii*) was built through integration of agarose-based fingerprinting and high information content fingerprinting [201] since *G. raimondii* (D genome) has the smallest genome (60% of the "A" genome) with 880 Mb, and a detailed genetic linkage map is available. Studies are in progress on the species *G. arboreum* and *G. hirsutum*, the next priorities after *G. raimondii* in the international strategy for characterizing the spectrum of *Gossypium* diversity [202]. The economic importance of cotton fibers and scientific interest in polyploidy suggest an ultimate goal of sequencing a *G. hirsutum* tetraploid. The possibility of intergenomic concerted evolution, much like the presence of recently amplified repetitive DNA families, may tend to support the need for a BAC-based rather than a whole-genome shotgun approach. Using a finished diploid genome as a template and guide, a BAC-based sequence of a tetraploid will elucidate the types and frequencies of changes that have distinguished polyploid from diploid cottons. An effective utilization of the existing genomic resources for precise identification of QTL/genes of relevance for enhancing the adaptive capability to moisture-limited conditions is need of the day.

53.7.1 Molecular Breeding

The marker technology has enabled breeders to utilize DNA markers for selecting desirable plants without exposing them to a critical and growth-limiting environmental conditions [203]. The range of DNA markers that can be easily used is quite extensive. The techniques utilize the polymorphisms in the actual DNA sequence of plant germplasm and identify the variations and use different DNA markers such as RFLP, AFLP, SSR, and so on [204–206]. Such DNA markers have been developed and used in cotton for fingerprinting [207, 208], linkage map construction [198, 199, 209–212], gene mapping [213, 214], and genetic diversity studies [209, 210]. Several studies and reviews have reported that QTL may play a critical role in mitigating abiotic stress in

Table 53.4 Few QTL affecting traits associated with drought tolerance in cotton.

Traits	Marker system	Mapping population	Remarks	References
Fiber length (6)[a], length uniformity (7), elongation (9), strength (21), fineness (25), and color (11)	RFLP markers	214 F_3 families (*G. hirsutum* × *G. barbadense*)	The F_3 family grown in two water regimes well-watered treatment (receiving 300 mm) and the water-limited treatment (receiving about 40–50% of that quantity)	[224]
Lobe length (3), lobe width (2), leaf-lobe angle (3), main sub-lobe number (1)	RFLP markers	180 F_2 (*G. hirsutum* × *G. barbadense*)	QTL affecting leaf-lobe length and width was found at the lower end of chromosome 15 corresponding approximately to the location of the "Okra-leaf" mutation [226]	[225]
Trichome density (4)	RFLP markers	F_2 (*G. hirsutum* × *G. barbadense*)	119–150 from each four F2 population were developed from crossing four *G. hirsutum* with common *G. barbadense*	[226]
Lobe length (10), lobe width (13), lobe angle (6), and leaf chlorophyll content (2)	SSR markers	BC (*G. hirsutum* × *G. barbadense*)	The genetic map was constructed using 590 SSR markers	[227]
Stomatal conductance (2)	RAPD and SSR markers	118 $F_{2.3}$ (*G. hirsutum* × *G. barbadense*)	The genetic analysis was done in F_2 individual and repeated in F_3 families	[228]
Low OP (11), high $\delta^{13}C$ (11), canopy temperature (4), chlorophyll-a (3), and chlorophyll-b (4)	RFLP markers	900 F_2 and 214 F_3 families (*G. hirsutum* × *G. barbadense*)	Two irrigation regimes were used, well watered and water limited	[229, 230]
Root weight (1)	RFLP and SSR markers	The two F_2 populations consisted of 138 and 107 progenies (*G. hirsutum* × *G. barbadense*)	Major QTL for root weight was identified on chromosome 7	[231]

a) Number in parenthesis in the first column indicates number of identified QTL.

many crop species. However, in cotton a majority of QTL identified in genetic mapping were associated with agronomic and fiber quality [212, 213, 215–223]. On the other hand, there are a few studies on QTL affecting traits associated with drought tolerance listed in Table 53.4.

Genomic approaches offer unique opportunities to dissect quantitative traits into their single genetic determinants (QTL), thus enabling transfer of specific genomic regions between different genetic backgrounds through MAS [196]. In cotton, MAS has been used in backcrossing transgenes from transformed cultivars to the elite cultivars and further genetic advancement of cultivars. QTL for yield and drought-related physiological traits such as osmotic potential (OP), carbon isotope ratio ($\delta^{13}C$), and leaf chlorophyll content have been introgressed via MAS to 12 NIL obtained from elite cultivars of the two cotton species *G. barbadense* cv. F-177 and *G. hirsutum* cv. Siv'on. Among nine NILs introgressed with OP QTL, five NILs exhibited significant reduction in OP under water-limited conditions and/or improved OA during two field trials. Similarly, among six NILs introgressed with high $\delta^{13}C$ (as indirectly measurement of WUE) only four showed significantly higher $\delta^{13}C$ under moisture stress conditions. Likewise, only two out of three NILs showed higher chlorophyll content [182].

Over the past decades, conventional linkage analysis (biparenteral QTL mapping) is being successfully used for dissection of trait inheritance mechanism. The approach has facilitated the identification of major genes and QTL in plant and animal species, particularly in model organisms. However, efficient gene discovery with this approach will probably continue to be largely limited to loci that have a large effect on quantitative variation. Although biparenteral mapping is used extensively to identify QTL associated with different traits, it is time consuming and takes several years to develop populations for fine scale mapping. Apart from inherently poor resolution (long-distance associations between marker and QTL, for example, 10 cM) resulting from limited meiotic crossover events in pedigreed populations, developing large full sib families for each major gene/trait may not be practical for plant genetic improvement, particularly in tree crops. A more efficient approach that does not require generation of large pedigreed mapping populations with higher resolution is therefore needed to complement conventional QTL mapping strategy. Recently, a population genomics tool termed "association mapping" [232, 233] has been developed. Association mapping seeks to identify specific functional variants (i.e., loci, alleles, etc.) linked to phenotypic differences in a trait, to facilitate detection of trait causing DNA sequence polymorphisms, and/or selection of genotypes that closely resemble the phenotype. In cotton (*Gossypium* spp.), association studies are very limited [25, 234–236].

Abdurakhmonov *et al.* [234] reported the extent of genome-wide LD in upland cotton (*G. hirsutum*) and association mapping of fiber quality traits using 95 microsatellite markers in a total of 285 exotic *G. hirsutum* accessions. A genome-wide average of LD declined ($r^2 \geq 0.1$) within the genetic distance at $<$10 cM in the landrace stocks of germplasm and $>$30 cM in varietal germplasms. Furthermore, genome-wide LD ($r^2 \geq 0.2$) reduced on an average $\sim$1–2 cM in the landrace stock germplasms and 6–8 cM in varietal germplasms. Recently, association mapping for fiber-quality traits was conducted using 202 microsatellite markers in 335 *G. hirsutum* germplasm grown in two diverse environments. The result indicates that genome-wide average of LD ($r^2 \geq 0.1$) extended up to a genetic distance of 25 cM in assayed cotton variety accessions. Genome-wide LD ($r^2 \geq 0.2$) was reduced to $\sim$5–6 cM

Table 53.5 Summary of the association mapping of root traits, $\Delta^{13}C$, TDM, and other associated physiological traits using MLM and GLM tests in TASSEL.

Traits	No. of significant associations	
	Experimental location 1	Experimental location 2
Plant height @ 100 DAS	27	26
Root length	15	23
Total root volume	28	27
Leaf weight	36	36
Total root weight	34	29
Stem weight	33	23
TDM	29	24
$\Delta^{13}C$	23	20
SCMR	25	39
SLA	19	20
LA	39	33
Root/LA	33	28
TDM/LA	26	30
Root/shoot	32	24

providing evidence for the potentiality of association mapping of agronomically important traits in cotton [235]. Similarly, Kantartzi and Stewart [236] evaluated 56 *G. arboreum* (diploid cotton) germplasm accessions for eight fiber characters that genotyped with 98 SSR markers. A total of 30 marker-trait associations were identified with 19 SSR markers located on 11 chromosomes and identified marker-trait associations ($P = 0.05$) for all traits evaluated.

The first study on LD-based association mapping for root traits and $\Delta^{13}C$ was done in our center, using 152 upland cotton germplasm accessions grown under two diverse agroclimatic locations in India. The results revealed the genome-wide average of LD ($r^2 \geq 0.1$) extended up to a genetic distance of 25–30 cM. Interestingly, it is the first study showing SSR markers associated with root traits and $\Delta^{13}C$ trait in upland cotton (Table 53.5). Although majority of SSR markers had significant associations only in one experimental location, a few of them showed significant association in both the locations with some traits, which can be potential markers for effective MAS program in cotton [25].

53.7.2
Transgenics to Improve Abiotic Tolerance

Plants must adapt to abiotic stress in order to survive; thus, a number of genes are upregulated and/or downregulated as a response to stress conditions. These stress-responsive genes are broadly classified as genes thought to be involved in protecting stressed cells (functional gene) and genes implicated in regulation of signal transduction

Table 53.6 Genes used in transformation to enhance stress tolerance in cotton.

Functional genes	Remarks	References
1. *Antioxidants*		
Superoxide dismutase (SOD), ascorbate peroxidase (APX), and glutathione reductase (GR)	Enhanced recovery of photosynthesis in plants exposed to chilling temperatures and high light intensity	[239, 240]
Glutathione *S*-transferase (GST)	Seedlings did not show improved tolerance to salinity, chilling conditions, or herbicides	[241]
2. *Membrane transporters*		
Tonoplast Na^+/H^+ antiporters (NHX1)	Transgenic plants had more biomass produced and fibers under salinity stress compared to the wild type	[242]
H^+-PPase gene (TsVP)	Transgenic plants showed high shoot and root growth, better photosynthetic performance, and accumulated more Na^+, K^+, $Ca2^+$, Cl^-, and soluble sugars in their root and leaf tissues under salinity conditions compared to the wild type	[243, 244]
3. *Osmotic potential*		
Choline monooxygenase (CMO)	The osmotic potential, electrolyte leakage, and malondialdehyde (MDA) accumulation were significantly lower in leaves of the transgenic lines than in wild type after salt stress. Net photosynthesis and F_v/F_m was less affected by salinity stress in transgenic	[245]
4. *Protein kinases*		
SOS2	Transgenic plant had better salt tolerance than the wild type	[246]
5. *Transcription factors*		
GF14λ, encodes 14-3-3 group of regulatory proteins	Overexpression of GF14λ in cotton conferred a "stay-green" phenotype under well-watered conditions and displayed increase water stress tolerance and maintained higher photosynthetic rates under conditions of low water availability	[247]
ABF3	Transgenic cotton plants enhanced expression of ABA-responsive genes under noninducting conditions, better root development, and enhanced survival under severe water deficit conditions	[246]

and expression (transcription factor genes) [237, 238]. These genes have been used extensively to enhance the stress tolerance in several of plant species. Some of the relevant genes, which enhance the stress tolerance in cotton, are provided in Table 53.6.

Although the first transgenic cotton plant (Bt cotton) was released and commercially cultivated since 1996, to date there is no transgenic cotton for abiotic stress tolerance. This is perhaps due to the complexity of abiotic stress and lack of efficient transformation technique in cotton. Therefore, there is a need to develop efficient transformation technique that can be used effectively in cotton. Recently, efficient

embryogenic calli-based method of obtaining transgenic cotton has been standardized in two chinese cultivars [248]. In cotton, due to its recalcitrance and poor regeneration, there has been limited progress in achieving effective transformation. A recent alternative method, tissue culture-independent *in planta* transformation strategy, has been successfully used for transformation in cotton [249].

53.8 Summary

Drought is perhaps the most complex abiotic stress and the varied adaptive mechanisms evolved by plants have made the task of improving drought tolerance a formidable challenge. Imperatively, projected prevalence and spread of drought stress due to water deficit situations worldwide has prioritized the efforts in crop improvement program to dissect the molecular and physiological basis of adaptations to drought stress and/or water-limited conditions by various crops. Past research efforts have emphasized on improving constituent drought tolerance traits through a "trait-based breeding" strategy. Thus, the major emphasis has to identify drought-tolerant traits such as root traits, WUE, and so on, and develop precise and high-throughput phenotyping technique for screening a large number of germplasm to select trait donor lines that can be utilized in breeding program. Modern genomic techniques have aided tremendously in identifying stress QTL and diagnostic DNA markers for specific stress-related traits in a number of crops including cotton. Improvement-specific traits by introducing new alleles by transgenic approach would be an essential option to pyramid traits for improving the adaptation. Furthermore, turning the gene-tagging efforts from biparental crosses to germplasm collection and from traditional linkage mapping to linkage disequilibrium (LD)-based association study holds promise for most effective utilization of *ex situ* conserved natural genetic diversity of cotton germplasm resources irrespective of their origin. The application of LD-based association mapping for cotton will not only accelerate the MAS programs in cotton but also add to our knowledge and understanding of the cotton genome and its evolution. Furthermore, genomic resources with drought-tolerant traits can be compatibly used for pyramiding to superior genetic background, which facilitates genetic improvement for higher yield of cotton germplasm and enhanced adaptability to drought stress conditions.

Tea: Present Status and Strategies to Improve Abiotic Stress Tolerance

Sanjay Kumar, Asosii Paul, Amita Bhattacharya, Ram Kumar Sharma, and Paramvir Singh Ahuja

Tea (*Camellia sinensis* (L.) O. Kuntze) is sensitive to several abiotic factors including low temperature, drought, frost, hail, and waterlogging. The published work largely relates to low temperature and drought, which are the most prominent environmental cues impacting tea survival and productivity. Low temperature leads to winter dormancy through a complex network wherein genes related to cell rescue, defense, and chaperones were upregulated, and the genes associated with cell cycle and DNA processing were downregulated. A positive correlation with the oxidative stress and winter dormancy necessitated modulating oxidative stress for regulating winter dormancy. Chaperonic activities and oxidative stress have also been reported to play prominent roles in modulating drought response of tea. Importantly, drought stress impaired catechins accumulation by downregulating several genes of the pathway. It is a critical parameter with the background that catechins are one of the important components determining the quality of black tea. In the area of genome mapping, bulk segregant analysis followed by complete genotyping of pseudo-test progeny of two heterozygous parental clones for yield, drought, and other important traits identified 260 informative RAPD and AFLP markers. Transgenic tea has been developed by *Agrobacterium* and biolistic gun methods. Tea overexpressing osmotin is a success story that opened up a new path of developing tea plants with improved traits of choice. Developments in systems biology, next-generation sequencing, microRNAs, epigenetics, transcriptomics, metabolomics, proteomics, molecular markers, and transgenic technologies offer immense opportunities for understanding tea response to varied abiotic stresses followed by utilizing the outcome for tea improvement.

54.1
Introduction

Tea (*Camellia sinensis* (L.) O. Kuntze) is one of the most important perennial crops of commerce grown in a wide range of climatic conditions from Georgia (formerly a part of the USSR) in the north (45°N) to South Africa (30°S) and from New Guinea (150°E)

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

in the east to Argentina (60°W) in the west [1, 2]. Recent statistics (2009) suggested that tea occupied 2.99 million hectare to yield 3.88 million ton [3]. Mid-term projections generated by FAO World Tea Model indicate that India would continue to be the largest producer of black tea with an output of 1.2 million ton by 2017, followed by Kenya and Sri Lanka with projected production of 344 000 ton and 341 000 ton, respectively. China is expected to follow with a projected production of 312 000 ton. [3].

Tea, as a commercial crop, includes several species within the genus *Camellia* in the family Theaceae. Three different types of tea, namely, China (*C. sinensis*), Assam (*C. assamica*), and the Cambod (*C. assamica* subsp. *Lasiocalyx*) contribute significantly to the entire genetic pool of cultivated tea worldwide [4]. Although, tea is grown primarily for beverage, recent reports showing its therapeutic value makes it an ideal health drink.

The apical buds and the associated two leaves (TAB), which are used for commercial tea production, contain many compounds of medicinal importance, such as volatile oils, vitamins, minerals, purines, alkaloids (e.g., caffeine), and polyphenols (catechins and flavonoids) [5]. Tea has been shown to have anticancerous [6], antioxidant [7], antimicrobial [8], and anticataract [9] properties. Epidemiological surveys have associated tea drinking with reduced risk of cardiovascular diseases, while studies in cell culture and animal models indicated a potentially beneficial effect of tea on gene transcription, cell proliferation, and other molecular functions. In the past few years, clinical studies revealed several physiological responses to tea that might be relevant to the promotion of health and the prevention or treatment of some chronic diseases [10].

54.2
Major Abiotic Stresses Affecting Tea Yield and Quality

Tea is an evergreen, perennial plant that grows naturally as tall as 15 m. However, under cultivated condition, the bush height is maintained at 60–100 cm to ease harvesting. Tea of commerce is produced from TAB; thus, vegetative growth of TAB is of prime importance for optimized yield. Environment coupled to genetic potential is critical to realize the yield potential. Unfavorable environmental conditions will impact growth processes, thereby the yield. The effects could be on canopy development, and production and partitioning of nutrients and the dry matter [11]. While nutrient application can be controlled, there may not be control on temperature, water availability, and solar radiations and hence these parameters result in abiotic stress in tea, as in any other crop/plant species. Tea industries across the world are always trying to increase production potential by optimizing management practices and improving cultivars.

Tea yield is sensitive to a number of abiotic factors, namely, low temperature, drought, frost, hail, soil pH, waterlogging, and light intensity. However, most of the published work relates to winter dormancy and drought stress, which are probably the major conspicuous factors impacting tea productivity and survival.

54.2.1 Winter Dormancy

Dormancy is defined as "the inability to initiate growth from meristems or other organs and cells with the capacity to resume growth, under favorable conditions" [12]. Dormancy is well-studied in seeds, tubers, corms, and apical buds of several plant species. However, the literature is scanty in tea, in spite of the fact that dormancy, particularly the winter dormancy, is a prominent and obvious phenomenon. It is one of the major bottlenecks to tea growing regions that lie away from the equator. Winter dormancy is characterized by the diminished growth of TAB during winter months. The growth rate of TAB during the dormant season can be reduced to 20% of the mean growth rate recorded, during the active growth period; during the peak of the growing season, TAB growth rate reached 900% of the growth rate during the dormant season [13]. Tea cultivated close to the equator produces almost the same yield every month, but farther from the equator, winter harvest gradually declines and at latitudes beyond about 16°, there is almost complete winter dormancy [1]. The crop remains dormant for a period up to 6 months in countries such as Turkey and Iran, whereas dormancy in Argentina and Mauritius may span over a period of 2–4 months. In Northeast India tea bushes remain dormant during winter for 2–3 months, whereas in Himachal Pradesh (Northwest India), dormant period spans for 5–6 months. Winter dormancy thus affects yield, land use, infrastructure, and manpower.

54.2.1.1 Physiological and Biochemical Basis

Data showed a positive correlation between free abscisic acid (ABA) and winter dormancy in tea [14]; the levels of free gibberellins, on the contrary, remained low during winter dormancy [15]. It was suggested that an altered balance of the endogenous growth regulators could lead to winter dormancy in tea. The efforts to modulate winter dormancy in tea by altering the interactions of plant growth regulators, however, yielded inconsistent results [1], possibly because of a lack of understanding of the mechanism underlying winter dormancy in tea.

Low temperatures prevailing during the period of winter dormancy, either alone or in combination with high solar radiation, can induce oxidative stress in tea. Oxidative stress has been proposed to affect growth and development of plants by limiting biomass production and hence productivity [16–18].

Results on 11 clones of tea, representing China and Assam types, showed that as the atmospheric temperature declined, net photosynthetic rates (P_N) declined (up to 286%) along with reduction in F_v/F_m ratios [19]. Reactive oxygen species (ROS), estimated as superoxide radicals, also increased in all the tea clones during the period of low temperature. The decrease in the rate of photosynthesis and F_v/F_m ratio (a measure of chlorophyll fluorescence) in all clones with concurrent increase in the ROS suggested imposition of oxidative stress in tea during winter months. A strong correlation was obtained between the levels of free radicals, P_N, F_v/F_m and the rate of bud growth. These results suggested that tea does experience oxidative stress during

winter months. Studies across the selected 11 clones showed distinct differences observed for this stress.

Clones with shorter dormancy periods exhibited higher induction of antioxidative enzymes and vice-versa. Results suggested that efficient scavenging of ROS was a desirable feature in tea because it leads to lower ROS accumulations during winter months and was associated with reduced period of winter dormancy [19]. It was also shown that the clones with lower period of winter dormancy exhibited lesser cellular damage in response to low temperature [20]. Glutathione reductase and Mn-superoxide dismutase [21] were identified to be critical in modulating the process of winter dormancy in tea. One of the remarkable features of the identified Mn-superoxide dismutase was its optimal temperature of functionality, which was at 0°C.

54.2.1.2 **Molecular Approaches**

Cultivated species of tea has a diploid chromosome numbers of 30 [22] carrying genome size of 4.0 GB [23]. Compared to 125 Mb for *Arabidopsis thaliana* [24] and 382.17 Mb for rice [25], genome of tea can be considered as a large genome. Transcriptome analysis offers a convenient route for such a large genome and this can be achieved by a number of methods such as using genome analyzers and analysis of expressed sequence tags (EST). As on January 2011, NCBI databank had a total of 13 054 ESTs chiefly contributed by Anhui Agricultural University, Hefei, P.R. China; Tea Research Association, Assam, India; Tea Research Institute, Chinese Academy of Agricultural, Zhejiang, P.R. China; Faculty of Horticulture, Uttar Banga Krishi Viswavidyalaya, West Bengal, India; Institute of Himalayan Bioresource Technology, Palampur, H.P, India; Tea Research Association Tocklai/North Bengal Agricultural, Assam, India; National Institute of Agricultural Biotechnology, Kyeonggi, Korea; and College of Horticulture, Northwest A&F University, Shaanxi, P.R. China. There are 14 more institutes/groups that have contributed ESTs to the database; however, their contribution was less than 1% of the total EST submissions and hence not detailed in this chapter.

First genomic work on molecular aspects in tea was published by Park *et al*. [26] to describe 588 clones of a subtracted library of tea. Thereafter, Chen *et al*. [27] reported random sequencing of a cDNA library from tea describing 1684 high-quality ESTs. The first winter dormancy-related EST data set at NCBI database was submitted between March 2008–Jan 2009 by the Institute of Himalayan Bioresource Technology, Palampur (accession numbers FF682697–FF682833; GH454303–GH454326; FE942774–FE943102). These ESTs were created by analyzing a subtracted library of tea prepared using RNA of the actively growing (AG) and the winter-dormant (WD) tissue. A prominent difference between the two libraries (Figure 54.1, unpublished work; analyzed on the basis of EST analysis) was the presence of comparatively large "cell rescue, defense and virulence" class (47%) in WD tissue comprising sequences encoding late embryogenesis abundant protein family, dehydrin (*Deh*), and metallothionein-like protein; a larger proportion of "cell rescue and defense" class was also reported in the dormant cambial meristems of *Populus tremula* [28] and the dormant buds of *Quercus petraea* (Matt.) Liebl. [29] and *Rubus idaeus* L. [30]. "Cell cycle and DNA processing" class was the major category (22%) in the AG tissue as evidenced by the large number of sequences for histone proteins. The number of genes involved in

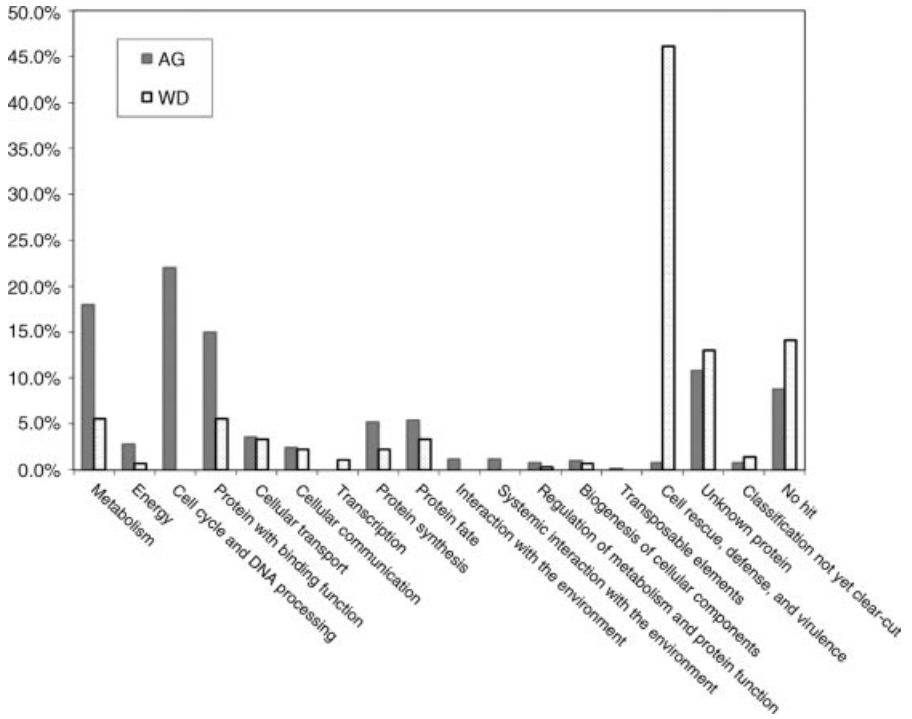

Figure 54.1 Functional classification of clones obtained in subtracted libraries. WD and AG represent the genes upregulated during winter dormancy and the period of active growth, respectively. The clones were grouped into functional classes based on the MIPS classification system [28].

metabolic activity (18%) was six times higher in AG compared to that observed for WD (5.6%). This suggested the need to produce larger amounts of metabolites for the newly forming and dividing cells of the actively growing meristems during PAG. Another dominated class of genes in AG was the "protein with binding function" dominated by *chlorophyll a/b binding protein (CAB)* (54 out of 75 sequences), which accounted for 10.8% of the total sequences in AG. Since CAB is involved in photosynthetic processes, data suggested reduction in net photosynthesis rate and photochemical efficiency of photosystem (PSII) during WD in tea as shown previously as well [19]. The remaining functional classes were comparable in size (in terms of number of transcripts) in AG and WD, though the type of transcript that constituted a particular functional class was different in the two transcriptomes. The combined AG and WD sequences in other functional categories were as follows: energy, cellular transport, cellular communication, transcription, protein synthesis, protein fate, interaction with the environment, regulation of metabolism and protein function, biogenesis of cellular components, transposable elements, and unknown protein.

Analysis of subtracted library also showed that the sequence complexity of the subtracted library representing the genes expressed during WD was less compared to

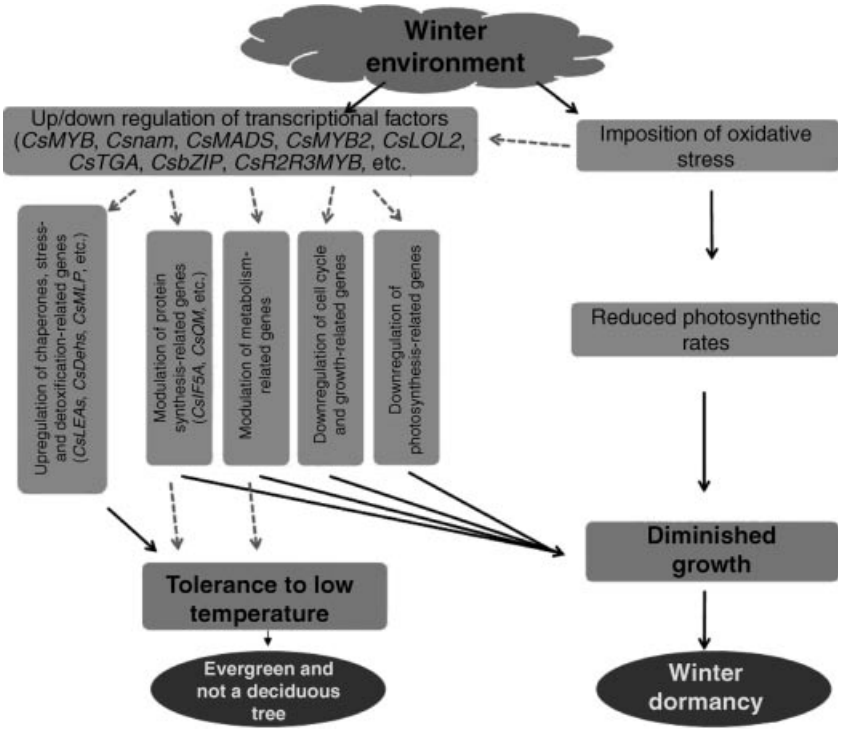

Figure 54.2 Possible mechanism of winter dormancy and evergreen nature of tea tree (19–21; winter dormancy-related ESTs available at NCBI). Solid lines with arrows suggest direct interaction, whereas dashed lines with arrows suggest possible interactions.

the subtracted library representing the genes expressed in AG tissue. Reduced transcriptome complexity during WD might be due to reduction in the number of genes involved in the processes typical for actively growing meristems such as cell division, expansion, and differentiation. For example, a significant reduction in the complexity of the transcriptome in *Populus tremula* L. was observed during cambial dormancy [28]. Thus, the available knowledge on winter dormancy in tea can be summarized as Figure 54.2, which suggests that winter environment-mediated imposition of oxidative stress coupled with reduction in cell division and associated activities might be responsible for winter dormancy in tea. The evergreen nature to this tree species could be attributed to the expression of a large number of genes associated with imparting stress tolerance. These processes might be mediated through several transcription factors.

54.2.2 Drought Stress

Tea is a perennial tree, and as such, encounters a large number of environmental stresses throughout its life span [31]. Drought effect on tea has been reported in

numerous tea growing areas of the world with yield penalty ranging from 14 to 33% [1, 2, 32–36]. Drought also leads to about 6–19% plant deaths depending upon the clone and the severity of the drought [37]. Generally, tea tolerates drought, but at the expense of photosynthates. If the moisture stress prolongs, defoliation and death of plants occurs [35]. Proline accumulation has been shown as one of the mechanisms of drought tolerance in tea; generally, the drought-tolerant clones had significantly higher proline content compared to susceptible ones [38–40]. Though indirect, the data suggest that proline accumulation is related to nonenzymatic detoxification of free radicals [41].

It is expected that with climate change, the main tea growing areas will experience an increase in the length of dry seasons per year and warmer temperatures or extreme rainfall intensity [42]. Thus, drought damages in tea producing regions are expected to increase in the years to come that would lead to greater economic, social, and environmental problems. Tolerance to drought stress is a key factor governing performance of tea in different environments.

Some genetic improvement for water-limited environments has been achieved in tea through breeding and improved crop husbandry. At least part of the slow progress in improving the genetic foundation of dehydration tolerance in tea has been due to a lack of sufficient genetic information about genes that govern this complex trait and its component secondary traits [43]. Research has shown that drought tolerance varies considerably between genotypes of tea [31, 32, 44–47], providing a good basis for investigating the genetic architecture and adaptive responses to water stresses.

Institutes/groups working on tea have realized drought as a major problem limiting productivity and hence the efforts have been to screen the available germplasm for tolerance to drought and to develop germplasm through conventional breeding approaches. For example, Tea Research Association, Tocklai [48], listed 164 clones of tea describing various attributes including response to drought for majority of the clones. TV1, TV17, TV19, TV20, TV23, Garboo parbat 19, Thowra2/11, Bormajan19, and Dhul41 were designated as drought-tolerant clones. Similarly, UPASI Tea Research Foundation [49] recommended clones for drought-prone areas, which include UPASI-2, UPASI-9, ATK-1, TRI-2025, UPASI-20, UPASI-26, UPASI BSS, and BSS-2.

The rapid advances in genomics technologies have led to an increased understanding of global gene expression in plants. As water is lost from the cell, regulatory processes are initiated that adjust cellular metabolism to the new cellular conditions [50]. At the same time, growth inhibition and alterations of developmental pathways will result in changes in gene expression. It is estimated that approximately 12% of the total plant transcriptomes are differentially expressed during water stress [51]. Many of these water deficit-induced genes encode gene products predicted to protect cellular function. Genes that function during changes in metabolism, regulation, signaling, and recognition of stress are also expected to be induced, but fewer of these classes of genes have been identified in tea.

By January 2011, the number of tea ESTs in the National Center of Biotechnology Information (NCBI) database was 13 054 among which 2387 were related to drought. Molecular study on the response of tea to drought was initiated by Sharma and

Kumar [45] reporting three drought-modulated ESTs through differential display of mRNA that represented a PR-5 family, calsequestrin, and novel genes. *PR-5* gene exhibited strong upregulation under drought stress compared to the irrigated control, and in plants during recovery from the drought, suggesting its involvement in the process of drought. Drought also accompanied decrease in nitrogen assimilation in tea as evidenced through downregulation of glutamine synthetase [52].

At least in embryo of tea seeds, proteomic work was carried out to understand the desiccation-responsive proteome [53]. Desiccation-mediated accumulation of hydrogen peroxide was noticed with concomitant increase in the activities of ascorbate peroxidase and superoxide dismutase. Upregulated proteins were associated with defense response, metabolism, and redox status. Data suggested that higher accumulation of ROS that is not efficiently scavenged by increased levels of antioxidant enzymes, impacted seed viability. And hence reduction of ROS was proposed as an efficient way to reduce desiccation damage and improve germination rates. Thus, management of oxidative stress appeared a common strategy either for winter dormancy or for improvement of desiccation stress in tea [19–21].

54.2.2.1 Drought Stress and Catechin Metabolism

Catechins are polyphenols that determine the quality of made tea and particularly for manufacture of black tea, higher catechin content is a desirable feature. Apart from the impact of drought on productivity, there is also an interest to study the impact of drought and the associated cues on catechin metabolism. Drought stress has been shown to impair catechin accumulation in tea (Figure 54.3) and similar was the response to exogenous application of hormone ABA [54–57]. Detailed analysis on various genes of the pathway included work on *phenylalanine ammonia-lyase* (*CsPAL*), *cinnamate 4- hydroxylase* (*CsC4H*), *p-coumarate:CoA ligase* (*Cs4CL*), *flavanone 3-hydroxylase* (*CsF3H*), *dihydroflavonol 4-reductase* (*CsDFR*), and *anthocyanidin reductase* (*CsANR*) [54–58]. *Cs4CL*, *CsPAL*, *CsC4H*, *CsF3H*, *CsDFR*, and *CsANR* exhibited downregulation in response to drought stress and ABA. Gene expression correlated positively with catechin content suggesting that the impact of drought on catechins was at the level of transcript. Lower catechin production under drought stress could be an adaptive feature with the background that higher catechin level (200 μM and above) severely retarded growth and development of plants [59].

54.2.2.2 Molecular Markers for Improvement of Drought Stress

The processes of domestication and selection have resulted in a drastic narrowing of genetic base of majority of crop species [60]. Breeding of such cultivars has led to greater susceptibility of many crops to biotic and abiotic stresses [61]. Furthermore, the genetic bottlenecks arising due to transitions between wild genotypes and landraces to early domestications and then modern cultivars have led to a significant loss of potentially useful genes. The negative impact of utilizing varieties with a narrow genetic base was demonstrated by the fact that of all released clonal teas for commercial use in Kenya, 67% share the same female parent clone TRFK 6/8, which has been observed to be susceptible to root knot nematodes [62]. Furthermore, abiotic and biotic stresses and narrow genetic background may result in huge losses in tea

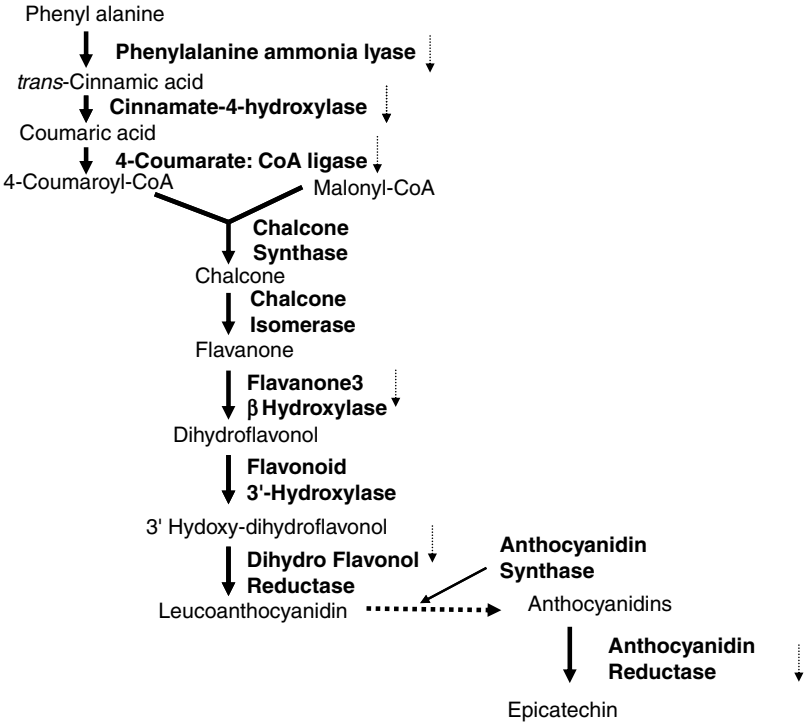

Figure 54.3 Catechin biosynthesis pathway in tea adapted from previous work (55–58). The gene downregulated under drought stress/ABA are marked with ↓.

production. Therefore, there is a thrust for molecular marker-based rationalization of breeding strategy to identify stress-tolerant (biotic and abiotic) and distantly related parents to serve as candidate genotypes for intraspecific and/or interspecific hybridization in the existing gene banks [63]. This strategy will broaden the genetic base as well as introgression of new genes and alleles controlling useful traits that were otherwise missing in the base populations.

Bandhopadhyay [64] discussed current status of various molecular markers that could be employed for genetic improvement of tea.

Most comprehensive molecular fingerprinting studies of 1644 Indian tea accessions in a national network project coordinated by IHBT suggest that the Indian tea gemplasm at national level is highly heterozygous [65]. However, amplified fragment length polymorphism fingerprinting study by Sharma *et al.* [66] revealed considerable genetic diversity (GS) among tea accessions associated with trait attributes [SMP, TRI-2043, UPASI-19, SA-6, and BS-26 (average genetic distance (AGS), 0.56; resistant to blister blight); UPASI-26 and UPASI-27 (AGS, 0.62; resistant to frost); UPASI-1, UPASI-10, UPASI-26, and CH-1 (AGS, 0.53; tolerant to wind); TV-9 (tolerant to waterlogging); and 26 accessions with an AGS of 0.57 (tolerant to drought)]. Overall, 44% genetic diversity was recorded in these accessions. Since these accessions were highly heterogeneous and were clustered in different groups

and subgroups, can be considered as potential parental groups for combing of these traits in quality tea accessions through controlled crossing in future tea improvement programs. These inferences based on AFLP markers, however, can be validated with set of highly polymorphic microsatellite or simple sequence repeat (SSR) markers in near future, as there are about 324 SSR markers that have been reported in tea [67–73]. Realizing the genome complexity, coupled with the reported genetic linkage map length [43, 74], a large repository of microsatellite markers might be required not only to saturate existing genetic maps but also for future quantitative trait loci (QTL) mapping and marker-assisted selection in tea.

Combining abilities and genetic parameters of parental groups for yield, drought tolerance, and quality-related traits in *C. sinensis* suggested significant phenotypic variation in the targeted traits measured among the progeny and their parents [75, 76]. Genetic improvement process would have been much enhanced with the availability of genome wide sequence based microsatellite and single nucleotide polymorphism (SNPs) markers. Quantitative trait mapping, however, will be more efficient if molecular markers were assigned to the linkage groups. Such linkage maps for tea were constructed with random amplified polymorphic DNA and AFLP markers and covered 1349.7 cM, with an average distance of 11.7 cM [74]. QTL controlling yield, drought tolerance, and quality traits (percent total polyphenols), fermentability, theaflavins, thearubigins, and pubescence were studied for initiating marker-assisted selection and breeding in tea [77]. Recently, QTL controlling yield, drought tolerance (DT), and quality traits (percent total polyphenols (%TP), fermentability (FERM), theaflavins (TF), thearubigins (TR), and pubescence (PUB) were studied for initiating marker-assisted selection and breeding in tea [77]. Bulk segregant analysis [78] followed by complete genotyping of a pseudo-test progeny of two heterozygous parental clones for yield, drought, and other important traits identified 260 RAPD and AFLP informative markers. Of these 100 markers that showed 1 : 1 segregation, a linkage map was generated with 30 (19 maternal and 11 paternal) linkage groups that spanned 1411.5 cM with mean interval of 14.1 cM between loci. On the basis of the map, QTL analysis was done on data over two sites. A total of 64 putative QTL controlling various traits across the two sites were detected. Of these, QTL linked to YLD-T, YLD-K, DT-K, and PUB were localized at 2 cM, 2.7 cM, 3 cM, and 1.4 cM from markers OPG-07-2800, E-AGC/M-CAG-725, OPT-18-2500, and OPO-02-650, respectively [77].

54.2.3
Transgenic Approaches for Improvement of Abiotic Stress Tolerance in Tea

Since conventional breeding of tea is highly time consuming and labor intensive, crop improvement by transgenic technology has gained considerable popularity over the recent years [79]. Genetic transformation of tea by *Agrobacterium* and biolistic gun methods were attempted by different workers from all across the world [80–88] and the success ranged from production of kanamycin-resistant callus tissue with strong *gus* expression [89] to transgenic plants with *gus* reporter gene and their transfer to polyhouse [90–92]. Mainly, the availability of well-standardized regeneration systems [93–95] made transgenic tea production by these two methods possible.

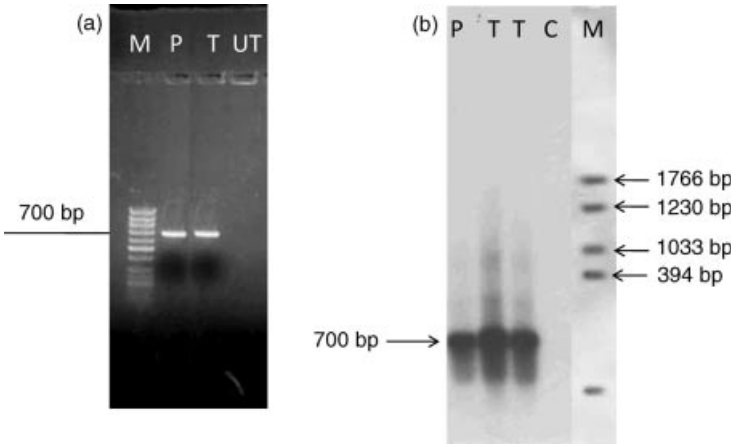

Figure 54.4 (a) Polymerase chain reaction (PCR) amplification of a 700 bp internal fragment of the *osmotin* gene in tea somatic embryos. P, plasmid; T, putatively transformed; UT, untransformed; M, molecular markers [99]. (b) Southern hybridization of *osmotin*-transformed somatic embryos of tea, showing the expected hybridization signals when DIG-labeled osmotin fragments from *Xba* I and *BamH* I sites were used as probes. C, untransformed; T, putatively transformed; P, plasmid harboring *osmotin*; M, molecular markers [99], reprinted with kind permission from Cambridge University Press © 2011.

Methods to overcome the resistance of hosts to *Agrobacterium* infection were also devised and successfully used [96, 97].

These successes opened up an alternative and attractive way of producing tea plants tolerant to abiotic stresses. In this regard, Saini [98] used the biolistic gun method to produce stress-tolerant transgenic plants expressing the *osmotin* gene from *Nicotiana tabacum* cv. White burley. Method optimization included a target distance of 9 cm with burst pressure of 1100 psi to bombard somatic embryos at globular stage of development. These were multiplied in recurrent cycles to produce more than 100 lines of osmotin transformants, which tested positive in both PCR and Southern hybridization (Figure 54.4a and b). When the growth performance of these lines was evaluated, healthier growth and higher multiplication rates were observed compared to either the untransformed control or the ones harboring the *gus* reporter gene. Moreover, when these lines were assessed for their tolerance to abiotic stresses, increased tolerance to desiccation was observed.

Tolerance to desiccation stress is crucial for any developing embryo, particularly in their late maturation stage [100, 101]. This tolerance helps the embryos to remain viable as the mature seeds begin to lose their inherent moisture content and dries up [102, 103]. However, tea seeds are of "recalcitrant type" and have embryos that are highly desiccation sensitive and lose viability on being dried below a critical average of 28% moisture [104]. This is much higher than the level to which most orthodox seeds can be desiccated, that is, 3–5%. Similar to their zygotic counterparts, the somatic embryos of tea are also desiccation sensitive and lack the ability to accumulate

adequate storage reserves during early maturation stage. They also show high frequency of precocious and abnormal germination [105] and are incapable of producing and accumulating sufficient amounts of osmolytes required for cellular adjustments [106]. One way of adapting to abiotic stress is through osmolyte accumulation for membrane stability and osmotic adjustments [107–109]. Thus, tea somatic embryos can serve as ideal system for understanding and devising strategies for overcoming the developmental blocks in recalcitrant type seeds.

In view of this, somatic embryos were used to study the influence of stable integration and expression of *osmotin* gene in the heart or early maturation stage of embryo development. When standard biochemical methods were used, interestingly enough, the somatic embryos showed several fold increase in storage reserves (Figure 54.5a). In contrast, the untransformed somatic embryos without the introduced *osmotin* gene showed poor accumulation of storage reserves. In histochemical studies also, *osmotin*-transformed heart-stage somatic embryos showed abundant depositions of starch, proteins, and also oils in the form of numerous droplets. On the other hand, the untransformed control and the somatic embryos with *gus* and *npt*II genes showed negligible or significantly lower depositions of starch, proteins, and oil globules (Figure 54.5b).

The effect of desiccation on the *osmotin*-transformed somatic embryos was also assessed by first desiccating the somatic embryos in open Petri dishes in laminar hood cabinet for 60 min and then germinating them on basal MS medium supplemented with 1 g/l L-glutamine, 3% sucrose, 0.2 mg/l BA, and 0.1 mg/l IBA as per the method of Bhattacharya *et al.* [110]. A distinct increase in osmotin transcript

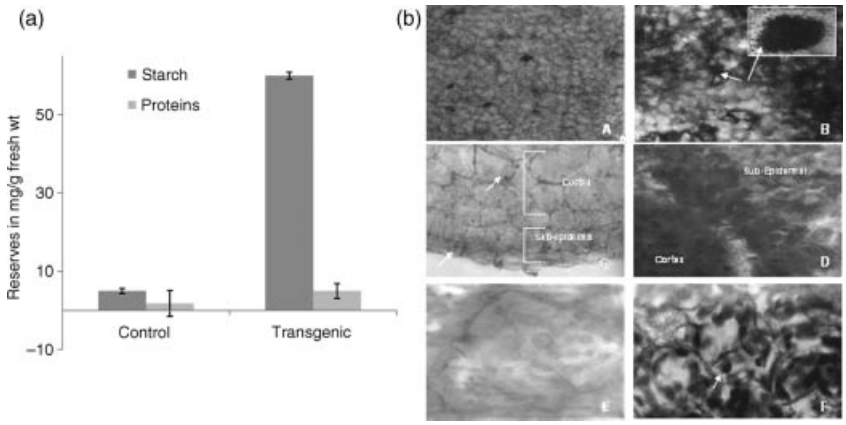

Figure 54.5 (a) Accumulation of reserves in untransformed control and *osmotin*-transformed somatic embryos during heart or early maturation stage of development. (b) Histochemical sections of somatic embryos at heart or maturation stage showing accumulation of storage reserves (A, C, and E) control and (B, D, and F) somatic embryos transformed with *osmotin* gene [99], reprinted with kind permission from Cambridge University Press © 2011).

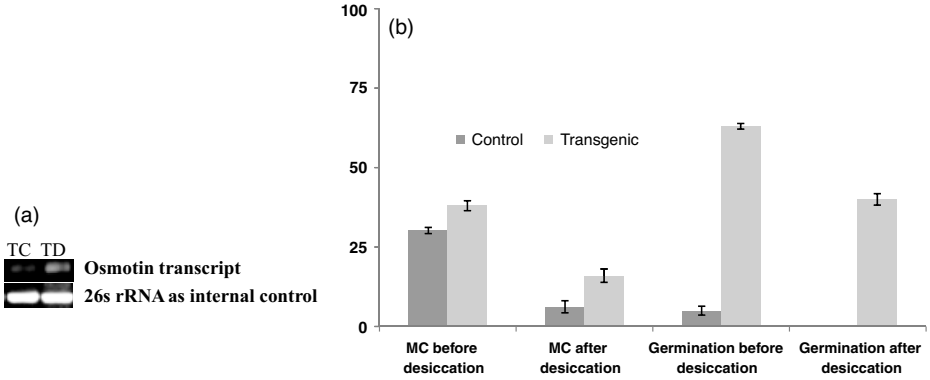

Figure 54.6 Effect of desiccation on the (a) accumulation of *osmotin* transcripts and (b) moisture content and germination of somatic embryos transformed with *osmotin* gene as compared to untransformed control [99], reprinted with kind permission from Cambridge University Press © 2011.

accumulation was observed in the desiccated osmotin transformants compared to the nondesiccated ones (Figure 54.6a). The consequent germination of the *osmotin* transformants was then compared with that of desiccated untransformed control, and also *gus* transformants. The results revealed 40% normal germination in the *osmotin* transformants after 60 min of desiccation, whereas the untransformed control somatic embryos failed to germinate after desiccation and died (Figure 54.6b). However, the germination of the undesiccated *osmotin* transformed somatic embryos was higher, that is, 57–63%, and that of untransformed control and *gus* transformants ranged between 1–5%. The critical moisture content (MC) of the *osmotin*-transformed somatic embryos as influenced by desiccation was also assessed (Figure 54.6b). While the lowering of MC below 20% resulted in total loss of germination capacity in the untransformed control and *gus* transformants, reduction in germination was recorded only in the *osmotin*-transformed somatic embryos. Certain degree of desiccation tolerance was indeed conferred by the introduced *osmotin* gene. This is not surprising because the cationic protein, osmotin, is known to bring about cellular adjustments through osmolyte accumulation and subsequent increase in tolerance to different stresses including the desiccation [111, 112]. These findings revealed that introduction of gene(s) that confer tolerance to abiotic stresses into somatic embryos of plants with recalcitrant seed types can be an important step toward engineering desiccation tolerance, reserve accumulation, and normal germination.

The plants generated from these osmotin-transformed somatic embryos were healthy and grew well under contained polyhouse conditions (Figure 54.7). When the shoots from such plants were subjected to osmotic stress induced by 5–20% polyethylene glycol, the transgenic leaves were more tolerant to PEG-induced osmotic stress in leaf disk assays (Figure 54.8a). While transgenic shoots recovered rapidly from PEG-induced osmotic stress, the untransformed control failed to do so.

Figure 54.7 Transgenic plants growing under contained poly house conditions.

Furthermore, when the PEG-stressed shoots were analyzed for stress tolerance, they showed increased accumulation of osmolytes such as raffinose and sucrose compared to untransformed control (Figure 54.8b).

These findings opened up a whole new way of developing tea plants with improved traits for better yield and quality. This is important because it will be now possible to utilize the transgenic technology for tea crop improvement, particularly with respect to drought, pests, and blister blight disease. Transgenic technology can also be used effectively for combating major reductions in yield due to winter dormancy, a problem experienced by many tea growing countries of the world.

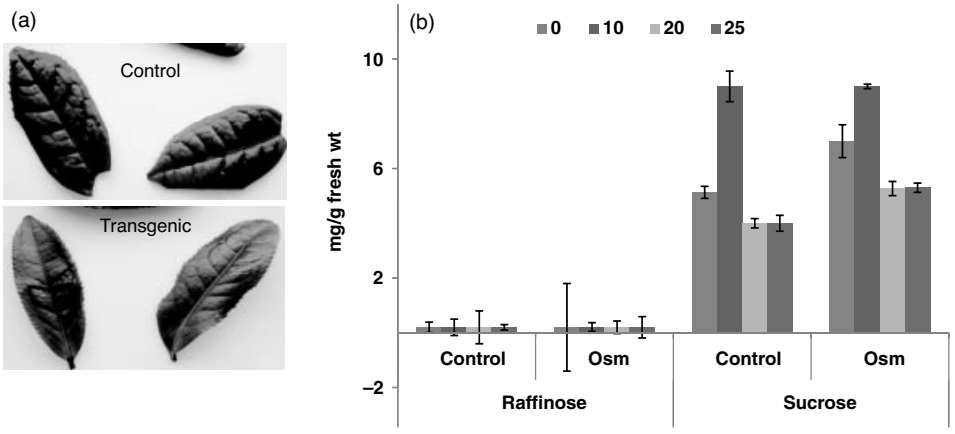

Figure 54.8 Response of untransformed control and transgenic plants to osmotic stress: (a) senescence of leaves at 20% PEG, (b) accumulation of osmolytes in response to increasing concentrations of PEG.

54.3 Areas for Future Research

Several books such as those by Barua [1], Wilson and Clifford [113], and Jain [2] combined together provided a global account on tea science. Palni *et al*. [114] reviewed various aspects of tea biotechnology covering *in vitro* propagation and its application, genetic transformation, artificial seeds, secondary metabolism, and biofertilizers. However, given the recent developments in the area of genomics, metabolomics, proteomics, and systems biology, tea needs enormous attention since research on this crop is still in its infancy.

1) Dormancy accompanies reduced rate of cell division and cell growth while dormancy release and vegetative bud growth is associated with the action of specific hormones and often accompanied by increased cell division [115–118]. Therefore, emphasis may be laid upon to understand the phenomenon of winter dormancy *vis-à-vis* cell cycle. For example, cell division is represented by a continuous cycle of "phases" G1, S, G2, and M phase. In dormant bud of potato, the cells are arrested in the G1 phase before the S phase of the cell cycle [116]. During dormancy release, upregulation of genes, such as D-type cyclins (CYCD) and histones [115, 117, 118], has been reported. From S phase, cell division proceeds to G2-M phase, which requires induction of the B-type cyclins (CYCB) and the cyclin-dependent kinase B (CDKB) gene [119].

   The plant hormones, auxin, cytokinin, and gibberellic acid, were implicated in expression and/or stability of CYCB and CDKB [120]. CYCB interacts with CDKB and initiates phosphorylation, activation of proteins, and expression of genes required for cytokinesis [121]. Abscisic acid induces expression of the p27CIP/KIP orthologue ICK1, an inhibitor of CDK action at the G1-S-phase transition [122]. Commitment to reenter the cell cycle is usually regulated at the G1-phase restriction point and is linked to protein kinase phosphorylation/dephosphorylation cascades, which are in turn activated by plasma membrane signaling machinery responsive to environmental or hormonal cues [123].
2) Another potent area would be to understand DNA methylation changes during winter dormancy. Along with the changes in gene expression, there are evidences for more general epigenetic changes associated with induction and release of endodormancy. Changes in DNA methylation and multiacetylation of histone have been observed during the induction and breaking of dormancy in potato buds [124, 125]. Increased DNA methylation following induction of dormancy suggested that chromatin remodeling might play a role in regulating bud dormancy. An intriguing observation was the strong induction of an aspen homologue of *FERTILISATION INDEPENDENT ENDOSPERM* (*FIE*), a polycomb family protein, during cambial dormancy [28]. *FIE* is believed to act as part of a complex that silences the transcription of genes necessary for proliferation through modification of chromatin structure [126, 127].
3) Yet another area would be combining kinematic approach [128] with transcriptomic, metabolomic, and proteomic experiments to unravel the important

processes such as mechanism of root growth under water stress [129]. For example, in soybean, three contiguous regions with distinct elongation characteristics can be identified in roots: (1) those where the elongation is maintained even under sever water stress (apical region), (2) the region where elongation takes place maximally under unstressed conditions but progressively inhibited under water stress, and (3) the regions where the growth decelerated in well-watered roots and was completely inhibited under water stress [130]. In such a situation, rather analyzing the whole root, which would give an average of event, it was essential to focus zone wise and analyze the proteome and transcriptome response. Indeed, the data showed differential proteome composition at these sites; enzymes related to isoflavonoid biosynthesis showed increased abundance in apical region, which was also positively correlated with increase in isoflavonoid content that possibly contributed to growth maintenance. Interestingly, region 2 was characterized by upregulation of caffeoyl-CoA *O*-methyltransferase, which is involved in lignin synthesis. Enhanced accumulation of lignin would lead to the inhibition of growth in this region. Similarly, Spollen *et al*. [131] studied transcriptome changes in these regions in maize tissue, wherein an increased expression of transcripts both for wall-loosening proteins in apical regions and for elements of ABA and ethylene signaling was evident under water stress.

4) Systems biology is yet another emerging approach to tackle various processes in tea. In a recent systems biology approach to unravel the underlying molecular program of apical bud development in poplar, combined transcript and metabolite profiling has been applied to a high-resolution time course from SD induction to dormancy [132]. Analysis of metabolite and gene expression dynamics allowed to reconstruct the temporal sequence of events during bud development. Importantly, to each of the following processes, bud formation, acclimation to dehydration and cold, and dormancy, specific sets of regulatory and marker genes and metabolites have been associated, which could provide a reference frame for future functional studies and for genetic approaches to assess adaptation of trees to climate change. Interestingly, the identification of a large set of genes commonly expressed during the growth-to-dormancy transitions in poplar apical buds, cambium, or *Arabidopsis* seeds suggested parallels in the underlying molecular mechanisms in different plant organs [133].

   Availability of high-throughput sequencing platforms by Solexa (Illumina, USA), 454 (Roche, USA), and SOLiD (Applied Biosystems, USA) offers opportunities to understand transcript/pathway shift in response to environmental cues. Novel genes and the pathways thus generated might help to improve the genetic potential of tea, particularly under the stressfull environment of drought, cold, or waterlogging. Even it would be important to decipher the performance of tea, both qualitatively and quantitatively, under the climate change scenario.

5) Deciphering the role of microRNA (miRNA) under abiotic stress could be yet another potent approach to decipher and improve tolerance in tea to abiotic

stress. MicroRNAs have been shown to participate in several plant processes including development, hormonal regulation, and response to environmental cues [133]. For example, miR159 was identified as a potent stress-responsive miRNA, and it also regulated the expression of transcription factors AtMYB33 and AtMYB101 [134]. Another stress-responsive and well-studied miRNAs were miR396 [135] and miR169 [136]. Tea offers opportunity to discover novel miRNAs that might be useful not only for tea but also for other crops.

6) Recent advances in DNA sequencing technologies have enriched genome-wide microsatellite and SNP markers. High-density SNP genotyping increased interest in genome-wide association (GWA) studies for the dissection of complex genetic traits in a number of crop plants including outbreed crops. Recent AFLP fingerprinting of 1644 tea accessions has led to identification of a set of core collections in Indian tea germplasm. Furthermore, sequencing of core collections with high-throughput next-generation sequencing will help generation of high-density genome-wide SNP data and will enable genome-wide association studies in tea for important traits including drought tolerance.

Acknowledgments

Authors thank Council of Scientific and Industrial Research (CSIR), India; Department of Biotechnology, Govt. of India; Indian National Science Academy, New Delhi, India; and National Tea Research Foundation, India for funding various projects on tea. Authors also thank Richard Chalo Muoki for his help. The work of some researchers might not have been reflected in this chapter due to space constraints.
