Foreword I

We are guests of green plants on this planet. Plants are a source of food, fiber, and materials for shelter. Ornamental plants contribute to our esthetic environment. Numerous plants are sources of pharmaceuticals. Our civilization developed progressively after the domestication of plants about 10 000 years ago. Since then plants were constantly improved through conscious and unconscious selection by ancient farmers for more than 9000 years. During the last century, crop improvement became a scientific endeavor after the rediscovery of Mendel's laws of inheritance. The science of genetics provided many additions to plant breeder's tool kit and major advances in food production were made. Green Revolution is a shining example of these advances. It has been possible to feed 6 billion of Earth's inhabitants.

Human population continues to increase unabated. It is estimated that there will be 9 billion people on this planet in 2050 and this will require doubling of food production. To meet this challenge, we must increase the yield potential of our food crops and close the yield gap. The average yield of most crops is about half their potential yield. For example, yield potential of rice is 10 ton ha^{-1}, but farmers on average harvest about 5 ton ha^{-1}. This yield gap is due to losses caused by biotic and abiotic stresses. Abiotic stresses include drought, submergence, salinity, and unfavorable temperatures.

Very little progress has been made in developing crops with tolerance to abiotic stresses through conventional breeding approaches. Breakthroughs in molecular biology and biotechnology have provided new tools such as molecular marker-aided selection (MAS) and genetic engineering. These technologies have opened new avenues for developing crops with tolerance to abiotic stresses.

Editors of this volume have done an admirable job of assembling a wealth of information on these new approaches for crop improvement. They have sought contributions from knowledgeable authors from all over the world. The number of crops included in the volume is comprehensive. These include grain, oil, fruits, vegetable, and ornamental crops and sugarcane, tea, tobacco, and cassava. Several chapters provide overview of latest advances in molecular biology such as genomics, transcriptomics, proteomics, and metabolomics, collectively called "omics." There is

an excellent chapter on the role of plant transporters in abiotic stress tolerance. The chapter on improving crop productivity under changing environment is a welcome addition in view of concerns about the impact of climate change on crop productivity. This comprehensive volume should prove useful for basic researchers, plant scientists, and students interested in crop improvement, as well as teachers.

I would like to congratulate the editors for their labor of love for preparing this valuable scientific resource.

Davis, California, USA

Gurdev S. Khush, FRS

Foreword II

Together with other photosynthetic organisms, plants are the primary producers and the foundation of the global biogeochemical cycles that sustain terrestrial life. As such, plants are also the main biological resource for humans by providing food, feed, and various biomaterials such as oils, fibers, and wood. Taking into account population growth, urbanization, climate change, and the limitation of natural resources, global food security has become a strategic challenge just half a century after the "Green Revolution." There is a need for higher stability of yield to ensure global food security and repartitioning and lowering the prices of plant products. Moreover, the need to cut CO_2 emissions and the foreseeable end of the oil era makes the transition from conventional fossil fuels to alternative and renewable resources a priority, resulting in a growing demand for plant biomass for alternative energies and green chemistry.

Agriculture is also challenged by increasing urbanization and industrial pollution, resulting in the overexploitation of fossil resources, water, and arable land. Seventy percent of freshwater is used for irrigation, making water one of the most critical parameters in plant production. The predictions in climate change for this century are estimated to further negatively affect water supplies and agricultural productivity leading to the potential amplification of catastrophic incidents. Forty percent of the Earth's land surface is now used for agriculture. However, this area cannot be enlarged and instead, we foresee a reduction in arable land due to urbanization, pollution, and climate change in the next decades. If this was not enough, the world population will reach 9.2 billion by 2050, revealing that food production will have to double and farm productivity to increase by 1.75% each year.

In the face of these challenges, there is an urgent need to develop new crop lines that can perform better but under conditions of less water, less nutrient inputs, and by better withstanding abiotic and biotic stresses. This book, edited by Drs. Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja, comes at the right time to tackle the problems plants face under abiotic stress conditions and will clearly be of major value for researchers and breeders. The editors have achieved to assemble a number of experts that share their knowledge in a very complementary

way. The volume thereby provides both an excellent overview and a detailed account of the field of plant abiotic stress response mechanisms. Importantly, the contributions range from established concepts in model plants to applied questions in specific crops. The book thereby will enlighten readers of various disciplines and at various levels, bridging text book knowledge to application.

Paris *Heribert Hirt*

Contents

Preface

World population is expected to increase from the present ~7 billion to ~10 billion by the year 2050; therefore, a critical question that needs to be asked is whether the rate of increase in crop yield would be sufficient to feed all the people. For example, the average world cereal yield will need to reach 5 ton ha^{-1} from its present 3 ton ha^{-1} to maintain population growth (FAO). On the other hand, the crops' productivity is continuously decreasing year by year due to the negative impact of various environmental stresses. The abiotic stress factors such as heat, cold, drought, salinity, wounding, heavy metal toxicity, excess light, flooding, high-speed wind, nutrient loss, anaerobic conditions and radiations are the key elements limiting agricultural productivity worldwide. For example, the continuous increase in only salt and water stress can lead to 50% loss of arable lands by the year 2050, which will lead to a significant decrease in crop production and ultimately will cause losses worth hundreds of millions of dollars each year. Therefore, increased water-use efficiency and salt tolerance are important challenges for agricultural production in an ever-decreasing area of arable land. Global warming and climate change indicate that in the future there may be more extreme weather events triggering flooding and extreme temperature. Managing risks from extreme flood and temperature events will be a crucial component of climate change adaptation. It is, therefore, of utmost importance to develop and implement techniques that enhance the crop productivity in the presence of continuous stress. Overall, the biotechnology and genetic engineering play important roles in innovative economy and is crucial in addressing global changes such as population growth and climate change. The transgenic approaches could be one of the fastest ways to produce GMOs that can tolerate the stress and can produce good yield in the presence of continuous stress. But the crops classified as GMO will have to undergo a costly authorization process, which involves extensive risk assessment for human and animal health and the environment. This is a lengthy process, and also the public acceptance for GMO products on the market is much lower compared to conventional or organic ones, which could be attributed to the nonawareness among the general public, media, and NGOs. However, the biotech crops could be as safe as conventional crops because in those countries where transgenic crops have been grown, there have been no verifiable reports of health or environmental harm (UN FAO). Overall, the improvement of

crop resistance to the stresses is very essential these days in order to cope with the upcoming problem of food security.

In this book, "Improving Crop Resistance to Abiotic Stress," we present a collection of 54 chapters written by more than 180 experts in the field of crop improvement and abiotic stress tolerance with special emphasis on crop plants. The book is divided into two volumes, each containing 27 articles. It is a timely contribution to a topic that is of eminent importance. The included chapters provide a state-of-the-art account of the information available on crop improvement and abiotic stress tolerance in crop plants. In this book, we present various approaches for improving crop resistance to abiotic stress.

Volume 1 containing Chapters 1–27 has been divided into two parts, "Part I Introduction to Plant Abiotic Stress Response" and "Part II Methods to Improve Plant Abiotic Stress Responses: Section II A Introductory Methods and Section II B Omics" and Volume II containing again 27 chapters, from 28 to 54, is further divided into "Part III Species-Specific Case Studies: Section III A Graminoids; Section III B Fruit and Vegetable Crops; Section III C Vegetable Crops: Solanaceae; Section III D Oil Crops Including Brassicas; and Section III E Other Crops." The Part I of Volume I deals with the understanding of commoneome operatives in response to various abiotic stresses in plants; industrial perspective of abiotic stress tolerance; ROS generation and scavenging under abiotic stress; salinity as major crop constraint; cold and abiotic stress signaling; sulfur dioxide toxicity and tolerance and excess soil phosphorus and remediation strategies, whereas Part II of the same volume covers various chapters under Section IIA that includes past, present, and future of genetically modified crops and translational biology approaches for abiotic stress tolerance. Section II B deals with the functional genomics of drought tolerance in crops; transcriptomic and metabolomic approaches for freezing tolerance and cold acclimation; overview of omics techniques in crop research and *Arabidopsis*; functional genomics and computational biology tools for gene discovery for abiotic stress tolerance; overview of transcriptomics and proteomics approaches for stress-responsive mechanisms; plant tissue culture and genetic transformation for crop improvement; systems-based molecular biology analysis of resurrection plants; molecular breeding for abiotic stress using halophytes; helicases for abiotic stress tolerance; transcription factors in general and MYB transcription factors for improving abiotic stress in plants; transporters in general and potassium and sodium transporters for improving abiotic stress tolerance in crop plants; fungus (*Piriformospora indica*) assisted abiotic stress tolerance; microRNA-mediated stress resistance in crop plants and polyamines in developing stress-resistant crops.

Volume II of the book starts with Part III "Species-Specific Case Studies: Section III A Graminoids," which uncovers the importance of various approaches such as functional genomics, omics, genomics-assisted breeding, physiological and molecular approaches for abiotic stress tolerance, and crop improvement in wheat, rice, maize, barley, sugarcane, and sorghum. Section III B covers different approaches like omics, grafting for improving crop productivity and abiotic stress tolerance of various vegetable crops such as chilli pepper, onion, soybean, chickpea, and peanut and fruit crops such as cassava. Section III C focuses on tomato, potato, and tobacco

for improving crop productivity and understanding the mechanism of abiotic stress tolerance. Section III D specifically deals with oil crops including Brassicas where various means to improve crop productivity and abiotic stress tolerance in oil crops such as sunflower, sesame, *Jatropha curcas*, and *Breassica* crop species including mustard have been included. Section III E includes genetic improvement approaches for drought tolerance in cotton with present status and research needs, and present status and strategies to improve abiotic stress tolerance in tea.

The editors and contributing authors trust that this book will provide a practical update on our knowledge of improving crop resistance in various crop plants and lead to new discussions and efforts to the use of various tools for the improvement of crop productivity.

We are highly thankful to Dr. Ritu Gill, Centre for Biotechnology, MD University, Rohtak for her valuable help in formatting and incorporating editorial changes in the manuscripts. We would like to thank Prof. Gurdev Singh Khush, University of California, USA, and Prof. Heribert Hirt, Paris, for writing the foreword and Wiley-Blackwell, Wiley-VCH Verlag GmbH & Co. KGaA Boschstr., Weinheim, Germany, particularly Senior Publishing Editor, Life Sciences, Gregor Cicchetti, Project Editor Books, Anne du Guerny, and Nitin Vashisht, Account Manager, Thomson Digital, for their support and efforts.

Part I
Introduction to Plant Abiotic Strees Response

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja
© 2012 Wiley-VCH Verlag GmbH & Co. KGaA. Published 2012 by Wiley-VCH Verlag GmbH & Co. KGaA.

1
Understanding the "Commoneome" Operative in Plants in Response to Various Abiotic Stresses

Hemant R. Kushwaha, Sneh L. Singla-Pareek, Sudhir K. Sopory, and Ashwani Pareek

Environmental conditions do play a major role in the overall development and productivity of various crop species, but the exact relationship between the two has not been clearly defined. One of the major limiting factors in today's agriculture is salinity, which has not only led to loss of crop productivity but has also surmounted the economical loss. Various transgenic approaches have been undertaken to identify and establish the association between the stress tolerance of various crop plants and their environment. But limited success has been achieved because of the complex interplay of various genes and gene families in stress tolerance mechanism. Latest technological advancements such as genome sequencing and high-throughput expression profiling experiments have produced large amount of data, which can assist in elucidating stress responsive network of various genes and gene families related to stress tolerance. A newly established area commonly known as comparative genomics has laid the foundation for comparing various contrasting cultivars, in order to understand the mechanism of differential tolerance and susceptibility. A "commoneome" between various plant species can fill the gaps that have till now inhibited the knowledge of complex interplay of various genes. Earlier, commoneome between *Arabidopsis*, rice, and common ice plant has been analyzed, but in order to have a broader perspective, commoneome has been worked out from the barrier of monocot/dicot divide. Thus, this chapter would not only benefit the identification of newer gene families in plant species but also assist in hypothesizing various transgenic varieties with better stress tolerance.

1.1
Introduction

Plants, due to their sessile nature, often have to deal with diverse environmental stresses. Productivity of various crop plants is critically affected due to prevailing stress conditions [1]. Although poorly understood, the relationship between crop productivity and stress is of great biological, agricultural, and economic importance. One of the major stresses that limits the crop productivity is salinity, contributed largely by NaCl [2]. According to an estimate, about 8 million hectares of agricultural

Improving Crop Resistance to Abiotic Stress, First Edition.

land in the world is exposed to salt stress conditions [3]. Despite the intensive technological advancements and management practices, modern-day agriculture is strongly influenced by salt stress. Therefore, an approach to increase the level of crop stress tolerance by activating a stress-responsive signal transduction pathway in transgenic plants seems to be a promising approach [4–7]. Owing to lack of precise knowledge about molecular and genetic basis of stress response, understanding the complex mechanism of the stress tolerance is still an arduous task.

Several processes in plants such as carbon metabolism, ion partitioning, energy metabolism, and growth have been observed to get affected by salt stress [8]. The mechanism of salt stress tolerance in various crop plants is hypothesized to be controlled by a large number of genes, which are further regulated by complex networks [9–11]. Hence, traditional breeding and marker-assisted breeding approaches have been used in the past, but they had limited success in terms of improving salt stress tolerance among various crop species. On the other hand, substantial efforts have been made using transgenic approach to understand, characterize, and improve salt stress tolerance, which also yielded limited success [12–15]. Many physiological and molecular biology studies carried out in recent past have generated many hypotheses by interpreting correlative evidence from many species based on biochemical and biophysical principles that govern stress tolerance [16]. Therefore, an analytical approach is required that can emphasize on the multigenicity of stress response and assist in developing crops tolerant to salt stress.

Genomics is one of the approaches considered to lay emphasis on the integrated analysis of stress-dependent behavior of the entire set of genes of a plant. It basically integrates traditional area of genetics analyzed with the help of bioinformatics tools and could possibly serve as a bridge between molecular biology and whole-plant physiology, agronomy, and crop breeding [11, 17]. The area of genomics has proven to be crucial in understanding the functional role of genes and their evolutionary history. It has been useful in identifying functionally important regions and deals with the study of complete genomes, particularly the set of techniques, analytical methods, and scientific questions related to the study of complete genomes.

In recent years, we have witnessed spectacular advances in functional genomics such as completion of the various genome sequencing [18, 19] and high-throughput expression profiling experiments [20] that have generated a large amount of data. This has led to the development of various computational approaches to analyze and predict unknown genes and gene families responsible for various responses. Also, with the assistance of computational genomics, genes responding to various environmental stimuli can be characterized and mapped on the whole genome, providing the essential foundation for more detailed analysis and thus elucidating the stress-responsive network of genes. Various attempts have been made earlier where genomics has laid the foundation for detailed analysis of various gene families performing diverse functions (Table 1.1).

Various specialized branches of genomics have now been used in order to develop a complete framework for understanding the complexity of stress response and tolerance. Classical genomics, which is related to the identification of various genes,

Table 1.1 List of gene families analyzed in various plant systems using genomics and expression profiling.

Gene Family	Function	Reference
CesA	Synthesis of wall	[21]
Lipocalins	Modulation of cell growth, metabolism, membrane biogenesis, and repair, induction of apoptosis, and environmental stress response	[22]
SAURs	Early auxin-responsive genes	[23]
Cysteine-rich antimicrobial peptides	Innate defense against pathogens	[24]
Calmodulin	Regulating cellular responses to stimuli by playing critical role as Ca^{2+} transducers	[25]
F-box	Critical for the controlled degradation of cellular proteins	[26]
Homeobox genes	Regulating plant growth and development	[27]

their structures, and localization on whole genomes can assist in developing various QTL maps and analyze linkage of salt stress-responsive genes. Functional genomics approach using various techniques such as microarray, SAGE, and so on can help in understanding the plethora of stress-responsive genes, while statistical genomics assists in analyzing the quantitative data obtained using intensive statistical methods. Comparative genomics is the one promising approach that is now-a-days used by a large number of research groups (Table 1.2), for understanding the mechanism of differential tolerance and susceptibility [28].

In our earlier study, we took a closer look at the transcriptome data obtained from various microarray analyses and thus reflecting the "commoneome" in *Arabidopsis*, rice, and common ice plant [36]. With the aim of underlining the commonality and differences in gene expression profiles, we have extended this study to other crop species, namely, maize, sorghum, and poplar and thus extended the commoneome in view of monocot/dicot divide. Furthermore, a general comment on the above-mentioned species related to their genome-related studies has also been made in order to shed light on the transcriptome analysis with respect to pre- and post-sequencing efforts.

1.2 Genomics-Based Studies in the Model Dicot Plants

1.2.1 Arabidopsis

Approximately two decades ago, *Arabidopsis thaliana*, a member of mustard family (Cruciferae or Brassicaceae), was accepted as a model plant for various plant biology

Table 1.2 List of some of the gene families analyzed using comparative genomics approach in various plant genera.

Gene family	Organism compared	Function	Reference
PDI	*Arabidopsis*, rice and maize	Formation of proper disulfide bonds during protein folding	[29]
PEBP	*Arabidopsis*, rice, maize, wheat, sorghum	Act on the control of flowering time	[30]
APx	*Arabidopsis* and rice	Catalyze the conversion of H_2O_2 to H_2O, using ascorbate as the specific electron donor in this enzymatic reaction	[31]
Dof	*Arabidopsis*, poplar, and rice	DNA binding with one finger domain transcription factor	[32]
TCS	*Arabidopsis* and rice	Signaling	[33]
Endo-β-mannase	*Arabidopsis*, poplar, and rice	Function in seed germination and other plant biological processes	[34]
CBS	*Arabidopsis* and rice	Probable role in salt stress response	[35]

studies, mainly due to its short generation time, small size, and a relatively small nuclear genome. The full-length 130 Mb sequence of *Arabidopsis* genome was made publicly available in 2000 [18]. Since then, *Arabidopsis* has come a long way in the area of plant biology research and has led to characterization of many plant genes and gene families. The observed synteny of *Arabidopsis* genome with other plant genomes such as rice, *Medicago*, and so on has assisted in the characterization of various stress-responsive genes, pathways, and processes in other plant species. Various genetic and molecular analyses of *Arabidopsis* mutants have shed light on various processes related to stress response and tolerance that were shadowed for long, in various plant species. Research groups around the world have been extensively involved in analyzing the plant system through *Arabidopsis*. Expression profiles pertaining to the physiological status of *Arabidopsis* such as time series data related to development, manipulative treatments, various stress treatments, and genetic intervention, obtained using microarray, have been made publicly available by *Arabidopsis* information resource (TAIR) (see www.arabidopsis.org) [37].

Transcriptome analysis using microarray data has revealed the relationships among stress-regulated transcripts and has enabled the prediction of their *cis*-regulatory elements [38, 39]. The correlation between expression profiles and the 5′ regulatory motifs of stress-regulated genes has been analyzed comprehensively [40]. In a recent analysis, osmotic stress-responsive genes have been identified in *Arabidopsis* [41]. Zeller *et al.* [42] have used whole-genome tiling arrays to analyze stress-induced changes with respect to salt, osmotic, cold, and heat stress, as well as ABA treatments, in the *Arabidopsis* transcriptome. With such a host of information

available on *Arabidopsis*, plant researchers can take advantage to develop a comparative view of the genome-based studies and contribute to engineering-improved crops with desirable and sustainable traits.

1.2.2 Common Ice Plant

One of the facultative halophytes, *Mesembryanthemum crystallinum*, known as common ice plant (because of its icy look due to enlarged bladder cells of leaf epidermis), has been accepted as another model plant for studying salinity stress responses at physiological, biochemical, and gene levels. Upon exposure to salinity, this facultative halophyte switches from C3 mode to CAM mode of photosynthesis. The other mechanism that helps common ice plant to adapt to salt stress condition involves synthesis and cytoplasmic accumulation of osmoprotective metabolites and accumulation of sodium in the vacuolar compartment [43]. Golldack and Dietz [44] suggested that the adaptation of the common ice plant to increased salinity is not because of its general and uniform cell response to stress, but because the response is a complex multicellular whole-plant response that depends on intercellular signaling processes. Comprehensive genomic analyses of salt stress-regulated genes have been performed in common ice plant [45]. Analysis shows that leaf tissues of well-watered and salinity-stressed common ice plant express ~15% more functionally unknown genes than the unstressed plant [46]. Recent analysis has established an extensive catalog of gene expression patterns in common ice plant that looks into the complex, transcriptional hierarchies that govern CAM-specific expression patterns [47].

1.2.3 Tomato

Tomato (*Solanum lycopersicum*), a member of Solanacae family, is one of the other major economic crops. The inherent features of tomato, such as diploidy, modestly sized genome (950 Mb), tolerance of inbreeding, amenability to genetic transformation, and availability of well-characterized genetic resources, makes it an important crop species for genetic and molecular research in Solanaceae [48]. In an initiative funded by National Science Foundation Plant Genome, EST sequences in tomato were made publicly available (http://www.tigr.org/tdb/tgi/lgi; http://www.sgn.cornell.edu) [48, 49]. According to an estimate, tomato genome has ~35,000 genes, considerably more than the 25,500 genes in the well-studied *Arabidopsis* genome. It has been predicted that tomato has diverged from the lineage leading to *Arabidopsis* approximately 150 million years ago (MYA). Through the comparative genomics approaches, it was observed that the majority of the tomato genes (70%) have significant matches to *Arabidopsis* genes, therefore, reflecting conserved gene functions [48]. Analysis of tomato genome, based on probing random cDNAs on genomic DNA gel blots, showed that ~47% of the tomato genes belong to multigene families [50]. In an analysis, correlated expression profile for 6758 genes across 25 different tomato tissues has been made and is compared to *Arabidopsis* and grape

tissues to identify differentially expressed and tissue-specific genes [51]. The cultivated tomato is essentially classified as a moderately salt-sensitive plant [52]. It has been considered that the salt stress response in tomato is regulated by a complex genetic mechanism [53]. Under salt stress conditions, tolerant genotypes of tomato maintain inner cellular osmotic status by accumulating higher content of inositol and sugars in their leaves [54]. Transcript profiling in tomato has shown that salt stress affects many pathways in the crop plant [55, 56]. Recently, a molecular mechanism for salt tolerance/sensitivity has been proposed using a comparative analysis between salt-treated and nontreated leaves of tomato [57].

1.3 Genomics-Based Studies in the Model Monocot Plants

1.3.1 Rice

Owing to the whole-genome sequencing and worldwide popularity, rice (*Oryza sativa*) is considered an important model crop among monocots for genomic analysis. For its small genome (430 Mb) and predicted high gene density, rice is considered an attractive target for cereal gene discovery efforts and genome sequence analysis [19]. The completion of the genome sequence of rice in 2005 has given plant biologist a platform to characterize various genes and genomes playing vital role in various stress responses and tolerance [58]. Even though rice is generally considered to be salt sensitive, there is huge genetic variation for salt tolerance at critical stages in the cultivated gene pool [59, 60]. Rice salt sensitivity varies considerably across cultivars, and this feature has been exploited to identify novel genes and proteins that contribute to salt stress tolerance [61]. Some traditional cultivars and landraces of rice are more tolerant toward various abiotic stresses. These tolerant varieties can be considered good source for the resistant traits [62]. Comparing the genetic variation in salt-sensitive and salt-tolerant varieties can aid in understanding the salt-tolerant behavior of the crop plant. Transcriptomics approaches have been used to identify differentially regulated rice genes in response to salt stress for shoots [2, 63–65] and roots [66] and by comparing rice with other cereals [67].

1.3.2 Maize

A member of Poaceae family, maize is one of the widely grown C4 crop with a high rate of photosynthesis. It is considered one of the major experimental crop plants because of its worldwide popularity and moderate genome size (~2400 Mb). Analysis shows that the substantial phenotypic variability of the maize crop plant is attributed to its molecular diversity at the genome level [68]. Various microarray experiments have been used to determine the gene-level expression and identify QTL associated

with transcript variation of coregulated genes under various environmental conditions. The gene expression profile in maize has also been used to study the effect of various abiotic stresses in the crop plant [69–72]. In order to understand the abiotic stress response and tolerance in maize, a web-based approach has been developed that keeps the updated compilation of various QTL maps and major genes associated with abiotic stress (http://www.plantstress.com/biotech/index.asp? Flag = 1). Xu *et al*. [68] have done a comprehensive analysis in maize.

1.3.3
Sorghum

Drought-tolerant sorghum (*Sorghum bicolor*) is considered one of the top cereal crops in the world, used not only for food but also as a biofuel. Due to its small genome size (~730 Mb), it is also accepted as a model plant for functional genomics of Saccharinae and other C4 grasses [73]. Under high-temperature conditions, sorghum improves its carbon assimilation by using its complex biochemical and morphological specializations [74]. Comparative genomic studies have shown the presence of similar gene families in sorghum to that in *Arabidopsis*, rice, and poplar (see Figure 1.1). Previous studies have identified genes and QTL related to abiotic stresses including postreproductive-stage drought tolerance [75–78]. Transcriptomics-related studies in sorghum have identified differentially expressed genes that play a major role in various responses to abiotic stress such as drought, salinity, and ABA [79]. Owing to its closeness to rice genome than any other major cereal crops with complex genomes and high levels of gene duplication, sorghum is considered one of the ideal candidates for genomic analysis.

1.4
Salt Stress-Related Transcriptome Changes Across Diverse Genera

Monocots and dicots have diverged from common ancestors between 12 and 20 MYA. Whole-genome sequencing projects have initiated the era of comparative

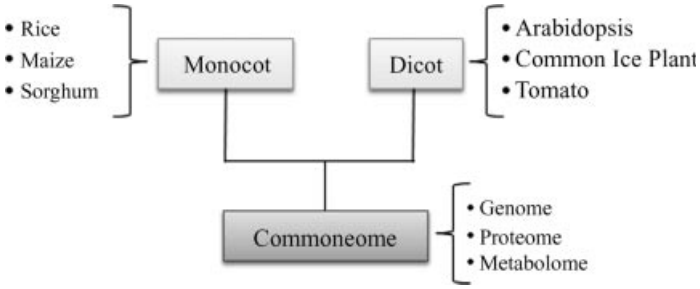

Figure 1.1 The "commoneome" approach – a possible route to identifying the "candidate genes" for stress tolerance in plants.

genomics, where the knowledge of key components of various stress-responsive genes and gene families is enhanced across monocot/dicot divide. Therefore, it has been accepted that the DNA sequence of the vascular plants has all the answers to the mystery of plant evolution and various responses that can be discovered only through comparative genomics. Stress response in plant is said to be multigenic in nature involving many genes and gene families. Our knowledge of complex stress response is ambiguous; therefore, a consolidated picture is still hidden. The identification of various convergent and divergent pathways between various stress responses can enhance the understanding of stress response in plants.

Earlier, we underlined the commonalities and differences in the gene expression profiles in three genera, namely, rice, *Arabidopsis*, and common ice plant by manually scoring the salinity-induced transcriptome changes [36]. Using the similar approach, we have now attempted to look beyond the monocot/dicot divide to elaborate our knowledge for salinity-induced transcriptomic changes. Here, we have emphasized on the genes that show alterations in species under consideration in response to salt stress. In this analysis, we have classified the gene expression as upregulated (depicted as $+$) and downregulated (depicted as $-$) under salt stress conditions. With the availability of extensive microarray expression data and widely popular species, *Arabidopsis* and rice, huge data sets are available for specific comparisons of the stress response. For other species, we relied on the microarray expression data (if available) or individual gene analysis carried out for those species.

1.5 Investigating the Salinity Stress-Related "Fingerprints"

The analysis of various model species in both monocots and dicots revealed a large repertoire of genes associated with salt stress response. These genes are further grouped into specific categories that are discussed in the following sections.

1.5.1 Stress Perception and Signaling

Crop plants often face varied environmental stresses. Therefore, in order to cope with these stresses, plants develop robust signaling mechanism for their perception. A complex cascade of molecules involved in processes ranging from stress perception to the final response in plants has been characterized that plays a vital role during the salt stress condition. These pathways include *S*alt *O*verly-*S*ensitive (SOS) pathway (SOS3-SOS2-SOS1) that regulates ion homeostasis under salt stress and results in Na^+ efflux and vacuolar compartmentation [80]; the calcium-dependent protein kinase (CDPK) pathway, which plays an important role in osmotic stress [80]; and the mitogen-activated protein (MAP) kinase pathway, which is important for counteracting both abiotic and biotic stresses [81]. In addition, two plant hormones, abscisic acid (ABA) and ethylene, also play an important role in abiotic stress response [82]. A recent study on the complex effects on root physiology in *Arabidopsis* has shown

upregulated ABA-marker genes in all cell layers of the roots, which suggests that ABA might primarily mediate semiubiquitous transcriptional responses to salt stress [83]. The overexpression of mouse calcineurin gene has led to higher salt tolerance in rice [40]. Wang *et al.* [84] identified a putative maize calcineurin B-like (CBL) gene that serves a function in salt stress-elicited calcium signaling and thus in tolerance to salinity. Guanylate kinase (GK), which encodes an enzyme important for the biosynthesis of nucleotides [85], and is hypothesized to be an important enzyme that is fundamental to second-messenger signal transduction pathways [86], has been characterized in three plant species, namely, *Arabidopsis*, lily, and tobacco [85, 87]. In another analysis, *AGK-1* and *AGK-2* were shown to be constitutively expressed in all tissues of *Arabidopsis*, but their transcription levels were found to be highest in roots [88]. A recent analysis has shown that overexpression of protein kinase SAPK4 in rice conferred increased tolerance to salt stress at the seedling stage and in mature plants [89].

1.5.2
Gene Regulation

Several regulatory molecules such as transcription factors (TFs) have been characterized that regulate gene expression under salt stress conditions including different classes of DNA binding proteins such as dehydration response element/C-repeat, Myb, and Myc proteins and proteins containing bZIP, Zn finger, or AP2 domains [2, 65, 66, 90–93]. The analysis of intronless *OSISAP1* gene that encodes for zinc finger protein shows that this gene gets induced in response to high levels of exposure to salt stress [90]. Zn finger protein Zat12 that plays a major role in metabolism of reactive oxygen species (ROS) as well as biotic and abiotic stress condition has been characterized in *Arabidopsis* [94]. Past studies have shown the role of C_2H_2-type zinc finger protein regulating stomatal aperture, thus playing a major role in salt and drought stress tolerance in rice [95–98]. Similar analysis shows that a receptor-like protein kinase and MYC-related DNA binding transcription factor is induced rapidly by high salt concentration [99, 100]. Another analysis shows that specific CaM isoform mediates salt-induced Ca^{2+} signaling through the activation of an MYB transcriptional activator, thereby resulting in salt tolerance in plants [101]. Another class of transcription factor known as NAC (NAM, ATAF, and CUC) family, which is one of the largest plant transcription factor families, was observed to be involved in diverse plant functions, and its overexpression in rice enhances drought resistance and salt tolerance in rice [97, 102]. Transgenic rice plants overexpressing one of the members of NAC gene family, *ONAC045*, showed enhanced drought and salt tolerance, indicating that it plays an important role in abiotic stress [103]. A subgroup of AP2/EREBP transcription factors known as dehydration-responsive element binding (DREB) proteins were found to play important role in plant response and tolerance to various abiotic stresses [104, 105]. Results have shown that some of the DREB genes were observed to be involved in both ABA signaling and stress-responsive pathways [106]. Also, it was observed that some DREB transcription

factors activated by ABA mediate their downstream gene expression, thus helping plants in stress tolerance [107–109].

1.6 Proteins Related to General Metabolism

Under salt stress conditions, several metabolic pathways in plants also get affected. Analysis of early salt stress-responsive genes in tomato root using suppression subtractive hybridization and microarray analysis identified genes involved in various metabolic pathways. Some of the genes involved in nitrogen fixation such as nitrate reductase, phenylalanine ammonia-lyase, (PAL), glutamine synthetase, and asparagine synthetase were found significantly upregulated during the salt stress treatment, while genes involved in methionine biosynthesis were found to be downregulated by the treatment [55]. Salinity stress enhances carbohydrate accumulation in tomato and leads to its movement from leaves to its fruit during early fruit development [110]. Salt stress (in roots of *Arabidopsis*) has shown to downregulate the enzymes involved in lignification, as well as the potentially cell wall-related lipid transfer proteins (LTPs). Interestingly, energy-evolving pathways were also found downregulated, and it is hypothesized that this may serve to conserve energy and limit growth [111, 112]. Many transporter proteins such as ABC (ATP binding cassette) transporter, LeOPT1-like transporters, and MATE-like (multiantimicrobial extrusion) efflux carriers were found to be induced by salt stress treatment [111]. Some of the cell wall-related families such as expansin and xylogulcanases were found to be induced by salt stress treatment that is also observed in response to osmotic stress in some species in order to increase the cell wall flexibility [111, 113]. In rice, genes involved in photosynthesis were also found to be downregulated upon salt treatment [114].

1.7 Stress-Induced Proteins with Some Protective Functions

Salt stress in crop plants induces various protective and adaptive responses in order to minimize the effect of stress. The dehydrin proteins that have been hypothesized to be associated with membrane and protein stability, metal scavenging, and suppression of ROS-induced damage were found to be upregulated in sorghum upon exposure to salinity. Salt treatment to the leaves of tomato plant led to the induction of ferredoxin thioredoxin reductase protein that plays a major role in maintaining redox status in plants [56, 57]. Similar response was also observed with LEA proteins to salt stress [79, 115–117]. In rice, senescence-related genes such as aspartic proteinase, ClpC protease, NAD-dependent malate dehydrogenase, and polyubiquitin were found upregulated in response to salt stress [114]. The genes involved in cell defense and detoxification such as glutathione reductase, dehydroascorbate reductase, and phospholipid hydroperoxide glutathione peroxidase

were found upregulated during the salt stress treatment [114]. Analysis has shown that salt stress induces oxidative stress in plants, thus leading to the accumulation of H_2O_2 that acts as a signal for triggering the cell defense mechanism [118, 119]. Several heat shock proteins (HSPs) were observed to play a crucial role in plant stress response by reestablishing normal protein conformations and thus maintain cellular homeostasis [120]. Overexpression of DnaK1 from halotolerant *Cyanobacterium aphanothece* in transgenic tobacco showed increased tolerance to salt stress [121].

1.8
Proteins Related to Maintenance of Osmotic Homeostasis

It is well established that salt stress in plants leads to disruption of cellular, ionic, and osmotic homeostasis [122]. Thus, a plant often tends to maintain homeostasis at every level to survive the stress environment. Analysis shows that various transmembrane transport proteins play a curial role in ionic and osmotic homeostasis under salt environments [123]. Transmembrane proteins such as sodium ATPase (PpENA1 and PpENA2), vacuolar H^+-ATPase, PpSHP1 and PpSHP2, chloride channel protein, and ABC transporters play important role in osmotic homeostasis [124–127]. Extensive studies have been performed on V-ATPase to study its response to the salinity stress environment [128, 129]. Microarray analysis of transcripts in *Populus euphratica* under salt stress showed upregulation of genes assisting in maintaining osmotic homeostasis such as magnesium transporter-like protein, syntaxin-like protein, seed imbibition protein, plasma membrane intrinsic protein PY-PIP2-1, and aquaporin. Analysis of barley microarray transcripts revealed an increase in the level of Δ-pyrroline-5-carboxylase synthase (P5CS), which is a rate-limiting enzyme for accumulation of proline in plants [62, 130]. Osmoprotectants such as glycine betaine and trehalose (which act by stabilizing quaternary structures of proteins and highly ordered states of membranes) were also found upregulated under salinity stress [62]. Interestingly, it was observed that transgenic rice overproducing glycine betaine and trehalose accumulated fewer Na^+ ions and maintained K^+ uptake [131, 132].

1.9
Protein with Unknown Function

Whole-genome sequencing projects in plants have generated vast knowledge about genes and gene families. The next big challenge after their identification is characterizing them and further associating them with probable functions. In *Arabidopsis*, identification of more than 5000 unknown proteins have led to the hypothesis of their probable role in various pathways and networks that might be playing major role in various abiotic stress tolerance [133, 134]. The unknown proteins were named as

proteins with obscure features (POFs) and the proteins that contained at least one previously defined domain or motif were named as proteins with defined features (PDF) [133, 135]. Recently, one of these PDF, a CBS domain-containing protein family, has been characterized in rice and *Arabidopsis* and has been hypothesized to play a major role in abiotic stress tolerance and development [35]. Another study in *Arabidopsis* has established the role of some of the unknown proteins in oxidative stress tolerance by using transgenic approach [136, 137]. A large number of unknown protein coding genes were found to be regulated in microarray analysis under salt stress in tomato that needs further analysis [55].

1.10 Analysis of Stress Transcriptome from other Plant Species

Since the inception of the idea to study the complex plant stress tolerance mechanism using whole-genome microarray, extensive analysis on various plant species has been performed. Analysis of plants living under extreme saline conditions has extended the knowledge base that has helped in understanding the salt stress behavior of plants. Recently, salt-responsive genes have been identified in genome-wide analysis using cDNA microarray in common wheat [138]. It was observed that genes encoding various ion transporters and osmotic regulators were upregulated in salt stress treatment. Analysis has shown the upregulation of genes belonging to various gene families such as AP2/EREBP, MYB, NAC, and WRKY. Nemoto and Sasakuma [139] have identified and analyzed early salt stress-responding genes (WESR1-4) in common wheat (*Triticum aestivum* L.).

Medicago tranculata is one of the model plant species among dicots being used for genomic analysis owing to its small, diploid genome and has short generation time, self-fertility, and high transformation efficiency. It is considered to be closely related to important forage legume, alfalfa, and can serve as a model organism for soybean and other economically important legumes [140–143]. A recent analysis in *Medicago* has characterized ERF gene family members that were also characterized in rice and *Arabidopsis* [144]. Members of ERF gene family encode transcriptional regulators with a variety of functions involved in the developmental and physiological processes in plants and were found to play a crucial role in nodulation and in early Nod factor signaling in *Medicago* [145]. In an analysis, two genotypes of *Medicago* were compared and analyzed using macroarray of 384 genes linked to salt stress and recovery responses in roots [146, 147]. Gruber *et al*. [148] have identified several transcription factor genes in the root region that not only respond to the salt stress but are also induced by osmotic, heat, and cold stress. This analysis shows that these TF genes not only are the part of general stress response of root apexes but also are strongly induced under high salt condition, suggesting the complex interlinking of these TFs in the root region. Recently, a database (TRUNCATULIX) was made available that integrates the sequence, annotation, and gene expression data from several *M. truncatula* databases [149] (see http://lily.cebitec.uni-bielefeld.de/truncatulix/app). Thus, with the kind of analysis available for this species, the understanding of the stress tolerance and response will get further elaborated.

One of the halophyte commonly known as mangrove plant (*Bruguiera gymnorhiza*) has also been studied to understand the salt stress behavior of the plants. The identification of various mechanisms such as detoxification of ROS by superoxide dismutase [150], osmotic adjustments via sucrose biosynthesis [151], and increased total amino acid pool, especially proline [152] and polyphenol [153], has furthered our understanding of tolerance to salt stress in mangrove plant. Wonga *et al*. [154] have elaborated on the genes playing a major role in salt stress tolerance in mangrove plant using subtractive hybridization and bacterial functional screening. Tada and Kashimura [155] have performed the proteome analysis of the main and lateral roots and the leaves in salt-treated mangrove plant *B. gymnorhiza* and have observed enhanced expression of FBP aldolase in the main root of the salt-treated mangrove plant, which leads to osmolyte production and contributes to stress tolerance.

Widely grown for forage purpose and as a grain crop, *Hordeum vulgare* L., commonly known as barley, has been analyzed for the salt stress tolerance trait, as it is one of the salt-tolerant crops. Characterization of salinity stress in barley has revealed the involvement of multiple genes that are responsive to salinity stress using microarray and differential display [66, 156–159]. Analysis done by Walia *et al*. [62] showed that a large number of abiotic stress (heat, drought, and low temperature)-related genes were also found to be responsive to salinity stress in barley.

Potato, another economically important and moderately salt-sensitive crop, is also studied for its response under salt stress condition. Salt stress treatment of potato revealed increased activation of antioxidant enzyme and accumulation of proline as its response [160–163]. Various transcription factors, signal transduction factors, and HSPs were found to be associated with abiotic stress response in transcript profiling of potato [164]. The overexpression of proline production enzyme, Δ-pyrroline-5-carboxylate synthetase, has been found to play an important role in salt stress tolerance [165]. Proteome analysis has revealed the photosynthesis-related proteins and those related to protein synthesis were downregulated, whereas osmotin-like proteins, HSP, and calreticulin proteins were upregulated under salt stress conditions [166] (see Table 1.3).

Grape (*Vitis vinifera*) is another economically important crop plant being studied for salt stress response as most of the researchers have ranked it moderately sensitive to salinity stress [167–170]. In a recent study, it was observed that grapevine growth was more sensitive to water deficit than to an equivalent salinity level suggesting that the salt uptake contributed to osmotic adjustment and thus facilitated water uptake and growth in young shoots [171]. Increased transcript accumulation of photorespiratory enzymes, glycolate oxidase and catalase, in the peroxisome shows the effect of salinity on photorespiration [171. Also, a large number of transcripts involved in ABA metabolism or responsive to ABA were enhanced due to saline conditions. Recently, a database has been developed that provides genomic resource for grape genome annotation and gene function (http://cropdisease.ars.usda.gov/vitis_at/main-page.htm) [172].

Thellungiella halophila, a close relative of *A. thaliana*, has also been adapted as a model crop for analysis of abiotic stress tolerance in plants [173]. *Thellungiella* has been widely characterized as an extremophile, known for its extreme tolerance to a variety of abiotic stresses such as low humidity, freezing, and high salinity [14, 173,

Table 1.3 Up- and downregulated genes in monocots (rice, maize, and sorghum) and dicots (*Arabidopsis*, common ice plant, and tomato) in response to salinity stress.

Gene notation	Monocots			Dicots		
	Rice	Maize	Sorghum	*Arabidopsis*	Common ice plant	Tomato
Stress perception and signaling

Adenine phosphoribosyl-transferase form 3	−			−		
Water channel protein (WCP-III)	−			−		
A-tubulin	−			−		
TMK (gibberellic acid induced)	−			−	−	
Peroxidase ATP19a	−			−	−	−
Putative translation initiation factor eIF-2Ba	−	−		−		−

Only those candidates have been selected that show a response common in at least two of the salinity-related transcriptome analyses. This analysis included both salinity upregulated (+) and downregulated (−) genes. Artificial grouping of these genes has also been done to reflect their possible physiological role(s).

174]. Gong *et al*. [175] observed activation of additional pathways that led to increase in metabolites in comparison to the pathways activated in *Arabidopsis* under salt stress. *Thellungiella* was observed to possess novel stress-relevant genes and also maintain higher expression of certain genes related to salt stress [175, 176]. In response to salt stress, proline levels were observed to have increased in *Thellungiella*, higher than that of *Arabidopsis* [174, 177–179]. Transcriptome analysis of the salinity-stressed plants of the Yukon ecotype of *Thellungiella* revealed a stress-specific response of the plant [180]. Knockout analysis of SOS1 gene by RNAi transformation method has shown the importance of SOS pathway in *Thellungiella* [181, 182]. Over the years, several cDNA libraries have been constructed from *Thellungiella* plants grown under various stress conditions, which were used for various comparative analyses [180, 183, 184]. Similar to *Thellugiella*, *Porteresia coarctata* is also considered a comparable halophytic model crop plant of *Oryza* spp. due to its salt-tolerant characterstics. A large number of genes related to the salt-stress tolerance in *Porteresia* have been isolated and characterized [185]. Recently, Sengupta and Majumder [186] took an initiative of proteomic analysis of *Porteresia* under salt stress. It has been considered that the analysis of physiological and metabolic

adaptation in *Porteresia* in comparison to *Oryza* spp. will provide finer details of the evolved salt stress tolerance mechanism.

1.11 Conclusions

With advancing technologies, the urge to understand and unravel the mystery of complex genomic response to various stresses in crop plants has led to the concussion in the existing knowledge. Till now we have information regarding the stress response in plants in the form of tessellating pieces. Therefore, these pieces need to be assembled to draw a complete picture (Figure 1.2). We have attempted to solve the jigsaw puzzle by elaborating on the "commoneome – common gene expression in various plant species" under salt stress condition. This attempt is rather complex as it is observed that various plants (monocots/dicots) seem to have varied gene expression in species-specific manner, though the response to the salt stress in terms of respective gene expression looks more or less similar.

Comparison of various plant species has helped not only in understanding their evolution, especially convergence and divergence, but also in getting valuable insights into their abiotic stress tolerance. Genome projects such as whole-genome

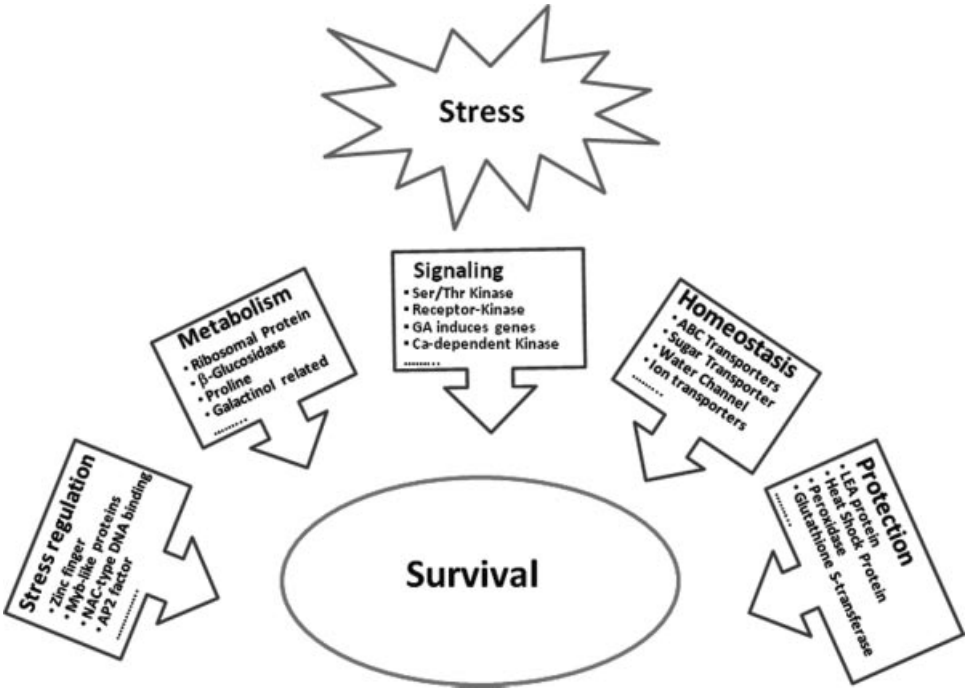

Figure 1.2 An overview of the role played by salinity-related transcriptome that assists plant survival under stress.

sequencing and transcript profiling under various conditions in *Arabidopsis*, rice, maize, and other plant species has provided basic knowledge bank for comparative genomic approaches. Availability of ESTs, microarrays, clusters of similarly expressing genes, molecular markers, mutants, and QTL maps in these plant species has ameliorated the current dogma of stress biology.

It is now widely accepted that salinity is one of the biggest problems gradually affecting the food crop production around the world. In order to develop crops that are able to tolerate salt stress, one needs to understand the effects of salt stress on crop plants that also vary from crop to crop. Approaches such as commoneome can help in developing a better understanding of such responses. In the earlier study, we attempted to compare three model crop plants, namely, rice, *Arabidopsis*, and common ice plant [36]. In this study, we have elaborated on the commoneome further, by looking at the salt stress response beyond the monocot/dicot divide. It is learnt that gene and gene families often play a role in multiple pathways and processes; therefore, they cannot be categorized specifically on one single function. Hence, these genes and gene families were arbitrarily clustered into specific tasks they majorly participate in such as signaling, regulation, metabolism, and so on.

Signaling plays a major role in the inception of the stress and hence the plants overall response. Several pathways, processes, and molecules play an important role in signaling mechanism. One of the widely studied pathways, the SOS pathway, is known to regulate ion homeostasis under salt stress. Other known pathways, namely, CDPK pathway and MAP kinase pathway, play an important role in osmotic stress. Plant hormones such as ABA and ethylene play a role in abiotic stress response. Several transcription factors also help in salt stress response by regulating various genes' expressions. Some of these DNA binding proteins that play important role are DREB, Myb, and Myc proteins, bZIP, Zn finger, AP2 domain proteins, and NAC family proteins that have been studied in various plants. Salt stress is known to affect many gene transcripts involved in metabolism, protein fate, transport, transcription, and cellular defense and also photosynthesis and photorespiration.

Complexity of salt stress response is a major cause of incomplete understanding of plant response to stress. A large number of genes and gene families are still either unrecognized or unknown, which might be playing a role in its response. A large number of pathways are still to be deciphered that can shed light on and enhance our knowledge of the plants adaptability to various stress conditions. There has been some development in this regard as glyoxalase pathway (which has been proposed to be involved in various essential functions in animal system) has been shown to have a direct correlation with enhancement in salinity tolerance in plants [187, 188]). However, the members of this important gene family are not picked up in our commoneome analysis. Thus, we can safely conclude that there may be still numerous genes "unidentified" and/or "uncharacterized" from various databases that are labeled "unknown," but may have important contribution to a given stress response in plants. Comparative analysis of transcriptomes and metabolomes between salt-sensitive and salt-tolerant lines can also help in identifying "candidate" genes. With integrative genomic approaches, we can hope to fill these gaps and develop a better crop that can survive under harsh environment conditions.

Acknowledgments

The research work in the author's laboratory is supported by the funds from the Department of Biotechnology, the Department of Science and Technology, Ministry of Science and Technology, Government of India, New Delhi and IAEA, Vienna, Austria. HRK would like to acknowledge the award of CSIR-Senior Research Fellowship.

2
Abiotic Stress Tolerance in Plants: An Industry Perspective

Shoba Sivasankar, Robert W. Williams, and Thomas W. Greene

After insect resistance and herbicide resistance, agronomic traits that define the extent and stability of economic yield are becoming recognized as the next-generation plant biotechnology traits. The stability of yield is determined by the tolerance of the plant to abiotic stresses, such as drought, cold, salt, and heat. Considerable research in the public and private sectors is devoted to the development of abiotic stress tolerance in plants, a good component of this being at the level of high-throughput gene discovery and gene evaluation. A functional relationship to stress tolerance has been demonstrated in model plant species for roughly 200 genes over the past 30 years. The challenge is to translate this functional efficacy to field performance, as demonstrated in reduced yield loss under stress. In addition, the extent of yield stability conferred by individual genes must be enhanced to the level at which it becomes commercially viable. While the complexity and multigene nature of abiotic stress tolerance make it a challenging undertaking, early indications of success are evident from research in both the plant biotechnology industry and the academia. In this chapter, we describe the various approaches to gene discovery used for abiotic stress tolerance, and discuss the challenges of high-throughput phenomics under controlled environment conditions. We conclude with a brief overview of the recent breakthroughs in abiotic stress research in the plant biotechnology industry.

2.1
Introduction

The postgenomics era, with its influx of enhanced technology in genome-scale transcript profiling, computational biology, metabolomics, and phenomics, has enabled continuously improving capabilities to explore functional plant biology. This makes it possible to address hitherto unexplored aspects of fundamental and applied crop research at high levels of throughput, though not without challenges. Consequently, the competitive landscape in the seed and plant biotechnology

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

industry is constantly changing, with existing players enhancing their research capabilities through mergers, acquisitions, and global extension of research facilities, and newer players rapidly filling emerging technological niches. First-mover advantage in existing and emerging seed and seed-related businesses is determined, as always, by the ability to deliver enhanced, stable yields under both optimal and challenging growth environments.

Agronomic traits that define the extent and stability of economic yield are rapidly becoming recognized as the next-generation plant biotechnology traits of commercial significance, following insect resistance and herbicide resistance. The extent of yield produced by a given crop species is determined both by its intrinsic yield potential and its capacity to perform under adverse growing conditions imposed both by abiotic and biotic stresses and by nutrient limitation. Narrowing the yield gap that exists between yield potential and realized yield is the subject of intense breeding and biotechnology research in commercial crop species. Development of crop plants that deliver enhanced and stable yields under changing climatic conditions, with the occurrence of multiple abiotic stresses during a single growing season, is a challenging undertaking. It requires (1) a mechanistic understanding of the response, acclimation and tolerance to individual stress conditions, and to naturally occurring combinations of multiple stresses; (2) the identification of critical physiological processes, biochemical pathways, allelic variants, and protein conformations associated with stress response and stress tolerance; (3) careful attention to precision phenotyping, growing conditions, and field heterogeneity in the testing process; and (4) the integration of these with transgenic efforts, QTL mapping, molecular breeding, and modeling [1–6].

Abiotic stresses such as drought, cold, and salt are of wide occurrence and have significant impact on crop productivity, and as such, tolerance to these stresses is a critical condition for yield stability. Tolerance to abiotic stress is complex and involves multiple component traits, physiological responses, and biochemical pathways. This complexity necessitates continued emphasis on efforts to identify and understand the morphophysiological, biochemical, and molecular components associated with tolerance, and to associate the contribution of these with yield stability and final yield. Whole-plant physiology combined with traditional breeding over the last several years has identified several component traits that contribute to yield stability under stress, especially with relevance to drought tolerance. Today, the establishment and continuous enhancement of high-throughput facilities including genome-scale transcript profiling, metabolomics, and phenomics capabilities are helping to achieve economies of both scale and scope that inform efforts toward crop improvement. Challenges continue to remain in the determination of associations between molecular events and whole-plant-level morphophysiological traits relevant to abiotic stress tolerance, and the utilization of such understanding for the development of commercial seed products.

Although abiotic stress tolerance is a typical quantitative trait, there are examples of single genes such as those controlling flowering time, plant height, ear type, and osmotic adjustment playing important roles in plant adaptation to stress, as analyzed

in relation to the impact of quantitative trait loci (QTL) in breeding for tolerance [7, 8]. However, the fact that numerous genes are involved in the expression of polygenic traits means that the individual genes generally have small effects at the phenotype level, and thus may need to be combined effectively in order to obtain a significant commercial impact. Breeding to manipulate more than one quantitative trait locus contributing to relevant traits in abiotic stress tolerance can help increase the impact on the phenotype. Biotechnology can enhance existing natural variation for the trait, and can facilitate the delivery of genetic variation not present in the crop species to be modified.

At the molecular level, the complex nature of abiotic stress tolerance can be evaluated by genome-wide evaluation of transcripts to identify genes with an association with the trait of interest, especially important when trait-relevant functionality of less than 1% of the genome has been established at the present time. Genome-wide targeted queries for assessment of trait-relevant functionality of transcripts are possible through forward genetics approaches such as the phenotypic evaluation of populations of activation-tagged, transposon-tagged, or T-DNA insertion mutants. Alongside of this, more defined forward genetics approaches and reverse genetics approaches in high-throughput mode are prevalent in the plant biotechnology industry. These include evaluation of functional gene classes such as transcription factors, gene families where more than one member has proven to be involved in the response or tolerance to abiotic stress, genes and gene networks predicted through computational biology, and stress-related transcripts from extremophile plant or bacterial species. In addition, comparative genomics, global profiling, knowledge-based gene discovery and directed evolution all play a role in identifying and applying molecular information to trait improvement.

Functional analysis of genes through phenomics and metabolomics approaches helps to unravel the complexity of the trait, to understand similarities and differences across plant species or within species, and to better define stress-adaptive metabolic pathways and regulatory gene networks. Integrated information from these functional analyses platforms can be structured into testable hypothesis with the aim to improve abiotic stress tolerance in commercial crop species, and for the continuous improvement of trait-specific screening under controlled environments and in the field. Leveraging information from high-throughput phenotypic screens of model systems to crop improvement, and the relationship between model system-based gene-to-phenotype confirmation and gene(s)-to-yield applicability, continues to be a subject of intense discussion.

In this chapter, we discuss recent trends in abiotic stress research in the plant biotechnology industry, emphasizing drought. Our focus is upon gene discovery through a variety of approaches, and upon functional analysis and evaluation of the plant phenotype conferred by selected genes through the use of phenomics approaches. We describe important challenges and breakthroughs in the development and deployment of stress-tolerant commercial seed products in the private sector.

2.2
Gene Discovery and Genomics in the Plant Biotechnology Industry

Research in the plant biotechnology industry aims to identify genes or "leads" that are capable of conferring a definitive phenotype in relation to the trait of interest, transfer of these leads into commercial crop species for evaluation of the resultant transgenic plants in the green house and field environments, and optimization of transgenic performance as necessary to deliver desirable agronomic performance in the farmer's field. With the completion of the DNA sequencing of the *Arabidopsis* genome in 2000, the subsequent DNA sequencing of the rice and sorghum genomes and, most recently, the release of draft genomes of wheat and maize through the last decade, the principal challenge to plant biologists has become the assignment of functionality to the sequenced genes and the association of genes with definitive phenotypes. In certain instances, the plant biotechnology industry has contributed to sequence information of crop species to publicly released genome information [9]. Sequence information of complete genomes of model plant species or commercial crop species has significantly enhanced the ability to identify genes associated with traits of interest in both the public and the private sectors.

In the broadest sense, there are two approaches to discover genes that have the potential to impart abiotic stress tolerance, or any trait, to plants, and these are forward and reverse genetics. Forward genetics identifies the phenotype of interest from screening populations and follows up with the cloning and identification of the gene(s) sufficient to confer the phenotype. Reverse genetics, on the other hand, works from the gene to the phenotype. It starts with a gene hypothesized to be involved in a specific phenotype and attempts to identify an alteration in the phenotype through perturbed expression of the gene. The distinction between forward and reverse genetics approaches is not necessarily absolute, and whole gene families or functional classes with potential to impact the trait of interest can be assessed for their effect on the phenotype.

In the following sections, we describe the methods of gene discovery and gene modification for trait improvement most commonly used in the plant biotechnology industry, including forward genetics, evaluation of gene families or functional gene classes, knowledge-based gene discovery, directed evolution, global profiling, comparative genomics, and computational biology.

2.2.1
Forward Genetic Screens Using Model Species

Forward genetics helps to associate a phenotype with a gene with no *a priori* assumptions about gene function or annotation. The widest adaptation of this approach involves the query of entire genomes through the use of mutant populations in which the expression of a good proportion of genes in the genome has been altered through the insertion of T-DNA, transposon, or activation tags [10–13]. The use of chemical or physical treatments such as ethyl methane sulfonate (EMS) or fast neutrons to generate mutant populations with disrupted gene expression is still

prevalent, though to a lesser extent. The process of identifying trait-relevant genes through forward genetics approaches involves a series of steps. First, tagged or insertion mutant populations are generated in the model species of choice, predominantly, *Arabidopsis thaliana*. Next, high-throughput phenotyping is executed on these populations to identify positive or negative effects on chosen secondary or component traits associated with the trait of interest. With this phenotyping process, mutants that produce definitive qualitative or quantitative evidence for altering chosen secondary traits of focus are identified. This is followed by cloning the gene whose activation or disruption produced the phenotype of interest and then validating its effect by retransformation into the same model species to recapitulate the mutant phenotype, using constructs designed to produce the desired expression. The last step involves the introduction of the confirmed or validated gene into the crop species of choice, and evaluation of the resultant transgenic plants in the greenhouse and/or the field.

The development of tagged populations in model plant species and their screening for the identification of genes associated with specific traits, including abiotic stress tolerance, is a practice as prevalent in the plant biotechnology industry as in academic research. One of the early examples of forward genetics approaches for response to multiple abiotic stresses attempted to identify genes responding to low temperature, drought, salinity, and the phytohormone, abscisic acid (ABA), utilizing bioluminescence of the luciferase reporter gene expressed from the dehydration-responsive promoter *RD(RESPONSIVE TO DEHYDRATION) 29A* [14]. This group screened an EMS-mutagenized *Arabidopsis* population homozygous for the transgenic construct, *RD29A::LUC (LUCIFERASE)* and identified several genes responsive to dehydration, salinity, low temperature, and ABA. Of these, *LOS5 (LOW EXPRESSION OF OSMOTICALLY RESPONSIVE GENES)* is under evaluation by FuturaGene Plc. (recently acquired by SuzanoTrading Ltd) for crop improvement, as part of FuturaGene's research portfolio that focuses on yield, abiotic stress tolerance, forestry, and biofuels (http://www.futuragene.com/06annual.pdf).

Dupont Agricultural Biotechnology and Pioneer Hi-Bred International, Inc. use activation-tagged populations of *A. thaliana* to screen for abiotic stress tolerance, keying in on critical secondary or component traits of relevance. The Monsanto Company has also reported the use of activation T-DNA tagging in *Arabidopsis* to obtain gain-of-function mutants related to critical traits [15]. *A. thaliana*, by virtue of its fully sequenced small genome, small plant size, and short growing period, need not necessarily be the only plant species utilized in forward genetics approaches to identify genes with the potential to confer abiotic stress tolerance. Both model species and commercial crop species with fully elucidated genomes can serve as targets for the development of screening populations. Ideally, in addition to having completely sequenced genome information and lending itself to easy cultivation in a high-throughput mode, these species should possess at least some characteristics of extremophiles, specifically in relation to drought, salt, or cold stress.

Thellungiella salsuginea (also known as *T. halophila*), a close relative of *A. thaliana*, is one such model species that is being explored for abiotic stress tolerance and nitrogen use efficiency [16–18]. Similar to *Arabidopsis*, it has a short lifecycle, small genome,

copious seed production, and is easily amenable to the floral-dipping method of plant transformation. Unlike *Arabidopsis*, however, it has the additional advantage of growing well under extreme conditions of cold, salt, and drought stress, and under nitrogen-limited conditions. *Thellungiella* genes exhibit high sequence identity (approximately 90% at the cDNA level) with *Arabidopsis* genes, and its extremophile characteristics result mostly from regulation of gene expression and to a lesser extent from a limited number of unique gene [19]. While full-genome sequencing is pending for this species, cDNA expression libraries have been transformed into *Arabidopsis*, and the resulting transgenic populations have been evaluated for abiotic stress responses [19, 20].

Physcomitrella patens, a moss highly tolerant to drought, salt, and osmotic stress, can serve as another excellent model species for forward genetics approaches in abiotic stress tolerance [21, 22]. A draft genome for this haploid is available, and the species is amenable to forward genetics approaches with faster turnaround rates than *A. thaliana* [23, 24]. Yet another model plant species, *Brachypodium distachyon*, can also render itself to the development of screening populations and can serve as a source of unique genes for trait improvement of commercial crop species [25]. *B. distachyon* is a wild grass related to small grain cereals, and is the first member of the Pooideae subfamily of grasses to be sequenced. Though its performance under abiotic stress conditions is not clearly described, its high-quality genome sequence, small genome, ease of cultivation and transformation, small size, and rapid life cycle all make it a good model species for gene discovery and phenomics. The extent of use of screening populations involving *Thellungiella*, *Physcomitrella*, *or Brachypodium* or model crop species for identification of genes of relevance to abiotic stress tolerance in the plant biotechnology industry is not known.

2.2.2
Functional Gene Classes and Families

A very good example of the evaluation of functional gene classes and gene families for the associated phenotype, including the ability to confer abiotic stress tolerance to plants, is the evaluation of the *A. thaliana* transcription factors by Mendel Biotechnology, Inc. (http://www.mendelbio.com/technology/index.php). Several research groups in both the public and the private sectors have used systematic functional genomics strategies to identify transcription factors with commercial potential. The *Arabidopsis* genome encodes over 1500 transcription factors, which account for roughly 5% of its genome, and about 45% of these transcription factors are unique to plants [26, 27]. Mendel Biotechnology was founded in 1997, with a focus on understanding the function of the large class of transcription factor genes in *A. thaliana*, based on the premise that these are upstream regulators capable of regulating and coordinating the expression of multiple downstream effectors that together confer specific plant characteristics.

The unique characteristics and modes of action of transcription factors make an overexpression strategy more attractive for assessment of gene function than does a knockout strategy [28]. As described on the Mendel Biotechnology web page

(http://www.mendelbio.com/aboutus/history.php), company scientists systematically analyzed the function of all *Arabidopsis* transcription factors, by overexpression in *A. thaliana*, and discovered individual transcription factors that control complex traits such as freezing tolerance, drought tolerance, intrinsic growth rate, photosynthetic output, plant form, disease resistance, water use efficiency, nitrogen use efficiency, and numerous other important processes. A well-studied class of transcription factors at Mendel is the AP2 transcription factor class, *C-BOX BINDING FACTOR(CBF)/DEHYDRATION-RESPONSIVE ELEMENT BINDING(DREB)* genes that are being evaluated for commercial development [29]. The *CBF* genes have been successfully used to engineer abiotic stress tolerance in a number of plant species [30]. According to public information (http://www.arborgen.us/index.php/products/product-pipeline/freeze-tolerant-eucalyptus), a commercial application for the *CBF* genes is closest to reality at Arborgen Inc., in the case of eucalyptus trees where *CBF* has been shown to contribute to freezing tolerance. The implication of another class of transcription factors, the *NF-Y* family, in drought tolerance in maize at Monsanto as described later, is a collaborative effort between Mendel and Monsanto [31]. For a commercial product, it is important to note that transcription factor technologies may require optimization mostly through the use of stress-inducible promoters, either to overcome pleiotropic effects resulting from constitutive overexpression or to enhance the desired trait to the level at which it is commercially viable. With the advent of "systems biology" approaches in the postgenomics era, it is possible to assemble all genes in the genome into transcription networks or protein interaction networks underpinning major biological processes. This enables researchers to investigate potential intervention points and gene combinations for coregulated expression to achieve abiotic stress tolerance and yield stability [32].

Other than transcription factors, a class of genes that has been evaluated through reverse genetics is involved in cell cycle regulation, including genes encoding the *KIP-RELATED PROTEINS (KRPs)* that are negative regulators of cell cycle [33]. Regulation of cell cycle is crucial to plant growth and development, and similar to the case of transcription factors mentioned above, plants have several unique genes involved in the process, though the cell cycle process in plants shares basic mechanisms with other eukaryotes [34]. The *KRP* genes are under advanced studies for commercial application both in canola and in camelina, an alternative oilseed energy crop, in the hands of Sustainable Oils, Inc. and one of its parent companies, Targeted Growth, Inc. (http://www.susoils.com/camelina/researchadv_resdev.php).

Genes involved in cell cycle, along with other classes of genes, have been subject to reverse genetics evaluation at Crop Design, founded in 1998 as a spin-off of the research work from Dirk Inze's group at the Flanders Inter-University Institute of Biotechnology, Ghent, Belgium. Crop Design's trait discovery and development program focuses on enhancing grain yield in corn and rice, and utilizes its TraitMill™ platform for applied genomics and phenomics. As indicated on Crop Design's web page (http://www.cropdesign.com/general.php), the company has discovered a range of proprietary leads through TraitMill™ for application in the areas of yield enhancement, drought tolerance, and improved nutrient use efficiency.

The TraitMill™ platform utilizes proprietary bioinformatics tools, high-throughput gene engineering systems, efficient methods for plant transformation, and automated high-throughput high-resolution phenotypic evaluation of transgene performance in rice (http://www.cropdesign.com/tech_traitmill.php).

2.2.3 Knowledge-Based Gene Discovery

In this approach, specific pathways known to be associated with a physiological trait or biochemical pathway that is triggered in response to a given abiotic stress is chosen for identifying key genes that can be targets for biotechnology. Examples are *POLY (ADP-RIBOSE) POLYMERASE (PARP)* and *POLY(ADP-RIBOSE) GLYCOHYDROLASE (PARG)* genes from Bayer CropScience (http://www.research.bayer.com/edition_16/16_Biotechnology.pdfx), and protein farnesyltransferase that forms the Yield Protection Technology® from Performance Plants, Inc. (http://performanceplants.com/technology-products/technology-solutions/yield-protection-technology). Stress-induced activation of *PARP* is the main cause of energy depletion in animals. Plants have two *PARP* genes, *PARP1* and *PARP2*, both of which are activated by DNA damage under stress, leading to energy depletion through NAD ($^+$) breakdown and ATP consumption. Inhibition of the activity or gene expression of these proteins, by chemical inhibitors or transgenic downregulation, contributes to tolerance to a broad range of abiotic stresses such as high light, drought, and heat. In this example, the focus was on improving energy efficiency under stress conditions, an aspect that is still not explored to the extent it deserves in the area of plant abiotic stress research [35]. Follow-up studies have shown that in addition to enhanced energy use efficiency, transgenic plants with downregulated *PARP* had altered levels of the hormone ABA that resulted in the induction of a wide range of defense-related genes [36]. Most recently, the *SNF1-RELATED PROTEIN KINASE, SnRK 2.6*, has been implicated in metabolic homeostasis and energy balance in *A. thaliana*, adding to earlier reports of similar roles for members of the *SnRK1* subfamily in plants [37]. This role of *SnRK2.6* is quite apart from its role as a positive regulator in ABA signaling, and its involvement in regulating ABA-mediated stomatal aperture.

Development of drought tolerance through manipulation of the response to ABA has been attempted across a variety of studies, and Performance Plants, Inc. has shown the involvement of the gene encoding the beta subunit of *Arabidopsis* farnesyltransferase, *ENHANCED RESPONSE TO ABA (ERA1)* in the regulation of ABA sensing and drought tolerance [38]. The *era1* mutant was identified from a fast neutron- and T-DNA-mutagenized *Arabidopsis* population for supersensitivity to ABA [39]. Downregulation of either the alpha or the beta subunit of farnesyltransferase enhanced the plant's response to ABA and drought tolerance [39]. This work specifically demonstrated that antisense constructs for the *Brassica napus ERA1* expressed from the dehydration stress-responsive promoter, *RD29A*, can produce transgenic plants with enhanced tolerance to moderate drought and significantly higher seed yield than control plants across 3 consecutive years of field test. Under drought conditions, these transgenic plants showed significant reduction in stomatal

conductance and transpiration, and were more resistant to drought-induced seed abortion during flowering relative to nontransgenic control plants. When grown under conditions of adequate moisture in the field, the yield of transgenic plants was the same as that of nontransgenic control plants.

2.2.4 Directed Molecular Evolution

Directed molecular evolution through multigene shuffling is a powerful technique to modify protein characteristics including improvement in specific activity or enzyme kinetics, formation of novel substrate specificities or novel products, and optimal performance in specific environments [40]. It has been successfully used in the generation of novel carotenoids, enhanced herbicide detoxification, and improvement of insect resistance genes. Maxygen Incorporated, California, USA, founded in 1997, uses its proprietary MolecularBreeding™ shuffling technology for the development of superior proteins, and its subsidiary, Verdia, has been a part of Dupont Agricultural Biotechnology since 2004, focusing on plant biotechnology. In the area of abiotic stress tolerance, Kurek *et al.* at Dupont have reported the generation of transgenic *Arabidopsis* with wild-type *RUBISCO ACTIVASE (RCA)* or *RCA* that had been shuffled for enhanced thermostability [41]. They observed enhanced photosynthesis, plant growth, and seed production under heat stress in the transgenic plants harboring the shuffled protein relative to the control plants transformed with the wild-type protein.

2.2.5 Global Profiling

With the elucidation of the complete genomes of both model plant species and commercial crop plants, and the continuous improvement of genome-scale transcript profiling methods, global transcript profiling is used widely in both the public and the private sectors to determine changes in gene expression under a variety of perturbations, including exposure to abiotic stresses. While the information from transcript profiling is valuable for understanding stress response at the gene expression level, it also serves as a source of genes for transgenic modulation or for marker-assisted breeding, when combined with other relevant data. Reported examples of the work in the private sector in transcriptomics includes that of Zinselmeier *et al.*, as well as Kollipara *et al.* at Pioneer-DuPont, and that of Kreps *et al.* at Syngenta [42–44]. Zinselmeier *et al.* focused on reproductive development in maize under drought stress, a developmental window critical for yield stability under drought, to conduct gene expression profiling using microarrays of maize expressed sequence tags [44]. While confirming the significance of the starch biosynthetic pathway in the regulation of stress responses, they also identified new pathways and genes in maize associated with drought stress. Again, at Pioneer-DuPont, Kollipara *et al.* reported a parallel transcriptomic and proteomic study across recombinant inbred lines of maize derived from B73 X Mo17 that showed differential behavior for

cold germination and seed desiccation tolerance [42]. This group identified a variety of genes and proteins that responded differentially to the two stresses, which could be classed into various functional groups such as carbohydrate and amino acid metabolism, ion transporters, stress and defense response, polyamine metabolism, chaperonins, cytoskeleton associated, and so on.

At Syngenta, researchers used microarray-based expression profiling of *Arabidopsis* responding to salt, osmotic, and cold stresses to identify a combination of over 2000 sequences that showed differential response across the three stresses [43]. Of all these differentially expressed sequences, the one that had the largest induction across all three stresses was identified to be *At5g52310* (*COLD RESPONSIVE 78 or COR78*). The above reports are from a period when transcript profiling was primarily done using microarrays with expressed sequence tags, and did not cover the entire transcriptome. However, EST- and oligonucleotide-based microarrays are likely to become obsolete in the near future with affordable and fast gene-expression analysis by cDNA sequencing.

Analysis of all available expression data for a given species can help identify *cis*-elements involved in the regulation of gene expression, when combined with genome sequence and transcript information, as has been reported by researchers at Ceres, Inc. [45]. Across the *Arabidopsis* genome, this group identified motifs associated with drought, heat, and cold stress, along with six other traits or tissue types. They were also able to validate the association of these *cis*-elements with known responses or tissue types, as in the case of the ABA responsive element, CACGT, which is known to be associated with drought, and was also strongly expressed in the drought data set the authors used.

Though significant research has been published in the public sector on global proteomic analysis in response to abiotic stress [46, 47], reports from the private sector are limited, one of those being the results from the work of Kollipara *et al.* mentioned above. Similar is the case with metabolomics, though this is an area receiving increasing interest in both the private and the public sectors due to enhanced capabilities leading to deciphering fundamental aspects of plant cell systems and their application to trait discovery [48, 49]. Metanomics GmbH, Berlin, Germany, with its focus on metabolic functional genomics, has developed large *Arabidopsis* populations with overexpression of an entire prokaryotic and an entire eukaryotic genome (http://www.metanomics.de/seiten/frameset.html). This population is being explored for commercially important metabolite changes, and has led to the identification and validation of several lead genes associated with tolerance to environmental stresses, as well as traits.

At Monsanto, Harrigan *et al.* conducted metabolite analysis of the grain of seven maize hybrids subjected to three separate moisture regimes during growth, namely, well-watered conditions, moisture stress during vegetative growth, and moisture stress during grain filling [50]. Their results showed that the magnitude of the mean differences between well-watered and drought-stressed samples were small, and statistically significant drought-induced differences were observable in at least four of the seven hybrids for only glutamine and proline of the various analytes measured.

2.2.6 Comparative Genomics

Owing to naturally occurring variations in the levels of tolerance and adaptation to abiotic stresses both between plant species and within species (as between wild progenitors and cultivated varieties), a comparative evaluation of the expression of these responses at the molecular level is critical to the identification of pathways and genes that are of significance to the tolerance response. In addition to pinpointing critical pathways and genes of interest, comparative genomics allows the evaluation of differences in the levels and timing of gene expression between tolerant and susceptible species or varieties, which contribute to their specific response to the stress. Furthermore, comparative genomics also provides an avenue for drilling into allelic differences in the regulatory regions of genes that lead to gene expression differences between closely related species or between varieties within the same species. Comparative genomics can be done at a global scale covering the entire genome or can be focused on specific classes of genes known to be associated with the trait of interest. Most published reports in this area are confined to the published genome sequences of *Arabidopsis* and rice.

Examples of focused comparative genomics of gene classes with relevance to abiotic stress research are the analysis of the *CCCH ZINC FINGER* and *PROTEIN PHOSPHATASE 2C (PP2C)* families in *Arabidopsis* and rice in the public sector [51, 52]. Genes encoding the former are known to play important roles in RNA processing as RNA binding proteins in animals. A role for these proteins in plants is only just emerging and the induction of their expression upon exposure to stress conditions implicates an association with the response to abiotic and biotic stresses. The *PP2C* family is associated with negative modulation of kinases involved in environmental stress responses and developmental processes, and their comparative evaluation across the genomes of *Arabidopsis* and rice has identified both similarities and differences in their response to abiotic stress and ABA. Expanding comparative genomics analysis to other stress-related gene families, to species beyond *Arabidopsis* and rice, and to varieties within species will be useful in understanding the tolerance response in terms of expression modulation. This is in addition to identifying novel divergent sequences that can serve as candidates for biotechnological interventions.

In addition to the above, the effect of transgenic perturbations or quantitative trait loci can be evaluated by comparative genomic analysis of the wild-type genome and the perturbed genome. In a collaborative effort between researchers at Dupont Agricultural Biotechnology and the Rockefeller University, the genome-wide expression profile of wild-type *Arabidopsis* was compared with that of the *ABA-INSENSITIVE* mutant, *abi1-1*, using massively parallel signature sequencing [53]. This work established that the regulation of gene expression of a majority of ABA-responsive genes was abolished in the mutant. On the basis of the response of wild-type *Arabidopsis* to ABA, the group identified more than a 1000 genes responding to ABA, including novel ABA-responsive pathways and genes.

A similar study reported by Syngenta and collaborators evaluated the expression profiles of parental and double-haploid rice accessions in an attempt to determine

general changes in gene expression under dehydration stress, differences in gene expression between parental lines with high or low osmotic adjustment, and differences in gene expression of transgressive segregants from these parental lines, with opportunity to identify candidate genes based on previously established drought tolerance QTL [54]. They identified 69 genes differentially upregulated in lines with high osmotic adjustment, 9 of which were not induced to any extent in lines with low osmotic adjustment. The latter included *SUCROSE SYNTHASE*, a pore protein, a *HEAT SHOCK PROTEIN*, and a *LATE EMBRYOGENESIS ABUNDANT* protein or *LEA*. Furthermore, this effort helped identify candidates associated with the drought tolerance QTL, which included a *snRNP AUXILIARY FACTOR*, a *LEA* protein, a *PROTEIN PHOSPHATASE 2C*, and a *SAR1* homologue.

2.2.7
Computational Biology

Advanced computational tools and specific algorithms can be applied to collections of large amounts of proprietary and/or public genomic information to enable the identification of key genes that could be critical targets for modification to alter traits of interest. Evogene Ltd, Rehovot, Israel, utilizes its proprietary "ATHLETE" platform (Agro Traits Harvest LEeads Technology) for such *en silico* gene identification and evaluates the identified genes in model plant systems prior to transfer and evaluation in target crop species (http://www.evogene.com/technology.asp?tid=7). Evogene also utilizes comparative genomics and utilizes evolutionary information across 70 plant species and approximately 8 million expressed sequence tags to facilitate gene identification. Researchers at Evogene, in association with the Hebrew University of Jerusalem, used computational mining of the large multifunctional gene family of tomato aquaporins on the basis of gene induction in response to abiotic stresses to identify one specific aquaporin, *SOLANUM LYCOPERSICUM TONOPLAST INTEGRAL PROTEIN 2;2* or *SlTIP2;2* [55]. Transgenic plants overexpressing this gene showed increased cell osmotic water permeability and enhanced whole-plant transpiration rates. When subjected to commercial greenhouse trials, the transgenic tomato plants showed increased fruit yield, harvest index, and plant biomass under both well-watered and drought-stressed conditions over 3 consecutive years.

2.3
High-Throughput Phenotyping and Phenomics

Following the trend of "omics" terminologies at the molecular level, phenomics is a term that is coming into increasing use to describe high-throughput precision phenotyping that enables evaluation of the physiological and morphological aspects of the plant under controlled environments or in the field. Phenomics methodologies are used to identify genes associated with the trait of interest by helping to establish functional relationship between genetics and the associated phenotype. They are also used to characterize plant performance under controlled environments and in the

field. In developing yield stability under abiotic stress conditions such as drought and cold, it is important to recognize that the selection can be targeted for escape or for tolerance. Escape responses are generally associated with a shorter growth duration that allows the plant to avoid periods of natural occurrence of the stress. This is possible in geographical locations where natural occurrence of stress at specific times of the growing season is predictable, as in the case of low temperatures at the beginning and end of the growing season in the maize-growing geographies of Northern United States and the maize-growing geographies of Canada. The short duration of growth that allows the escape response is also associated with lesser yields due to the naturally short period of growth available. Tolerance, on the other hand, allows the plant to encounter and withstand stress occurring during its growing season, through the use of physiological, morphological, and biochemical mechanisms that protect growth and reproduction under stress. Phenotyping for yield stability under abiotic stress is predominantly targeted toward tolerance to exposure to the stress.

Research on drought tolerance in the plant biotechnology industry employs high-throughput screens in model plant species to identify genes that confer a chosen secondary trait or response associated with stress tolerance, with the goal of employing these genes for the development of commercial seed products with stable yields under stress. A schematic of the process in relation to the associated concept and challenges is presented in Figure 2.1, specifically with regard to the development of

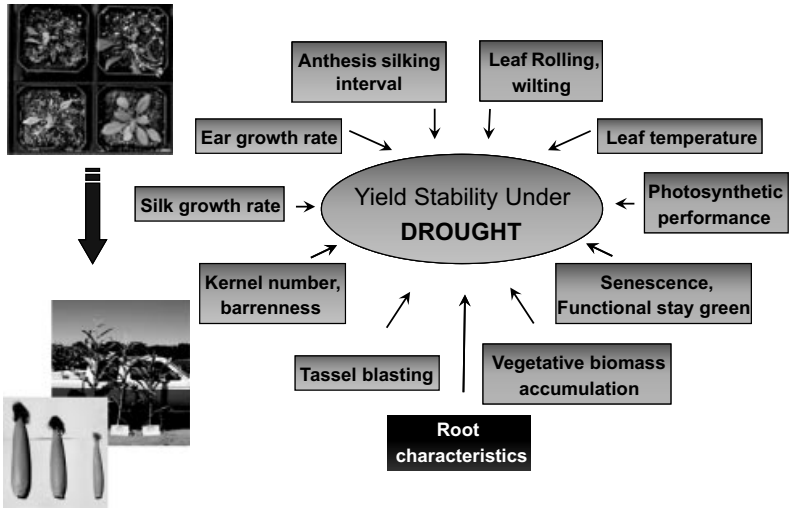

Figure 2.1 High-throughput phenotyping for drought tolerance – from model systems to maize. High-throughput phenotyping is most commonly applied to a model plant system such as *Arabidopsis*, usually at the vegetative stage in forward and reverse genetics approaches. The genes identified are utilized to modify yield stability under abiotic stress conditions in crop species. The challenge becomes even more daunting when one recognizes the fact that yield stability under a stress such as drought is determined by multiple component traits attributable to vegetative, reproductive, and root growth aspects.

drought tolerance in maize. As described in Section 2.2, model plant species such as *Arabidopsis* are used in high-throughput screens under controlled environments, wherein drought stress is usually applied at the vegetative stage, to identify genes that confer tolerance to stress. Plant treatments in these screens normally involve either (1) the withholding of water over a period of time to determine if the gene involved allows the plant to stay turgid for a longer period or to wilt slower, than others, or (2) the withholding of water to a soil moisture content that is close to permanent wilting point, and then rewatering to identify the effect of the gene on plant survival after the drastic stress. Genes identified from such screens are then transferred to commercial crop plants and optimized there, with the aim of providing tolerance to the crop plant under field drought such that yield stability can be achieved. Yield stability thus achieved is defined at the product level in terms of reduced yield loss upon the occurrence of drought during the growing season in plants harboring the transgene, relative to control plants that do not have the transgene.

There are certain crucial factors to be considered in the process of identifying a drought-relevant gene from a model species screen and applying it to trait improvement in crop species. Depending on the time of occurrence of drought during the growth period, and the varying impact of the stress upon different developmental stages, yield stability under drought stress can be affected to varying degrees by seedling establishment, vegetative tolerance, reproductive tolerance, rooting characteristics, osmotic adjustment, growth regulators, rate of senescence, and remobilization of reserves [56]. The need for high throughput in the screening of large numbers of transgenic plants to identify genes of relevance to drought tolerance necessitates the adherence to small plant sizes and short growth durations. Thus, the high-throughput nature of the screen itself imposes constraints both upon the growth stage of the plant at which drought stress can be imposed and upon the species of plants that can be phenotyped in a cost- and time-efficient manner. Furthermore, a screen aimed at gene discovery is confined, due to its high-throughput nature, to measuring only a proportion of the morphophysiological component traits known to be influenced by drought, and heritability of the trait might not always be a consideration in the choice of the traits to be measured. Finally, screens are conducted in pots under controlled environments, where pot-bound roots experience drought stress at a rate of occurrence that is significantly more acute than the slower natural progression of drought under field conditions. Though direct screening for yield in the field can overcome much of the above limitations of model-system vegetative screens, this will be at the cost of time and space efficiency. Such field screens are also subjected to significantly higher variability of the field environment relative to controlled environment conditions. Although field-based yield screens in commercial crop species are done to a limited extent for gene discovery, model species screens under controlled environments for a vegetative phenotype under drought remain the preferred option for high-throughput gene discovery in most instances. The question that is under considerable discussion at present is the relevance of a screen conducted at the vegetative stage in a model plant species under controlled environments to the prevention of yield loss under drought in crop plant species in the field [2, 57–61].

In addressing this question, first we have to acknowledge the fact that relative to single-gene traits such as herbicide tolerance and insecticide tolerance, abiotic stress tolerance is complex and multigenic, and the final yield under stress is a composite of multiple physiological and biochemical responses integrated over the duration of the crop growing period. The final yield of the crop is the composite result of the integrated contributions of these various responses or secondary traits, expressed over time, under varying drought environments. Although a single response pattern cannot be expected to be highly correlated with yield under all drought environments, the physiologically relevant integrators of the effects of drought are the water content and the water potential of plant tissues [59]. Both of these are measurable, and they integrate the effects of drought into the ability to retain turgor at the tissue or the whole-plant level. The utilization of a visible wilting or turgid phenotype at the vegetative stage as a screening criterion in high-throughput controlled environment screens, therefore, is indicative of such integrated response of the plant to drought stress. Under full-cycle growth in the field, this same capacity to maintain tissue- and whole-plant turgor or water potential under drought stress impacts critical responses and secondary traits known to be associated with yield under stress and having high heritability, for example, leaf expansion rate and anthesis-silking interval, as applied to maize [62, 63].

The response to low water potential has been elaborated at the organism and cellular levels by [58] building upon the original concept of stress avoidance and stress tolerance described by Levitt in 1972 [64]. According to this elaboration, stress avoidance happens at low stress levels where plant tissue avoids low water potential and decreased water content by attempting to maintain a balance between water uptake and water loss through stomatal closure and increased root/shoot ratio. If the stress becomes more and the plant tissue cannot avoid low water potential, dehydration avoidance or dehydration tolerance mechanisms are used. In dehydration avoidance, stress responses such as osmotic adjustment and cell wall hardening are used to maintain a high water content despite a reduced water potential. In dehydration tolerance, the tissue employs mechanisms to tolerate cellular damage caused by the water loss, including protective solutes and proteins, metabolic changes, and detoxification of reactive oxygen species. It is important to note that molecular events initiated by water stress do not exclusively fall into one or the other of the above categories of avoidance and tolerance, and that avoidance and tolerance do not occur in a linear progression upon the onset of stress.

Thus, the water content and water potential of plant tissues under drought are influenced by morphophysiological factors such as rooting characteristics, stomatal conductance, and hormonal effects, along with biochemical processes such as osmotic adjustment, membrane and macromolecular protection, antioxidative defense, and signaling. Individual molecular events are involved in determining the expression of these tissue-level morphophysiological and biochemical events, which are integrated into the expression of the phenotype identifiable as wilted or turgid at the whole-plant level. Thus, a gene or a molecular event that is capable of affecting the tissue- and cellular-level phenomena identified above will produce measurable wilting or turgidity, and a screen for such a phenotype identifies genes

involved in the expression of those responses that integrate the effects of water content and water potential of the tissue.

Genes discovered to be associated with a slow-wilting phenotype might not necessarily translate immediately to yield under stress. The impact of a gene on tolerance to drought and on yield stability is determined by the secondary trait affected by it, the heritability of this secondary trait and its contribution to final yield, the intensity of the gene's effect on the secondary trait, and the timing and tissue-type of expression of the gene. Thus, identification of a gene's association with a slow-wilting phenotype may not in itself ensure a commercial product with yield stability under drought. Information on the secondary trait impacted by the gene, the extent of contribution of the specific secondary trait to final yield, and the requisite timing and tissue-type of expression of the gene for optimal manifestation of the secondary trait in question are all critical to the design of the plant transformation construct that maximizes the potential of the gene to impact yield under stress. In instances where the impact of the gene is on secondary traits with small but heritable contributions to final yield, combining two or more of such genes can capture any additive effects. In instances where definitive spatial and temporal modulation of gene expression is necessary, promoter optimization becomes important.

Though a visual or quantitative wilting screen is the most common high-throughput technique applied to model species for discovery of genes associated with drought tolerance, several of the secondary traits that respond to specific molecular events upon the onset of drought, and that integrate the effects of water content and water potential, can be measured quantitatively or qualitatively. Measurement of these secondary traits associated with drought tolerance can be incorporated into screens or into functional characterization efforts to provide relevant information to help determine the functional effect of the gene. Studies that have evaluated the relevance of specific physiological secondary traits for the response to drought conditions have been reviewed recently by Cattivelli *et al*. [4]. The traits evaluated include stomatal conductance, leaf temperature, photosynthetic capacity, timing of phenological phases, anthesis-silking interval in maize, starch availability during ovary/embryo development, partitioning and stem reserve utilization, stay green, single plant leaf area, rooting depth, cuticular resistance and surface roughness, osmotic adjustment, membrane composition, antioxidative defense, and accumulation of stress-related proteins.

Relating the effect of a gene or a genotype to its associated phenotype or secondary trait with sufficient confidence and precision requires carefully planned experimentation and can be done in controlled environments. Determining the contribution of a given secondary trait to final yield is more challenging and requires carefully planned field experiments under managed drought stress and under naturally occurring drought in targeted environments. Such field experimentation attempts to integrate responses to drought over the entire growing season and allows the characterization of gene or genotype effect, and genotype $\times$ environment (G $\times$ E) interaction. Ideally, these experiments should include the measurement of as many secondary traits associated with yield stability as known.

Both vegetative and reproductive screens under controlled environments are employed in gene discovery in much of the plant biotechnology industry addressing

abiotic stress tolerance, including companies such as DuPont Agricultural Biotechnology, Wilmington, DE, USA, and its subsidiary, Pioneer Hi-Bred Inc., Johnston, IA, USA; Monsanto, St Louis, MO, USA; BASF Plant Science, Research Triangle Park, NC, USA, and its subsidiary, Crop Design, Ghent, Belgium; and Ceres, Thousand Oaks, CA, USA. In the public sector, the Leibniz Institute of Plant Genetics and Crop Plant Research, Gatersleben, Germany; the Plant Accelerator, Adelaide, Australia; and the Australian Plant Phenomics Facility, Canberra, Australia are key centers engaged in high-throughput plant phenotyping. Phenomics technologies used in gene discovery and in functional gene characterization, under both controlled and field environments, continue to evolve and have been recently summarized [65, 66]. The bioimaging company LemnaTec GmbH provides imaging and quantification capabilities for high-throughput plant phenotyping in controlled environments.

2.4
Recent Breakthroughs in Abiotic Stress Tolerance in the Plant Biotechnology Industry

Over the past two decades, there have been several studies on the use of single genes for the transgenic modification of abiotic stress tolerance, and a majority of these have been on model plant species, such as *Arabidopsis*. The genes used to modify abiotic stress tolerance address several different stress-related secondary responses and biochemical pathways including osmolyte synthesis and osmotic adjustment, hormonal regulation, antioxidants, transcription factors and other signaling genes, dehydrins, and so on [67, 68]. Almost all of the published studies report transgene evaluation under controlled environments with a focus on the vegetative phenotype. Only in very few instances has the phenotype conferred by the transgene been evaluated in the field in commercial crop species over full-growth cycle. These include studies both from the public sector and from the private sector [31, 69–71].

In the public sector, Xiao *et al*. identified Late Embryogenesis Abundant gene from rice, *OS LEA3-1*, on the basis of its drought-induced expression in microarray studies, and overexpressed this in rice from both a drought-inducible and a constitutive promoter, to obtain a drought-tolerant phenotype with higher grain yield than the wild type under drought stress in the field [69]. In another instance, Oh *et al*. studied genes containing the *APETALA2 (AP2)* domain in rice and identified several with stress-inducible expression [71]. They focused on two of the identified genes for functional characterization, and overexpression of *AP37* in rice from a constitutive promoter conferred a drought-tolerant phenotype with enhanced yield compared to the wild-type control in the field under severe drought stress. The yield of the transgenic plants was on par with that of the wild-type control under normal growth conditions of optimal soil moisture.

A majority of the research on this topic in the private sector remains unpublished as yet. Transgenic evaluation of the plant *NUCLEAR FACTOR (NF-Y)B* and that of the bacterial RNA chaperone, the *COLD SHOCK PROTEIN B* or *CSPB*, from Monsanto are two published studies on drought tolerance, where single transgenes

transformed into commercial crop species have been evaluated for yield and associated traits under drought stress in the field [31, 70]. An application for *NF-YB* to drought was identified from screens for drought tolerance using over 1500 *Arabidopsis* transcription factors in the Mendel Biotechnology-Monsanto collaboration [31]. Overexpression of the *Arabidopsis NF-YB1* gene in *Arabidopsis* from the constitutive cauliflower mosaic virus *35S* promoter was found to confer drought tolerance in the form of reduced wilting, increased survival, enhanced water potential, and photosynthesis under drought-stressed conditions, compared to the wild-type nontransgenic control. The maize homologue of the *Arabidopsis* gene, *ZM NF-YB2*, when constitutively expressed in maize from the rice actin promoter conferred enhanced drought tolerance as observed by less wilting and increased seedling survival in the greenhouse. In the field, transgenic maize plants showed less leaf rolling, higher chlorophyll index, higher photosynthesis rate, cooler leaf temperature, higher stomatal conductance, and enhanced yield compared to nontransgenic check plants.

Castiglioni *et al*. at Monsanto reported the effect of bacterial *COLD SHOCK PROTEINS*, *CSPA* and *CSPB*, on stress tolerance under controlled environments in *Arabidopsis* and rice, and both under controlled environments and in the field in maize [70]. In *Arabiodpsis*, both proteins showed enhanced growth when subjected to cold stress, and in rice, both showed enhanced plant height, an indication of better growth, under cold and heat treatment. *CSPB* also produced similar positive effects on rice under drought treatment. When *CSPB* was transformed into maize, seedling vegetative performance was improved compared to nontransformed control plants when subjected to drought stress, and this was demonstrated by improved leaf elongation rate, a measure of growth, chlorophyll content, and photosynthetic performance. One *CSPB*-expressing maize event was tested in the field across three different hybrid backgrounds, two different stress regimes (stress during vegetative phase and stress during reproductive phase), and five replicated locations. The tested event consistently outyielded the nontransgenic controls in a majority of these treatments. In 3-year trials, it showed yield advantage over the control in a variety of stress environments where yield reductions ranged from 20 to 80% due to the occurrence of some level of water stress.

The above results indicate that yield stability under drought can be achieved either through single-gene modifications, where the transgene might constitute enhancement of inherent variability in the crop species, or through the introduction of new variability hitherto nonexistent in the crop species. The yield advantages reported in these published studies are high, although consistent adherence to these early published results across time, multiple locations, and different genetic backgrounds remains yet to be proved. Even if the yield advantages do not remain as high as the reported early results, the fact remains that drought tolerance can be transgenically modified by single genes, and careful studies should allow the combination of smaller effects of more than one such "positive" gene in order to capture additive effects. One aspect that continues to stand out and that needs constant consideration in transgenic research on drought tolerance is that genes capable of conferring drought tolerance under water-limited environments should ideally show yields

comparable to control plants under well-watered environments. Failure to satisfy this condition will prevent the wider deployment of drought-tolerant crop products and necessitate confinement to regions of extreme drought occurrence.

2.5 Conclusions and Future Perspectives

A vast volume of scientific literature over the past three decades has addressed gene discovery for abiotic stress research, focusing on model plant species, primarily *Arabidopsis*. More recently, the complexity and multigenic nature of abiotic stress tolerance has directed this research into high-throughput gene discovery and gene evaluation. The very high-throughput nature of the present research necessitates the adherence to short-duration small-sized model plant species to enable economies of space and time for gene discovery, while recognizing the challenges of translating functional gene efficacy from model species to field relevance and yield in commercial crop plants. Single-gene functional efficacy has been reported to confer changes in morphophysiological, biochemical, and molecular traits associated with tolerance to abiotic stresses, essentially with relevance to the vegetative performance of the plant. Most recent research has also seen the translation of this single-gene functional efficacy to yield improvement in the field under drought. Challenges remain in achieving yield stability that can be transferable across more than one growing environment, and tolerance that can address stress occurring at more than one physiological growth phase during the cropping season.

3
Generation and Scavenging of Reactive Oxygen Species in Plants under Stress

Sarvajeet Singh Gill, Lamabam Peter Singh, Ritu Gill, and Narendra Tuteja

Reactive oxygen species (ROS) such as singlet oxygen ($^1O_2$), superoxide radicals ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2), hydroxyl radicals ($OH^{\bullet}$), and perhydroxyl radicals ($HO_2^{\bullet -}$) are constantly produced as by-products of various metabolic processes in plants and continuously reduced/scavenged by plant antioxidative defense system to maintain at a certain steady-state levels. Any disruption in this delicate balance between ROS generation and reduction/scavenging leads to high accumulation in plant cells, which causes oxidative stress. Plants counteract ROS toxicity through enzymatic antioxidant systems comprising a range of ROS scavengers, such as superoxide dismutase (SOD), ascorbate peroxidase (APX), glutathione peroxidase (GPX), catalase (CAT), monodehydroascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR), guaiacol peroxidase (GPOX), glutathione reductase (GR), and glutathione *S*-transferase (GST), and nonenzymatic low molecular metabolites, such as ascorbic acid (ASH), glutathione (GSH), α-tocopherol, proline, carotenoids, and flavonoids. Various biotic and abiotic stresses such as plant diseases, drought, salinity, extreme temperatures, excess light, pollutants, nutrient deficiency, and so on disturb the equilibrium of ROS production and scavenging, eventually leading to overproduction and higher accumulation of ROS. High amount of ROS in plant cells affects various cellular functions through damaging nucleic acids, protein oxidation, and lipid peroxidation, eventually resulting in cell death. ROS toxicity resulted from various biotic and abiotic stress factors is considered to be one of the major causes of low crop productivity worldwide. Despite this, it has also become clear that ROS play an important signaling role in plants, controlling various processes such as cellular growth, control of stomata closing, plant–harmful/beneficial microbe interactions, programmed cell death, and stress responses, and can also initiate responses such as new gene expression.

3.1
Introduction

Stress, in the context of plants, is "any unfavorable condition or substance that affects or blocks a plant's metabolism, growth, or development." Factors that induce

Improving Crop Resistance to Abiotic Stress, First Edition.

stress to plants can be of two types: "biotic," resulting from living organisms, such as fungi, bacteria, viruses, pests, herbivores, and so on, and "abiotic," resulting from nonliving factors, such as drought, salinity, extreme temperatures, excess light, pollutants, xenobiotics, ultraviolet radiation, ozone, hypoxia, nutrient deficiency, and so on. The balance between tolerance and sensitivity of a particular plant may determine whether a stress factor has a positive or negative effect on that plant [1]. As the stress factors are variable, the mechanisms of damage and, consequently, the plant signaling and metabolic responses differ from each other. Yet, plants respond to all these stresses by increasing generation/production of reactive oxygen species (ROS), although their identity and compartment of origin may certainly differ [2, 3].

Reactive oxygen species comprise $O_2^{\bullet -}$, H_2O_2, $^1O_2$, $OH^{\bullet}$, $HO_2^{\bullet -}$, ROOH, $ROO^{\bullet}$, and $RO^{\bullet}$. ROS are the spin-off, invariably generated by plants during various metabolic processes in different cellular compartments, such as chloroplast, mitochondria, peroxisomes, cytosol, plasma membrane, and apoplastic space [4–6]. Under stable/normal conditions, the ROS molecules are scavenged by various antioxidative defense mechanisms [7]. The equilibrium between the production and scavenging of ROS may be disturbed by various biotic and abiotic stress factors, such as salinity, UV radiation, drought, heavy metals, temperature extremes, nutrient deficiency, pollutants, herbicides, and pathogen attacks. These disturbances in equilibrium lead to sudden increase in intracellular ROS level, which can cause significant damage to cell structures. It has been estimated that 1–2% of O_2 consumption leads to the formation of ROS in plant tissues [8]. Through a variety of reactions, $O_2^{\bullet -}$ leads to the formation of H_2O_2, $OH^{\bullet}$, and other ROS. ROS are highly reactive and toxic and cause damage to proteins, lipids, carbohydrates, and DNA, which eventually results in cell death. Accumulation of ROS as a result of various environmental stresses is a major cause of loss of crop productivity worldwide [9–15]. High ROS production and accumulation affects many cellular functions by damaging nucleic acids, oxidizing proteins, and lipid peroxidation (LPO) [7].

Conversely, now it has become apparent that ROS also play an important signaling role in plants, controlling various processes such as cellular growth, stomata closing [16], plant–pathogen interactions [10], programmed cell death [17], and stress responses [18, 19]. ROS can also initiate responses such as new gene expression, regulate and involve in legume–*rhizobia* symbiosis [20, 21], and establish both endo- and ectomycorrhiza [22]. It is the evolution of highly efficient scavenging mechanisms that most likely enabled plant cells to overcome ROS toxicity and led to the use of several of these ephemeral reactive molecules as signal transducers. The recent identification of ROS-generating enzymes, such as the plant homologue of respiratory burst NADPH oxidases, has led to the demonstration that plant cells, similar to mammalian cells, can initiate and most likely amplify ROS production for the purpose of signaling. Localized ROS production in organelles such as plastids, mitochondria, and peroxisomes may also initiate signaling cascades [23]. It is important to note that whether ROS will act as damaging, protective, or signaling factors depends on the delicate equilibrium between ROS production and scavenging

at the proper site and time [24]. Stress-induced ROS accumulation is counteracted by enzymatic antioxidant systems that include a variety of scavengers, such as superoxide dismutase (SOD), ascorbate peroxidase (APX), GPX, glutathione *S*-transferase (GST), and catalase (CAT), and nonenzymatic low molecular metabolites, such as ascorbic acid (ASH), glutathione (GSH), α-tocopherol, carotenoids, and flavonoids [15, 25]. Besides, proline has also been added to an elite list of nonenzymatic antioxidants that microbes, animals, and plants need to counteract the inhibitory effects of ROS [26]. The above-mentioned antioxidants are found in almost all cellular compartments, signifying the importance of ROS detoxification for cellular survival [15]. Plant stress tolerance may therefore be improved by the enhancement of *in vivo* levels of antioxidant enzymes [4]. At present, it has also been shown that ROS influence the expression of a number of genes and signal transduction pathways, suggesting that cells have evolved strategies to use ROS as biological stimuli and signals that activate and control various genetic stress–response programs [27]. Recently, it has become evident that plants actively produce ROS, which may control many different physiological processes such as biotic and abiotic stress responses, pathogen defense, and systemic signaling [4].

3.2 ROS Production

ROS are perpetually produced through cellular metabolism and plant cells are well equipped with antioxidants and scavenging enzymes to keep their levels in check under normal growth conditions. Biotic and abiotic stresses can increase the rate of ROS production and collectively with the compartment-specific (down) regulation of the cells' antioxidant capacity, it can lead to significant ROS accumulation in plant cells. Till date, numerous studies have well documented the harmful effects of ROS on cellular components [5], and now, a role in plant signaling has also been firmly established [28].

Chloroplasts are the prime source of ROS in photosynthetic tissues due to their capacity to produce high amounts of $O_2^{\bullet -}$ and H_2O_2, especially during reduced rate of photosynthetic carbon fixation, which is a typical condition during abiotic stresses [29]. Oxygen generated in the chloroplasts during photosynthesis can accept electrons passing through the photosystems, thus resulting in the formation of $O_2^{\bullet -}$. Therefore, the presence of ROS producing centers, such as triplet chlorophyll and electron transport chain (ETC) in PSI and PSII, makes chloroplasts a major site of ROS ($O_2^{\bullet -}$, $^1O_2$, and H_2O_2 production. Various abiotic stresses such as excess light, drought, salt stress, and CO_2-limiting conditions enhance the production of ROS in chloroplasts. Normally, the electron flow from the excited photosystem centers is directed to $NADP^+$, which is reduced to NADPH. Then, it enters the Calvin cycle and reduces the final electron acceptor, CO_2. In case of overloading conditions of the ETC, a part of the electron flow is diverted from ferredoxin to O_2, reducing it to $O_2^{\bullet -}$ via Mehler reaction [30, 31]. Later studies reveal

that the acceptor side of ETC in PSII also provides sides (QA, QB) with electron leakage to O_2 producing $O_2^{\bullet -}$ [32]. $^1O_2$ is a natural by-product of photosynthesis, mainly formed at PSII even under low light conditions [33]. On the external, "stromal" membrane surface, $O_2^{\bullet -}$ is spontaneously dismutated to H_2O_2 by Cu/Zn-SOD [32]. Recent researches have linked chloroplast-produced ROS with the hypersensitive response [34]. Chloroplast-produced ROS have been shown to be capable of transmitting the spread of wound-induced PCD through maize tissue [35]. The expression of animal antiapoptotic Bcl-2 family members in transgenic tobacco has revealed the involvement of chloroplast in oxidative stress-induced PCD [36]. It has been shown that in *Arabidopsis thaliana* cell suspension cultures, the cells contain well-developed, functional chloroplasts when grown in the light, but not in the dark, and can be used as model systems to study PCD. In a study, treatment with antioxidant of light-grown cultures resulted in increased apoptotic-like PCD induction, which suggests the involvement of chloroplast-produced ROS apoptotic-like PCD regulation. It has been suggested that chloroplasts can play a significant role in apoptotic-like PCD regulation [37].

Mitochondria are the major source of ROS in nonphotosynthetic tissues, but in a green cell of a plant, their contribution is considered small in comparison to chloroplasts [3]. The redox status of the mitochondrial ETC is an important indicator of the cell energy status, and ROS, especially $O_2^{\bullet -}$ from complexes I and III, and the reduction status of the ubiquinone pool are integral parts of this monitoring system [38]. The mitochondrial ETC harbors electrons with sufficient free energy that directly reduce O_2, which is considered an unavoidable primary source of mitochondrial ROS generation and a necessary accompaniment to aerobic respiration [39]. However, ROS production in mitochondria takes place under normal respiratory conditions that can be enhanced in response to various biotic and abiotic stress conditions [4]. $O_2^{\bullet -}$ in aqueous solution is moderately reactive, but it can be further reduced by SOD dismutation to H_2O_2 [40–42]. It has been estimated that about 1–5% of mitochondrial O_2 consumption leads to H_2O_2 production [41]. This H_2O_2 can react with reduced Fe^{2+} and Cu^{+} to produce highly toxic $OH^{\bullet}$, and these uncharged $OH^{\bullet}$ can penetrate membranes and leave the mitochondrion [39, 42, 43]. Peroxidation of mitochondrial membrane PUFA is initiated by the abstraction of a hydrogen atom by ROS, especially by $OH^{\bullet}$. This leads to the formation of cytotoxic lipid aldehydes, alkenals, and hydroxyalkenals, such as the much studied 4-hydroxy-2-nonenal and malondialdehyde (MDA). Once LPO products are formed, they can cause cellular damage by reacting with proteins, other lipids, and nucleic acids. Key oxylipins and smaller, lipid-derived reactive electrophile species may also be produced from LPO [44]. It has also been noted that UV-C exposure induces quick appearance of ROS in the protoplasts, which is restricted to chloroplasts and mitochondria. It is suggested that the mitochondrial transmembrane potential loss and the changes in distribution and mobility of mitochondria, as well as the production of ROS, play important roles during UV-induced plant PCD [45]. It is a well-established fact that abiotic stresses strongly affect the plant cell bioenergetics. Plant mitochondria may control ROS generation by means of energy dissipating systems. Thereby, mitochondria may play a

significant central role in cell adaptation to abiotic stresses, which are known to induce oxidative stress at cellular level [4].

Peroxisomes are also probably one of the major sites of intracellular ROS production. They contain several oxidases that produce H_2O_2 and $O_2^{\bullet -}$ as by-products of the reactions they catalyze. The photorespiratory glycolate oxidase is located in peroxisomes, its function is especially relevant during abiotic stresses, which are often accompanied by stomatal closure, and the resulting decrease in gas exchange leads to reduction in carbon dioxide availability for Rubisco, followed by increased photorespiration and H_2O_2 production [28]. Peroxisomes, such as mitochondria and chloroplasts, produce $O_2^{\bullet -}$ radicals as a consequence of their normal metabolism. Two sites of $O_2^{\bullet -}$ generation are established in peroxisomes [46]. The first site is in the organelle matrix, where xanthine oxidase (XOD) catalyzes the oxidation of xanthine and hypoxanthine to uric acid [47], and the second site is in the peroxisome membranes dependent on NAD(P)H, where a small ETC is composed of a flavoprotein NADH and cytochrome *b*, and here $O_2^{\bullet -}$ is produced by the peroxisome ETC. Monodehydroascorbate reductase (MDHAR) participates in $O_2^{\bullet -}$ production by peroxisome membranes [46]. The main metabolic processes responsible for the generation of H_2O_2 in different types of peroxisomes are the photorespiratory glycolate oxidase reaction, the fatty acid β-oxidation, the enzymatic reaction of flavin oxidases, and the disproportionation of $O_2^{\bullet -}$ radicals [46, 48]. Intensification of H_2O_2 and $O_2^{\bullet -}$ production in the peroxisomes leads to oxidative damage and possibly cell death [46]. Conversely, it has also been shown that small levels of H_2O_2 and $O_2^{\bullet -}$ act as signal molecules that mediate pathogen-induced PCD in plants [49, 50]. Hence, it has been suggested that peroxisomes should be considered as cellular compartments with the capacity to generate and release important signal molecules such as $O_2^{\bullet -}$, H_2O_2, and $NO^{\bullet}$ into the cytosol, which can contribute to a more integrated communication system among cell compartments [47].

Besides these metabolic ROS sources, hydroxyl radicals ($OH^{\bullet}$) can be formed from H_2O_2 in the presence of redox-active metals through the Fenton reaction or from H_2O_2 and $O_2^{\bullet -}$ through the Haber–Weiss reaction. The extremely reactive $OH^{\bullet}$ radical can run rampant in the cell, causing extensive oxidative damage. Although it is not considered to have signaling function, the products of its reactions can elicit signaling responses, and cells sequester the catalytic metals to metallochaperones efficiently avoiding $OH^{\bullet}$ formation [5, 51]. NADPH oxidases (Rbohs for respiratory burst oxidase homologues) are an important ROS-generating system in plants producing $O_2^{\bullet -}$, which is usually dismutated to hydrogen peroxide (H_2O_2) rapidly [52]. *Arabidopsis* Rboh isoforms have been shown to participate in different processes: RbohC is necessary for root hair tip growth and mechanosensing [53] and RbohD and F function in pathogen defense and abscisic acid (ABA) signal transduction [54]. Recently, the role of Rbohs in heavy metal-induced accumulation of ROS [55] and early response to salt stress [56] has been established. In case of salt stress, the ROS-generating activity was localized to internalized plasma membrane vesicles in contrast to the apoplastic ROS production during biotic interactions, root hair growth, and ABA signaling. In addition, *Arabidopsis* RbohD was demonstrated to be responsible for the

fast-moving ROS signal mediating the systemic acclimation to several abiotic stresses [57]. Other important sources of ROS gaining attention are detoxification reactions catalyzed by cytochrome P450 in cytoplasm and endoplasmic reticulum [58]. ROS are also generated in plasma membrane. A number of other ROS-generating systems, such as pH-dependent cell wall peroxidases, amine oxidases, and oxalate oxidases, are present in apoplast, and being dependent on pH, they are activated by alkaline pH, which in the presence of a reductant produces H_2O_2. Alkalization of apoplast upon elicitor recognition precedes the oxidative burst, and generation of H_2O_2 by a pH-dependent cell wall peroxidase has been proposed as an alternative way of ROS production during biotic stress [59]. It was recently shown that H_2O_2 produced by apoplastic polyamine oxidase can influence the salinity stress signaling in tobacco and can play a role in balancing the plant response between stress tolerance and cell death [60].

3.3 ROS Scavenging

ROS are highly toxic, they can react with cellular components such as lipids, proteins, and nucleic acids, and cause lipid peroxidation, membrane damage, and inactivation of enzymes, thus affecting many physiological processes as well as cell viability. Even so, plants have evolved a complex array of mechanisms to retain low ROS level and avoid the detrimental effects of excessively high ROS concentrations [61]. ROS are rapidly detoxified by various cellular enzymatic and nonenzymatic mechanisms in plants. Oxidative stress occurs when there is a serious imbalance between the production of ROS and the antioxidative defense [62]. The components of antioxidant defense system consist of various soluble (ASH, GSH) and membrane (α-tocopherol) compounds as well as enzymes (SOD, APX, GPX, CAT, MDHAR, DHAR, and glutathione reductase (GR)) [4, 61].

3.3.1 Enzymatic Antioxidants

SODs are the most effective intracellular enzymatic antioxidants, which are ubiquitous in all aerobic organisms and subcellular compartments prone to ROS-mediated oxidative stress. Superoxide dismutases act as the first line of defense against the toxic effects of ROS by dismutating superoxide to H_2O_2 [4, 10]. The upregulation of SODs is implicated in combating oxidative stress caused due to biotic and abiotic stresses and has a critical role in the survival of plants under stressful environments [4]. Significant increase in SOD activity under salt stress has been observed in various plants, namely, mulberry [63], *Cicer arietinum* [64], and *Lycopersicon esculentum* [65]. Pan *et al.* [66] investigated the effects of salt and drought stress on *Glycyrrhiza uralensis* Fisch and observed a significantly increased SOD activity, but an additional Mn-SOD isoenzyme was also detected under only salt stress. Increased SOD activity has also been detected following Cd treatment in

Hordeum vulgare [67], *A. thaliana* [68], *Oryza sativa* [69], *Triticum aestivum* [70], *Brassica juncea* [71], *Vigna mungo* [72], and *C. arietinum* [73]. Similarly, increased SOD activity following drought stress was also observed in three cultivars of *Phaseolus vulgaris* [74], *Alternanthera philoxeroides* [75], and *O. sativa* [76]. Wang and Li [77] studied the effect of water stress on the activities of total leaf SOD and chloroplast SOD in *Trifolium repens* L. and observed a significantly increased SOD activity under water stress. Similar result was reported by Simonovicova *et al.* [78] in *H. vulgare* L. cv. Alfor root tips under Al stress. APX, GPX, and CAT subsequently scavenge H_2O_2; however, unlike CAT, APX requires an ascorbate and GSH regeneration system, the ascorbate–glutathione cycle. Detoxifying H_2O_2 to H_2O by APX occurs by oxidation of ascorbate to MDA, which can be regenerated by MDA reductase (MDAR) using NAD(P)H as reducing equivalents. MDA can spontaneously dismutate into dehydroascorbate. Ascorbate regeneration is mediated by dehydroascorbate reductase (DHAR) driven by the oxidation of GSH to GSSG. Finally, GR can regenerate GSH from GSSG using NAD(P)H as a reducing agent [10]. Enhanced expression of APX in plants has been demonstrated under various stress conditions. Increased leaf APX activity under Cd stress has been reported in *Ceratophyllum demersum* [79], *B. juncea* [71], *T. aestivum* [70], and *V. mungo* [72]. Hsu and Kao [80] reported that pretreatment of *O. sativa* seedlings with H_2O_2 under nonheat shock conditions resulted in an increase in APX activity and protected rice seedlings from subsequent Cd stress. Enhanced activity of APX was also observed in *Anabaena doliolum* under salt stress [81], in three cultivars of *P. vulgaris* [74] and *Picea asperata* [82] under water stress, and in *H. vulgare* L. cv. Alfor root tips exposed to Al stress [78]. Sharma and Dubey [76] found that mild drought-stressed plants had higher chloroplastic APX activity than control-grown plants, but the activity declined at the higher level of drought stress. Akin to APX, GPX also detoxifies H_2O_2 to H_2O, but uses GSH directly as a reducing agent. The GPX cycle is closed by regeneration of GSH from GSSG by GR [10]. Abiotic stress increases GPX activity in cultivars of *Capsicum annuum* plants [83], but decreases in roots and causes no significant change in the leaves of Cd-exposed *Pisum sativum* plants [84]. Gapinska *et al.* [65] reported that 150 mM NaCl stress significantly increased the GPX activity in *L. esculentum* Mill. cv. "Perkoz" roots. Leisinger *et al.* [85] reported the upregulation of a GPX homologous gene (Gpxh gene) in *Chlamydomonas reinhardtii* following oxidative stress.

CATs are tetrameric heme-containing enzymes with the potential to dismutate H_2O_2 directly into H_2O and O_2 and are indispensable for ROS detoxification during stress conditions [86]. CAT is important in the removal of H_2O_2 generated in peroxisomes by oxidases involved in β-oxidation of fatty acids, photorespiration, and purine catabolism [4]. Unpredictable response of CAT activity under metal stress has been reported by various researchers. Under Cd stress, CAT activity declined in *Glycine max* [87], *Phragmites australis* [88], *C. annuum* [83], and *A. thaliana* [89], whereas its activity increased in *O. sativa* [69], *B. juncea* [71], *T. aestivum* [70], *C. arietinum* [73], and *V. mungo* roots [72]. Hsu and Kao [80] reported that pretreatment of rice seedlings with H_2O_2 under nonheat shock conditions resulted in an increase in CAT activity and protected rice seedlings from subsequent Cd stress. It has been reported that a significant increase in CAT activity was observed in

C. arietinum leaves [90] and roots [64] under salinity stress. Srivastava *et al.* [81] reported a decrease in CAT activity in *A. doliolum* under NaCl and Cu^{2+} stress. Simova-Stoilova *et al.* [91] reported increased CAT activity in wheat under drought stress. However, Sharma and Dubey [76] reported a decrease in CAT activity in rice seedlings following drought stress. Pan *et al.* [66] observed that the combined effects of salt and drought stress decrease CAT activity in *G. uralensis* seedlings. It has also been reported that high light condition increased CAT activity in *P. asperata* under drought stress [82]. UV-B stress also led to a significant increase in CAT activity in *Cassia auriculata* seedlings [92]. The extent of oxidative stress in a cell is determined by the amounts of superoxide, H_2O_2, and hydroxyl radicals. Therefore, the balance of SOD, APX, and CAT activities will be crucial for suppressing toxic ROS levels in a cell. Changing the balance of scavenging enzymes will induce compensatory mechanisms. For example, when CAT activity was reduced in plants, scavenging enzymes such as APX and GPX were upregulated. Unexpected effects can also occur [10]. Compared to plants with suppressed CAT, plants lacking both APX and CAT were less sensitive to oxidative stress [93]. Because photosynthetic activity of these plants was decreased, reduction in APX and CAT might result in suppression of ROS production via chloroplasts [10].

MDHAR associated with APX is also located in peroxisomes and mitochondria, where it scavenges H_2O_2 [46]. Schützendübel *et al.* [94] observed enhanced MDHAR activity in Cd-exposed *Pinus sylvestris* and a declined MDHAR activity in Cd-exposed poplar hybrids (*Populus* × *Canescens*). Sharma and Dubey [76] reported that the activities of enzymes involved in regeneration of ASH, that is, MDHAR, DHAR, and GR, were higher in drought-stressed rice seedlings. It has also been reported that the increase in MDAR activity contributes toward chilling tolerance in tomato fruit [95]. DHAR regenerates ASH from the oxidized state and regulates the cellular ASH redox state, which is crucial for tolerance to various abiotic stresses, leading to the production of ROS [4]. It has also been found that DHAR overexpression also enhances plant tolerance against various abiotic stresses. Plants overexpressing DHAR showed tolerance to Al stress by maintaining high ASH level [96]. Overexpression of DHAR in tobacco protected the plants against ozone toxicity [97], increased salt tolerance in *Arabidopsis* [98], and drought and ozone stress tolerance in tobacco [99]. Guaiacol peroxidase (GPOX) decomposes indole-3-acetic acid (IAA) and has a role in the biosynthesis of lignin and defense against biotic stresses by scavenging H_2O_2 [4]. GPOX prefers aromatic electron donors such as guaiacol, and pyrogallol usually oxidizes ascorbate at the rate of around 1% that of guaiacol [100]. The activity of GPOX varies considerably depending on plant species and stress conditions. It increased in Cd-exposed plants of *T. aestivum* [101], *A. thaliana* [89], and *C. demersum* [79]. Radotic *et al.* [102] found an initial increase in GPOX activity in spruce needles subjected to Cd stress; however, subsequent Cd treatments caused a decline in the activity. A concomitant increase in GPOX activity in both leaf and root tissues of *Vigna radiate* [103] and *O. sativa* [104] has also been reported under salinity stress.

GR, a flavoprotein oxidoreductase, is a potential enzyme of the ASH–GSH cycle, which plays an essential role in defense system against ROS by sustaining the

reduced status of GSH [105]. GR and GSH play a crucial role in determining the tolerance of a plant under various stresses [106]. GR activity was found increased in the presence of Cd in *C. annuum* [83], *A. thaliana* [68], *V. mungo* [72], *T. aestivum* [70], and *B. juncea* [71]. It has been reported that increased GR activity was observed in the leaf tissues of *C. arietinum* L. cv. Gokce [90] and roots [64] under salt stress. Srivastava *et al.* [81] reported a decline in GR activity in *A. doliolum* under Cu^{2+} stress, but it increased under salt stress. Sharma and Dubey [76] found a significant increase in GR activity in drought-stressed *O. sativa* seedlings. Under high light condition, drought increased the GR activity in *P. asperata* Mast. seedlings, but no prominent drought-induced differences in GR activities were observed in low light seedlings [82]. Plant GSTs are known to have roles in herbicide detoxification, hormone homeostasis, vacuolar sequestration of anthocyanin, tyrosine metabolism, hydroxyperoxide detoxification, regulation of apoptosis, and responses to biotic and abiotic stresses [107]. Noctor *et al.* [108] reported that GSTs have the potential to remove cytotoxic or genotoxic compounds, which can react or damage the DNA, RNA, and proteins. In fact, GSTs can reduce peroxides with the help of GSH and produce scavengers of cytotoxic and genotoxic compounds. Increased GST activity was reported in leaves and roots of Cd-exposed *P. sativum* plants [84] and in roots of *O. sativa* and *P. australis* plants [88, 109]. Gapinska *et al.* [65] observed an increased GST activity in *L. esculentum* roots under salinity stress. Drought-tolerant sorghum cv. M35-1 and drought-sensitive cv. SPV-839 were studied for their salinity tolerance to find that cv. M35-1 exhibited efficient H_2O_2 scavenging mechanisms with significantly higher activities of GST and CAT [110].

3.3.2
Nonenzymatic Antioxidants

Ascorbic acid is the most abundant, powerful, and water-soluble antioxidant that prevents or minimizes the damage caused by ROS in plants [111, 112]. ASH is considered as a most powerful ROS scavenger because of its ability to donate electrons in a number of enzymatic and nonenzymatic reactions. It can provide protection to membranes by directly scavenging the $O2^{\bullet -}$ and $OH^{\bullet}$ and by regenerating α-tocopherol from tocopheroxyl radical [4]. Mutants with decreased ascorbic acid levels [113] or altered glutathione content [114] are hypersensitive to stress. While GSH is oxidized by ROS forming GSSG, ascorbate is oxidized to MDA and DHA. Through the ascorbate–glutathione cycle, GSSG, MDA, and DHA can be reduced reforming GSH and ascorbate [10]. Plants increase the activity of GSH biosynthetic enzymes and GSH levels in response to chilling, heat shock, pathogen attack, and drought stress [108, 115, 116]. Demirevska-Kepova *et al.* [117] reported that oxidized ascorbate content was increased during Cd exposure in *H. vulgare* plants. Yang *et al.* [82] observed a significant increase in ASH content in *P. asperata* seedlings under high light condition and drought condition. Agarwal [92] reported that ASH and DHA content, as well as the GSH/GSSG content, was significantly increased by the UV-B stress in *C. auriculata* seedlings. Conversely, a decrease in ASH content in the roots and nodules of *G. max* under Cd stress was also

observed [87]. Cd also decreased the ASH content in *Cucumis sativus* chloroplast and in the leaves of *A. thaliana* and *P. sativum* [118–120], whereas it remained unaffected in *Populus* × *Canescens* roots [119, 120].

GSH is necessary to maintain the normal reduced state of cells so as to counteract the inhibitory effects of ROS-induced oxidative stress [121]. It is a potential scavenger of $^1O_2$, H_2O_2 [122, 123], and most dangerous ROS such as $OH^{\bullet}$ [124]. The role of GSH in the antioxidant defense system provides a strong basis for its use as a stress marker. However, the concentration of cellular GSH has a major effect on its antioxidant function and it varies considerably under abiotic stresses. Furthermore, strong evidence has indicated that an elevated GSH concentration is correlated with the ability of plants to withstand metal-induced oxidative stress. Increased concentration of GSH has been observed with the increasing Cd concentration in *P. sativum* [125], *Sedum alfredii* [126], and *V. mungo* [127]. Srivastava *et al.* [81] reported an appreciable decline in GR activity and GSH pool under Cu stress and a significantly higher increase under salt stress. A high ratio of reduced to oxidized ascorbate and GSH is essential for ROS scavenging in cells. Reduced states of the antioxidants are maintained by GR, MDAR, and DHAR using NADPH as reducing power [128, 129]. In addition, the overall balance among different antioxidants must be tightly controlled. The importance of this balance is evident when cells with enhanced glutathione biosynthesis in chloroplasts show oxidative stress damage, possibly due to changes in the overall redox state of chloroplasts [114].

Tocopherols are considered as a major antioxidant in biomembranes, where they play both antioxidant and nonantioxidant functions and potential scavengers of ROS and lipid radicals [130]. Tocopherols are considered general antioxidants for protection of membrane stability, including quenching or scavenging ROS such as $^1O_2$. Tocopherols have been shown to prevent the chain propagation step in lipid autooxidation, which makes it an effective free radical trap. In addition, it has been estimated that one molecule of α-tocopherol can scavenge up to 120 $^1O_2$ molecules by resonance energy transfer [131]. Recently, it has been found that oxidative stress activates the expression of genes responsible for the synthesis of tocopherols in higher plants [132]. Increased levels of α-tocopherol and ASH have been found in tomato following trizole treatment that may help in protecting membranes from oxidative damage, and thus chilling tolerance in tomato plants [133]. Increase in tocopherol during water stress in plants has also been reported by many workers [132, 133]. Srivastava *et al.* [81] reported a general induction in α-tocopherol content in *A. doliolum* under NaCl and Cu^{2+} stress.

3.4 Transgenic Approach in ROS Toxicity in Plants

To combat ROS toxicity and overcome its damaging effects on plant cells, specific roles for antioxidant enzymes have been explored via transgenic approaches. Unlike other organisms, plants possess multiple genes encoding antioxidant enzymes. Different isoforms are specifically targeted to chloroplasts, mitochondria,

peroxisomes, as well as to the cytosol and apoplast [128]. There have been numerous studies on development of abiotic stress-tolerant transgenic plants overexpressing various antioxidant enzymes (Table 3.1). Transgenic rice plants overexpressing *OsMT1a* demonstrated an increased CAT activity and thus an enhanced drought tolerance [134]. Protoplasts with Mn-SOD overexpression showed less oxidative damage, higher H_2O_2 content, and a significant increase in SOD and GR activities under photooxidative stress [135]. Overexpression of a Mn-SOD in transgenic *Arabidopsis* plants also showed increased salt tolerance [136]. Cu/Zn-SOD overexpressing transgenic tobacco plants showed multiple stress tolerance [137], and transgenic *O. sativa* Pusa Basmati-1 were more tolerant to MV-mediated oxidative stress, salinity stress, and drought stress [138]. Overexpression of Mn-SOD in transformed *L. esculentum* plants also showed enhanced tolerance against salt stress [139]. In a study, the maize Cu/Zn-SOD and CAT genes were targeted to the chloroplasts of *Brassica campestris* L. ssp. pekinensis cv. Tropical Pride, and it was reported that exposure of SOD + CAT *B. campestris* plants to 400 ppb SO_2 showed enhanced tolerance than wild type [140]. Furthermore, it was also reported that enhancement of SOD or CAT activity individually had only a minor effect on 400 ng ml^{-1} SO_2 tolerance in *B. campestris* transformed with *E. coli* SOD and CAT genes. It was suggested that the cotransformed strains that overexpressed both SOD and CAT showed high resistance to SO_2 [141]. CAT overexpressed *O. sativa* L. cv. Yuukara or Matsumae showed low-temperature stress tolerance due to effective detoxification of H_2O_2 by CAT [142]. *Nicotiana tabacum* plants transformed with a CAT3 gene from *B. juncea* possessed enhanced tolerance to Cd toxicity and showed better seedling growth and longer roots [143].

Overexpression of APX in *N. tabacum* chloroplasts enhanced plant tolerance to salt and water deficit [137]. Yang *et al.* [134] correlated the enhanced tolerance of *OsMT1a* overexpessing transgenic rice plants to drought stress with an increase in APX activity. Transgenic *A. thaliana* plants with APX1 gene from *H. vulgare* L. exhibited enhanced salt tolerance due to higher APX, SOD, CAT, and GR and lower H_2O_2 and MDA content [144]. Transformed *N. tabacum* plants, which possess *Ipomoea batata* swpa4 gene, displayed improved tolerance to various stresses such as MV, H_2O_2, NaCl, and mannitol and better resisitance to *P. parasitica nicotianae*. swpa4 function as a positive defense signal in the H_2O_2-regulated stress response, and transgenic plants showed 50-fold higher POD specific activity [145]. Transgenic wheat plant overexpressing *E. coli* GR gene showed higher GSH content and GSH/GSH + GSSG ratio than control, but no increase in SOD and GR activities [135]. Overexpression of GR in transgenic *Gossypium hirsutum* L. cv. Coker 312 enhanced chilling stress tolerance and photoprotection [146]. MDAR1 expressing transgenic *N. tabacum* lines exhibited greater tolerance to ozone, salt, and PEG stress owing to higher MDAR activity and higher level of reduced AsA [147]. Transgenic tobacco plants overexpressing DHAR demonstrated better drought and salt tolerance with higher DHAR activity and reduced AsA content [147]. DHAR expressing *A. thaliana* L. (ecotype Wassilewskija) transgenic lines showed better salt tolerance due to a slight increase in DHAR activity and total ascorbate content [97]. Overexpression of GST in transgenic *O. sativa* cv. Zhonghua No.11 improved tolerance to salt and paraquat

Table 3.1 Some instances of ROS scavenging by antioxidant-overexpressing transgenic plants to various abiotic stresses.

Gene/source	Transgenic	Stress tolerance	Reference
Cu/Zn-SOD/*Avicennia marina*	*O. sativa*	Transgenic plants were more tolerant to MV-mediated oxidative stress, salinity stress, and drought stress	[138]
Mn-SOD/*N. plumbaginifolia*	*T. aestivum*	Photooxidative stress tolerance, lower oxidative damage, higher H_2O_2, and significant increase in SOD and GR activities	[135]
CAT/*T. aestivum*	*O. sativa*	Low-temperature stress tolerance due to effective detoxification of H_2O_2 by CAT	[142]
CAT3/*Brassica juncea*	*N. tabacum*	Cd stress tolerance, better seedling growth, and longer roots	[143]
APX1/*H. vulgare*	*A. thaliana*	Salt tolerance due to higher APX, SOD, CAT, and GR and low H_2O_2 and MDA content	[144]
swpa4/*I. batatas*	*N. tabacum*	Resistance to various stresses such as MV, H_2O_2, NaCl, mannitol, and *P. parasitica nicotianae*; swpa4 functions as a positive defense signal in the H_2O_2-regulated stress response and transgenic plants showed 50-fold higher POD specific activity	[145]
GR/*Escherichia coli*	*T. aestivum*	Higher GSH content and GSH/GSH + GSSG ratio than control, no increase in SOD and GR activities	[135]
GR/*A. thaliana*	*G. hirsutum*	Chilling stress tolerance and photoprotection	[146]
MDAR1/*A. thaliana*	*N. tabacum*	Ozone, salt, and PEG stress tolerance due to higher MDAR activity and higher level of reduced AsA	[147]
DHAR/*A. thaliana*	*N. tabacum*	Drought and salt tolerance with higher DHAR activity and reduced AsA content	[147]
DHAR/*O. sativa*	*A. thaliana*	Salt tolerance due to slight increase in DHAR activity and total ascorbate	[147]
GST/*Suaeda salsa*	*O. sativa*	Salt and paraquat stress tolerance due to GST, CAT, and SOD activities	[148]
GST + GPX/*N. tabacum*	*N. tabacum*	Increased thermal or salt stress tolerance due to glutathione and ascorbate content	[110]
GPX/*Chlamydomonas*	*N. tabacum*	Tolerant to MV under moderate light intensity, chilling stress under high light intensity, or salt stress due to low MDA and high photosynthesis and antioxidative system	[149]
GPX-2/*Synechocystis* PCC 6803	*A. thaliana*	Tolerance to H_2O_2, Fe ions, MV, chilling, high salinity, or drought stresses	[150]

stress due to GST, CAT, and SOD activity [148]. GST + GPX expressing transgenic tobacco exhibited increased thermal or salt stress tolerance due to glutathione and ascorbate content [110]. Transgenic tobacco plants that overexpressed GPX demonstrated better tolerance to MV under moderate light intensity, chilling stress under high light intensity, or salt stress due to low MDA and high photosynthesis and antioxidative system [149]. GPX-2 expressing *Arabidopsis* transgenic lines showed enhanced tolerance to H_2O_2, Fe ions, MV, chilling, high salinity, or drought stresses [150].

3.5 Conclusions

ROS, which are partially reduced or activated derivatives of oxygen ($^1O_2$, $O_2^{\bullet -}$, H_2O_2, $OH^{\bullet}$, and $HO_2^{\bullet -}$) invariably generated as spin-off by plants during various metabolic processes in different cellular compartments such as chloroplast, mitochondria, peroxisomes, cytosol, plasma membrane, and apoplastic space, are highly reactive and toxic and can lead to the oxidative destruction of cells (oxidative stress). ROS can react with cellular components (lipids, proteins, and nucleic acids) and cause lipid peroxidation, protein oxidation, DNA damage, membrane damage, and inactivation of enzymes, thus affecting various physiological and biochemical processes as well as cell viability. Plants have evolved a complex array of ROS scavenging mechanisms to retain low ROS level, and thereby the detrimental effects of excessively high ROS concentrations could be avoided. Enzymatic antioxidant defense systems of plants consist of a variety of ROS scavengers, such as SOD, APX, GPX, CAT, MDHAR, DHAR, GPOX, GR, and GST, and nonenzymatic low molecular metabolites, such as ASH, GSH, α-tocopherol, proline, carotenoids, and flavonoids. However, numerous biotic and abiotic stresses such as plant diseases, drought, salinity, extreme temperatures, excess light, pollutants, xenobiotics, ultraviolet radiation, ozone, hypoxia, nutrient deficiency, and so on upset the equilibrium between ROS generation and scavenging, leading to overproduction and higher accumulation of ROS and eventually oxidative stress. High accumulation of ROS in plant cells affects various cellular functions through damaging nucleic acids, protein oxidation, and lipid peroxidation, which eventually results in cell death. ROS toxicity resulting from various biotic and abiotic stress factors is considered to be one of the major causes of low crop productivity worldwide. However, they cannot be eliminated completely because plants use ROS as second messengers in signal transduction cascades in diverse physiological processes. It has become evident that ROS also play an important signaling role in plants controlling processes such as growth, development, response to biotic and abiotic stresses, and programmed cell death. This suggests a dual role for ROS as both toxic by-products of aerobic metabolism and key regulators of growth, development, and defense pathways. It is still not clearly understood how this dual role is controlled in plants; however, it is quite clear that the steady-state level of ROS in cells needs to be tightly regulated. Further genomics, proteomics, and metabolomics studies, combined with newly emerging technologies, may provide an insight

into the networks involved in different ROS-related plant processes. A thorough and complete understanding of the ROS gene network may lead to the identification of genes, which can be exploited to modulate/transform ROS-related metabolisms in plant for the development of better performing transgenic crop plants against biotic and abiotic stress.

Salinity Stress: A Major Constraint in Crop Production

Narendra Tuteja, Lamabam Peter Singh, Sarvajeet Singh Gill, Ritu Gill, and Renu Tuteja

Salinity is a major constraint in crop production worldwide. Salinity affects nearly 20% of the world's cultivated area and about half the world's total irrigated lands. Saline soil is characterized by the toxic levels of chlorides and sulfates of sodium. The problem of soil salinity is increasing due to irrigation, improper drainage, entry of seawater in coastal areas, and salt accumulation in arid and semiarid regions. Sodium is an essential micronutrient for some of the plants, but most crop plants are natrophobic. Salinity is detrimental to plant growth as it causes nutritional constraints by decreasing uptake of phosphorus, potassium, nitrate, and calcium and leads to ion cytotoxicity and osmotic stress. Under salinity, ions such as Na^+ and Cl^- penetrate the hydration shells of proteins and interfere with the function of these proteins. Ionic toxicity, osmotic stress, and nutritional defects under salinity lead to metabolic imbalances and oxidative stress. Plant salt tolerance mechanisms can be grouped into cellular homeostasis (including ion homeostasis and osmotic adjustment), stress damage control (repair and detoxification), and growth regulation. Osmotic stress induces several proteins in vegetative tissues of higher plants, which are related to late-embryogenesis abundant (LEA) proteins and thought to play an important role in osmotic adjustment. Numerous genes that are involved in stress tolerance mechanisms (e.g., genes encoding osmolytes, antioxidant enzymes, components of calcium signaling, and other regulatory signaling factors) are also upregulated in response to salt stress. By and large, tolerance of plant to salinity stress is a synchronized action of multiple stress responsive genes, which also crosstalk with other components of stress signal transduction pathways.

4.1
Introduction

Being sessile organisms, plants cannot escape but often face and are compelled to grow under various unfavorable conditions in natural environment, such as drought, salinity, chilling, freezing, high and low temperature, flooding, or extreme light, and so on, which are collectively known as abiotic stresses. Any of these extreme conditions can delay growth and development, reduce productivity, and, in extreme

Improving Crop Resistance to Abiotic Stress, First Edition.

cases, lead to plant death [1]. Abiotic stress conditions cause extensive losses to agricultural production worldwide. Soil salinity is among one of the major abiotic stresses that adversely affects crop productivity and quality. Salinity affects nearly 20% of the world's cultivated area and about half the world's total irrigated lands [2]. By and large, reduction in growth and yield caused by salinity is mainly due to salt-induced water stress, nutritional imbalance, specific ion toxicity toward photosynthesis, hormonal imbalance, and generation of reactive oxygen species (ROS), which may cause membrane destabilization [3–10]. Soil salinity is characterized by the toxic levels of chlorides and sulfates of sodium in the soil. It is mainly caused by irrigation with groundwater of high salt content, improper drainage, entry of seawater during cyclones in coastal areas, and salt accumulation in arid and semiarid regions due to high evaporative demand and insufficient leaching of ions owing to inadequate rainfall [11, 12]. Excess salts in the soil reduce permeability of soils [13]. Salt-affected soils usually contain a variety of inorganic salts with cations such as Na^+, Ca^{2+}, Mg^{2+}, and K^+ and anions such as Cl^-, SO_4^{2-}, HCO_3^-, CO_3^{2-}, and $NO3^-$ [14] that adversely affect plant growth and productivity causing ion toxicity or osmotic effect on plants [5, 15].

The most important effects of salinity on plants are lowering of water potential, specific ion toxicity (sodium and chloride), and interference with the uptake of essential nutrients. The interference with the uptake of essential nutrients, however, may not be considered important because it has no immediate effect due to mobile reserve nutrients present in plants [16]. Decreased water potential and ion toxicity are considered important factors in reducing plant growth under salt stress. Salt-sensitive cultivars accumulate ions more quickly than salt-tolerant cultivars leading to leaf death and progressive death of plant [9]. Ion imbalances due to ion accumulation caused by salt stress show their negative effects by reducing shoot and root growths and increasing some amino acids including proline [17].

Sodium is an essential micronutrient for some of the plants, but most crop plants are natrophobic. Salinity causes nutritional constraints as it decreases uptake of phosphorus, potassium, nitrate, and calcium, while leading to ion cytotoxicity and osmotic stress [2]. Salinity may also cause denaturation of functional and structural proteins [18]. Under salinity, ions like Na^+ and Cl^- penetrate the hydration shells of proteins and interfere with the function of these proteins. Ionic toxicity, osmotic stress, and nutritional defects under salinity lead to metabolic imbalances and oxidative stress. Plant salt tolerance mechanisms can be grouped into cellular homeostasis (including ion homeostasis and osmotic adjustment), stress damage control (repair and detoxification), and growth regulation [2]. Antioxidant enzyme activities are usually affected by salinity and used as indicators of oxidative stress in plants [19]. To protect against oxidative stress, plant cells produce both antioxidant enzymes such as superoxide dismutase (SOD), peroxidase (POX), and catalase (CAT) and nonenzymatic antioxidants such as ascorbate, glutathione, and tocopherol [19, 20]. The presence of high concentration of salt in the growth medium also often results in accumulation of low molecular mass compounds such as proline and glycine betaine (GB), commonly termed compatible solutes, which do not interfere with the normal biochemical reactions [4, 13, 21].

4.2
Effects on Plant Growth and Development

Salinity affects almost every aspect of the physiology and biochemistry of plants and significantly reduces growth and yield. High exogenous salt concentrations affect seed germination, lead to water deficit, and cause ion imbalance of the cellular ions resulting in ion toxicity and osmotic stress [22]. The most important process that is affected in plants, growing under saline conditions, is photosynthesis. Most of the cultivated plants are sensitive to salt stress, in which NaCl salinity causes reduction in carbohydrates that are needed for cell growth. Carbohydrates are supplied mainly through the process of photosynthesis, and photosynthesis rates are usually lower in plants exposed to salinity and especially to NaCI [5, 23]. This would further lead to restriction in water availability and imbalance in nutrient uptake by plants [24, 25] with inhibition in seed germination due to ionic disturbance and osmotic and toxic effects [26, 27]. Burman *et al.* [28] emphasize that the reduction of photosynthesis due to salinity is primarily by a decrease in stomatal conductance (g_s), while Wilson *et al.* [29] and Yang and Lu [30] suggested it is due to a decrease in CO_2 diffusion to the chloroplast. Reduced photosynthesis under salinity is attributed not only to stomata closure leading to a reduction in intercellular CO_2 concentration but also to non-stomatal factors such as depression in PSII activity, electron transport, photophosphorylation activity [31], photosynthetic enzymes, chlorophyll, and carotenoids. However, it is a well-accepted fact that photosynthetic activity decreases when plants are grown under saline conditions leading to reduced growth and productivity [32]. Stomatal conductance (g_s) can be reduced with increasing environmental salinity. Like drought stress, salt stress involves a decrease in soil water potential. Stomata are sensitive to changes in soil water potential and usually close during the times of drought and salt stress [33]. A decrease in g_s reduces incoming CO_2 and thus can reduce photosynthesis rates. Salinity reduces the ability of plants to utilize water and causes not only a reduction in growth rate but also changes in plant metabolic processes [9].

High salinity causes both hyperionic and hyperosmotic stress effects in plants and the consequence can be fatal [7]. Osmotic effects are caused by salt-induced decrease in the soil water potential. Salinity results in a reduction in K^+ and Ca^{2+} content and an increased level of Na^+, Cl^-, and SO_4^{2+}, which forms its ionic effects [34]. Reduction in biomass, reduction in photosynthetic capacity, and changes in leaf water potential and leaf turgor have been reported to have a cumulative effect attributed to salinity stress [35]; it is also clear that several soil and other environmental factors do influence plant growth under salinity conditions [36]. Salt ion toxicity has numerous deleterious effects on plants such as denaturing cytosolic enzymes and facilitating the formation of reactive oxygen species that can damage membranes, proteins, and nucleic acids [2, 19]. Lipid peroxidation, induced by free radicals, is also important in membrane deterioration [22, 37–39]. Soil salinity also increases P, Mn, and Zn and decreases K and Fe concentrations in plants [40]. Shoots are generally more sensitive to cation disturbances than roots, and there are great differences among plant species in their ability to prevent or tolerate excess salt

concentrations [41]. Increasing levels of NaCl induces a progressive absorption of Na and Cl in both shoot and root [40]. Excessive Na concentration in the plant tissue hinders nutrient balance and osmotic regulation, and causes specific ion toxicity [24, 25]. Accumulation of Cl in the root tissue is disruptive to membrane uptake mechanisms, and these result in increased translocation of Cl to the shoots [42]. Cordovilla *et al*. [43] reported that NaCl decreased N concentration in the shoot tissues. Salinity has a negative interference in the nitrogen acquisition and utilization [44], reason being the antagonism between Cl^{-1} and $NO_3{}^{-1}$ [45]. The mechanism of plant adaptation required to survive in saline conditions is the same in all the plants. However, adaptations are at their extreme in halophytes, but can also be found in different degrees in glycophytes [16]. Variation in salt tolerance of glycophytes occurs between and within species and has been quantified for many crops [46].

4.3 Ionic Stress

Restriction of Na^+ entry into the root cells and then into the transpirational stream is crucial to prevent a buildup of toxic levels of salt in the shoot. Plants (both glycophytes and halophytes) must exclude about 97% of the Na^+ present in the soil at the root surface itself to prevent toxic levels of Na^+ accumulation in the shoots [11]. Sodium entry into the transpirational stream depends upon the amount of Na^+ uptake by Na^+ and nonspecific cation transporters and the proportion of water entry in the apoplastic/bypass pathway into the xylem. Na^+ in the soil gains initial entry into the cells of the root epidermis and cortex. The casparian strip in the endodermis plays a crucial role in preventing apoplastic Na^+ influx into the root stele [12]. Increased Na^+ accumulation in the plant due to high concentrations of Na^+ in the soil causes ionic stress in plants [47]. The complexity of the plant response to salt stress can be partially explained by the fact that salinity imposes salt toxicity in addition to osmotic stress [4]. Accumulation of sodium in the cytoplasm is prevented by restricting its uptake across the plasma membrane and by promoting its extrusion or sequestration in halophytes [4]. High salt concentrations (>400 mM) inhibit the activities of most enzymes because of perturbation of the hydrophobic–electrostatic balance between the forces maintaining protein structure [47]. However, toxic effects on cells occur at much lower salt concentrations (about 100 mM) [48]. Many studies have demonstrated that toxic effects of Na^+ in the cytosol is not the only reason of Na^+ toxicity but is also caused by disruption in K^+ homeostasis, possibly owing to the ability of Na^+ competing for K^+ binding sites [47]. Substantial advancement has been made in understanding ion homeostasis [4, 49, 50] and ion transporters are considered to play a significant role in salt tolerance. Bartels and Sunkar [47] suggested three mechanisms that prevent excess Na^+ accumulation in the symplast of plant cells: (1) restriction of Na^+ infiltration and entry into plants by Na^+ transporters, whose molecular identity is unknown; (2) compartmentalization of Na^+ in the vacuole; and (3) extrusion of Na^+: cytosolic Na^+ can be transported

back to the external medium or the apoplast via plasma membrane Na^+/H^+ antiporter activity.

4.3.1 Ion Selectivity

A major feature of the solute transport by plants in saline conditions is the degree of selectivity, particularly between potassium and sodium [51]. One of the most important physiological mechanisms of salt tolerance is the selective absorption of K^+ by plants from the saline media [52]. Halophytic or salt-tolerant species differ from salt-sensitive ones in having restricted uptake or transport of Na^+ and Cl^- to the leaves despite an effective compartmentalization of these ions. This is critical in preventing the buildup of toxic ions in cytoplasm [6, 9]. Ion imbalance, particularly that caused by Ca^{2+} and K^+, is the most important and widely studied phenomenon affected by salt stress, which is directly influenced by the uptake of Na^+ and Cl^- ions [9, 53]. Maintaining better concentrations of K^+ and Ca^{2+} and limiting the Na^+ uptake are vital for the salt stress tolerance in plants [54]. Higher K^+/Na^+ or Ca^{2+}/Na^+ ratios are characteristic of the tissue salt tolerance and are often used as a screening criterion for salt tolerance [6, 55, 56].

4.3.2 Na^+ Exclusion

Control of Na^+ levels at the entry point is crucial to avoid ionic stress [9]. The Na^+ uptake across the plasma membrane has been attributed to low Na^+ permeability properties of systems that transport essential K^+ [4]. The mechanism involves transport of Na^+ to the leaves and subsequently excreted out of the plant body, thereby reducing Na^+ concentration in plant tissues. Na^+ that is translocated in the transpiration stream is deposited and its concentration increases with time. This leads to much higher Na^+ concentrations in older leaves than those in younger leaves [57]. Na^+ exclusion is the most important adaptive strategy regulating the internal Na^+ load of halophytes. For instance, about 98% of Na^+ was reported to be excluded in the mangrove species *Avicennia marina* growing in 500 mM NaCl [58]. In perennial plants, exclusion is particularly important and it is more vital to regulate the incoming Na^+ load in the plant body [4, 59]

4.3.3 Na^+ Sequestration

Besides, efficiently excluding Na^+, halophytes effectively compartmentalize Na^+ in their vacuole that is why they can survive in high concentration saline soil. Conversely, glycophytes exclude Na^+ but cannot compartmentalize it [57]. In plants, the central vacuole plays a vital role in the regulation of cytoplasmic ion homeostasis. Exclusion of excess Na^+ from the cytoplasm and its accumulation in the vacuole represents one of the adaptive mechanisms during salt stress [47]. The vacuolar sodium sequestration or

compartmentalization of Na^+ into the vacuole is mediated by vacuolar Na^+/H^+ antiports at the tonoplast and uses the proton motive force generated by the vacuolar H^+ translocating enzymes, H^+-adenosine triphosphatase (ATPase) and H^+-inorganic pyrophosphatase (PPiase), to couple the downhill movement of H^+ with the uphill movement of Na^+ against the electrochemical potential [60].

4.4 Osmotic Stress

High salinity disturbs uptake and conductance of water. Most commonly, the stress is caused by high Na^+ and Cl^- concentrations in the soil solution [4]. An increase in the external salinity decreases water flow into the plant, limits water uptake to cells, and reduces turgor potential and cell volume [61]. Altered water status most likely brings about initial growth reduction; this reduction does not appear to depend on salt concentration in the growing tissues, rather it is a response to osmolarity of the external solution [9]. Plants maintain a high cytosolic K^+/Na^+ ratio under optimal conditions. Salt stress-induced decrease in the K^+/Na^+ ratio is inimical to cellular biochemical processes. In addition, K^+ provides necessary osmotic potential for water uptake by plant cells [62]. Thus, K^+ uptake is pivotal to cell turgor and maintenance of biochemical processes under salinity. In plants, Na^+ competes with K^+ for uptake under saline conditions. Membrane disorganization, reactive oxygen species, metabolic toxicity, inhibition of photosynthesis, and attenuated nutrient acquisition are factors that initiate more catastrophic events [63]. Salt stress that affects water supply leads to changes in stomatal opening that can, if stress persists, set in motion a chain of events originating from a decline in the leaf internal CO_2 concentration, consecutively inhibiting the carbon reduction cycle, light reactions, energy charge, and proton pumping [64]. Other pathways are affected by increased shuttling of carbon through the photorespiratory cycle [65, 66]. Eventually, carbon and nitrogen allocation and storage require readjustment, reactions that lead to the consumption of reducing power become favored, and development and growth may get altered [67].

4.4.1 Osmotic Adjustment

Under osmotic stress, plants need to maintain internal water potential below that of soil and maintain turgor and water uptake for growth [7]. This requires an increase in osmotica, either by uptake of soil solutes or by synthesis of metabolic (compatible) solutes [68]. To accommodate the ionic balance in vacuoles, cytoplasm accumulates osmotically active compounds called osmolytes in order to lower the osmotic potential. These compounds are referred to as compatible metabolites because they do not apparently interfere with the normal cellular metabolism [21]; rather, they replace water in biochemical reactions [68]. These organic solutes protect plants from salt stress by (i) osmotic adjustment, which helps in turgor maintenance; (ii) detoxification of reactive oxygen species; and (iii) stabilization of the quaternary

structure of proteins [66]. Although some compatible solutes are essential elemental ions, such as K^+, a majority are organic solutes [69], and accumulation of osmolytes varies between plant species. Generally, these molecules are not highly charged, but are polar, highly soluble, and have a larger hydration shell. Such molecules will be preferentially solubilized in the bulk water of the cell where they could interact directly with the macromolecules [70]. Compatible solutes consist of simple sugars (mainly fructose and sucrose), sugar alcohols (such as mannitol, sorbitol, and inositol) and complex sugars (such as trehalose and fructans), and quaternary amino acid derivatives or charged metabolites such as glycine betaine and proline. There may be more than one function for a particular solute [71, 72], and according to the results from *in vitro* experiments [73], different compatible solutes seem to have different functions [67]. The main function of compatible solutes may be stabilization of proteins, protein complexes, or membranes under environmental stress. In *in vitro* experiments, compatible solutes at high concentrations have been found to reduce the inhibitory effects of ions on enzyme activity [74], to increase thermal stability of enzymes [75], and to prevent dissociation of the oxygen evolving complex of photosystem II (PSII) [76].

Genes involved in osmoprotectant biosynthesis are upregulated under salt and drought stresses [77, 78]. Enhanced tolerance to salt stress was observed in transgenic plants engineered to overaccumulate mannitol [71, 79], glycine betaine [80–82], and proline [83, 84]. Transgenic rice plants expressing a peroxisomal betaine aldehyde dehydrogenase of barley accumulated fewer Na^+ and Cl^- ions and more K^+ ions [81].

4.4.1.1 **Soluble Sugars**

Numerous studies have shown that under salt stress conditions plant accumulate nonstructural carbohydrates (sucrose, hexoses, and sugar alcohols), though in varying degrees in different plant species [47]. A strong correlation between sugar accumulation and osmotic stress tolerance has been reported [85]. Of the various organic osmotica, sugars contribute up to 50% of the total osmotic potential in glycophytes subject to saline conditions [86]. The accumulation of soluble carbohydrates in plants has been widely reported as a response to salinity or drought, despite a significant decrease in net CO_2 assimilation rate [87]. Carbohydrates such as sugars (glucose, fructose, sucrose, and fructans) and starch accumulate under salt stress [88], playing a leading role in osmoprotection, osmotic adjustment, carbon storage, and radical scavenging. A decrease in starch content and an increase in both reducing and nonreducing sugars and polyphenol levels have been reported in leaves of *Bruguiera parviflora* [88]. In leaves of tomato, the contents of soluble sugars and total saccharides are increased significantly, but the starch content is not affected [89]. Ashraf and Tufail [90] found that although total soluble sugar content increased significantly in all five sunflower lines with increasing salt concentrations, the salt-tolerant lines had generally greater soluble sugars than the salt-sensitive ones. On the contrary, in safflower the pattern of accumulation of soluble sugars differed, even within salt-tolerant accessions, while one salt-tolerant line accumulated a high content of soluble sugars, another line was salt tolerant despite solute accumulation similar to that in

salt-sensitive accessions [91]. Ashraf [92] compared salt-tolerant wild populations with cultivated populations of *Melilotus indica* and *Eruca sativa* and found that *M. indica* had significantly higher soluble sugars in their leaves than the latter salt-sensitive populations at varying levels of salt concentrations. It has been reported that trehalose, a disaccharide that accumulates in many organisms, acts as both osmolyte and osmoprotectant under various abiotic stresses [93], protects membranes and proteins in cells exposed to stresses such as salinity and drought that cause water deficit [94], and reduces aggregation of denatured proteins [95]. Recently, Yamada *et al.* [96] have reported that trehalose has a suppressive effect on apoptotic cell death. It has also been reported that many higher plants possess trehalose activity, which is perhaps responsible for rapid degradation of any trehalose synthesized [47]. *Arabidopsis thaliana* has at least one gene that encodes trehalose-6-phosphate phosphatase required for trehalose synthesis, but the physiological role of this enzyme is not yet clear [97].

4.4.1.2 **Polyols**

Polyols, the polyhydric alcohols, which exist in both acyclic and cyclic forms, are involved in osmoregulation and are believed to play a role in plant salt tolerance [98]. The most common polyols found in plants consist of acyclic forms, mannitol, glycerol, sorbitol, and cyclic (cyclitols) forms ononitol and pinitol. Generally, they are thought to be accumulated in the cytoplasm of some halophytes to overcome the osmotic disturbances caused by high concentrations of inorganic ions compartmentalized in vacuoles [99]. Besides their role in osmoregulation, polyols also function as oxygen radical scavengers. For example, mannitol was found *in vitro* to act as a scavenger of reactive oxygen species [100], thereby protecting proteins from oxidative damage in drought-stressed plants [101]. Smirnoff [18] found that mannitol, sorbitol, glycerol, ononitol, and pinitol were all active scavengers. Polyols make up a considerable percentage of all assimilated CO_2 as scavengers of stress-induced oxygen radicals [102].

Transgenic tobacco plants synthesize mannitol-1-phosphate from fructose-6-phosphate. Although *Escherichia coli mtlD* gene-transformed tobacco plants and wild type have similar growth in the absence of salt stress, transgenic plants have growth advantage over the wild type in the presence of 250 mol m^{-3} of salt [103]. Binzel *et al.* [104] found that tobacco cells adapted to 428 mM of NaCl could maintain cytosolic Na^+ and Cl^- level less than 100 mM. Though mannitol only partially decreases the amount of inorganic ion accumulation in the cytosol, its protective effect as a compatible solute may be sufficient to give marginal growth advantage to transformed plants [70]. Su *et al.* [105] obtained three rice transgenic lines with bacterial *mtlD* and demonstrated that biosynthesis and accumulation of mannitol in plants are correlated with salt stress tolerance of plants. These solutes are widely believed to function as a protector or stabilizer of enzymes or membrane structures that are sensitive to dehydration- or ion-induced damage [70].

Pinitol and other *O*-methyl inositols may play an important role both in intracellular osmotic adjustment between the vacuole and the cytoplasm and in scavenging free radicals [23]. Pinitol and ononitol are found stored in a variety of species, which are consistently exposed to saline conditions or accumulate in tolerant species when exposed to salt stress [17]. Pinitol increases considerably in plants in response to water

deficit [106]. It has been reported that pinitol was accumulated in *Honkenya peploides* [107] and *Sesbania aculeate* [108] exposed to salt stress; however, the inositol content in the *S. aculeate* leaves remained unchanged under salt stress [108]. A significant accumulation of pinitol and ononitol in alfalfa was found by Fougere *et al.* [109], suggesting that pinitol might contribute to tolerance to salt stress. Facultative halophyte such as *Mesembryanthemum crystallinum* accumulates these compounds only when subjected to water and salinity stresses. The proposed synthetic pathway consists of methylation of myo-inositol to the intermediate ononitol followed by epimerization to pinitol [110]. An inositol methyl transferase (*Imt*) cDNA was isolated from transcripts induced in *Mesembryanthemum* plants by NaCl [111]. Transgenic tobacco for inositol methyl transferase has been obtained [112]. Similar to plants transformed with mannitol-1-phosphate dehydrogenase, growth of wild-type and *Imt*-transformed plants is not distinguishable in the absence of stress, but the transgenic plants have growth advantage over wild type in the presence of salt stress [70].

4.4.1.3 **Proline**

Many plants (not all) synthesize and accumulate proline, a major osmoprotectant osmolyte, in response to various stresses including salinity stress [113]. Generally, proline accumulation occurs in cytosol where it contributes significantly to the cytoplasmic osmotic adjustment [114]. In higher plants, the amino acid proline is synthesized by glutamic acid by the actions of two enzymes, pyrroline-5-carboxylate synthetase (P5CS) and pyrroline-5-carboxylate reductase (P5CR). Overexpression of *P5CS* gene in transgenic tobacco resulted in increased production of proline and salinity/drought tolerance [115]. The exogenous application of proline also provided the osmoprotection and facilitated the growth of salinity-stressed plants. Proline can also protect cell membranes from salinity-induced oxidative stress by upregulating activities of various antioxidants [116]. It is reported that the salt stress enhances proline utilization in the apical region of barley roots [117]. The function of proline is thought to be an osmotic regulator under water stress, and its transportation into cells is mediated by a proline transporter. However, recently, Ueda *et al.* [118] have reported that altered expression of barley proline transporter (*HvProT*) causes different growth responses in *Arabidopsis*, as it leads to a reduction in biomass production and decreased proline accumulation in leaves. Impaired growth of *HvProT*-transformed plants was restored by exogenously adding proline, which implies that growth reduction was caused by a deficiency of endogenous proline. Petrusa and Winicov [119] and Fougere *et al.* [109] reported that salt-tolerant alfalfa plants rapidly increased proline content twofold in the roots, whereas the increase was rather slow in salt-sensitive plants. Ahmad *et al.* [120] observed that salt-tolerant ecotypes of *Agrostis stolonifera* accumulated more proline in response to salinity than the salt-sensitive ecotypes. Moderately salt-tolerant plants of *Brassica juncea* showed a higher degree of osmotic adjustment in the leaves and a higher critical point concentration of NaCl, at which the endogenous level of free proline rose sharply, than the moderately salt-sensitive genotypes [121]. Higher proline accumulation was found in salt-tolerant *B. juncea* plants with better growth than the control [122].

Transgenic approaches provided direct evidence for the role of proline during osmotic stress. Different strategies were employed to manipulate proline biosynthesis including overexpression of P5CS in tobacco, rice, and *Arabidopsis* plants, overexpression of OAT, expression of a feedback inhibition-insensitive form of *P5CS*, and antisense suppression of proline oxidation by ProDH [83, 123]. All approaches resulted in elevated proline pools and improved osmotic stress tolerance. However, contrary to these observations, a study on antisense ProDH transgenic *Arabidopsis* plants observed that these plants accumulated proline but showed no change in osmotic stress tolerance [124].

4.4.1.4 Glycine Betaine

Glycine betaine is thought to protect the plant by maintaining the water balance between the plant cell and the environment and by stabilizing macromolecules [1]. This organic compound is mainly localized in chloroplasts and plays a vital role in chloroplast adjustment and protection of thylakoid membranes, thereby maintaining photosynthetic efficiency and plasma membrane integrity [69]. Plants synthesize glycine betaine via a two-step oxidation of choline: choline → betaine aldehyde → glycine betaine [125]. The first reaction is catalyzed by a ferredoxin-dependent choline monooxygenase (CMO) and the second step by an NAD^+-dependent betaine aldehyde dehydrogenase (BADH) [1]. Although other pathways such as direct N-methylation of glycine is also known, the pathway from choline to glycine betaine has been identified in all GB accumulating plant species [126]. Glycine betaine accumulation is associated with upregulated CMO and BADH gene expression concomitantly leading to elevated enzymatic activity [47].

GB accumulates in response to stress in many crops, including spinach, barley, tomato, potato, rice, carrot, and sorghum [127]. Murata *et al.* [128] reported that GB protects the photosystem II complex by stabilizing the association of the extrinsic PSII complex proteins under salt stress. The concentration of GB in plant species that utilize it as a compatible osmoticum is inconsistent; for example, in sorghum it is as much as 10-fold compared to maize. GB-deficient genotypes of both species have also been identified [68]. Accumulation of glycine betaine under saline conditions is also reported to be high in some salt-tolerant plants of mulberry in comparison to sensitive ones [129]. Saneoka *et al.* [130] reported that glycine betaine-containing lines of maize exhibited less shoot growth inhibition under saline conditions than deficient lines. Glycine betaine accumulation marginally improves osmotic stress tolerance in transgenic plants [131]. The levels of glycine betaine thus far obtained by engineering are low, and the increments in stress tolerance are small [132]. The major factors that limit the accumulation of glycine betaine are the available choline as the substrate for the reaction and its transport from the chloroplast (where it is synthesized) to the cytosol [1, 133, 134]. Foliar application of GB resulted in a significant improvement in salt tolerance of rice plants [135] and tomato plants subjected to either salt stress or high temperatures resulted in about 40% increase in fruit yield compared to untreated plants [136]. However, there are also few studies suggesting a lack of such positive effects or even apparent negative effects of exogenous GB on plants growing under stress conditions [68].

4.5
Salt Stress-Induced Proteins

Osmotic stress induces several proteins in vegetative tissues of higher plants, which are related to late-embryogenesis abundant (LEA) proteins. The correlation between LEA protein accumulation in vegetative tissues and stress tolerance in various plant species indicates its protective role under dehydration stress [137]. Proteins that accumulate in plants grown under saline conditions may provide a storage form of nitrogen that is reutilized when stress is over [138] and may play a role in osmotic adjustment. Proteins may be synthesized *de novo* in response to salt stress or may be present constitutively at low concentration and increase when plants are exposed to salt stress [139]. Hasegawa *et al*. [4] reported that a number of proteins induced by salinity are cytoplasmic that can cause alterations in cytoplasmic viscosity of the cells. A higher content of soluble proteins has been observed in salt-tolerant cultivars of barley, sunflower, finger millet, and rice [23]. Soluble protein increases at low salinity and decreases at high salinity in mulberry cultivars [129]. Despite the reports on decrease in soluble-protein content in response to salinity, Ashraf and Fatima [91] found that salt-tolerant and salt-sensitive accessions of safflower did not differ significantly in leaf soluble proteins. Singh *et al*. [138] detected a 26 kDa protein called osmotin during characterization of salt-induced proteins in tobacco. An osmotin-like protein was found increased in salt-stressed *M. crystallinum* compared to nonstressed plants [140]. In barley, two 26 kDa polypeptides, not immunologically related to osmotin, identified as germin were increased in response to salt stress [141]. Lopez *et al*. [142] found a 22 kDa protein in response to salt stress in radish and in finger millet (*Eleusine coracana*), and Uma *et al*. [143] found 54 kDa and 23–24 kDa proteins responsible for salt or drought tolerance.

Engineered rice plants overexpressing a barley *LEA* gene, *HVA1*, under the control of the rice actin 1 promoter, showed better stress tolerance under 200 mM NaCl than the wild type [144]. *Arabidopsis* LEA-like stress proteins are encoded by *COR* genes (*RD29A*, *COR47*, *COR15*, *KIN1*, and *KIN2*) that are induced by cold, dehydration (due to water deficit or high salt), or ABA. Promoter analysis of the *COR* genes showed that many of them contain dehydration-responsive elements (DRE) or C-repeat (CRT) and ABA-responsive elements or ABREs. Transcription factors that regulate the LEA-like genes include CBFs (C-repeat binding proteins, also known as dehydration-responsive element binding proteins, DREBs) and bZIP proteins [12]. The expression of *COR* genes is regulated by both ABA-dependent and -independent pathways [145]. Constitutive overexpression of *CBF3* or stress-induced expression of *CBF3* driven by the *RD29A* promoter resulted in enhanced expression of *COR* genes under salt stress in transgenic *Arabidopsis* and also conferred higher osmotic stress tolerance [146]. *CBF3* overexpression in *Arabidopsis* also resulted in elevated accumulation of proline and total soluble sugars, including sucrose, raffinose, glucose, and fructose. The increase in proline levels is considered due to the increased expression of the key proline biosynthetic enzyme Δ1-pyrroline-5-carboxylate synthase [147]. Hence, LEA-like proteins appear to protect plants under salt stress. Osmotic or salt stress-induced calcium signals may activate the LEA-like genes through DREB2

transcription factors, while salt stress-induced ABA accumulation appears to induce the genes through ABA-responsive element binding factors [77, 148].

4.6 Oxidative Stress

4.6.1 Reactive Oxygen Species

A secondary effect of salt stress is the increase in the production of ROS, which consist of singlet oxygen ($^1O_2$), superoxide radicals ($O_2^{\bullet -}$), hydroxyl radicals ($OH^{\bullet}$), and hydrogen peroxide (H_2O_2) [18, 149]. The oxidative stress arising under environmental stresses including salinity and may exceed the scavenging capacity of the natural defense system of the plant. ROS are predominantly generated in the chloroplast either by direct transfer of excitation energy from chlorophyll to produce singlet oxygen or by univalent oxygen reduction at photosystem I, in the Mehler reaction [150], and to some extent in mitochondria. Chloroplasts are the first targets in plant cells since this is the major site of ROS production. The increased concentration of ROS inhibits the ability to repair damage to photosystem II and inhibits the synthesis of the D1 protein. Stress-enhanced photorespiration and NADPH activity also contributes to an increased H_2O_2 accumulation, which may inactivate enzymes by oxidizing their thiol groups. The toxicity of H_2O_2 is not due to its reactivity as such, but requires the presence of a metal reductant to form the highly reactive hydroxyl radical, which potentially reacts with all biological molecules. Transition metals such as cuprous and ferrous ions may be released from enzymes and electron carriers during stress and promote the Fenton reaction to produce highly reactive hydroxyl radicals, which extensively oxidize proteins, lipids, and nucleic acids [151]. Hence, ROS detoxification forms a crucial defense against salt stress.

4.6.2 Oxidative Stress Management

4.6.2.1 Antioxidant Enzymes

Plants have developed strategies to keep the concentrations of ROS under tight control through detoxification/scavenging by antioxidant enzymes. ROS detoxification mechanisms can be broadly divided into nonenzymatic and enzymatic mechanisms. Major nonenzymatic antioxidants include ascorbate (vitamin C) and glutathione (GSH) in plants, although tocopherol (vitamin E), flavonoids, alkaloids, and carotenoids can also act as antioxidants. Enzymatic mechanisms include SOD, ascorbate peroxidase (APX), monodehydroascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR), POX, CAT, guaiacol peroxidase (GOPX), glutathione reductase (GR), and glutathione-*S*- transferase (GST) [19, 149]. The alleviation of oxidative damage and increased resistance to environmental stresses is often correlated with an efficient antioxidative system [18, 152, 153]. Increase in the activity

of SOD, APX, GR, DHAR, CAT, and POX in response to salinity stress, as well as higher antioxidant activity in tolerant species/varieties, has also been reported by various workers [4]. Sairam and Srivastava [154] reported comparatively higher Cu/Zn-SOD, Fe-SOD, APX, and GR activity in chloroplastic fraction and Mn-SOD in mitochondrial fraction in tolerant wheat genotypes in response to salt stress. Hernandez *et al.* [37] reported NaCl-induced enhanced mRNA expression and activity of Mn-SOD, APX, GR, and MDHAR in tolerant pea cv. Granada, while in salinity-sensitive cv. Chillis, no significant changes in activity and mRNA levels of the above enzymes were observed. Significantly higher constitutive concentrations of catalase and α-tocopherol were found in salt-tolerant cotton plants than in salt sensitive lines [155]. Salt stress caused a considerable increase in the activities of peroxidase and glutathione reductase in the salt-tolerant cultivars, whereas the activities of these enzymes remained unchanged or decreased in the salt-sensitive cultivars. The salt-tolerant cultivars also had a lower oxidized/reduced ascorbate ratio and a higher reduced/oxidized glutathione ratio than the salt-sensitive lines under saline conditions. Lipid peroxidation in the salt-sensitive lines increased more than in the salt-tolerant lines under salt stress, suggesting that high levels of antioxidants and an active ascorbate-glutathione cycle are associated with salt tolerance in cotton. Shalata and Tal [156] assessed the possible involvement of the antioxidant system in the salt tolerance of cultivated tomato and its wild salt-tolerant relative *Lycopersicon pennellii* and reported that in the wild type the constitutive level of lipid peroxidation and activities of catalase and glutathione reductase were lower, whereas the activities of SOD, ascorbate peroxidase, and dehydroascorbate reductase were inherently higher than those in the cultivated tomato species. Mittova *et al.* [157] correlated the better protection of wild salt-tolerant tomato (*L. pennellii*) root plastids from salt-induced oxidative stress with increased activities of SOD, APX, and POD (guaiacol peroxidase).

Overproduction of SOD, APX, and catalase has been shown to improve oxidative stress tolerance in transgenic plants [158, 159]. Roxas *et al.* [160] reported overexpression of a tobacco glutathione-*S*-transferase (GST) and glutathione peroxidase (GPX) in transgenic tobacco seedlings under a variety of stresses. Salt stress treatment inhibited the growth of the wild type and caused increased lipid peroxidation, while GST-transformed seedlings did not lead to increased lipid peroxidation. GST/GPX overexpression provides increased glutathione-dependent peroxidase scavenging and alterations in glutathione and ascorbate metabolism, leading to reduced oxidative damage. Studies on transgenic rice overexpressing yeast Mn-SOD showed increased levels of ascorbate peroxidase and chloroplastic SOD in the transformed rice compared to the wild type. The transformed rice also showed more salinity tolerance than the wild type [161].

4.7
Calcium Signaling and SOS Pathways

Extreme salinity results in increased cytosolic Ca^{2+} that is transported from the apoplast and the intracellular compartments. Cytosolic Ca^{2+} oscillations occur

within 5–10 s of salt stress, persist up to 1–10 min, and, hence, are thought to be one of the earliest events in salt signaling [162]. Thus, it is essential to analyze how such Ca^{2+} signatures are generated by a salt stress signal and what are the components downstream that decode salt stress-specific Ca^{2+} signatures [12]. Cytosolic Ca^{2+} signatures can be the net result of influx and efflux of Ca^{2+}. Calcium efflux occurs through Ca^{2+} ATPases and H^+/Ca^{2+} antiporters, while influx is controlled by Ca^{2+}-permeable ion channels [163]. The transient increase in cytosolic Ca^{2+} due to salt stress initiates the stress signal transduction leading to salt adaptation. This Ca^{2+} release is primarily of extracellular source (apoplastic space) and also takes place from the activation of phospholipase C (PLC), leading to hydrolysis of phosphotidylinositol-4,5 bisphosphate (PIP_2) to inositol (1,4,5)-triphosphate (IP_3) and subsequent release of Ca^{2+} from intracellular Ca^{2+} stores [164, 165]. The Ca^{2+} binding proteins sense and relay the information downstream to initiate a phosphorylation cascade leading to the regulation of gene expression [166].

In *Arabidopsis*, osmotic stress (NaCl or sorbitol) induces the synthesis of IP_3 to significantly higher levels within 1 min of stress initiation, and it continues to increase for more than 30 min. Treatment with U-73122, an inhibitor of PLC, blocked IP_3 accumulation. The temporal pattern of IP_3 accumulation is similar to that observed for stress-induced calcium mobilization, implicating IP_3 in salt stress-induced Ca^{2+} signaling [167, 168]. In cell cultures of *Arabidopsis*, a few seconds of osmotic stress (caused by dehydration, mannitol, or NaCl) led to a rapid and transient increase in IP_3 and expression of dehydration-inducible genes (*RD29A*/*LTI78*/*COR78* and *RD17*/*COR47*). This response was abolished when the cells were treated with inhibitors of PLC, such as neomycin and U73122, indicating the involvement of PLC and IP_3 in hyperosmotic stress signaling [168]. Osmotic stress caused by NaCl/mannitol/sorbitol significantly increases cellular PIP_2 synthesis [167, 169]. Consistent with this, it has been shown that a *PLC* gene is also upregulated by osmotic stress [170]. Salt stress-induced PIP_2 synthesis and cleavage into IP_3 may help in delayed Ca^{2+} signaling. Genetic evidence for the implication of IP_3 signaling in abiotic stresses including salinity stress came from the analysis of the *FRY1* locus of *Arabidopsis*. *FRY1* encodes an inositol polyphosphate 1-phosphatase, which functions in the catabolism of IP_3. Upon ABA treatment, *fry1* mutant plants accumulated more IP_3 than the wild-type plants. In wild type, IP_3 accumulation was transiently induced by ABA, while in *fry1* IP_3 accumulation was persistent, which implies that IP_3 catabolism is mediated by FRY1. The *fry1* mutant is hypersensitive to ABA and salinity stress [171]. The *Arabidopsis SAL1* gene, a homologue of *FRY1* conferred increased salt tolerance to yeast cells [172]. These results showed that IP_3 transient induced by salt and ABA is necessary for stress tolerance. Besides IP_3-gated Ca^{2+} channels, stretch-/mechanosensitive Ca^{2+} channels may also be involved in primary Ca^{2+} oscillations, as these Ca^{2+} channels can be activated immediately by a change in cell volume/turgor in salt-stressed cells. Hence, salt stress-induced IP_3 oscillations are an integral part of Ca^{2+} signaling in salt stress.

Wu *et al.* [173] commenced a mutant screen for *Arabidopsis* plants, which were oversensitive to salt stress. As a result of this screen, three genes *SOS1*, *SOS2*, and

SOS3 (Salt Overly Sensitive) were identified. *SOS3* gene (also known as *AtCBL4*) encodes a calcineurin B-like protein (CBL, Ca^{2+} sensor), which is a Ca^{2+} binding protein and senses the change in cytosolic Ca^{2+} concentration and transduces the signal downstream. The SOS pathway results in the exclusion of excess Na^+ ions out of the cell via the plasma membrane Na^+/H^+ antiporter and helps in reinstating cellular ion homeostasis. The discovery of SOS genes paved the way for elucidation of a novel pathway linking the Ca^{2+} signaling in response to a salt stress [77, 174]. SOS genes (*SOS1*, *SOS2*, and *SOS3*) were genetically confirmed to function in a common pathway of salt tolerance [83]. In the SOS pathway, the salinity stress signal is perceived by an unknown hypothetical plasma membrane sensor resulting in increased cytoplasmic Ca^{2+} perturbations, which is sensed by *SOS3* followed by transduction of the signal to the downstream components. The myristoylation motif of *SOS3* results in the recruitment of SOS3–SOS2 complex to the plasma membrane, where *SOS2* phosphorylates and activates *SOS1* [175]. The *SOS1* is a Na^+/H^+ antiporter and sos1 mutant was hypersensitive to salt and showed impaired osmotic/ionic balance. The SOS pathway also seems to have other branches, which help remove excess Na^+ ions out of the cell and thereby maintain the cellular ion homeostasis. In *Arabidopsis*, Na^+ entry into root cells during salt stress appears to be mediated by AtHKTI, a low affinity Na^+ transporter, which blocks the entry of Na^+ [77, 164]. *SOS2* also interacts and activates NHX (vacuolar Na^+/H^+ exchanger) resulting in sequestration of excess Na^+ ions and pushing it into vacuoles and thereby further contributes to Na^+ ion homeostasis. Some other Ca^{2+} binding proteins such as calnexin and calmodulin (CaM) also sense the increased level of Ca^{2+} and can interact and activate the NHX. Overexpression of AtNHX1 antiporter substantially enhanced salt tolerance of *Arabidopsis* [176]. CAX1 (H^+/Ca^{2+} antiporter) has been identified as an additional target for SOS2 activity reinstating cytosolic Ca^{2+} homeostasis. This reflects that the components of SOS pathway may crosstalk and interact with other branching components to maintain cellular ion homeostasis, which helps in salinity tolerance.

So far, the main avenue in breeding crops for salt tolerance has been to reduce Na^+ uptake and transport from roots to shoots. It has been demonstrated that retention of cytosolic K^+ could also be considered as another key factor in conferring salt tolerance in plants. Recently, Zepeda-Jazo *et al.* [177] have shown that the expression of *NORC* was significantly lower in salt-tolerant genotypes. As NORC is capable of mediating, K^+ efflux coupled to Na^+ influx, suggesting that the restriction of its activity could be beneficial for plants under salt stress.

4.8 ABA-Mediated Signaling

ABA, a phytohormone that regulates plant growth and development, plays a crucial role in plants' response to abiotic stresses including salinity stress [77, 164, 178]. Salt stress induces ABA accumulation, although the amount depends upon the

tissue type. Salt stress-induced ABA accumulation is due to both ionic and osmotic stresses in roots, while that in the leaf is mainly due to osmotic stress [179]. Sequentially, turgor loss caused by osmotic stress leads to ABA synthesis and accumulation, which in turn regulates part of the cellular response to osmotic stress under salinity. ABA regulates cell water balance through stomatal regulation and genes involved in osmolyte biosynthesis, while it imparts dehydration tolerance through LEA-like genes [4, 77, 145]. The induction of osmotic stress-responsive genes imposed by salinity is transmitted through either ABA-dependent or ABA-independent pathways, though some depend only partially on ABA [180]. However, the components involved in these pathways often crosstalk through Ca^{2+} in stress signaling pathways. ABA signaling for stomatal closure and gene expression is transduced through Ca^{2+} [181]. The importance of ABA-mediated stomatal regulation in salt tolerance was revealed by the analysis of *OSM1* locus of *Arabidopsis*. Root growth of the *Arabidopsis* T-DNA insertion mutant, *osm1* (osmotic stress-sensitive mutant), was hypersensitive to NaCl or mannitol stress. Molecular cloning revealed that *OSM1* encodes a protein similar to SNARE-type mammalian syntaxins [182]. SNARE proteins are required for fusion vesicle trafficking and to control membrane Ca^{2+} and Cl^{-} channel activity and guard cell volumes [181]. Consistent with this, ABA-mediated guard cell function is impaired in the *osm1* mutant. *OSM1* is strongly expressed in roots and leaf guard cells. The *osm1* mutant showed enhanced wilting and decreased survival when salt or drought stress was imposed on soil-grown plants. Thus, OSM1 plays a critical role in root growth and in ABA regulation of stomatal responses under osmotic stresses [182].

The transcript accumulation of *RD29A* gene is reported to be regulated in both ABA-dependent and ABA-independent manner [183]. The proline accumulation in plants can be mediated by both ABA-dependent and ABA-independent signaling pathways (see Ref. [77]). The salinity stress-induced upregulation of transcript of pea DNA helicase 45 (PDH45) followed ABA-dependent pathway [184], while calcineurin B-like (CBL) protein and CBL-interacting protein kinase (CIPK) from pea followed the ABA-independent pathway [185]. The role of Ca^{2+} in ABA-dependent induction of *P5CS* gene during salinity stress has been reported [162]. Overall, the ABA-dependent pathways are involved essentially in osmotic stress gene expression. Transcriptional regulatory network of *cis*-acting elements and transcription factors involved in ABA and salinity stress-responsive gene expression has been described [165]. The ABA-dependent salinity stress signaling activates basic leucine zipper transcription factors called AREB, which bind to ABRE element to induce the stress-responsive gene *RD29A*. Transcription factors such as DREB2A and DREB2B transactivate the DRE *cis*-element of osmotic stress genes and thereby are involved in maintaining the osmotic equilibrium of the cell. Some genes such as RD22 lack the typical CRT/DRE elements in their promoter suggesting their regulation by some other mechanism. The MYC/MYB transcription factors, RD22BP1 and AtMYB2, could bind MYCRS and MYBRS elements, respectively, and help in the activation of *RD22* gene [164, 165]. Overall, these transcription factors may also crosstalk with each other for their maximal response to stress tolerance.

4.9 Conclusions

In spite of the substantial efforts put in to unravel plant salt tolerance mechanisms, our understanding of the underlying molecular basis of salt tolerance is not clear yet. Though, recent advances in genetic analysis of *Arabidopsis* mutants defective in salt tolerance, and molecular cloning of these loci, have given us some insight into salt stress signaling and plant salt tolerance. Future research should be directed at (1) the identification of molecules connecting pathways and the key components of each pathway and (2) the characterization of individual genes and assessment of their contribution to salt stress tolerance, which will facilitate to engineer agronomically important salt-tolerant crop varieties.

Cold and Abiotic Stress Signaling in Plants

Wenqiong Joan Chen

Plants, unlike animals, are not mobile, and therefore unable to avoid stressful environmental conditions. As a consequence, plants have developed a wide variety of protective and defensive mechanisms in order to survive adverse conditions. Abiotic stresses, such as low temperature, high salinity, drought, or osmotic stress, are common challenges to plant survival, and negatively affect plant growth and development. From the point of view of molecular biology and biochemistry, stress signals are, in most cases, perceived by cellular receptors sitting on the cell membranes. These receptors transmit their information through multiple intermediate components in the signal transduction pathways, in order to finally activate the effector proteins, which are involved in executing physiological changes inside plant cells. However, most abiotic stress signalings, such as low-temperature stress signaling, are not linear, but are interconnected with each other. A myriad of molecules and proteins, including ions, lipids, protein kinases, and transcription factors, participate in the stress signal transduction networks. Such complex signaling networks pose a huge challenge to scientists attempting to understand the molecular and biochemical mechanisms plants employ to survive life-threatening conditions. Nevertheless, with the development of a number of advanced technologies, such as DNA microarray for global mRNA profiling, LC/MS/MS mass spectrometry for global proteomic profiling, and an abundance of new functional genomics tools, significant progress has been made in illuminating the mechanisms of plant abiotic stress responses. This chapter summarizes the most recent discoveries about the components involved in plant abiotic stress, with an emphasis on cold stress responses, and focuses on elucidating the functions of these components and their contribution to cold signaling.

5.1
Introduction

Plants, as sessile organisms, are constantly exposed to a variety of unfavorable environmental conditions, and their ability to cope with such conditions is essential

Improving Crop Resistance to Abiotic Stress, First Edition.

to their survival. A large number of temperate plants handle sudden chilling (<10 °C) and freezing (<0 °C) stress through a process known as cold acclimation, an acquired plant defensive response. This response involves transcriptional activation and expression of a large number of genes that function in signal transduction, transcriptional regulation, and synthesis of protective enzymes and metabolites. However, many tropical and subtropical plants, including important crop species such as rice, maize, tomato, cotton, and soybean lack basic tolerance to low or freezing temperatures, and do not have the ability to acclimate to cold temperatures; thus, they are subject to chilling and freezing damage. As a result, cold stress negatively affects many ecologically and economically important plant species, and can be an important limiting factor in plant growth and yield.

Cold acclimation has been extensively studied for the past 10–15 years, and significant progress has been made in understanding the underlying molecular mechanisms by which this process is regulated during plant cold and freezing responses [1–3]. Transcriptomic and metabolomic analyses have indicated that a dramatic reprogramming of gene expression and cellular metabolism occurs during cold acclimation, and it appears that a large number of signaling molecules and transcription factors play key roles in the regulation of this process [4–8].

In this chapter, the latest studies are summarized, emphasizing cold signaling perception, transduction, and transcriptional and posttranscriptional gene regulation. Owing to the power of genetics and most recently the development of functional genomics, most of the fundamental discoveries in plant cold stress response have been in *Arabidopsis*. Consequently, this chapter is mainly focused on the model plant *Arabidopsis thaliana*, while only briefly mentioning other plant species. Many of the signaling molecules and pathways discussed in this chapter are also involved in plant response to other abiotic stresses, such as salt, drought, and osmotic stresses. However, due to the extensive details of the comprehensive signaling pathways known for each of those stresses, mainly plant cold stress response is covered here.

5.2
Gene Expression and Regulation during Plant Cold Stress Response

Genome-wide transcriptome analyses have shown that as much as 10–20% of the genome displays changes at transcript levels following cold stress treatment [1, 9]. These substantial changes in gene expression result in a complete reprogramming of the cellular metabolism, physiology, and subsequent remodeling of plant growth and development. The genome-wide transcriptional responses to cold stress can be divided into two stages: the early and the late stage. Genes involved in the early-stage response mainly encode transcriptional factors, and genes involved in the late-stage cold stress response belong to a set of core cold-inducible genes. The late-stage cold-inducible gene set includes *COR* (cold regulated), *KIN* (cold induced), *LTI* (low-temperature induced), *RD* (responsive to dehydration), and *LEA* (late embryogenesis abundant), whose products are directly involved in stress protection and

maintenance of cellular homeostasis. The rapid transcriptional activation of a number of transcription factor genes is considered to be key to the subsequent activation of a vast number of genes involved in cellular metabolisms and stress protection. Among these transcription factors, the C-repeat-binding factors (*CBFs*), or dehydration-responsive element binding factors 1 (*DREB1s*), have been shown to be essential for plants to tolerate cold stresses [10, 11], although a number of other transcription factors are also indispensable.

5.2.1 The CBF/DREB-Dependent and Independent Pathways

The *CBF/DREB1* genes were originally identified in *Arabidopsis* through yeast one-hybrid screening, using the CRT (C-repeat)/DRE (dehydration response element) elements as the bait [10, 11]. The corresponding proteins, which belong to the plant-specific ERF/AP2 superfamily transcription factors, can activate the expression of a battery of downstream target genes, also called CBF/DREB regulon genes, by binding to CRT/DRE elements in the promoter regions of the target genes [12]. In *Arabidopsis*, there exist three *CBF/DREB1* genes, namely, *CBF1–3*, or *DREB1b*, *c*, and *a*, respectively. These three genes are organized in tandem array at the same chromosomal location. More importantly, it has been shown that the message levels of all three *CBF/DREB* genes are quickly (within 15 min) and specifically induced by cold stress [4, 5, 7, 10, 11]. The essential role of the *CBF/DREB1* gene during plant cold stress response was demonstrated through reverse genetic studies where the overexpression of the *CBF3/DREB1A* or *CBF2/DREB1C* in transgenic *Arabidopsis* plants resulted in the activation of *COR* gene expression even at the moderate temperature and significantly enhanced cold and freezing tolerance [13]. Although cold signaling pathways other than those mediated by *CBF/DREB1* do exist (discussed later), it has been shown that CBFs/DREBs play a major role in the regulation of the cellular transcriptome following cold stress.

The CBF/DREB1-like proteins are present in a variety of plant species, including not only the plants from temperate regions, such as *Arabidopsis*, barley, wheat, and *Brassica napus* [14, 15], which can cold-acclimate, but also the plants from tropical and subtropical regions, such as rice, maize, and tomato [15–18], which do not cold-acclimate, indicating that the CBF/DREB1 cold-responsive pathway is conserved among the plant kingdom. However, the higher cold and freezing sensitivity of crop plants clearly suggests that CBF/DREB1 is not sufficient and other components and/or pathways are needed to confer improved resistance to cold stress.

Through a genetic mutant screening, the *Arabidopsis Eskimo1* gene was identified as a negative regulator in plant cold stress response [19]. The loss-of-function *esk1* mutant accumulates higher levels of compatible osmolytes, such as proline, under normal growth conditions, is constitutively tolerant to freezing, and has much higher freezing tolerance (5.5 °C improvement) than wild-type plants. Transcriptome analysis showed that only 12 of the total 312 genes with altered mRNA expression were also present in the *CBF2* gene regulon, indicating that ESK1 mostly functions

independent of CBF/DREB1 [20]. The *ESK1* gene encodes a DUF231, which belongs to a large family of proteins with domain of unknown function [20]. It is important to note that the expression of the *ESK1* gene itself is not altered by cold stress [20], suggesting that posttranscriptional regulatory mechanisms might be involved in activation of the ESK1 protein. However, the molecular mechanism by which ESK1 regulates cold stress signaling pathways still remains elusive.

Other CBF/DREB-independent pathways include the HOS9-mediated pathway. HOS9 was identified through a genetic screening that employed the promoter of the cold-inducible *RD29A* gene fused to the luciferase reporter gene [21, 22]. Transgenic *Arabidopsis* plants containing the P_{RD29A}-LUC system were screened for mutants that have enhanced luciferase expression specifically following cold stress treatment. The *hos9* null mutants have defects in freezing resistance, regardless of whether they have been cold acclimated or not [22]. More intriguingly, the expression of a number of cold-responsive genes such as *RD29A* and *COR15* were much stronger than wild type [22]. From microarray data analysis of the *hos9* null mutant, it appears that the HOS9 regulon is distinct from the CBF regulon [22]. *HOS9* encodes a homeodomain transcription factor, and like *ESK1* gene, the mRNA expression of the HOS9 gene is constitutively high and not responsive to cold treatment [22], thus raising the possibility that this gene is also subject to posttranscriptional regulation.

Another important and well-characterized CBF/DREB1-independent, cold-responsive pathway is the ABA-mediated pathway. ABA is an important plant hormone involved in stomatal closure, seed maturation, and dormancy [23, 24]. The role of ABA in plant stress response, especially to dehydration/drought and osmotic stress, has been well recognized [3, 25]. However, its role in cold stress response remains somewhat inconclusive. It was shown that plants have increased levels of endogenous ABA following salt, drought, and cold stresses, although such increase after cold stress is not as pronounced as the other two stresses [26, 27]. In a study with mutants that were either ABA deficient (*aba1-1*) or ABA insensitive (*abi1-1*), it was shown that ABA was required for the cold acclimation process, and mutants that had blocked ABA biosynthesis and signaling lost the ability to cold acclimate, thus were hypersensitive to freezing stress [28].

In addition, it was found that the mRNA expression of many cold stress-responsive genes could also be induced by exogenous ABA treatment [29–31]. In a transcriptome analysis with *Arabidopsis* plants following 3 and 24 h cold stress treatment, both the ABRE (ABA-responsive element) and the CRT/DRE element were significantly enriched in the cluster of late-cold-responsive genes [4], suggesting that these two independent pathways might act synergistically in regulating the expression of cold-responsive genes. Transcription factors belonging to the class of bZIP transcription factor are called ARE proteins or ABFs and bind to the ABRE [32]. Most importantly, through a transient expression analysis using a protoplast system, it was found that transcription factors AREB1/ABF2, AREB4/ABF4, and ABF3 could directly activate the reporter gene expression by binding to the ABRE element, and the transcriptional activities were much more compromised in both the ABA-deficient *aba2* and the ABA-insensitive (*abi1*) mutants,

strongly suggesting that these transcription factors play crucial roles in the ABA signaling and stress responses [33].

5.2.2 Regulation of ICE1-CBF/DREB Gene Expression

5.2.2.1 Transcriptional Regulation

Although extensive knowledge has been accumulated about transcriptional events downstream of the CBF/DREB1 proteins, the regulatory and signaling events upstream of CBF/DREB1 proteins have just begun to be uncovered. Owing to the rapid and transient induction of mRNA expression of the *CBF/DREB1* genes following cold stress treatment, it was hypothesized that one or more constitutively expressed gene(s) may be required. The search for such genes resulted in the identification of *ICE1* from a genetic screening for inducers of the *CBF/DREB1* expression [34]. *ICE1* encodes a MYC-like bHLH transcription factor. The phenotype of the *ice1* null mutant plant includes loss of the inducible expression of the *CBF3/DREB1A* gene, and compromised ability in cold stress tolerance [34]. The constitutive expression of the *ICE1* gene at the mRNA level raised the question about how this gene is activated by cold stress. A number of potential serine/threonine phosphorylation sites were identified, suggesting posttranslational modification might play a role in regulating the activity of this protein; however, the exact roles of these phosphorylation sites have not been reported.

Although ICE1 regulates the expression of the *CBF3/DREB1A* gene, it does not have any effect on the other two *CBF/DREB1*s, regardless of the existence of a consensus recognition site for the bHLH transcription factors within the *CBF2/DREB1c* promoter [35]. This suggests that other MYC-like bHLH transcription factors might be involved in the regulation of this gene. In the search for other transcriptional mechanisms that regulate *CBF/DREB1* gene expression, promoters of the *CBF/DREB1* genes were rescanned and potential binding sites were revealed for both MYC- and MYB-like transcription factors [36].

The *Arabidopsis MYB15* gene, which belongs to the R2R3-MYB family of transcription factors, was then identified through microarray data analysis of genes whose expression was induced upon cold treatment [36]. More interestingly, microarray data also indicated that the expression of the *MYB15* gene was enhanced in the *ice1* mutant, while yeast two-hybrid analysis showed that MYB15 physically interacted with ICE1. This suggests that MYB15 is negatively regulated by ICE1, and likely functions in cold stress signaling through the ICE-CBF pathway. However, rather than acting as a transcription activator like ICE1, a transient expression assay showed that MYB15 acts as a transcription repressor and represses the expression of *CBF1–3/DREB1A–C*. Further supporting this data, it was found that the expression of the *CBF1–3/DREB1A–C* genes was enhanced in the *myb15* loss-of-function mutant, which in turn resulted in improved freezing tolerance.

Another negative regulator involved in the regulation of *CBF/DREB1* expression is ZAT12. The *Arabidopsis ZAT12* gene, which encodes a C2H2 zinc finger transcription

factor, was identified through microarray data analysis as one of the six transcription factor genes whose mRNA expression is upregulated within only 1 h of cold stress treatment [37]. Overexpression of the *ZAT12* gene in transgenic *Arabidopsis* plants results in small but reproducible improvement in freezing stress tolerance [37]. Consistent with such marginal improvement, the ZAT12 regulon is much smaller in comparison to the CBF regulon that comprises about 28% of the cold-inducible genes [37]. However, it is interesting to note that the expression of the *CBF1–3/DREB1A–C* genes is significantly reduced, although not completely abolished, in transgenic *Arabidopsis* plants overexpressing *ZAT12*. Moreover, there is a considerable overlap between the ZAT12 regulon and the CBF regulon, suggesting that CBFs/DREBs and ZAT12 might interact in coordinating the cold signaling pathways [37].

In addition to the different types of transcription factors that are involved in the regulation of *CBF/DREB1* expression, surprisingly, CBFs appear to be involved in the feedback regulation of their own genes [38]. A case in point: it was found that the expression of *CBF3/DREB1A* and *CBF1/DREB1B* was much stronger and more sustained in the *cbf2/dreb1b* mutant, and this mutant has higher resistance to freezing and other abiotic stresses.

5.2.2.2 **Posttranscriptional Regulation**

Posttranscriptional regulation of plant gene expression during cold stress response was relatively overlooked until recently when genes involved in mRNA processing, translocation, and stability were identified from a variety of molecular genetic studies. The transcriptional activation of a large number of genes following cold stress results in the accumulation of a large amount of nascent mRNAs inside the nucleus. These pre-mRNAs need to be properly processed and exported to the cytosol, where the mRNAs can be translated into functional proteins [39].

One of the genes involved in the splicing process of the cold-inducible *COR15* gene and possibly other genes is the *Arabidopsis STA1* (for *STABILIZED1*) [40]. The *STA1* gene was cloned via the same P_{RD29A}-LUC imaging system used to search for mutants with enhanced stability of the luciferase activity. It was found to encode a 102-kD nuclear protein similar both to the human U5 small ribonucleoprotein-associated protein and to the yeast pre-mRNA splicing factors Prp1p and Prp6p. The mRNA expression of the *STA1* gene is itself cold inducible, and plants harboring mutation in the *STA1* gene contain substantially higher levels of unspliced *COR15* mRNA than wild-type plants. They also displayed reduced chilling tolerance, as well as hypersensitivity to ABA and salt stress [40].

The nucleoporin protein, *AtNUP160*, and the DEAD-box RNA helicase encoded by the *LOS4* (low expression of osmotically responsive genes 4) gene were found to play essential roles in properly unwinding tight RNA secondary structures and transporting unwound RNAs from the nucleus to the cytoplasm [41–43]. While the *los4* mutant was identified through the same P_{RD29A}-LUC imaging system, the *atnup160* mutant was identified through a slightly different screening system that involved the promoter from the *CBF3/DREB1A* gene fused to luciferase. Both the *los4* and the *atnup160* mutants were hypersensitive to chilling and freezing stresses, and poly(A)-mRNA export from nucleus to cytoplasm was much lower under cold stress

conditions in both these mutants, compared to wild-type plants, suggesting that the defects in cold response of these mutants might be caused by the retention of cold-responsive mRNAs in the nucleus. Consistent with their possible role in RNA metabolism and transportation, both LOS4 and AtNUP160 proteins are enriched at the nuclear rim [41, 43].

The *Arabidopsis FIERY2 (FRY2)/CPL1* gene is another important factor worth mentioning. This gene is involved in coordinated pre-mRNA processing, functional mRNA formation, and mRNA export [25, 44]. *FIERY2 (FRY2)/CPL1* encodes a protein phosphatase that directly regulates the activity of RNA polymerase II by dephosphorylating the RNA polymerase II C-terminal domain (CTD). It has been shown that the phosphorylation states of the CTD domain directly correlate with the functional involvement of RNA polymerase II (RNAP II) in transcription, as RNAP II with a hypophosphorylated CTD (RNAP IIA) is included preferentially in the transcription preinitiation complex formed at the promoter, whereas RNAP II with a hyperphosphorylated CTD (RNAP IIO) is associated with elongation complexes [44]. The *fry2/cpl1* mutants were obtained through the P_{RD29A}-LUC imaging system and displayed more enhanced cold-responsive gene expression. It is worth noting that while the *fry2/cpl1* mutants showed a much more reduced freezing tolerance, the expression of *CBF/DREB1* genes was surprisingly higher in these mutants, suggesting that the FRY2/CPL1 protein functions independent of CBF/DREB1 [25].

5.2.2.3 Involvement of Small RNAs in the Plant Cold Stress Response

Plant small RNAs, including microRNA (miRNA) and short interfering RNA (siRNA), are a class of highly conserved, nonprotein-coding RNAs ranging in size between 20 and 24 nucleotides. Generally considered as transcriptional repressors, microRNAs and siRNA exert their functions mainly through mRNA cleavage or translational repression of complementary target mRNAs [45–51]. Interestingly, it has been predicted that one of the major classes of target genes for plant small RNAs is transcriptional regulator, and translational repression of these transcription regulators consequently leads to the inhibition of mRNA expression of a large number of downstream genes [52, 53]. In accordance with this prediction, plant small RNAs, especially miRNAs, have been found to be involved both in a number of developmental processes, such as leaf and flowering development, and in other cellular processes, such as auxin signaling [45, 47, 54, 55]. Only recently have researchers discovered that they also play significant roles in plant stress responses [1, 56].

The identification of cold-responsive miRNAs came from the pioneer work of sequencing a library constructed from *Arabidopsis* seedlings that had been exposed to cold, dehydration, salinity stresses, and ABA [57]. The expression of miR393, miR397b, and miR402 was upregulated by a number of stress treatments, while miR319c was specifically upregulated by cold. It was also found that miR389a was downregulated by cold and other stresses.

Following this study, a number of laboratories have taken additional approaches such as computational analysis and microarray data analysis to further expand the

number of miRNAs that respond to cold stress treatment. In one study, the authors were able to identify 19 more miRNAs that are potentially cold inducible by intelligently integrating the data from diverse resources, such as microarray data from stress-treated samples, promoter data from cold-responsive protein-coding genes, and bioinformatic predictions of miRNA-target gene pairs (database), and combining them using computational methods such as support vector machine (SVM) and *k*-nearest neighbors (k-NN). Further analyses of the promoters of these 19 miRNAs revealed that more than half of them contain the ABRE and/or CRT/DRE elements, which are known to be cold inducible, confirming the validity of their bioinformatic method [58].

In an independent study, 117 probes corresponding to the same number of *Arabidopsis* miRNAs were spotted on an in-house fabricated cDNA-type microarray. This microarray was then hybridized with small RNAs extracted from samples treated with cold stress [59]. A total of 11 cold-inducible miRNAs were identified from this experiment, and all but two of them were also identified through the integrated computational approach from the first study discussed, suggesting that a skillfully designed computational approach could potentially be employed to accurately and more efficiently annotate the functions of miRNAs in a systematic fashion.

Although these methods have successfully identified a number of miRNAs whose expression is cold inducible, they have barely begun to identify miRNAs whose expression is downregulated by cold stress. Since microRNAs generally act as translational repressors, their targets will represent those genes with expression that is repressed by cold stress. On the contrary, for those target genes playing positive roles during plant cold stress response, their corresponding miRNAs have to be downregulated. These miRNAs certainly should not be overlooked. Microarray technology, as well as the deep sequencing strategy, might be a better way to identify miRNAs that are downregulated during stress [60–62] than traditional approaches such as cloning-based technology or Northern blot analysis [63], illustrated in an example in the next paragraph.

Recent technological advancements have made important contributions to the identification of novel miRNAs in other plant species, especially in those species whose genome sequences were not known. Nevertheless, investigation of these species might reveal novel adaptive strategies plants have evolved in response to environmental stresses. It was proposed that the winter-habit temperate plant *Brachypodium distachyon* might represent a better model monocot system than rice to study plant cold acclimation and cold stress response [61]. A study using high-throughput sequencing with the Solexa next-generation sequencer (www.illumina.com) identified 27 species-conserved miRNAs and 129 species-specific miRNAs from *B. distachyon*. Interestingly, among the conserved miRNAs, three were found to be regulated by cold stress, while the expression of all of them was upregulated. Meanwhile, 25 out of the 129 *Brachypodium* unique miRNAs displayed significant changes following cold stress treatment. However, 76% of them (19/25) had repressed expression following cold stress, suggesting that in *Brachypodium*, mRNA repression is by far the major mode of cold regulation on miRNA expression [61].

5.2.2.4 Posttranslational Regulation

The mRNA expression of transcription factor genes *CBF/DREB1* can be rapidly induced in as short as 15 min following cold treatment. Thus, it is apparent that other mechanisms including posttranslational regulation must also be involved in the regulation of cold-responsive genes. Among all posttranslational pathways, the ubiquitin/proteasome degradation pathway constitutes an essential regulatory mechanism in controlling the activities of central cold-responsive genes such as ICE1 [64]. The involvement of the ubiquitin/proteasome degradation pathway in plant cold response began to be understood when it was discovered that treatment with the proteasomal inhibitor PI II MG132 or DMSO significantly enhanced the promoter activity of the cold-responsive gene RD29A [64]. Later on, it was found that the *Arabidopsis* HOS1 (high expression of osmotically responsive protein 1), which belongs to a family of C3HC4 RING finger domain containing protein, negatively regulates the ICE1 activity through ubiquitination [64]. The *HOS1* gene encodes a functional ubiquitin E3 ligase, which is involved in the last step of ubiquitination. This last step recruits specific target proteins to the ubiquitin complex and directs the ubiquitinated proteins to a proteasome complex for degradation [65]. It was shown through both *in vivo* and *in vitro* studies that HOS1 mediated ubiquitination, and subsequent degradation of ICE1 is functionally involved in the cold signaling pathway [64]. While the *hos1* null mutant displays both enhanced ICE1 protein activity and enhanced cold-responsive *CBF/DREB1* expression, overexpression of the HOS1 gene results in a much more reduced cold response and freezing tolerance. It is also interesting to note that the localization of HOS1 moves from the cytoplasm at warm temperatures to the nucleus after a plant's exposure to cold temperatures, indicating that other regulatory mechanisms, such as protein translocation, are also involved in the HOS1-ICE1 regulatory pathway [64].

Another important gene involved in the ubiquitin-mediated regulation of ICE1 is the *Arabidopsis SIZ1* gene. The *SIZ1* gene encodes SUMO (for small ubiquitin-related modifier) E3 ligase, an enzyme that catalyzes the last step of SUMO conjugation to the protein substrates [66]. The reversible sumoylation/desumoylation of the target proteins determines their activity and final destination and, thus, is involved in many important processes such as transcriptional regulation, protein subcellular compartmentalization, and ubiquitin/proteasome-mediated protein degradation [67]. The *Arabidopsis SIZ1* gene was originally identified as one of the essential genes during plant response to phosphate starvation [68, 69]. Later on, it was found that this gene was also involved in the plant cold stress response since the *siz1* null mutant showed reduced cold and freezing tolerance. In addition, the expression of *CBF/DREB1* genes was also reduced in the *siz1* null mutant. Interestingly, the mRNA expression of a negative regulator, the *MYB15* gene, was substantially higher in the *siz1* mutant than the wild-type plants, suggesting that SIZ1 positively regulates the cold-responsive gene expression by downregulating the expression of *MYB15* gene [66].

Since SIZ1 encodes a SUMO E3 ligase, it was speculated that the SUMO conjugates in the *siz1* mutant might be compromised. As predicted, the antibodies against SUMO1 detected fewer SUMO conjugates in the *siz1* mutant than those in

the wild-type plants, confirming that SIZ1 is indeed involved in the sumoylation process [66]. However, it has not been investigated whether sumoylation is directly involved in the regulation of CBF/DREB1 and MYB15 protein or not. On the other hand, it was found that ICE1 could indeed be sumoylated, and the amount of sumoylated ICE1 is moderately increased by cold treatment. The cold-inducible SUMO conjugation of ICE1 was blocked in the *siz1* mutant if the ICE1 protein was mutated at position 393, which changes lysine (K) to arginine (R) [66].

When the expression of *CBF/DREB1* and *MYB15* was tested, a positive correlation was found between the degree of ICE1 sumoylation and the level of CBF/DREB1 mRNA expression, but there was a negative correlation with MYB15 mRNA expression. The increased sumoylation of ICE1 probably resulted in the enhanced stability of the ICE1 proteins since it was found *in vitro* that polyubiquitination of ICE1, likely mediated by HOS1 or other related proteins, was reduced if ICE1 were sumoylated, as compared to the unsumoylated control. The functional significance of ICE1 sumoylation was further confirmed by reverse genetic studies, where overexpression of the mutant version of ICE1 (K393R) resulted in the reduced freezing tolerance in the transgenic *Arabidopsis* plants [66].

5.3 Signaling Molecules Involved in the Early Events of Cold Stress Response

5.3.1 Phospholipids

A plant cell membrane is comprised of a lipid bilayer containing many integral and peripheral proteins that function as ion channels and membrane receptors. The plant cell membrane is quite fluid and selectively permeable. More than simply being a rigid structure holding the entire cell, the cellular membrane also conveys an abundance of information. This is mainly attributed to one of its predominant lipid components, the phospholipids. Upon exposure to cold stress and other adverse environmental stresses, the production of one of the phospholipids, phosphatidylinositol 4,5-bisphosphate (PIP_2), was found to increase rapidly through the activation of phosphatidylinositol 4-phosphate 5-kinase (PI5K) [70]. The increase in the PIP_2 level subsequently results in the increased production of diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3), which is catalyzed by phosphoinositol-specifc phospholipase C (PI-PLC) [71]. It has been shown that both the transcript level and the protein activity of *Arabidopsis* AtPLC1 are coordinately induced by cold stress [71–73]. The DAG and IP_3 are two important secondary messengers that can activate protein kinase C and the release of Ca^{2+} from intracellular storage [74, 75]. The transient surge in the cytoplasmic Ca^{2+} level then triggers a series of signal transduction cascades, which will be discussed next.

In addition to PLC, phospholipase D (PLD) is also involved in the plant stress responses [76]. The phosphatidic acid (PA), generated from phospholipids by PLD, is another important secondary messenger that can activate protein kinase C [77]. In

Arabidopsis plants, it was found that the endogenous PA level correlated well with the expression of one of the *Arabidopsis* PLD genes, *AtPLDδ*. In the *atpldδ* knockout mutant, which had significantly reduced levels of PLD activity, the PA level was also much lower than that of the wild-type plants, and the mutant plants displayed decreased freezing tolerance [78]. On the other hand, transgenic *Arabidopsis* plants overexpressing *AtPLD* have much higher levels of PA than wild-type plants, and also have enhanced freezing tolerance, suggesting that PA and PLD are directly involved in plant cold stress response [78]. Using *Arabidopsis* suspension cells, it was found that the enzymatic activities of both PLC and PLD were rapidly activated following exposure to cold temperature [79]. Interestingly, the PLC- and the PLD-dependent pathways may have different signaling components since treatment with the PLC inhibitor and PLD inhibitor results in the inhibition of the expression of two different sets of genes [80].

The stimulation of PLC and PLD activities can also be achieved through activation of G-protein-coupled receptors (GPCRs) following perception of external stimuli [81]. This will be discussed later in this chapter.

It is also worthwhile to mention that the protein product of the *Arabidopsis Fryγ1* gene, which is directly involved in plant lipid metabolism, also contributes to the cold stress response. The *Fryγ1* gene was identified through a genetic screening for mutants with altered cold stress response [82], and encodes inositol polyphosphate 1-phosphatase (Ins1Pase), an enzyme responsible for the hydrolysis of IP_3. The null *fryγ1* mutant displays an enhanced cold-responsive gene expression, consistent with the notion that IP_3 is an important signaling molecule involved in cold stress response.

5.3.2
Reactive Oxygen Species as Secondary Messenger

Reactive oxygen species (ROS) is generated when free, high-energy electrons are transferred to molecular oxygen (O_2) to form unstable intermediates such as $^1O_2$, H_2O_2, $O_2^{\bullet}-$ and $HO^{\bullet}$. Under optimal plant growth conditions, the level of cellular ROS is kept very low inside the plant cells. However, during exposure to adverse environmental stresses, the ROS level is drastically elevated to an extent that could cause damage to plant cells due to reactions such as cell membrane lipid peroxidation, protein oxidation, and enzyme inhibition [83–85]. As a result, the cellular scavenging system, including superoxide dismutase (SOD), ascorbate peroxidase (APX), catalase, and glutathione transferase (GST), has to be activated quickly to clear up excess ROS and to restore whole cell redox homeostasis. Many previous reports have shown that by manipulating the mRNA expression levels of genes encoding ROS scavengers, different levels of tolerance to environmental stresses could be observed (reviewed in Ref. [84] and references therein). For example, the *atvtc-1* mutant, which is deficient in cellular ascorbate, is significantly more sensitive to salt stress [86]. On the other hand, transgenic *Arabidopsis* overexpressing the glutathione peroxidase 3 gene (*AtGPX3*) shows increased drought stress tolerance [87].

Interestingly, ROS appears to have a dual function inside the plant cells. In addition to its stress damage to cells, ROS also plays an essential role as a secondary messenger

in stress signaling, and this has already been demonstrated in osmotic, drought, salt, heat, and high light intensity stress studies [84]. One of the examples came from a study of the *Arabidopsis APX1* gene, which codes for a plant ascorbate peroxidase. It was found that, compared to wild-type plants, the *atapx1* knockout mutant accumulated a much higher level of H_2O_2 within the cells, most likely due to a low level of ascorbate peroxidase activity available to scavenge the extracellular H_2O_2. As a consequence, this mutant plant was found to be hypersensitive to light stress [88]. Surprisingly, the *atapx1* mutant appeared to be more tolerant to osmotic, salt, and cold stress, and a number of stress-responsive genes were induced even without stress treatment [89]. This result suggests that higher levels of H_2O_2 might, on the one hand, cause hypersensitivity to oxidative stress but, on the other hand, trigger a ROS-mediated stress signaling pathway that could result in enhanced tolerance to certain types of abiotic stresses.

There have been quite a few studies elucidating the activities of ROS in plant abiotic stress signaling. In animal cells, numerous studies describe ways in which oxidative stress signals, such as H_2O_2, can trigger a wide array of cellular responses mediated by mitogen-activated protein kinases (MAPKs). The plant MAPKs are known to play critical roles in cold stress and other abiotic stress signal transduction. It was found that one of the *Arabidopsis* MAPKs, the AtMPK6, which can be activated by cold or osmotic stress, is also activated by H_2O_2 treatment [90], raising the possibility that ROS, as a secondary messenger, relays abiotic stress signals by acting on downstream signaling molecules such as protein kinases.

Transcription factors also mediate H_2O_2 signaling. In a microarray study in which the authors compared the difference during early responses to chilling stress between chilling-insensitive japonica rice and the chilling-sensitive indica rice, they found that the expression of one of the b-ZIP transcription factors, later called *ROS-bZIP1*, was induced within 2 h of chilling treatment in the japonica ecotype background, but the induced expression was much less robust and delayed in the indica background [91]. Interestingly, the expression of *ROS-bZIP1* was also H_2O_2 inducible. Moreover, the authors also identified a group of genes that responded to chilling stress at a later time point (6 h) and found that the promoters of these genes contained the *as1/ocs*-element, the canonical binding site for b-ZIP-type transcription factors [92], implying that the induced expression of the late-responsive genes might be caused by activating ROS-bZIP through an ROS-mediated pathway.

In addition to the b-ZIP-type transcription factors, the ERF/AP2-type transcriptional factors have also been linked to cellular H_2O_2 responses. The tomato JERF3 protein, which belongs to the ERF/AP2 superfamily of transcription factors, was identified through a yeast one-hybrid screening that bound to the GCC-box of the ethylene response element [93]. This gene, when overexpressed in transgenic tobacco, confers enhanced tolerance to salt, drought, and freezing stresses. Further expression analysis indicated that the enhanced stress tolerance might be a result of the activation of a ROS-mediated pathway since phenomena such as the increased activity of the tobacco SOD and a reduced accumulation of cellular H_2O_2 were observed, as well as the transcriptional activation of ROS-responsive genes [94].

The last category of transcription factors involved in the ROS-mediated signaling pathways during plant abiotic stress responses is that of the C2H2-type zinc finger transcription factors. Two examples of this type are the *Arabidopsis ZAT7* and *ZAT12* genes, which were identified through a microarray data analysis that revealed elevated mRNA expression of both genes in the *atapx1* mutant [95]. Like *AtAPX1*, the mRNA expression of *ZAT7* and *ZAT12* can also be induced upon application of exogenous H_2O_2. In the *zat12* knockout mutant, the inducible expression of *ZAT7* and *AtAPX1* following H_2O_2 treatment was blocked, and the mutant was more sensitive to oxidative stress. In contrast, transgenic plants that overexpress *ZAT12* are more tolerant to oxidative stress, suggesting that ZAT12 is involved in mediating H_2O_2 signaling [95, 96]. Most compelling is the idea that overexpression of the *ZAT12* gene in transgenic *Arabidopsis* plants could result in improvement in freezing stress tolerance, pointing to a central position for ZAT12 in bridging the ROS-mediated cold stress signaling pathway [37].

ZAT7 was shown to possess a capability similar to ZAT12. Overexpression of ZAT7 in transgenic *Arabidopsis* plants also resulted in a dramatic tolerance to salinity and cold stresses [95, 97]. In contrast, ZAT7 RNAi lines showed decreased osmotic stress tolerance [97]. With the support of these data, a comprehensive deletion and mutational analysis of the ZAT7 C2H2-zinc finger domain concluded that this domain was required for abiotic stress response in plants [97].

5.3.3
Calcium Binding Proteins and Signal Decoding

One of the earliest signaling events preceding the onset of transcriptional activation of early cold-responsive genes such as *CBF* expression is a rapid increase in Ca^{2+} concentration in cytoplasm, which happens within the first 5 min after a sudden temperature drop [2, 74, 98]. The transient spike of Ca^{2+} concentration in the cytosol serves as a potential signal that must be perceived by calcium binding proteins, also called calcium sensors, or else the downstream signaling cascades will not occur [99–101].

Typically, the calcium binding proteins contain four signature motifs, called helix–loop–helix EF-hands, which function to physically interact with Ca^{2+} ions. Binding of Ca^{2+} results in conformational changes in the calcium binding proteins for subsequent interaction with other signaling components and relay of the signals. In general, there are three types of Ca^{2+} binding proteins in plants. The first type encompasses the calmodulins and calmodulin-like proteins (CaM and CML, respectively), the second type includes calcium-dependent protein kinases (CDPKs), and the third type is comprised of the calcineurin B-like proteins (CBLs) [102, 103].

CaMs are found universally in both animal and plant kingdoms. They are versatile Ca^{2+} binding proteins involved in numerous cellular processes by binding to effector proteins in response to Ca^{2+} signals [104]. The *Arabidopsis* genome contains 9 CaMs genes and an even larger CML family that contains at least 50 CML proteins. The magnitude of this CML family suggests that they are probably required for many cellular and physiological responses; however, the functions for many of these CMLs are not known [105, 106].

CML24 appears to be involved in a number of stress responses [107]. This gene was first identified as a touch-inducible gene and later its mRNA expression was found to be induced by other stresses, including cold and heat. Transgenic plants over- or underexpressing the *CML24* gene display a variety of phenotypes. However, its direct involvement in cold stress response has not been tested. In addition to CML24, the *Arabidopsis* CML9 gene was also shown to be involved in plant abiotic stress responses and response to treatment with plant hormone ABA [108].

The second group of the Ca^{2+} binding proteins contains the calcium-dependent protein kinases. CDPKs are serine/threonine protein kinases characterized by phosphorylation activities that are altered with Ca^{2+} binding. Previous studies have shown that a number of plant CDPKs are activated following cold stress treatment [109–111]. A piece of direct evidence came from a study in which overexpression of the rice *OsCDPK7* gene resulted in the induced expression of a number of stress target genes, which correlated with enhanced cold, drought, and salt tolerance in the transgenic rice plants [112, 113]. However, questions still remain: what are the downstream phosphorylation targets for CDPKs and how are CDPK proteins connected to other signal transduction molecules such as CBF/DREB1 transcription factors? A search for proteins that interact with CDPKs was initiated using a yeast two-hybrid system and did yield some clues as to how the stress signals were relayed from CDPK protein kinases. One study determined that *Arabidopsis* CDPK32 interacts with AREB4/ABF4, a bZIP transcription factor involved in the ABA response [114]. CDPK32 phosphorylated AREB4/ABF4 *in vitro* on the serine residue at position 110. Phosphorylation at this particular site was functionally important since a mutation at Ser110 dramatically reduced ABF4 transcriptional activity in protoplasts [114]. Using a slightly modified yeast two-hybrid approach, a zinc finger nuclear protein, AtDi19, was identified that interacts specifically with the *Arabidopsis* CDPK4 and CDPK11 proteins [115]. In previous studies, the expression of AtDi19 was shown to be drought inducible, but the inducible expression was independent of ABA [115]. Thus, it appears that some plant CDPKs can also function through an ABA-independent stress pathway [116]. A recent study was performed that systematically identified potential target proteins that were differentially phosphorylated by CDPKs when the plants were subjected to salt treatments [117]. The authors compared the whole-cell threonine phosphorylation pattern of wild-type *Arabidopsis* to that of *atcpk3* mutants and found 28 proteins that were possibly phosphorylated by AtCDPK3 following the salt stress treatment [117]. Interestingly, most of these proteins were predicted to be membrane associated; however, the annotation of these 28 proteins did not yield much valuable information in regard to how CDPKs might function in any known cold response pathway [117].

5.3.3.1 The Calcineurin B-Like Proteins in Decoding the Ca^{2+} Signals

Finally, the last group of Ca^{2+} binding proteins is that of the CBLs. Unlike CDPKs, these proteins do not possess protein kinase activities [103]. Many studies have demonstrated that CBL proteins, which are unique to plants, are involved in plant responses to multiple abiotic stresses, including cold, salt, drought, and osmotic stresses [118–122]. *Arabidopsis* CBL1 is one of the best-studied CBL class of proteins

pertaining to plant abiotic stresses. The *CBL1* gene was first identified through a homology screen using primers designed from the conserved regions of calcineurin B genes of animal species [121]. *CBL1* contains four typical EF-hand-like sequences and functionally binds to Ca^{2+}. The mRNA and protein expression of the *CBL1* gene is induced by cold, drought, and wounding [120, 121]. The involvement of CBL1 in plant stress responses was further confirmed by the characterization of both *cbl1* mutant plants and *CBL1*-overexpressing transgenic plants [118, 120]. Notably, the CBL1 protein appears to differentially regulate plant responses to different abiotic stresses. Although CBL1 functions as a positive regulator in salt and drought stress responses, its role in cold stress response appears to be negative since the overexpression of *CBL1* results in a reduced tolerance to freezing. By contrast, the *cbl1* null mutant displays enhanced freezing tolerance, in concert with enhanced *CBF*/*DREB1* gene expression [118, 120].

What interacts with CBL proteins and how are stress signals relayed to the downstream components in the signaling pathway? The search for CBL interacting proteins with conventional methods, such as yeast two-hybrid screening, yielded rapid results in the identification of the CBL-interacting protein kinases (CIPKs) in *Arabidopsis* and other plant species [123]. The CIPKs belong to the class of serine/threonine protein kinases, which contain an N-terminal kinase catalytic domain and a C-terminal regulatory domain. It is the C-terminal regulatory domain that is responsible for the interaction between CBLs and CIPKs, and such interaction depends on Ca^{2+} [119, 124, 125]. Indeed, CIPKs are the primary target kinases of CBL proteins upon exposure to high concentrations of Ca^{2+} ions [126]. For most CIPKs, the downstream substrates are not clear, nor how they relay the Ca^{2+} signals. The *Arabidopsis* SOS1 protein is among the very few CIPK targets identified so far (discussed below).

Another intriguing observation from the study of the *Arabidopsis* and the rice genomes is that it appears that the plant genome contains large CBL and CIPK families. In *Arabidopsis*, there are at least 10 members of the CBL family and at least 25 members in the CIPK family [127]. The rice genome contains a similar number of CBL proteins, but the size of CIPK family is bigger than *Arabidopsis* (30 proteins) [127].

So how is the specificity of cellular responses determined when the concentration of Ca^{2+}, a universal signal molecule, increases upon multiple stress stimuli, such as cold, salt, drought, and wounding? In other words, how are the different Ca^{2+} signals decoded? Specific interactions between CBLs and CIPKs might account for part of the specificity [124, 126]. It was found that the two highly similar CBLs, CBL1 and CBL9, interact exclusively with both CIPK1 and CIPK23; that is, they do not interact with any other CIPKs [122, 128]. While the interaction between CBL1/CBL9 and CIPK1 is involved in osmotic stress response [128], the CBL1/CBL9-CIPK23 complex is involved in the regulation of plant potassium (K^+) channel and water loss in guard cells and root hairs [129–132]. CBL10 interacts only with CIPK24 during salt stress, and such interaction subsequently results in sequestration/compartmentalization of Na($^+$) in plant vacuoles [133]. However, CIPK24 also interacts with CBL4, also known as SOS3 [134–137]. The *Arabidopsis CIPK24*, also known as *SOS2*, was identified

through the same genetic screen where the P_{RD29A}-LUC system was applied [138]. It was found that the catalytic and regulatory domains of the CIPK24/SOS2 protein interact with each other under nonstress conditions, probably by blocking the kinase activity of CIPK24/SOS2 [139, 140]. The interaction between CIPK24/SOS2 and CBL4/SOS3 upon an internal Ca^{2+} spike relieves the repression and activates CIPK24/SOS2 kinase activity [139]. The activated CIPK24/SOS2 then phosphorylates the SOS1 protein, a Na^+/H^+ antiporter, which finally leads to salt tolerance [141, 142]. The CBL4/SOS3- CIPK24/SOS2-SOS1 represents one of the best-studied salt stress pathways in plants [25, 101, 143].

Another hypothesis for specificity is based on distinct target sequences located at the N-terminal domain of the CBL proteins. While some of the CBL proteins contain N-terminal myristoylation and S-acylation signals that target them to the plasma membrane, some CBL proteins do not, suggesting that their corresponding CBLs/CIPKs might function in the cytoplasm [119, 144]. For example, CBL1, CBL4/SOS3, CBL5, and CBL9 are all located on the plasma membrane, whereas CBL2, CBL3, CBL6, and CBL10 are located on the vacuole membrane. The last two CBLs, CBL7, and CBL8 are located in the cytoplasm [144]. The discrete localization of the CBLs/CIPKs complexes might be an important strategy plants adopt to decode Ca^{2+} signals in response to specific developmental and environmental stimuli. This is exemplified in the interaction between CBL4/SOS3, CBL10, and CIPK24/SOS2. CIPK24/SOS2 can interact with both CBL10 and CBL4/SOS3, but its final cellular localization is different. Upon salt stress, in the root cells, CBL4/SOS3 directs CIPK24/SOS2 to the plasma membrane where CIPK24/SOS2 exerts its function by phosphorylating the SOS1 Na^+/H^+ antiporter [2, 141, 143]. However, in shoots, upon the same salt stress, CBL10 directs CIPK24/SOS2 not to the plasma membrane but to the vacuolar membrane (tonoplast), in order to control intracellular salt homeostasis [133].

5.3.4 Mitogen-Activated Protein Kinase Proteins: Essential Roles in Plant Stress Responses

The MAPK proteins have received a substantial amount of attention in regard to plant stress responses, and this is mainly due to the critical roles their counterparts play in a variety of yeast and animal stress signal transduction pathways and networks [145, 146]. The MAPK pathway is typically comprised of three linearly organized components. The last component in the pathway, the MAPK, is activated by phosphorylation at threonine and tyrosine residues in the conserved T-x-Y motif, by the middle component, the MAPK kinase (MKK). The MAPK kinase/MKK in turn is regulated by phosphorylation on the two serine/threonine residues by the upstream MAPK kinase kinase (MAPKKK or MEK).

A variety of approaches were employed to investigate the possible involvement of MAPKs in plant stress responses. Using yeast two-hybrid analysis and functional complementation studies, as well as protoplast transient expression systems, it has been shown that *Arabidopsis* contains complete sets of functional MAPK cascades that may play roles integral to various biotic and abiotic stress signal transductions [147–150].

To date, two complete sets of MAPK cascades have been characterized in *Arabidopsis*. The AtMEKK1–AtMKK4/AMKK5–AtMPK3/AtMPK6 cascade has been shown to be specifically involved in plant response to bacterial flagellin elicitor in a protoplast system [151], while the AtMEKK1–AMKK2–AtMPK4/AtMPK6 has been shown to be preferentially activated by abiotic stresses, such as cold or salt, in a transient assay combined with mutant analysis [152]. Notwithstanding this result, how AtMEKK1 interprets different stress signals and activates corresponding downstream MAPK pathways still remains to be answered. The mRNA expression for most of the components in MAPK cascades does not change in response to stress treatments, except for AtMEKK1, which is strongly induced by cold [153, 154]. Protein levels for most of the components also stay constant; however, their kinase activities were found to be rapidly turned on following different stress treatments, strongly suggesting that posttranslational modification is mostly responsible for the change. The kinetics for most of the kinase activation is consistent with what was hypothesized previously: that *de novo* protein synthesis is not required for the activation of key transcription factors such as *CBF* genes. These results also place the MAPK cascades as a potential upstream event required for the activation of transcription factors such as *ICE1* and *CBFs*.

One of the more controversial MAPKs in stress responses is AtMPK4. Analysis of the *mpk4* null mutant revealed a negative role of this gene in plant response both to pathogen infection [155] and to hyperosmotic stress [156]. However, the positive role of AtMPK4 in cold and salt stresses was also suggested by another study where it was shown that AtMPK4 was one of the direct and preferred phosphorylation targets by the MAPK kinase, AtMKK2 [152]. AtMPK4 also strongly interacted with AtMKK2 in a yeast two-hybrid system. Constitutive activation of AtMKK2 resulted in the strong activation of AtMPK4 kinase activity, as well as the induced mRNA expression of a number of cold stress marker genes such as *CBF2* and *CBF3* [152]. These results implied that AtMPK4 might play very specific roles in response to various types of stresses. Similar findings have been reported with the rice *OsMAPK5* gene, where it was shown that disease resistance and abiotic stress tolerance appear to be inversely modulated by the rice OsMAPK5 [157]. Nevertheless, the role of AtMPK4 in directly mediating AtMKK2 activity in the expression of stress-responsive genes requires further examination.

Regarding the direct targets or phosphorylation substrates downstream of the MAPK cascades, only limited studies have been reported so far. Through a yeast two-hybrid screening, an AtMPK4 interacting protein, named MKS1, was identified, which might mediate the expression of some WRKY-type transcription factors in plant defense response [158]. In addition, it was shown that AtMPK4 could phosphorylate MKS1 *in vitro*, suggesting that MKS1 acts downstream of AtMPK4. However, the specific role of MKS1 phosphorylation by AtMPK4 in defense signal relay was not investigated. Systematic approaches such as protein microarray-based methods have also been developed to identify target substrates of MAPKs. Using this approach, 48 potential substrates of AtMPK3 and 39 of AtMPK6 were identified [159]. Although the aim of this study was to identify proteins involved in the inflorescence meristem development mediated by AtMPK3 and AtMPK6, a similar approach can nevertheless be applied to identify potential MAPK targets.

5.3.5
Do Ca^{2+}-Mediated Signaling Pathways Crosstalk with the MAPK-Mediated Pathways?

The CDPK-mediated stress signaling and MAPK-mediated signaling represent two major signaling pathways activated in many organisms in response to stress conditions. In animals, voluminous data clearly showed that there are crosstalks between these two pathways [160]. However, it does not seem to be the case in plants, especially during plant response to salt stress [117]. It was found that the *atcdpk3* mutant displayed a salt-sensitive phenotype similar to the *atmkk2* mutant. However, mRNA expression of a number of genes that were known to be regulated at transcriptional levels by *MKK2* remained unchanged in the *atcdpk3* mutant, indicating that *AtCDPK3* is not involved in the same mode of transcriptional regulation of the salt-responsive genes. The subsequent proteomic analysis identified 28 proteins with altered phosphorylation patterns between wild-type and *atcdpk3* mutant plants. Interestingly, most of these proteins were predicted to be membrane located, for example, VDAC1 (voltage-dependent anion channel 1) and VDAC2 [117]. At the same time, it was found that the AtCDPK3 protein itself contains a myristoylation site and a substantial amount of this protein was membrane located [117]. This prompted the authors to propose the hypothesis that while the MAPK pathway is primarily responsible in mediating transcriptional regulation of salt-responsive genes during salt stress response, CDPKs might regulate mainly through the direct activation of membrane-associated proteins such as ion channels [117]. However, it is not clear if this hypothesis also works for plant responses to cold, drought, or osmotic stresses.

5.4
Other Signaling Molecules Involved in Cold Signaling Pathways

A large body of evidence strongly suggests that cold and other abiotic stress signaling pathways are extremely complicated, and legions of signaling molecules are involved in transducing specific external signals to their corresponding targets, in order to trigger the right cellular responses. Thus, beyond the essential signaling molecules that have been discussed in the previous sections, I will also mention a few additional members that most likely play pivotal roles in plant cold and abiotic stress responses.

5.4.1
MAPK-Specific Phosphatases and Other Protein Phosphatases

As already discussed, MAPKs are involved in the signaling of many physiological processes, including plant response to abiotic stress. However, continuous activation of MAPK pathways under unnecessary conditions is costly and detrimental to plants; thus, the activities of MAPKs must be tightly regulated. While MAPKs are activated by MKKs through phosphorylation at the threonine and tyrosine residues, they are inactivated by the MAPK-specific phosphatases (MKPs). MKPs belong to a group of

dual-specificity phosphatases (DSPs; Ser/Thr and Tyr), and they dephosphorylate MAPKs at the same amino acid residues [161]. There are 22 DSPs in the *Arabidopsis* genome; however, only 5 of them were functionally characterized [161]. Of these, MKP1 is most likely involved in plant response to abiotic stress [162]. MKP1 is able to dephosphorylate MAPK6 both *in vitro* and *in vivo*, and an *mkp1* mutant displays enhanced resistance to salt stress, consistent with the hypothesis that MAPK6 is a positive regulator in plant abiotic stress response and that the regulation depends on its kinase activity. An increase in MAPK6 activity in the *mkp1* mutant background would then be expected to lead to increased abiotic stress tolerance. Microarray analysis confirmed this idea and showed that the expression of a number of salt stress-regulated genes was induced in the *mkp1* mutant background [162].

In addition to the MKPs, other protein phosphatases are involved in the inactivation of MAPKs, thus controlling the balance between active and inactive MAPKs. The PP2C plant family of serine/threonine protein phosphatases constitutes another group of phosphatases that can dephosphorylate threonine residues within the T-x-Y motif of MAPKs. The *Arabidopsis* PP2C-type phosphatase AP2C1 can inactivate MAPK4 and MAPK6 *in vitro* and *in vivo*, and increased levels of AP2C1 result in a compromised response to pathogen infection in the *AP2C1* overexpression transgenic *Arabidopsis* plants [163]. It is not clear if AP2C1 is involved in plant responses to abiotic stresses. However, since both MAPK4 and MAPK6 are involved in abiotic stress signaling, and AP2C1 negatively regulates MAPK4 and MAPK6 activities, it is likely that AP2C1 might also be involved in plant abiotic stress responses.

Another group of PP2C-type phosphatases, the plant tyrosine-specific phosphatases (PTPs), were also shown to be able to deactivate MAP kinase activities. One example came from the study of the *Arabidopsis* PTP1 protein. Interestingly, the mRNA expression level of *AtPTP1* is upregulated by salt stress but downregulated by cold stress [164]. The AtPTP1 protein was also found to interact with MAPK6 in a yeast two-hybrid study, suggesting that MAPK6 might be the target of AtPTP1 to regulate plant abiotic stress responses [165].

5.4.2
Two-Component Systems

The two-component sensor regulator system was originally found in prokaryotes, and this predominant signal transducing system was found to be involved in response to different environmental stimuli [166]. However, a large body of experimental data has demonstrated that eukaryotes, including plants and animals, also use two-component systems (TCS) to transduce external signals [167–169]. The conventional TCS found in most of the prokaryotic organisms is typically composed of two proteins, a membrane-localized histidine kinase (HK), which senses the input signals, and an aspartate response regulator (Asp-RR), which is normally a transcription factor that outputs the signal. The perception of external signals by HK causes an autophosphorylation of its own His residue, effecting transfer of the phosphoryl group to the Asp residue, which then leads to the activation of the Asp-RR. However, in most of the eukaryotes, the two-component system has evolved to include an intermediate

component that sits between HK and Asp-RR. This protein is an independent histidine phosphotransfer (HPT) protein [168].

In *Arabidopsis*, proteins homologous to all the components of the eukaryotic two-component system have been identified [167]. One of the most thoroughly studied functional two-component systems in plants is the cytokinin signaling pathway, where the plant phytohormone cytokinin signal is perceived by a HK and transduced to an Asp-RR through an intermediate HPT [170, 171].

Multiple pieces of evidence point to the plant two-component system as being involved in abiotic stress responses, yet a complete and functional HK-HPT-Asp-RR is still lacking [172–174]. For example, the *Arabidopsis* HK protein, AtHK1, which is essential for cytokinin signal perception, is also involved in drought, osmotic, and salt stress responses, both in an ABA-dependent and in an ABA-independent manner [175]. This is further supported by microarray data analysis demonstrating that the mRNA expression of many abiotic stress- and/or ABA-inducible genes, including *AREB1*, *ANAC*, and *DREB2A* transcription factors genes, is downregulated in the *athk1* mutant [175]. Further expression analysis of the *Arabidopsis HK2*, *HK3*, and *HK4* genes in response to various abiotic stresses showed that the transcripts of all three *AtHK2*, *AtHK3*, and *AtHK4* were rapidly induced by dehydration [173]. Expression of *AtHK2* appears to be regulated by salt stress and ABA treatments, and *AtHK3* mRNA is induced by salt and cold stress treatments [173]. What is not clear is that if the HPTs and Asp-RRs work together with the AtHK1-4 during stress responses.

Not much data have been presented so far from the investigation of Asp-RR protein involvement in plant abiotic stress responses. The rice *OsRR6* gene is among the few plant response regulator genes being studied, which may participate in abiotic stress signaling [176]. The mRNA expression of this gene is induced upon cold, salt, and drought stress treatments [176]. The *Arabidopsis* calmodulin-like protein, AtCML9, was previously shown to be involved in abiotic stress response [108]. Using a yeast two-hybrid system, an AtCML9-interacting protein was identified [177]. The corresponding gene encodes AtPRR2, a pseudo response regulator [177]. TheAtPRR2 sequence resembles an authentic plant response regulator; however, it lacks the conserved Asp residue that serves to accept the phosphoryl group [177]. The functional significance of the interaction between CML9 and PRR2 has not been investigated.

An interesting story about the plant Asp-RRs springs from a study between salt-sensitive and salt-resistant ecotype rice [178]. The authors discovered that the expression patterns for all putative members of the rice two-component system, including genes encoding HKs, HTPs, and Asp-RRs, changed in response to stress treatments. More significantly, the mRNA expression of nearly all the two-component system genes is higher in the salt-resistant ecotype rice than in the salt-sensitive ecotype rice, suggesting that these genes might play a role in rice salt stress response.

5.4.3
Heterotrimeric G-Protein-Mediated Signaling in Plant Abiotic Stress Responses

The heterotrimeric G-protein complex is composed of three different subunits: G-alpha (Gα), G-beta (Gβ), and G-gamma (Gγ). It is somewhat surprising that unlike

animal systems, which include multiple members of each subunit gene family (the alpha gene family has 20 members [180], the beta has 5 [180], and the gamma has 12 [181]), the plant genome contains only one or, at most, two members in each subunit gene family. For example, the *Arabidopsis* genome contains only one canonical Gα gene, the *AtGPA1* [182], one Gβ gene, the *AGB1* [183], and two Gγ genes, the *AGG1* and *AGG2* [184, 185]. However, it appears that the plant heterotrimeric G-proteins are involved in a wide range of developmental processes, such as ABA signaling and cell cycle regulation [186, 187].

Recently, their roles in plant responses to environmental signals have begun to emerge [188, 189]. For example, it was shown that the mRNA expression of the pea Gα and Gβ genes was upregulated by heat and salt stresses, as well as by H_2O_2 [189]. Moreover, the overexpression of the pea Gα and Gβ genes in transgenic tobacco resulted in enhanced salt stress tolerance [189], clearly demonstrating that G-proteins are directly involved in plant abiotic stress responses. A Gα gene cloned from *B. napus* [190] also displays interesting expression patterns. Although drought and salt stresses induce the Gα mRNA expression, heat and cold stresses inhibit the expression, suggesting that the functions of G-proteins are specific to various environmental signals [190].

How are the activities of G-proteins regulated? In animal cells, the three G-protein subunits form a complex under regular conditions, with GDP bound to the Gα subunit. In this state, the G-protein is inactive. Once the external stimuli are sensed by a group of proteins called G-protein-coupled receptors, the GPCRs in turn activate Gα subunits by exchanging their bound GDPs for GTPs. The activated Gα subunit then dissociates itself from the Gα–GβGγ complex and subsequently activates its downstream effectors [191, 192].

In mammalian systems, GPCRs play extremely important roles in a multitude of signal transduction pathways. There are about 1000 GPCR genes in human genome [193]. However, there is only a single GPCR gene, called GCR1, to be found in *Arabidopsis* [194], regardless of the existence of 394 divergent GPCR candidate genes [195]. A typical GPCR protein contains seven transmembrane domains, which function in ligand binding, followed by a cytoplasmic domain that is involved in the Gα protein subunit interaction. The binding of ligands to the GPCR proteins initiates their activation, which in turn activates the Gα subunits, and consequently triggers a cascade of cellular responses [81, 193].

Some exciting results were produced in Assmann's laboratory, where they discovered that two *Arabidopsis* GPCR proteins, GTG1 and GTG2, are ABA receptors, which bind ABA specifically *in vitro* [196]. In addition, these proteins also interact with the only *Arabidopsis* G-protein, AtGPA1, suggesting that the ABA signaling might be initiated with the membrane-located GPCR proteins, GTG1 and GTG2, and then relayed to AtGPA1 [196].

So how do G-proteins communicate specific abiotic stress signals? It was found that the alpha subunit of G-proteins could physically interact with phospholipase C (PLC) in both an *in vitro* assay and an *in vivo* assay [189], suggesting that G-proteins relay external signals by stimulating the activities of PLCs. As already discussed in previous sections, the activation of PLCs results in the production of two important

secondary messengers, DAG and IPs, both of which are involved in the release of intracellular Ca^{2+} storage into the cytosol. The sudden increase in cytoplasmic Ca^{2+} triggers a series of signaling cascades, which then leads to final physiological changes inside the cells [81].

PLD also interacts with G-proteins [197, 198]. An *Arabidopsis* PLD, AtPLDα1, preferentially interacts with the inactive GDP-bound Gα subunit, whereas the GTP-bound Gα subunit inhibits the PLDα1 activity [198]. The physical interaction between GDP-Gα and PLDα1 was found to be functionally involved in the ABA-mediated stomatal opening of guard cells [199]. However, direct evidence of any functional interactions between G-proteins and PLCs/PLDs in plant abiotic stress responses is still lacking.

5.4.4 Receptor-Like Protein Kinases

Receptor-like protein kinases (RLKs) constitute one of the largest protein families in plants. There are predicted to be about 600 RLK encoding genes in the *Arabidopsis* genome and more than 1100 genes in the rice genome (see Ref. [200] and references therein). Owing to the presence of a large number of RLKs in plant genomes, it is believed that they are the major components of signaling perception and transduction. As being the predominant class of membrane receptors, RLKs feature an extracellular domain, a single transmembrane domain, and a cytosolic Ser/Thr protein kinase domain.

The plant RLKs possess highly diverse functions in growth and development, and biotic stress responses, as well as in nodulation and rhizobial symbiosis [201]. Their involvement in abiotic stress responses has also been widely documented in literature. In one example, the *Arabidopsis RPK1* gene was rapidly induced upon ABA, dehydration, salt, and cold stress treatments [202]. In another example, overexpression of *RPK1* in transgenic *Arabidopsis* conferred increased ABA sensitivity, drought tolerance, and increased tolerance to oxidative stress, while the knockout *rpk1* mutant displayed opposite phenotypes [203]. Apparently, the RPK1 effect on drought tolerance depends on its kinase activity since a mutation on the conserved lysine residue within the kinase domain abolished this effect [203].

Recently, a detailed gene expression profiling study was conducted by spotting 604 *Arabidopsis RLK* genes on a Syngenta custom GeneChip® microarray, to understand, on a global scale, the transcriptional regulation of the entire complement of *Arabidopsis RLK* genes simultaneously in response to a wide range of environmental and developmental stimuli [204]. The mRNA expression of a significant portion of *RLKs* was found to be regulated during abiotic stress treatments. What is intriguing is that a majority of the *RLKs* responded to more than one signal treatment [204]. Salt stress and cold stress had more shared responses, disclosing 6 (10%) RLK genes with increased expression levels and 27 (19%) with decreased levels. Cold and osmotic stress revealed 3 shared respondents (5%) with increased expression and 16 (8%) with decreased expression. When all the stress treatments were grouped together – biotic, abiotic, and hormonal – it was found that 48 RLKs were induced, while 83 genes were

repressed, by both biotic and abiotic stress and hormone treatments [204], suggesting that most of the *Arabidopsis* RLKs likely perform multiple functions inside the cells.

5.5 Conclusions and Prospects

Abiotic stresses, such as cold, high salinity, drought, osmotic, and heat stresses pose tremendous challenges to plants in their daily lives, negatively affecting their growth, development, and reproductivity. Plants have evolved a battery of mechanisms to adapt themselves to such adverse environments. Through genetics, molecular, biochemical, physiological, and functional genomics approaches, a large number of genes and molecules were discovered that carry out diverse sets of functions during plant responses to abiotic stresses. These molecules, including transcription factors, protein kinases, ubiquitination/proteolysis-related proteins, osmolytes, and other cellular protectants, and even small RNAs, function at various stages of stress signal transduction and responses (Figure 5.1). A thorough understanding of molecular and biochemical mechanisms of plant cold and other abiotic stress responses will be a prerequisite for efficiently designing strategies for improving plant abiotic stress tolerance. However, the number of molecules that have been identified is believed to be far below than what plant scientists expected.

The forward genetics approach, that is, mutant screening for phenotypes, has proved extremely useful in identifying gene components during stress signal transduction. The P_{RD29A}-LUC system discussed in this chapter demonstrates the power of genetic screening in uncovering genes and proteins that play various roles during plant abiotic stress responses. Unfortunately, this approach might have limitations in studying plants, due to problems such as gene functional redundancy, a consequence of the existence of multiple gene families with a large number of members. Reverse genetic approaches, that is, transgenic plants overexpressing a particular gene, or RNAi to silence a particular gene, have been widely used to complement the forward genetic approach to study gene functions. However, previous reverse genetic studies have been limited to individual genes of interest, and systematic analysis of functions of genes that belong to large gene families, such as the CBL family and the RLK family, is still lacking. A number of international consortiums have been organized to focus on tackling some of these large gene families in *Arabidopsis*, and data released from these consortiums to the public database in the future will be extremely beneficial to the plant research community.

Protein kinases are indispensible to plant abiotic responses. Although significant progress has been made toward understanding the mechanisms protein kinases employ during stress signal transduction, many questions remain. A central question is what is the connection between protein phosphorylation and transcriptional activation of stress-responsive genes? Clearly, a major priority is the search and identification of proteins and substrates that are specifically phosphorylated by protein kinases following stress treatment. This information is greatly needed in producing a more complete picture of cold and other abiotic signal transduction

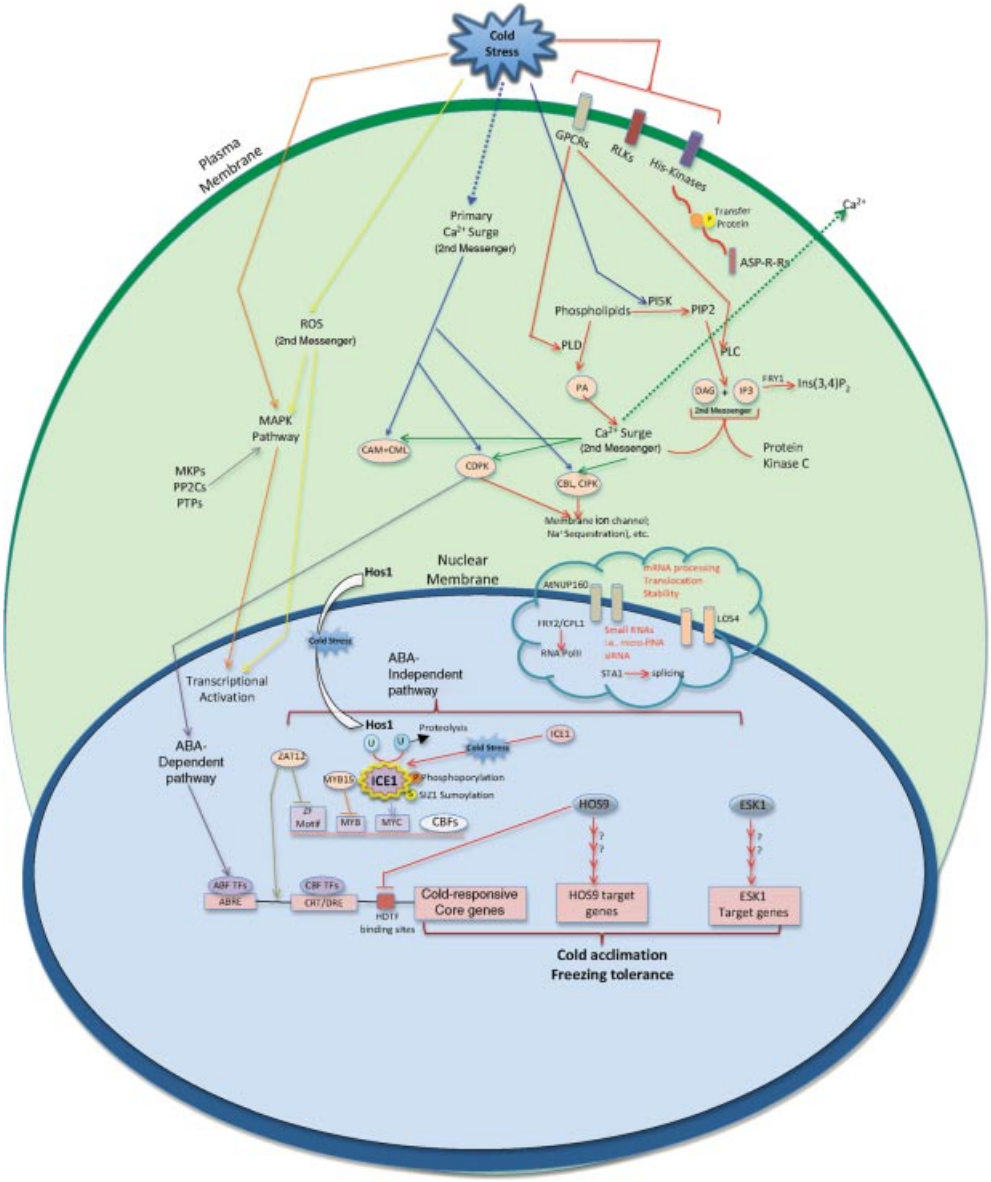

Figure 5.1 Diagram of plant cold stress signaling pathways. Plants might sense cold stress signal through membrane-located receptors, such as GPCRs, RLKs, and histidine kinases (HKs) of the two-component systems. GPCRs regulate PLC and PLD activities through direct protein–protein interaction. Cold stress directly stimulates PI5K activity. PI5K catalyzes phospholipids into PIP2, which in turn is metabolized to two secondary messengers, DAG and IP_3 by PLCs. Cold stress also stimulates PLD activities to produce another secondary messenger, phosphatidic acid. Intracellular Ca^{2+} surge occurs rapidly following cold stress. This Ca^{2+} surge is achieved one way by pumping Ca^{2+} from

networks. Approaches such as the yeast two-hybrid screening have been employed to identify kinase substrates. One of the drawbacks, however, is that often the screening results gained in the identification of proteins have nothing to do with protein phosphorylation. Methods aimed toward specifically identifying phosphoproteins are sorely needed.

Recent technological advancements in the proteomics field, such as the development of a number of methods for phosphopeptide enrichment (including immobilized metal–ion affinity chromatography (IMAC) and TiO_2 chemo-affinity chromatography) coupled with mass spectrometry, made possible the analysis of entire phosphoproteomes. One of the first studies in *Arabidopsis* by Nühse *et al.* (2004) [205] provides an excellent example of applying the IMAC method and mass spectrometry in the identification of phosphoproteins from *Arabidopsis* plasma membrane following fungal elicitor treatment in a cell suspension system. Since many of the receptor-like protein kinases were expected from the elicitor-triggered signaling response, the identification of a large number of phosphorylated RLKs validated this as a powerful approach in phosphoproteomic research [205]. Although future work is still needed to investigate more complex samples from whole cell extracts, and to make quantitative comparisons of the amount of phosphoproteins under different conditions, the results of this work demonstrate that this approach could be a promising alternative to many conventional methods in yielding new insights into the regulatory mechanisms of phosphorylation in stress signaling transduction.

So far, majority of the research on plant abiotic stress responses focuses on *Arabidopsis*, a model plant but economically unimportant. Plants such as soybean,

periplasma space into cytosol. In addition, DAG and IP_3 stimulate Ca^{2+} release from intracellular storage. Cytosolic Ca^{2+} serves as another secondary messenger to activate calcium binding proteins, including CaMs and CMLs, calcium-dependent protein kinases (CDPKs), and CBLs. CBLs and their CIPKs act on membrane ion channels to keep the cellular ion homeostasis. CDPKs, on the one hand, may directly act on membrane ion channels. On the other hand, they may interact with transcription factors to activate stress gene expression, in an ABA-dependent manner. Cold stress also increases the levels of ROS, which subsequently activate stress gene expression at transcriptional levels. Mitogen-activated protein kinase pathways are activated by cold stress too. MAPK pathways might be directly involved in transcriptional activation of cold stress gene expression.

Inside nucleus, the constitutively expressed ICE1 protein is activated by cold stress through phosphorylation and sumoylation. SIZ1 is responsible for sumoylating ICE1. Proteins that phosphorylate ICE1 remain to be identified. ICE1 is a positive regulator of CBF gene expression, while MYB15 and ZAT12 are negative regulators. However, ZAT12 positively regulates the expression of some CORE cold stress-responsive genes. HOS1 translocates from cytosol to nucleus upon cold stress and then inactivates ICE1 through ubiquitination-mediated proteolysis. HOS9 and ESK1 function through ICE1/CBF-independent pathways and positively regulate plant responses to cold stress by activating genes that are different from CBF regulons. HOS9 also counteracts on some of the genes within the CBF regulons. The ICE1/CBF pathway, HOS9-, and ESK1-mediated pathways are independent of abscisic acid (ABA). The ABA-dependent pathway is also responsible for activating cold stress gene expression, and this pathway functions through ABRE binding factors (ABF transcription factors or ABF TFs).

corn, rice, and tomato received less attention due to technological difficulties and less functional genomics resources compared to *Arabidopsis*. Although plant scientists hope to extend the *Arabidopsis* work to these economically important plants, apparently there are differences between *Arabidopsis* and other plant species. For example, the *Arabidopsis AtCBF3* gene was found to be the homologue of the tomato *LeCBF1-3*. However, while overexpression of the *LeCBF1* gene in transgenic *Arabidopsis* results in the enhanced freezing tolerance, overexpression of either the tomato *LeCBF1* gene or the *Arabidopsis AtCBF3* gene in transgenic tomato did not result in the expected enhanced stress tolerance [18].

International efforts for functional genomics studies on genes from economically important plant species are urgently needed since these plant species are directly related to human lives. Hundreds and millions of dollars are lost each year as a result of yield loss due to adverse abiotic stress challenges. Meanwhile, the world population is increasing rapidly, and it is possible that we might be facing food shortages in the near future. Thus, a complete understanding of the molecular and genetic basis of abiotic stress responses in economically important plant species is crucial to the development of genetically modified plants as a major solution to successfully overcome such alarming situation.

Acknowledgments

I thank Mrs. Felis Wolven for making a critical reading of this book chapter. I also thank Mr. Edgar Campos for helping me in preparing Figure 5.1. I apologize if any references were omitted from citing due to space constraints.

Mechanism of Sulfur Dioxide Toxicity and Tolerance in Crop Plants

Lamabam Peter Singh, Sarvajeet Singh Gill, Ritu Gill, and Narendra Tuteja

Air is an important and vital resource both for the sustenance and for the development of every living organism. The composition of its minor constituents often varies as a result of the emission or contaminants from various activities. A huge amount of toxic materials and gas including SO_2 is released into the atmosphere originated from different kinds of industries and other human activities that eventually pollute the atmosphere. A mere change in the gaseous composition of the atmosphere has many different impacts on terrestrial plants. Sulfur dioxide pollution is known to have a substantial effect on agricultural production and is still of great significance in many developing countries. Conversely, due to strict regulatory control on SO_2 emissions, the level of atmospheric SO_2 in developed countries has radically declined causing S-deficiency symptoms in crop plants, resulting in a drastic reduction in crop productivity and quality. Increased uptake of SO_2 can impair plant metabolism leading to reduced growth and productivity due to accumulation of sulfite and sulfate within the plant. Phytotoxicity of SO_2 is determined by the environmental conditions, the duration of exposure, the atmospheric SO_2 concentration, the sulfur status of the soil, the genetic constitution of the plant, and the developmental phase of plants. Plants form a sink for atmospheric SO_2, which is taken up by the foliage. Since the internal (mesophyll) resistance to SO_2 is low due to its high solubility and rapid dissociation in the cell sap, foliar SO_2 uptake is determined by its diffusion through the stomata. Foliar injury may be caused by the negative effects of acidification of tissue/cells after the dissociation of the absorbed SO_2 and the reaction of the formed sulfite with cellular components. There is also a wide inter- and intraspecific variation in susceptibility between species; however, the physiological basis for the variation in air pollution response is still largely unresolved. Paradoxically, atmospheric SO_2 may also be used as plant nutrient where SO_2 absorbed by the leave can enter the S assimilatory pathway directly or after oxidation to SO_4^{2-} and be reduced to sulfide, incorporated into cysteine and subsequently, organic S compounds, and utilized as S nutrient. Plants may also benefit from SO_2 exposure given that it can contribute to the plants' S nutrition, and result in enhanced crop productivity, especially in plants growing in sulfur-deficient soils.

Improving Crop Resistance to Abiotic Stress, First Edition.

6.1 Introduction

Sulfur dioxide (SO_2) a colorless, nonflammable gas is one of the most prevalent phytotoxic gaseous pollutants released as a result of combustion of fossil fuels in developing countries including India [1–3] and causes disorders in plants with specific symptoms [4, 5]. However, SO_2 at low concentration can stimulate physiology and growth of plants, especially in plants growing in sulfur-deficient soil [6], where the sulfate might be metabolized to fulfill the demand for sulfur as a nutrient [7]. Sulfur is necessary for proper growth and development of living organisms; however, it is attributed rather catalytic and regulatory than structural functions because it is much less abundant than other macroelements. The plant biomass consumed as food and feed serves as the main source of organic sulfur for animals and humans [8]. Plants, bacteria, and fungi, unlike animals, are able to assimilate inorganic sulfur and incorporate it into organic compounds. Plants utilize sulfate for the synthesis of diverse primary and secondary metabolites [9]. However, increased uptake of SO_2, causes toxicity and reduces growth and productivity of plants due to accumulation of sulfite or sulfate ions in excess [6, 10, 11].

6.2 Emission Sources

6.2.1 Natural Sources

Natural sources of sulfur dioxide include volcanoes and volcanic vents, microbial activities (decaying organic matter), solar action on seawater, and oxidation of dimethyl sulfide emitted from the ocean [12]. According to Hazardous Substances Data Bank (HSDB) [13], although volcanoes are a sporadic source of sulfur dioxide, they are potentially a significant natural source. Decaying organic matter indirectly results in a natural source of SO_2. Decaying organic matter on land, in marshes, and in oceans results in the release of hydrogen sulfide, which is quickly oxidized to SO_2.

6.2.2 Anthropogenic Sources

On a global scale, anthropogenic emissions represent a significant contribution to the SO_2 emitted to the atmosphere [14], and these emissions are approximately equal to natural emissions [15]. Friend [16] estimates that, on a global basis, 75–85% of SO_2 emissions are the result of fossil fuel combustion, while the remainder of the emissions is the result of refining and smelting. It is estimated that approximately 93% of the global SO_2 emissions occur in the northern

hemisphere and the remaining 7% in the southern hemisphere [14]. The greatest anthropogenic sources of SO_2 result from the combustion of fossil fuels and from the smelting sulfide ores [12]. Another significant source is petroleum refining [13]. Other less significant sources include chemical and allied products manufacturing, metal processing, other industrial processes, and vehicle emissions [17].

Together, natural and anthropogenic sources emit an estimated 194 million ton of SO_2 per annum, of which 83% is due to fossil fuel combustion [18]. Although considerable progress has been made in the development and implementation of SO_2 control technologies in North America, Europe, and Japan, ambient SO_2 concentrations is still a significant problem in many parts of the world particularly the developing countries including India [19–21]. Nearly two-thirds of the total mined coal is burnt in thermal power stations to generate electricity in India and other developing countries. Coal combustion liberates high concentrations of oxides of sulfur and nitrogen into the environment. The ambient concentration of SO_2 varies with the distance from the source and direction of wind. The surrounding environment of approximately 10–20 km diameter may experience much higher concentrations of SO_2. Khan and Khan [22, 23] recorded 169–298 μg SO_2 m^{-3} at a site 2 km away from a coal-fired power plant in the usual wind direction. According to CPCB, New Delhi, permissible level of SO_2 for agricultural areas is 50 μg m^{-3} for annual and 80 μg m^{-3} for 24 h means (see Table 6.1). Once emitted, SO_2 is transferred from the atmosphere to surfaces by diffusion (both dry and wet deposition) at variable rates that are strongly influenced by meteorological conditions. It is also important to note that SO_2 in the atmosphere is also transformed to SO_4^{2-} at variable rates, and these SO_4^{2-} particles are deposited on surfaces by Brownian motion (dry deposition) and by precipitation (wet deposition). Any observed foliar injury or changes in plant growth and productivity due to SO_2 exposures are the result of dry/wet deposition and subsequent uptake of sulfate and sulfite ions in the leaf tissue and their uptake by plants [24].

Table 6.1 National ambient quality standard for sulfur dioxide (SO_2).

	SO_2 (μg m^{-3})	
Time-weighed average	**Annual**	**24 h**
Industrial, residential, rural and other areas	50	80
Ecologically sensitive areas (notified by Govt. of India)	20	80
Methods of measurement	Improved West and Gaeke	Ultraviolet fluorescence

6.3 Effects on Plants

6.3.1 Visible Foliar Injury

As leaves are more sensitive to SO_2 exposure than stems, buds, and reproductive parts, SO_2 injury to plants is first seen on the foliage. The degree to which foliage responds to SO_2 is generally determined by both biotic (genetic makeup, developmental stage of growth, plant nutrient status, and pests and diseases) and abiotic factors (soil moisture and nutrient status, air and soil temperature, relative humidity, radiation, precipitation, and metrological conditions, as well as the presence of other air pollutants), as well as by the concentration, duration, and frequency of SO_2 exposure. Basically, when biotic and abiotic factors are favorable for plant growth and development, there is a high probability that plants exposed to SO_2 will be adversely affected. When one or more biotic and/or abiotic factors limit a plant's growth and development, there is a lowered probability that the plant will be adversely affected. Besides, SO_2 concentration, as well as duration and frequency of SO_2 exposure that are determined by meteorological conditions, play a significant role in determining the potential for an adverse response of vegetation to SO_2 [25].

Sulfur dioxide when present at higher concentrations causes foliar injury in plants. It diffuses in plants through open stomata and reacts with moisture to produce sulfite ions [24]. If the formation of sulfite ions is slow, they are oxidized to sulfate ions and utilized by plants. However, excess accumulation of sulfite and sulfate ions is toxic to plants [26]. The sulfite ions are about 30 times more toxic than sulfate ions [27]. Generally, two types of markers or symptoms designated as acute and chronic are produced by plants due to the accumulation of sulfite ions in the leaf tissue. An acute SO_2 exposure is considered as a short duration SO_2 exposure (from minutes to hours) that is of sufficient concentration to result in the expression of necrotic injury to the foliage within a few hours or days. These acute SO_2 injury symptoms commonly consist of bifacial, marginal, and/or interveinal necrosis and chlorosis on leaves at the full stage of development on broad-leaved plants. The necrotic areas can range from white to reddish brown to black in color depending on the plant species, and the margins of the necrotic areas are mostly irregular and occasionally dark pigmented. In monocotyledonous plants, acute injury symptoms start at the tip of the leaves and spread downward as necrotic and chlorotic streaks with occasional reddish pigmentation. In coniferous plants, acute symptoms appear on second-year or older needles and consist of a tan-to-reddish brown necrosis that starts at the needle tips, spreads downward toward the base, and is commonly preceded by chlorosis [25]. In case of severe injury, abscission layer develops at the base of petiole and the leaves fall down [28]. Although the above acute foliar SO_2 injury symptoms are standard/accepted symptoms of acute SO_2 exposure, very similar injury symptoms can also be caused by other air pollutants and biotic and abiotic stress factors [29]. When leaf surfaces are wet at the time of exposure, SO_2 can be absorbed by the water droplets on the leaf surface and the water becomes acidic as the SO_2 is converted into sulfuric acid

(H_2SO_2) and can cause acute foliar injury. Acute foliar injury from this "acidic wet deposition" occurs as necrotic areas with regular margins that reflect the outline of the acidified water droplets on the leaf surface. These short-term, acute foliar injury symptoms may or may not lead to long-term reductions in plant growth and productivity [30]. Low concentration SO_2 exposures that occur during the entire growth cycle or life of a plant with periodic intermittent and random peak levels is considered as chronic SO_2 exposure [31]. Such exposures may or may not result in chronic foliar injury symptoms such as marginal and/or interveinal chlorosis in broad-leaved plants, chlorosis in second-year and older conifer needles, premature fall coloration, and premature leaf/needle abscission [29]. In the same way as in the case of acute foliar injury symptoms, symptoms similar to chronic injury can be caused by other air pollutants and biotic and abiotic stress factors. Chronic SO_2 exposures can lead to reduction in the rate of plant growth and productivity (biomass), for example, grasses [32] and pines [33]. It is important to note that the reduction in plant growth and productivity from chronic exposure may occur without any development of visible chronic foliar injury symptoms. Physiological, biochemical, cellular, and tissue-level markers can be used to identify the presence of chronic SO_2 stress when visible symptoms are present or absent [34]. It is also important to mention that in the vicinity of point source, acute SO_2 exposures can occur on top of chronic SO_2 exposures. Furthermore, depending on the SO_2 concentration, duration, and frequency, acute and chronic SO_2 injury symptoms can cooccur on the same or different foliage of the same plant [25]. The expression of acute and/or chronic SO_2 symptoms is highly variable and can vary at the genus, species, variety or cultivar, provenance, and population levels [35, 36].

Shaw *et al.* [37] reported the effects of 34 and 58 $\mu g\ SO_2\ m^{-3}$ on needle necrosis in Scots pine (*Pinus sylvestris* L.) during the fumigation period of the Liphook Forest Fumigation Project. Regression analysis showed that the appearance of foliar injury was related to the mean SO_2 concentration during a critical growth period although injury did not become visible until 5 weeks later. SO_2 at 58 $\mu g\ m^{-3}$ caused foliar injury to a greater number of trees in 2 of the 3 survey years and foliar injury appeared on the same trees in consecutive years suggesting that the sensitivity was genetic. Furthermore, to see if the injury symptoms observed in the field could be duplicated, a subsidiary fumigation chamber experiment was performed. The result revealed that exposure to 655, 1310, and 2619 $\mu g\ m^{-3}$ of SO_2 for 4 h on Scots pine seedlings produced no effect in any treatment suggesting that this may have been due to a low replicate number resulting in a few plants at the most sensitive stage of growth and/or due to low humidity during fumigation. Intermittent exposure of tomato (cv. Pusa Ruby) to SO_2 at 286 $\mu g\ m^{-3}$ (3 h every third day for 75 days) induced slight chlorosis in leaves; however, considerable chlorosis with browning developed on the foliage at 571 $\mu g\ m^{-3}$ of SO_2. Symptoms were more pronounced and appeared earlier on SO_2-exposed plants infected with *Meloidogyne incognita* race 1 especially in post- and concomitant inoculation exposure [1]. Clapperton and Reid [38] screened genotypes of timothy (*Phleum pratense*) for SO_2 sensitivity in experiments conducted in closed fumigation chambers. Plants exposed to 393–524 $\mu g\ m^{-3}$ of SO_2 for 3 weeks developed chlorotic areas, browning, and necrosis of the leaves. Foliar and flower

injury occurred in *Calendula officianalis* [39] and *Zinnia* [40], and the intensity of symptoms increased with SO_2 concentration and duration of exposure. Rakwal *et al.* [41] observed distinctive reddish brown necrotic spots and interveinal browning appeared on the leaf surface of rice seedling cv. Nipponbare after exposure to SO_2 over control, partly reminiscent of the hypersensitive reaction lesions. Intermittent exposure to SO_2 at 200 and 300 $\mu g\, m^{-3}$ caused chlorosis of the leaves of pumpkin with or without inoculation of *M. javanica*. Only a mild chlorosis appeared in the infected plants at 100 $\mu g\, m^{-3}$ of SO_2 [42]. Sulfur dioxide (0.1 ppm) induced foliar chlorosis on two cultivars of cowpea, namely, V-38-1 and V-218, which appeared earlier in the presence of root-knot nematode (*M. incognita*) [43].

6.3.2 Sulfur Uptake and Plant Sulfur Content

Sulfur is prominently taken up by the roots in the form of sulfate ions. Sulfate is then transported to the shoot through xylem, where it gets reduced in the chloroplast prior to its assimilation into organic sulfur compounds. Sulfate is activated by ATP to APS (adenosine 5′ phosphosulfate), catalyzed by TP sulfurylase, and subsequently reduced by APS reductase to sulfite and then by sulfite reductase to sulfide. Sulfide is incorporated into cysteine by *O*-acetyl-L- serine (thiol) lyase. Cysteine is used as sulfur donor for the synthesis of methionine and both amino acids are incorporated into proteins. Cysteine is also the precursor for several other sulfur compounds including glutathione [44, 45]. The sulfate uptake by the roots and its transport to the shoots is mediated by specific sulfate transporters [46]. The regulation and expression of sulfate transporters is controlled by the plant's sulfur nutritional status [47]. Sulfate itself or a metabolic product of sulfate assimilation, such as cysteine or glutathione, may be involved in the regulatory control of uptake and transport of sulfate. Despite being highly toxic, the effect of SO_2 on plants is ambiguous, as a part of it is metabolized and utilized by the plants [7, 48–50]. The absorbed SO_2 in the mesophyll cells of the shoot may enter the sulfur reduction pathway either as sulfite or as sulfate. Excess SO_2 is transferred into the vacuole as sulfate, where it is slowly metabolized [51, 52]. Even at relatively low atmospheric concentrations, SO_2 exposure results in an enhancement in the sulfur content of the foliage because of accumulation of sulfate in the vacuole [7, 53]. It is also evident that in addition to sulfate taken up by the roots, plants are able to metabolize sulfur gases, H_2S and SO_2, by the shoot [7, 47, 54]. The gaseous sulfur enters the shoot via open stomata since the cuticle is impermeable to the gas [55]. The rate of uptake depends on the stomatal and mesophyll conductance and the atmospheric concentration. The mesophyll conductance toward SO_2 is very high since SO_2 is highly soluble in the aqueous phase of the mesophyll cells (in either apoplast or cytoplasm). Furthermore, it is rapidly hydrated/dissociated yielding bisulfite and sulfite ions ($SO_2 + H_2O \rightarrow H^+ + HSO^{3-} \rightarrow 2\ H^+ + {SO_3}^{2-}$), which are either reduced in the chloroplast or are enzymatically or nonenzymatically oxidized to sulfate [7, 53]. The stomatal conductance is generally the limiting factor for the foliar uptake of SO_2, which is reflected by a nearly linear relationship between the uptake and the atmospheric SO_2 concentration [53, 56, 57].

E. rudis Endl. plants exposed to 132 and 274 $\mu g\,m^{-3}$ of SO_2 for 8 h per day in open-top chambers for 17 weeks showed no effect on S content at the lower concentrations, but SO_2 at 274 $\mu g\,m^{-3}$ significantly increased the sulfur content of leaves [58]. Appraisal of the effects of the power plant emissions on the nutrient status of six species of tropical trees (two species of evergreen trees *Mangifera indica* and *Eucalyptus* hybrid and four species of deciduous trees *Psidium guajava*, *Cassia siamea*, *Delonix regia*, and *Bougainvillea spectabilis*) from a low rainfall area along a pollution gradient (seasonal average of 49–233 $\mu g\,m^{-3}$ of SO_2) around two coal-fired power plants in India revealed that a higher total foliar sulfur content in all six species at the most exposed location compared to the reference location. Deciduous species showed a greater increase in the foliar sulfur content after the emergence of new leaves possibly due to translocation of sulfur from woody plant parts [59]. Assessment of the sensitivity of *Prosopis ciceraria*, *Azadirachta indica*, and *Phoenix dactilifera* in the vicinity of an oil refinery based on sulfate accumulation showed that plants responded differently to SO_2 exposure. Plants grown in the close vicinity have maximum sulfate accumulation and injury than the distant ones [60]. Chinese cabbage is highly susceptible to sulfur dioxide showing a linear relation between the rate of uptake of SO_2 and the atmospheric concentrations (0.03–1.4 $\mu l\,l^{-1}$). Biomass of cabbage was reduced upon prolonged exposure to $\geq$0.1 $\mu l\,l^{-1}$ of SO_2 and resulted in an increase in SO_4^{2-}, water-soluble nonprotein thiols, and total S content of the shoot at concentrations $\geq$0.1 $\mu l\,l^{-1}$; however, the ratio of organic S to total S and organic N content was not affected. The impact of SO_2 on Chinese cabbage seemed to be ambiguous; SO_2 taken up by the shoot also served as a source of S for growth and was even beneficial when the SO_4^{2-} supply to the root was cut off. A 5 day exposure of plants to 0.06–0.18 $\mu l\ SO_2\ l^{-1}$ resulted in an alleviation of the development of S deficiency symptoms upon SO_4^{2-} deprivation. An atmospheric SO_2 level as low as 0.06 $\mu l\,l^{-1}$ appeared to be sufficient to cover the plants' S requirement for growth. The N/S ratio of shoot and root was much lower in SO_4^{2-} sufficient plants than in SO_4^{2-}-deprived plants. Exposure of SO_4^{2-}-deprived plants to SO_2 resulted in a decrease in the N/S ratio of the shoot, but did not affect that of the root. The N/S ratio of the shoot decreased with increasing SO_2 levels as a consequence of the increase in total S and SO_4^{2-} content. In contrary, the N/S ratio of shoot and root of SO_4^{2-}-sufficient plants was not significantly affected upon exposure to 0.06–0.18 $\mu l\,l^{-1}$ of SO_2. SO_4^{2-} deprivation resulted in a shift in shoot-to-root biomass partitioning during growth in favor of root production, which was not rapidly alleviated when SO_2 was used as S source for growth [61]. According to Dwivedi *et al.* [62], there is a positive correlation between ambient sulfur dioxide and sulfate (accumulation) in the leaves.

SO_2 readily reacts with water and forms sulfite ions that impact deleteriously on plant health. Modulation of the level of sulfite oxidase (SO) that catalyzes the transformation of sulfites to the nontoxic sulfate showed that *Arabidopsis* and tomato plants can be rendered resistant or susceptible to SO_2/sulfite. Plants in which sulfite oxidase expression was abrogated by RNA interference (RNAi) accumulated relatively less sulfate after SO_2 application and showed enhanced induction of senescence- and wounding-associated transcripts, leaf necrosis, and chlorophyll

bleaching. In contrast, SO overexpression lines accumulated relatively more sulfate and showed little or no necrosis after SO_2 application. The transcript of sulfite reductase, a chloroplast-localized enzyme that reduces sulfites to sulfides, was shown to be rapidly induced by SO_2 in a sulfite oxidase-dependent manner. Transcripts of other sulfite-requiring enzymatic activities such as mercaptopyruvate sulfur transferases and UDP-sulfoquinovose synthase 1 were induced later and to a lesser extent, whereas SO was constitutively expressed and was not significantly induced by SO_2. The results imply that plants can utilize sulfite oxidase in a sulfite oxidative pathway to cope with sulfite overflow [63].

6.3.3 Photosynthesis

There have been numerous efforts to measure the effect of SO_2 on metabolic processes in plants that can affect photosynthesis and other related processes such as stomatal conductance, photochemical efficiency, carbon dioxide assimilation, chlorophyll content, dark respiration, and carbohydrate metabolism. In a study designed to examine the changes in leaf gas exchange resulting from SO_2 exposure, Gerini *et al.* [64] exposed maize (*Zea mays* L.) in fumigation chambers to 113, 186, or 291 $\mu g\,m^{-3}$ of SO_2 for 4 weeks resulting in a 20% decrease in photosynthetic activity in plants exposed to 113 and 186 $\mu g\,m^{-3}$ of SO_2. They observed photosynthetic activity decreases by 10% at 291 $\mu g\,m^{-3}$ of SO_2 compared to control plants. Stomatal conductance, transpiration rate, and intercellular/ambient CO_2 were enhanced at the lowest SO_2 treatment, but decreased to near control levels at 291 $\mu g\,m^{-3}$ of SO_2 treatment. In contrast, water use efficiency and CO_2 assimilation rate declined at the lowest concentration of SO_2 and then increased at the higher SO_2 levels but not back to control levels. Sulfur dioxide levels used were representative of ambient SO_2 levels observed in the environment. The authors attributed the decrease in photosynthetic activity to reduced mesophyll assimilation capacity. Stomatal effects were ruled out as stomatal conductance and intercellular CO_2 were enhanced at these levels of SO_2. Utilizing an open-air fumigation system, Darrall [65] examined the effects of SO_2 at ambient, low (100 μg), medium (113 μg), and high levels (126 μg) on photosynthesis, dark respiration, transpiration, stomatal conductance, and internal CO_2 concentration and correlated the changes with grain yield in winter barley, *Hordeum vulgare* cv. Igri. Experiments were conducted for 3 years and the SO_2 concentrations varied within each year. The average concentrations for the highest SO_2 treatment for each year were 100, 113, and 126 $\mu g\,m^{-3}$. It was observed that SO_2 significantly increases net photosynthesis on some occasions, significant decreases were also frequently observed, and most of the photosynthetic changes were transient and were attributed to simultaneous changes in stomatal conductance and transpiration. Dark respiration was significantly enhanced at 84 and 113 $\mu g\,m^{-3}$ of SO_2. The author concluded that increase in dark respiration could have been resulted from the enhanced detoxification and repairing processes.

Panigrahi *et al.* [66] determined the effect of SO_2 on chlorophyll content, by exposing 20, 40, 60, 80, and 100 days old rice (*Oryza sativa* L.) and 15, 30, 45, and 50

days old mung bean (*Phaseolus aureus* R.) cv. Dhauli to 655–5240 $\mu g\,m^{-3}$ of SO_2 for 6–48 h. Chlorophyll content in rice and mung bean decreased by 20 and 40% at 655 and 1310 $\mu g\,m^{-3}$ of SO_2, respectively. The decrease was directly related to the exposure period. Exposure to 5240 $\mu g\,m^{-3}$ of SO_2 level resulted in almost complete destruction of chlorophyll. It was summarized that a decrease in chlorophyll leads to a decrease in growth parameters including biomass, productivity, and yield. The gas exchange response of 2-year-old seedlings of oak (*Quercus pubescens* Wild.) and Turkey oak (*Q. cerris* L.) on exposure to 73, 160, and 244 $\mu g\,m^{-3}$ of SO_2 for 23 weeks in fumigation chambers was evaluated by Lorenzini *et al.* [67]. After 11 weeks of exposure, a significant decrease in photosynthetic activity, stomatal conductance, transpiration rate, and water use efficiency was noticed. In addition, the vapor pressure deficit increased with increasing SO_2 concentration, but the internal/ambient CO_2 ratio was not affected. For *Q. cerris* there was a significant linear decrease in photosynthetic activity, vapor pressure deficit, and water use efficiency, but stomatal conductance and transpiration rates remained unaltered. The internal/ambient CO_2 ratio increased by 15% at 244 $\mu g\,m^{-3}$ of SO_2. Ranieri *et al.* [68] investigated long-term exposure of barley cv. Panda and Express to 210 $\mu g\,m^{-3}$ of SO_2, in a greenhouse, to establish whether negative impacts of SO_2 could be linked to specific changes in the photosynthetic apparatus. Exposure for 75 days did not result in any visible injury to either cultivar, while photosynthetic activity decreased by 29 and 49% in cultivars Panda and Express, respectively. Stomatal conductance reduced by 56% (Panda) and 58% (Express), and the whole electron transport chain activity was reduced by 27 (Panda) and 29% (Express). There was 7 and 11% and 18 and 24% reduction in electron transport activities of photosystem I and II in cv. Panda and Express, respectively. Chlorophyll a decreased by 44 (cv. Panda) and 10% (cv. Express), while the corresponding decrease in carotenoids was 46 and 10%. Pigment–protein complexes from thylakoid membranes did not show any qualitative or quantitative differences between control and SO_2-exposed plants. The effect of SO_2 treatments (1.3 and 0.6 ppm) on photosynthesis of *Augea capensis* Thumb, a succulent exhibiting C3 mode of photosynthesis, was investigated on the basis of CO_2 assimilation and chlorophyll a florescence measurements. The study revealed that the inhibitory effects on photosynthesis were induced only when SO_2 fumigation occurred in the dark. An inhibition of 38 and 62% in carboxylation efficiencies and CO_2 saturated rates, respectively, in photosynthesis was observed. However, these effects occurred only at the highest concentration and were fully reversible, indicating no permanent metabolic damage. Only minor effects on photosystem II were observed, indicating that photochemical reactions were not the primary site of inhibition. Cellular capacity for SO_2 detoxification differs during day and night [69].

6.3.4
Stomatal Conductance and Transpiration

Any alteration in the gaseous composition of the atmosphere affects terrestrial plants. In most cases, stomata are affected worst by the environmental pollution. Evolution has provided highly complex mechanisms by which stomata respond to a wide range

of environmental factors to balance the conflicting priorities of carbon gain for photosynthesis and water conservation. These mechanisms involve direct responses of the guard cells to the aspects of the aerial environment and hormonal communication within the plant enabling conductance to be adjusted according to soil moisture status. Various aspects of these delicately balanced mechanisms can be disturbed by air pollutants. Stomata are the main avenues for the diffusion of gases and water vapor in plants. Any factor that influences stomatal conductance is likely to affect plant–water relations as well as diffusion of carbon dioxide and oxygen. Sulfur dioxide exerts a marked influence on the stomatal conductance [70]. Sulfur dioxide-induced stomatal opening has great physiological and ecological implications. It seems certain that maximum damage to plants by SO_2 occurs when the stomata are open. Prolonged opening of stomata results in excessive loss of water through transpiration. Consequently, the water requirement of plants in the polluted areas will be relatively greater. Any condition that promotes stomatal opening will enhance sulfur dioxide diffusion and damage, whereas any factor that can nullify SO_2-induced stomatal opening may provide protection against the gas injury. High humidity and fog increase the sensitivity of plants to the gas and promote the formation of acidic mist. Under such conditions, stomata remain open for longer periods, permitting greater diffusion of sulfur dioxide and other air pollutants into the leaf [4]. Khan and Khan [1] reported that exposure to SO_2 decreased the number and size of stomata but increased the number and length of trichomes on both leaf surfaces. Stomatal aperture was significantly wider in plants exposed to 286 or 571 $\mu g\, m^{-3}$ of SO_2. Stomatal aperture was directly related to foliar injury and reductions in growth, yield, and leaf pigments. Number and size of stomata in the leaves of eggplants grown at sites 1 and 2 km away from the SO_2 source (thermal power plant) were decreased, but their apertures were wider. Number and length of trichomes were greater at the polluted sites, being more on upper leaf surface [71].

Han [72] investigated the relationship between stomatal infiltration and SO_2 injury and the protective effect of abscisic acid (ABA). The study revealed that the effect on infiltration of the same species under different SO_2 concentration was little less than one grade, while K^+ efflux increased with the increase in SO_2 amount absorbed by the leaves. Higher ABA solution concentration and the K^+ efflux were lower when the leaves were sprayed with ABA solution. When leaves sprayed with ABA solution were smoked with 2.5 $mol\, l^{-1}$ for 4 h, the infiltration of leaves with 30 $mol\, l^{-1}$ ABA solution dropped by 1.5–3.0 and K^+ concentration on leaves decreased by 36.5%–54.8%. It indicates that the ABA solution on leaves has a remarkable effect of protection of SO_2 injury. Dhir *et al.* [73] investigated the stomatal responses of *Cichorium intybus* leaves to sulfur dioxide treatment at different stages of plant development in 50 day-old *C. intybus* L. plants exposed to 1 ppm sulfur dioxide gas 2 h per day for 7 consecutive days that resulted in a greater length and width of stomatal apertures on lower and upper epidermis. Stomata were longer on the adaxial epidermis, but shorter on the abaxial epidermis, except at the preflowering stage; moreover, stomatal widths varied widely. Compared to the controls, the abaxial epidermis on treated leaves showed consistently lower stomatal densities and stomatal indices. This was also true for the adaxial epidermis during the postflower-

ing stage. The stomatal conductance was reduced in the SO_2-exposed plants, but intercellular CO_2 concentrations increased at the preflowering stage and, subsequently, declined. According to Rao and Dubey [74] stomatal conductance decreased by 26–28% in *Zizyphus mauritiana* Lam., *Syzygium cuminii* L., *A. indica* A. Juss, and *M. indica* L. at the sites contaminated with of 90 $\mu g\,m^{-3}$ of SO_2 in comparison to the control site. Wali *et al.* [75] found that stomatal conductance and intercellular CO_2 concentration in *C. officinalis* L. decreased with 0.5 ppm SO_2 treatment, the reverse being the case with higher concentration, that is, 1.0 and 2.0 ppm.

6.3.5 Leaf Pigments

The adverse effects of sulfur dioxide on photosynthesis are partly due to its action on photosynthetic pigments. Sulfur dioxide can react with chlorophyll molecules in three distinct ways: bleaching (i.e., loss of color), phaeophytinization (i.e., degradation of chlorophyll molecules to photosynthetically inactive pigment phaeophytin), and the process responsible for a blueshift in the pigment spectrum as observed in lichens [76]. Prasad and Rao [77] studied the relative sensitivity of soybean (*Glycine max* (L.) Merr.) and wheat (*Triticum aestivum* L.) to SO_2 and found that the amount of total chlorophyll in SO_2-treated wheat plants increased at low SO_2 doses, but this was not the case with soybean plants. However, at 120 and 160 ppm h^{-1} of SO_2, total chlorophyll content reduced by 19% in soybean and 17% in wheat. The loss of chlorophyll a was relatively greater than that of chlorophyll b in both the species following exposure. Chlorophyll a and b in treated soybean plants were reduced, respectively, by 21 and 12% at the cumulative dose of 120 ppm h^{-1} of SO_2 and in wheat by 19 and 14% at 160 ppm h^{-1} of SO_2. The maximum reductions in the amounts of carotenoids, that is, 12 and 7% were recorded in soybean and wheat plants at the cumulative doses of 120 and 160 ppm h^{-1} of SO_2, respectively. Dhir *et al.* [73] reported that photosynthesis rate was reduced in the SO_2-exposed plants, but intercellular CO_2 concentrations increased at the preflowering stage and declined subsequently. Chlorophyll a, carotenoid, and total chlorophyll contents increased at the preflowering stage and then decreased. The level of chlorophyll b was reduced throughout plant development compared to the untreated controls. Prakash *et al.* [78] investigated the effect of three different concentrations of sulfur dioxide (320, 667, and 1334 $\mu g\,m^{-3}$) exposure on the chlorophyll contents in *Raphanus sativus* L. and *Brassica rapa* L. and found that both the chlorophyll a and b content decreased with increasing concentration, maximum decrease being at the highest concentration, that is, 1334 $\mu g\,m^{-3}$ of SO_2. However, chlorophyll a showed more reduction than chlorophyll b. Wang *et al.* [79] reported the effects of artificial acid rain and SO_2 on characteristics of delayed light emission (DLE) by using a home-made weak luminescence detection system with the lamina of zijinghua (*Bauhinia variegata*) and soybean (*G. max*) as testing models. The results showed that the changes in DLE intensity of green plants reflect the changes in chloroplast intactness and function. It has been concluded that DLE may provide an alternative means for evaluating environmental acid stress on plants. Seedlings of maize cv. CO-1 when exposed to

SO_2 at LD_{50} underwent a significant decline in total chlorophyll, chlorophyll a and b contents, and carotenoids [80]. Wali *et al*. [75] evaluated the anatomical and functional responses of *C. officinalis* to 0.5, 1.0, and 2.0 ppm SO_2 and found that the high SO_2 doses caused significant decline in the photosynthetic pigments at each stage of plant development, although 0.5 ppm concentration had a stimulatory effect on leaf pigmentation.

6.3.6 Growth and Yield

The physiological and/or biochemical disorders induced by SO_2 are finally manifested as the structural and quantitative alterations in plants. Since plants show varied response to SO_2 under varied exposure conditions, the effects under ambient and simulated conditions are different and being presented separately.

6.3.6.1 Ambient Condition

Since the first observation of a plant disease incited by an air pollutant under ambient conditions [81], many such studies have come up, but a general concern among scientists toward suppressive effects of pollutants on plant growth emerged in the 1940s. The smog injury on plant foliage in Los Angeles provided an impetus to research on phytotoxic effects of pollutants [82]. The forest decline, in fact, drew the attention of environmentalists and researchers on the response of forest trees to sulfur dioxide. Haywood [83, 84] reported severe damage to different pine and oak species from smoke (primarily SO_2) of a copper smelter in California. Sulfur dioxide from a copper smelter in British Columbia also caused severe damage to ponderosa pine (*P. ponderosa* Douglas), lodgeople pine (*P. contorta* Douglas), Douglas fir (*Pseudotsuga menziesii* Carriere), western larch (*Larix occidentalis* Nutt), and so on up to 52 mile southward [85]. Ponderosa pine and Douglas fir grown over 5200 acres in Montana, USA, has shown a gradual decline. Needle necrosis and premature senescence are the most peculiar symptoms of sulfur dioxide damage [86]. Sulfur dioxide from copper smelters [87], nickel smelters [88], iron sintering plants [89], and coal-fired thermal power plants [90, 91] has significantly contributed to the decline of forest trees in the United States and Europe.

SO_2 in the coal smoke may cause chlorosis and browning of leaves, suppress plant vigor, inhibit fruit setting, and decrease the yield as observed in trees such as *Dalbergia* and *Psidium* [92, 93], weeds such as *Commelina benghalensis*, *Croton bonplandianum*, and *Euphorbia hirta* [94–96], grasses such as *Cynodon dactylon*, *C. dactylis glomerata*, and *Lolium perenne* [97, 98], cereals such as wheat and barley [99, 100], and vegetables such as tomato, okra, eggplant, and cucurbits [22, 23, 96, 101, 102]. Garcia *et al*. [103] studied the response of two populations of holm oak (*Q. rotundifolia* Lam.) to SO_2. One-month-old potted plants were grown for 130 days in an atmosphere enriched with SO_2 (0.23 ppm, 14 h per day) in a growth chamber. Both northern and southern plants underwent a significant decrease in growth rate. The southern population was more sensitive to the treatment, as reflected in the bigger decrease in both growth and photosynthesis rates. The author concluded that the

differences in resistance appear to be related to the biogeographic origin of the populations underlining the importance of biogeographic aspects in studies of resistance to air pollutants. Abdul-Wahab and Yaghi [60] made an assessment of the impacts of long-term SO_2 emissions from an oil refinery on three different plant species, namely, *P. cineraria*, *A. indica*, and *P. dactilifera* using sulfate contents of the plants as bioindicators for monitoring SO_2 concentration. The results showed that the three plant species responded differently to SO_2 in terms of sulfate contents. All three species were found to be sensitive to SO_2 exposure and the concentration of sulfate was found to be much higher in plants closer to the refinery.

6.3.6.2 **Simulated Condition**

There are numerous experiments/studies that have been conducted in simulated conditions for the evaluation of the effect of SO_2 on plant growth and yield. Coleman *et al.* [104] presented results on the variability of biomass production for wild radish (*R. sativus* x *raphanistrum*) and cultivated radish (*R. sativus*) cv. Cherry Belle exposed to 262, 629, or 1048 $\mu g\,m^{-3}$ of SO_2 in fumigation chambers with 10 h light period for 24, 30, or 35 days. Variability in biomass production increased with increase in SO_2 exposure period on radish. It has been concluded that genetic differences between the individual plants (differential sensitivity to SO_2) might be the reason for the increased variability as the SO_2 concentration increased. Weigel *et al.* [105] investigated growth and yield responses of different crop species to long-term fumigation with SO_2 in open-top chambers. Potted plants of commercial cultivars of rape (*B. napus* L., cv. callypso), summer barley (*H. vulgare* L., cv. Arena and Hockey), and bush beans (*P. vulgaris*, cv. Rintintin and Rosisty) were continuously exposed in open-top chambers to SO_2 for the whole growing season. Treatments consisting of charcoal-filtered air (CF) and CF supplemented with four levels of SO_2 resulted in mean exposure concentrations of approximately 8, 50, 90, 140, and 190 $\mu g\,m^{-3}$. With the exception of the 1000 seeds weight, which was slightly reduced, dry matter production and yield parameters of rape remained unaffected by all SO_2 concentrations or were even stimulated. Compared to CF, vegetative growth of both bean cultivars was reduced by 10–26% at all SO_2 levels, with significant effects only for cv. Rintintin, however. While all SO_2 additions reduced significantly the yield (dry weight of pods) of the bean cv. Rosisty by 17–32%. The cv. Rintintin showed a significant reduction up to 42% only at the two highest pollutant concentrations. Dry matter production of the barley cultivars was mainly impaired at SO_2 concentrations $>100\,\mu g\,m^{-3}$ with a reduction of 30–52%. While nearly all yield parameters of cv. Hockey reacted similar to the dry matter production, the yield of cv. Arena was reduced already at the low SO_2 levels. At a treatment concentration of 90 $\mu g\,m^{-3}$ of SO_2, a significant yield loss of 30% was recorded. A reduction of the 1000 grains weight mainly contributed to these yield losses observed for both barley cultivars. It has been concluded that SO_2 concentrations within the range of 50–90 $\mu g\,m^{-3}$ are potentially phytotoxic to some crop species.

Murray and Wilson [106] conducted an open-top chamber experiment to examine the effect of sulfur dioxide exposure on sulfur accumulation and alteration of growth and yield of barley (*H. vulgare* L.) cv. Schooner. Exposure to 110 $\mu g\,m^{-3}$ of SO_2 for 4 h

per day for 79 days increased the shoot length and weight by 10%. This increase in growth was attributed to the fertilizer effect of SO_2. SO_2 at 317 $\mu g\, m^{-3}$ or higher significantly decreased the height, weight, number of tillers, and yield in barley. These increases were proportional to the concentration of the SO_2 exposure. In addition, the shoot sulfur content increased linearly from 0.14% (control plants) to 0.77% at 1354 $\mu g\, m^{-3}$ of SO_2. Effects of long-term SO_2 (132 and 274 $\mu g\, m^{-3}$ for 8 h per day for 17 weeks) exposure on growth and development of *Eucalyptus rudis* Endl. plants in open-top chambers was studied by Clarke and Murray [58]. Plants exposed to 132 $\mu g\, m^{-3}$ of SO_2 for 17 weeks increased the height, leaf area, and dry weight of leaves because of an increase in size of leaves, but total number of leaves remained unaltered. Sulfur dioxide levels of 274 $\mu g\, m^{-3}$ did not affect plant height, leaf area, and dry weight of leaves, but increased the rate of leaf abscission. Kropff [107] performed field experiments with an open-air fumigation system to interpret and explain the observed yield loss in broad bean (*Vicia faba* L.) by quantifying the contribution of different physiological processes. Fumigation with 74 $\mu g\, m^{-3}$ of SO_2 throughout the growing season resulted in 9 and 10% decrease in dry matter and pod yield, respectively. These losses were accompanied by visible injury (brown/red spots), which progressed from the oldest leaves upward and also resulted in some leaf abscission. When exposed to 165 μg of SO_2, dry matter and yield were reduced by 17 and 23%, respectively. The dry matter production was primarily decreased due to loss of green leaf area in SO_2 exposed plants. In an open-top chamber study, barrel medic (*Medicago truncatula* Gaerm.) cv. Paraggio was exposed to 107–1349 $\mu g\, m^{-3}$ of SO_2 for 4 h per day, 7 days per week for 72 days [108]. Less than 10% reduction in the plant growth was recorded at concentrations upto 314 μg SO_2; however, at 668 $\mu g\, m^{-3}$ of SO_2, there was 40–50% reduction in growth accompanied by 85% increase in the S concentration. There was significant reduction in flowering with the increase in SO_2 concentration, and at 1349 $\mu g\, m^{-3}$ of SO_2, there was little or no plant growth. Potato (*Solanum tuberosum* L.) was exposed to 288 or 786 $\mu g\, m^{-3}$ of SO_2, for 105 days in closed top field chambers for 4 h per day under well-watered or water-stressed conditions to study the interactive effects of soil water stress and SO_2 [109]. Visible symptoms appeared after 9 weeks of exposure to 288 $\mu g\, m^{-3}$ of SO_2 and after 6 weeks of exposure to 786 $\mu g\, m^{-3}$ of SO_2. At harvest, the leaf S content of well-watered plants had increased by more than 100 and 125% in the 288 and 786 $\mu g\, m^{-3}$ SO_2 treatments, respectively. When water stressed, the lower SO_2 treatment had little effect on S content, whereas the 786 $\mu g\, m^{-3}$ SO_2 treatments resulted in a 100% increase in leaf sulfur. Leaf chlorophyll of 35 day-old leaves from well-watered plants decreased significantly, by approximately 30% at 288 $\mu g\, m^{-3}$ of SO_2 and by 40% at 786 $\mu g\, m^{-3}$ of SO_2. In contrast, water stress resulted in a maximum chlorophyll loss of 11% at 786 $\mu g\, m^{-3}$ SO_2. Exposure of well-watered potato plants to 786 $\mu g\, m^{-3}$ of SO_2 resulted in a significant decrease in dry weight of leaves (25%) and tuber (35%) compared to control. In contrast, dry weight reductions in water-stressed plants did not occur on exposure to SO_2. This might be due to increased stomatal resistance in response to mild water stress that limits SO_2 uptake.

Colls *et al*. [110] used an open-air fumigation system to expose winter barley (*H. vulgare* L.) cv. Igri to a single dose (defined as concentration × time) of SO_2 to

determine if concentration peaks or long-term averages had the greatest effects on the plants. The treatments were based upon achieving an equivalent dose of 534 μg m^{-3} of SO_2 for 6 days. The treatments included continuous exposure to 89 μg m^{-3} of SO_2 for 6 days, 178 μg m^{-3} of SO_2 for 3 days, followed by ambient air for 3 days, or 534 μg m^{-3} of SO_2 for 1 day followed by 5 days of exposure to ambient air. This 6-day cycle was repeated 24 times during the growing season. There were no effects on shoot dry weight accumulation or on grain yield in any treatment. This was attributed to plants' ability to metabolize excess sulfate during the SO_2-free days. Julkunen-Tiitto *et al.* [111] studied the effects of SO_2 exposure on growth and on phenol and sugar production in six clones of willow (*Salix mysrsinifolia* Salisb). A disruption in secondary metabolism could alter plant response to herbivores and microorganisms. Clones were exposed to 300 μg m^{-3} of SO_2 for 7 h per day, 5 days per week, for 3 weeks in fumigation chambers. Salicin and chlorogenic acid content decreased by 15 to >70% depending on clone, while there was no significant effect on salicortin, 2′-*O*-acetylsalicortin, (+)-catechin, and two unknown phenolics. Since SO_2 exposure did not affect salicortin and 2′-*O*-acetylsalicortin (key molecules in the defense chemistry), it was concluded that willow resistance to herbivory and microorganism attack was not reduced. Glucose, fructose, and sucrose contents were not significantly affected. Willow exposed to 300 μg m^{-3} of SO_2 produced 14–48% greater biomass (leaf, stem, and root dry weights) compared to control plants. Exposure to SO_2 at 0.1 and 0.2 ppm in *M. javanica* individually caused significant reduction in plant growth of pea; moreover, this reduction was much greater in joint treatment [112].

Greenhouse studies were conducted by Ashenden *et al.* [113] to examine the effect of SO_2 on growth of 41 British herbaceous species to determine whether the species differed in their sensitivity to SO_2. Plants were exposed to a constant background concentration of 262 μg m^{-3} of SO_2 with peaks applied during daylight. During the first 4 weeks, peak SO_2 concentration used was 524 μg m^{-3} for 2 h, twice a week. For the next 3 weeks, 786 μg m^{-3} was applied for 3 h, thrice a week. Finally, for the last 3 weeks, peaks of 786 μg m^{-3} were applied for 3 h, five times a week to maximize any growth differences between the tested species. There was 43% reduction in total dry matter content of different plants. The mean response of all 41 species was a 25% decrease in total dry mass. Of the seven statistically significant responses of total leaf area, there was an average decrease of 40%. The mean response for all 41 species was a decrease of 10% in total leaf area. Leaf area ratio increased by 45% in 20 plants, and an average increase of 23% was recorded for all 41 species. In 13 species, an average decreases of 36% in the root:shoot ratio occurred due to SO_2 exposure, whereas for all species the decrease was 14%. This study reveals that while there were differences in growth response of the species tested and the same responses may not be observed under field conditions because SO_2 concentrations in the field are not expected to be as high as those used in this study. Plants growing in natural communities may also respond differently from plants grown in individual containers. Moreover, the nutrient supply in this study was nonlimiting, while in the field nutrients may be limiting and may alter responses to SO_2. Agrawal and Verma [10] determined whether varying the levels of nitrogen (N), potassium (K), and phosphorous (P) in the growth medium could affect the response of wheat (*T. aestivum* L.) cv. Malviya 206 and Malviya

234 to SO_2. Thirty-day-old plants were exposed to $390 + 20\,\mu g\,m^{-3}$ of SO_2 for 4 h per day, 5 days a week, for 8 weeks in open-top chambers. Visible injury symptoms appeared earlier and were the greatest in both cultivars grown with no additional nutrients. Unfertilized plants exposed to SO_2 had the greatest dry weight, height, and yield reductions, while plants grown with recommended or two times the recommended levels of NPK were able to alleviate SO_2 effects to the greatest extent. Leaf area and total chlorophyll content decreased significantly when plants were exposed to SO_2. Ascorbic acid was significantly reduced in treated plants as it was utilized in removal of free radicals generated by SO_2 in foliar tissue. Sulfur dioxide treatment also resulted in an increase in sugars and a decrease in starch. Sulfate-sulfur increased in treated plants and the greatest increase was in plants grown with no additional nutrients. An increase in the root:shoot ratio was also observed in SO_2-treated plants suggesting a modification in the carbon allocation pattern when plants were exposed to SO_2. It was concluded that both nutrient deficiency and SO_2 reduced the considered parameters, but addition of NPK in different combinations ameliorated the adverse effects of SO_2. Dhir *et al.* [73] observed that when 50 day-old *C. intybus* L. plants were exposed to 1 ppm sulfur dioxide gas, 2 h per day for 7 consecutive days, the number, dimensions, area, and biomass of leaves were less in the treated plants. Growth dynamics of wheat, *T. aestivum* L., cv. Aurelio, Mec Manital, and Chiaram, was investigated in relation to SO_2 exposures by Lorenzini *et al.* [99]. All the cultivars responded differently to long-term exposure to SO_2. The cv. Mec showed significant reductions in several of the growth and yield parameters, while the other cultivars were only marginally affected. Fumigation with SO_2 reduced the yield of cv. Mec by 33%. Two-week-old wheat cv. Banks seedlings exposed to 0.004, 0.042, 0.121, 0.256, or $0.517\,\mu l\,l^{-1}$ of SO_2 for 4 h per day for 79 days resulted in a significant reduction in plant height, shoot weight, development stage, number of tillers, ear weight per plant, average ear weight, and total number of ears at and above $0.042\,\mu l\,l^{-1}$ [48]. SO_2 at LD_{50} could not affect growth of maize (*Z. mays*) cv. Co-1 though the shoot length decreased [80]. Tiwari *et al.* [114] studied the seasonal variations and effects of ambient air pollutants on the root, shoot length, number of leaves per plant, leaf area, and root and shoot biomass of lettuce, *Beta vulgaris* L. cv. Allgreen, at a suburban site situated in dry tropical area of India, experiencing elevated levels of ambient air pollutants. Air monitoring data showed that mean concentrations of SO_2 and NO_2 were higher during winter. Plants grown in nonfiltered chambers showed stunted growth, reductions in biomass and yield, and modification in biomass allocation pattern compared to those grown in charcoal-filtered air. Biomass allocation pattern revealed that during summer photosynthate allocation to roots reduced with consequent increment in leaf weight ratio, which helped in sustaining nutritional quality of the lettuce even after more yield reductions in NFCs compared to FCs.

6.3.7
Pollen and Fertilization

Pollution also influences reproductive processes in terms of smaller pollen sizes, reduced germination rates, and shorter pollen tubes. Reduced seed size, seed

germination capacity, and a lower share of flowering trees in polluted areas have been reported [115, 116]. Effects of wet and dry exposure, both *in vivo* (on the anthers) and *in vitro* (culture dishes) on germination of pollen from oilseed rape (*B. napus* L.) cv. Tapidor and Libravo was investigated by Bosac *et al.* [117]. For *in vivo* treatments, inflorescences were exposed in special chambers (excluding the rest of the plant) to 524 $\mu g\,m^{-3}$ of SO_2 for 6 h. *In vitro* exposures (wet or dry) lasted for 3 h. Exposure to 524 $\mu g\,m^{-3}$ of SO_2 had no effect on germination or pollen tube length, *in vivo* or *in vitro* (dry); however, there was a significant reduction in germination when pollens were exposed to SO_2 while in unbuffered medium droplets. Pollen tube length was also greatly reduced under these conditions, but too few pollen grains germinated and grew to calculate reliable mean values. It was concluded that the reduction in germination in the unbuffered medium was due to acidification of the medium (pH dropped form 6.5 to 5.5) during SO_2 exposure. Sulfur dioxide is highly soluble in water; therefore, it would get dissolved and acidify the medium during exposures. Agrawal *et al.* [118] utilized a nightshade (*S. nigrum*) complex, which exhibits three natural cytotypes (diploid *S. americanum*, tetraploid *S. villosum*, and hexaploid *S. nigrum*) to determine the effects of SO_2 on pollen chromosomes. Flowering plants were exposed to 524 $\mu g\,m^{-3}$ of SO_2 for 2 h pre day for 3, 7, or 11 days. When pollen mother cells (PMCs) were examined, it was found that meiotic chromosomal abnormalities were highest in diploid plants (19.67–26.0%) and least in hexaploid plants (4.45–7.0%). In addition, abnormalities increased with length of exposure for all plants. Pollen sterility followed the same pattern as chromosomal abnormalities, 19.5–21.6% in diploid, 13–15% in tetraploid, and 10–13% in hexaploid, with sterility increasing with length of exposure. The authors concluded that the observed abnormalities might have resulted either from free radical splitting of phosphodiester linkages of DNA or from bisulfite combining with cytosine or uracil that may result in alteration of DNA or RNA functions.

6.3.8
Proteins and Antioxidant Enzymes

Several studies have been conducted to assess the effects of SO_2 on plant proteins and antioxidant enzymes and to explain the role of antioxidant enzymes in SO_2 tolerance and its possible mechanism(s). The role of superoxide dismutase (SOD) in defense against SO_2 toxicity was investigated using leaves of poplar and spinach by Tanaka *et al.* [119]. Young poplar leaves with five times the SOD of the old leaves were more resistant to the toxicity of SO_2. The SOD activity in poplar leaves was increased by fumigation with 0.1 ppm SO_2, and this was more evident in young leaves than in the old ones. The poplar leaves having high SOD activity due to 0.1 ppm SO_2 fumigation were more resistant to 2.0 ppm SO_2 than the control leaves. The finding suggested that SO_2 toxicity is in part due to the superoxide radical and that SOD participates in the defense mechanism against SO_2 toxicity. Elemental sulfur and many sulfur-containing compounds such as cysteine-rich antifungal proteins, glucosinolate (GSL) and phytoalexins, play important role in plant disease resistance. Pierre and Queiroz [120] investigated the enzymatic and metabolic changes in bean (*P. vulgaris* L.) leaves on

continuous exposure to subnecrotic levels of SO_2. The study revealed a rapid increase in enzyme capacity at 0.1 ppm or 3 $\mu g\, m^{-3}$ of SO_2. Peroxidases are the key enzymes of the metabolic pathways. The composition of organic acids, amino acids, and polyamines was altered with change in enzymes. The effect of low levels of SO_2 (3, 5, and 10 ppm) on peroxidase was evaluated on the foliage of *B. nigra* L., *P. radiatus* L. (SO_2 sensitive), and *Z. mays* L. (SO_2 resistant) [121]. SO_2 enhanced the peroxidase activity in all species, but least increase was observed in *Z. mays*. Six weeks fumigation with 3, 5, and 10 ppm SO_2 increased peroxidase activity by 32, 40, and 45% in *B. nigra*; by 25, 30, and 43% in *P. radiatus*; and by 4, 8, and 13% in *Z. mays*, respectively. Peroxidase activity was found to increase as a function of concentration and duration of SO_2 exposure. SO_2 fumigation increased the intensity and thickness of individual isoenzyme bands without affecting the overall isoenzyme pattern except in *P. radiatus*, where a 6-week exposure altered the isoenzyme pattern. The sulfite turnover rate was faster in *Z. mays* compared to *B. nigra* and *P. radiatus*. It was postulated that the high peroxidase activity and high sulfite turnover rate possessed by *Z. mays* provides a relatively high resistance against SO_2 toxicity.

The amount of glutathione (GSH), an important element in both plant and insect antioxidant systems, is known to increase after exposure to stresses. The effect of SO_2 on GSH concentration in soybean was investigated [122]. GSH levels were found to vary with SO_2 concentration in the same manner as did the insect response. Chauhan [123] performed a study on the early diagnosis of SO_2 stress and the mechanism of SO_2 damage in crop plants by measuring volatile emissions from treated tissues. Emissions from tomato (*Lycopersicon esculentum* Mill.), mung bean (*Vigna radiata* L.), and maize (*Z. mays* L.) were measured after exposure to 262 $\mu g\, m^{-3}$ of SO_2 for 2 h per day or 524 $\mu g\, m^{-3}$ of SO_2 for 1 h per day. Tomato and maize were exposed for 60 days and mung bean was exposed for 45 days. Ethylene, ethane, acetaldehyde, and ethanol contents were measured at 15 day intervals. Ethylene emissions substantially increased in all the three species, until visible injury symptoms (chlorosis followed by necrosis) appeared, after which ethylene concentration declined. Ethane emissions were detected just prior to the appearance of visible injury symptoms and increased with increase in injury levels. It was suggested that ethane production was a result of lipid peroxidation caused by sulfate oxidation. To verify this, an additional experiment with mung bean was performed to establish the relationship between antioxidants and SO_2 damage. Addition of antioxidants substantially reduced ethylene and ethane production supporting the idea that lipid peroxidation was caused by free radicals resulting from sulfite oxidation. Acetaldehyde and ethanol emissions increased as exposure duration increased up to 45 days, but emissions declined after the appearance of visible injury symptoms. As acetaldehyde and ethanol are not normal by-products of aerobic metabolism, it was concluded that their production was a result of SO_2-induced alteration of respiratory metabolism. The rates of emissions of ethane, acetaldehyde, and ethanol were related to the degree of SO_2 resistance displayed by the species in the study; the greater the resistance, the greater the rate of emissions.

Antioxidant production and its role in protecting four tropical tree species, *Z. mauritiana*; *S. cumini*, *A. indica*, and *M. indica* from air pollution was studied

by Rao and Dubey [74]. Four exposure sites were selected downwind from an industrial source with an average SO_2 concentration of 48–90 $\mu g\,m^{-3}$, while the site 10 km away in upwind direction served as control. Samples were collected once a month for 12 months. SO_2 was the primary pollutant in the area affecting plant response alone and in combination with other pollutants. Sulfate accumulation in the leaves corresponded to the ambient SO_2 level. When exposed to 90 $\mu g\,m^{-3}$ SO_2, the sulfate content of leaves increased by 72, 69, 65, and 92% for *Z. mauritiana*, *S. cumini*, *A. indica*, and *M. indica*, respectively, in comparison to the control site. Increase in sulfate content of four species ranged from 26–48% at the site with an ambient level of SO_2 (48 $\mu g\,m^{-3}$). Stomatal conductance decreased by 26–28% in the four species at the site with the highest SO_2 level in comparison to the control site. Oxidation of proteins, superoxide dismutase activities, and peroxidase activities increased in all four species. The magnitude of the response varied with species and was related to the ambient SO_2 concentration. It was concluded that increased peroxidase and superoxide dismutase activities could increase SO_2 tolerance under field conditions. *Z. mays* was grown for 2 weeks in a fumigation chamber and exposed to 45, 70, and 110 $\mu l\,l^{-1}$ of SO_2. No visible symptoms on plants exposed to charcoal-filtered air were recorded, but differences occurred between the control and the fumigated plants. The amount of cysteine and free amino acids in leaf increased, while that of soluble proteins decreased. Qualitative and quantitative differences found in the soluble protein patterns suggested that low concentrations of SO_2 affect the protein metabolism [124]. Gupta *et al.* [125] studied the effects of SO_2 exposure on ABA production in soybean (*G. max* L.) cv. Elf at the end of the exposure period and after a recovery period of 18 h. Exposure of 30 day-old soybean seedlings to 131, 524, or 1048 $\mu g\,m^{-3}$ of SO_2 for 1, 2, or 4 h resulted in no visible injury at a 131 $\mu g\,m^{-3}$ of SO_2. Although, a mild chlorosis occurred on top leaves after the 18 h recovery period in the 524 $\mu g\,m^{-3}$ SO_2-treated plants. Leaf curl and necrotic areas were visible in plants exposed to 1048 $\mu g\,m^{-3}$ of SO_2 within 4 h of treatment. The authors found both the exposure concentration and duration significantly increased ABA content of leaves. At SO_2 concentration of 131 $\mu g\,m^{-3}$, ABA content increased by 28% after 1 h, 87% after 2 h, and 141% after 4 h exposure. The 18 h recovery period resulted in a reduction in ABA levels in all treatments, but ABA levels were still higher than the controls.

Long-term effects of 39, 73, and 100 $\mu g\,m^{-3}$ of SO_2 (seasonal means) on nitrate reductase, nitrite reductase, glutamine synthetase, glutamate dehydrogenase, and glutathione reductase activity and total glutathione content of winter barley (*H. vulgare* L.) cv. Igri were studied in an open-air fumigation system by Borland and Lea [126]. Nitrate reductase activity in tissues harvested in February, March, and April was significantly decreased by 100 $\mu g\,m^{-3}$ of SO_2. Nitrite reductase activity was relatively constant except for significant increases in April (at 100 $\mu g\,m^{-3}$ of SO_2) and May (at 39 $\mu g\,m^{-3}$ of SO_2). There was no effect of any SO_2 concentration on glutamine synthetase or glutathione reductase. Exposure to SO_2 significantly increased glutamate dehydrogenase activity in samples obtained in December, January, and June. Total glutathione varied with the season, but there was no increase in accumulation on SO_2 exposure. The role of antioxidants and enzymes in metabolic

processes of two pea cultivars, Progress (insensitive) and Nugget (sensitive), which are known to differ in their sensitivity to SO_2, was investigated by Madamanchi and Alscher [127]. Plants were exposed in continuously stirred tank reactors to 2095 μg m^{-3} of SO_2 for 210 min. Total glutathione (ratio of exposed/control) content increased from 1.11 (at 0 min) to 2.04 (at 210 min exposure) in the cv. Progress and from 1.42 (at 0 min) to 1.69 (at 210 min exposure) in the cv. Nugget. Reduced GSH increased in the cv. Progress from 1.11 to 1.93 and in Nugget from 1.37 to 1.59 for 0 and 210 min exposure, respectively. No significant effects were found on ascorbic acid or oxidized glutathione content. Superoxide dismutase activity increased by 90% in Progress, but was unaffected in Nugget. Mean glutathione reductase activity increased by 35 and 21% in cv. Progress and Nugget, respectively. The authors suggested that the significantly increased glutathione content, glutathione reductase, and superoxide dismutase activities in cv. Progress might be a part of its metabolic resistance to SO_2 exposure. Impact of SO_2 on SOD and the ascorbate–glutathione cycle was investigated in a tolerant (cv. Punjab-1) and a sensitive cultivar (cv. JS 7244) of soybean (*G. max* (L.) Merr.) [128]. Despite SO_2 stimulation, SOD activities in cv. JS 7244 increased significantly. This differential response was attributed to the ability of cv. Punjab-1 to enhance glutathione reductase (GR) activity and to maintain high GSH/GSSG and ASA/DHA ratios. Postfumigation analysis indicated that cv. Punjab-1 was able to maintain SO_2-enhanced antioxidants, while they declined in cv. JS 7244 the moment fumigation was terminated. Exposure of SO_2-acclimated plants (cv. Punjab-1) with their enhanced antioxidants to 250 μg m^{-3} of SO_2 for 6 h exhibited no enhanced cellular injury (MDA content) compared to control plants with their normal antioxidant levels. The results indicated the existence of a relationship between the plants' ability to maintain the reduced GSH and ascorbate (ASA) levels and the SO_2 tolerance, to tolerate SO_2-induced oxygen-free radical toxicity with elevated antioxidants.

Changes in thylakoid proteins and antioxidants in two wheat cultivars, namely, Mec and Chiarano with different sensitivity to SO_2, were studied [129]. It was found that thylakoid protein composition depends on a differential ability of the cultivars to maintain elevated levels of ascorbic acid rather than on increasing detoxifying enzyme activities. Bernardi *et al.* [130] studied levels of soluble leaf proteins and the response of the SOD complex of bean plants (*P. vulgaris* L.) cv. Groffy after exposure to SO_2 at 79, 157, or 236 μg m^{-3} for 2, 4, or 7 days. No visible injury symptoms were observed in any of the treated plants. Newly synthesized polypeptides were detected in all treatments and there were quantitative differences between the control and the treated plants for six other protein subunits. The observed changes in protein synthesis were linked to a SO_2 resistance. In addition, SO_2 exposure induced the activation of an additional SOD isoform, which when tested exhibited the characteristics of an iron superoxide dismutase (FeSOD). The authors summarized that the increased activity of the FeSOD was the initiation of activation of the antioxidant system in response to radical formation due to SO_2 oxidation. Jeyakumar *et al.* [80] reported that stomatal frequency and stomatal index of maize seedling cv. Co-1 were not affected when exposed to LD_{50} of SO_2. However, the size of the stomata was significantly reduced and there was also reduction in the amount of

starch and sugar in the stressed plants compared to control. Amylase activity and proline contents were increased in response to SO_2 stress. SO_2 is highly damaging to rice, *O. sativa* japonica-type cv. Nipponbare, and triggers multiple events linked to defense/stress response [41]. Sodium dodecyl sulfate polyacrylamide gel electrophoresis and immune blotting analysis revealed induction of ascorbate peroxidase(s) (APX) and changes in cysteine proteinase inhibitors (phytocystatus) like proteins. Two-dimensional electrophoresis (2DE) followed by amino acid sequencing also revealed several changes in the 2DE protein profiles of SO_2 fumigated leaves. Most prominent changes in leaves were the induced accumulation of a pathogenesis-related (PR) class 5 (OsPR5) proteins, three PR 10 class proteins (OsPLr10s), ATP-dependent CLP protease, and an unknown protein. Mass spectrometry analysis revealed production of phytoalexins, sakuranetin, and momilactone A in SO_2-stressed leaves. Hao *et al.* [131] studied the responses of superoxide anion radical O_2 and antioxidant enzymes of wheat to SO_2 exposure by introducing gas at different concentrations into the culture boxes. When the concentration of SO_2 was 10 and 40 $\mu l\,l^{-1}$, the O_2 content and peroxidase (POD) and catalase (CAT) activities of wheat leaves were increased, while the activity of SOD was reduced. At 50 $\mu l\,l^{-1}$ of SO_2, the activities of POD and CAT were reduced. On the uppermost leaves, necrosis appeared and more fungi multiplication was recorded on green leaves. Presoaking of wheat seeds with 1 $mmol\,l^{-1}$ salicylic acid (SA) for 6 h or with 10 $mmol\,l^{-1}$ of H_2O_2 for 12 h alleviated the oxidative stress caused by SO_2, as the O_2 content decreased and the activities of antioxidant enzymes increased. Under SO_2 fumigation, ethylene significantly inhibited the activities of test enzymes and promoted the O_2 production rate. With simultaneous application of SA and ethylene, SA almost completely eliminates the influences of ethylene on O_2 production and enzyme activities.

The facultative halophyte *Mesembryanthemum crystallinum* shifts its mode of carbon assimilation from C3 pathway to crassulan acid metabolism (CAM) in response to factors generating reactive oxygen species (ROS) in cells [132]. Exogenous application of SO_2 to *M. crystallinum* plants was employed to assure the role of ROS production in CAM induction. The finding suggests that oxidative stress caused by SO_2 fumigation was not sufficient enough to induce functional CAM. Further evaluation of the influence of SO_2 fumigation/sulfite incubation on the activity and level of SOD isoenzymes, especially FeSOD, which is one of the first indicators correlated with the X_3/CAM transformation, revealed that the activity of FeSOD and SOD CuZn isoforms increased under SO_2/sulfite stress. The pattern of FeSOD and CuZnSOD is probably due to the action of sulfite per second. Tseng *et al.* [133] explored the possibility of overcoming the highly phytotoxic effect of SO_2 and salt stress, by introducing the maize Cu/Zn SOD and/or CAT genes into chloroplasts of Chinese cabbage (*B. campestris* L. ssp. *Pekinensis* cv. Tropical Pride) (referred to as SOD, CAT and SOD + CAT plants). SOD + CAT plants showed enhanced tolerance to 400 ppb SO_2 and visible damage was one-sixth of that in wild-type (CK) plants. Moreover, when SOD + CAT plants were exposed to a high salt treatment of 200 mM NaCl for 4 weeks, the photosynthetic activity of the plants decreased by only 6%, where as that of CK plants by 72%. SOD plants had higher total APX and GR activities than CK plants. SOD plants showed protection against SO_2 and salt stress that were

moderately improved compared to CK plants. However, in CAT plants there was inhibition of APX activity limiting tolerance to stress. Moreover, SOD + CAT plants accumulated more K^+, Ca^{2+}, and Mg^{2+} and less Na^+ in their leaves compared to those of CK plants. The results suggest that the expression of SOD and CAT simultaneously is suitable for the introduction of increased multiple stress protection. In an attempt to improve the tolerance of plants to the toxicity of reactive oxygen species produced in the presence of SO_2, Tseng *et al.* [134] engineered transgenic Chinese cabbage (*B. campestris* L. ssp. *Pekinensis* cv. Tropical Pride) by infection with individual strains of *Agrobacterium* (LBA44o4), each carrying a distinct disarmed T-DNA containing *Escherichia coli* SOD and/or CAT gene(s). Transgenic lines were examined by polymerase chain reaction, Northern blot hybridization, and enzyme activity determination. The study revealed that the frequency of cotransformation with two T-DNAs was greater than 40%. Enhancement of either SOD or CAT activity individually had only a minor effect on 40 $\mu g\ ml^{-1}$ of SO_2 tolerance. Mostly, cotransformed strains that overexpressed both SOD and CAT had high resistance to SO_2. Further analyses showed that not only the activities of SOD and CAT but also the activities of total antioxidant enzymes, such as ascorbate peroxidase and glutathione reductase (GR), were higher in transgenic plants treated with SO_2 than in treated wild-type plants, indicating that the ability to eliminate ROS in transgenic Chinese cabbage was increased significantly. It has been concluded that the cotransformation systems could serve as a good method for plant improvement.

6.3.9
Genotoxicity

Vascular plants are endowed with a useful genetic system for screening and monitoring environmental pollutants. Mutagenic activity of toxic chemicals has been analyzed with different plant systems such as *Allium cepa*, *V. faba*, *Arabidopsis thaliana*, and *H. vulgare*, where chromosomal aberration assays, mutation assays, and cytogenetic tests were performed [135–140]. Plant bioassays, which are considerably sensitive and simple in contrast with animal bioassays, have been authenticated in the international collaborative studies under the United Nations Environment Program (UNEP), World Health Organization (WHO), and US Environmental Protection Agency (US-EPA) and confirmed to be efficient tests for genotoxicity monitoring of environmental pollutants [141, 142]. Sulfur dioxide, as a ubiquitous gaseous air pollutant, influences both human health and the global ecological systems of animals and plants [143]. Numerous studies have shown that SO_2 or its hydrated forms (bisulfite and sulfite) caused visible foliar injury/damage such as chlorosis and necrosis [143], inhibited seedling growth and cell division [144], impaired photosynthetic process [145], and also influenced the activities of enzymes for scavenging reactive oxygen species in plant cells [143]. However, there is rather inadequate information in relation to genotoxic effect of SO_2 in plants [136, 146, 147].

Yi and Meng [147] investigated the genotoxic effect of SO_2 using *A. stavium* and *V. faba* cytogenetic tests (a highly sensitive and simple plant bioassay), by treating a

mixture of sodium bisulfite and sodium sulfite (1 : 3), at various concentrations from 1×10^{-4} to 2×10^{-3} M. The study revealed that genotoxicity expressed in terms of anaphase aberration (AA) frequencies in the *Vicia*-AA test and in terms of micronuclei (MCN) frequencies in both the tests. On average, a 1.7–3.9-fold increase in AA frequencies and a 3.5–4.5-fold increase in MCN frequencies in *Vicia* root tips was observed compared to the negative control. Similarly, *Allium* root tips also showed a significant increase in MCN frequencies in the treated samples and pycnotic cells (PNCs) appeared in the treated groups as well. The frequencies of MCN, AA, and PNC increased independent of doses and the cell cycle delayed at the same time in bisulfite-treated samples. The authors concluded that the *Vicia* and *Allium* cytogenetic bioassays are efficient, simple, and reproducible in genotoxicity studies of bisulfite. Verge *et al.* [148] conducted two experiments (1981 and 1997) and estimated the genotoxic effects of the atmosphere of the industrial estate South of Toulouse, using tobacco plants (heterozygous for two independent *loci* involved in the chlorophyll parenchyma differentiation), on the basis of cellular rate of reversion, which was counted and calculated from the somatic spots of green cellular colonies on yellow green background. The authors observed a general decrease in genotoxic effects and construed it as due to a general decrease in air pollution evaluated by the development of the concentrations of three toxic gases before and after the implementation of cleanup devices. It has been suggested that this bioindicator is efficient, easy to use, and capable of integrating, *in situ*, genotoxic variations throughout the duration of plant growth and development. Longauera *et al.* [149] studied the effects of air pollution on the genetic structure of Norway spruce, European silver fir, and European beech at four polluted sites in Slovakia, Romania, and Czech Republic, and the genotypes of sampled trees were determined at 21 isozyme gene loci of spruce, 18 loci of fir, and 15 loci of beech. The results revealed that in comparison to Norway spruce, fewer genetic differences were in beech and almost no differentiation between pollution-tolerant and -sensitive trees in fir. In adult stands of Norway spruce, sensitive trees exhibited higher genetic multiplicity and diversity. The authors suggested that the decline of pollution-sensitive trees may result thus in a gradual genetic depletion of pollution-exposed populations of Norway spruce through the loss of less frequent alleles with potential adaptive significance to altered stress regimes in the future. Comparison of the subsets of sensitive and tolerant Norway spruce individuals, as determined by the presence or absence of discolorations ("spruce yellowing"), revealed different heterozygosity at 3 out of 11 polymorphic loci.

6.3.10
Sulfur Deficiency

Sulfur is an essential macronutrient for normal plant growth and development. During the last decades, sulfur availability in soils has become the major limiting factor for plant production in many developed countries due to significant reduction in anthropogenic sulfur dioxide emission forced by introduction of stringent environmental legislations. Ironically, it is a result of the positive phenomenon,

namely, a strong reduction in atmospheric pollution in industrialized areas of developed countries [9]. The main cause is the fall in the amount of coal used in electricity generation. Introduction of new technologies such as flue gas desulfurization and "gas reburn" has also contributed to the fall. Beside coal combustion, the biggest source of sulfur dioxide emissions is the combustion of petroleum. However, this has also fallen considerably due to large reductions in fuel oil use in favor of gas in electricity generation and a general option of gas as the fuel of choice for industries. The already small amount of sulfur dioxide emitted from motor spirit and diesel fuel has also fallen and is believed to fall further due to the introduction of ultralow sulfur petrol and diesel. In a majority of the European countries, including Poland, emission has fallen by more than 60% in the years 1990–2004 [150], whereas in Asia these trends are still reverse compared to Europe and the United States. Decreased atmospheric sulfur deposition on agricultural land due to the reduction in sulfur dioxide emission to the atmosphere and the utilization of sulfur-free (however, rich in nitrogen and phosphorus) fertilizers have led to insufficient sulfur supply to a variety of crops, especially those with high sulfur requirements such as oilseed rape [9].

Inadequate sulfate nutrition leads to reduced plant growth, vigor, and resistance to abiotic and biotic stresses [151–153]. Sulfur deficit influences not only the crop yield but also the food quality. For instance, certain sulfur-rich proteins in wheat determine the baking quality of flour [154, 155] and malting quality of barley [156]. A decreased sulfur content in wheat may increase the level of carcinogenic acrylamide in processed food [157]. Furthermore, a sufficient metabolic supply of sulfur amino acids from diet and tissue protein breakdown is necessary for the normal functioning of animal organs, including the mammalian immune system [158, 159]. Sulfur deficiency that decreases the level of sulfur-containing defense compounds, such as elemental sulfur, H_2S, glutathione, phytochelatins, various secondary metabolites, and sulfur-rich proteins, is clearly associated with a decreased resistance of plants, while sulfur fertilization increases their resistance against biotic and abiotic stresses, and this phenomenon is known as sulfur-induced resistance (SIR) [153, 160]. Conversely, sulfur metabolism is also influenced by both the abiotic stresses (which increases the ROS formation) and the oxidative stress. The biochemistry of sulfur assimilation is well characterized; however, many questions remain unsolved concerning regulation of sulfur metabolism in response to both the availability of sulfur in the environment and the increased demand of plants for sulfur metabolites under certain environmental conditions [9].

Numerous studies have demonstrated and it is now a well-documented fact that plants growing in sulfur-deficient soils can benefit by taking up sulfur from the atmosphere during chronic exposures [27, 161–163]. The ability of plants to accumulate atmospheric sulfur is species specific; for example, cotton is more efficient than tall fescue in accumulating atmospheric sulfur [164]. Moreover, nitrogen supply in the soil also has an influence on the degree of the positive growth response to SO_2. This positive growth response will vary accordingly with the nitrogen supply in the soil; that is, being low under low nitrogen and high under sufficient nitrogen [165]. Undoubtedly from a mechanistic point of view, exposure to SO_2 can

be used for sulfur nutrition and to counteract SO_4^{2-} uptake through the roots and transport to the shoots. This way, the negative effects of SO_2 absorption by the shoot and the resulting acidification and excess sulfur accumulation in the foliage may be reduced [166].

6.4 Conclusions

Among all the gaseous air pollutants, SO_2 was the first to be designated as a phytotoxic air pollutant, with that the most important one, and its effects on plants have been the most extensive and longest studied subject in this field. However, since the past few decades it has attracted less attention because of its declined concentrations in the atmosphere in much of the developed countries due to the stringent environmental legislations introduced. Nonetheless, it presents a potential threat in other developing and underdeveloped countries that are still facing its adverse effects on vegetations and agricultural crops resulting in low crop production.

Numerous studies have been undertaken to evaluate crop responses to SO_2. Since SO_2 is an accumulative pollutant in plant tissue, high concentrations of SO_2 can cause acute injury in the form of foliar necrosis, even after relatively short duration exposure. However, in the field such effects are far less important than chronic injury, which results from long-term exposure to much lower concentrations and is essentially cumulative in nature, resulting in reduced growth and yield and increased senescence, often with no clear visible symptoms or else with some degree of chlorosis. Hitherto, much knowledge has been gained on the mechanism of foliar injury and responses of plants to SO_2 exposures. Present efforts to overcome SO_2 stress comprise detoxification processes in plants and evolution of resistance. A few studies have also addressed the beneficial effects of SO_2 on plant growing in sulfur-deficient soils. That being said, other pollutants that are present in the atmosphere can also influence the effect of SO_2 on plants. Thus, the effects of a specified dose of SO_2 can be modified by prevailing environmental conditions. Conversely, SO_2 can also modify the response of plants to other environmental stresses, both biotic and biotic, often intensifying their adverse impacts.

Dose–response relationships have been investigated for various crop plants. The information used in deriving such relationships have been on controlled fumigations, under quasi-field or defined environmental conditions, from filtration experiments and from field studies such as transects along SO_2 gradients. In many of these studies, SO_2 has been considered the sole factor governing plant growth and productivity. For this reason, field and filtration studies provided data on responses under realistic conditions, but these data are confounded by the presence of other pollutants and variable environmental conditions. Nevertheless, reasonably accurate values for no-response thresholds for adverse effects have been derived for broad categories of plants. Though, in the past few decades this perception has changed to a more holistic approach, which includes the joint effects of multiple air pollutants, plant growth-regulating climatic factors, pathogens, and insect pests. To advance our

knowledge and understanding of this subject, research in the future needs to execute this holistic approach and it requires interdisciplinary cooperation among scientists from multiple areas of specialization.

Excess Soil Phosphorus: Accelerated P Transfer, Water Quality Deterioration, and Sustainable Remediation Strategies

Nilesh C. Sharma and Shivendra V. Sahi

Phosphorus is a limiting nutrient for plant growth. Yet its high accumulation in agricultural soils causes grave environmental concerns affecting human health. The problem is more acute in temperate climate where large farms with intensive animal-based agriculture generate and dump huge amounts of organic litter or manure – a potential source of phosphorus (P). Need for removal of excess P is increasingly felt in recent times giving rise to various remediation strategies: chemical, physical, and biological. Application of chemical amendments, such as lime, ferric chloride, or alum to animal manures or soils enriched with P is one of the methods used commonly in recent times. P immobilization in soil by these amendments may not be stable on a long-term basis. Another strategy to address the excess manure P involves the treatment of animal feed with additives such as phytase and vitamin D that can increase the digestibility of P in diet. Although phytase can decrease total P in litter, it can increase the water-soluble phosphorus in the litter and hence the potential for P losses to surface waters following land application. Likewise, application of biosolids as P fertilizer is also not considered the best management practice from P loss standpoint. Alternatively, phytoremediation, plant-assisted removal of water-soluble P, could be an attractive strategy. Mining of soil P, which includes harvesting P taken up from the soil by a crop grown without external P application, is being examined as one of the crop management strategies for P-impacted soils. It has also been suggested that for the success of P mining, the remedial strategy should include plants that can accumulate P manifold higher (>1% DW) than the P content of common plants. Employing plant species with capabilities like overexpression of root phosphatase and assimilation of organic P from soil P pool could enhance the efficacy of P phytoremediation. Studies suggest that integrating best management practices for all the operations involved in P use, from animal feeding strategies to manure management, to soil and crop management, and to soil P test methods or P loss tools can effectively reduce the environmental risks of diffuse P pollution.

Improving Crop Resistance to Abiotic Stress, First Edition.

7.1
Phosphorus Conundrum

Phosphorus (P) content of soil presents a paradoxical scenario in different regions of the world. While many tropical regions with low-input systems of agriculture are faced with low availability of soluble P, some temperate regions with intensive animal-based agriculture have to deal with excessive P in the soil that is threatening the ecosystem.

7.1.1
P Deficiency

The principal form of P in nature is phosphate in inorganic form or bound in ester bonds into organic compounds. Inorganic P (Pi) forms in tropical, relatively unweathered, environments are associated with Ca or Mg. A typical solubility for natural calcium phosphates at neutral pH is near $3\,\mu g\,l^{-1}$. In more weathered soils, which have lost most of their cations, P is increasingly associated with iron (Fe) and aluminum (Al) oxides that further lower P solubility. Soil solution P concentrations vary from 9–36 $\mu g\,l^{-1}$ over a range of tropical soils [1]. This places them well below the P requirement of productive crops ($200\,\mu g\,l^{-1}$), thus creating augmentation needs for P fertilizers. Oxisols cover large areas in the tropics and subtropics, accounting for 50% of the world's P requirements for crop production. The low-input soils of these geographical regions are characterized by high P adsorption capacity and thus a large proportion of total P is converted to P forms that are not available to plants [2]. More than 1 billion ha of soil in the tropics and subtropics exhibit significant P fixation resulting from an increase in the amount of sesquioxides that occurs during the weathering process in Oxisols and Ultisols. It is estimated that 95% of the acidic soils located in tropical Africa, America, Asia, Australia, and the Pacific islands are deficient in P [3].

7.1.2
P Abundance

In many parts of the United States and Europe, where enormous quantities of nutrient-rich manures (chicken, swine litter, and other animal wastes) are spread over the soils, P in manures often exceeds crop requirements [4, 5]. Over last decades, there has been a dramatic shift in the structure of animal production across the United States. Large livestock operations have replaced small and medium-sized operations and have become more concentrated spatially across the United States. This trend has resulted in a huge supply of animal manure for disposal on a limited amount of land area (Table 7.1). Intensive, long-term application rates of manure to soils in these regions have contributed to frequent reports that the quantity of manure nutrients relative to the assimilative capacity of the land has grown out of balance [6, 7]. For example, in Chesapeake Bay region – an area with concentrated poultry production – over 70% of the soils that have been used for long-term poultry waste

Table 7.1 US annual production of manure, nitrogen, and phosphorus from livestock and poultry.

Species	Dry manure million ton	N % of dry manure	P concentration	N thousand ton/annum	P
Swine	15.5	4.7	2.97	730	460
Poultry	15.4	5.13	1.62	790	250
Beef cattle	96.6	3.96	1.07	3828	1029

application are now considered to have optimal (no P input needed to maximize yield) or excessive P contents [8]. Sims *et al*. [9] reported that in Sussex Co., DE (USA), which alone produces 230 million broilers and 52 000 head of swine per year, approximately 92% of soils in the county were rated as optimum or excessive in P. The link between high-density animal production and high soil test P (STP) has been clearly established by researchers [6, 9]. Figure 7.1 shows the farm-level excess manure P for the United States [10]. The darker areas represent areas where local crop P requirements are exceeded by local manure P production, and there is concern that these manure P excesses can cause rising STP following land application over a period of years.

Fertilizer P use increased dramatically in the decades following World War II in most developed countries, and over the past few decades, animal production has also become more geographically concentrated. Withers *et al*. [12] reported that the

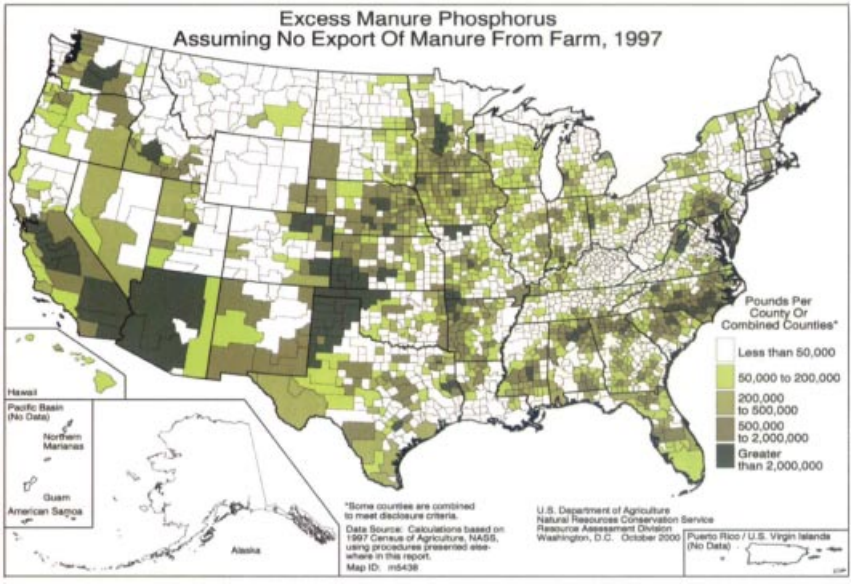

Figure 7.1 Excess manure phosphorus in different counties of US states. Reproduced from Ref. [10], with kind permission from ASA, CSSA, SSSA.

productive grassland and arable areas in the United Kingdom had on average accumulated about 1000 kg P ha^{-1} over the past 65 years. The cumulative mean surplus of German agricultural soils was estimated at 1100 kg ha^{-1} for the period 1952–1990, and for the Netherlands this estimation varied between 1000 and 5000 kg ha^{-1} [13].

7.1.3 Pathways of P Loss

Bulk of runoff P (85–95%) from pastures fertilized with poultry or swine litter is in the soluble form, which is the most readily available form for algal uptake [14]. Surface runoff P is the generous output not only from intensive animal-based agriculture but also from low-input systems of agriculture that augments agricultural fields with P-based fertilizers to boost productivity. Other than overland flow, a potential pathway for P movement is P leaching from soils oversaturated with P. Some 10% of P export from land occurs by leaching and groundwater transport, while 90% is transported by overland flow as sediment or dissolved P. Phosphorus losses by overland transport range from 0.1 to10 kg ha^{-1} yr^{-1} or more on highly erosive sites. On average, surface runoff waters carry 10 μg l^{-1} of dissolved and 1000 μg l^{-1} of sediment P [15, 16]. Several researchers reported that it is not the quantity of P in a soil that determines how much P will be released, but the degree of soil saturation with P that determines the intensity of the solution P concentration a soil can maintain and hence the concentration of P that can be lost in runoff and leaching [17]. Calculating the degree of phosphorus saturation (DPS) of a soil provides a measure to determine whether a soil might leach P. A positive linear relationship occurs between measured soluble P and the DPS of a soil. Studies suggest that STP on its own is a useful indicator of the potential for P losses, but other P loss tools such as the "P index," which incorporate factors such as (i) transport processes that connect a site with surface waters, (ii) management factors, such as manure application and tillage practices, and (iii) proximity to a water body sensitive to P inputs, will be more accurate means of P loss risk assessment [18].

7.1.4 Soil P Dynamics

The development of sustainable land management practices for agroecosystems requires a fundamental understanding of the chemical, biological, and physical processes in soils that affect the availability of P to terrestrial plants, and ultimately to animals and humans [19]. Phosphorus cycling in soils is a complex phenomenon that is strongly influenced by the nature of inorganic and organic solid phases present, type and an extent of biological activity occurring, chemistry of the soil solution (e.g., pH, ionic strength, and redox potential), and many environmental factors such as soil moisture content and temperature (Figure 7.2). Soils, plants, and microorganisms all play a major role. The quantity of P in the soil solution at a given time is generally on the order of <1 kg ha^{-1} or $<1\%$ of the total quantity of P in the soil. This requires that

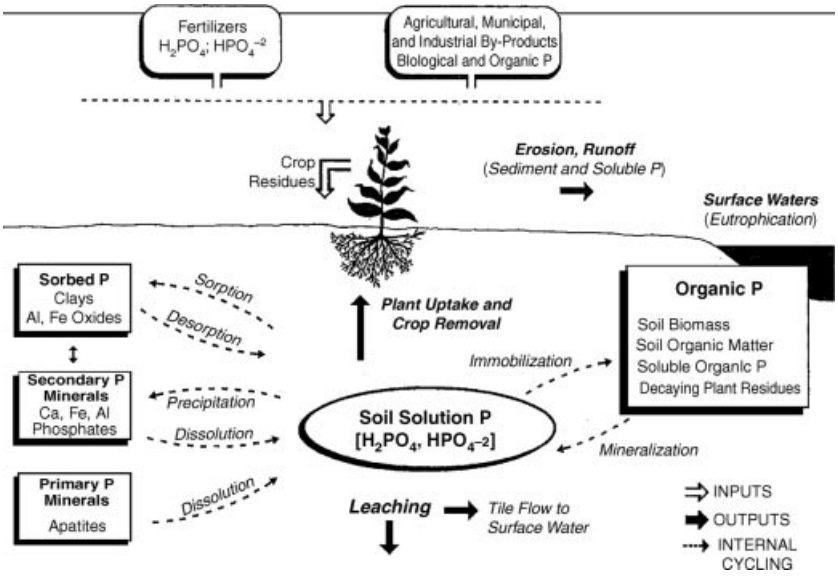

Figure 7.2 The soil P cycle. Reproduced from Ref. [19], with kind permission from with kind permission from ASA, CSSA, SSSA.

the P in the soil solution must be replenished many times over the life of the plant to meet P demands. As the soil interacts with runoff or becomes part of the sediment load in a receiving body of water, the same exchange phenomenon becomes important from an environmental standpoint. "Labile P" is often used to describe soil or sediment P that rapidly equilibrates with an aqueous solution while forms of P that are slow to equilibrate are termed "nonlabile." The mechanisms that control the rate and extent of P exchange between the aqueous and the solid phases in soil or sediment systems are not well known [19].

Maintaining the concentration of P in soil solution in an optimum range for plant growth, often cited as $>200\,\mu g\,l^{-1}$, while restricting P in surface waters to $>30\,\mu g\,l^{-1}$ is a challenge faced both in the agriculture and in the environmental management. This requires to manage the soil P cycle, and the chemical and biochemical processes such as dissolution–precipitation, sorption–desorption, mineralization–immobilization, and oxidation–reduction (Figure 7.2).

Total P concentrations in soil vary in the range of 100–3000 $mg\,kg^{-1}$. Typically, organic P constitutes 30–65% of total P. However, high organic matter soils can contain up to 90% organic P [20]. Organic P transformations in soil are important in determining the overall biological availability of P, which in turn influences ecosystem productivity. The amounts, forms (Table 7.2), and dynamics of organic P in the soil are determined by a combination of biological, chemical, and physical factors (Figure 7.3). The transfer of P in drainage from agricultural soils to watercourses is a key component of the global P cycle and thus has important implications for water

quality. The enrichment of receiving waters with P can contribute to eutrophication. Organic P is a key component of the P transfer process because it can account for a large proportion of the total P in soil solution, runoff water, and stream water [21]. Some organic P forms are mobile in the soil, leading to penetration of soluble organic P to depth, notably where animal manure is applied to the soil [22]. Organic P is also

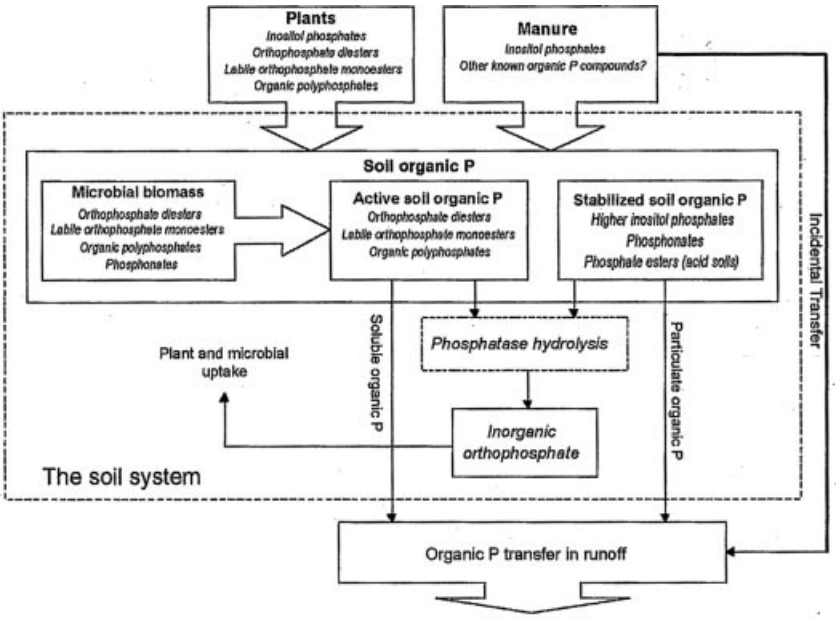

Figure 7.3 Soil organic P dynamics – conceptual model. Reproduced from Ref. [25] with kind permission from ASA, CSSA, SSSA.

biologically available in surface waters following hydrolysis by phosphatase enzymes, and many species of cyanobacteria grow well on a wide range of organic P compounds, including inositol hexakisphosphate [23]. DeLaune *et al.* [24] showed that while P concentrations in runoff were highly dependent on STP for unfertilized soils ($R = 0.93$); the relationship was extremely poor after poultry litter was applied to the same plots ($R = 0.004$), indicating that the effect of STP was overwhelmed when poultry litter was surface applied. This study further demonstrated that annual P loads in runoff water were closely correlated with the soluble P concentration of poultry litter ($R = 0.87$) than to the total P content of the litter ($R = 0.67$). Despite the importance of organic P in the P transfer process, its precise role remains poorly understood. However, the fact is now accepted that diffuse P pollution cannot be effectively managed without a comprehensive appreciation of the role of organic P [21].

7.2
Consequences of P Overloading

Eutrophication is the enrichment of surface waters by plant nutrients, a form of pollution that restricts the potential use of impacted water bodies. Eutrophication of fresh waters is a growing environmental problem worldwide and excess P is well documented as its most common cause in many aquatic systems [14]. It decreases dissolved oxygen and concurrently increases biological oxygen demand of a water body, adversely affecting aquatic wildlife and species diversity. Consequences of eutrophication include increased biomass of phytoplankton; shifts in phytoplankton to bloom-forming species; increase in blooms of gelatinous zooplankton (in marine environments); increased biomass of benthic and epiphytic algae; changes in macrophyte species composition and biomass; death in coral reefs and loss of coral reef communities; decrease in water transparency, taste, and odor; increased incidence of fish kills; reductions in harvestable fish and shellfish; decrease in esthetic value of the water body; and so on [27].

Losses of phosphorus from agricultural soils in the United States have recently been identified as one of the major causes of decreased surface water quality [28]. Nonpoint sources are now the dominant inputs of P to most US surface waters (Table 7.3). The geographical concentration of the poultry and swine industry and its vertically integrated nature have caused water quality problem in many parts of the United States. For example, the City of Tulsa, OK, derives its municipal drinking water supplies from the Eucha/Spavinaw Watershed at Arkansas–Oklahoma boarder. This watershed has a high density of broiler houses. Excessive algal blooms in the two lakes have caused very high levels of geosmin [*trans*-1,10-dimethyle-*trans*-9-decalol] present in the drinking water in recent years [18]. Geosmin is an earthy smelling metabolite of several organisms including actinomycetes and cyanobacteria such as *Anabaena* [29]. Geosmin starts causing taste and odor problems in water supplies when levels exceed $25\,\mathrm{ng\,l^{-1}}$. Research on cyanobacterial toxins has advanced greatly since the mid-1980s, focusing on their characterization and

distribution [30, 31]. Toxic strains are now recognized as having a wide distribution throughout lakes and have been divided into the fast acting neurotoxins and the slower acting hepatotoxins. For example, 65 different types of the commonly occurring microcystin toxin have been identified and these are not simply confined to the genus *Mcrocystis*. Impacts of toxin vary widely; Anatoxin A(s), for an example, is an organophosphorus compound that acts as a cholinesterase inhibitor; it may not thus be logical to say that P in the aquatic environment is nontoxic [31]. Some of these are tumor promoters and a study from China links eutrophic drinking water sources to an elevated incidence of liver cancer in humans [32]. One potentially carcinogenic agent is trihalomethanes (THM) that can enter potable water supplies if – during chlorination process – chlorine reacts with dissolved organic compounds formed by algal cell lysis or algal excretion. The most tragic manifestation of the impact of toxins was seen in 1997, when 55 persons died within 7 months of exposure to cyanobacterial toxins in Brazil [33]. Reports from Australia, along with the Brazil episode, of adverse effects on human health associated with eutrophic drinking water – contaminated with cyanobacterial toxins – have led to an increased awareness of toxins as an environmental health issue [31]. In addition to toxins, cyanobacteria, and also algae, can produce other dissolved organic compounds, principally geosmin and isoborneol, which cause taste and odor problems [34].

The nature, degree, and implications of exposure to algal toxins via potable drinking water remain uncertain. However, phosphorus runoff from poultry and swine farms has also been implicated in the emergence of a dinoflagellate, *Pfiesteria piscicida*, in waterways on the eastern coast of the United States [35]. *P. piscicida* is a microscopic alga that lives in estuaries – where freshwater streams or rivers mix with salt water – along the Atlantic and Gulf coasts. Researchers at North Carolina State University first identified *P. piscicida* in 1988 in fish cultures. Since then, scientists have advanced many theories about the organism's life cycle and its possible effects on the health of fish and humans. In 1998, the US Congress appropriated funds to the Centers for Disease Control and Prevention (CDC) to address concerns about human health effects possibly associated with exposure to *P. piscicida*. Toxins from *Pfiesteria*

strains were isolated and characterized recently [35]. Eutrophication of the Chesapeake Bay, its tributaries, and other surface water systems in the Atlantic Coastal Plain continues to be a serious environmental problem [36].

7.3
Remediation Strategies

7.3.1
Chemical Amendments of Animal Waste or Manure

Methods to reduce the off-site movement of P from fields receiving manure have attracted much attention in recent times. As most of the P runoff from fields fertilized with poultry manure was in the dissolved form, several studies were conducted to determine if Al, Ca, and Fe amendments to poultry litter or manure could cause reduction in soluble P levels [37–39]. These studies demonstrated that chemical amendments of litter decreased soluble P levels by several orders of magnitude, and Al amendments particularly was better in controlling P losses than Ca amendments. It was also suggested that alum additions to poultry litter decrease P solubility by either direct precipitation of amorphous aluminum phosphate or by adsorption of P by aluminum hydroxide formed after the hydrolysis of alum takes place. Moor *et al.* [38, 39] measured P runoff from paired watershed, one of which was fertilized with alum-treated litter; the other with normal litter. They found that P concentrations in runoff were 73% lower in pastures fertilized with alum-treated poultry litter than the normal litter. Long-term studies on the effects of various fertilizers have also shown that soluble P levels in soils are much lower with alum-treated litter than untreated litter. Dou *et al.* [40] have shown the efficacy of different coal combustion by-products in stabilizing manure phosphorus. Three coal combustion by-products, namely, fluidized bed combustion (FBC) fly ash, flue gas desulfurization (FGD) by-product, and anthracite refuse fly ash (ANT), were added to dairy, swine, and broiler litter manures in a laboratory incubation study. FBC reduced readily soluble P by 50–60% at a rate of 400 g kg^{-1} for all three manures. FGD reduced soluble P further to nearly 80% when added to swine manure and broiler litter at 150 and 250 g kg^{-1}, respectively. ANT was not found effective for any of the manures tested. In all cases, reduction in readily soluble P was primarily associated with inorganic P (Pi) with little change in organic phosphorus (Po). In another study, efficacy of alum-amended poultry litter in reducing P release from three Delaware Coastal Plain soils, Evesboro loamy sand, Rumford loamy sand, and Pocomoke sandy loam, was investigated [41]. All soil types were incubated with alum-amended or unamended poultry litter. Long-term desorption of the incubated material resulted in approximately 12–13% reductions in cumulative P desorbed when comparing soil treated with unamended and alum-amended litter. In addition, the P release from the soil treated with alum-amended litter was not significantly different from the control (soil alone). The overall implication from this study is that the application of alum as a manure amendment is useful in coarse-textured soils of the Coastal Plain [41]. In one recent study, Wilson

et al. [42] showed that the application of mineral amendments to manure reduces P availability in manure (liquid dairy, laying hen, and broiler chicken) and soil without affecting crop productivity. Mehlich 3 extractable P (M3P) was reduced by 59–97% in all manure treated with mineral aluminum sulfate and ferric chloride. A container experiment was then carried out to examine the effect of soil with pretreated manure on timothy (*Phelum pretense* L.) growth and soil P levels [42]. Dairy manure plus aluminum sulfate (200 g kg^{-1}) reduced water-soluble P by 82% relative to the N–P–K control. This study demonstrated that mineral pretreatment of manure can reduce the soluble P content of the manure and soil without negative effects on plant growth.

The impact of alum addition on organic P transformations in poultry litter and litter-amended soil was investigated by Warren *et al*. [43]. Liquid-state ^{31}P nuclear magnetic resonance (NMR) indicated that phytic acid was the only organic P compound present, accounting for 50 and 45% of the total P in untreated and alum-treated litters, respectively, before incubation. After 93 days of storage-simulating incubation, phytic acid values declined to 9 and 37% in untreated and treated litters, respectively. Thus, these results show that adding alum to litter inhibits organic P mineralization during storage and promotes the formation of alkaline extractable organic P that sustains lower P solubility in the soil environment. The P speciation in poultry litter was analyzed using solid-state ^{31}P-NMR spectroscopy, and the mineralogy was analyzed by powder X-ray diffraction (XRD) after storing the samples moist and dried for up to 5 year under controlled conditions [44]. Struvite (magnesium ammonium phosphate mineral) concentrations were generally lower in dried samples than in samples stored moist. The moist samples also had higher concentrations of phosphate bound to aluminum hydroxides.

7.3.2 Chemical Amendments of Soil

Application of chemical amendments such as aluminum, calcium (Ca), and iron to soils enriched with P has also been tried in many studies [45–47]. The ability of water treatment residuals (WTR) to alter P solubility and leaching in Immokalee sandy soil amended with biosolids and triple superphosphate (TSP) was investigated in laboratory and greenhouse studies [46]. Several by-products are generated in drinking water purification process, but two major types of WTR are produced in large quantities and have potential for P immobilization. Conventionally, sedimentation–flocculation process produces residuals using either Al salts (Al-WTR) or Fe salts (Fe-WTR) as the primary coagulant. The other major residual type, Ca-WTR, is produced in water-softening facilities where lime is used for hardness removal. In above equilibration studies [46], the ability to reduce soluble P followed the order Al-WTR $>$ Ca-WTR $=$ Fe-WTR. Differences in the P-fixing capacity of the sesquioxide-dominated materials (Al-WTR and Fe-WTR) were attributed to their varying reactive Fe- and Al-hydrous oxide contents as measured by oxalate extraction. Leachate P was monitored from greenhouse columns where Bahia grass (*Paspalum notatum*) was grown on Immokalee soil amended with biosolids or TSP at an equivalent rate of 224 kg P ha^{-1} and WTR at 2.5% [46]. In the absence of WTR,

21% of TSP and 11% of biosolids total P leached over 4 months. With coapplied WTR, losses from TSP columns were reduced to 3.5% (Fe-WTR), 2–5% (Ca-WTR), and <1% (Al-WTR) of applied P. However, for biosolid treatments, all WTRs retarded downward P flux such that leachate P was not significantly different from control columns. In another growth chamber study [45], three different types of soil with M3P levels above 800 mg kg^{-1} were treated with 0–50 g kg^{-1} IRR (Fe-rich residue). Three crops of wheat were grown in succession. Water-soluble P and M3P concentrations were lowered with an increase in IRR application rate for each soil and correlated positively with tissue P for three soils. Biomass yield and tissue P concentrations were significantly reduced with the addition of IRR in all soil types [45]. Novak and Watts [47] also demonstrated that alum-based WTR can reduce extractable P concentrations in three P-enriched coastal plain soils. Incorporation of WTR into the three soils caused a near-linear and significant reduction in soil M3P and WSP concentrations (Figure 7.4). In two soils, 6% WTR [w/w] application caused a soil M3P concentration decrease to below the soil P threshold level (150 mg kg^{-1} soil). The results also showed that WTR incorporation into soils with higher P concentrations caused larger relative reductions in extractable WSP than M3P concentrations [47].

Chemical amendments do not prevent the accumulation of P in soils but merely reduce the amount of water-soluble phosphorus, thus regulating the runoff loss [48]. Moreover, P immobilization in soil by these amendments may not be stable on a long-term basis and instead result in higher soluble phosphates as in the case of Ca and ferric phosphate dissolution under certain normal soil conditions [49]. Though the use of Al salts to precipitate P in manures or soils is considered a better choice [49], these applications may also affect soil chemistry on a long-term basis. The stability of the P complexes formed with Al-oxides, as it relates to P lability in the environment, is uncertain [41].

7.3.3
Animal Diet Modification with Phytase

One of the major breakthroughs in recent years has been the commercialization of the phytase enzyme for use in swine and poultry feeds and its positive impact on P excretion. Phytase mediates the conversion of phytate – an organic form of P – into bioavailable P in diet, thus decreasing the need of feed P quantity [50]. The use of diet modifications to decrease the total P concentration in poultry and swine manure, and hence decrease P loading rates on agricultural lands and P transfer to surface waters, is considered an effective way of source management. Incorporating present technologies into diet formulations could reduce the amount of P in poultry manures and litters by at least 40%, while it is anticipated that future technologies could lead to decreases of more than 60% [50]. However, concerns were raised that although phytase can decrease total P in litter, it could increase the water-soluble phosphorus in the litter and hence the potential for P losses to surface waters following land application [51]. DeLaune *et al.* [24] found the average P concentration in the runoff from litter of birds fed phytase was 85 mg P l^{-1}, compared to 39 mg P l^{-1} from the litter of birds fed the normal diet, even though total P application rate used in their

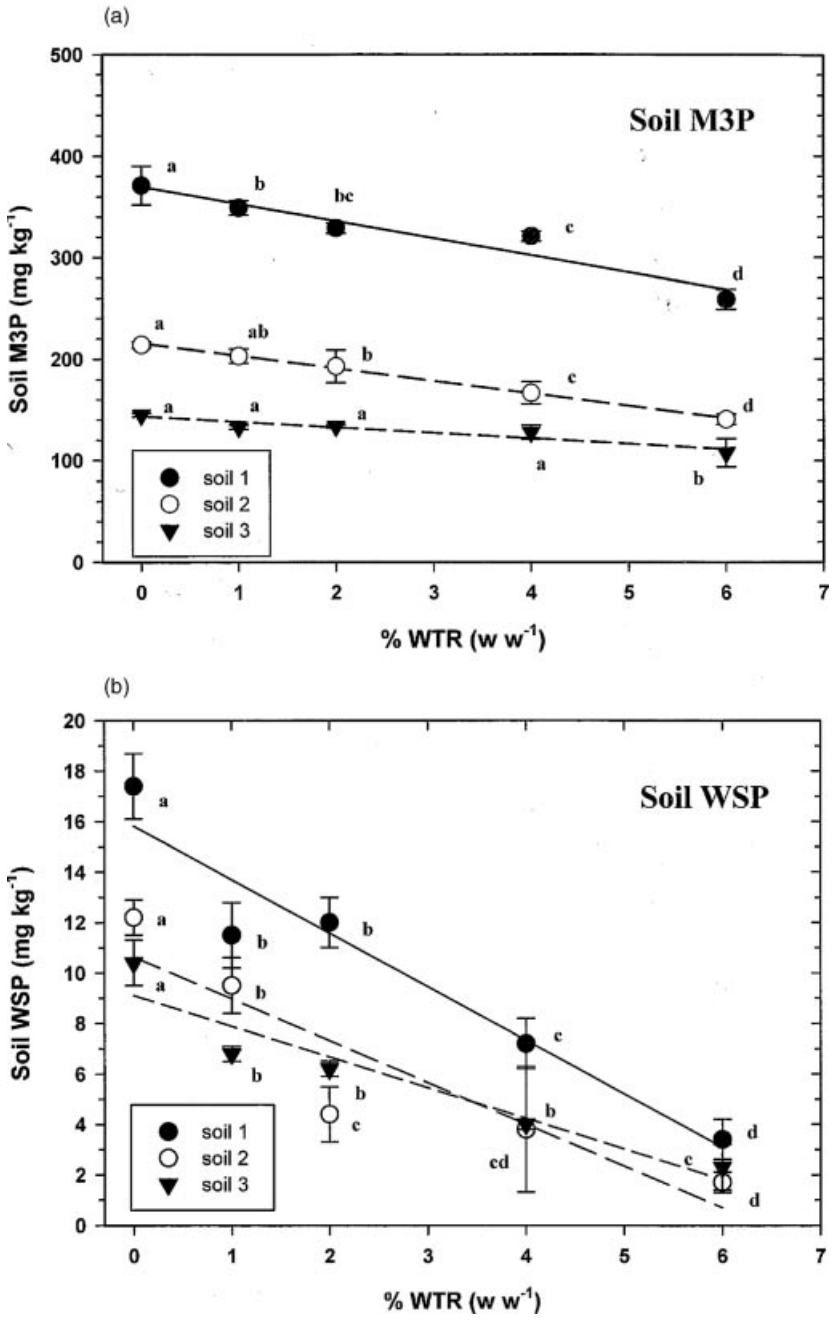

Figure 7.4 Linear regression relationship between reductions in soil Mehlich 3 phosphorus (a) and water-soluble (WSP) concentrations (b) and percent water treatment residual (WTR) incorporation. Reproduced with kind permission from the Journal of Environmental Quality [47].

experiment was roughly 40% lower with the phytase diet than normal diet. These researchers showed that the increased P concentration in runoff water was due to higher soluble P in the phytase litter than normal litter (3283 versus 1176 mg P kg^{-1}). Studies by Maguire *et al.* [52, 53] and Smith *et al.* [54], however, contradict previous findings and suggest that dietary phytase actually decreases both litter water-soluble P and dissolved P in runoff following litter application. Like poultry feed, swine diets were also amended with phytase in a number of studies. These studies conclusively show that digestibility of (or bioavailability) of P in cereal grains and oilseed meals is markedly improved with phytase supplementation. This means that reduced amounts of supplemental inorganic P are needed in swine diets to maximize growth and bone mineralization. As a result, fecal P is markedly reduced when phytase is included in the diet. Again, the fear of increased soluble P in swine litter following phytase treatment was allayed by several studies [54, 55]. Smith *et al.* [54] countered that dietary phytase significantly decreased water-soluble P in manure by 17%, but had no significant effect on dissolved P loss in runoff. However, a study at the University of Kentucky by Xavier *et al.* [56] presented a mixed picture showing 41% reduction in total P excretion, >2.5% increase in soluble P, and an insignificant difference in the amount of soluble P per day in swine excreta when phytase-supplemented diets were compared to control diets. Abioye *et al.* [57] conducted a study to determine if higher phytase levels can result in greater reduction in swine manure P without increased P solubility. These researchers reported that the greatest reduction in manure P was in pigs fed a diet containing 2000 U phytase per kg (without supplemental P), with 33% reduction in manure P. Although, there has been a great deal of research on the efficacy of phytase and other dietary strategies in poultry and swine performance and P excretion, little data exist on how these technologies will affect P runoff from fields fertilized with animal manure.

7.3.4
Phytoremediation

Various methods have been attempted to reduce soil P and halt the loss of P via runoff and leaching. These strategies though produce a varying degree of results, none seems to work without environmental risks. Alternatively, plant-assisted extraction of phosphate (Pi) could be an attractive strategy. Current P uptake rates are low for common row crops and forage grasses used to assimilate P from soil [58]. It is felt that the present cropping systems will require several decades, at the normal rate of P removal by plants, to reduce high P concentrations to an environmentally safe level. Thus, it is important to develop a method for the rapid removal of soil phosphorus. Mining of soil P, which includes harvesting P taken up from the soil by a crop grown without external P application, has been proposed as a possible management strategy for P-enriched soils [5, 7, 59, 60]. Phytoremediation is an inexpensive, nonintrusive, and often highly effective technique [61]. Plant-based cleanup strategies offer a number of advantages both over traditional cleanup methods and over other bioremediation technologies. There are several reports of metal hyperaccumulators

that are immensely useful in phytoremediation [61, 62]. Plants, generally referred to as metal hyperaccumulators, have the inherent potential to survive and accumulate excessive amounts of metal ions in their biomass without incurring damage to basic metabolic functions [61]. However, the ability of vegetation to assist in the remediation of P remains largely unknown. Some researchers suggest that for P phytoremediation to be effective, plants should have high biomass and accumulate P significantly higher ($\geq$1% DW) than the common plants do [7]. P remediation potentials of a number of crops were evaluated in a pot and field study indicating a differential pattern of phosphate (Pi) uptake by those crops [63]. Other studies also indicate usefulness of phytoremediation using stargrass [60] and perennial ryegrass [5] for P-impacted soils. Studies reflect the usefulness of plant-assisted P remediation, but no phosphorus hyperaccumulator has been identified [5, 60]. Both soil and crop management practices may thus require optimization for the P hyperaccumulator plant to compete with other plant species.

7.3.4.1 P Accumulation Potential of Annual Ryegrass

7.3.4.1.1 Hydroponic Study Annual ryegrass (*Lolium multiflorum*) is a closely related and interfertile species with perennial ryegrass (*L. perenne*), and both are grown all over the world as key forage grasses [64]. These are among the most palatable and highly digestible grasses for livestock. Annual ryegrasses, screened among several grass species for tolerance to high P levels, were selected for tissue P accumulation study [65]. A hydroponic method was preferred in this study to eliminate the effects of variable soil pH and microflora on P solubility and mobility. The objectives primarily were to (i) determine Pi accumulation potentials in Marshall and Gulf ryegrass, two cultivars of *L. multiflorum*, grown in a nutrient medium enriched with high levels of Pi, and (ii) to map out the Pi transport pathways across plant tissues. Both grasses accumulated high concentrations of P (>2% of tissue dry weight) in their roots and shoots in a medium containing 5 g l^{-1} KH_2PO_4 (Figure 7.5). Root P declined while shoot P rose rapidly with further increase in Pi in the medium.

The channel of P transport and accumulation in leaves and roots of ryegrass was mapped out by scanning electron microscopy (SEM) and electron dispersive X-ray spectroscopy (EDS) techniques. The SEM of roots excised from experimental plants (grown on 5 g l^{-1} KH_2PO_4) showed a higher accumulation of P in epidermal and cortical cells. Bright fibrillar spots of Pi can be seen in these cells (Figure 7.6a). These observations support the notion that epidermal and cortical cells are the primary entry points for P uptake. Though cells of the stellar region show intense formation of bright patches, P is distributed unevenly throughout the root section. In the micrograph of control roots (supplied with no Pi), such bright formations are conspicuously absent (Figure 7.6b). Leaf samples from the experimental plants showed concentrations of brighter P spots from pericycle to epidermis. Some of the epidermal and cortical cells revealed the presence of bright fluffy structures rich in P and K (Figure 7.6c). SEM of control leaf samples is clearly distinguishable from those of P-supplemented plant specimen with respect to fluffy structures (Figure 7.6d).

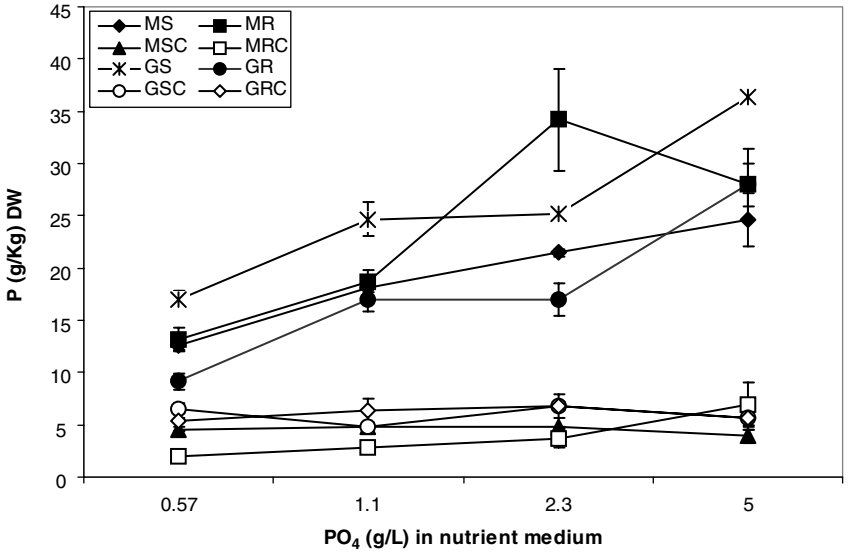

Figure 7.5 Accumulation of P in Marshall and Gulf ryegrass grown in nutrient solution containing 0.57–5 g l^{-1} of KH_2PO_4 for 2 weeks. Corresponding controls were set up with equal amounts of K_2SO_4. Each point represents a mean of six replicates (± SE). Reprinted from [65] with permission from American Chemical Society, © 2004.

The EDS analysis (P peaks) of KH_2PO_4-exposed plant parts is also distinguishable from those of controls (Figure 7.7a–d). SEM and EDS observations presented in this study lead to the belief that high levels of Pi flow into the cells via symplastic (via cell-to-cell connections) pathways. However, apoplastic (outward flow via cell walls) migration of Pi cannot be ruled out. Both apoplastic migration and symplastic transportation of heavy metals have been reported in heavy metal hyperaccumulator species [66].

7.3.4.1.2 **Greenhouse Study** As annual ryegrass demonstrated a large P accumulation in hydroponic conditions [65], experiments were designed to characterize phosphate accumulation from P-impacted soils under greenhouse conditions [67]. Biomass of plants increased with increasing concentrations of soil P until the concentration reached to a level of 20 g P kg^{-1} soil, where growth was affected. Significant increase ($p < 0.05$) in biomass with respect to control and also among the treatments was observed in both grass types supplied with P up to 10 g kg^{-1} soil, while decrease in biomass was significant ($p < 0.05$) at 20 g P kg^{-1} soil. Both crops accumulated increasing amounts of P ($p < 0.05$) in their shoots and roots with an increase in soil P (Figure 7.8a and b). P accumulations in Gulf ryegrass varied from 8.2 to 13 g kg^{-1} shoot dry weight, while P accumulations in Marshall ryegrass was 7.8–11 g kg^{-1} shoot dry weight depending on soil P concentrations [67].

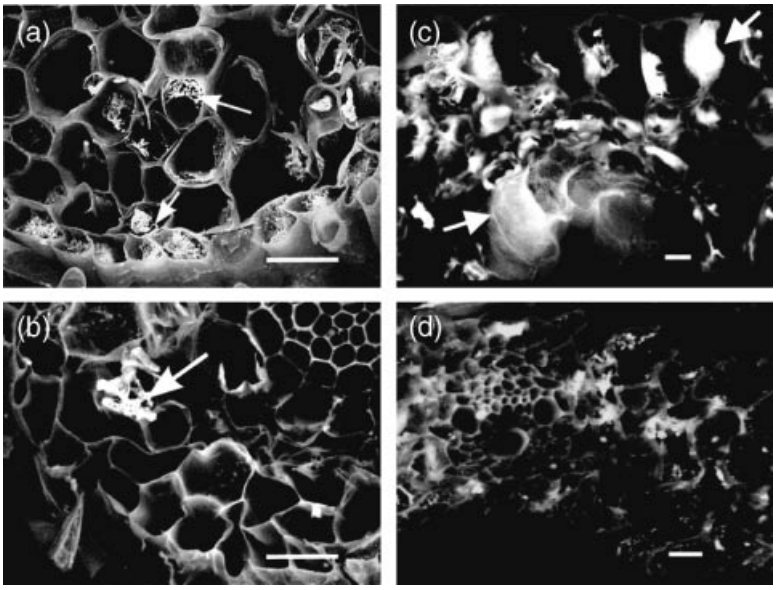

Figure 7.6 Scanning electron micrographs of the root of Gulf ryegrass seedlings grown in modified Hoagland's medium in the presence (a) and absence (b) of 5 g l^{-1} of KH_2PO_4. (a) Root section (scale marker = 10 μm) shows bright fibrillar spots (arrowheads) in epidermal and cortical cells. (b) Control root section (scale marker = 10 μm) shows no comparable spots (arrowhead indicates a dense, superimposed sheet of aluminum as a contaminant). Scanning micrographs of the leaf of Marshall ryegrass seedlings grown in modified Hoagland's medium in the presence (c) and in the absence (d) of 5 g l^{-1} of KH_2PO_4. (c) Leaf section (scale marker = 10 μm) shows abundance of bright fluffy structures (arrowheads) in epidermal and cortical cells. (d) Control leaf section (scale marker = 10 μm) shows no such structures. Reprinted from [65] with permission from American Chemical Society, © 2004.

In another study, three cool-season turf grasses, Kentucky bluegrass (*Poa pratensis*), tall fescue (*Festuca arundinaceae*), and perennial ryegrass (*L. perenne*), were investigated for phosphate removal capacity from enriched soils [68]. Shoot P differed significantly among these three grasses ranging from 0.3 to 0.45% of dry mass. This study also showed that genetic differences in P absorption might exist among turf grasses at both the interspecific and intraspecific levels.

Effect of pH on P Accumulation The form of P most readily accessed by plants is orthophosphates (Pi) and their forms in soil solution change according to soil pH [69]. The p*K* values for the dissociation of H_3PO_4 into $H_2PO_4^-$ and then into HPO_4^- are 2.1 and 7.2, respectively. Thus, below pH 6.0, most Pi will be present as the monovalent $H_2PO_4^-$ species, whereas H_3PO_4 and HPO_4^- will be available only in trace amounts [69]. Plant uptake is also affected by fixation of P by soil components, which is greatest in the presence of Fe- and Al-hydroxylated surfaces and, at higher pH, calcium carbonate [70]. Therefore, to study how varying soil pH conditions in the Pembroke silt loam influence P uptake in Gulf and Marshall ryegrass, plants were grown in P-enriched (2.5 g P kg^{-1} soil) soils maintained at pH 5.6, 6.5, and 7.8 [67]. A significant increase in shoot P was observed in both grass types at pH 5.6 with respect to

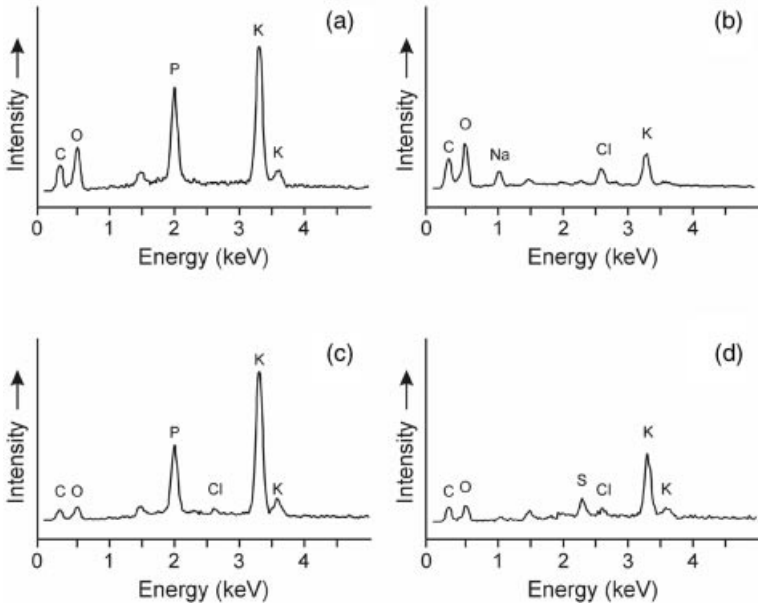

Figure 7.7 Electron dispersal X- ray spectroscopic analysis. (a) Spectrum of one of the bright spots (arrowheads) shown in Figure 5a. (b) Spectrum of control root shown in Figure 5b. accumulation at pH 7.8 (Figure 7.9a and b). However, difference in shoot P between pH 6.5 and 7.8 was significant ($p < 0.05$) in Gulf but not in Marshall ryegrass. Most studies on the pH dependence of Pi uptake in higher plants have found that uptake rates are highest between pH 5.0 and 6.0, where plant-assimilable $H_2PO_4^-$ dominates [69].

The experiment was also designed to study the effect of the changing temperature that may be encountered by the crops during different seasons on the dry mass productivity and corresponding P uptake [67]. Variations in the shoot dry matter and P accumulations were significant ($p < 0.05$) at different temperature regimes in these grasses (Table 7.4). Biomass growth in Marshall ryegrass was greater than Gulf ryegrass at all temperatures, which is consistent with earlier studies involving solution culture [65]. As differences in biomass growth are greater, total P removal capacity of these plants will also be significantly different. Studies suggest that air or soil temperature may influence both dry mass accumulation and P uptake in plants [71, 72]. Cool soil temperatures generally result in reduced P uptake from soil reserves by plant roots. Even soils with high levels of P may not provide adequate P to plants when the temperature is suboptimal during the cold season. Annual ryegrass is generally cultivated as winter crop in the temperate climates, but this study suggests that they can be grown also during the summer when temperature exceeds 30 °C, while serving the purpose of P mining.

Production of phosphatases is a potentially important way for plants to enhance P availability, as a large proportion of soil P occurs in organic forms [73]. Phosphatases are required for the mineralization of organic forms of soil P to release phosphate (Pi) – the form of P readily acquired by plants. More recently, phytase (EC 3.1.3.26), a class

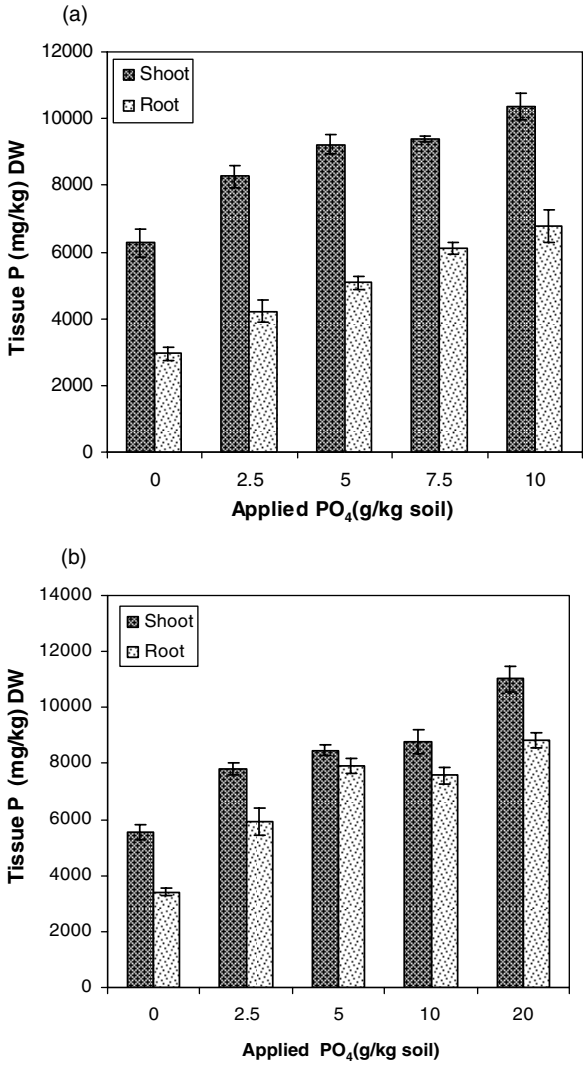

Figure 7.8 (a) P accumulation in Gulf ryegrass grown in soils enriched with 0–10 g P kg^{-1} soil for 6 weeks. of phosphomonoesterases with high specific activity against phytate, has been described in plant roots [73]. Acid phosphomonoesterase and phytase activities in the annual ryegrass plant roots – grown in acidic and slightly alkaline soils under P sufficiency or P deficiency conditions – were determined [67]. The results indicate that phosphomonoesterase and phytase activities were more or less similar in both Marshall and Gulf grasses when grown in acidic soils, but activities were significantly higher in Marshall than Gulf when grown in alkaline soil (Table 7.5).

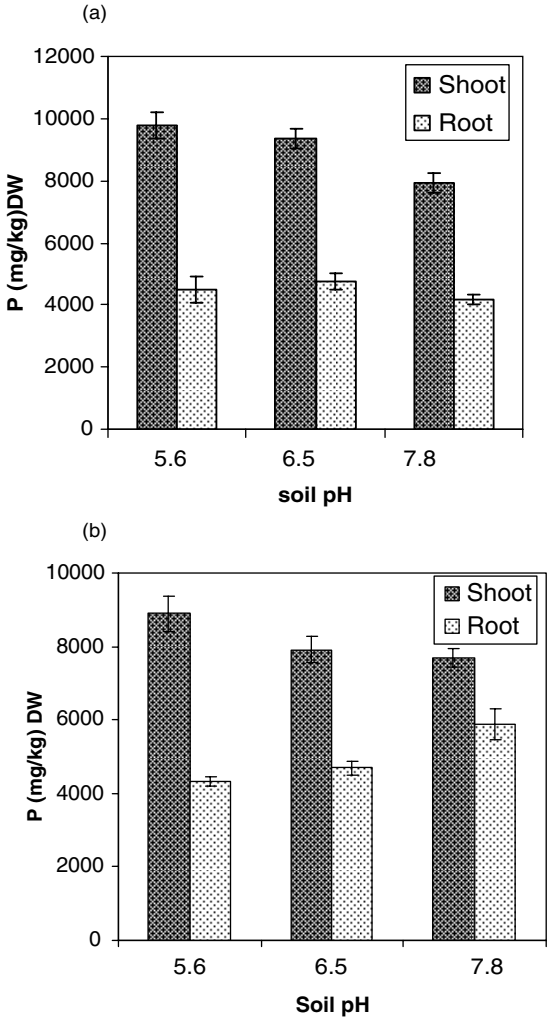

Figure 7.9 (a) P accumulation in Gulf ryegrass grown in soils (pH 5.6–7.8) enriched with 2.5 g P kg^{-1} soil for 6 weeks. Phosphomonoesterase activity in annual ryegrass was significantly higher [67] than the corresponding values reported for wheat grown in sterile medium containing various sources of P [74]. Phytase activity expressed in terms of a percentage of the total phosphomonoesterase activity was low (0.7–1.0%) in annual ryegrass but greater than *Arabidopsis* [75] and pasture grasses [76]. Plants with high phytase activity in their roots can hydrolyze phytates, which account for a large proportion of unavailable soil P pool, and can thus deplete excess P source more efficiently [75]. The enzyme activities in annual ryegrass also varied in respect of soil pH (Table 7.5). The activities

Table 7.4 Effect of temperature on shoot biomass and P accumulation in annual ryegrass grown in P-enriched soil*.

were about twofold higher in alkaline soil than acidic ones in case of both enzyme types. Possibility of P immobilization with Ca under alkaline condition may necessitate conditions for plants to express high enzyme activity [67].

The effect of P supply on the activity of enzymes was also significant in annual ryegrass where both phosphomonoesterase and phytase activities were higher in P-rich plants than P-deficient plants [67]. This feature, though not uncommon, was not compatible with many studies that show enhanced activities, particularly of phytase in plant root extracts [76, 77]. Therefore, enhanced P uptake in annual ryegrass though cannot be directly correlated with the determined enzyme activities, the interesting pattern in enzyme activities may be one of the unique features that influence P nutrition and accumulation in these plants [67].

7.3.4.2 Phytoremediation Potential of Food Plants

In an attempt to identify a P hyperaccumulator, several plants belonging to legume, vegetable, and herb (foliage) crops were screened in P-enriched soils in the greenhouse [78]. The goal was to identify economically valuable crop species that contain both high biomass and high shoot P. The promising plant species were further characterized for P accumulations under different soil P concentrations.

Among the various groups of plants (legumes, vegetables, and herbs), a large variation in P accumulation was noticed, and only few plant species demonstrated the P accumulation at a level of 1% (10 g P kg^{-1} shoot DW) or more in their shoots (Table 7.6). However, among herbs, pigweed (*Amaranthus* spp.), and goosefoot (*Chenopodium* spp.) plants were promising P accumulators, with some of the varieties accumulating in the range of 1.1–1.4% P (DW) in their leaves. The ratio of shoot-to-root P was also high (2 or >2) in these varieties. On the basis of P contents in aerial parts, these plants can be suitable for P phytoremediation, but some of the pigweed and goosefoot species are known for their invasive nature, and thus can be difficult to remove when not desired. However, a cautious approach involving harvesting shoots before flowering can be effective in reducing soil P levels, particularly, in fallow lands [78].

While screening vegetable crops, cucurbits, namely, cucumber and yellow squash, demonstrated an appreciable P accumulation in their aerial parts [78], consistent with earlier observations on their trials in the phosphatic clay soil [79]. With an accumulation of about 1.8% in stem and 1% in leaves (DW), cucumber can remove a substantial quantity of soil P. Like cucumber, yellow squash also accumulated over 1% (as much as 1.4% DW) in their aerial parts. Cucumber stem showed an increasing accumulation with increase in soil P concentration after 8 weeks, but leaves had higher accumulations depending on soil P after 12 weeks. It is likely that cucumber stems first acquire P from soil and then distribute it in parts like leaves and fruits after a period of time. Accumulation in fruits also increased significantly ($p < 0.05$) with time. The pattern of P accumulation in squash was different in that stems and leaves both had increasing concentrations of P as time increased. However, squash fruits had an accumulation of about 1.4% (DW), irrespective of P concentrations in soil. Even control plants grown in soils without any external addition of P had high P concentrations in fruits (after 8 weeks) and stems (after 12 weeks). This may be because of high efficiency of squash plants for P acquisition from soils having even low concentrations of P [78].

In an earlier study, shoot accumulations of P were determined for oil crops such as Indian mustard, canola, and rape oilseed, and a maximum level of 0.46% P (shoot DW) accumulation was observed in Indian mustard [63]. It was interesting to determine the P accumulation pattern in sunflower, which is one of the most widely used edible oil crops worldwide [78]. Sharma *et al.* [78] showed that sunflower accumulates more P than Indian mustard, canola, and rape oilseed with stem, leaf, and flower accumulations of 0.6, 0.8, and 1.0% (DW), respectively. The effect of soil P concentration (>1 g kg^{-1} soil) and duration of time had no significant effect on the accumulation potential of sunflower plants. Increase in root P was noticeable with increase in duration of time. Like cucumber and squash, sunflower also displayed growth in biomass in the presence of a high concentration of soil P as much as control

plants. As this crop is known for its high biomass in fields, the cumulative P removal capacity may be significantly higher at the demonstrated levels of P accumulation in aerial parts. Besides element accumulation and harvestable biomass, what is important to determine the phytoextraction potential of a plant species is the depth of rooting zone, as suggested by Mertens *et al*. [80]. Notably, sunflower was observed to have extensive growth of root system extending deep into soils (data not presented) under high P conditions. That is also true of *Amaranthus* and *Chenopodium* species.

Sharma *et al*. [78] analyzed phosphomonoesterase and phytase activities in plant species that showed increased P accumulations (cucumber, squash, and sunflower). Activities of both enzymes were increased in cucumber and squash grown in P-enriched soils compared to the activities in controls (with no addition of P). When the activity of phosphomonoesterase increased to about 35% in both cucumber and squash, the phytase activity increased about 400% in cucumber and 40% in squash with respect to controls. Sunflower plants, however, demonstrated either comparable (phosphomonoesterase) or higher activity (phytase) under the P-deficient condition (controls). The pattern of enzyme activities in cucumber and squash was remarkably different from the pattern of activities in sunflower and other plant species [74, 76]. However, it was comparable to the enzyme activity in Marshall and Gulf ryegrass that also show higher P accumulations from P-enriched soils [67]. A similar trend was also observed in *Trifolium repens* (a legume pasture), which demonstrated higher phytase activity in high P conditions [76]. Plants having high phytase activity in their roots can hydrolyze phytates, which account for a large proportion of unavailable soil P pool, and can thus deplete excess P source more efficiently. Higher enzyme activities in cucumber and squash thus may be one of the factors contributing to their P accumulation efficiency. The molecular mechanism of P nutrition in plants under the conditions of P adequacy is not well known; however, much information is available on the acquisition of P under P deficiency [81]. Although the investigation by Sharma and Sahi [67] identified some economically important plant species with affinity for high P acquisition, the P accumulation potential of these plants needs to be verified under natural conditions of high soil P.

7.4 Conclusions

The present research strongly establishes the relationship between high-density animal production, often referred to as confined animal feeding operations (CAFOs), and high soil test P. Elevated STP again correlates directly with an accelerated P transfer to receiving lakes, streams, or watersheds. Increased P loading to aquatic ecosystems, and in particular lakes and rivers, is considered a prerequisite to eutrophication and water quality deterioration. All these associations have sparked global concerns, propelling the US Environmental Protection Agency to set up the National Regional Nutrient Criteria Program, European Commission to launch the Water Framework Directive, and other countries to find various water quality monitoring agencies, to identify water impairment and target remediation.

Remediation strategies ranging from chemical amendments of animal manures to soil applications of water treatment residues, to animal feed modifications, to the use of cover or buffer crops as scavengers of P have been tried to halt P transfer to aquatic ecosystems. Each method has its pros and cons. For example, chemical amendments of manure or soil were reported to decrease water-soluble or runoff P levels by several orders of magnitude, and Al amendment was particularly better in controlling P losses than Ca amendments. However, chemical amendments do not prevent the accumulation of P in soils but merely reduce the amount of water-soluble phosphorus, thus regulating the runoff loss. Moreover, P immobilization in soil by these amendments may not be stable on a long-term basis and instead may result in higher soluble phosphates as in the case of Ca and ferric phosphate dissolution under certain normal soil conditions. Animal feed modifications (particularly poultry and swine feed modifications) by addition of phytase enzyme show a great promise. Diet formulations based on present methodologies could reduce the amount of P in poultry manures and litters by 40%, while future technologies could lead to further P decreases, as anticipated by the US Council for Agricultural Science and Technology. However, this remedial measure is also not free from risks. Concerns were raised that although phytase can decrease total P in litter, it can increase the water-soluble phosphorus in the litter and hence the potential for P losses to surface waters following land application. In addition to finding an efficient P source management, phytoremediation could be another tier of output remediation as it involves application of P-accumulating plant species in scavenging excess P. Phytoremediation is a sustainable, relatively inexpensive, and highly effective technique. Harvesting P taken up from the soil by a crop grown without external P application has recently been argued as a possible management strategy for P-impacted soils. However, the ability of vegetation to assist in the remediation of P remains largely unknown. Studies suggest the usefulness of plant-assisted P remediation, but no phosphorus hyperaccumulator has been identified. The potential of phytoremediation can be fully realized when P hyperaccumulating plant types are identified and used in the process of P removal from soils. The P-accumulating species will find value enhancements also when applied as cover or buffer crops. As organic P is a critical contributor in P loadings to waterways, plant species capable of increased phytase secretion and organic P assimilation can be a desirable candidate in the search for a P accumulating plant. Recently constructed transgenic plant species that overexpress root phytase and accumulate P from organic P sources can be tested under field conditions for phytoremediation potential.

A variety of best management practices (BMPs) have recently been developed to minimize the potential for soil P transport. These include, but are not limited to, cultivation practice such as conservation tillage; the use of cover crops, for example, grasses, legumes, and other herbaceous species, as a seasonal cover to protect against soil erosion and P loss; methods of soil P testing such as STP or P index; artificial drainage, for example, tile drains; creation of buffers such as riparian buffers or filter strips, alley cropping, and vegetative barriers; and streambank protection. Research on all aspects of agricultural P, from new approaches to animal P nutrition, to modifying the physicochemical characteristics of P sources,

and to advancing our understanding of the interactions between soil and crop management on P transport, has intensified in the past decade. Research also shows that the use of BMP systems (combinations of several BMPs tailored to the specific conditions and environmental concerns at a given site) is a more effective approach of addressing P problems. The evolution of sustainable P management is an ongoing process that is the responsibility of all involved: from farmers to consuming public, to policy makers.

8
Genetic Modification of Crops: Past, Present, and Future*

Nina V. Fedoroff

Agricultural productivity has markedly increased, while the labor intensiveness of agriculture has decreased over the past two centuries of increasing incorporation of science and technology into agricultural practice. Mechanization, chemical fertilizers, plant breeding, and molecular genetic modification (GM) have all promoted rapid increases in agricultural productivity. Recent decades have witnessed a decrease in the rate of agricultural productivity growth, however. The reasons include declining investment in agricultural research, increasing human population pressure, decreasing fresh water availability, increasing temperatures, and societal rejection of GM crops in many countries.

8.1
Introduction

The world has experienced a succession of shocks over the past 2 years: a global food crisis, spiraling energy costs, accelerating climate change, and a financial meltdown. The food crisis sparked riots in countries on every continent [1]. Unfortunately, the food crisis is not a transient phenomenon. The present situation developed over a very long time as a result of relentlessly increasing demand pushing against a shrinking natural resource base, even as investment in agricultural research and development declined decade after decade. The oil price spike combined with widespread droughts in 2007 and 2008 to aggravate the underlying trends and send grain prices upward. While prices moderated in the following year, they have recently renewed their upward trend persists. Indeed, the adequacy of the food supply may be the most critical issue of the twenty-first century [2].

Food security is a long-standing concern. Thomas Malthus' famous essay on population, published in 1798, crystallized the problem of balancing food and human population [3]. Curiously, Malthus penned his essay at about the time when science began to play a major role in boosting agricultural productivity. Late eighteenth-century milestones were Joseph Priestley's discovery that plants emit oxygen [4] and Nicholas-Théodore de Saussure's definition of the chemical composition of plants [5]. Malthus could not have envisioned the extraordinary increases in productivity that the integration of science and technology into agricultural practice would stimulate over the ensuing two centuries.

Both organic and mineral fertilization of plants have been practiced since ancient times. Long before the reasons were understood, people knew that certain chemicals, such as saltpeter and lime, as well as a wide variety of biological materials ranging from fish and oyster shells to manure and bones stimulated plant growth [6]. In the early nineteenth century, Justus von Liebig identified the major chemical requirements for plant growth, laying the foundation for the modern chemical fertilization methods [7]. Although it was known by mid-nineteenth century that biological sources of nitrogen could be replaced by chemical sources, supplying nitrogen in the forms that plants use remained a major limitation until the development of the Haber–Bosch process for fixing atmospheric nitrogen in the early twentieth century [8]. Today, agriculture in the developed world relies primarily on chemical fertilizers.

8.2
Crop Domestication

People practiced what might be thought of as generic "genetic modification" long before chemistry entered agriculture, transforming inedible wild plants into the crop plants that feed people and their animals today. (The term "genetic modification," or "GM," has come most often to refer only to the use of recombinant DNA technology, a confusing state of affairs).

Corn, or maize (*Zea mays*), remains one of humanity's most spectacular feats of genetic modification. Its huge ears, packed with starch and oil, provide one of humanity's most important food and feed crops. Corn bears little resemblance to its closest wild relative, teosinte. Indeed, when teosinte was first discovered in 1896, it was assigned to a different species and named *Euchleana mexicana*. By the 1920s, it was known that teosinte and corn have the same number of chromosomes and readily produce fertile hybrids, yet controversies about their relationship and about the origin of corn continued throughout most of the twentieth century.

The work of Dr. John Doebley and his colleagues, commencing with the genetic analysis of maize–teosinte hybrids, has made substantial progress in identifying the genetic changes that transformed teosinte into modern corn [9]. Doebley's more recent work with evolutionary geneticist Svante Paabo traced the key genetic changes that transformed teosinte into corn to the Balsas River Valley in Mexico and dated them to roughly 6000–10 000 years ago. It has become apparent that the difference between teosinte, a grass with hard, inedible seeds, and modern corn resides in just a handful of

genes that control plant architecture and the identity of reproductive organs. Remarkably, once this handful of mutations were brought together, the suite of genetic modifications stayed together and spread very rapidly, so that the same group of alleles had already penetrated into the American Southwest more than 3000 years ago. Fossilized cobs recovered from caves in Mexico and dated to be more than 6000 year old already possessed the multirowed character of the modern corn ear, as do almost 4000 year-old cobs from the Ocampo Caves in northeastern New Mexico [10].

Perhaps the most important insight that has been gained through the molecular analysis of crop domestication is that people have markedly changed wild plants to make them suitable as crop plants and that this has been done over many thousands of years. They selected phenotypic traits and thereby the underlying genetic changes occurring concomitantly. Each crop has its own interesting history, but one of the most fundamental traits distinguishing wild from domesticated plants is the retention of mature seeds on the plant. Plants have a variety of mechanisms for dispersing their seeds, central to which is the shattering of the seed structure upon maturation. It is much easier for people to harvest seeds that remain attached to the plant, hence the selection of mutations that prevent seed dispersal is thought to be among the earliest steps in crop domestication [11].

Among the many other traits altered during domestication are the size and shape of foliage, tubers, berries, fruits, and grains, as well as their abundance, toxicity, and nutritional value. There are many underlying genetic differences that distinguish a domesticated crop plant from its wild progenitors, but molecular analysis reveals that key changes are often in genes that encode transcription factors – proteins that regulate the expression of many other genes [12]. Differences in nutrient composition among varieties of the same crop are attributable to mutations in genes coding for proteins of certain biosynthetic pathways. For example, mutations in genes for enzymes involved in the conversion of sugar to starch gave rise to sweet corn varieties.

8.3
Modern Crop Improvement

Crop improvement benefited from both the Mendelian and the molecular genetic revolutions of the twentieth century. Austrian monk Gregor Mendel's pioneering observations on inheritance, published in 1865, were made independently by Dutch botanist Hugo de Vries. Only then did Mendel's observations gain the interest of other geneticists [13]. A simple demonstration project to illustrate Mendelian inheritance led to the discovery of hybrid vigor, a phenomenon whose incorporation into crop breeding resulted in a dramatic expansion of the corn ear and, thereby, crop yield. The discovery is attributed to George Harrison Shull, working at the Carnegie Institution of Washington's Station for Experimental Evolution. He was asked by the Station's director to develop a demonstration of Mendel's rules of inheritance. In the course of these experiments, he observed that some kinds of corn made more rows of kernels than others. Curious about the genetic basis of this difference, he inbred the respective varieties and then crossed them to see whether the row number trait would

segregate according to Mendel's simple rules. He found that when he crossed the inbred lines to each other, the F_1 progeny were taller, more robust plants with bigger ears [14]. This phenomenon, called hybrid vigor or heterosis, is the basis of today's extraordinarily productive hybrid corn varieties [15].

However, when they were first introduced in the United States during the 1930s, corn hybrids faced resistance and criticism similar to that of GM crops. The hybrids were complex to produce and agriculture experiment stations weren't interested. Eventually, a company was formed to produce hybrid seed. But farmers accustomed to planting seed from previous year's crop saw no reason to buy it. It was only after farmers realized the yield benefits and the drought resistance of hybrid corn during the 1934–36 dust-bowl years that hybrid corn was rapidly adopted [16].

Techniques for accelerating mutation rates with radiation and chemicals and through tissue culture were developed and widely applied in the genetic improvement of crops during the twentieth century [17]. Such techniques introduce mutations rather indiscriminately and require the growth of a large numbers of seeds, cuttings, or regenerants to detect desirable changes. Nonetheless, all these approaches have proved valuable in crop improvement and by the end of the twentieth century, more than 2300 different crop varieties, ranging from wheat to grapefruit, had been developed using radiation mutagenesis [18].

8.4
Mechanization of Agriculture

A major development the impact of which Malthus could not have envisioned is the mechanization of agriculture. Human and animal labor provided the motive force for agriculture throughout most of its history. Early tractors powered by steam engines were large and unwieldy, but the invention of the internal combustion engine at the turn of the twentieth century led to the development of smaller and more maneuverable machines. The mechanization of plowing, seed planting, cultivation, fertilizer and pesticide distribution, and harvesting accelerated in the United States, Europe, and Asia following World War II [19]. Agricultural mechanization drove major demographic changes virtually everywhere. In the United States, 21% of the workforce was employed in agriculture in 1900 [20]. By 1945, the fraction had declined to 16% and by the end of the century the fraction of the population employed in agriculture had fallen to 1.9%. At the same time, the average size of farms increased and farms increasingly specialized in fewer crops.

8.5
The Green Revolution

Malthus penned his essay when the human population of the world stood at less than a billion. The population tripled over the next century and a half. As the second half of the twentieth century began, there were neo-Malthusian predictions of mass famines

in developing countries that had not yet experienced science- and technology-based advances in agriculture. Perhaps, the best known of the mid-twentieth century catastrophists was Paul Ehrlich, author of *The Population Bomb* [21].

The predicted Asian famines were averted by the dedicated work and extraordinary accomplishments of several scientists and their teams, principally plant breeders Borlaug, Swaminathan, and Khush [22]. The Green Revolution was based on the development of rice and wheat varieties with mutations in genes that controlled their growth rate, resulting in dwarf varieties able to respond to fertilizer application without lodging. Subsequent breeding for increased yield continued to improve the productivity of these crops by as much as 1% per year. Instrumental in these advances were the first two institutes established by the Consultative Group on International Agricultural Research (CGIAR), the International Rice Research Institute (IRRI) [23] in the Philippines, and the International Maize and Wheat Improvement in Mexico (CIMMYT) [24]. Perhaps most remarkably, the Green Revolution of the late twentieth century reduced the fraction of the world's hungry from half to less than a sixth, even as the population doubled from 3 to 6 billion.

8.6
Molecular Genetic Modification of Crops

The molecular genetic revolution that began in the 1960s led to the development of new methods of crop improvement. Researchers in the 1950s and 1960s discovered the existence of bacterial plasmids that could replicate independently of the bacterial chromosome. Other discoveries led to the identification of restriction enzymes and ligases, making it possible to insert and link covalently a piece of genetic material from a completely different organism, then clone (amplify) the plasmid in bacteria. Amplification of such "recombinant" plasmids in turn made it possible to develop the DNA sequencing techniques that underlie today's genomic revolution. Additional techniques were developed for the introduction of genes into plants using either the soil bacterium, *Agrobacterium tumefasciens*, which naturally transfers a segment of DNA into wounded plant cells, or mechanical penetration of plant cells using tiny DNA-coated particles [25]. This combination of techniques has made it possible to transfer genetic material from either the same or a related plant or from a completely unrelated organism into virtually any crop plant.

Several crop modifications achieved using these methods are now in widespread use. Perhaps, the best known of these are crop plants into which was introduced a gene from the soil bacterium, *Bacillus thuringiensis*, long used as a biological pesticide because it produces a protein that is toxic to the larvae of certain kinds of insects, but not to animals or humans [26]. The gene coding for the toxin is commonly called simply "the Bt gene," although there is actually a family of Bt toxin genes that express numerous closely related proteins. These genes have been introduced into a number of different crops, primarily corn and cotton. In the United States and Europe, pest-protected crop varieties are produced almost exclusively by companies such Monsanto, DuPont, and Syngenta. In other parts of the world, including in China and

India, such crop modifications are being performed by both the public and the private research sectors.

Another widely accepted crop modification is the introduction of genes that confer resistance to herbicides, commonly used compounds that inhibit biosynthetic pathways unique to plants [27]. Among the most widely used today are compounds that interfere with the production of amino acids that plants synthesize, but animals do not [28]. Herbicide-tolerant crop plants, which make it possible to control weeds with a herbicide without damaging the crop, have been derived through natural and induced mutations, as well as by introduction of genes from either bacterial sources or modified genes from plant sources. Today, herbicide-tolerant varieties of many crops, most importantly soybeans and canola, are very widely grown.

Papaya varieties resistant to papaya ringspot virus (PRSV) are a public sector GM achievement that saved the $64 million/year Hawaiian papaya industry [29]. Papaya ringspot virus is a devastating insect-borne viral disease that wiped out the papaya industry on Oahu in the 1950s, forcing its relocation to the Puna district of the big island. By the 1970s, the Puna district was producing 95% of Hawaii's papayas. PRSV was first detected in the Puna district in 1992; by 1995 it was widespread and threatened the industry. Dennis Gonsalves and his colleagues at Cornell University began a project in 1985 to introduce a viral gene into papayas based on the observations made in Roger Beachy's laboratory at Washington University that introducing a viral gene could make a plant resistant to the virus from which the gene came [30].

The first transgenic papaya plants expressing a PRSV gene were ready in 1991, small field tests began in 1992 and large-scale field tests began in 1994. Approvals from the Animal Plant Health Inspection Service (APHIS) of the US Department of Agriculture (USDA), as well as the Environmental Protection Agency (EPA) and the Food and Drug Administration (FDA), for release of the seeds to farmers took another 3 years, by which time many papaya farmers had gone out of business. Transgenic seeds were released in 1998 and by 2000 the papaya industry had come back to pre-1995 levels. Although it was not known at the time, recent studies have shown that the resistance is attributable to posttranscriptional gene silencing [31]. This remarkable method of crop protection enhances a mechanism present in plants that is responsible for protecting the plant from subsequent infection by the same and closely related viruses, much as the development of immunity protects people and animals from reinfection by pathogens.

8.7 Adoption of GM Crops

Although the use of molecular modification techniques in crop improvement engendered controversy – much of it gratuitous – from the beginning, GM crops have experienced unprecedented adoption rates since their introduction in 1996. By 2008, roughly 10% of cropland was planted with GM crops [32]: transgenic crops were grown on more than 300 million acres in 25 countries by more than 13 million

farmers, 90% of whom were small-holder, resource-poor farmers. The vast majority of transgenic cropland is devoted to just four crops, namely, cotton, maize, soybean, and canola, but the list of commercialized transgenic crops is growing and already includes papaya, tomato, poplar, petunia, sweet pepper, squash, rice, alfalfa, and sugar beet.

Few of the widely anticipated adverse effects have materialized. While some resistance to the Bt toxin has developed, it has not been as rapid as initially feared and second-generation, two-Bt gene strategies to decrease the probability of resistance are already being implemented [33]. Predicted deleterious effects on nontarget organisms, such as monarch butterflies and soil microorganisms, have either not been detected at all or are insignificant. Moreover, while the use of conventional pesticides decreases the abundance of beneficial insects, the planting of Bt crops does not.

The many studies that have been done to assess the safety of foods containing or consisting of GM crops have reached the conclusion that GM foods are as safe or safer than as non-GM foods [34]. This is in part because of the close attention paid during product development to the potential for toxicity and allergenicity of the proteins encoded by genes being added, as well as the inherently greater precision and predictability of GM constructions.

To date, the unexpected effects have been beneficial. For example, many grains and nuts, including corn and peanuts, are commonly contaminated by mycotoxins, toxic compounds made by fungi that follow boring insects into the plants. Two of these, fumonisins and aflatoxin, are extremely toxic and carcinogenic. Bt corn, however, shows as much as a 90% reduction in mycotoxin levels because the fungi that follow the boring insects into the plants cannot get into the Bt plants [35].

There is evidence as well that planting Bt crops reduces insect pressure on other crops growing nearby. Bt cotton has been widely planted in China. Analysis of the population dynamics of the target pest, the cotton bollworm, showed that Bt cotton not only controls the bollworm on transgenic cotton designed to resist this pest but also reduces its presence on other host crops, thereby decreasing the need for insecticide sprays in general [36].

8.8
Future Challenges in Agriculture

The scientific and technological advances in agriculture of the nineteenth and twentieth centuries have been extraordinary. Since Malthus' time, the human population has expanded more than sixfold. In the developed world, agriculture has become far less labor-intensive and has kept pace with population growth worldwide. Today, fewer than 1 in 50 citizens of developed countries grows crops or raises animals for food. This means that most people in developed countries live in cities and find livelihoods that pay higher wages than farming. Those remaining on farms often also work in off-farm jobs, raising average farm income. However, this also means that most citizens of developed countries have little understanding of what it takes to create the foods that stock contemporary supermarkets.

Moreover, after a half century's progress in decreasing the fraction of humanity experiencing hunger from half to less than a sixth, the food crisis and the more recent global financial crisis have begun again to swell the ranks of the hungry [37]. Population experts anticipate an addition of another 2–4 billion people to the planet's population within the next 3–4 decades [38], but the amount of arable land has not changed appreciably in more than half a century, increasing by only about 10% [39] and it is not likely to increase much in the future because we are losing it to urbanization, salinization, and desertification at least as fast as we are adding it.

Another variable that is becoming critical is the availability of fresh water for agriculture. Today, about a third of the global population lives in arid and semiarid areas, which cover roughly 40% of the land area. Climate scientists predict that in coming decades, average temperatures will increase and dry land area will expand [40]. Even now, inhabitants of arid and semiarid regions of all continents are extracting ground water faster than aquifers can recharge and often from fossil aquifers that do not recharge [41].

Thus, the challenges to agriculture in the twenty-first century are profound: to increase agricultural productivity on land largely already under cultivation, at higher temperatures, and using less water. Can it be done? There are biological, political, and cultural impediments.

The major crops that now feed the world – corn, wheat, rice, and soy – require a substantial amount of water. For example, the production of a kilogram of wheat requires between 500 and 2000 L of water, most of which is lost through transpiration [42]. But almost half the grain produced worldwide is fed to animals, and the amount of water required to produce a kilogram of meat is 5–10 times greater than that required to produce a kilogram of grain.

The optimal growth temperature to produce maximal yields of our major crop plants is determined by the temperature optimum for photosynthesis, the process by which plants convert solar energy into chemical energy, and other physiological processes. Yield is also determined by the temperature range that supports optimal development of the harvested storage organs (grain, bean, and kernel) [43]. A recent study reports that yields increase with temperature up to 29 °C for corn, 30 °C for soybeans, and 32 °C for cotton, but then decline precipitously at higher temperatures [44]. This study predicts that yields of these crops in their present growing areas will decline by 30–46% by the end of the twenty-first century under the most moderate climate change scenario and by 63–82% under the most rapid warming scenario.

The expected pressures on water availability and increasing temperatures present critical challenges to agricultural researchers to increase crop water efficiency and heat tolerance. Whether our highly productive food and feed crops can be modified and adapted to be even more productive at the higher temperatures expected or at more northern latitudes is simply not known. It is therefore imperative not only to increase research on the salt, drought, and temperature tolerance of existing crop plants but also to invest in research on plants that are not now used in agriculture, but that are capable of growing at higher temperatures and using brackish or salt water

for irrigation. Indeed, the array of molecular tools and knowledge available today may make it possible to design a wholly new kind of agriculture for a more arid, hotter world.

Even though the molecular tools, physiological knowledge, and genomic information available today are extraordinary, there are also political and cultural barriers to their widespread use in crop improvement. While scientific communities worldwide largely recognize the safety of GM crops, the political systems of Japan and most European and African countries remain opposed to growing GM crops. Many countries lack GM regulatory systems or have regulations that prohibit growing and even, in some countries, importing GM food and feed. Moreover, even where there exist regulatory frameworks that support the testing and introduction of GM crops, the regulatory process is both complex and expensive. Contrary to the claims of anti-GM activists, GM crops and food derived from them are excessively regulated.

These factors have largely eliminated the participation of university and other public sector researchers in molecular crop improvement that involves field trials in most countries around the world. Productivity gains based on earlier scientific advances can still increase food production in some countries, particularly in Africa. But such productivity gains appear to have peaked in most developed countries and recent productivity gains have been made largely through molecular modification. If modern science is to contribute to the agricultural productivity increases required in coming decades as the climate warms and the human population continues to grow, it is imperative to get beyond the cultural and political biases against molecular crop modification, assess the safety record of GM crops, and ease the regulatory barriers to their development and deployment.

Translational Biology Approaches to Improve Abiotic Stress Tolerance in Crops

Rina Iannacone, Francesco Cellini, Giorgio Morelli, and Ida Ruberti

In the last decades, several genes that regulate abiotic stress response were identified in the model plant *Arabidopsis*. The completion of the *Arabidopsis* genome sequence in 2000 and the development of molecular high-throughput "omics" platforms have speeded up the simultaneous functional characterization of genes that regulate the abiotic stress tolerance in plants. The fundamental molecular mechanisms that underlie the plant abiotic responses are quite conserved among plant species and therefore the knowledge gained in the model plant *Arabidopsis* can be exploited to improve stress tolerance in crop species. Many examples demonstrate that ectopic expression of key genes involved in the stress response can induce stress tolerance in different crops, demonstrating the potential of the translational approaches. Nevertheless, generation of crops that have improved tolerance under field conditions is still a challenge. However, systems biology studies in model plants and "omics" approaches in crop species can certainly contribute to the understanding of the interplay between response pathways to different abiotic stresses, a condition that is commonly found in open fields.

9.1
Introduction

Plants represent our main food supply both directly or indirectly via the production of feed for bred animals. The agricultural production greatly increased during the Green Revolution thanks to the introduction of new cultivars and the use of fertilizers and pesticides. The gene revolution, which started with the use of genomic and biotechnology approaches for plant genetic improvement, was expected to give a big speedup in the selection of new varieties. However, the development of an ideal crop for different environments is still a challenge. Plant growth and production are greatly influenced by the environment and particularly by climate stresses. The global climate changes that we are experiencing in recent years is worsening the losses of

Improving Crop Resistance to Abiotic Stress, First Edition.

plant production. The higher frequency of long drought periods alternated with flooding, which are becoming common even in temperate regions, increases the unpredictability of crop yield.

Plants can afford mild abiotic stresses putting in place molecular mechanisms that ensure survival and reproduction. Since sessile, plants have evolved the ability to reprogram the expression of their genome in response to environmental changes. However, survival under abiotic stresses is costly in terms of energy and metabolism. The adverse effect of abiotic stresses is reflected on plant health, *habitus*, and production. It is estimated that abiotic stresses account for 70% reduction in the yield for main crops [1]. Several pathways that regulate the changes in metabolism, upon environmental stresses, were studied in detail in model plants. However, there is need to "translate" the fundamental studies, conducted on model plants, into applied research for crop improvement [2].

The concept of "translational biology" is borrowed from medicine where there is an urgent need to translate into practical protocols discoveries coming from the fundamental science. Nevertheless, this approach might have a useful application in agriculture as well, and can be translated as the use of knowledge developed in model plants (*Arabidopsis thaliana*, *Indica rice*, *Medicago truncatula*, *Populus* spp., etc.) for crop genetic improvement. The recent progresses made in model plants in the field of genomics, transcriptomics, and proteomics can give great opportunities for the genetic improvement of crops.

On the other hand, the swift adoption of next-generation sequencing (NGS) technologies, which are producing reference genome data directly on crops, will allow the development of comparative genomic approaches with model plants in order to find new genes and new markers useful for breeding traits of interest. A big discrepancy between the vast quantity of data already available at genomic DNA sequence level and the information regarding the function of genes and meaningful phenotypes still exists. This limitation hampers the possibility of fully exploiting the potential of genomics tools for breeding, such as genome-wide association and genomic breeding.

An exciting area of development, which very likely will allow to tackle this problem, is represented by high-throughput plant phenotyping, the so-called plant phenomics, which is aiming at the development of platforms that support fast and efficient phenotype screening in mutants, populations, and their relations with environmental factors.

9.2 *Arabidopsis* as a Model System

During the past 10 years, *Arabidopsis* has underpinned the genomic revolution in plant science. A number of powerful genomic tools have been developed: a high-quality genome sequence that now includes detailed information on whole-genome patterns of DNA methylation, histone modifications, and small RNAs; T-DNA

insertions in around 90% of genes; whole-genome expression profiles at different development stages in a wide range of environments (www.arabidopsis.org; January 15, 2011). Largely through the use of these genomic tools, *Arabidopsis* research has in the past decade made substantial progress in identification of key genes that underlie the major processes of plant development and responses to the environment. As an example, here we describe the recent advances made in understanding the transcriptional regulatory networks and upstream regulators in response to cold and drought.

9.2.1 Cold Stress

In *Arabidopsis*, *CBF/DREB* (C-REPEAT-BINDING FACTOR/DEHYDRATION-RESPONSIVE ELEMENT BINDING) genes are rapidly and transiently induced following exposure to low temperature, and the CBF/DREB factors in turn induce the expression of around 100 other genes, collectively termed the CBF regulon, which is central to cold acclimation (see Refs [3, 4] and references therein). Recent work identified two cold-sensing pathways that control expression of *CBF/DREB* genes. ICE1 (INDUCER OF CBF EXPRESSION 1), a basic helix-loop-helix transcription factor, binds to multiple Myc DNA regulatory elements present in the *CBF3/DREB1a* promoter and stimulates *CBF3/DREB1a* transcription (see Refs [3, 4] and references therein). The *ICE1* gene is constitutively expressed and regulated at the posttranslational level through low-temperature-induced sumoylation of the ICE1 protein mediated by SIZ1, a SUMO E3 ligase [5]. Interestingly, this activation process is countered by HOS1 (High Expression of Osmotically Responsive Genes 1), a RING finger E3 ligase that mediates ubiquitination and degradation of ICE1 (see Ref. [4] and references therein). The other cold-sensing pathway involves calcium. A number of studies have established that exposure of plants to low temperature induces calcium spikes that in turn influence gene expression (see Ref. [4] and references therein). Recently, Doherty *et al.* [6] showed that calmodulin binding transcription activator (CAMTA) factors bind to a regulatory element in the *CBF2/DREB1c* gene promoter. Single *catma* mutants showed no obvious growth phenotypes. However, the *camta3* mutation resulted in a significant reduction in cold induction of *CBF2/DREB1c*, and *camta1 camta3* double-mutant plants were impaired in freezing tolerance, indicating an important role the CAMTA transcription factors play in cold acclimation [6].

Cold induction of *CBF/DREB* genes is gated by the circadian clock: plants exposed to cold at ZT4 (4 h after dawn) have greater induction of *CBFs/DREBs* compared to plants given the same treatment at ZT16 [7]. Intriguingly, the CBF pathway is also controlled by light quality [8]. A low red to far red (R/FR) ratio light signal at the beginning of the day induced the *CBF/DREB* genes and their downstream *COR* (cold-regulated) genes at 16 °C but not at 22 °C. Remarkably, this low R/FR-induced increase in *CBF/DREB* expression was sufficient to confer freezing tolerance at 16 °C. The reduced ambient temperature together with a low R/FR light environment

at the beginning of the day might mimic autumn, and it is possible that the activation of the CBF/DREB regulon represents an adaptive response in *Arabidopsis* for minimizing winter freezing injury [3, 8].

Natural variation studies further highlighted the regulatory role of *CBF/DREB* genes in cold acclimation. Natural accessions of *A. thaliana* are distributed over a broad geographic range where selection pressures for tolerance to low temperature are diverse [9]. Relative to accessions from northern regions, accessions of *Arabidopis thaliana* from the southern part of their geographic range exhibit higher levels of nucleotide polymorphism in both regulatory and coding regions. Relaxed selection on the *CBF/DREB* genes in southern accessions compromised the ability of these genes to act as efficient transcriptional activators during cold acclimation [10].

Transgenic overexpression of individual *CBF/DREB* genes induces the cold acclimation pathway and results in enhanced freezing tolerance in the absence of a cold acclimation treatment [11]. However, *Arabidopsis* plants constitutively overexpressing *CBF1/DREB1b*, *CBF2/DREB1c*, or *CBF3/DREB1a* grow slowly, have a dwarf stature, and have delayed flowering [11, 12]. Recently, Achard *et al.* [13] discovered that constitutive overexpression of *CBF1/DREB1b* results in the accumulation of DELLA proteins (DELLAs), a family of nuclear growth-repressing proteins that are key components of the gibberellin (GA) signaling pathway (see Ref. [14] and references therein). According to the current model, DELLAs restrain plant growth, whereas GA promotes growth by overcoming DELLA-mediated growth restraint (see Ref. [14] and references therein). The binding of bioactive GAs to the nuclear receptor GID1 (GA-INSENSITIVE DWARF1) promotes an interaction between GID1 and the DELLA domain of DELLAs. Subsequently, this interaction enhances the affinity between DELLAs and a specific SCF E3 ubiquitin–ligase complex involving the F-box protein SLY1 (SLEEPY1), thus targeting DELLAs for destruction by 26*S* proteasome (see Ref. [14] and references therein). Achard *et al.* [13] found that overexpression of *CBF1/DREB1b* enhances expression of GA-inactivating *GA 2-oxidase* genes. Accordingly, transgenic plants that constitutively express *CBF1/DREB1b* accumulate less bioactive GA and as a consequence exhibit dwarfism and late flowering. Both phenotypes are suppressed when *CBF1/DREB1b* is expressed in a line lacking two DELLA proteins, GAI (GA-INSENSITIVE) and RGA (REPRESSOR OF GA1).

The CBF/DREB cold response pathway is highly conserved in plants. Components of this pathway are also present in species that suffer chilling injury at low temperatures and are unable to tolerate freezing, such as tomato, rice, and maize [15, 16]. Targeted manipulation of these regulatory genes may be able to improve freezing tolerance in winter crops [17].

9.2.2
Drought Stress

Plant responses to drought are complex and different pathways have been identified in *Arabidopsis* (see Ref. [18] and references therein). Among them, the

abscisic acid (ABA) signaling pathway plays a crucial role in plant survival under drought stress. Drought triggers the production of ABA that in turn causes rapid stomatal closure to limit water loss through transpiration and induces genome reprogramming to survive this adverse environment (see Ref. [19, 20] and references therein).

Several ABA binding proteins have been identified and implicated in ABA signaling (see Ref. [19] and references therein). However, the recent identification of the PYR/PYL/RCAR PYRABACTIN (4-bromo-N-[pyridin-2-yl methyl]naphthalene-1-sulfonamide) RESISTANCE (PYR)/PYRABACTIN RESISTANCE 1-LIKE (PYL)/REGULATORY COMPONENT OF ABA RECEPTOR (RCAR) family of ABA receptors and their mechanism represents a major breakthrough in the field and may open up the possibility of new approaches to improve drought tolerance in crops [21–24]. Three research groups independently identified different members of this new receptor family as ABA binding proteins that interact with clade A protein phosphatase 2Cs (PP2Cs), which function as negative regulators of ABA signaling [22–24]. Group A PP2Cs consists of nine proteins including ABA insensitive 1 (ABI1), ABI2, and homologue of ABI1 (HAB1), very well known for their role in ABA response (see Ref. [19] and references therein). The use of ABI2 and HAB1 as baits in yeast two-hybrid screens led to the identification of PYL9/RCAR1, PYL8, and PYL5 as PP2C binding proteins [22, 23]. Independently, Nishimura *et al*. [24] identified several PYR/PYL/RCAR proteins as interactors of ABI1 *in vivo*. Taking a different approach, Park *et al*. [21] identified pyrabactin, a new synthetic selective ABA agonist, and determined by genetic analysis that PYR1 is necessary for pyrabactin action *in vivo*. Subsequent *in vitro* studies demonstrated that both pyrabactin and ABA cause PYR1 to bind and inhibit ABI1, ABI2, and HAB1 [21].

The *Arabidopsis* genome encodes 14 highly conserved PYR/PYL/RCAR proteins [25] belonging to the START/Bet v I superfamily that contain a central hydrophobic ligand binding pocket [26, 27]. The structures of PYR1, PYL1, and PYL2 in apo, ABA-bound, and ABI1 or HAB1 complexed forms were recently reported and revealed how ABA binding to PYR/PYL/RCAR receptor proteins leads to PP2C inhibition [28–32].

Although the single *pyr/pyl/rcar* mutants characterized so far do not display ABA phenotypes, a quadruple *pyr1/pyl1/pyl2/pyl4* mutant shows defects in several ABA responses demonstrating a major role of the PYR/PYL/RCAR proteins in ABA signaling [21, 24]. Moreover, transgenic plants overexpressing *RCAR1/PYL9* are hypersensitive to ABA-promoted guard cell closure [22], and overexpression of *PYL5* enhances drought tolerance of transgenic *Arabidopsis* plants highlighting the biotechnological potential of this gene [23].

In the past years, several binding partners of PP2Cs have been identified (see Ref. [19] and references therein). Among them are protein kinases implicated as positive regulators of ABA signaling such as OST1 (Open Stomata 1)/SnRK2.6 (SNF1-related kinase 2.6) [33, 34] and SnRK2.2 [21]. Triple mutants lacking OST1/SnRK2.6 and its two close relatives SnRK2.2 and SnRK2.3 are almost completely unresponsive to ABA, indicating that these kinases are central to ABA signaling [35–37]. Accumulated evidence indicates that group A PP2Cs directly inhibit SnRK2

kinase activity by dephosphorylating them [38–40]. Therefore, the PYR/PYL/RCAR-mediated inhibition of PP2C activity results in SnRK2 kinase activation, which in turn leads to phosphorylation of downstream targets including AREB/ABFs transcription factors that bind to ABA-responsive promoter elements (ABREs) (see Ref. [21, 41] and references therein). Remarkably, the core PYR/PYL/RCAR–PP2C–SnRK2 pathway, originally proposed by Park *et al*. [21], is sufficient for mediating an ABA response. ABA-triggered phosphorylation of the ABRE binding transcription factor AREB1/ABF2 was reconstituted *in vitro* by combining recombinant PYR1, ABI1, and OST1/SnRK2.6 proteins [42].

The PYR/PYL/RCAR receptor family is well conserved in crop species; thus, it is likely that the modulation of these proteins and their interacting partners will enable new strategies to increase crop tolerance both to drought and to other stresses [43, 44]. Moreover, the discovery of a selective ABA agonist, pyrabactin, and the understanding of its structural mechanism of action and selectivity point to a potential chemical strategy for improving crop yield under drought stress [21, 45, 46].

9.3 Abiotic Stress Tolerance in Crops

During the process of selection of crops that was made in the last century, most attention was devoted to productivity, while abiotic stress tolerance traits were not considered intensively. Nowadays, we are facing a period of progressive drought, usually accompanied with increasing salinization, all around the world so that regions that were considered temperate or with good water resources are becoming dry regions. Furthermore, the global population is projected to increase in the next 30 year from 6.7 billion to 9 billion (http://timeforchange.org/growing-world-population; February 28, 2011) [47], so the need for increasing crop productivity is becoming more and more urgent. Drought stress causes severe losses in plant biomass and seed production. It is estimated that more than 50% of the potential production is lost to drought periods (see Ref. [48] and references therein).

Plants can face drought stresses accumulating in their tissue water either by absorbing more efficiently water from the soil by expanding the length of roots or by decreasing the loss of water via the reduction of the stomatal aperture. In contrast, drought resistance plants are able to limit their metabolism to survive in extreme drought and restore their biological functions once the environmental conditions such as water availability are restored. An example of drought-resistant plant is the *Craterostigma plantagineum*, also called resurrection plant, which has been intensively investigated to understand the molecular mechanisms that regulate the stress response [49].

In recent years, significant progress has been made to improve the abiotic stress tolerance in crops using conventional breeding, marker-assisted breeding, and genetic engineering (reviewed in Ref. [50]). The unraveling of *Arabidopsis* genome has allowed identification of key genes in this model plant that were

demonstrated to control many transcriptional regulatory networks as described in the previous paragraph.

In the following section, the progress made in recent years to obtain stress-tolerant crops (mainly to drought, salt, and cold) is summarized.

Several crops have been engineered to cope with water shortage. Attention was focused on important crops such as tomato, tobacco, wheat, rice, barley, sugarcane, corn, and rape using genes codifying for the production of organic solutes, plant growth regulators, antioxidants, late embryogenesis proteins (LEAs), heat shock factors (HSFs), and heat shock proteins (HSPs). Furthermore, the use of transcription factors (TFs) that regulate the expression of several genes has been investigated (see for recent reviews Refs [18, 50–52]).

The one-gene approach was broadly used in the past 20 years to obtain plants with better performances under stress. The identification of genes coding for water-deficit-induced genes started in the early 1990s [53], and in the following years many of them were transferred to crop's genome. Attention was focused on osmoprotectants (proline, glycine betaine (GB), and trehalose) and several crops were transformed with genes encoding compatible osmolytes [54–58]. Compatible solutes are small molecules that are highly soluble in water and have no effect on macromolecules even at high concentration [59]. One of the main actions of osmolytes is to maintain the turgor pressure in the presence of dehydration, which is the first effect of drought, salt, or heat stress.

9.3.1 Proline

Among osmolytes, proline is the most investigated and several data on its role during stress, signaling, and development have been unraveled [60–62]. Genes codifying proline were isolated from plants (*Vigna aconitifolia*) or bacteria (*Escherichia coli*) and transferred into crops. The first evidence that proline overexpression renders tolerance to osmotic stress was demonstrated by Kishor *et al.* [54]. In this work, tobacco plants constitutively overexpressing mothbean (*V. aconitifolia*) P5CS (Δ^1-*pyrroline-5-carboxylate synthetase*), which is the rate-limiting enzyme in proline biosynthesis, showed greater root biomass and higher number of capsules under salt stress. Furthermore, the overexpression of a mutated form of P5CS (P5CSF129A), in which the feedback regulation by proline was impaired, resulted in an increased production of proline under stress. Transgenic seedlings were able to grow on medium containing 200 mM NaCl, and the level of proline in seedlings expressing P5CSF129A was twofold compared to P5CS seedlings [63]. However, it was also suggested that the role of proline during stress is not limited to osmolytes, but this amino acid acts as a free radical scavenger. The *P5CS* gene from mothbean was also inserted into the rice genome under transcriptional control of the ABA-inducible promoter complex (*AIPC*) by Zhu *et al.* leading to rice plants that showed an increased root biomass under drought stress and less severe wilting compared to the control [55]. A similar result was obtained with the *P5CSF129A* gene that lacked the

feedback control as discussed earlier [64]. In this case, transgenic plants accumulated more proline (four- to fivefold compared to the wild type), were more resistant to salt stress, and showed lower lipid peroxidation, confirming the role of proline as osmoprotectant and as free radical scavenger. The accumulation of proline can be achieved by inhibiting the proline degradation via the antisense regulation of *PDH* (proline oxidase). However, contrasting results were obtained using this approach. While Nanjo *et al.* [65] found an increased tolerance to salt and cold in *Arabidopsis*, other studies highlighted an abnormal plant development and almost no influence on the plant ability to cope with stress [66]. By comparing these results, it can be argued that the rate of proline biosynthesis is more critical than the proline content for stress tolerance.

9.3.2 Glycine Betaine

GB is a quaternary compound widely distributed in various organisms that accumulates in chloroplasts and plastids of many plants. High levels of GB are found in halotolerant plants under stress conditions [67]. However, GB has multiple roles in the cell during abiotic stress: it acts as osmoprotectant maintaining the water balance between the cell and the environment, helps in membrane protection, and stabilizes the quaternary structure of enzymes and proteins at nonphysiological temperatures and salt concentrations [68]. The production of GB in many plants occurs via a two-step oxidation of choline via betainealdehyde involving the choline monoxigenase (CMO) and betainealdehyde dehydrogenase (BADH) [69], while in some extremophile microorganisms an alternative pathway of GB synthesis, via a three-step methylation of glycine, was identified [70]. Although most plants accumulate GB, some of them, including *Arabidopsis*, tobacco, and rice, are considered nonaccumulating. Both naturally accumulating GB and nonaccumulating plants were genetically transformed with GB codifying genes isolated from various organisms such as *E. coli* (*BADH*, *CDH*, [71] *BetA*, *BetB* [72]), *Arthrobacter globiformis* [73, 74], and plants (*CMO* [75] and *PEAMT* [76] from *Spinacia oleracea*). Transgenic crops accumulating GB in their cells showed an increased tolerance to several injuries (drought, salt, and cold). However, the level of accumulation of GB in transgenic plants was not very high and the maximum amount of 5.7 $\mu mol\ g^{-1}$ FW was obtained in *betA* transgenic maize [77, 78]. These plants were found resistant to drought and cold compared to their wild-type counterpart and showed a greater grain production under drought conditions. Accumulated evidence demonstrates that targeting GB in distinct cell compartments leads to different effectiveness in protection against environmental injuries. For instance, in the study by Park *et al.* [79], the *A. globiformis CodA* gene was targeted at cytosol or at chloroplasts and at both compartments simultaneously; the highest levels of GB were obtained in plants that accumulated GB in the cytosol, but the protection against salt and cold stress was much effective in transgenic lines in which the GB gene was targeted at chloroplasts, in spite of the low amount of GB obtained in this subcellular compartment. The authors argued that the presence of GB in chloroplasts reduces the detrimental effect of ROS and enhances tolerance of PSII to photoinhibition.

9.3.3 Transcription Factors

The approach involving the use of TFs is likely to be one of the most promising to obtain an effective abiotic stress resistance in crops. TFs are involved in several basic plant metabolisms and regulate entire gene networks that are involved in plant response to biotic and abiotic stresses. In the history of plant domestication, TFs have played a great role allowing selection of plants more suitable for agriculture purposes. Take, for instance, the case of the selection of maize from teosinte: the selection of a mutant altered in the regulation of the *Tb1* (*teosinte branched 1*) allele (that regulates the lateral branching determining the outgrowth of branches when it is expressed) resulted in a dramatic change in the architecture of the progeny starting the domestication of the modern corn [52, 80].

Several TFs belonging to different large protein families (e.g., HD-Zip, AP2/EREBP, MYB, and NAC) have been identified and overexpressed in *Arabidopsis* [81–86]. Jung *et al.* found the TF gene *AtMyb44* was either overexpressed or downregulated in transgenic *Arabidopsis* and the tolerance of these plants to drought and salt was verified. The authors observed a plant survival rate of 82% for AtMyb44 overexpressing plants, 17% for wild type, and 8% for *atmyb44* downregulated plants, demonstrating a major role of this TF in preventing water loss under drought stress. Furthermore, roughly the same survival rate was recorded in experiments in which transgenic plants were watered with increasing concentration of NaCl (up to 300 mM).

However, TFs isolated in *Arabidopsis* have been transferred to crops to verify their action in heterologous systems. It is quite clear that in many cases the *Arabidopsis* TFs are able to modulate the expression of crop genes involved in the abiotic stress responses [87, 88]. Most attempts have been performed using *Arabidopsis* genes belonging to the *CBF* family since *CBF1-like* ESTs were previously identified in several crops including tomato [15]. Hsieh *et al.* found out that the ectopic expression of *Arabidopsis CBF1* cDNA was able to confer drought, chilling, and oxidative stress tolerance in transgenic tomato plants [87, 89]. In the drought trial, transgenic tomatoes were able to survive after 4 weeks of water deprivation, while the wild-type counterpart was not. In the cold experiment, a very high percentage (ranging from 75% to 83.3%) of transgenic plants was able to recover after 7 days at 0 °C in contrast to the wild-type plants that eventually died. However, the cold-tolerance plants exhibited a dwarf phenotype and reduced seed number probably caused by the constitutive expression of *CBF1*. The alteration in the growth of transgenic plants was overcome by exogenous GA_3 treatment, suggesting that CBF1 may influence genes coding for hormones involved in plant growth. Importantly, the use of *CBF1* demonstrates that the ectopic expression of key regulatory genes can confer tolerance to multiple stresses in relevant crops probably due to the crosstalk of different stress signaling pathways. Recently, it has been suggested that the chilling tolerance observed in CBF1 overexpressing plants could be imputed to the protection of the photosynthetic activity during cold stress [90]. In fact, the *Arabidopsis CBF1* gene was transferred in a cold-sensitive tobacco

cultivar and the photochemical function of PSII and PSI under low irradiance was evaluated. It was found out that all parameters relative to photochemical efficiency (Fv/Fm, NPQ, and ETR) were more favorable in transgenic lines compared to control, thus showing a protective mechanism of CBF on the activity of chloroplasts.

In the last decade, the availability of the genome sequence for several crops allowed identification of *Arabidopsis* TF orthologues in important plants such as rice, tomato, wheat, and maize. Overexpression of rice *CBF/DREB1A* orthologues (*OsDREB1A* and *OsDREB1B*) in *Arabidopsis* gave rise to transgenic plants with better ability to cope with drought, salt, and freezing stresses [91]; in addition, the overexpression of the same genes in rice led to the obtainment of transgenic plants with enhanced tolerance to drought, salt, and cold stress [92].

Lately, AREB-like transcription factors (abscisic acid-responsive element binding factor) were used by two different groups to obtain drought-resistant tomato [93, 94]. *SlAREB1* and *SlAREB2* were isolated from tomato and constitutively overexpressed in the same species. Plants showed a high degree of drought and salt tolerance and were phenotypically equivalent to wild type. Microarray analysis revealed that several abiotic stress-regulated genes were upregulated and, more importantly, genes related to the biotic stress response were upregulated as well, suggesting a crosstalk between biotic and abiotic stress response in plants.

However, in several studies it was observed that the constitutive overexpression of transcription factors caused phenotypic changes in the regenerated plants (e.g., stunted plants, delayed flowering, and reduced seed set) [92, 95, 96], though there are some exceptions in which transgenic plants showed a normal phenotype [88, 93, 97]. To reduce the influence of the exogenous gene on plant phenotype, many researchers expressed the gene of interest under transcriptional control of stress-inducible or tissue-specific promoters. An ideal promoter should have a tight regulation and it should be rapidly and transiently activated upon stress. These characteristics are typical of the *HSP* genes in which the transcription is regulated by heat shock elements present in the upstream region of the *HSP* genes [98]. However, only few examples are available on the use of *HSP* promoters for the transcriptional regulation of stress-related genes [99, 100]. The use of stress-related genes under transcriptional control of inducible promoters may minimize the adverse effect of the exogenous gene at phenotypic level. Kasuga *et al*. compared the growth of transgenic plants containing the CaMV35S :: DREB1A and *29A* :: DREB1A [101] and observed that the use of the *rd29* promoter allowed regeneration of tobacco plants that were almost not affected in their growth and showed a comparable level of drought and cold stress tolerance compared to the CaMV35S :: DREB1 transgenic plants. Lee *et al*. transformed tomato cotyledons with *CBF1* driven by the stress-inducible promoter *ABRC1* isolated from barley and obtained transgenic plants with enhanced tolerance to chilling, drought, and salt stress. Transgenic plants did not show any growth retardation and, notably, the fruit production in transgenic tomatoes was comparable with wild-type plants under nonstress condition and better under the above-mentioned stress conditions [102].

9.4 From Arabidopsis to Crop

The convergence of research effort in *Arabidopsis* and in other model systems is generating a knowledge base and variety of valuable tools that are amenable to crop research. The main abiotic stresses that adversely affect plant growth and productivity are being extensively studied and include drought, salinity, heat, cold, chilling, freezing, nutrient, high light intensity, ozone, and anaerobic stresses (reviewed in Ref. [18]).

Based on the examples discussed in this chapter, it seems reasonable to anticipate that TF-based technology will be a significant component of near-future agricultural biotechnology products, conferring enhanced intrinsic yield and yield stability under stress conditions. Of course, a detailed understanding of the response of plants to abiotic stress is a prerequisite to the discovery and use of key regulatory molecules to activate a balanced acclimation response that will enhance the tolerance of plants to different stresses. Various strategies can be used to enhance the tolerance of plants to abiotic stress by genetic engineering. Strategies for the use of selected genes in crops include gain- and loss-of-function approaches that target single genes at various levels. However, as discussed in the previous paragraphs, constitutive ectopic expression of these components often causes reduced plant growth, presumably due to an adverse effect of accumulated molecules on cellular functions or energy consumption. The improved tolerance to abiotic stresses could be facilitated during normal stress episodes in the field via the use of tissue-specific or abiotic stress response promoters [103]. Another promising strategy is the use of chemical-specific inducible promoters driving the expression of regulatory factors relevant for stress adaptation. For instance, the improved tolerance to certain abiotic stresses could be triggered prior to the stress event using different chemicals, a strategy similar to the priming used to alleviate biotic stresses. The nonprotein amino acid, β-aminobutyric acid (BABA), a potent inducer in plants against microbial pathogens, was found to increase drought, salt stress tolerance [104], and thermotolerance in *Arabidopsis*. In addition, thiourea treatment coordinately regulates different signaling and effector mechanisms in *Brassica juncea* at an early stage to alleviate stress even under a high degree of salinity [105]. This also indicates the potential of thiourea to be used to impart salinity tolerance under field conditions. Therefore, the same chemical could be used both as an effective bioregulator to impart stress tolerance under field conditions and as an inducer of chemical-specific inducible promoters driving the expression of selected TFs.

Another strategy for optimizing the phenotype is by protein modification. Some transcription factors may be converted to constitutive active forms by deleting the inhibitory domains or changing phosphorylation-accepting amino acid residues to phosphorylation-mimicking amino acid residues (e.g., serine to asparatic acid). In addition, transcription factors may be converted to dominant negative forms either by fusing a repressor domain to the protein (e.g., the EAR repressor domain) [106] or by removing the DNA binding domain when acting in homo- or heterodimeric

complexes [107]. A different approach to introduce specific amino acid changes by point mutation in the coding sequence is the TILLING technology (see Ref. [108] and references therein).

In some cases, stress resistance may also be conferred by gene downregulation. This may be achieved by RNA interference [109], cosuppression [110], or loss-of-function mutants [111–113]. Artificial microRNAs (amiRNAs) may be an alternative strategy to knockdown the expression of specific genes. The major role of short single-stranded RNA molecules (miRNAs) in stress responses has been elucidated only recently and is reviewed in Ref. [114].

To better understand plant stress responses, transcript profiling experiments have been successfully carried out for many abiotic and biotic stresses [115–120]. One common theme emerging from microarray analysis is that the response initially is composed of a core set of multistress responsive genes and becomes gradually more stress specific as time progresses. Significantly, key molecular components of the multistress responsive genes have been shown to be evolutionarily conserved in all organisms [121]. Furthermore, the *Arabidopsis* multistress responsive genes contain in their promoters a DNA motif that is sufficient to confer a rapid response to both biotic and abiotic stresses *in vivo*. This *cis*-regulatory element may be useful for the construction of artificial stress-inducible promoters to drive the expression of specific TFs [120].

Plant acclimation to a particular abiotic stress condition requires a response adapted to the precise environmental condition that the plant encounters [122]. Therefore, it is not surprising that biochemical, physiological, and molecular events triggered by a specific environmental stress are different from those caused by a different set of abiotic factors [123–126]. However, combined abiotic stresses have been reported to cause unpredicted physiological changes in plant cells [122, 127]. Drought and heat stress represent an excellent example of two distinct environmental stress conditions that occur together in the field [122]. When these stresses are applied together, the physiological and metabolic response of plants is unique and cannot be directly extrapolated from the response of plants to drought or heat stress applied individually [125–127]. Transcriptome profiling of *Arabidopsis* plants indicated that the acclimation response involved changes in gene expression, with more than 400 transcripts specifically expressed in plants during a combination of drought and heat stress [126]. Distinct responses were also observed in plants exposed to a combination of heat and high light intensity [128] and heat and salinity [129]. In addition, abiotic stress and ABA responses interact with the defense response against pathogens in a highly intricate manner (reviewed in Ref. [130]).

At this point, it should be evident that physiological knowledge of the processes of abiotic stress tolerance is still developing, and significantly more effort needs to be invested to both complement and guide breeding and genetic manipulation programs. For instance, the root:shoot ratio has been shown to be an important determinant in the ability of plants to respond to environmental stress, and in the field the root systems is a fundamental component in the plant strategy for stress avoidance [131]. The genetic complexity and the difficulty in scoring and selecting traits affecting the development of this organ that grows below the surface of the soil

have made it very complex to breed for improved root systems. Very recently, it has been shown that the root-specific expression of genes encoding cytokin-oxidase (CKX) enzymes in *Arabidopsis* and tobacco allows the production of transgenic plants with an enlarged root system without negative side effects on aerial organs. Interestingly, these CKX transgenic plants showed a higher survival rate after severe drought treatment [132]. Therefore, it would be very interesting to test the performance of CKX transgenic plants experiencing drought stress in the field.

So far, in many studies describing stress tolerance of mutants or genetically manipulated plants, the levels of plant tolerance against a stress were examined only over short periods. Consequently, crops harboring transgenes or mutated genes designed to improve the tolerance to a specific stress might encounter unexpected problems when grown in the field. The plant should be always tested under experimental settings that mimic the various combinations of restrictive conditions that occur in the field [18]. However, these are time-consuming experiments, especially for testing new hypothesis. The multiplicity of stressing environments, difficult to handle, can be better addressed by systems biology approaches [133] owing to the development of models [134–138]. Of course, the final goal would be to understand the molecular mode of action of the whole stress response system of plants.

High-throughput experiments in model plant systems can already provide us with essential, albeit partial, information. Integration of transcript profiling with other multiple "omics" (e.g., metabolic and proteomic profiling) and phenotypic data is required to reconstruct complex networks and to identify key regulatory steps that characterize the response of the plant under changing environmental conditions. However, it is important to point out that to date most of the key components are still unidentified. In *Arabidopsis*, the molecular function, biological process, or cellular compartment of approximately 30% of the genes is known and a further 40% have mere experimental annotations in the *Arabidopsis* database of genetic and molecular biology data (TAIR, www.arabidopsis.org; January 15, 2011). The situation is worse with respect to metabolites, even in the *Arabidopsis* model. Of the estimated 10 000 metabolites in *Arabidopsis* [139], only approximately 1000 have been structurally resolved [140–142]. In addition, it has been shown that abiotic stress induces the accumulation of novel antisense overlapping transcripts [143] and transcripts from transposons or pseudogenes, which are a source of siRNAs [144, 145], implying a role for siRNAs in abiotic stress responses in plants. Recent studies have also shown that abiotic stresses cause long-term regulation of gene expression, mostly conferred by epigenetic gene regulatory mechanisms, for example, chromatin remodeling through various histone modification or DNA methylation processes [146]. Such mechanisms allow organisms to respond to the environment through changes in gene expression patterns that are subsequently retained through mitosis [147].

Nevertheless, modeling strategies can already be used to discover molecular events that result from complex circuit behavior. Recently, a systems biology approach in the *Arabidopsis* model system has been used to strongly improve our understanding of the photoperiodic regulation of flowering time [148]. Recent controlled environment studies have included more complex temperature and photoperiod interactions and

perhaps as a result have uncovered more subtle environment-dependent effects of known flowering time genes [149–151]. Together, these studies have highlighted how a combination of field and controlled environment studies can be used to explore genetic determination of phenological traits and their role in adaptation to environment.

In conclusion, we can predict that sophisticated model-assisted strategies will be applicable to crop research. Models that integrate genetic, molecular, and biochemical information will help understand the complex behavior, such as pathway integration. Models that include the molecular, cellular, whole plant, or field level will show immense potential in crop improvement and crop yield prediction.

9.5 The Genomic Revolution

The comparative approach is central to plant genetic research for both gene isolation and identification of gene function. Similarity in gene sequence between model organisms, in which knowledge is more advanced, and crops has been extensively used in order to identify key genes useful for agronomical and qualitative traits.

During the past 40 years, the study of DNA sequences certainly revolutionized plant genetics and breeding, and, more recently, deep genome sequencing is producing massive amount of information on gene sequences, structures, and functions. Thanks to the modern sequencing technologies, the so-called next-generation sequencing (NGS), the deciphering of complete genomes is advancing with an unprecedented pace, challenging scientists to find new high-throughput methods for gene function studies and to develop dense genetic and physical association maps for breeding.

The first plant genome sequencing was completed in 2000 on the model plant *A. thaliana* [152], by implementing an ordered hierarchical strategy that involved the construction of bacterial artificial chromosomes (BAC) libraries, physical mapping, and establishment of a minimum tilling path constituted by the minimum number of partially overlapped BACs that cover the entire genome. The 150 Mbp *Arabidopsis* genome was a relevant milestone that prompted other research groups to run new plant genome projects. After few years, the 398 Mbp rice genome was completed [153]. These first approaches were implemented by using the classical Sanger method that produces high fidelity large reads and can be robustly automated. These achievements demonstrated that with a good organization, human resources, and enough money, complex eukaryotic genomes could be deciphered in a limited time span. However, sequencing work was quite cumbersome, involving hundreds of scientists, and overall costs were quite high. Despite these limiting factors other plant genomes quickly followed, by using variants of the Sanger method, named whole-genome shotgun, which is based on the random sequencing of different genomic libraries of various sizes, in order to have appropriate genome coverage: poplar tree, grapevine, papaya, sorghum, cucumber, maize, soybean, *Brachypodium*,

peach [154–162] (http://www.appliedgenomics.org/news/pressroom/article/2010/apr/02/welcome-peach-genome/; March 1, 2011).

To overcome the limitations of the Sanger method, new technologies that allow sample high throughputs, require no cloning step, and have lower costs, have been rapidly deployed and are now commercially available. These NGS platforms are able to produce large amount of DNA sequence reads (usually millions of bases) of short lengths ranging between 25 and 500 bp (for comprehensive reviews of NGS, see Refs [163–165].

Present plant genome projects are quickly adopting NGS approaches to gain deep insights into chromosomal structures. Recently, apple genome draft assembly has been accomplished by using a combination of Sanger and Roche 454 sequencing (23× and 51× coverage, respectively) [166]. Assembly covered 80% of the 740 Mbp genome.

The same approach was used to compile the genome of *Theobroma cacao*, an economically important tropical fruit-tree crop that is the source of chocolate. The assembly corresponds to 76% of the estimated genome size and contains almost all previously described genes, with 82% of these genes anchored on the 10 *T. cacao* chromosomes [167]. The first application of a complex genome sequence being completed without the help of the Sanger method has been achieved in oil palm genome. In this case, Roche 454 sequencing, using a combination of whole genome and BAC sequencing, was used to produce the 1.7 Gbp genome sequence (http://tinyurl.com/palmgenome; March 1, 2011). A combined Illumina Solexa and Roche 454 sequencing has been used to read the genome of a wild Peruvian cotton species, *Gossypium raimondii* (http://www.monsanto.com/newsviews/Pages/Monsanto-Illumina-Key-Milestone-Cotton-Genome-Sequencing.aspx; March 1, 2011). *De novo* approach with NGS was used to sequence the 240 MBp genome of *Fragaria vesca*, the woodland strawberry, a model plant relative of the cultivated strawberry. The draft *F. vesca*, genome sequenced with a combination of Roche 454, Illumina, and Solid platforms to ×39 coverage was anchored to the genetic linkage map into seven pseudochromosomes [168].

An important effort is taking place in China where the Beijing Genome Institute in Shenzhen (BGI), a high-tech core sequencing facility, in collaboration with other national research institutes, is on the way of sequencing many crop genomes. By using a hybrid strategy that combines 4× Sanger and 68× Illumina Solexa BGI produced more than 96% of the cucumber genome [159]. This achievement was followed by the 50× coverage of the *Brassica rapa* genome by using the Illumina GAII technology.

Several sequencing projects are active at international levels and, given the speed of the sequencing technology developments, it is highly likely that in few years major crop genome sequences will be available to plant scientists and breeders.

The principal advantage of NGS is that their throughputs are much higher than that of classical sequencing. Modern platforms are able to produce more than 100 Gbp compared to the 100 Kb capacity of the Sanger machines [163]. Also, the sequencing cost has dropped dramatically in 10 years from 10,000 $/Mbp to 1 $/Mbp of the last-generation instruments. Although the cost of the NSG technology is now

halving every year, the short reads and the frequent sequencing errors and artifacts pose novel relevant problems in annotation and assembly. Today, the major cost in the production of a complete assembly of a genome sequence lies in the bioinformatics cost, computing power, and in algorithm development and tailoring.

These problems are limiting NGS mostly to resequencing projects, particularly for the discovery of point mutation (SNPs, single-nucleotide polymorphisms) and the development of molecular markers useful for plant breeding. Although it is certainly possible, and sooner than ever before, *de novo* sequencing is still a challenging and expensive effort.

However, it must be stressed that while a complete genome assembly is relevant to address fundamental biological problems, such as the structure and the evolution of plant genomes, for most of the practical implications in plant genetics and breeding, a lot of knowledge can be gathered from not assembled and low-coverage shotgun sequencing by NGS. Using short paired read data from even 1× coverage can help in identifying *in silico* numerous sequences that are similar in relative or model species. By using the sequence, the entire locus can be isolated and characterized by PCR reconstruction approach. By using this straightforward comparative method, new genes and promoters involved in agronomical traits can be isolated in economically important crops. NGS can effectively support the development of molecular markers, directly sequencing the genome of the crop of interest by finding polymorphism that can be associated with genes of interest.

Molecular markers linked to traits of interest can be used in breeding schemes for marker-assisted selection (MAS), speeding up the production of new varieties, allowing breeders to achieve early selection of the trait. SNPs are by far the most prominent markers in plant genetics, thanks to the advancement achieved with NGS (for an exhaustive review, see Ref. [169]). SNP discovery is based on the finding of single-nucleotide differences between sequences. Classically, differences are found either by amplifying time in PCR target DNA regions in different individuals, followed by direct sequencing of fragments, or by using methods that exploit differences in fragment conformation and mobility, such as high-resolution melting (HRM) or single-strand conformation polymorphism (SSCP) analyses. These approaches are time consuming, particularly in genetic mapping studies and population genotyping, where a high number of samples and large screening is required.

The availability of reference genomes in crops allows an efficient *in silico* search for SNP and SSR by resequencing and comparing the diversity in sequences among strains, lines, and genotypes. The large amount of data produced by NGS allows efficient mining of molecular markers [170].

Many plants have large and complex genomes with an abundance of repeated sequences. Many plants are also polyploid. Large genome sizes, an abundance of repeated sequences, and polyploidy typical of many plants present challenges for genome-wide SNP discovery of total genomic DNA using NGS. In fact, making alignment and clustering of short reads generated by NGS platforms is difficult, particularly in the absence of a reference genome sequence. Despite these hurdles, specific strategies can be developed to mine SNPs. For instance, a pipeline platform

was developed and used for genome-wide SNP discovery in *Aegilops tauschii*, the diploid source of the wheat D genome and with a genome size of 4.02 Gb, of which 90% is repetitive sequences. Roughly, 500 000 SNPs were discovered and were dispersed across the entire *A. tauschii* genome [171].

The use of high-density SNPs association maps can be exploited for genome-wide association (GWA) mapping and genomic selection (GS), which will be increasingly adopted for crop improvement and require a large number of genetic markers. By using reduced representation libraries (RRLs), libraries produced by digesting DNA with a common enzyme increasing the coverage probability, from 17 DNA grapevine sample sequence with Illumina Genome Analyzer, 470 000 SNPs were discovered. Among total SNPs, a subset of 9 000 was chosen to design an array able to discriminate genotypes with high efficiency [172].

In a similar work, a total of 7108–25 047 predicted SNPs were discovered in rapeseed using a reduced representation library that was subsequently sequenced by the Illumina sequence-by-synthesis method on the clonal single-molecule array platform. A high-resolution genetic map using 444 recombinant inbred lines was created with 1790 SNP markers [173]. SNPs can also be discovered by interrogating the plant transcriptome. Massively parallel pyrosequencing technology was used to sequence the transcriptomes of shoot apical meristems isolated from two inbred lines of maize using laser capture microdissection (LCM). A computational pipeline that uses the POLYBAYES polymorphism detection system was adapted for 454 ESTs and used to detect SNPs between the two inbred lines. Over 36 000 putative SNPs were detected. Stringent postprocessing reduced this number to $>$7 000 putative SNPs [174]. The exponential development in genome sequencing technology will not only allow whole-genome sequencing to become the standard in marker discovery, mapping, and population genotyping but also help in functional genomics studies by cDNA sequencing to render microarray technology obsolete [164].

9.6
Plant Phenomics: Bridging the Gap between Genomics and Phenotype

In the last decade, we have been immersed in the era of genomics revolution that is radically changing plant biology and breeding. Today, the continuous annotation of plant and crop genomes is providing scientists with an enormous amount of information on genome structure and evolution, with the potential to revolutionize the way new crop varieties are developed in order to fight agriculture and food production problems worldwide. However, digging into genomics and transcriptomics data to extract meaningful information on gene functions requires still intense efforts. The recent fast adoption of NGS technologies is producing daily terabytes of data worldwide that must be analyzed to search for functional meanings. Despite the high throughput in sequence data production, the association of genes with their function is lagging behind. The study of the relationship of specific genes with the measurable characteristics of a plant, that is, the study of the phenotype, is crucial to understand the specific role and function of genes.

The phenotype is a result of the interaction between genes and environmental stimuli. To discover gene function, scientists usually play with these two factors, using mutants of target genes, either naturally available within the genetic diversity of the species or experimentally induced, and growing plants under different specific environmental conditions. Eventually, changes in phenotypes will give clues for the role of the target gene in plant physiological functions or metabolisms.

The genetic strategy involves the generation of knockout, that is, mutants, in which the gene function is disrupted, and gain-of-function mutants, in which the gene is overexpressed by using genetic engineering technologies. The two approaches should give rise to opposite phenotypes, although they often result in no visible phenotypes. On the other hand, the study of phenotype responses to the stressful environment requires the growth of plant under various environmental conditions. In plant breeding, selection schemes are applied in different fields, years, and seasons requiring intense human efforts and often subjective sampling.

The measurement of the phenotype is a time-consuming step characterized by laborious manual sampling and disruptive measurements.

In plant abiotic stress response breeding, reliable phenotyping protocols are extremely important and their poor development has limited the number of success stories available so far [175].

High-throughput plant phenotyping or phenomics, in "omics" term, is evidently becoming the bottleneck in plant biology to close the gap between plant genetics and physiology. This strong demand recently stimulated various research institutions to invest in developing technologies and platforms able to speed up the phenotyping process. The investments started earlier in the private sectors (Cropdesign, Gent, Belgium; Keygene, Wageningen, Holland), and more recently this has been embraced by public research institutions that are developing an international collaboration network (www.plantphenomics.com; March 1, 2011). Large phenotyping platforms are present in Australia, Germany, France, Canada, and Italy, and others are being developed throughout the world [176, 177].

Plant phenomics platforms represent so far an ensemble of technologies that are mainly based on nondestructive image analyses that exploit either the reflectance properties of the incident light on plant tissues or structural and functional features obtained by sophisticated technologies such as MRI and X-ray CT scanning [178, 179]. In a typical robotized experimental lab setup, cameras can be moved to plants [135, 180] or an entire greenhouse can be fully automated with conveyor belts that carry plants to imaging stations. The latter setup is becoming a standard in plant phenomics, being present in several laboratories around the world (CropDesign, Belgium; The Plant Accelerator, Australia; PhenoPhab, Holland; Metapontum Agrobios, Italy; IPK, Germany), and has the advantage of acquiring images from different angles, allowing 3D analyses.

High processing phenotyping is also possible in open field conditions where cameras can be moved over the plants [181] or taking images from long distance [182]. As for other high-throughput technologies, data storage, data management, and high power computing are essential in plant phenomics for the development of a robust approach. A single high-resolution image has the potential to yield a vast set of

phenotypic descriptors, which must be accurately analyzed and meaningful data selected.

Images can be dynamically taken using light at various wavelengths, such as visible (RGB), near-infrared (NIR), and ultraviolet (UV), which will produce reflectance data useful for morphometric and physiological analyses, such as tissue water potential and photosynthesis efficiency. Thermal infrared imaging can be implemented to interrogate plant transpiration rates. All these parameters are particularly relevant to study abiotic stress responses such as drought stress (for detailed review, see Ref. [183]).

A commercially available image capture and analysis system (Lemnatec Scanalyzer 3D) was used to take nondestructive measurements of plant growth and health in 12 *Triticum monococcum* accessions, and the data thereof complemented with chemical and physical analyses, to identify three main components of salinity tolerance [184].

An automated platform for reproducible phenotyping of plant responses to soil water deficit in *A. thaliana* was developed in France [135]. Using this system, nine accessions were grown in four experiments in a rigorously controlled growth chamber equipped with an automated system to control soil water content and take pictures of individual plants.

The simultaneous detection of the reaction of plant growth and chlorophyll fluorescence-related parameters was obtained using a novel approach that combines existing imaging technologies (GROWSCREEN FLUORO). Three different abiotic stress situations were investigated demonstrating the benefit of this approach to distinguish between effects related to (1) growth, (2) chlorophyll-fluorescence, or (3) both of these aspects of the phenotype in *Arabidopsis* and tobacco [180].

Expansive growth of leaves or of reproductive organs, such as silks, is affected by water deficit before any reduction in photosynthesis or root growth. A specific platform, Phenodyn, was set up to perform a genetic analysis of growth and gas exchanges that vary rapidly with environmental conditions in hundreds of maize lines. In particular, authors intended to disentangle the genetic basis of the differences in growth rate and of its responses to temperature, evaporative demand, and soil water deficit [185].

9.7 Conclusions

In the last few decades, extraordinary progress has been made in unraveling the molecular basis of plant responses to the environment. Research from many laboratories has uncovered key regulatory circuits underlying gene expression reprogramming occurring in response to diverse abiotic stresses, to demonstrate the existence of multiple interactions and crosstalks among different signaling pathways, and to identify a core set of multistress responsive genes evolutionarily conserved in all organisms. However, much remains to be done to fully understand the whole stress response system of plants. Major efforts will be needed to expand our knowledge of transcription networks underpinning abiotic stress responses, to

integrate transcriptional control with other levels of regulation, such as noncoding RNAs and chromatin remodeling, to develop experimental settings that mimic the various combinations of environmental stresses occurring in the field. Systems biology approaches will help understand complex plant behavior in a changing environment and will show immense potential in crop improvement and crop yield prediction.

Due to both the complexity of plant stress response mechanisms and the large data sets generated by the "omics" technologies, knowledge transfer into crop breeding still poses big challenges and needs significant efforts in the mining of meaningful information. The characterization of plant phenotypes, useful for variety constitution, represents today the bottleneck of plant biology and the number of known agronomical traits is very low compared to the power of production of NGS and the application potential of genomic sequences.

A bridge between genomics and plant phenotype must be quickly developed in order to fill the gap and meet the increasing world demand for food both in quality and quantity. The recent growth of plant phenomics platforms and initiative at world level indicates that the era of the application of genomics is just starting.

10
Functional Genomics of Drought Tolerance in Crops: Engineering Transcriptional Regulators and Pathways

Bala Rathinasabapathi

Drought stress is a major limitation for crop productivity worldwide, especially in irrigated agriculture. One solution to this problem is the use of cultivars that are tolerant to drought. However, conventional breeding to improve drought tolerance has proven difficult because drought and dehydration tolerance in plants are not fully understood. As a result of research during the past two decades, networks of genes participating in plant adaptations to drought stress have been identified. In this chapter, I present this research progress and indicate the use of specific genes to engineer crops for improved drought tolerance.

10.1
Introduction

Drought stress causes severe devastation to crop productivity worldwide. Economic losses due to the occurrence of a combination of drought and high-temperature stress on crops are enormous. For example, one estimate for economic losses caused by drought and high-temperature stress for a 5-year period (2005–2009) totaled up to US $19 billion in the United States [1].

Because water resources are becoming limited, genetic improvement of crops for increased tolerance to drought has become an important aim in agricultural research. Drought and high-temperature tolerance in plants are complex traits with various interacting components. These include plant adaptations related to cellular tolerance to oxidative, osmotic, and high-temperature stress. Other adaptations relate to physiological features that enhance water uptake by the roots, and adaptations that decrease the loss of water through transpiration. Developmental adaptations related to flowering time and partitioning of biomass between leaves and grain are also important for crop productivity under stress. Some progress has been made by the use of conventional breeding to improve drought tolerance in important crops such as rice [2], corn [3], cowpea [4], and chickpea [5], but the use of recombinant DNA and genomic methods are likely to be crucial in the near future.

Improving Crop Resistance to Abiotic Stress, First Edition.

With the availability of genome sequence data for plants, microbes, and other organisms, and technologies to transfer and express foreign genes in crop plants, metabolic engineering has become an important tool for improving crops for tolerance to drought and high-temperature stress. Much of our current understanding of the genes playing roles in drought tolerance has come from the studies of model species such as *Arabidopsis thaliana* and rice. High-throughput functional genomic tools to assess gene and protein expression in response to stress have greatly contributed to rapid advances in this area. The objective of this chapter is to highlight some of the most successful metabolic engineering attempts in improving drought and high-temperature tolerance in crops by using rice as a crop model and suggest future opportunities with the greatest promise.

10.2
Transcriptional Regulation of Stress Signaling Networks

Upon stress, specific networks of plant genes are upregulated leading to improved plant tolerance to stress. In a metabolic engineering strategy termed "regulon engineering," ectopic expression of specific transcription factors (TFs) at the early part of a signaling cascade is used to upregulate the transcription of a number of genes resulting in stress tolerance [6, 7]. An estimated 1300 TFs are known in rice genome and about 45% are from gene families specific to plants [8]. Ray *et al*. [9] showed that in rice 5611 transcripts were modulated by water-deficit stress conditions [8]. Among about 50 families of TFs, several have been identified to have possible roles in drought-stress tolerance. Members of the zinc finger TFs were upregulated under drought and NAC family transcription factors were upregulated by multiple abiotic stresses such as water deficit, salt, and cold stress [9].

However, constitutive expression of the TFs often results in stunted growth and other developmental problems in the plant [10]. Expression of TFs under stress-inducible promoters such as RD29a, OsNAC6, and HSP101 have eliminated or reduced these problems [10]. Many early studies concentrated on evaluating transgenic plants of model species for stress tolerance under laboratory conditions. These have suggested roles for specific transcription factors in drought tolerance. Recent studies, however, have evaluated transgenic crops expressing TFs under the control of inducible or tissue-specific promoters, under field drought conditions [11–13]. Table 10.1 lists examples for successful regulon engineering to improve drought and high-temperature stress tolerance in rice, although much of the basic information on the transcription factors emerged from studies in the model plant *A. thaliana*.

10.2.1
ABA-Inducible Transcription Factors

The growth regulator abscisic acid (ABA) is synthesized from the C40 carotenoid precursor phytoene [20]. The step that leads to zeaxanthin, catalyzed by β-carotene

Table 10.1 Examples of successful regulon engineering to improve drought stress tolerance in cultivated rice.

Gene	Transcriptional factor	Promoter	Parameters evaluated	References
AtABF3	bZIP	ZmUbi1	Leaf rolling, wilting, photosynthesis	[14]
OsWRKY11	WRKY, Zn-finger	HSP101	Leaf wilting, water loss	[15]

OsNAC10	NAC	GOS2, RCc3	Relative grain yield	[11, 13]
AtHardy	AP2/ERF	35S	Water use efficiency, transpiration, photosynthesis	[17]
OsZFP252; DST	TFIIIA-type Zn finger	35S, LOF	Proline and sugars, hydrogen peroxide	[18, 19]

hydroxylase (BCH), has been shown to be critical for drought tolerance and oxidative stress resistance [21]. Figure 10.1 shows the enzymes participating in ABA synthesis beginning from zeaxanthin [20]. ABA is catabolized via hydroxylation and conjugation to glucose to produce less active forms (Figure 10.1). Although ABA concentration in plants is regulated at multiple levels, upon drought stress induction of 9-*cis*-epoxycarotenoid dioxygenase especially in the vascular tissue has been observed [22, 23]. This step should be a good target for metabolic engineering.

Transcription factors named "ABA-responsive element binding proteins/factors (ABREB/ABF)" are part of a family of basic leucine zipper (bZIP) TFs. Upon ABA signaling, an activated form of AREB/ABF binds to the conserved regulatory *cis*-element sequence ACGTGT/GC to induce gene expression [24]. Several aspects of ABA-regulated gene networks have been elucidated in the last decade. Figure 10.2 shows the gene products known in the ABA signaling network involved in plant tolerance to drought stress. Poly ADP-ribose polymerase (PARP), an NAD-dependent enzyme known to be induced by drought and ionizing radiation [25], mediates a unique posttranslational protein modification by tagging long-branched poly(ADP-ribose) polymers to nuclear target proteins. Silencing of PARP resulted in a broad-spectrum stress resistance partly due to an increase in ABA levels (Figure 10.2), and this strategy has been used in building drought-tolerant transgenic crops [26].

Type 2C protein phosphatases ABI1 and HAB1 negatively regulate ABA response. There are proteins named "regulatory components of ABA receptors, RCARs" that bind to ABI1 and HAB1 [27] that act as ABA sensors. Farnesyltransferase, ERA1, expressed in the guard cells [28], proteins involved in mRNA splicing, export, and degradation such as mRNA cap binding protein ABH1 [29] and Sm-like SnRNP

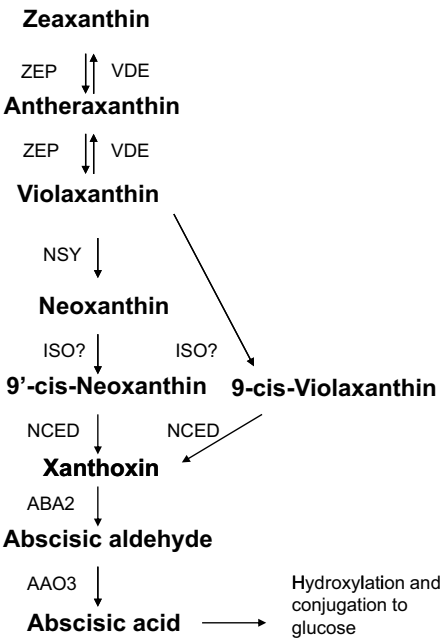

Figure 10.1 Synthesis and catabolism of abscisic acid. The enzymes are ZEP: zeaxanthin epoxidase; VDE: violaxanthin deepoxidase; NSY: neoxanthin synthase; ISO: isomerase; NCED: 9-*cis*-epoxycarotenoid dioxygenase; ABA2: short-chain alcohol dehydrogenase; and AAO3: aldehyde oxidase.

protein, SAD1, are negative regulators of ABA signaling [30]. PYR1 and other ABA receptors PYL1 and PYL2 bind to ABA to inhibit type 2C protein phosphatases, thus controlling SnRK2 kinase activity [30–32]. PYR1's role in negative regulation on ABA signaling was discovered by the use of a synthetic growth inhibitor pyrabactin [33] employing a chemical genetics approach.

Other inhibitory factor DOR, a putative F-box protein interacting with ASK14 and CUL1, is a negative regulator of ABA-mediated stomatal closure [34]. When two negative regulators of ABA signaling were mutated simultaneously [35], the double mutants showed strong hypersensitivity to ABA, and decreased water loss, suggesting this approach to be a way to improve crop performance under drought.

ABA signaling is also regulated via protein modifications and degradations. Isoprenylated proteins contain an isoprenylcysteine methyl ester at the C-terminus. An isoprenylcysteine methyltransferase (ICMT) is a negative regulator of ABA signaling [36]. Recently, an E3 ubiquitin ligase (AIRP1), a cytosolic protein involved in degradation of ubiquitinated proteins, was demonstrated to function as a positive regulator of ABA-dependent response to drought stress [37]. In contrast, E3 ligase KEG (KEEP ON GOING), which ubiquitinates ABI5, negatively regulates ABA signaling [38]. ABA promotes ABI5 accumulation by inducing the ubiquitination and degradation of KEG [39]. A multitude of regulatory controls on ABA-mediated signaling has given a number of new technologies to engineer crops for improved drought tolerance [40].

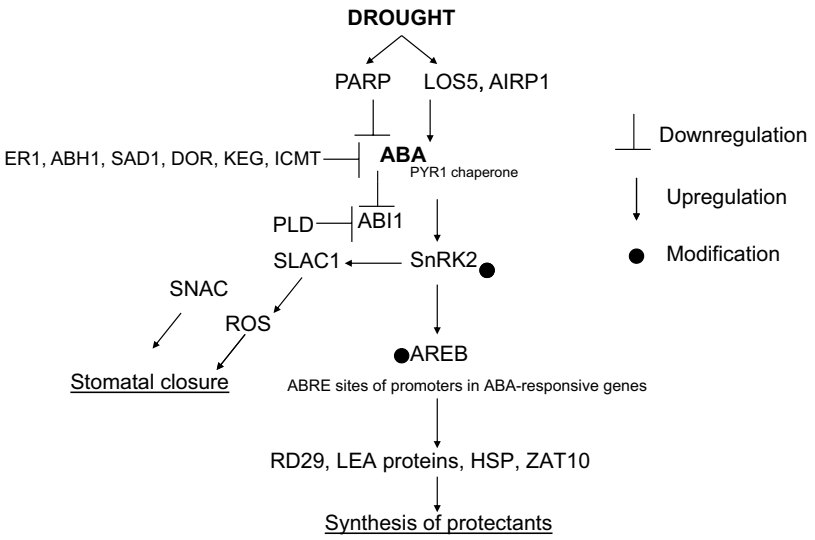

Figure 10.2 ABA-dependent signaling pathway leading to drought tolerance in plants. AIRP1: ABA-insensitive RING protein1; PARP: poly(ADP-ribose) polymerase; LOS5: molybdenum cofactor sulfurase; PYR1: ABA receptor; PLD: phospholipase D; SLAC1: slow anion channel-associated 1; ABI1: type 2C protein phosphatase; ER1: farnesyltransferase β-subunit; ABH1: mRNA cap-binding protein; ICMT: isoprenylcysteine methyltransferase; SAD1: Sm-like SnRNP protein; SnRK2: kinase; AREB: ABA-responsive element binding protein; LEA: dehydrin; HSP: heat shock protein; ZAT10: salt tolerance zinc finger; RD29A: responsive to desiccation 29A.

However, antagonistic crosstalk between ABA signaling and systemic acquired resistance (SAR), mediated by salicylic acid [41], suggests that protecting crops from drought stress damage via modulating ABA-signaling could have unintended consequences on crop tolerance to biotic stress. More research is needed to examine this point.

10.3
ABA-Independent Signaling Networks

10.3.1
NAC Transcription Factors

Plants also regulate stress tolerance-related genes via ABA-independent pathways. Figure 10.3 shows the gene products involved in ABA-independent response to drought stress. NAM, ATAF, and CUC (NAC) transcription factors contain a highly conserved N-terminal DNA binding domain and a variable C-terminal domain [42]. Stress-related NAC TFs (SNACs) belong to group III, phylogenetically distinct from four other groups [43]. Specific NAC TFs induced by stress were identified in different plant species. SNAC1 in *Arabidopsis* is expressed in the stomata. Transgenic crops overexpressing SNAC1 protein had improved tolerance to drought [11].

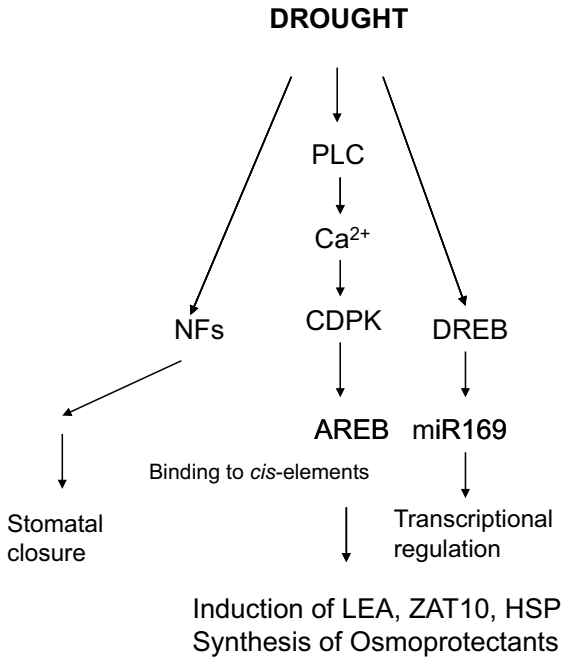

Figure 10.3 ABA-independent signaling pathway for drought stress tolerance. PLC: phospholipase C; CDPK: Ca-dependent protein kinase; AREB: ABA-responsive element binding protein; DREB: dehydration-responsive element binding; SNAC: stress-responsive NAC; miR169: microRNA169; NFs: nuclear factor Y proteins.

10.3.2 DREB/CBF Transcription Factors

Yamaguchi-Shinozaki and Shinozaki identified TFs that are induced by drought but are not under ABA control. Some of these ABA-independent TFs (DREB1/CBF) are involved in cold tolerance and DREB2 (dehydration-responsive element binding 2) is important in drought tolerance [24, 43]. DREB2s interact with a *cis*-acting DRE/CRT (C-repeat) sequence to activate the expression of downstream genes. Overexpression of DREB2-type transcription factors has been used as a strategy to achieve improved tolerance to drought in many crop species [43–46]. In rice, and in other cereals, two types of transcripts of DREB2B – active and inactive – are produced by alternative splicing. Upon stress, the relative amounts of active transcripts increase, likely by a regulation on the splicing machinery [46].

MicroRNAs are small noncoding single-stranded RNAs that regulate gene expression by target mRNA cleavage and translational repression. Zhao *et al.* [47] showed that in rice miR-169g was the only member induced by drought in the miR-169 family [47] and they suggested that miR-169g could transiently inhibit NF-YA transcription factor [48].

Although manipulation of TFs would continue to be an important strategy for achieving drought-tolerant plants, its limitation in its present form would be that only a level of stress tolerance already available within the species could be achieved. While further intricate details on the roles of genes involved in these stress regulatory pathways will continue to emerge, we also need studies searching for structural genes involved in pathways leading to stress tolerance in naturally stress-tolerant species. Future metabolic engineering strategies should combine the manipulation of transcriptional network and introduce novel pathways from stress tolerant species.

10.4
Pathways for Osmoprotectant Synthesis

Many plants synthesize small molecules in response to stress. Osmoprotectants are compatible solutes usually derived from amino acids and sugars. Amino acid proline; the quaternary ammonium compounds glycine betaine, proline betaine, and β-alanine betaine; sugar alcohols mannitol, sorbitol, and trehalose; and raffinose family oligosaccharides have been identified as osmoprotectants in plants [49]. Accumulation of osmoprotectants could have multiple benefits for the plant including osmotic adjustment, turgor maintenance, and protection of proteins, DNA, and membranes from damage by stress [50]. A series of studies on engineering plants for glycine betaine overproduction has identified constraints in the availability of the precursor choline and its import into chloroplasts [51]. Engineering plants for overproduction of glycine betaine has resulted in plants with improved drought tolerance [52, 53]. In another study, simultaneous stress-inducible expression of choline oxidase (for glycine betaine synthesis) and superoxide dismutase and ascorbate peroxidase (to improve oxidative stress tolerance) resulted in transgenic potato plants with increased tolerance to drought [54]. In *Arabidopsis*, raffinose family oligosaccharides galactinol and raffinose may function as osmoprotectants against drought stress [55] and oxidative damage [56]. Transgenic plants overexpressing DREB genes had increased levels of proline suggesting that proline synthesis may be under the control of DREB. A comparative functional genomics study on maize genotypes differing in drought tolerance concluded that sugar synthesis, sugar transport, and cell injury prevention are key factors in determining drought tolerance [57]. Studies are needed to link the signaling pathways for stress to understand how osmoprotectant synthesis, accumulation, and degradation are regulated both at the transcriptional and at the translational levels.

10.5
Transporters

Drought stress tolerance can be improved if solute concentration in the vacuole could be increased, thus favoring water uptake. Apse *et al.* [58] reported a strategy to increase

the activity of a vacuolar sodium/proton antiporter, thus improving plant tolerance to salinity stress [58]. Similarly, when the activity of H + pump on the vacuolar membrane (vacuolar H + pyrophosphatase) is increased, the plants gain improved tolerance to both salinity and drought [59]. This strategy has now been applied to improve drought tolerance in a number of crops including cotton [60, 61] and maize [62].

Aquaporins (or major intrinsic proteins, MIPs) facilitate water transport over cellular membranes. In plants, they occur as a family of 30–35 proteins classified as tonoplast intrinsic proteins (TIPs), plasma membrane intrinsic proteins (PIPs), NOD26-like intrinsic proteins (NIPs), and small basic intrinsic proteins (SIPs). In *A. thaliana*, many of them were downregulated by drought stress at the transcriptional level, but two PIPs whose promoters had drought stress response elements were upregulated [63], suggesting these two PIPs with possible roles in drought tolerance. Constitutive overexpression of PIPs in transgenic plants improved vigor under favorable growth conditions, but not under drought or salt stress [64]. More research is needed to engineer stress-regulated PIPs.

10.6
Combination of Drought and High-Temperature Stress and Oxidative Stress

In the field, drought often occurs together with high-temperature stress. The biology of the combination of these two stress factors on plants has not been examined at the molecular level, although it is well known that both drought and high-temperature stress induce oxidative damage. Ectopic expression of single transgenes involved in osmoprotection or oxidative stress tolerance has resulted in plants with improved tolerance to high-temperature stress [65, 66]. Plant breeders have recognized that genotypes that are resistant to oxidative stress are also resistant to drought and high-temperature stress [67], providing a correlating evidence for the importance of oxidative stress tolerance. Functional genomic studies on naturally dehydration tolerant species and the effects of simultaneous application of drought and high temperature on plants have revealed key roles for antioxidant enzymes in both drought and high-temperature stress tolerance [68, 69]. Future work is needed to identify differences, similarities, and overlaps between signaling pathways leading to high-temperature stress and those leading to drought tolerance.

10.7
Conclusions

Although *Arabidopsis* and model crop rice have contributed to our understanding of how plants adapt to drought and high-temperature stress, time is ripe for beginning functional genomic studies on species that are naturally tolerant to stress. Wild relatives of major crops could be a starting point [70], although they have not been used extensively in conventional breeding. Drought tolerance has been identified in wild emmer (*Triticum dicoccoides*) [71], certain barley genotypes from Tibet [72], wild

Oryza spp. and accessions of cultivated rice [73], and pearl millet (*Pennisetum glaucum*) [74]. Analysis of orthologues of *Arabidopsis* and rice genes with key roles in drought stress tolerance pathways in these wild grasses should be useful both to uncover novelties and to improve cereal crops for drought tolerance.

Understanding drought tolerance in plants is a long-term goal as this is a valuable but complex trait. Genome sequences, high-throughput technologies such as microarrays, metabolomics, and proteomics have provided us unprecedented tools with capabilities to identify genes and gene products with potential roles in drought tolerance. However, functional tests on specific genes using mutant and overexpression lines are still laborious and time consuming. To facilitate these tests, new rapid technologies to create and analyze stable transgenic lines in major crops are needed. Despite that, as illustrated above, transgenic crops improved for drought tolerance with great promise are tested under field conditions and perhaps represent the first steps toward our next green revolution.

Transcriptomic and Metabolomic Approaches to the Analysis of Plant Freezing Tolerance and Cold Acclimation

Dirk K. Hincha, Carmen Espinoza, and Ellen Zuther

Freezing tolerance is an important trait in plants because it limits the geographical distribution of wild species and the growth performance and yield of crop plants. Plants from temperate climates are able to increase their freezing tolerance by a process called cold acclimation. This process is driven by a complex reprogramming of the plant transcriptome and metabolome. In the last decade, several transcript and metabolite profiling studies on the model species *Arabidopsis thaliana* and on crop plants and trees have been reported. These studies point not only to many molecular changes during cold acclimation that are common to most or all investigated species but also to more species-specific changes. In addition, some profiling studies allow a first estimate of the relative importance of transcriptional regulation compared to translational and posttranslational regulation of plant metabolism in the cold.

11.1
Introduction

Cold has a major influence on plant growth and survival, limiting the geographical distribution of natural species and the yield and growing season of agricultural crops. Considerable effort has, therefore, been directed toward understanding how plants respond and adapt to low temperature. While plants of tropical or subtropical origin are sensitive to low temperatures above the freezing point (chilling sensitive), plants adapted to cooler climates are chilling resistant. Even at temperatures below 0 °C, they show damage only when their tissues freeze, that is, after ice crystallization has occurred. Freezing damage is therefore in general not a consequence of low temperatures *per se* but rather the result of cellular dehydration brought about by extracellular ice crystallization (see Refs [1–3] for reviews). The major sites of freezing injury in plants are the cellular membranes. There is extensive evidence for damage to the plasma membrane [1, 4], to chloroplast thylakoid, and to envelope membranes during a freeze–thaw cycle [5–7]. However, it can be expected that other cellular membrane systems are also damaged by freezing, and inactivation of sensitive enzymes cannot be excluded, although evidence to this effect is still lacking.

Improving Crop Resistance to Abiotic Stress, First Edition.

Freezing tolerance can differ strongly depending on the thermal history of the plants. Nonacclimated tolerance denotes the capacity to survive a freezing event without prior adaptation. Acclimated tolerance is usually higher and reflects the ability of many plant species from temperate climates to increase their freezing tolerance in response to low but nonfreezing temperatures. Subzero acclimation can lead to an additional increase in freezing tolerance after cold acclimation when plants are exposed to a mild, nondamaging frost. The molecular basis of nonacclimated tolerance is poorly understood although it has been reported that it may be genetically determined by loci independent of acclimated tolerance in potato [8], willow [9], and oilseed rape [10, 11]. Equally, while subzero acclimation has been repeatedly described, mainly in cereals [12–16], and also in the model plant *Arabidopsis thaliana* [17, 18], no large-scale profiling or genetic mapping studies have been published in this area and no key genes or metabolites have yet been identified.

Using the barley Affymetrix microarray [19], the gene expression of wheat was compared under nonacclimated, cold acclimated, and subzero acclimated conditions [12]. Up to now this is the only transcriptomic study of subzero acclimation, which, however, suffers from the restrictions inherent to cross species microarray hybridization, in particular with arrays that use short oligonucleotides for hybridization. Nevertheless, this study did clearly show that the additional freezing tolerance obtained during subzero acclimation is the result of complex biological processes that, at least at the level of gene expression, are clearly different from cold acclimation. In the future, more comprehensive studies will be necessary to draw firm functional conclusions for the understanding of subzero acclimation.

In contrast, cold acclimation is well studied in a large range of both wild and crop plant species and involves a wide array of metabolic changes governed by extensive reprogramming at the level of gene expression. Consequently, this chapter will focus on transcriptomic and metabolomic studies of cold acclimation and the associated increase in freezing tolerance.

The degree of freezing tolerance differs vastly between plant species, from around $-1\,^{\circ}C$ to $-2\,^{\circ}C$ in some tender plants such as tobacco [20] to the temperature of liquid nitrogen ($-196\,^{\circ}C$) in some hardy trees and shrubs [21–23]. In addition, most plants from temperate climates follow an annual cycle of acclimation and deacclimation, with their maximum freezing tolerance in winter and the minimum during summer.

In herbaceous plants, acclimation is triggered by exposure to low, nonfreezing temperatures, usually in the range between 10 and $0\,^{\circ}C$ over several days and increases the freezing tolerance in different species by approximately 2–25 °C [4, 22, 24–27]. In woody species, photoperiod is an additional determinant of acclimation, with a combination of low temperature and short days inducing the highest freezing tolerance [28, 29]. The freezing tolerance of cold acclimated plants is a multigenic and quantitative trait. From QTL mapping studies in various species [9–11, 30–37], it is obvious that many genetic loci contribute to the freezing tolerance of any given species and that the loci differ even between different mapping populations within a species. In addition, it has recently been shown that there is large variation in the freezing tolerance of different geographical populations (accessions) within a single species (*A. thaliana*; [25, 38–40]). Such natural

genetic variation, which is also present, for example, in breeding lines and cultivars of crop species, is an excellent basis to study the molecular mechanisms underlying complex quantitative traits [41, 42].

The genetic complexity of plant freezing tolerance is reflected in the complex physiological and biochemical changes associated with cold acclimation in plants. These changes are extensive and include growth and water balance, the accumulation of compatible solutes, changes in membrane and cell wall composition, increased antioxidant production, and changes in gene expression and protein levels (see Refs [1–3, 43] for reviews).

Especially low-temperature signal transduction and the resulting regulation of cold-responsive gene expression have received much attention in recent years. The main breakthroughs in this area have come from molecular genetic studies in the model plant species *A. thaliana* and this field has been reviewed repeatedly (e.g., [44–48]). Forward and reverse genetics have defined some of the key regulatory components of cold acclimation in *Arabidopsis*. A prominent role has been demonstrated for the *C-repeat binding factors (CBF) 1*, *2*, and *3* [49], which are also known as *dehydration-responsive element binding1 (DREB1)b*, *c*, and *a* (At4g25490, At4g25470, At4g25480), respectively [50]. These AP2/ERF type transcription factors are rapidly induced in response to cold and reach a peak of expression after 2–3 h of exposure to cold [38, 49–51]. The CBF proteins, in turn, activate the expression of a set of target genes by binding to a core sequence in their promoters, called the C-repeat (CRT), the dehydration-responsive element (DRE), or the low-temperature response element (LTRE), which is involved in cold responsiveness [52, 53]. Genes containing this motif have been denoted as *COR* (cold-regulated), *(E)RD* ((early) responsive to dehydration), *KIN* (cold-induced), or *LTI* (low-temperature-induced) genes, and are collectively referred to as the "CBF regulon." It has been estimated that 12–20% of all cold-induced transcriptional changes in *Arabidopsis* are accounted for by the action of CBF1–3 [54]. Moreover, it has been found that overexpression of any individual *Arabidopsis CBF* gene leads to constitutive expression of CBF regulon genes and an increase in freezing tolerance without cold exposure [51, 55, 56].

The overexpression of *CBF* genes induces many cold-regulated downstream genes and increases the contents of metabolites under nonacclimating conditions that also accumulate in response to cold [55, 57–59]. The overexpression studies also indicated that the activities of the three transcription factors might be functionally redundant [55]. There is, however, evidence for negative regulation among the *CBF* genes. Analysis of a *CBF2* null mutant in the *Arabidopsis* accession Col-0 indicated that CBF2 might negatively regulate *CBF1* and *CBF3* expression [60, 61]. A recent analysis of the expression of the *CBF* genes in RNAi lines, generated to downregulate the expression of all three genes in different accessions, however, indicated that this regulatory function of CBF2 was evident in Col-0, but not in several other accessions [34], indicating that mechanisms of gene regulation may differ between accessions of the same species.

Reduced *CBF3* expression in the *ice1* mutant was associated with enhanced *CBF2* expression after 6–12 h of cold treatment [62], pointing to a possible compensatory

effect. *Inducer of CBF expression 1* (*ICE1*) encodes a MYC-like bHLH transcriptional activator that is not cold induced at the transcript level and acts upstream of the *CBF* genes enhancing specifically *CBF3* expression in the cold [62]. In addition, ICE1 also seems to be involved in stomatal differentiation [63] through a presumably unrelated signal transduction pathway. In the *ice1* mutant, several genes in the CBF regulon are no longer cold induced [64]. *High expression of osmotically responsive genes 1* (*HOS1*), encoding a RING finger motif protein, negatively regulates the *CBF* genes [65] by mediating ubiquitination and degradation of ICE1 [66], while the presence of the SFR6 (sensitive to freezing 6) protein, which is itself also not strongly cold induced, is required for the induction of downstream genes through an as yet unknown mechanism [67]. CBF-dependent roles in freezing tolerance have also been demonstrated for *low expression of osmotically responsive genes 1* (*LOS1*), a translational elongation factor 2 gene, whose product is involved in protein synthesis in the cold [68] and for *LOS4*, a gene encoding a DEAD box RNA helicase that is essential for mRNA export [69]. In addition, *ZAT12* was shown to downregulate the expression of the *CBF* genes and to have a cold-responsive regulon that partially overlaps with that of CBF2 [70]. While the CBF-related signal transduction pathway is by now fairly well characterized, it should not be forgotten that it does not regulate more than approximately 20% of all cold-regulated genes [54]. It has, for instance, been suggested that the gibberellin-regulated DELLA proteins [71] not only function in reducing plant growth in the cold but also directly contribute to cold acclimation through a mechanism that does not involve the CBF regulon [72]. Other regulators that function independent of the CBFs, such as ESK1 (eskimo1) [73], are not as much studied. Clearly, the transcriptional regulation of cold-responsive gene expression is complex and still only partly understood.

CBF genes, however, appear to be ubiquitous in plant species and are almost always present as gene families. In *Arabidopsis*, there are four characterized *CBF* genes, *CBF1*, *2*, and *3*, located in a tandem array on chromosome 4, are cold induced, while *CBF4* is reported to be involved in drought tolerance [74]. Homologues have been described in many species including wheat, rye, and *Brassica napus*, all of which can acclimate, and even in tomato, which is chilling sensitive [75, 76]. Some species have large *CBF* gene families, for example, barley, which has at least 20 family members [77] of which, however, only a part is cold induced [78]. *CBF* homologues are also present in tree species including poplar [79] and Eucalyptus [80].

During cold acclimation, not only is the plant transcriptome massively remodeled but also are many of these changes in gene expression reflected in biochemical and physiological changes that include increases in the cellular concentration of many metabolites such as sugars and amino acids, which are thought to contribute to the increased freezing tolerance. Such metabolites are generally referred to as osmolytes or compatible solutes.

Compatible solutes are synthesized by many organisms ranging from bacteria to animals and plants, in response to desiccation, osmotic stress, salt stress, or low temperature. This chemically heterogeneous group of substances comprises some amino acids (e.g., proline), quaternary ammonium compounds (e.g., glycine-betaine),

many sugars, sugar alcohols, and several others (see Refs [81, 82] for reviews). Physiologically compatible solutes should have no adverse metabolic effects even at very high concentrations. They are thought not only to stabilize sensitive cellular components such as enzymes and membranes under stress conditions but also to act as bulk osmoprotectants. Therefore, they may act colligatively by increasing the osmotic potential and thereby improving the water status and increasing the cell volume in the frozen state. In addition, they can stabilize macromolecular structures such as proteins by preferential exclusion from the hydration shell of proteins [83], assist refolding of unfolded polypeptides by chaperone proteins [84], and stabilize membranes during freezing and drying [85, 86]. Of particular interest in the context of plant freezing tolerance are raffinose family oligosaccharides [87], fructans [88], proline [89], and glycine-betaine [90, 91]. For example, proline, one of the most studied amino acids in cold acclimation, is able to protect enzymes and other proteins from denaturation during freezing [92, 93]. Photosynthesis can also be affected by oxidative stress-induced damage of photosystems [94]. Sugars can act as ROS scavengers. For instance, ROS-dependent photoinhibition of PSII can be reduced by the accumulation of galactinol and raffinose in transgenic plants [95].

The biochemical, physiological, and genetic studies that have been briefly reviewed above have tremendously advanced our understanding of freezing tolerance and cold acclimation. But since they are usually targeted at specific groups of substances or particular biosynthetic or signal transduction pathways, they will not reveal the whole gamut of the regulatory and metabolic networks that respond to low temperature. The coordinate responses of these networks, however, will ultimately determine the level of freezing tolerance attained by a specific genotype and therefore, for example, the winter survival of a particular cultivar of a crop plant species. The substantial technical advances in the fields of transcript and metabolite profiling technologies over the years have enabled researchers to study plant–environment interactions and adaptation with a much wider scope. High-quality microarrays that cover (almost) all genes in a genome are not only available for model plants such as *A. thaliana* and in addition the recent development of next-generation sequencing methods [96] now enables full transcriptome analysis even for species with very little or no genome sequence information, such as resurrection plants [97].

It is implicit in the interpretation of most transcript profiling studies that the amount of a specific mRNA is quantitatively related to the amount of the encoded protein, its biochemical activity, and its effect on the physiological phenotype. This, however, is an oversimplification and a complete description of the environmental adaptation of a plant such as cold acclimation will require not only an analysis of the abundance of transcripts and metabolites but also information on translation, protein abundance, posttranslational modifications of proteins, protein–protein interactions, and enzyme kinetics, preferably at tissue or cell-type resolution. However, only transcript abundance and the content of central metabolites have been analyzed in sufficient detail until now in profiling studies to draw more general conclusions. Proteomic studies of cold acclimation have been reported less frequently and the number of identified proteins is still comparatively low [98–104]. Only a single

profiling study has so far suggested a link between secondary metabolism and plant freezing tolerance [105].

11.2
Transcriptomic Studies of Plant Cold Acclimation

During the last decade, the analysis of low-temperature-driven changes in the transcriptome of *Arabidopsis* has come into the focus of many research groups, especially after the first description of the CBF signal transduction pathway and the CBF regulon [58]. Around 200 cold-responsive genes could be identified by traditional approaches such as the differential screening of cDNA libraries and Northern blotting (see Ref. [54] for a compilation), but since expression profiling technologies became available, this list has dramatically expanded [25, 54, 106–110]. Furthermore, gene expression profiling technologies have been used to characterize regulatory pathways, including the CBF signal transduction pathway [62, 64, 70, 111]. In some studies, the effects of low temperature were compared with the effects of other abiotic stresses [107, 109, 112], indicating overlapping transcriptional responses to drought, salinity, cold, and abscisic acid (ABA). In addition, gene expression profiling was also combined with metabolite and enzyme activity profiling [25, 113–115] to gain more information on downstream effects of changes in gene expression on metabolic regulation.

Also, the transcriptomic cold responses of crop plants such as wheat [12, 77, 116–118], barley [119, 120], and blueberry [121], as well as those of trees such as poplar [122], Scots pine [123], and Sitka spruce [124] have been investigated during the last years. Most microarray data sets are publicly available, for example, at http://affymetrix.arabidopsis.info/, http://www.arabidopsis.org/portals/expression/microarray/ATGenExpress.jsp, and http://www.ncbi.nlm.nih.gov/geo.

11.2.1
Cold-Responsive Genes Identify Cold-Regulated Pathways in Arabidopsis

In the first microarray study of *Arabidopsis* cold acclimation (4 °C for up to 7 days), 306 cold-responsive genes were identified, 218 up- and 88 downregulated, using an Affymetrix array that represented approximately 8000 genes, or less than one-third of the genome [58]. By extrapolation, it was estimated that around 4% of the genome was responsive to low temperature and this estimate was confirmed by a subsequent study [64]. Five hundred and fourteen genes (302 up- and 212 downregulated) were considered as a cold-responsive core set using the Affymetrix ATH1 array containing probe sets for approximately 24 000 *Arabidopsis* genes [70]. Different growth conditions, experimental treatments, and criteria for determining differential gene expression (i.e., different fold-change cutoff values and/or *p*-values from statistical tests with or without multiple testing corrections) resulted in different numbers and identities of cold-responsive genes identified in various

microarray experiments. A comprehensive statistical analysis of gene expression data available at that time [54] indicated that 45% of all transcripts, including genes with small but statistically significant changes in expression, respond to low temperature, in a marked contrast to the previously published estimates of 4 [58] or 14% [107].

When the data were separated into short-, medium-, and long-term responses to low temperature, 808, 1224, and 672 genes were found to be upregulated and 240, 1364, and 915 downregulated in different response categories [54]. In general, differentially expressed genes were divided into two groups, either encoding proteins that presumably directly protect plant cells from freezing damage or that are involved in signal transduction and the regulation of gene expression [125, 126]. Late-embryogenesis abundant (LEA) proteins, enzymes catalyzing the biosynthesis of compatible solutes, antifreeze proteins, chaperones, proteases, enzymes for detoxification of reactive oxygen species (ROS), and lipid desaturases belong to the first group, whereas the second group includes transcription factors, protein kinases, and phosphatases; phospholipases and enzymes involved in phosphoinositide metabolisms; and enzymes involved in the synthesis and degradation of plant hormones [109, 111, 125, 127].

Upregulated genes after exposure to low temperature include the *CBF* transcription factor family and the genes belonging to the CBF regulon [58]. Meta-analysis of available microarray data sets revealed that approximately 15% of all cold-regulated genes and 23% (478 genes) of the upregulated genes are members of the CBF regulon [54], significantly extending earlier estimates of 12% [58] or 38 genes [111]. In the CBF regulon are 41 known or putative transcription factors, mainly from the AP2/EREBP, CO-like, and C2H2 families [54], indicating the complexity of the regulatory pathways downstream of the CBFs.

Approximately, 80% of the cold-responsive genes are not under the control of the CBF transcription factors, indicating the importance of additional regulatory pathways during cold acclimation [54, 128]. Long-term upregulated genes include several known or putative transcription factors (*ZAT12*, *RAV1*, *AtMYB73*, *ATHB-12*, H-protein binding factor 2a, *RAP2.1*, a zinc finger protein, and *RAP2.7*, *ZAT10*, *COL1*, and members of the NAC and basic leucine zipper (bZIP) families) [54, 58, 64, 128]. ZAT12 is a negative regulator of *CBF* expression and its target genes partially overlap with the CBF2 regulon [70]. These transcriptional regulators that are persistently induced under low-temperature conditions might be responsible for maintaining the cold acclimated status. Several genes encoding transcription factors are downregulated as a short-term response to low temperature [58]. However, the fraction of downregulated transcription factor-encoding genes compared to the total number of downregulated genes was much smaller than the corresponding fraction among upregulated genes [64]. Transcription factors of the Aux/IAA and the bHLH families were overrepresented among long-term downregulated genes [54].

Genes encoding protein kinases and phosphatases represented a large group among cold-regulated genes, and in addition the identification of eight upregulated and one downregulated gene encoding enzymes involved in phospholipid signaling

underscores the importance of phospholipid second messengers in cold signaling [64].

At least 55 genes encoding proteins with known or proposed protective functions are cold induced [2, 54]. Many of these proteins can be classified as LEA proteins [129] or hydrophilins [130], showing high hydrophilicity and, in the case of the hydrophilins, a high glycine content.

Another well-known response to low temperature is the accumulation of compatible solutes, such as sugars and proline [131]. Upregulated genes, for example, *P5CS2* and *AtGolS3*, encode parts of the proline and raffinose biosynthesis pathways. Proline synthesis was found to be induced at temperatures below 14 °C, and only a small decrease in temperature was sufficient to induce genes encoding raffinose biosynthesis enzymes [114]. Transcript levels of genes encoding galactinol synthase and raffinose synthase also increase during cold acclimation [113]. During a mild temperature reduction, genes encoding enzymes for sucrose synthesis are cold induced, while genes responsible for sucrose and starch breakdown are repressed [114]. Under short-term cold acclimation conditions, on the other hand, genes encoding enzymes for sucrose and starch degradation (e.g., β-amylase) are upregulated, while in the medium to long term, sucrose degradation by invertase and starch degradation are downregulated [54]. In addition, only one sucrose synthase gene showed a transient increase in expression, but sucrose phosphate synthase transcript levels were generally increased, while transcript levels for sucrose phosphate phosphatase were unchanged [113]. A general increase in the expression of genes encoding enzymes of the TCA cycle was also reported during cold acclimation [54].

After a short-term cold stress, a significant upregulation of genes encoding transport proteins, including ATP binding cassette, sugar and phosphate transporters, and ATPases was found [54, 58]. After a long-term rearrangement of carbohydrate metabolism, sugar transport seems to become less important as indicated by downregulation of genes encoding sugar transporters [54].

The production of reactive oxygen species is induced under cold conditions and the induction of genes encoding ROS scavenging proteins was described after exposure of *Arabidopsis* to low temperature [110]. Likewise, nuclear genes encoding the thylakoid membrane localized early light-inducible proteins (ELIPs) are among the most highly induced genes during cold acclimation [58, 107]. They are thought to function as protectors against photooxidative damage. Enhanced freezing tolerance upon cold acclimation was also connected with the concerted induction of the genes encoding enzymes involved in flavonoid metabolism [25], including the transcription factors PAP1 and PAP2 that are known to regulate this biosynthetic pathway. Flavonoids are also well-known antioxidants [132, 133].

In the cold, growth is reduced and central metabolism is adjusted accordingly. This reduction in growth is an active process that involves the downregulation of photosynthesis-related genes and genes encoding proteins involved in transcription, signaling, and cell wall biogenesis [109]. Downregulation of photosynthesis-related genes is not a main factor in the early response to cold [64] but becomes more important as a medium and long-term adaptation [54], involving also aspects

such as tetrapyrrole synthesis and light signaling. Changes in the expression of photosynthesis-related genes might also reflect adaptations to the low light conditions used in most cold acclimation experiments to prevent photoinhibition [54]. However, a correlation with freezing tolerance also suggests more direct adaptive benefits [25].

Light is a prerequisite of increased freezing tolerance during cold acclimation [134] and it increases the amount of transcripts of cold-responsive genes. The combination of light and cold induces specific genes important for the development of freezing tolerance [110]. A cold treatment in the light induced twice as many genes, including several transcription factors, than a cold treatment in the dark. Two genes encoding AP2 domain transcription factors and novel zinc finger, MYB and NAC transcription factors, are significantly upregulated under cold/light conditions compared to a cold/dark treatment. Cold/light treatment also causes the specific induction of ABA biosynthesis genes, genes encoding enzymes necessary for scavenging of reactive oxygen species, for protection of membranes, and for modulation of the electron transport chain in the thylakoid membrane [110].

The downregulation of genes related to lipid metabolism, such as those encoding enzymes involved in fatty acid biosynthesis and elongation, synthesis of phospholipids and steroids/squalene and lipid degradation by lipases and lysophospholipases [54] could also be related to reduced growth. However, this could also reflect the regulation of processes involved in altering membrane lipid composition, such as the frequently observed increased unsaturation of fatty acids in membrane lipids in response to low temperatures [3, 4, 135].

The functional group of genes related to hormone metabolism is overrepresented among downregulated genes after both long- and short-term low-temperature treatments. The downregulation of auxin transport and auxin-responsive genes can be interpreted as a contribution to reduced plant growth in response to cold [54, 64]. In addition, downregulation of brassinosteroid (BR)-responsive genes and of genes related to BR biosynthesis could also play a role in controlling the reduction of growth in response to low temperature [54].

All data discussed above were obtained from either leaf tissue or whole *Arabidopsis* rosettes. The cold responses of roots, in contrast, are much less well studied. An investigation of gene expression under various stress conditions including low temperature revealed that roots and leaves display significantly different transcriptional responses [107], with less than 14% of the cold-specific changes shared between roots and leaves. These results are in agreement with the fact that roots are generally considered to have a much lower capacity for cold acclimation than leaves.

11.2.2
Transcriptomic Responses to Low Temperature in Nonmodel Species

Perhaps not very surprisingly, there is a large overlap between genes identified as cold regulated in *Arabidopsis* and in the few studied nonmodel species. A remarkable similarity between genes that have been reported to be cold regulated in *Arabidopsis*

and wheat have, for instance, been reported from a transcriptomic analysis of the cold responses of winter and spring wheat [118]. A possible link between the signal transduction mechanisms during cold acclimation in dicots and monocots was suggested from the increased expression of one of the *PHYA*-like genes in wheat, while the other *PHYA*-like and the *PHYB*-like genes were downregulated. Similarly, phytochromes have been suggested to be involved in the upstream regulation of cold acclimation in *Arabidopsis* [79]. Several recent studies on gene expression of trees under cold conditions show that herbaceous annual and woody perennial plants also share cold acclimation mechanisms and cold-regulated genes [136].

In all investigated species, carbohydrate metabolism-related genes were induced in the cold, including galactinol, raffinose, and sucrose synthases, galactosyltransferases, and genes encoding enzymes involved in starch breakdown [117, 121, 122, 124]. In addition, the downregulated autumn transcriptome in Sitka spruce pointed to a redirection of resources from photosynthesis to stress response during cold acclimation [124], similar to the downregulation of photosynthesis-related genes in *Arabidopsis*, described in more detail above. These common changes will not be discussed separately again for different species.

11.2.2.1 **Cereals: Barley and Wheat**

While in *Arabidopsis* 45% of the investigated genes were cold responsive [54], 28% of the wheat [116] and 25% of the barley [119] transcriptome showed a significant cold regulation. From a comparison of the transcriptomic cold responses of wild-type barley with those in chloroplast-defective mutants, it could be shown that only about 11% of the cold-regulated genes are regulated in a chloroplast-independent way. Significantly, most of the genes that are cold regulated independent of chloroplast function are under CBF control, whereas 67% of the genes regulated in the wild type were not cold-regulated in the mutants and were therefore designated as chloroplast-dependent cold-regulated genes. Strikingly, the effect of the chloroplast on the expression of cold-regulated genes was much larger than the effect of the chloroplast on the transcriptome overall [119].

The largest group of cold-regulated genes in the wild type encodes ribosomal proteins, while the mutants with inactive chloroplasts show constitutively active photooxidative stress signaling pathways and a disruption of low-temperature signaling pathways [119].

The transcriptomic cold response of barley cv. Morex was investigated over 33 days and 2331 genes were identified as low-temperature responsive [120]. These genes are, for instance, involved in signaling cascades and transcriptional control, in biogenesis of cellular components, cell cycle, and DNA processing, protein modification and destination, cellular transport, antioxidant defense, and metabolism of osmoprotectants and lipids.

In wheat 303 upregulated and 378 downregulated genes were identified in the moderately freezing-sensitive cultivar CS and in two CS-derived substitution lines in which chromosome 5A originated from either a more freezing-tolerant (Ch) or a more freezing-sensitive cultivar (Tsp) [117]. In this case, alterations of transcript levels during the first days of low-temperature treatment were larger than during later

stages of cold, similar to the situation in *Arabidopsis* [54]. Upregulated genes encoded, for example, enzymes of proline and ethylene biosynthesis, transcription factors, and known stress-related proteins, and enzymes involved in secondary and polyamine metabolism, whereas downregulated genes included, among others, those encoding enzymes of lipid, protein, and antioxidant metabolism and proteins involved in photosynthesis, respiration, transcription, and transport processes.

11.2.2.2 **Perennial Shrubs: Blueberry**

In floral buds from blueberry transcriptomic analyses were performed under both field and controlled growth chamber conditions [121]. In addition to many genes that had already been identified as cold regulated in *Arabidopsis*, several other genes were identified, including genes encoding an auxin-repressed protein, the protein kinase PINOID, pectate lyase-like protein, and *S*-adenosylmethionine decarboxylase proenzyme. Interestingly, under growth chamber conditions more genes were upregulated in the cold than under field conditions, including stress tolerance genes, genes encoding enzymes of the glycolytic and TCA cycle, and genes associated with protein biosynthesis. Some of the genes exclusively induced under field conditions were related to light stress [121].

11.2.2.3 **Trees: Poplar, Pine, and Spruce**

During the induction of cambial dormancy in *Populus tremula*, a massive remodeling of the transcriptome and a significant reduction in the complexity of the cambial transcriptome occur [122]. The establishment of dormancy is accompanied by an increase in freezing tolerance, as observed at the transcript level by an induction of genes encoding, for example, LEA proteins, osmotin, chitinases, and enzymes involved in sucrose and raffinose biosynthesis and in oxidative stress responses.

Scots pine (*Pinus sylvestris*) seedlings were analyzed for transcript abundance in apical buds under different conditions (three field experiments, two growth chambers, two seasons, and two plant ages) using a cDNA microarray containing about 1500 expressed sequence tags (ESTs) from buds of cold-treated Scots pine seedlings [123]. Samples from three locations in Sweden, Denmark, and Scotland and four provenances were compared. Correlations between physiological parameters, environmental conditions, and gene expression could be shown and led to the identification of potential marker genes for freezing tolerance, including genes encoding antifreeze and LEA proteins, metabolic enzymes, and other stress- or ABA-induced proteins.

Sitka spruce (*Picea sitchensis*) was monitored for gene expression within and among populations comparing late summer and early winter when cold acclimation is initiated [124]. Among the 1257 and 967 genes that were at least twofold up- or downregulated, respectively, many are already well known from *Arabidopsis*. Possible members of signal transduction pathways include genes encoding calcium-binding proteins, such as calmodulins, calcineurin B-like (CBL), and CBL-interacting protein kinases (CIPKs) and the Ca^{2+}/H^{+} antiporter *CAX1*. However, 549 upregulated and 387 downregulated genes have no homology to any *Arabidopsis* genes, indicating also more specific cold responses in this conifer.

11.2.3
Influence of Deacclimation on Plant Gene Expression

Only little effort has been directed toward the analysis of gene expression during deacclimation, that is, the loss of cold acclimation when plants are shifted back to nonacclimating conditions after low-temperature treatment. At a physiological level, it has been shown that *Arabidopsis* and other plants rapidly lose freezing tolerance when transferred back to warm growth conditions [137, 138]. In *Arabidopsis* plants grown on agar plates, 292 genes were identified as upregulated and 320 as downregulated during deacclimation for 1–24 h [108]. They belong to various functional groups, such as transcription factors, detoxification, biosynthesis or catabolism of amino acids, cell wall-related proteins, and proteins involved in photosynthesis or carbohydrate metabolism. Differentially regulated genes were clustered and a large group of genes that were found to be strongly downregulated during deacclimation were also strongly upregulated during cold acclimation. The fact that most of the already known cold-inducible genes belong to this cluster strengthens the hypothesis that these genes might be involved in key metabolic pathways important for cold acclimation. Transcription factors upregulated during deacclimation are obvious candidates for the downregulation of such cold upregulated genes.

11.2.4
Profiling Gene Expression during Cold Acclimation Using SAGE Technology

In addition to the numerous microarray studies discussed above, the SAGE (serial analysis of gene expression) technology [139] has been used only in a few studies and exclusively in *Arabidopsis*, to analyze gene expression during cold acclimation [140–143]. Since SAGE is a sequencing-based technology, it is independent of previously established gene models. It can, therefore, be used to detect the involvement of novel genes, different splice variants, or antisense transcripts in a biological process.

In a comparison of SAGE libraries from 3 days cold-treated leaves with a nonacclimated control, 272 differentially expressed genes, 190 of them highly upregulated in cold-treated leaves, were found [141]. Upregulated genes encode proteins involved in cell rescue, defense, cell death, aging, protein synthesis, metabolism, transport facilitation, lipid metabolism, and protein destination, whereas downregulated genes encode proteins involved in photosynthesis and photorespiration. Examples of the most strongly induced transcripts (*COR15a*, *RD29A/COR78*, *LTI130*, alcohol dehydrogenase, β-amylase, chalcone synthase, and a lipid transfer protein) show that SAGE technology recognizes the same cold-induced genes as microarray technology. However, from 134 genes with at least 10-fold changes in expression, 87 were newly identified as cold-stress-related genes, reflecting the great potential of SAGE to identify novel stress-related genes.

In a time course experiment from the perception of cold to the acquisition of freezing tolerance, using five SAGE libraries from 30 min up to 1 week of low-temperature treatment, 920 low-temperature responsive genes were identified [143].

Only 24% of these genes were identical to those previously identified using microarrays. The identification of novel genes independent of CBF and ABA regulation was possible and pointed to complementary signaling pathways. In addition, alternative transcript processing, such as retained introns, modified exon structure, and polymorphic UTR sequences, was identified as important for the plasticity of the stress-induced transcriptome.

Recently, the LongSAGE technology [144] was used to analyze the initial events involved in signal transduction after cold exposure (0 °C, 1 h) in *Arabidopsis* leaves [140]. In comparison to conventional SAGE tags, the longer tags from this technology increase the chances for the identification of novel genes. By comparing control with cold-treated leaves, 315 differentially expressed genes could be identified that, however, mostly corresponded to the expected changes in gene expression. Interestingly, differential expression of miRNAs was detected, most of which were downregulated. The functional significance of these changes in miRNA abundance in the early responses of leaves to cold stress remains to be elucidated.

In addition to leaf tissue, SAGE technology was also used to investigate gene expression in *Arabidopsis* pollen at low temperature [142]. Comparing a SAGE library from pollen with a library from cold-treated leaves showed that most of the highly abundant genes responsible for pollen function are not greatly affected by a cold stress at 0 °C for 72 h, whereas seed production was reduced. Most of those genes that are cold induced in vegetative tissue showed unchanged expression levels or only a weak induction in pollen under cold stress. This might explain the high sensitivity of *Arabidopsis* pollen to low temperature.

11.2.5
Effects of Low Temperature on Circadian Clock-Regulated Gene Expression

A first suggestion that the circadian clock is involved in plant cold responses came from the upregulation of the transcript from the *GIGANTEA* gene, involved in flowering time regulation and circadian clock function [58]. *GIGANTEA* was also found to be fivefold induced in the autumn transcriptome of Sitka spruce following natural cold acclimation [124]. Kreps *et al.* [107] observed a stress response for 68% of the known circadian controlled genes that supported the role of the circadian clock in stress anticipation and activation of cold stress pathways. A strong upregulation of *APRR1* (*pseudo-response regulator 1*), an essential component of the central oscillator of the circadian clock in *Arabidopsis*, after exposure to low temperature was an additional indication for the involvement of the circadian clock in the cold response [64].

In a microarrays analysis of diurnal (light/dark) and circadian (constant light) time courses under nonacclimating and acclimating conditions in *Arabidopsis*, it could be shown that under diurnal conditions cold reduces the amplitude of the clock cycles and disrupts the cycling of some of the circadian output genes, while in continuous light all cycles become arrhythmic [115, 145]. Similarly, circadian clock function is disrupted in chestnut during winter dormancy [146, 147]. Expression analysis of approximately 1900 genes encoding transcription factors of *Arabidopsis* by quanti-

tative real-time RT-PCR [148] showed diurnal gating with a stronger cold induction for 75% of the cold-induced transcription factor genes and a higher absolute transcript abundance for most of them in the morning [145]. These findings confirmed and massively extended previous results [149] showing gating of the cold induction of the *CBF1, 2,* and 3 and *RAV1* and *ZAT12* genes. These strong circadian effects on the expression patterns of cold-regulated genes are contrary to results from AtGenExpress [106] where, however, very different culture conditions were used. Interactions between stress and diurnal regulation of gene expression not only influence the cold-responsive transcriptome but also gene expression in response to drought stress [150], reflecting the importance of time-of-day on the identification of stress-responsive genes and should be taken into account in future gene expression analysis experiments.

11.2.6
Using Natural Genetic Variation to Identify Genes Important for Cold Acclimation and Freezing Tolerance

Several studies in *Arabidopsis* have shown a large variability in acclimated freezing tolerance between different accessions that follows a clear latitudinal cline with increasing freezing tolerance in accessions from more northern habitats [25, 38, 40]. Likewise, cultivar differences in freezing tolerance have been reported in various crop plants (e.g., [31, 32, 35]). Comparisons of transcriptomic cold responses of accessions, cultivars, or populations differing in freezing tolerance have been published for *Arabidopsis* [25, 151], wheat [116–118], and Sitka spruce [124].

In *Arabidopsis*, an investigation of nine accessions that differed widely in freezing tolerance [25] found differential transcriptional regulation between accessions after exposure to low temperature. Both the number of significant changes in gene expression during cold acclimation and the amplitude of those changes were significantly correlated with the ability of the accessions to increase their freezing tolerance. In particular, the downregulation of photosynthesis-related genes and the upregulation of genes encoding enzymes of the flavonoid biosynthesis pathway were correlated with improved freezing tolerance. Furthermore, the expression of 32 genes encoding transcription factors, including the *CBF*s, correlated positively, while the expression of 24 such genes correlated negatively with freezing tolerance, providing candidates for key transcriptional regulators of cold acclimation.

In a study of 10 *Arabidopsis* accessions from a wide range of latitudes, the impact of low temperature was investigated with special consideration of the adaptive significance of regulated genes [151]. Genes with high plasticity in their expression patterns exhibited higher among-ecotype variation that was also strongly correlated with the habitat temperature at the geographic origin of the ecotypes. Forty-three genes with significant expression plasticity combined with adaptive value were found.

Similar to *Arabidopsis*, in wheat a freezing tolerant cultivar showed 1.5 times as many differentially expressed genes during cold acclimation than a sensitive cultivar [117]. Over 450 genes were differentially cold regulated between the highly freezing tolerant winter wheat cultivar CDC Clair and the less tolerant spring cultivar

Quantum, including 130 genes involved in gene regulation or signaling [118]. Within the first hours of cold acclimation, more genes were upregulated in the sensitive than in the tolerant cultivar, whereas after 2 weeks of acclimation the response was reversed, with the winter wheat finally showing more up- and downregulated genes than the spring cultivar. Similarly, in another pair of wheat cultivars (Glenlea; sensitive and Norstar; tolerant), 65 cold-regulated genes were found differentially regulated after 1–36 days of cold acclimation [116].

In a comparison between three populations of Sitka spruce (*Picea sitchensis*) with a central population from British Columbia and northern and southern peripheral populations from Alaska and California that markedly differed in freezing tolerance, a substantial differential gene expression among populations was reported [124]. In the northern and central populations, 326 genes showed higher expression than in the southern population. Among these genes were several that encode proteins that are presumably directly involved in freezing tolerance and also several that encode regulators of gene expression. In the light of future climate change predictions, the search for markers characterizing the local adaptation of a species will become increasingly important for molecular breeding especially of long-lived woody plants [124].

11.3
Metabolomic Studies of Plant Cold Acclimation

Recently developed metabolic profiling tools such as GC-MS and LC-MS methods have been used to study global changes in metabolite content of *Arabidopsis* in response to low temperature and have led to a detailed description of the massive metabolic reprogramming occurring after a shift of plants from ambient conditions to cold [25, 57, 59, 131, 152]. The functional role of these complex metabolic changes during cold acclimation is not clear. However, it can be assumed that they are in part related to the strong reduction in growth rate at low temperatures, which is an active regulatory process rather than a passive result of temperature reduction [72]. Equally, it is very likely that many molecules synthesized during cold acclimation contribute directly to increased freezing tolerance. They could have cryoprotective effects, such as soluble sugars, sugar alcohols, and some amino acids. In addition, some are likely to function, for example, as antioxidants.

To obtain a broader overview of the influence of cold acclimation on metabolic regulation, we recently performed metabolic network analysis using time course GC-MS metabolic profiling data [115]. Figure 11.1 presents the metabolic networks reconstructed from these data for *Arabidopsis* plants grown either at 20 °C or at 4 °C. In these undirected metabolic networks, the nodes represent metabolites and the edges (i.e., the lines connecting the nodes) represent highly significant correlations in the amounts of the two respective metabolites over time. Visual comparison of the two networks indicates significant differences. Topological network analysis indicates a higher network density with a higher number of edges (i.e., connections between metabolites) at 4 °C (205 edges) than at 20 °C (121 edges). Also, the number

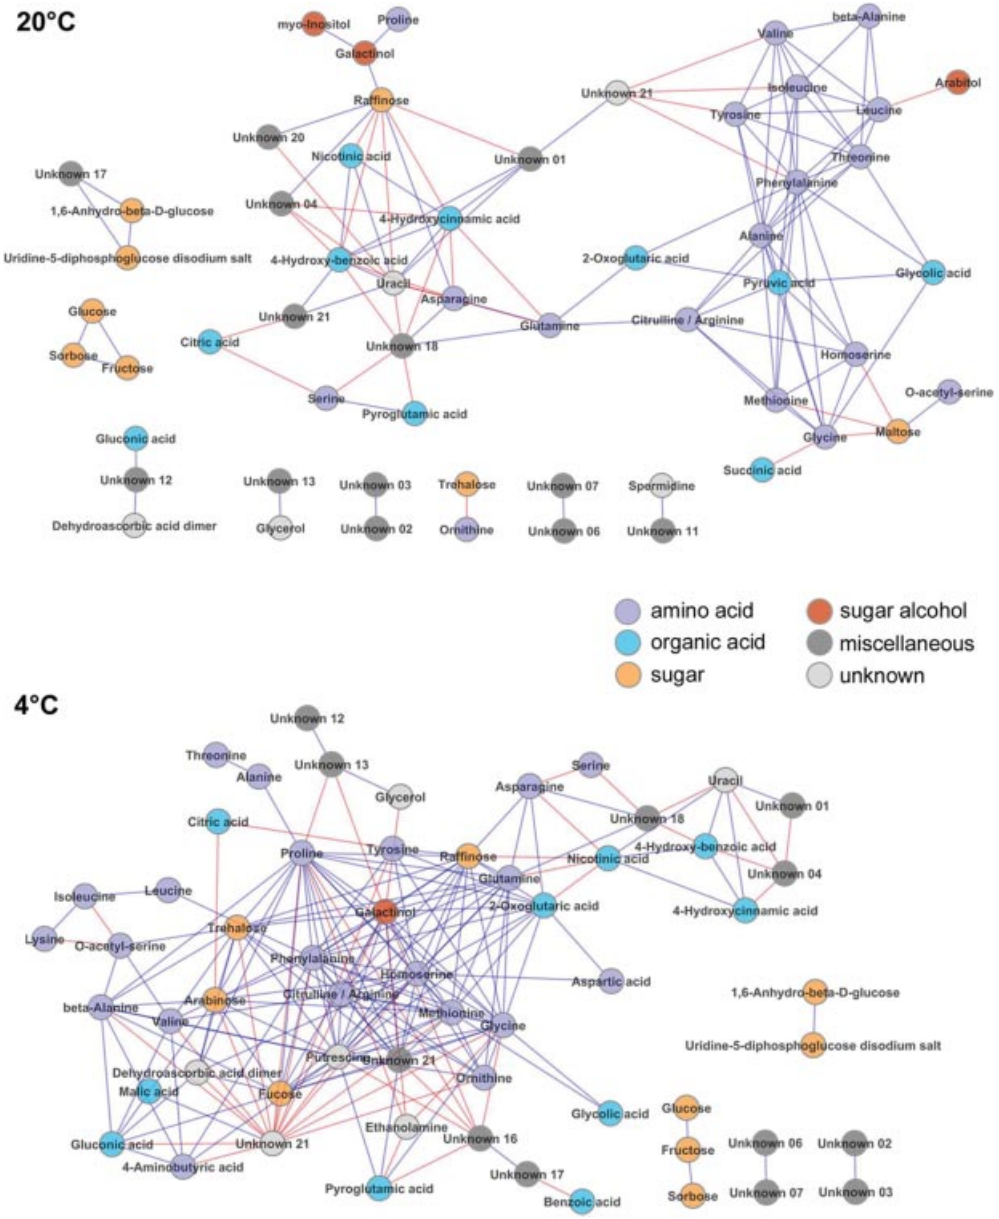

Figure 11.1 Effect of low temperature on the metabolite–metabolite correlation network. Networks were constructed on the basis of Spearman metabolite–metabolite correlations, with nodes (colored dots) representing the measured metabolites. Undirected edges (lines) indicate highly significant (Bonferroni corrected p-value < 0.001, corresponding to a correlation coefficient R of about 0.54 for the given sample size) positive (blue) and negative (red) pairwise correlations between metabolite pool sizes. Massive metabolic changes occurring at low temperature are indicated by the higher number of significant correlations observed at 4 °C, compared to 20 °C. These additional correlations mainly involve molecules acting as compatible solutes. Reproduced from Ref. [115].

of connected pairs significantly increased from 1434 at 20 °C to 2462 at 4 °C [115]. These and other parameters clearly indicate that the metabolic reprogramming during cold acclimation is a tightly regulated process and not simply the result of metabolic dysfunction due to low-temperature stress.

The three cold-induced CBF transcription factors have a prominent role in this metabolic reconfiguration, with around 80% overlap between metabolic responses to the constitutive overexpression of *CBF3* and cold acclimation [57]. However, it is widely recognized that cold acclimation is a highly complex process not only at the level of gene expression but also at the metabolic level. Consequently, it could be shown that metabolic reconfiguration at low temperature is strongly influenced by stress duration [152] and the developmental state of the plants [152, 153]. Another factor contributing to the complexity of the plant response to low temperature is the widely recognized diurnal regulation of many metabolic pathways in plants, such as starch and sugar metabolism [154, 155]. This can lead to the superposition of diurnal changes in metabolite pools on changes induced by low temperature [131, 152]. Therefore, both diurnal and circadian regulation of metabolism can affect the identification of cold-responsive metabolites [115] similar to the situation with transcripts described above [115, 145]. Nevertheless, many metabolic pathways have clearly been shown to be influenced by cold acclimation.

11.3.1 Primary Metabolism

The reconfiguration of the metabolome of *Arabidopsis* during cold acclimation involves dramatic changes in central metabolism. These changes include modifications in the pool sizes of amino acids such as alanine, citrulline, glutamine, and *O*-acetylserine [57]. Moreover, due to the increase in aspartate, ornithine, and citrulline, an upregulation of the urea cycle has been suggested and the increased levels of several intermediates of the TCA cycle, such as α-ketoglutarate, fumarate, malate, and citrate, also support an upregulation of this central metabolic process [131].

Changes in the size of hexose phosphate pools and the free hexose pools that occur at low temperature suggest a modification of carbon metabolism in photosynthetic tissues toward the accumulation of a variety of sugar phosphates and simple sugars [156]. In particular, photosynthesis is negatively affected by low temperature, leading to an accumulation of phosphorylated intermediates with a concomitant decrease in inorganic phosphate levels [157, 158]. Changes in central carbohydrate metabolism are also subject to temporal regulation during acclimation. For instance, at early stages of low-temperature exposure, compounds such as maltose, fructose, fructose-6-phosphate, glucose, glucose-6-phosphate, and glycerol-3-phosphate seem to have a relevant role, while after longer acclimation times the accumulation of sorbitol and galactinol becomes significant [152].

The analysis of changes in approximately 200 metabolites by GC-MS during cold acclimation in nine *Arabidopsis* accessions has not revealed a clear correlation between global metabolic changes and acclimation capacity. Nevertheless, the pool

sizes of metabolites such as glucose, fructose, galactinol, raffinose, xylose, and sucrose were significantly correlated with acclimated freezing tolerance, reflecting the importance of carbohydrate metabolism [25]. Similar correlations or a lack thereof has previously been reported in many plant species (see Ref. [1] for a review of the older literature in this field), casting doubt on the functional relevance of particular sugars for freezing tolerance. More recent work on *Arabidopsis* suggested that it may not be a specific sugar that is important for plant freezing tolerance, but that sugars may constitute a highly redundant cryoprotective system [105, 159]. However, an increase in total sugar content is also not sufficient to significantly increase leaf freezing tolerance [20]. These data suggest that several metabolites may act together with other factors such as cold-induced proteins [2] to increase cellular freezing tolerance. Metabolite profiling together with more sophisticated statistical data analysis tools is uniquely capable of providing solutions for such complex problems. For a panel of *Arabidopsis* genotypes (accessions and F1 crosses), this approach led to the identification of a small group of metabolites that allowed to predict both acclimated and nonacclimated freezing tolerance with high accuracy [160]. This group contained not only sugars, amino acids, and organic acids but also some unidentified metabolites. The latter finding indicates that there may still be important metabolites even in a well-studied species such as *Arabidopsis* that play important physiological roles but have not been characterized yet.

In addition, such analyses can provide evidence for novel functions of already well-characterized metabolites. For example, it was found that increased freezing tolerance during cold acclimation is preceded by maltose accumulation [161]. Maltose, as a starch degradation product, has usually not been considered a compatible solute, although it is able to stabilize membranes during desiccation [162] and was shown to contribute, either alone or by increasing other soluble sugars, to the protection of photosynthetic electron transport during freezing stress [161]. Moreover, maltose could act as a carbon source as the process of cold acclimation requires considerable energy supply. Experimental data point to a key role for starch breakdown during the process of cold acclimation [163]. This finding is well validated by the demonstration that two mutants that are impaired in starch breakdown have reduced ability to cold acclimate [161, 164].

11.3.2 Secondary Metabolism

While there is large interest in the biosynthesis and properties of flavonoids and isoflavonoids in plants, both from the perspective of plant biology and that of their potential medical applications, very little clear information on the specific roles of any of these compounds is available (see Ref. [165] for a recent review). The effect of low temperatures on secondary metabolism has been widely recognized and flavonoid biosynthesis is strongly upregulated during cold acclimation [25, 105, 114, 166].

Flavonoids constitute a family of aromatic compounds synthesized from L-phenylalanine and malonyl-coenzyme A, through the phenylpropanoid pathway. Several of the genes encoding key enzymes in this pathway have been identified as cold

responsive, including, for example, L-phenylalanine ammonialyase (PAL) and chalcone synthase (CHS) [133, 167]. Flavonoids comprise the chalcones, flavones, flavonols, flavandiols, anthocyanins, and condensed tannins. Anthocyanins are strongly accumulated in response to different environmental factors, such as low temperature, drought, and high light. One of the main properties of flavonoids is their ability to absorb ultraviolet (UV) light and together with the fact that they are often present in tissues highly exposed to light (epidermal cell layers in leaves, pollen, and apical meristem), it has been proposed that the main role of flavonoids is protection against UV-light [133]. Cold acclimation has a major influence on the amount and composition of flavonols [105]. Even when cold stress induces the synthesis of anthocyanins and flavonoids, glucosinolates, terpenoids, and phenylpropanoids [113], the biological significance of this remains to be demonstrated. However, the positive correlation between flavonol content and leaf freezing tolerance strongly suggests that flavonols can play a role in plant acclimation and freezing tolerance [105]. Putative physiological functions suggested for flavonoids during cold and freezing include scavenging of reactive oxygen species [132] or their function as a carbon sink during cold stress [168, 169]. In addition, flavonols may also have direct effects on membrane stability. Some flavonols can partition into the lipid phase of membranes [170]. Under freezing conditions, when a large part of the water is removed from the cells to intercellular ice crystals, it can be expected that amphiphiles such as flavonoids will partition even more strongly into the hydrophobic phase of membranes [171]. While there is as yet no experimental evidence for a membrane stabilizing function of plant flavonoids, it has been shown that the glucosylated phenol arbutin (4-hydroxyphenol-β-D-glucopyranoside) that is found in some extremely frost- or desiccation-tolerant plants is able to specifically stabilize membranes that contain nonbilayer lipids [172, 173]. Similar functions could be envisaged for flavonoids, but this needs to be experimentally tested.

11.3.3 Lipid Metabolism

A decrease in temperature reduces the fluidity of membranes and can in extreme cases lead to a phase transition of the lipids from the liquid-crystalline to the gel state (thermotropic phase transition). Owing to the crystallization of ice, freezing also leads to dehydration, which further increases the lipid-phase transition temperature and the propensity of the lipids to enter the gel state (lyotropic-phase transition). Such a phase transition can cause the segregation and aggregation of membrane proteins into a remaining liquid–crystalline phase with the consequent inactivation of the proteins. Furthermore, membranes can become leaky at the phase boundaries due to nonideal packing, leading to the loss of semipermeability of cellular membranes and loss of compartimentation [174]. In addition, chilling-sensitive plants and cyanobacteria show an inhibition of photosynthesis [175] that could be related by mutational and transgenic approaches to the ratio of saturated to unsaturated phosphatidylglycerol in chloroplast membranes [176–178]. In chilling-tolerant plants such as *Arabidopsis*, a high content of polyunsaturated lipids is required for growth and

development at low temperatures (e.g., [135, 179, 180]) and cereals increase the content of unsaturated fatty acids in their membrane lipids during cold acclimation [4]. Fatty acid analysis has also revealed increases in polyunsaturated molecules in *Arabidopsis* in response to cold (C18 : 2; C18 : 3; and C16 : 3), while less unsaturated fatty acids decrease in their content (C16 : 2 and C16 : 1) [114]. Cold acclimation and mild freezing (i.e., subzero acclimation) can also increase the proportion of bilayer lipids, such as phosphatidylcholine and digalactosyldiacylglycerol, and decrease the proportion of nonbilayer lipids such as cerebrosides, phosphatidylethanolamine, and monogalactosyldiacylglycerol (e.g., [181, 182]), thus reducing the incidence of fatal interbilayer fusion events.

11.3.4
Sulfur and Nitrogen Metabolism

The pool size of *O*-acetylserine (OAS) in *Arabidopsis* leaves is strongly increased in response to low temperature [115]. OAS, a direct precursor of cysteine, is synthesized by the activity of serine acetyltransferase (SAT) from serine. OAS is then converted to cysteine by *O*-acetylserine (thiol) lyase (OASTL). It has been proposed that OAS acts as part of the regulatory network signaling metabolic demand for sulfur-containing compounds [183]. Glutathione is the most abundant thiol compound in plant cells, playing a major role as an antioxidant during stress [183]. It is, therefore, possible that the increase in OAS levels during cold acclimation is related to an increased freezing tolerance through the antioxidant defense system. Consistent with this, many genes encoding enzymes involved in ROS scavenging are also cold responsive.

Nitrogen metabolism plays a key role in plant physiology. Glutamic acid and glutamine act as ammonium donors in the synthesis of all other amino acids. Aspartic acid and asparagine further act as active ammonium donors or transport/storage compounds, respectively [184]. Both glutamine and asparagine are accumulated at low temperatures [57]. GABA (γ-aminobutyric acid) levels highly increase after plants are exposed to cold. GABA is synthesized in the cytosol from glutamine and is an important amine-containing metabolite with cryoprotective properties and with a putative role in stress signaling [185–187].

11.4
Both Transcriptional and Posttranscriptional Regulation of Metabolism are Important During Cold Acclimation

As already briefly discussed in Section 11.1, interpretation of changes observed in transcript abundance during cold acclimation in profiling studies assumes that mRNA amounts are the limiting factor that determines physiological responses. We will briefly discuss two recent studies that have shed some light on the limitations of this assumption.

One study used expression profiling combined with enzyme activity measurements and metabolite profiling to investigate the responses of *Arabidopsis* 6 and 78 h after transfer from 20 °C to a progressively lower temperature between 17 and 8 °C [114].

Transcript abundances showed stronger changes as the temperature difference increased and the changes were generally larger after 6 h than after 78 h. Changes in enzyme activities and metabolite pool sizes showed a similar dependence on temperature, but here the changes were larger after 78 h than after 6 h. The correlations between the abundance of specific transcripts and the encoded enzyme activities were very poor after 6 h of cold treatment and significantly improved after 78 h. However, also after 78 h of cold treatment, a considerable part of the changes in gene expression and enzyme activity were unrelated, pointing to important contributions of translational regulation and/or protein stability to the observed changes in enzyme activities. In addition, discrepancies between changes in extractable enzyme activity and changes in metabolite pool sizes were noted, indicating the importance of further regulatory mechanisms that influence enzyme activity *in vivo*. Interestingly, this study suggests that a large part of the transcriptional responses to small changes in temperature were driven by the observed increases in *CBF* expression.

In another study [115], transcripts and primary metabolites were quantified during diurnal time courses at either 20 °C or at 4 °C. These data provide a comprehensive

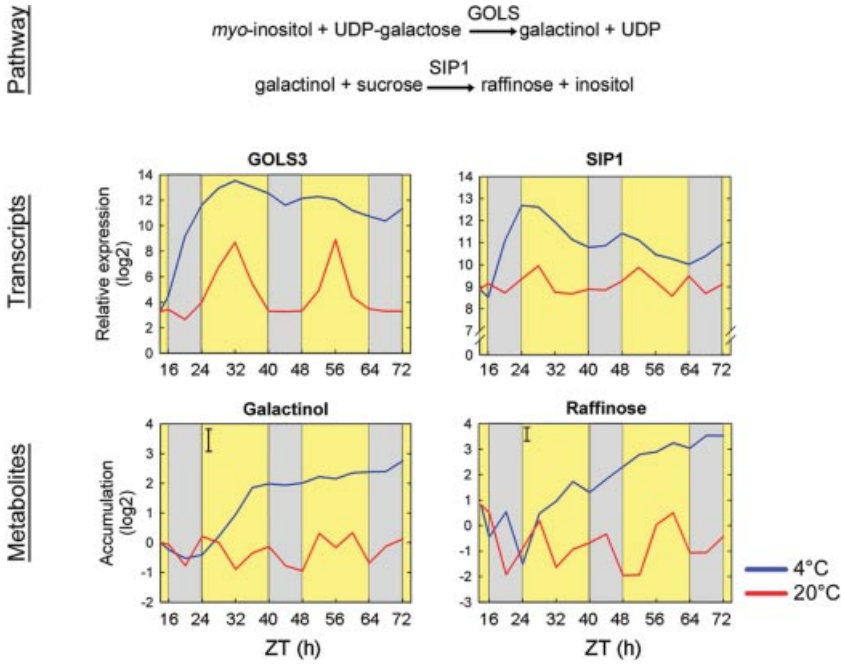

Figure 11.2 Coordinated transcriptional regulation of the raffinose biosynthesis pathway. Summary of the metabolic pathway, transcript, and metabolite profiles of the raffinose biosynthesis pathway. For transcripts, relative expression (log2) estimates from Affymetrix ATH1 microarrays are indicated. Metabolite accumulation (log2) was measured by GC-TOF-MS and it is expressed as the normalized mean peak apex intensities from five biological replicates. GOLS3: galactinol synthase 3 (At1g09350); SIP1: raffinose synthase (At5g40390). Reproduced from Ref. [115].

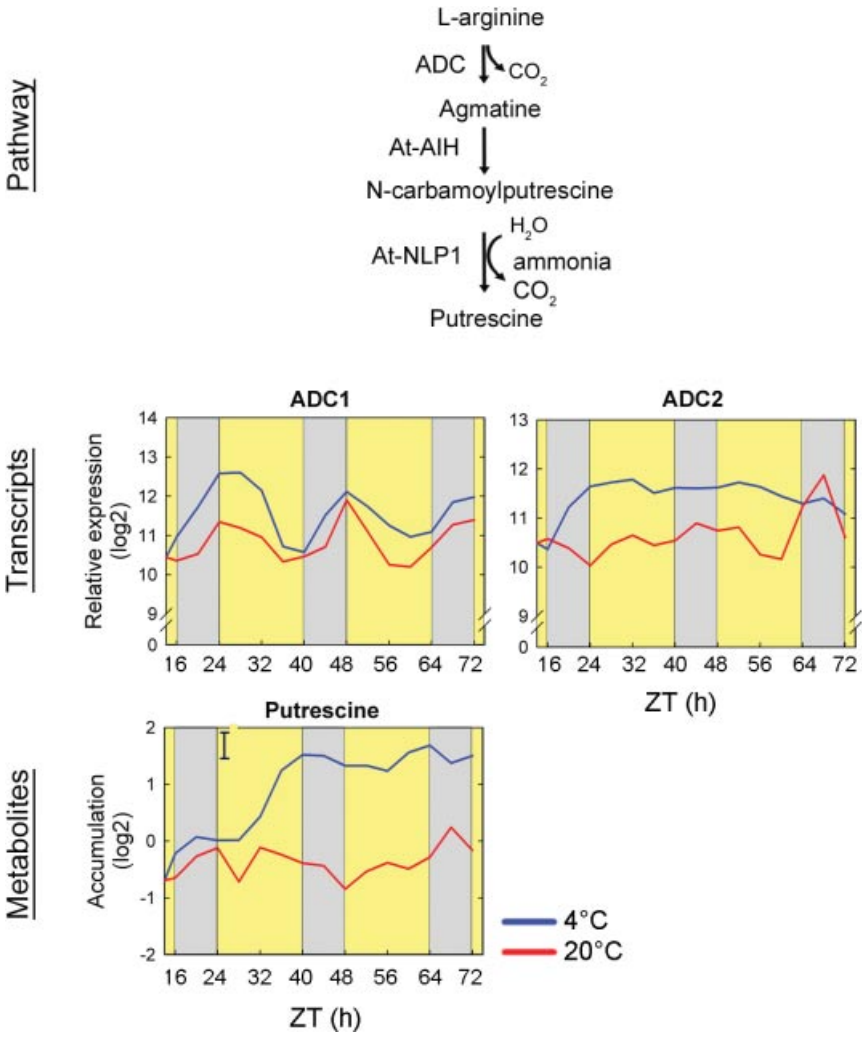

Figure 11.3 Coordinated transcriptional regulation of the polyamine biosynthesis pathway. Summary of the metabolic pathway, transcript, and metabolite profiles of the polyamine biosynthesis pathway leading to putrescine. For transcripts, relative expression (log2) estimates from Affymetrix ATH1 microarrays are indicated. Metabolite accumulation (log2) was measured by GC-TOF-MS and it is expressed as the normalized mean peak apex intensities from five biological replicates. ADC: arginine decarboxylase 1 (At2g16500) or 2 (At4g34710); At-AIH: agmatine iminohydrolase; At-NLP1: *N*-carbamoylputrescine amidohydrolase. Reproduced from Ref. [115].

analysis of the diurnal regulation of both gene expression and primary metabolism that interact with the cold regulation of both processes. A previous study had shown that the diurnal cycling of clock genes becomes strongly dampened in the cold [145] and this extends to the diurnal cycling of metabolites. However, 80% of those

metabolites that show cycles at 20 °C still do so at 4 °C [115]. The transcripts encoding enzymes for biosynthesis of well-known cold-induced metabolites such as raffinose and putrescine also cycled at 20 °C and diurnal cycling was maintained in the cold (Figures 11.2 and 11.3). Also, in both cases, increased transcript abundance preceded the cold induction of the related metabolites, in agreement with a predominantly transcriptional regulation of these pathways.

Interestingly, in the raffinose pathway *GOLS3* expression was rapidly induced and stayed high until the end of the experiment, while *SIP1* was also rapidly induced, but here the induction was transient and the expression level approached control values after 2 days at 4 °C (Figure 11.2). Nevertheless, a continuous increase in raffinose content was observed indicating additional regulatory mechanisms even in this case. Another regulatory mechanism is illustrated in Figure 11.3. In *Arabidopsis*, two genes encode the enzyme arginine decarboxylase and while *ADC1* expression is only slightly influenced by cold, *ADC2* is more strongly upregulated, pointing to the specific role of only one of the genes in stress adaptation. In addition, in many cases no correlation between changes in transcript abundance and metabolite pool sizes could be observed [115], emphasizing the importance of translational and posttranslational mechanisms in metabolic regulation.

Omics Techniques in Crop Research: An Overview

Bashasab Fakrudin, Roberto Tuberosa, and Rajeev K. Varshney

12.1
Introduction

Omics is a collective, broad discipline largely referring to analysis of the interactions of biological information obtained from the profiling of the genome, transcriptome, proteome, metabolome, and several other relevant -omes. While phase one of omics technologies aims at nontargeted identification of transcripts, proteins, and metabolites (essentially gene products) in a given biological sample, phase two deals with a very challenging analysis of data eventually leading to the dissection of the qualitative and quantitative dynamics of biological systems. Essentially, the omics science is enabled by a host of diverse, high-throughput technologies and platforms [1]. The full range of omics technologies can now be applied to understand the same fundamental biological processes [2]. Mapping and defining the relationships among genes, proteins, and metabolites require relative comparison of the networks that eventually help in understanding the regulatory mechanisms. A diverse but converging approaches such as forward and reverse genetics and transgenics (overexpression and knockdowns) can define the function of a gene to the specific phenotype, the omic technologies aim at revealing the function of each and every gene in the genome, which collectively contribute toward elucidating the networks and better understanding the whole plant phenotype [3–5]. Access to omics tools at an affordable price is becoming a reality, which together with a large inventory of candidate genes, proteins, and metabolites and their databases deduced from profiling efforts in model systems and crop plants have speeded up the analysis of biological functions operating in various plant stress responses [2, 6]. These new strategies have begun to piece together the physiological and phenotypic observations with information on transcription and transcript regulation, the behavior of proteins, protein complexes and pathways, and the metabolites and metabolite fluxes, finally shedding light on evolutionary adaptive diversifications of organisms.

Improving Crop Resistance to Abiotic Stress, First Edition.

12.2 Transcriptomics

Transcriptomics, a global mRNA expression profiling of a particular tissue, is essentially genome wide, yielding information about the transcriptional differences between defined states of tissues. Elucidated global differences in gene expression are expected to help in the understanding of genes and pathways involved in biological processes: gene statements showing similarity in quantitative and qualitative expression are functionally related and would be the result of possible common genetic regulation [2, 7]. Rapid sequencing of many eukaryotic genomes has provided unprecedented opportunities to understand gene function, genome structure, and genome evolution [8]. However, an accurate annotation of all expressed genes in the sequenced genomes remains one of the most challenging tasks. Therefore, genomic resources and platforms provide new opportunities for crop research and breeding programs [8–10].

Transcriptomics can be used to understand taxonomic position to gain a deeper understanding of molecular and physiological bases of complex phenotypes such as crop response to abiotic stresses. Common platform technologies used for genome-wide or high-throughput analysis of gene expression are microarrays, serial analysis of gene expression (SAGE), massively parallel signature sequencing (MPSS), and next-generation sequencing platforms (NGSPs) [11–13]. High-throughput quantitative real-time PCR has proven to be a platform of choice for validation of a large number of genes elucidated through omics approaches in the tissue and treatment of choice [14].

12.2.1 Closed Omics Technologies

Microarray technology represents a "closed" profiling strategy limited by the target genes/gene statements imprinted on gene chips. Microarray technology has become a useful tool for the analysis of genome-scale gene expression. This technology was first demonstrated by analyzing 48 *Arabidopsis* genes for differential expression in roots and shoots [15]. Microarrays are artificially constructed grids of known DNA samples such that each element of the grid probes a specific RNA sequence wherein the RNA transcripts from the target sample are captured and quantified. To date, many different protocols and types of microarrays such as oligonucleotide and cDNA arrays, commercially available whole-genome arrays and custom-made, tissue-specific arrays have been developed. All these invariably require (a) isolation of RNA from target sample, (b) conversion of RNA to either cDNA or cRNA, (c) a simultaneous incorporation of either fluorescent nucleotides or a tag that is later used for fluorescent labeling, (d) hybridization to a chosen microchip, (e) washing and labeling (depending on the protocol adopted), (f) scanning under laser light and image processing to extract data, and (g) data analysis [16, 17]. Bioinformatic clustering tools are required for delineation of closely related expression patterns of genes [17]. The sources for cDNA arrays are generally PCR products from expressed sequence tags (ESTs) or from cell (tissue)-specific sources, which are "spotted" on glass slides. In the case of oligonucleotide

arrays, relatively short, 25-mer, oligonucleotides specific for transcripts of interest are generated by photolithography and solid-phase DNA synthesis [18]. Various modifications to these approaches and the use of fluorophore dyes have allowed a more accurate and reliable expression profiling.

Microarrays have been extensively used in most of the experimental systems including major crop plants [19–22]. For instance, in *Arabidopsis*, full-length cDNA libraries from plants under different conditions, such as drought-treated and cold-treated plants, have been developed [23, 24] and a set of 1300 full-length cDNAs were monitored for the expression patterns under drought and cold stresses [25]. This platform has been widely used in crop research for elucidation of differentially expressed genes in crop plants as a result of biotic and abiotic stress interactions [7, 21, 26].

There are two microarray-based methods for genotyping in crop research: (a) one involves arraying thousands of short oligonucleotides on glass slides for detection of many single-nucleotide polymorphism (SNP) loci in target DNA, which is particularly well suited for genotyping thousands of markers, and the other (b) involves arraying amplified PCR products on glass slides to detect a few SNPs. The latter is useful to detect limited number of SNPs in large number of samples [27, 28]. Biotin-terminated, allele-specific PCR products are spotted unpurified on glass slides coated with streptavidin and visualized through fluorescent oligonucleotides attached to the allele-specific PCR primers. These approaches of genotyping hold great promise in high-throughput genotyping the candidate genes and their trait association in crop plants. A maize expression array containing 57 452 genes has been developed and used in the context of maize nitrogen utilization, root growth under drought, water, and phosphate stress, seed development, photosynthesis, pathogen response, aluminum stress in roots, tassel development, and hybrid vigor (www.maizearray.org). Furthermore, microarray-based gene expression technology is a powerful tool to also monitor changes in the expression of a large number of genes simultaneously and provide new insights into physiological and biochemical pathways of abiotic and biotic stress tolerance and identify novel candidate genes that can be used in plant breeding programs [6, 17, 29].

12.2.2 Open Omics Technologies

In the past decade, various sequencing-based strategies, such as ESTs [30], full-length cDNA [24], SAGE [31, 32], and MPSS have been developed for transcriptome studies [33, 34]. These approaches have contributed valuable resources for gene discovery and genome annotation, but their application in most molecular studies has been limited. In contrast to microarray technology, these technologies are of "open" architectural systems that can be used to identify novel genes and to quantify differentially expressed mRNAs.

12.2.2.1 ESTs, SAGE, and MPSS

Single-pass sequencing of cDNAs to generate ESTs has been a much-used method of elucidation of genes and has contributed a lot of entries to public DNA databases. The error-prone ESTs have remained not only a powerful means of gene discovery but also

a source of biologically informative probes in genome mapping and cloning studies. ESTs have become an invaluable resource for gene discovery, genome annotation, alternative splicing, SNP discovery, molecular markers for population analysis, and expression analysis in animal, plant, and microbial species [16, 35]. Generally, EST and full-length cDNA sequencing techniques are not deep enough to isolate rare transcripts responsible for complex traits or address transcript variability that persists within and between closely related pathways and phenotypic traits. Sequencing millions of cDNA clones from various tissues can sample only about 60% of the expressed genes [36]. Although various computer-based gene prediction methods play a role in genome annotation, experimental data are an essential evidence for determination of gene structure and function [12]. This limitation has been addressed through high-throughput and short tag-based approaches such as SAGE and MPSS, and much recently employing NGSP. Notably, these technologies are most useful for gene expression analysis in plant species whose genome has been sequenced [11, 37].

The SAGE library construction involves several tedious steps before tags can be cloned into a plasmid vector. The process includes isolation of short tags (14–26 bp) from the 3′ or 5′ ends of transcripts, ditag formation, and concatenation and sequencing of SAGE clones. Taking advantage of the high-throughput made possible by the classical SAGE technology [32], new approaches for cloning of 5′-end-specific sequencing tags from mRNA-cap analysis gene expression (CAGE), *trans*-spliced exon-coupled RNA-end determination (TEC-RED), and 5′ serial analysis of gene expression (5′SAGE), gene identification signatures (GIS), the tags comprising information from both terminal ends, were developed [12, 31]. However, the time-consuming procedure of colony picking and storage and the high cost of sequencing individual clones in SAGE library construction have discouraged the use of this approach in many biological studies [31, 38].

The MPSS strategy involves *in vitro* cloning of cDNA molecules on the surface of microbeads and nongel-based sequencing of millions of tags (17–20 bp). It is considered to be more sensitive over SAGE technology [36, 38]. The multiple location-matching of 17–21 bp tags from SAGE or MPSS libraries in a sequenced genome is problematic when mapping tags to the EST or genomic sequence. To obtain accurate matches for positive tags in the genome, longer transcripts are required. This is usually accomplished using techniques such as rapid amplification of cDNA ends (RACE) or generation of longer cDNA fragments using the GLGI method. Integration of pyrosequencing in sequencing technology with SAGE tags has resulted in an increased sensitivity for deep transcript profiling: robust analysis of 5′ gene expression (5′RATE), which involves the use of pyrosequencing of ditag libraries, achieves higher sensitivity of transcript profiling. It consists of three major steps including 5′-oligocapping of mRNA, *Nla*III tag and ditag generation, and pyrosequencing of *Nla*III tags. Complicated steps such as purification and cloning of concatemers, colony picking, and plasmid DNA purification are eliminated and the conventional Sanger sequencing method is replaced with the newly developed pyrosequencing method [39]. Taken together, these techniques provide a panoramic profile of the entire pool of mRNA transcripts that make up the transcriptome.

12.2.2.2 Next-Generation Sequencing

At present, numerous strategies and platforms are under development including sequencing by synthesis (SBS), sequencing by hybridization, and nanopore sequencing. In 2005, two new sequencing technologies were introduced. Both are based on sequencing by synthesis: the 454 system (http://www.454.com) using pyrosequencing technology and the Solexa/Illumina system (http://www.illumina.com) that depends on detection of fluorescence signals [40]. These methods employ parallel sequencing in millions of reactions that generate a very large number of data points. The read lengths are averaging 100–230 bp and 300–400 bp for 454FLX and 454Titanium, respectively, and 35–105 bp for Illumina Solexa platforms. The Applied Biosystems SOLiD (http://www3.appliedbiosystems.com) is another addition with a greater potential in transcriptome sequencing and gene discovery approaches. These platforms offer a variety of experimental approaches for characterizing a transcriptome, discovering genes, small RNAs, and variations in homologues [8, 11, 41]. These sequencing technologies collectively are referred to as next-generation sequencing (NGS) technologies. Potential applications of NGS technologies in gene expression analysis and crop breeding research have been accounted and compared in detail [8, 9, 13, 42, 43]. In addition, several organizations are working on third-generation sequencing technology mainly based on single-molecule synthesis [44]. Furthermore, both the nanopore sequencing and the transmission electron microscopy-based sequencing hold greater promise as third-generation sequencing technologies [41, 45, 46]. The generation of millions of tags at low cost makes these technologies the system of choice for gene expression analysis. A reduction in the cost of sequencing services, which is expected to happen in the near future, will have a major positive impact not only on gene expression studies but also on molecular breeding in agri-hort crops and tree species.

12.3 Metabolomics

Metabolomics is considered the ultimate level of postgenomic analysis as it can reveal changes in metabolite fluxes that are controlled by only minor changes within gene expression measured using transcriptomics and/or by analyzing the proteome that elucidates posttranslational control over enzyme activity [47, 48]. Metabolome refers to a set of metabolites that are formed within a biological system and their types and levels can be regarded as the ultimate response of biological systems to genetic or environmental changes [47]. Central to metabolomics is a range of metabolite fingerprinting and profiling technologies and extraction methods, which profile an entire extract without bias; the richest metabolite profiles will most easily be obtained by employing a range of extraction methods and analytical instruments due to the fact that none is without bias toward certain groups of compounds. Hence, metabolomics is the study of final downstream product of a genomic response as the total quantitative collection of small molecular weight compounds (metabolites) present in a cell/tissue type to whole organism [49]. Metabolomics as of now is considered a

technically demanding interdisciplinary research field that requires expertise in the fields of biology, analytical chemistry, organic chemistry, chemometrics, and informatics sciences. Metabolomic analysis consists of three distinct experimental parts: (a) preparation of the sample, (b) acquisition of data using analytical chemical methods, and (c) data mining using appropriate chemometric methods [47]. Essentially, all these steps are strongly interrelated and interdependent.

Two main metabolite profiling strategies are (i) mass spectrometry (MS) and (ii) nuclear magnetic resonance (NMR). The gas chromatography–mass spectrometry (GC-MS), gas chromatography–time-of-flight mass spectrometry (GC-TOF-MS), and liquid chromatography–mass spectrometry (LC-MS) are extensively used MS-based techniques in metabolite analyses. The GC-MS technology enables the identification and quantification of over a few hundred primary metabolites within a single extract [47, 50]. The GC-TOF-MS offers fast scan times, resulting in an improved peak deconvolution and higher sample throughput. On the other hand, LC-MS measures a far broader range of metabolites including primary and secondary metabolites [51]. In addition to this, capillary electrophoresis–mass spectrometry (CE-MS) and fourier-transformation cyclotron resonance–mass spectrometry (FT-ICR-MS) are also used. CE-MS is considered a highly sensitive methodology to detect low-abundance metabolites in plant samples [47]. The FT-ICR-MS relies solely on very high-resolution mass analysis, which potentially enables the measurement of the empirical formula for thousands of metabolites, although it is somewhat limited by the lack of chromatographic separation. NMR approaches rely on the detection of magnetic nuclei of atoms after application of a constant magnetic field for metabolite profiling [52]. NMR can provide subcellular information and it is easier to derive atomic information for flux modeling from NMR than from MS-based approaches [47]. In plant systems, metabolomics approach has already been used to study metabolomic changes during a variety of stresses, for example, temperature [53], water and salinity [54], sulfur [55], phosphorus [56], and oxidative [57] and heavy metals [58]. These tools have recently been turned to evaluation of the natural variance apparent in metabolite composition. Metabolomics approaches have great value in both phenotyping and diagnostic analyses in plants that might eventually enable metabolomics-assisted breeding in crop plants [59].

12.4 Proteomics

Proteomics is the qualitative and quantitative comparison of proteomes under different conditions to further unravel biological processes. The term proteome refers to all proteins expressed by a genome in the targeted tissues at a defined time point. It encompasses a broad range of tools and techniques in determining the identity and quantity of the expressed proteins in cells/tissues, their 3D structure, and other interacting partners that help to disclose gene function. Changes that occur at the protein level can be traced to genetic sequences, thus forming a unique cross reference to the complex biological phenomenon being investigated. This involves

separation, identification, determination of function, and its interactions with other proteins and biological molecules [60]. Protein profiling techniques allow a rapid comparison of complex samples and direct investigation of tissue specimens. In addition, proteomics has been complemented by the analysis of posttranslational modifications and techniques for the quantitative comparison of different proteomes [60, 61].

Techniques such as matrix-assisted laser desorption/ionization (MALDI) has been employed for rapid determination of proteins in particular mixtures besides electrospray ionization (ESI). Most proteins function in collaboration with other proteins, and one goal of proteomics is to identify which proteins interact. This is especially useful in determining potential partners in cell signaling cascades [60]. There has been extensive research over the last few years to study the technical aspects of proteomics in plants [62] and studies have been conducted in *Arabidopsis*, rice [63]), maize [64], barley [65], and chickpea [66]. Proteomics not only enables the study of protein–protein interaction but also helps in identification of multisubunit complexes [67]. Furthermore, proteomics can act as a powerful approach to organize and identify the proteome through development of 2DE gel protein reference maps of subproteomes in different plant species.

12.5 Interactomics

The complexity of an organism or even a complex trait of an organism cannot be completely explained by mere total number of genes alone. The organism would utilize combinatorial complexity to manifest required form of growth and/or resources in time and space [5, 68]. Therefore, to elucidate the complete functioning of an organism, one not only need to learn the biochemical function(s) of every protein and every domain but also need to discover all protein–protein interactions: developing an interactome is a prerequisite to understand the complex web of interactions that link biological molecules in a cell [3, 4, 69]. The network of all interactions is called the interactome that thus aims to compare such networks of interactions. The interactome maps are important in defining gene function and understanding the function of macromolecular complexes. Various experimental approaches for creating large-scale protein–protein interaction maps in plants have been reviewed by Morsy *et al.* [70].

The study of the interactome requires collection of a large amount of data from a single organism under a small number of perturbations. The two-hybrid screening (Y2H), tandem affinity purification, X-ray tomography, and optical fluorescence microscopy are generally employed for this purpose [71]. High-throughput versions of some of these methods have already been developed, although there is room for further improvement. It is envisaged to combine microarrays and mass spectrometry to enhance throughput of the technique. Tandem affinity purification (TAP) is a technique for studying protein–protein interactions. It involves creating a fusion protein with a designed piece, the TAP tag, on the end. The protein of interest with the

TAP tag first binds to beads coated with IgG, the TAP tag is then broken apart by an enzyme, and finally a different part of the TAP tag binds reversibly to beads of a different type [72]. After the protein of interest has been washed through two affinity columns, it can be examined for binding partners. Interactomic approaches are increasingly becoming relevant to gain a comprehensive understanding of both basic and applied aspects of complex plant–environment interactions [35, 73].

12.6 Genomics (or High-Throughput Genotyping) and Phenomics

The omic strategies, as mentioned above, can highlight candidate genes, metabolites, proteins, and so on that are responsible for a particular phenotype [74, 75]. Importantly, this information can be used in applied breeding programs through molecular marker technologies [8, 76]. Although many kinds of marker technologies have been developed, at present, simple sequence repeats (SSRs) or microsatellite, diversity array technologies (DArT), and SNPs are the marker systems of choice [37, 77–80]. Among these systems, SNP and DArT marker systems can be used for very high-throughput genotyping.

Several high-throughput SNP genotyping platforms are available with varying levels of suitability in practical use. Two platforms, namely, Illumina's GoldenGate assay and whole-genome genotyping Infinium assay, hold practical significance. In the former platform, the genomic DNA is activated using paramagnetic particles and PCR-amplified using three oligos and a universal PCR primer pair for each SNP. Two of the oligos used are allele-specific oligos that, upon ligation to the target allele, extends and ligates to the third locus-specific oligo (LSO) that contains SNP-specific tag and sequence complementary to the universal primer. The universal primer carries allele-specific fluorescent label and contains an address sequence that helps in binding the amplified product to the beads of fiber optic array. Genotyping is done in multiple of 96. GoldenGate assays have been developed for several crop species such as barley [81], wheat [82], maize [83], and common bean [84]. SNP genotyping based on GoldenGate assay has been very successful in constructing a genetic map and trait mapping [81, 84]. Crop-specific efforts are at different levels of success in developing first-generation GoldenGate assays for SNP genotyping worldwide. It is expected that in the next couple of years, the SNP GoldenGate assays would be available and large-scale use of SNPs will become integral to genetics and breeding efforts in most of the crop plants [9, 43].

The whole-genome profiling Infinium assay is done through comparative genomic hybridization. The change in the allele composition is measured through varying signal intensities. This assay includes whole-genome amplification to increase the amount of DNA followed by fragmentation and capturing onto bead array through SNP-specific primer. The primer anneals adjacent to a SNP and extension takes place that involves incorporation of hapten-labeled nucleotide corresponding to the SNP allele. Incorporated hapten-labeled nucleotides are detected by adding fluorescent-labeled antibodies during various steps to amplify the signal. Development of Infinium assays is in progress for some crop species such as soybean, maize, and so on.

The advent of a number of omics technologies and especially high-throughput genotyping has now made phenotyping the priority in crop research. Phenotypes that can be studied across species are more attractive, particularly given the rapid development in transgenic modeling. With advances in high-throughput genotyping technologies, the rate-limiting step of large-scale genetic investigations has been the accurate high-throughput phenotyping in a large number of samples. Phenomics is an emerging transdiscipline dedicated to the systematic study of phenotypes on a genome-wide scale. It is the systematic measurement and analysis of qualitative and quantitative traits, including clinical, biochemical, and imaging methods, for the refinement and characterization of a phenotype. Phenomics require deep phenotyping, the collection of a wide breadth of phenotypes with fine resolution, and phenomic analysis composed of constructing heat maps, cluster analysis, text mining, and pathway analysis (Figure 12.1). Many technologies have been developed to help explain the phenotypic consequences of genetic and/or environmental modifications in areas such as functional genomics, pharmaceutical research, and metabolic engineering [85–87]. The advances in metabolomics

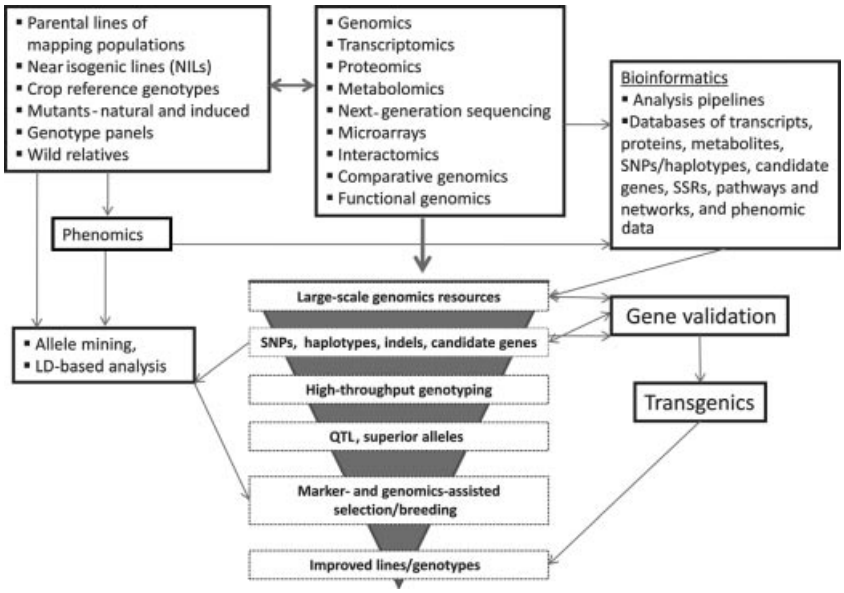

Figure 12.1 An overview of omics technologies and their applications in crop research and breeding. The omics platforms have potential to generate large-scale genomic resources, protein, and metabolite profiles from specific tissues that on their own and in combination with parallel but converging platforms can aid in pinning down the superior alleles, QTL, and candidate genes, besides contributing towards a deeper understanding of complex traits for crop improvement. Recent advances in these platform technologies and the bioinformatic pipelines have led to an accelerated development of robust and high-throughput marker systems. These advancements have ushered in new opportunities and strategies in crop research and breeding of even orphan crops.

and proteomics have a direct bearing on the large-scale phenotyping with a greater sensitivity in a high-throughput manner.

12.7 Integrated Omics Technology Approach

Availability of a number of omics technologies coupled with the vast quantity of genotyping data and volumes of precise phenotyping data opens an opportunity for displaying these techniques in an integrated approach in crop research and breeding [8, 10, 37, 42, 88]. This approach is expected to aid in gaining a better understanding of complex traits and environmental interactions [6]. This would be true both at cellular and whole-plant/crop level. Single-cell analysis was once considered beyond the capacity of omics technologies, but the recent examples of single-cell genomics, transcriptomics, proteomics, and metabolomics indicate an accelerated change largely owing to the rapidly emerging technologies that range from micro/nanofluidics to microfabricated interfaces for mass spectrometry to second- and third-generation automated, high-precision DNA sequencers. Such integration will enable the identification of genes and gene products, and can elucidate the functional relationships between genotype and observed phenotype, thereby permitting a system-wide analysis from genome to phenome, enabling accurate trait mapping, introgression of superior alleles, and in some cases the cloning of major QTL [88] for hitherto considered complex characters such as abiotic and biotic stress tolerance (Figure 12.1; see also Refs [89, 90]). Results of such an integration of omics technologies in model systems and selected crops is highly encouraging. Within next half a decade or so, omics technologies should be available for crop research and breeding in most of the crop plants.

Acknowledgments

Authors are thankful to the Indo-US Agricultural Knowledge Initiative of Indian Council of Agricultural Research (ICAR) (BF, RKV) and Department of Biotechnology (DBT) of Government of India (BF, RKV), CGIAR Generation Challenge Programme (RKV), and the European Union Framework Programs 6 and 7 (RT) for supporting research in authors' laboratories.

The Use of "Omics" Approaches in *Arabidopsis* for the Improvement of Abiotic Stress Tolerance

Aleksandra Skirycz and Matthew A. Hannah

The recent progress in "omics" approaches, which allow the identification and quantification of hundreds to thousands of biological molecules in a single sample, has allowed their wide application in the plant sciences. Their use has permitted the detailed characterization of the developmental and environmental factors that control plant responses to abiotic stress and provided a basis upon which to base approaches to improve plant stress tolerance. This chapter reviews relevant aspects of the "omics" technologies themselves and highlights the main considerations in getting from a plant sample to analyzed data. As the majority of fundamental plant research uses *Arabidopsis* as a model plant, we restrict this chapter to review examples of how the application of "omics" approaches has allowed the characterization of abiotic stress responses and the use of these data to support early discovery research to engineer plants with improved stress tolerance.

13.1
Introduction

Over the past decade, there has been an unprecedented progress in technologies to allow a detailed molecular characterization of organisms. These so-called "omics" approaches, including, to name but a few, transcriptomics, proteomics, and metabolomics, have been applied on a broad scale to numerous aspects of plant biology and have fueled the development of plant systems biology. These technologies allow identification or quantification of hundreds to thousands of molecules in a single biological sample. While previous approaches studied single or a few molecules, analysis on a much more detailed level has now become possible. The biological questions (or samples) to which these have been applied are familiar from the fields of developmental biology and environmental responses, and have increasingly incorporated genetic, temporal, and spatial resolutions.

Plants must survive and reproduce in the environment in which they grow, yet these environments are changeable and thus may often become suboptimal. These so-called abiotic stress conditions, such as drought or temperature extremes,

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

substantially affect plant growth and development and lead to major crop yield losses. Therefore, there is a considerable interest in improving fundamental knowledge of plant–environment interactions and leveraging of this knowledge to generate crops with improved yield under abiotic stress conditions in the field. As with most basic plant science, *Arabidopsis* is the model plant of choice for most laboratories and additionally can represent an intermediate testing phase in the process to improve abiotic stress tolerance in crop species.

The combination of the technological advances in "omics" approaches and the considerable interest in plant abiotic stress tolerance means there is an increasing body of knowledge that is of potential direct or indirect relevance to efforts to improve plant abiotic stress tolerance. While other chapters consider crop species directly, we will restrict ourselves to review the relevant progress and knowledge in *Arabidopsis*. We will thus briefly review relevant aspects of available "omics" technologies and the resulting data analysis before describing the application of these technologies in fundamental *Arabidopsis* abiotic stress research and finally discussing how this knowledge can be used in applied early discovery research to improve plant tolerance to abiotic stress.

13.2 "Omics" Approaches

13.2.1 Genomics

Genomics should be regarded as the enabler and namesake of those technologies that (rightly or wrongly) today have "omics" as a suffix and that will be discussed in this chapter. In plant science, the completion of the *Arabidopsis* genome sequence [1] allowed the emergence of the era of "postgenomics" whereby theoretically the entire catalog of transcripts, proteins, and (indirectly via encoded enzymes) metabolites could be discovered. It was upon this base that subsequent technological developments in "omics" approaches became possible. Furthermore, "omics" approaches are often described as the analysis of subsequent layers of information with respect to the fields of genomics, transcriptomics, proteomics, and metabolomics, as they become closer to the observed whole-plant phenotype (also called "phenomics"). Although it is these "postgenomic" technologies that are predominantly being referred to as "omics" approaches, genomics is worth highlighting here due to its integral place in the overall field of plant systems biology and the fact that with the advent of new-generation sequencing tools its importance is set to increase further. The increase in sequencing capabilities is well known and described [2], and for the purpose of this chapter it is sufficient to say that the sequencing of DNA (or RNA (transcriptomics) or modified DNA (epigenomics)) is becoming much faster and much cheaper than ever before. This makes the sequencing of genomes (species, accessions, cultivars, mutants, etc.), previously taking years of effort for a worldwide consortium, possible in days for a single

researcher to accomplish. In this context, approaches that will likely have a particular impact in the field of plant abiotic stress research will include the mapping of mutations [3], comparative genomics of *Arabidopsis* accessions, stress-tolerant relatives, and diverse plant species.

13.2.2 Transcriptomics

Of all "omics" approaches, transcriptomics has been by far the most widely applied. This was predominantly because of the availability of microarray technology that was best able to leverage the completed genome sequence, although high-throughput quantitative PCR (QPCR) and increasingly direct sequencing are also important. Microarrays are essentially glass slides that have thousands of DNA spots attached to them allowing the detection of the corresponding transcripts within a given sample. As knowledge on all known or predicted transcripts became available, they were able to be rapidly included in in-house or commercial microarrays making the "genome-wide" quantification of transcripts routine. Historically, the most popular platform has been the Affymetrix ATH1 array, for which there are now data from more than 10 000 biological samples in the public domain [4], while for other platforms, for example, the commercial Agilent and the academic CATMA array [5], there are thousands more deposited in public databases. Microarrays are still in common use, aided by the development of more sophisticated and comprehensive microarrays such as the AGRONOMICS1 Tiling array [6], but their dominance is already being challenged by sequencing-based approaches.

It should be noted that microarrays, common to any sequence hybridization-based technology, have technical limitations relating to sensitivity and specificity. It is therefore possible to detect only "known" transcripts (i.e., those sequences included in the array), which are within the dynamic (quantifiable) range of the microarray, and it may not be possible to distinguish closely related transcripts. QPCR is more sensitive and was the method of choice for the validation of microarray results; however, due to technical robustness of commercial microarrays, it is now viewed to be better to have biological validation of results (i.e., independent experiments) rather than technical repetitions (i.e., duplicate arrays) or validation (via QPCR, Northern, etc.) on the same RNA samples. Combined with automation, QPCR has also emerged as a useful platform to quantify focused subsets of genes, for example, transcription factors [7]. Other technical platforms have recently emerged that offer similar sensitivity to QPCR, notably the nanostring technology [8], although these have not yet been adopted on a broad scale. All of these technologies have in common the need for *a priori* knowledge on transcript identity. As sequencing costs have come down, it is therefore becoming increasingly attractive to directly sequence transcripts in a given biological sample. The most notable benefits are that knowledge on transcript identity is not required and the discrimination of closely related transcripts or splice variants can be improved. It should nonetheless be noted that without a

genome sequence the downstream data analysis may be prohibitively difficult or even not possible in the case of some "tag"-based methods (i.e., cutting a specific sequence) that require sequence information. Furthermore, the discussion on sequence bias is still relevant as because most sequencing technologies utilize an amplification step (i.e., requiring sequence hybridization) they will have sequence bias in transcript detection, although it is hoped that direct sequencing [9] may in the future overcome this. In summary, transcriptomics has become a routine part of plant molecular biology through the application of microarrays and QPCR, and the advent of new-generation sequencing-based methods means that there will likely be further interesting developments in the near future.

13.2.3 Proteomics

Proteomics not only refers to the measurement of cellular protein but may also encompass the study of modifications (notwithstanding, other terms may be used, for example, phosphoproteomics). Protein analysis is more challenging than for transcripts due to the more diverse structural properties of proteins (e.g., membrane bound, chemically modified, or resistant to trypsin digestion) in comparison to mRNA. Methodologies generally use some form of chromatographic separation, followed by protein identification by on- or offline mass spectrometry (MS), usually of peptides derived from proteolytic digestion (reviewed by Wienkoop *et al.* [10]). The measured peptides are mapped to the corresponding proteins using sequence information, and there are different approaches that can be used for the (semi)quantification of the corresponding proteins. In general, the peptides that map to a specific gene can be counted and the total count can indicate the abundance of the corresponding protein. Alternatively, and more quantitatively, differential labeling of the proteins contained in different biological samples may be used. This can be utilized at the level of the biological samples before harvest by supplying isotopically labeled metabolites during their growth [11], but the need to fully label samples should be considered as this can present limitations or difficulties in experimental design and plant growth conditions. For example, most labs favor the use of liquid culture as few have the specialized equipment necessary to control the CO_2 atmosphere, or the use of young seedlings may be compromised by the presence of unlabeled isotopes in seed reserves. It is therefore unsurprising that methods have been developed to allow differential labeling of samples postharvest using isotope-coded covalent tags (e.g., iTRAQ). In either approach, samples can be combined and analyzed in parallel and the differential mass of the resulting peptides can be determined via MS and used to derive accurate ratios of protein abundance in the samples. Despite such methodological and technological advances, proteomics remains challenging and time consuming meaning that it is the "omics" approach that is least frequently applied. However, despite this the importance of studying changes at the protein level is becoming increasingly recognized and no doubt its use will become more widespread.

13.2.4 Metabolomics

Metabolite profiling was adopted early with respect to the plant sciences and there are many excellent reviews [12, 13]. Generally, metabolomics refers to the simultaneous quantification of multiple metabolic compounds (e.g., primary and secondary metabolites, plant hormones, etc.) in a given biological sample. Owing to the diverse chemical nature of the substances and the greater dynamic range of their abundance, it is more technically difficult to quantify them (at a global level) than transcripts or proteins. In common to proteins, approaches usually couple chromatography-based separation followed by MS. The most widely used is gas chromatography MS (GC-MS) that routinely allows the detection of a few hundred metabolites, mostly from primary metabolism. Liquid chromatography has been mostly applied to secondary metabolites or to specific classes of metabolites, such as amino acids. Recently, advances in technology based on Fourier transform MS (FT-MS), which allow very high mass accuracy (i.e., sufficient to determine the atoms comprising a molecule), have enabled broader profiling of several metabolite classes [14]. In addition to improvements in MS technologies, the chromatography has also improved with the availability of nano-HPLC and UPLC allowing shorter run times and better resolution. Similar to proteomics, differential isotopic labeling can be used to quantify ratios of metabolites between samples, although it is more common to use chromatographic peak area or height to determine abundance [13]. Metabolic profiling is affected by "ion suppression," whereby the presence of one molecule interferes with the detection/quantification of another, which increases in relevance when little or no chromatographic separation is used. An elegant methodology to overcome this has been the use of an istopically labeled full metabolome as a "standard" that is included in each sample and against which accurate ratios can be derived to compare biological samples [14]. Taken together, metabolic profiling technologies are today a powerful approach able, in combination, to measure several hundred metabolites in a biological sample of interest; however, limitations in sample quantity, time, and resources mean that often only a subset of these possible metabolites is measured.

13.2.5 Other "Omics" Approaches

The general term "-ome" and the derived "omics" can seemingly be suffixed to any and all biological entities; however, for the purpose of this chapter, we will limit the scope to those more broadly adopted or studied by the community. There are several "omics" approaches that are based on adapted forms of those technologies already described for genomics or transcriptomics, that is, they measure modified DNA or noncoding RNAs/DNA/RNA associated with a certain protein. There are several relevant "omics"-type approaches in the field of epigenetics, which is important in the context of abiotic stress [15] and relates to the direct (e.g., methylation) or indirect (e.g., histone acetylation) modifications of DNA and the small RNA molecules that influence them. Several methodologies have been applied to study small RNAs,

including microRNAs, where their abundance can be measured in approaches analogous to those described for transcriptomics [16]. Second, genomic DNA can be treated with bisulfite or digested with methylation-sensitive restriction enzymes and combined with microarrays or sequencing to characterize DNA methylation (methylome) [16]. The next group of approaches uses chromatin immunoprecipitation (ChIP), which via the precipitation of specific proteins (or modified proteins) can be used to isolate DNA or RNA molecules that are associated with them [17]. This can be done using antibodies specific to modified histones to further characterize the "epigenome," or can be applied either to transcription factors (or any other nucleic acid binding protein), where the DNA binding sites can be identified [18], or to a specific ribosome (possibly expressed in a specific tissue) to identify transcripts being translated (i.e., "translatome") [19]. The "translatome" can also be identified by using density-based separation of polysomes and then characterizing the bound mRNA. Similarly, sequencing or microarrays can be directly applied to other RNA species, not just mRNA transcripts to detect their changes in response to stress. Other possibilities include the inhibition of transcription or translation combined with "omics" approaches in order to follow transcript turnover times or to see if a specific change occurs directly or rather indirectly via the synthesis of an intermediate protein [20].

If instead proteins are isolated rather than nucleic acid, then obviously proteomic approaches can be used to identify interacting proteins. This has been successfully applied on a large scale to obtain comprehensive interaction networks. Other methods have also been adapted to obtain protein–protein interaction data sets such as large-scale yeast two-hybrid screens or bimolecular florescence interaction that can yield large data sets. Collectively, such protein–protein data sets are increasingly referred to as the "interactome" [21].

Although the proliferation of "omics" has been most noticeable with respect to nucleic acids and proteins, there have been relevant developments in the study of small molecules. The most prominent of these has been the measurement of inorganic molecules that are important plant micro- or macronutrients, for which the term "ionomics" has been coined [22]. In summary, there are many "omics" approaches for the multilevel analysis of biological systems, which may be used either independently or in combination (i.e., integrated approaches) to investigate plant abiotic stress responses at the systems level.

13.3 Data Analysis

"Omics" approaches move beyond the study of single molecules as they generally quantify hundreds to thousands of molecules in parallel. However, as common to all biological experimentation, it is essential to note that their application and success are nonetheless based on good experimental design and appropriate data analysis. Many of these factors are well known and common to more classical experiments; however, there are also unique factors relating to the preprocessing and analysis of "omics" data that are unique and also worth highlighting in the following sections.

Top of the list for any biologist is good experimental design, for which randomization, blocking, and replication are essential considerations [23]. The variation in all factors beyond those being studied should be limited and controlled for at all stages of the experiment. Particularly, common sources of variation from environmental conditions such as temperature or light or temporal differences such as those across the day or following treatment should be closely monitored, minimized, and controlled for using appropriate experiment designs. It should be realized that variation in these factors can easily obscure the identification of the molecular basis of even seemingly drastic phenotypes or treatments. Furthermore, even if molecular changes are identified, their biological validity is ensured only by having independent biological repeats. Therefore, while pooling of plant material can help increase the number of sampled individuals, it is essential to have appropriate and sufficient biological replication from spatial or temporal repeats for statistical evaluation. The inclusion of "technical replicates" into classical statistical tests will always lead to overestimation of the significance of the observed changes.

The general approaches for primary data analysis will be covered in the following two sections either looking directly at molecular changes or considering "network analysis" based on correlation or association between molecules. The other two sections deal with the key steps of preprocessing (including normalization) of data prior to analysis and the visualization and analysis of the results from the primary analyses.

13.3.1 Data Preprocessing

Prior to analysis, all raw data from "omics" approaches require some form of preprocessing and/or normalization. The more intricate details of the diverse methods available for the various technologies are far beyond the scope of this chapter, but there are a few key considerations that are important to understand "omics" data and their limitations. First is the link between the data for a given sample and the biological molecules in that sample, that is, the "omics" data must be associated with the corresponding molecules. This is evidently relatively simple for transcriptomics but increases in complexity for proteomics and particularly metabolomics. However, even for transcriptomics, genome annotation can change over time and so the latest annotations should be sought and the potential ambiguities realized. The second key point is to ensure that different samples are comparable to each other – a process that additionally requires normalization. This is usually performed by using an algorithm that basically adjusts the "mean measurement signal" of all samples to the same value. This is very effective at removing technical variation that results from sample-to-sample variation in the labeling or detection of molecules. However, it is important to note that there can be actual biological variation in the total quantity of transcripts, proteins, or metabolites that will inevitably be removed by this process. This is best conceptualized by considering the effect on the total mRNA pool when a treatment causes a global inhibition of transcription [24], and while the absolute quantity of "all transcripts" will decline, a conventional microarray experiment assumes it does not. The only way to overcome

this is to include standards or "spiked" controls into the biological samples and to use these for normalization. Such approaches are not used in the vast majority of experiments and the possibility of such global changes are generally overlooked, although methods have been developed to control for this, particularly in transcriptomics [24, 25]. In general, the inclusion of appropriate external controls in "omics" experiments and the underlying assumption in data interpretation in their absence should be considered, particularly where a large proportion (e.g., >25%) of the measured molecules are described as changing.

13.3.2 Differential Abundance

The most common biological question addressed using "omics" approaches is to identify which molecules are changed in abundance in response to a given experimental factor; for example, which genes are induced by cold or drought? There is perhaps a surprising diversity of methods for how this question can be answered even for a single "omic" technology, let alone for diverse technologies. Although fold change and rank-based methods have and can be used, the most common and appropriate approaches are based on statistical evaluation of the comparisons of interest. This can be viewed similarly to the widely known *t*-test or ANOVA for comparison of two or more groups, respectively. However, mixed models have become the favored method for comparison due to their flexibility in evaluating experiments from the simplest design considering just a single factor (e.g., genotype A versus B) to complex designs incorporating several factors (e.g., genotype, + treatment across time) [23]. These models allow comparisons of biological interest to be easily made, such as the treatment or genotype effects, and allow a valid statistical comparison of the "interaction term" between two factors (rather than comparing lists from two tests). This area is most advanced for transcript analysis and there are many algorithms in the literature, the most favored of which "borrow" information across all molecules to increase statistical power over conventional statistics when only few replicates are used [26], an approach that has also been applied to proteomics data [27].

As generally "omics" approaches result in hundreds or thousands of tests being conducted simultaneously, the resulting *p*-values should be corrected for multiple testing. Methods that control the false discovery rate (fdr) are most popular as they allow biological conclusions to be drawn by accepting that a small (e.g., 0.01 or 0.05) proportion of the list of significant molecules will be wrong. Another often overlooked fact is that due to the low replication in many "omics" studies, the number of false negatives can be very high, which means that perhaps hundreds of molecules that are truly differentially abundant are not identified as significant.

13.3.3 Correlation and Network Analysis

Rather than comparing groups, it is also possible to use correlation-based (univariate or multivariate) approaches to identify transcripts, proteins, or metabolites of

biological interest. In general, this can be performed within a single "omics" data set, for example, looking at transcriptional correlation networks, or between multiple layers of information, such as between metabolites and transcripts or between "omics" data and an experimental (e.g., time) or physiological parameter of interest such as biomass or freezing tolerance [28]. Such approaches can be used to visualize molecules as "networks" or to group them into "modules" for further analysis. The use of correlation-based approaches, fueled by the large amount of data available, has been particularly evident for transcriptomics. Further developments have also incorporated other "omics" data such as interactome (protein–protein interactions) or transcription factor binding sites (*cis*-elements) in order to include other molecular relationships in such a "network." Additional information can also be utilized in various software algorithms to predict regulatory interactions (i.e., transcription factor – target gene relationships) to prioritize genes for functional studies [29, 30]. Similar correlation approaches have been used to associate metabolites and transcripts either to predict gene function [31, 32] or to reveal candidate metabolite signals [33]. The use of network approaches is an area of increasing interest and will no doubt lead to additional applications of relevance for the application of "omics" approaches.

13.3.4
Visualization and Comparative Analysis

The analysis of "omics" data usually results in the identification of a list of molecules of biological interest. For genes and proteins, it is useful to identify the associated molecular function or biological process, often referred to as gene ontology (GO) analysis or functional testing. In a more specific context, it is also useful to associate genes, proteins, and metabolites with the metabolic pathways in which they participate. There are many tools that are useful for GO analysis including BINGO [34] and MapMan [35] and PageMan [36]. MapMan and other tools such as KAPPA-view [37] and Aracyc [38] are able to visualize molecular changes displayed on biological pathways (or diagrams) of interest, which can be very useful for biological interpretation of complex sets of changes. Visualization of the regulation of specific genes is also aided by the development of comprehensive online tools such as the Botany Array Resource (BAR) with its popular Electronic Florescent Protein (eFP Browser) that allows tissue-, cell-, and treatment-specific gene expression changes to be visualized [39]. Furthermore, Genevestigator [40] allows a similar analysis where such differences can be visualized in graphs and heatmaps for desired genes of interest. Such tools are based on the growing abundance of public data sets, and it should be regarded that one of the main benefits of "omics" approaches has been the dissemination of thousands of data sets and the rise of computational biology. As mentioned in the preceding section, coexpression "network" analysis has been particularly successful and has benefited from data and numerous tools available online. The reader may refer to recent comprehensive reviews for both the applications (and limitations) of coexpression analysis [41] and the more general online data sources [42] on which they are mainly based. Finally, as online tools become increasingly comprehensive and integrate

multiple levels of "omics" data and allow the user to upload their own data and analyze them in the context of other data sets, for example, VirtualPlant [43], these tools will likely become more powerful for their biological application.

13.4 Characterization of Environmental Responses

Since plants are unable to escape a changing environment, plants reprogram their metabolism, growth, and development. Abiotic stress is defined as a nonliving environmental factor such as cold, drought, and heat of a potentially harmful nature. Such stressful conditions are rapidly perceived and trigger adaptation responses in plants to minimize the damage and eventually secure reproduction. In the literature, plant stress responses are often characterized using "avoidance–tolerance" models [44]. For example, osmotic stress that is common to freezing, salinity, or drought conditions will trigger osmolyte production helping plants to maintain low water potential and thus avoid dehydration while minimizing the effects of harmful reactive oxygen species (ROS) by producing protective proteins and antioxidants. These often vast physiological alterations are mediated by complex signaling pathways and are associated with changes on every "-ome" level (reviewed, for example, in Refs [45, 46]. During the last decade, functional genomics technologies have been used extensively to understand this complexity, and despite a significant progress it has become clear that stress responses are more intricate than initially expected. At first, many of the experiments focused on whole plants or mature organs and using rather severe or lethal stress conditions [47–50]. The obtained data provided a glimpse into stress expression profiles revealing hundreds of responsive genes, including key regulators, for example, class of DREB transcription factors and downstream genes such as those encoding (LEA) proteins, heat shock proteins, glutathione-*S*-transferases, and the biosynthetic enzymes of compatible solutes. The intricate hormonal regulation, including a central role for abscisic acid, became obvious. Metabolite profiling delineated a set of stress-responsive compounds, for example, galactinol and amino acid proline (reviewed by Seki *et al.* [51]), whereas proteomics studies revealed major changes in primary plant metabolism [52–55]. As expected, while some of the responses, for example, activation of ROS scavenging and repair mechanisms [48, 56], are shared between different stresses, others such as accumulation of heat stress proteins are condition specific [57]. It also became clear that stress severity, duration, time of the day, or tissue specificity can have a dramatic effect on molecular responses [19, 58–62], consistent with the fact that physiological outcome has to be precisely tailored to the surrounding environment. For example, severe drought stress is often accompanied by a collapse of photosynthesis and carbon starvation, which is in sharp contrast to moderate drought that, in fact, results in a favorable carbon balance, leading to very different molecular profiles [63]. In this chapter, we will focus on a number of recent -omics studies to demonstrate how the use of genetic variation, temporal and cellular resolution, and stress combination can help better understand plant stress responses.

13.4.1
The Use of Temporal Resolution

In a simplified view, stress imposition triggers a sequence of molecular events that will eventually translate into a new steady state and associated phenotype. Obviously, how this new steady state is reached is extremely interesting and can be addressed by introducing time component into study of interest. A comprehensive abiotic stress transcriptome data set obtained as part of the AtGeneExpress consortium will be used as an example [56]. Two weeks old plants grown in hydroponics were subjected to heat, cold, drought, salt, high osmolarity, UV-B light, and wounding. Roots and shoots of these plants were subsequently harvested at multiple time points (30 min, 1 h, 3 h, 6 h, 12 h, and 24) following stress imposition. Importantly, all treatments were done in parallel allowing direct comparison. Assisted by temporal resolution the authors could, for example, delineate an initial stress regulon that was common to all abiotic stimuli, whereas condition-specific responses developed only at the later time points. Transcripts that changed only transiently and those that stayed high or low across different time points could be identified. The obtained data were used by the authors and many other groups to generate hypotheses about causative relations between stress-responsive genes. For instance, the CERMT tool was developed taking into account the assumption that changes in transcription factor expression would precede those of downstream target genes [29]. Using simulated and real data, the authors could demonstrate that using multiple expression time series can provide reliable target gene lists for stress-responsive transcription factors. Time resolution was also successfully applied to dissect short- and long-term metabolic responses to salt stress using *Arabidopsis* cell cultures in combination with GC/MS and LC/MS technologies [64]. It is likely that predictions could be further improved by increasing the resolution of sampled time points, although this is at the moment hampered by the relatively high cost of profiling techniques.

13.4.2
The Use of Genetic Variation

Using genetic variation together with "omics" approaches is a powerful approach to dissect plant abiotic stress responses and several example cases will be given below. In the majority of cases, genetic variation is represented by loss- or gain-of-function mutants in genes associated with stress tolerance, which are then characterized alongside the corresponding wild-type plants under control and/or stress conditions. In this way, for instance, mutants in ABA synthesis and signaling assisted in discriminating between ABA-dependent and -independent transcripts and metabolites associated with drought stress [65]. Among other findings, the authors demonstrated that accumulation of proline, but not raffinose or galactinol, required functional ABA signaling. Omics approaches, particularly transcript profiling, have been also widely used to identify target genes of transcription factors central to stress responses such as CBF1–3, DREB2A, or ZAT12 [66–68]. In addition to mutants, another source of genetic variation in *Arabidopsis* is a natural variation encompassing

hundreds of different accessions that through evolution have adapted to specific, often very extreme environments. Thus, in contrast to mutant studies that are restricted to single or few genes, natural variation has the potential to provide information on how whole networks are adapted to particular stress stimuli. Significant variation in many phenotypic characteristics of *Arabidopsis* accessions including stress performance has been described in the literature and together with genetic information has provided the basis for the identification of genetic loci (QTL) responsible for the observed phenotypes (see Ref. [69] and references therein). Obviously, the underlying molecular basis of phenotypic variation can also be indirectly examined using molecular profiling. In an example study, natural variation in freezing tolerance among nine *Arabidopsis* accessions was correlated with metabolite and transcript changes to identify molecular changes that may be causally linked to differences in freezing tolerance [28]. Although only relatively few accession were used, the authors were able to delineate biological processes associated with freezing tolerance such as flavonoid biosynthesis, the CBF pathways, and downstream metabolites. A similar approach was used to identify candidate genes underlying physiological differences in drought adaptation between two extreme accessions Tsu-1 and Kas-1 [70]. Similar to the previous study, transcript profiling identified vast constitutive differences between accessions, as well as a set of genes exhibiting differential response to relatively mild drought treatment. Another example, although not directly linked to abiotic stress, indicates the power of using large numbers of contrasting lines to identify direct links between observed phenotype and molecular profiles [71]. Rather than using many different accessions, phenotypic variation in plant biomass was captured in a collection of recombinant inbred lines (RILs) obtained from Col-0 × C24 cross. Using multivariate correlation, metabolite profiles obtained for more than 200 RILs, and biomass information was sufficient to identify combinations of metabolites that significantly correlated with plant size. Surprisingly, the number of primary metabolites including energy sources such as sucrose and fumarate was negatively correlated with growth suggesting that in contrast to the former dogma that it is not metabolism that drives growth but it is rather growth that drives metabolism. In a subsequent study, the obtained data were used to successfully overlay QTL for biomass and metabolite concentrations providing list of candidate target genes such as those involved in myo-inositol metabolism [72].

13.4.3
The Use of Tissue and Cell-Specific Analysis

It is obvious that physiological responses to stress vary between the plant organs and the underlying cell types, with some of the effects being restricted to only certain cell types, while other responses are more general. This was elegantly demonstrated to also apply at the molecular level via a transcript profiling study of *Arabidopsis* roots subjected to high salt concentration, which showed that transcriptional stress responses depended highly on the cell type [60]. More specifically, roots were divided into four longitudinal regions corresponding to their developmental fate (meristematic, elongation, and mature) and six different GFP-marker lines were used to capture different

cell types present in the root. Remarkably, only a small proportion of the genes showed significant transcriptional changes in multiple developmental zones and tissue layers, whereas most of the responses were development or tissue specific. When compared to whole-root profiles, many of the specific effects were masked and thus not reported previously. Moreover, the observed changes made logical connections to the observed root phenotypes and physiology. For example, inhibition of root hair outgrowth, which prevents salt uptake into the vasculature, could be linked to downregulation of genes involved in root hair initiation in epidermis [60]. Similar conclusions could be drawn from the consequent work of Skirycz *et al.* (2010) comparing expression and metabolite profiles of growing (fully proliferating and fully expanding) versus mature *Arabidopsis* leaves harvested from plants subjected to prolonged mild osmotic stress [61]. Only very few genes and metabolites responded to stress at all leaf stages, and mature and proliferating leaves were particularly distinct. While the "classical" abscisic acid-mediated stress response was prevalent at the mature stage, ethylene and gibberellin signaling played a more prominent role in the growing leaves, and effector genes were proliferation or expansion specific. These two studies highlight the importance of tissue- or even cell-specific profiling of stress responses in order to understand the molecular basis of stress phenotypes.

13.4.4
The Use of Stress Combinations

In their natural habitats, in contrast to lab conditions, plants are usually subjected to a combination of abiotic stresses that will interact with each other (reviewed by Mittler [73]). For example, drought is often combined with heat, and while drought promotes the closure of stomata, this will lead to an increase in leaf temperature that is not optimal if combined with heat stress. In agreement, the molecular response to the combination of drought and heat stress was found to be distinct from that of plants subjected to drought or heat stress alone. Several hundred transcripts and a number of metabolites specific to the combination could be identified. For instance, plants subjected to heat and drought combination accumulated sugars rather than proline as the major osmoprotectants, as proline aggravated deleterious effects of heat. Analogous findings were also reported for other stress combinations emphasizing the importance of optimizing lab testing conditions in a way that they more resemble field conditions of interest.

13.5
Applications of "Omics" Data in the Improvement of Stress Tolerance

13.5.1
Lead Gene Discovery

"Omics" approaches are powerful tools for hypothesis generation with respect to lead discovery in the context of applied research. In the simplest sense, genes that respond

to a certain abiotic stimulus can be interesting direct or indirect candidate genes to direct approaches for engineering a specific trait including abiotic stress tolerance. This concept was demonstrated even before the adoption of "omics" approaches using the strongly cold-induced transcription factors C-repeat binding factor1 (CBF1), CBF2, and CBF3 [74], also known as dehydration-responsive element binding1b (DREB1b), DREB1c, and DREB1a, respectively [75], to engineer *Arabidopsis* plants with increased freezing tolerance [75, 76]. Subsequently, the CBF genes have been shown to be among those most consistently observed to be cold induced in expression profiling studies (reviewed in Ref. [77]) and they were also genes identified by regression analysis that were significantly correlated with acclimated freezing tolerance [28], validating that "omics" approaches can, in principle, be used to select candidate genes that are likely to give positive abiotic stress phenotypes.

Although a positive phenotypic effect is clearly desired from an applied perspective, negative phenotypes are arguably more informative in the characterization of intrinsic plant stress responses. For example, a broad comparison of transcript profiles obtained from plants exposed to 2 heat stress regimes, which led to different heat acclimation phenotypes, allowed the identification of 8 genes (from approximately 30 tested) where heat acclimation was perturbed in loss-of-function mutants [57]. Besides identifying genes relevant to stress response pathways, such negative loss-of-function phenotypes can also indicate an increased likelihood that the overexpression of those same genes may lead to improved stress tolerance. For example, the double loss-of-function mutant for two hypoxia-responsive ERF genes, HRE1 and HRE2, had increased susceptibility to anoxia, whereas the overexpression of HRE1 increased tolerance [78]. Obviously, it can also be the case that genes identified through "omics" approaches can be negative regulators and thus have a positive phenotype for loss of function. This was the case for the cold-induced cytokinin nuclear response regulator ARR7, where the *arr7* mutant had increased freezing tolerance [79].

As mentioned in the earlier sections, "whole-plant" analyses using "omics" approaches can have a low resolution and potentially miss genes that are essential components of the stress response. The utility of cell- or tissue-specific analyses for the discovery of genes affecting plant abiotic stress tolerance has been investigated only in a few cases, but has yielded promising results. For example, using cell-specific analysis, POPEYE, a bHLH transcription factor, was identified to be induced in root pericyle cells by iron deficiency and to be necessary for iron homeostasis [80]. With respect to tissue-specific differences, the analysis of different leaf stages identified alternative oxidase1a (AOX1a) as being responsive to mild osmotic stress specifically in growing tissues and that its overexpression conferred increased drought tolerance [61]. Another consideration, which has similarly been demonstrated to be useful for gene discovery, is the use of "omics" approaches in combination with exposure to a combination of abiotic stresses. For instance, analysis of the response of *Arabidopsis* seedlings to heat, anoxia, and combined heat and anoxia stress identified heat shock factor A2 (HsfA2) as a candidate gene and that loss-of-function lines were impaired in heat-dependent acclimation to anoxia, while overexpression lines were more tolerant to anoxia [81].

Given that transcriptomics data can be generally useful for gene discovery and there is an increasing body of publicly available data sets, it is perhaps not surprising

that the combined analysis of multiple data sets is gaining increasing attention. The utility of such an approach was demonstrated by Kant *et al*. who performed a meta-analysis of multiple data sets, including their own, for the most consistent stress-responsive genes. After filtering these genes for those annotated with "regulatory" functions (e.g., transcription factors or kinases), they ended up with a large number of candidate genes [82]. Among the first genes they tested, they showed reduced tolerance for a loss-of-function mutant in the clock component genes CCA1/LHY [82] and enhanced stress tolerance in loss-of-function mutants of two RNA helicases named stress-responsive suppressor1 and 2 (STRS) [83].

Metabolomics data and combined analysis of transcripts and metabolites have also proven a useful strategy for directing functional characterization efforts for determining the contributions of key metabolic pathways to plant abiotic stress responses. The observed accumulation of galactinol and raffinose and the concomitant increases in transcripts for galactinol synthase led to the demonstration that its overexpression could increase galactinol and raffinose and confer increased tolerance to drought [84]. Such approaches are not always so clear; for example, although similar increases in galactinol synthase transcripts and galactinol and raffinose are seen during cold acclimation, raffinose was demonstrated to be neither necessary nor sufficient for increased freezing tolerance [85]. On the other hand, other similar approaches investigating cold responses in *Arabidopsis* have been successful. The use of parallel transcript and metabolite profiling identified maltose and beta-amylase transcripts as being strongly induced, and the RNAi downregulation of beta-amylase reduced cold acclimation [86]. Similarly, the cold induction of polyamines and their biosynthetic enzymes directed efforts to characterize their role in plant cold acclimation. Here, the *adc1* and *adc2* loss-of-function biosynthetic mutants had reduced freezing tolerance, although in this case the effect seemed to be at least partially indirect due to interaction with ABA signaling pathway [87].

Most of these examples are based on candidate genes that were identified using data analysis approaches essentially as described in detail in Section 13.3.2. It was already noted that correlation or network approaches and more advanced software allowing data integration and visualization are becoming more important for hypothesis generation. In the context of plant environmental responses, an interesting approach was recently described in which the authors used network-based approaches including coexpression analysis to identify ELF3 as the best candidate gene for a shade-avoidance QTL they had identified [88]. In the future, it is likely that such approaches will be increasingly used, and become sophisticated, for the identification of lead genes or gene combinations for applied discovery research programs.

13.5.2
Promoter Discovery

The need for inducible or specific promoters can be a key tool in plant biotechnology and their need will increase as more complex and refined approaches are utilized in trait engineering. The potential for such approaches has been demonstrated for engineering drought tolerance via stress-inducible expression of a transcription factor [89] or for improving salt tolerance via specific expression of a sodium transporter in the root

stele [90]. Although the promoters in these two examples were not identified via "omics" approaches, specific experiments or publicly available microarray data can be a useful tool with which to identify genes from which to isolate such tissue- or cell-specific promoters. This approach is elegantly demonstrated by Yang *et al.*, who used a combination of public microarray data and their own experiments to identify genes that were highly expressed in stomata guard cells but lowly expressed in leaves, from which they isolated a specific promoter [91]. Several other cell-specific promoters isolated either individually or from GFP enhancer-trap screens [92] are available and have been used to characterize cell-specific responses to stress either at the transcriptome [60] or at the translatome [19] level. Although there are at present few examples of engineered cell-specific stress tolerance, it is likely that the availability of these lines and the genes identified via such cell-specific "omics" approaches will prove useful for future efforts to engineer abiotic stress tolerance via cell-specific approaches. Equally, the use of stress-specific promoters will also be of high value, and although the potential for cell × environment-specific promoters is clear, the obvious complexity is daunting and will likely require several years before their application becomes routine.

13.5.3
Mode-of-Action Characterization

The other main use of "omics" approaches is for the functional characterization of candidate loss- or gain-of-function lines with altered phenotype. This is somewhat analogous to the characterization of mutants described in Section 13.4.2; however, it is distinct as in this case that it is specifically directed at understanding the mode of action underlying candidate genes/events already being examined in an applied context. In *Arabidopsis*, detailed characterization using "omics" approaches is mainly used to drive additional rounds of discovery research by directly or indirectly providing additional candidate genes. One such example is the characterization of *Arabidopsis* plants with RNAi downregulation of poly-ADP-ribose polymerase 2 (PARP2), which provided new insight into how stress tolerance may be conferred through the activation of a known stress signaling pathway. Transcript profiling showed that ABA-responsive genes were upregulated and directed subsequent analysis demonstrating that ABA levels were increased [93]. However, such analysis is not always informative as either few genes may be altered or those that change may not provide any insight into the mode of action, particularly if it is previously unknown or is beyond the cell, tissue, or time resolution investigated – this proved to be the case in the characterization of the transcriptome in *Arabidopsis* lines overexpressing nuclear factor B subunits [94], where no particular molecular basis could be observed.

13.6
Conclusions and Prospects

The application of "omics" approaches in plant sciences in general and in abiotic stress research in particular has become increasingly routine over the past decade.

Although they offer unique coverage of molecular changes, these approaches are useful provided good experimental design is applied, data are appropriately analyzed, and the underlying technical limitations and assumptions are kept in mind when biologically interpreting results. Despite these caveats, their use has greatly accelerated the characterization of plant abiotic stress responses and provided a wealth of data for hypothesis generation. Their utility has been demonstrated in the context of applied research for candidate gene and promoter discovery and the characterization of plants in which improved abiotic stress tolerance has been engineered. However, given the complexity of plant stress responses it can be anticipated that we are only at an early phase in terms of engineering plants with improved stress tolerance when the complexities such as cell and tissue specificity, stress combinations, and interaction between them are considered. There is no doubt that considering the advances already made in these aspects, we will see in the future increasingly elegant solutions to improve plant stress tolerance, often driven by expert knowledge on plant physiology. However, given the potential search space that is available in this potential matrix, it is likely that computational approaches, based on the increasing availability of "omics" data, will become ever more important in order to generate hypotheses and predict which combinations to test.

Functional Genomics and Computational Biology Tools for Gene Discovery for Abiotic Stress Tolerance

Kailash C. Bansal, Amit Katiyar, Shuchi Smita, and Viswanathan Chinnusamy

Unraveling the molecular details of plant response and defense against abiotic stress factors such as drought, salt, and temperature extremes is a crucial and challenging issue in plant research. Functional genomics and computational biology have enhanced the pace of molecular dissection of abiotic stress response mechanisms. In the past two decades, significant progress has been made in identification of genes involved in abiotic stress responses in model plants *Arabidopsis* and rice through forward and reverse genetic analyses. Besides, QTL analysis is a powerful complementary technology with functional genomics to discover and isolate the genes of agronomic importance. Several QTL associated with abiotic stress responses of plants have been mapped. The availability of complete genome sequence of important model plants, namely, *Arabidopsis* and rice, QTL databases, and mapping tools facilitates genomics-based strategies for gene discovery, coupled with high-throughput techniques, for abiotic stress tolerance. Fine mapping of these QTL will help the identification of major genes and development of tightly linked molecular markers that can be employed to genetically improve crops through genetic engineering and marker-assisted selection (MAS) breeding.

14.1
Introduction

Burgeoning population imposes huge pressure on agriculture to produce more food from shrinking land and other natural resources. Hence, development of high-yield and input use-efficient crops is necessary to meet the growing food, fiber, fodder, and fuel demand. Unfortunately, plants are constantly exposed to a variety of environmental factors such as biotic and abiotic stresses, causing deleterious effects on growth, development, and thus productivity of crops [1]. Biotic stress includes insect and pathogen infection, while abiotic stresses include extremes of temperature (low/high), water availability (drought/water logging), light (low/high), and minerals

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

(deficiency and toxicity). To overcome the yield losses due to biotic and abiotic stresses, plants have evolved different strategies to avoid or manage with the stress conditions. Higher plants have evolved multiple interconnected strategies that enable them to survive under stress conditions. Plants exhibit various responses to these stresses at the molecular, cellular, and whole-plant levels [2–7]. Plants respond to stresses partly by activating the expression of stress-responsive genes that leads to adaptation at morphophysiological and cellular levels. Besides molecular genetic approaches, quantitative trait loci (QTL) mapping is an important approach for genetic dissection of complex agronomic traits for plants and thus key to the improvement of crop yield. QTL cloning by high-resolution mapping enables identification of gene(s) underlying the QTL [8]. Stress-responsive genes/expressed sequence tags (ESTs) provide a valuable source for development of gene-based markers for fine mapping of QTL. For instance, ~200 SNP markers have been developed and mapped in barley, on the basis of their differential transcription response to abiotic stresses [9]. The availability of complete genome sequence of the model plant *Arabidopsis* [10] and rice [11, 12] spp. *indica* [13] and *japonica* [14] was the first step toward the understanding the genetic complexity of abiotic stress responses. These genome sequencing programs have been complemented by rapid gene discovery from large-scale EST sequencing in *Arabidopsis* [15–18] and rice [19, 20]. In important crops that have not been sequenced or their sequencing is in progress, large-scale EST sequencing initiatives provide a cost-effective source of obtaining information about the transcribed genes of individual species [21]. Complete genome sequence and ESTs provide the necessary prerequisite for high-throughput, large-scale gene expression profiling. EST resources generated by large-scale transcript profiling reveal differential expression patterns that can often provide clues to gene function [22]. The publicly available ESTs are growing rapidly and can be obtained from NCBI-dbEST (http://www.ncbi.nlm.nih.gov/dbEST/). The recently emerged "omics" technologies (e.g., genomics, proteomics, transcriptomics, and metabolomics) have enhanced the power of deciphering the functional information at the gene level in a shorter period of time [23]. Gene characterization by forward and reverse genetics under stress conditions has significantly boosted transgenic development. Functional genomics and computational biology tools (e.g., QTL mapping and trait viewer) provide precious support to decipher genetic determinants of abiotic stress tolerance, accelerating the ongoing research on QTL/gene discovery. The objective of QTL mapping is to determine candidate genes that are responsible for variation in complex, quantitative traits [24]. They also open up new opportunities to improve stress tolerance by incorporating genes involved in stress protection from any source into agriculturally important crop traits. The availability of genomic information provides systematic candidate gene discovery with the help of various bioinformatics-based QTL mapping tools. Recently, three QTL genes have been successfully identified as candidate genes in rice, which help to understand plants' response to abiotic stresses [25–27]. Understanding the mechanisms of regulation of stress-responsive genes will help us to breed or engineer stress-tolerant crop plants. For a sustainable development of agriculture, future crops should have abiotic stress-resistant traits.

14.2
Gene Discovery in Model Organism

Agriculturally important traits such as yield, quality, and disease resistance are controlled by many genes and are known as quantitative traits (also known as "polygenic," "multifactorial," or "complex" traits). The regions within genomes that contain genes associated with a particular quantitative trait are known as quantitative trait loci. DNA (or molecular) markers are used to construct linkage maps, which are useful for gene and QTL mapping [28]. The process of QTL analysis – to identify genomic regions associated with traits – is known as QTL mapping (also called "genetic," "gene," or "genome" mapping) [28–30]. Mapping agronomically important genes can provide useful information to plant breeders. The QTL approach will facilitate gene discovery and will focus on the mechanisms that allow plants to adapt to harsh environments. As plants experience stress at different stages of growth and development, it would be useful if the genes/QTL are identified with a specific role at a given growth stage in model plant species. Discovery of genes controlling economically important traits can be used for applications in marker-assisted selection (MAS) breeding and improving crops using transgenic approaches. Gene identification from model organisms was successfully used to demonstrate their possible use in improving stress tolerance of transgenic crop plants [31–33]. Past efforts to improve plant tolerance to drought, high salinity, and low temperature through breeding and genetic engineering have had limited success owing to the genetic complexity of stress responses. The discovery of novel genes and functional variation in their roles in stress adaptation is fundamental to effective engineering strategies to impart plants greater stress tolerance. A large number of genes involved in abiotic stress responses have been cloned and characterized in recent years. Rice and *Arabidopsis* model plants have played an important role in understanding abiotic stress tolerance mechanisms [34]. Identification of abiotic stress-responsive *cis*-regulatory elements helped unravel stress signaling mechanisms, for example, dehydration-responsive element (DRE)/C-repeat (CRT) (A/GCCGAC) binding transcription factors and DRE binding protein (DREB)/C-repeat binding factor (CBF) [35, 36]. The future of crop improvement through genetic improvements can be accomplished in three major phases: First, identification of loci involved in the environmental stress tolerance at reproductive stage. Forward and reverse genetics in model plants, such as *Arabidopsis* and rice, and their tolerant relatives will play a key role in this process in years to come. Second, the appropriate alleles for the major loci will need to be identified. Association (linkage disequilibrium) mapping with genome-wide association studies will help identify useful alleles. Wild relatives of each crop will be essential for this. Finally, the translational research to develop stress-tolerant genotype by MAS and/or transgenic approach is necessary. The completion of several plant genome sequencing projects has provided public resources of genomic data for forward and reverse genetics, comparative genomics, *in silico* predictions, QTL mapping, and cloning. Some genome sequence and annotation databases for plant species are listed in Table 14.1.

14.3 High-Throughput Gene Expression Analysis

The availability of complete genome sequence of *Arabidopsis thaliana* and *Oryza sativa* model plants and other important crops has provided sufficient genomic information to perform high-throughput genome-wide functional analysis. Functional annotation and measurement of expression level of genes under various abiotic stresses are accomplished by various molecular biology techniques [37]. cDNA-AFLP (cDNA-amplified fragment length polymorphism), MPSS (massively parallel signature sequencing), and especially SAGE (serial analysis of gene expression) have been successfully used to quantify transcript abundance for different kinds of tissues or developmental stages in higher plants [38–43]. However, these techniques are time consuming and labor-intensive. High-throughput gene expression measurements have the potential to provide clues to many important biological questions involving stress response and tolerance [37]. Microarray and real-time polymerase chain reaction (RT-PCR) are

powerful functional genomics tools widely used in gene expression analysis in plants [44–51]. Microarray experiments provide significant information about stress-related genes to improve biotic and abiotic stress tolerance in plants. SAGE is another useful technique that allows rapid and detailed analysis of thousands of transcripts. The important fact about SAGE is that this technique does not require a preexisting clone; thus, it can be used to identify and quantitate both new genes and known genes [52–54]. Digital gene expression (DGE) is another approach to study transcriptome of plant crops taking less time and in a cost-effective manner [55–59]. Over the past 5 years, a new technique known as tiling array is being widely used and has become a powerful tool for the whole-genome transcriptome analysis. Tiling array technology is derived from microarray technology. In tiling array, whole genome is tiled on the chip that allows identification of noncoding RNAs. mRNA processing (intron retention/alternate splicing) is useful for ChIP-Chip to identify DNA–protein interaction. The recently developed rapid genome sequencing technology, the next-generation sequencing (NGS), has changed the way a biological problem is studied. NGS-based transcriptome analysis is superior to other available techniques since sequencing-based method is digital, highly accurate, and easy-to-perform and is capable of identifying allele-specific expression. ChIP-Chip (chromatin immunoprecipitation-on-chip), also known as location analysis (LA), is a high-throughput genome-wide identification and analysis of DNA fragments that are bound by specific proteins such as histones and transcriptional factors [60–67]. ChIP is a well-established procedure to investigate interactions between proteins and DNA. This strategy may be used to annotate functional elements, such as promoters, enhancers, repressor elements, and insulators, in genomes by mapping the locations of protein markers associated with these sites. ChIP-Sequencing, also known as ChIP-Seq, is used to analyze protein interactions with DNA. ChIP-Seq combines chromatin immunoprecipitation (ChIP) with massively parallel DNA sequencing to identify the cistrome of DNA-associated proteins. It can be used to precisely map global binding sites for any protein of interest. Chip-Seq is used primarily to determine how transcription factors and other chromatin-associated proteins influence phenotype-affecting mechanisms. Determining how proteins interact with DNA to regulate gene expression is essential for fully understanding many biological processes and disease states. CLIP-Seq [68], also called RIP-Seq [69] or HITS-CLIP [70], is a method in molecular biology used for finding which RNA species interact with a particular RNA binding protein or an RNA [71]. It employs cross-linking between the RNA and the protein, followed by immunoprecipitation with antibodies for the protein, fragmentation, high-throughput sequencing, and bioinformatics. Recently, CLIP-Seq has been applied to decode microRNA–target interaction maps [72–74]. The application of CLIP-Seq methods has significantly reduced the rate of false-positive predictions of miRNA binding sites and has also reduced the size of the search space for miRNA target sites [72, 73]. Frequently used techniques for gene expression analysis are listed in Table 14.2.

Table 14.2 Frequently used techniques for gene expression analysis in plants.

Techniques	Application	References
Microarrays	Microarray analysis has enabled the measurement of thousands of genes in a single RNA sample	[75]
Tiling arrays	Tiling arrays are an improved technology of microarray chips and basically used for the whole-genome transcriptome analysis	
ChIP-Chip (or ChIP-on-chip)	ChIP is a well-established procedure for identification and analysis of DNA fragments that are bound by specific proteins such as histones and transcriptional factors	
ChIP-Seq	ChIP-Seq is a powerful method to identify genome-wide DNA binding sites for proteins of interest	
CLIP-Seq (RIP-Seq or HITS-CLIP)	CLIP-Seq is a method in molecular biology, used to find which RNA species interact with a particular RNA binding protein or RNA	[68–71]
Real-time PCR	PCR is a method that allows exponential amplification of short DNA sequences (usually 100–600 bases) within a longer double-stranded DNA molecule	[76]
cDNA-AFLP	cDNA-amplified fragment length polymorphism is a PCR-based method that starts with cDNA synthesis from total or mRNA using random hexamers as primers	[77]
SAGE	SAGE is an experimental technique that allows a rapid and detailed analysis of thousands of transcripts	[52, 54, 78]
MPSS	Massively parallel signature sequencing is a sequencing-based technology that uses a unique method to quantify gene expression level, generating millions of short-sequence tags per library	[79]
EST	Analysis of expression sequence tags is an efficient way to obtain information about gene expression and coding sequences of uncharacterized genomes. It also gives us clue about transcripts coming from different tissues, cell types, and developmental stages	

14.4 Computational Resources: Databases and Software

Rapid genome sequencing and development of high-throughput "omics" technologies such as genomics, transcriptomics, proteomics, and metabolomics have generated a huge amount of biological data. To fully understand biological processes, researchers require to process and analyze the huge volume of data that requires high computational power. Bioinformatics is increasingly becoming an essential tool for many biological areas including systems biology [80] and plays an important role in processing and extracting biologically relevant information from this vast data. Leading bioinformatics companies are developing software to allow research scientists

to integrate their diverse data and tools under common Graphical User Interfaces (GUIs). Scientists from various organizations are continually submitting biological information in databases, which significantly contributes toward the availability of the same data sets for a wide group of researchers and thus permit rapid analysis of data. Recently, new genomic resources (e.g., QlicRice, Gramene-QTL, etc.) and tools (QTL Cartographer, MapCharts, etc.), facilitating QTL mapping and cloning, have been developed and are maintained by various laboratories. Identification of the responsible genes and their allelic variation underlying, or associated with, phenotypic trait is desired for an effective marker-assisted breeding to enhance tolerance to abiotic stress. Some handy databases and tools useful in stress biology, QTL mapping, and plant genomics are listed in Tables 14.3–14.5.

Table 14.3 Databases dedicated to abiotic stress in plants.

Database	Description	Web	Reference
QlicRice	Platform for abiotic stress-responsive QTL in rice. Database also provides information on gene ontology, biochemical pathway, and 3D structure of proteins related to abiotic stress	http://202.141.12.200/	
PLANT STRESS	Dedicated to plant environmental stress in agriculture and biology	http://www.plantstress.com/	
STIFDB (Stress Responsive Transcription Factor Database)	Collection of abiotic stress responsive genes in *A. thaliana*, including transcription factor binding sites in their promoters. Abiotic stress (drought, cold, salinity, high light, heat, etc.) responsive transcription factors have been included in this database	http://caps.ncbs.res.in/stifdb/index.html	[81]
PSGD (Plant Stress Gene Database)	Database contains ~259 biotic and abiotic stress-related genes of 11 species (*A. thaliana*, *Arachis hypogaea*, *Glycine max*, *Hordeum vulgare*, *O. sativa*, *Pennisetum glaucum*, *Phaseolus vulgaris*, *Saccharum officinarum*, *Solanum lycopersicum*, *Triticum aestivum*, and *Zea mays*). Orthologue and paralogue of stress-related genes product have also been incorporated in this database	http://ccbb.jnu.ac.in/stressgenes/	

Table 14.4 Software's for QTL mapping.

Tool	Description	URL	References
RiceGene Thresher	RiceGeneThresher is a powerful web-based server for mining genes underlying QTL in rice genome. It provides biologically supported evidence essential for targeting groups or networks of genes involved in controlling traits underlying QTL. It also contains information on genetic markers, genome annotation, ESTs, protein domains, gene ontology, plant stress-responsive genes, metabolic pathways and protein–protein interactions	http://rice.kps.ku.ac.th/Site/index.html	[82]
MapChart	Computer package that produces charts of genetic linkage maps and QTL data. It reads the linkage information (i.e., the locus and QTL names and their positions) from text files. MapChart program is freely available, but license is required before use. It can run on MS-Windows (95/98/ME/NT4.0/2000/XP) platform	http://www.biometris.wur.nl/UK/Software/MapChart/download/	[83]
QTL Cartographer	Suite of programs for mapping QTL on genetic linkage map. The programs use linear regression and composite and multiple interval mapping methods to dissect the underlying genetics of the quantitative traits. QTL Cartographer program is freely available and can run on MS-Windows, UNIX, and Mac platforms	ftp://statgen.ncsu.edu/pub/qtlcart/	[84]
PLABQTL	PLABQTL is a program written for the detection of loci that affect the variation in quantitative traits. Its main purpose is to localize and characterize QTL. The program employs the interval mapping approach. PLABQTL program is freely available and can run on MS-Windows, UNIX, and Mac platforms	https://www.uni-hohenheim.de/plantbreeding/software/	
QTL Network 2.0	QTLNetwork-2.0 is a user-friendly software for mapping QTL. The software is programmed by C++ programming language under Microsoft Visual C++ 6.0 environment. QTLNetwork-2.0 program is freely available and can run on Windows NT, 2000, XP, and 2003server	http://ibi.zju.edu.cn/software/qtlnetwork/	[85, 86]

Table 14.4 (*Continued*)

Tool	Description	URL	References
GridQTL (QTL Express)	QTL Express is a freely accessible web server. QTL Express is a user-friendly software for the analysis of quantitative trait data from outbred populations. This server is used for a wide variety of pedigree structures involving outbred populations, some of which are also relevant for crosses between inbred lines. The database contains tools for permutation analysis to set significance levels and bootstrap analysis to estimate confidence regions for the QTL location	http://www.gridqtl.org.uk/index.htm	[87]
MCQTL	The aim of MCQTL software package is to perform QTL mapping in a multicross design. MCQTL package is composed of three software. The first component reads the data from MAPMAKER files. The second component, ProbaPop, computes QTL genotype probabilities at specific chromosome location giving multiple marker data on each family, and stores them in XML-formatted files. The last component, Multipop, builds the pooled model and fits the observations on genotype probabilities. MCQTL program is freely available, but license is required before use, and can run on UNIX platform	http://carlit.toulouse.inra.fr/MCQTL/	[88]

14.5
Case Study: Development of QlicRice: a Web Interface for Abiotic Stress-Responsive QTL and Loci Interaction Channel in Rice

QlicRice database assists researchers to identify genes/QTL associated with abiotic stress tolerance and agricultural productivity. QlicRice provides a convenient navigation of QTL related to abiotic stress tolerance and its genomic, proteomic, and other information in a very user-friendly manner. QTL, their corresponding loci, and other details were collected from various biological databases such as Gramene (http://www.gramene.org/), TIGR (http://rice.plantbiology.msu.edu/), and other public repositories for having all information together in a single storehouse. QlicRice has a vibrant search page "Qlic Browser" with multiple search options in three query types: (i) Abiotic stress: detailed information on abiotic stresses affecting rice production; (ii) QTL Accession ID: complete details of QTL governing the abiotic stresses; and (iii) Locus ID: exploration of related loci. Autocomplete function in the search text area has been provided for easy and fast navigation by users by querying

Gramene QTL	Database contains a number of identified QTL from various plant crops	http://gramene.agrinome.org/qtl/	[89, 90]
TIGR	Database for rice model plant	http://rice.plantbiology.msu.edu/	[91]
TAIR	Database for *Arabidopsis* model plant	http://www.arabidopsis.org/	
PLACE	*cis*-acting regulatory DNA element finder in plants	http://www.dna.affrc.go.jp/PLACE/	[92]
Plant Transcription Factor Database	Comprehensive annotations for TF, such as functional domains, 3D structures, gene ontology, and expression information derived from ESTs and microarray	http://planttfdb.cbi.pku.edu.cn/	
Eukaryotic Promoter Database (EPD)	Annotated nonredundant collection of eukaryotic promoters, for which the transcription start site has been determined experimentally	http://www.epd.isb-sib.ch/	[93]
BLAST	Sequence alignment tool	http://blast.ncbi.nlm.nih.gov/Blast.cgi	
FASTA	Sequence alignment tool	http://www.ebi.ac.uk/Tools/fasta/	
Motif finder	A tool for identification of functional motifs	http://motif.genome.jp/	
MEME	A tool for identification of functional motifs	http://meme.sdsc.edu/meme/	[94]
Gene Evaluator (ChemGenome 1.1)	Gene identification tool	http://www.scfbio-iitd.res.in/chemgenome/index.jsp	[95]

without any accidental mistakes. It is a compendium of 974 QTL and 460 TIGR loci on different rice chromosomes related to abiotic stress. These QTL and their corresponding loci that are dispersed on different rice chromosomes have been provided in the database through 12 pie charts and physical map developed with R-statistical package (http://www.r-project.org/). Tissue-specific expression analysis can be sited to know the tissue-specific expression analysis of the QTL that are highly expressed in a particular tissue. Data on tissue-specific expression of various abiotic stress-related QTL have also been given, and it will be really useful particularly to researchers looking for promoters that are inducible but at the same time responsible for driving tissue-specific expression of the abiotic stress tolerance gene(s). The tandem repeats with their consensus sequences have also been provided in

the database, which is helpful to determine an individual's inherited traits and in the context of genomic loci/QTL evolution. Understanding the molecular functions of QTL and their role in biochemical pathways that finally determine plant phenotype during various abiotic stresses is an essential prerequisite [96]. Gene ontology analyses (http://rice.plantbiology.msu.edu/GO.retrieval.shtml) and biochemical pathway analyses by KEGG Automatic Annotation Server (http://www.genome.jp/kegg/kaas/) that assigns KEGG pathway has been used to identify the GO and KO ontologies. This information tells us about the role of the underlying genes in a metabolic pathway, in addition to the nature of their interaction with other loci. 3D structures have been included, and users can download the template structure and model, integrated in QlicRice, which have been modeled by Swiss Modeller (http://swissmodel.expasy.org/). To bridge the gap between available sequences and their unknown structure, protein structure prediction methods are important tools; thus, it is an important technique to build 3D model for further functional annotation [97–99]. As the plants experience stress at different stages of growth and development, it would be useful if the genes/QTL are identified with a specific role at a given growth stage. Several laboratories are aiming to identify such robust QTL as will remain unchanged across growth stages. Such information will be added when the database is updated on a regular basis. Moreover, owing to the global environmental changes, rise in temperature is likely to add to the existing problem of the drought affecting rice production. Hence, a deep understanding of the abiotic stress responses in crop plants on a genome-wide scale is vital for developing improved stress-tolerant crop plants [100, 101]. Overall, the QlicRice is a step forward in communicating some excellent information collected and put together in a useful database on QTL related to abiotic stresses in rice.

14.6 Conclusions and Prospects

Farmers regularly suffer from loss of crop yields due to biotic and abiotic stress factors. Development of stress-tolerant crops is a step forward in providing a tangible solution. Identification of stress-responsive genes underlying QTL is a fundamental requirement to enhanced plant tolerance to abiotic stresses. Even with rapid genome sequencing of important agricultural crops during the past decade, the execution of truthful, high-throughput phenotyping for abiotic stress tolerance traits remains a big challenge for QTL mapping studies. In recent years, a number of quantitative traits in rice (8646), sorghum (136), wheat (23), and maize (1447) have been discovered by QTL mapping and are listed at Gramene QTL database released in November 2010 (http://www.gramene.org/qtl/index.html). Scientist could enhance the progress of gene discovery for abiotic stress tolerance by effectively using the advanced genomics techniques. Through expression profiling of many genes or making whole-transcriptome chip, researchers can analyze stress-responsive gene networks, providing significant information about the role of the stress-responsive genes and their interactions with other genes. Development of

genetically improved stress-tolerant crop genotypes might be facilitated with precision by the combined use of QTL mapping and high-throughput "omics" data as discussed in this chapter.

Understanding Stress-Responsive Mechanisms in Plants: An Overview of Transcriptomics and Proteomics Approaches

Naser A. Anjum, Sarvajeet Singh Gill, Iqbal Ahmad, Narendra Tuteja, Praveen Soni, Ashwani Pareek, Shahid Umar, Muhammad Iqbal, Mário Pacheco, Armando C. Duarte, and Eduarda Pereira

Plants are static in nature and, therefore, they encounter a number of biotic and abiotic stress factors during their life cycle. Plants' responses to these stress factors are differential and complex. Since the past decade, "omics" technologies are providing the major clues for understanding plant stress response mechanisms important for crop improvement. This chapter will critically evaluate the current literature on the plant transcriptomics and proteomics for understanding plant stress responses in detail in addition to the basic concept, principles, and procedure outlines of these approaches, and will also suggest important future perspectives.

15.1
Introduction

Abiotic stresses negatively impact plant growth and development and hence are the primary cause of crop loss worldwide. Plants' adaptation to these stresses is very differential and complex and depends on the activation of cascades of molecular networks involved in stress perception, signal transduction, and expression of specific stress-related genes and metabolites [1]. Although the development of "omics" technologies including transcriptomics and proteomics is in its infancy, it indeed has helped, to a great extent, unravel the possible mechanism of plant responses to a number of stress factors. The following sections will present introduction, principle and advantages, and limitations of, first, the transcriptomic and, subsequently, of the proteomic approaches in detail.

Improving Crop Resistance to Abiotic Stress, First Edition.

15.2
Transcriptomic Approaches and Plant Stress Responses

In the layman's language, the transcriptome refers to the pools of RNA transcripts in a cell and the transcriptomics is the global analysis of gene expression at the RNA level and provides tools for the study of gene function. In fact, transcriptomics provides information on the presence and relative abundance of RNA transcripts and thus offers a better view of the active components in the cell than a genomic approach [2].

Transcriptomic approaches can be divided into two broad categories, hybridization-based approaches and sequencing-based approaches.

15.2.1
Hybridization-Based Approaches

15.2.1.1 Suppression Subtractive Hybridization

A detailed study involving identification and cloning of the relevant subsets of differentially expressed genes of interest is required to understand the molecular regulation of the major biological processes such as cellular growth and organogenesis. The subtractive cDNA hybridization has been a powerful approach in this regard to identify and isolate cDNAs of differentially expressed genes. This technique can be used to compare two mRNA populations and obtain cDNAs representing genes that are either overexpressed or exclusively expressed in one population compared to another. It can also be used for comparison of genomic DNA populations. In general, cDNA subtraction methods involve hybridization of cDNA from one population (tester) to excess of mRNA (cDNA) from other population (driver) and then separation of the unhybridized fraction (target) from hybridized common sequences. However, these subtraction techniques are labor-intensive, involve multiple or repeated subtraction steps, and often require more than 20 μg of poly $(A)^+$ RNA. In fact, suppression subtractive hybridization (SSH) is a PCR-based cDNA subtraction method that is used to selectively amplify target cDNA fragments (differentially expressed) and simultaneously suppress nontarget DNA amplification.

15.2.1.1.1 **Principle** The SSH method is based on a suppression PCR effect, introduced by Lukyanov *et al.* [3]. In this method, the normalization and subtraction steps are simultaneously performed, where the normalization step equalizes the abundance of DNA fragments within the target population and the subtraction step excludes sequences that are common to the two populations being compared [4]. It is pertinent to mention here that SSH eliminates any intermediate steps demanding the physical separation of single-stranded (ss) and double-stranded (ds) DNAs, requires only one round of subtractive hybridization, and can achieve a more than 1000-fold enrichment for differentially presented DNA fragments [5] (Figure 15.1).

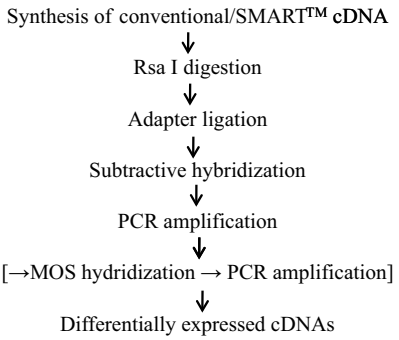

Figure 15.1 Schematic representation of the SSH procedure.

15.2.1.2 Serial Analysis of Gene Expression

*S*erial *A*nalysis of *G*ene *E*xpression (SAGE) is a method developed by Velculescu *et al*. [6] for a comprehensive analysis of gene expression patterns where it allows a rapid and detailed analysis of thousands of transcripts. SAGE technology is the second most popular high-throughput gene expression technology after microarray and does not require preexisting knowledge of the genome that is being examined and therefore SAGE can be applied to many different model systems.

Although SAGE has the capability of producing large amounts of gene expression data with the potential of providing novel insights into fundamental processes underlying (a) plant–pathogen, (b) plant–diseases, and (c) plant–stresses interactions, it has been found very effective for small-scale sequencing. Most importantly, SAGE provides an affordable and fast comparison of many experiments, stages, and so on and altogether it requires a very small amount of starting material (single-cell studies are possible).

15.2.1.2.1 **Principle** SAGE is based on three major principles: (a) a short oligonucleotide sequence, defined by a specific restriction endonuclease (anchoring enzyme, AE) at a fixed distance from the poly(A) tail, contains sufficient information to uniquely identify a mRNA transcript. As there are four nitrogen bases (A, T, G, and C), a 10 bp tag theoretically can give 4^{10} different possible sequence combinations. (b) End-to-end concatenation of short oligonucleotides form the long serial molecules that can be cloned and sequenced. (c) Quantization of the number of times a particular tag observed provides the expression level of the corresponding transcript [7] (Figure 15.2).

15.2.1.3 Microarrays

This is one of the hybridization-based approaches. A microarray is a glass microscopy slide onto which gene fragments are spotted, in the form of cDNA fragments (cDNA microarray) or *in-situ*-synthesized oligonucleotides (oligonucleotide microarray). Therefore, the microarray technology employing cDNAs or oligonucleotides is a powerful tool for analyzing gene expression profiles of plants exposed to various environmental stress factors. In fact, depending on the target nucleic acid

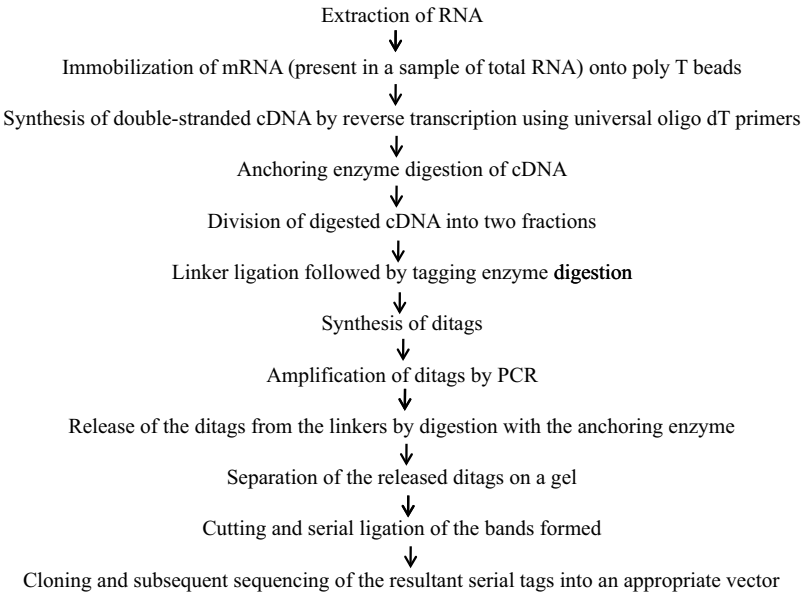

Figure 15.2 Schematic overview of major events in SAGE.

components, cDNA microarray-based technologies have been subdivided into following two formats:

i) Oligonucleotide array
ii) cDNA microarray

15.2.1.3.1 **Oligonucleotide Array** The oligonucleotide type of array consists of oligonucleotide targets, generally less than 25 mer in length, which are generated *in situ* on a solid surface by light-directed synthesis [8, 9]. Synthetic linkers modified with photochemically removable protecting groups are attached to the glass substrate. Light is then directed through a photolithographic mask to specific areas on the surface to produce localized photodeprotection. Hydroxyl-protected deoxynucleotides are incubated with the surface so that chemical coupling occurs at the sites that have been illuminated in the preceding step. By repeating these procedures with new masks, hundreds of thousands of oligonucleotides can be synthesized in a very small area [9, 10]. Alternatively, oligonucleotide arrays can be constructed by spotting presynthesized oligonucleotides on the solid surface [11–13].

Because oligonucleotide arrays are designed and synthesized on the basis of sequence information, physical intermediates such as cloning and polymerase chain reaction (PCR) are not required. Specific sequences, which are nonoverlapping if possible or minimally overlapping if necessary, can be designed to increase the hybridization sensitivity, even through their shorter sequences [10]. The oligonucleotide array is applied when more precise analysis, including the detection of single-nucleotide polymorphisms, is required [14].

15.2.1.3.2 **cDNA Microarray** The principle of microarray studies is based on the ability of an mRNA molecule to hybridize to its original DNA sequence spotted on the array. Messenger RNA is extracted from samples such as control organisms and test organisms. The mRNA is reverse transcribed to cDNA and labeled with a fluorescent label. One sample is labeled with a green fluorescent dye (Cy3), whereas the cDNA from the other sample is labeled with a red fluorescent dye (Cy5). Cy3- and Cy5-labeled samples are mixed together in equal quantities and hybridized to the microarray. The array is then scanned using laser emission. A software is used to visualize the expression levels of mRNAs of the genes and the amount of each labeled target bound to each spot on the array is quantified. Now, it has become possible to identify induced, repressed, or unchanged mRNA expression by determining the ratio of signal intensities between control and test cDNA. However, readers may consult review article by Hegde *et al.* [15] for insights into the major technical aspects of microarray fabrication, hybridization, and analysis; in addition, an article by Lettieri [16] may be useful on the applications of the microarray technique in a toxicological context.

The cDNA microarray can also be differentiated on some other ground such as the fabrication of cDNA microarray by printing cloned and amplified cDNAs onto the solid surface. Furthermore, the advantages of the cDNA microarray compared to the oligonucleotide array include less susceptibility and higher specificity due to the longer sequences of the targets [17, 18]. However, cDNA may contain repetitive sequences that are often observed in various genes, or similar sequences that are found in family member genes. These nonspecific sequences may affect the sensitivity of the cDNA microarray. The cDNA microarray can be easily used for screening steady-state mRNA expression levels [14] (Figure 15.3).

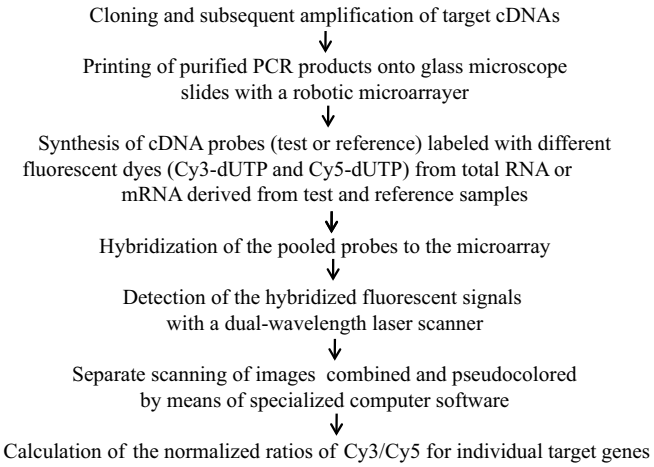

Figure 15.3 Outline of the principle of the cDNA microarray analysis system.

Advantages of Microarray Technology

- Microarray technology has largely helped in the global gene expression analysis.
- Analyses of plant defense responses.
- Microarray has been used in genomic-wide research, mutational analyses, pharmacology, toxicology, aging research, and molecular analyses of fatal diseases.

Disadvantages of Microarray Technology In addition to the significant advantages listed above, several weaknesses of microarray technology can be summarized as follows:

- High cost and time consumption, and necessity of special devices.
- Difficulty of data interchanges between individual microarrays.
- Microarray is difficult for the expression levels between individual targets to be compared in the same RNA sample (because of different hybridization rates due to variations in melting temperature depending on sequence and length of target gene fragments).

15.2.2 Sequencing-Based Approaches

Sequencing-based approaches have largely replaced the hybridization-based approaches and significantly helped gene expression analysis over the past 5 years. For the study point of view, sequencing-based approaches can be divided into two: (a) DNA sequencing of expressed sequence tag (EST) libraries and (b) next-generation sequencing (NGS).

15.2.2.1 DNA Sequencing of Expressed Sequence Tag Libraries

Expressed sequence tags represent short, unedited, and randomly selected single-pass sequence reads derived from cDNA libraries, providing a low-cost alternative (also called "poor man's genome) to whole genome sequencing, with a glimpse of the transcriptome of an organism at various stages of development. EST sequences are generated by single-pass DNA sequencing of clones randomly selected from cDNA libraries and represent partial descriptions of the transcribed portions of genomes [19]. EST sequences are widely used for a rapid and cost-effective discovery of new genes, verification of the exon–intron structure of predicted genes, and as resources for gene mapping and cDNA array construction [20]. ESTs are used as a fast and efficient method of profiling genes expressed in various tissues, cell types, or development stages [21]. One of the many interesting applications of EST database (dbEST) is gene discovery where many new genes can be found by querying the dbEST with a protein or DNA sequence.

ESTs have become an invaluable resource for gene discovery, genome annotation, alternative splicing, SNP discovery, molecular markers for population analysis, and expression analysis in animal, plant, and microbial species [22]. Although

several alternatives have been described since the emergence of EST sequencing projects, none has yet totally supplanted the use of bacterial vectors and Sanger sequencing [23].

15.2.2.2 Next-Generation Sequencing

Next-generation sequencing technologies are a set of new, state-of-the art, high-throughput sequencing technologies that came into existence after the dramatic progress in sequencing instrumentations, from Sanger-based methods, using slab gels, to capillary electrophoresis (CE). In fact, the NGS technologies differ from conventional capillary-based sequencing in that NGS has departed from Sanger sequencing chemistry and sequencing is often performed on templates formed as beads or spots of DNA [24]. NGS platforms are being utilized for targeted sequencing of candidate genes or genomic intervals to perform sequence-based association studies.

Several NGS technologies have recently emerged that can be discussed under following subheadings:

- Pyrosequencing
- Fluorescent-labeled sequencing by synthesis
- Sequencing by hybridization and ligation, and microchip-based CE

15.2.2.2.1 **Pyrosequencing** The pyrosequencing technique is based on the process of sequencing by synthesis. It was developed by 454 Life Sciences and Roche Applied Science.

Principle Pyrosequencing is based on the principle that when a nucleotide is incorporated into the growing DNA strand, the pyrophosphate is released, which is subsequently converted to ATP by enzyme; a light is produced when ATP comes in contact with enzyme luciferase (Luc). Individual and sequential addition of dNTPs to the growing DNA molecules takes place. The incorporation of a nucleotide emits the flash of light signals that can be easily correlated with the incorporation of specific nucleotide.

454 Life Sciences has developed several machines for pyrosequencing. Genome Sequencer (GS)-20 was the first next-generation DNA sequencer on the market released in 2005. Margulies *et al.* [25] reported that GS-20 was able to read up to 25 million bases of bacterial genome in a single 4 h run. The Genome Sequencer FLX (GS-FLX) was released in 2007. This instrument is able to read lengths of 250 bases and is able to perform mate-paired reads. In addition, an average of 100 million DNA bases can be sequenced in a 7.5 h run [26]. In 2008, 454 Life Sciences launched the GS-FLX Titanium series reagents for use on the present instrument, with the ability to sequence 400–600 million base pairs with 400–500 base pair read lengths. With its high accuracy, low cost, and long reads, many researchers have switched from traditional Sanger capillary sequencing instruments over to the 454 sequencing platform for a variety of genome projects.

15.2.2.2.2 **Fluorescent-Labeled Sequencing by Synthesis** Genome Analyzer (GA) system developed by Illumina uses a polymerase-based sequencing-by-synthesis

(SBS) chemistry. This platform utilizes fluorescent-labeled and reversible terminator chemistry, unlike the instrument by 454 Life Sciences, but produces read lengths of approximately 50 bp and >2000 Mb of sequence data per run over the course of approximately 4 days [24]. In addition, Illumina's GA system can be used in gene expression, SNP discovery, base resequencing, and ChIP experiments (ChIP-seq).

15.2.2.2.3 **Sequencing by Hybridization and Ligation, and Microchip-Based Capillary Electrophoresis** The instrument based on the method of sequencing by hybridization followed by ligation was developed by Applied Biosystems (ABI) generally called sequencing by oligonucleotide ligation and detection (SOLiD) [27]. In fact, The SOLiD technology platform uses emulsion PCR and sequencing by oligonucleotide ligation and detection. SOLiD technology can be potentially used in gene expression analysis and other approaches. The overall accuracy rate for the SOLiD system is greater than 99.94% and this applies to paired end runs that produce 50 bp reads.

The microchip-based capillary electrophoresis-based sequencing systems involve the separation of fluorescent-labeled sequencing samples on hair-thin, 30–50 cm long capillary gels. CE array chips have been fabricated on the basis of the well-understood behavior of a single-channel chip system. Different materials, for example, silicon [28], glass [29], and plastics [30, 31] have been used. A variety of different fabrication processes have also been developed to accommodate the complicated requirements and materials used for making such a device. Microchip-based CE systems have demonstrated use in diverse applications such as the separation of amino acids [32], analysis of blood serum cortisol [33], examination of polymerase chain reaction amplicons [34], and analysis of metal–ion complexes [35]. However, readers are advised to consult recent, excellent reviews by Hert *et al*. [26] and Simon *et al*. [24] for a detailed working principle and application of ABI-SOLiD and CE array-based sequencing.

Almost all the instruments for next-generation sequencing are able to generate three to four orders of magnitude more sequences and are considerably less expensive than the Sanger method on the ABI 3730xL platform (hereafter referred to as ABI Sanger) [36–39]. These next-generation sequencing methods promise a cost-effective means of either deeply sampling or fully sequencing an organism's transcriptome, with even small experiments tagging a very large number of expressed genes.

15.3
Proteomic Approaches in Plant Stress Responses

The study of complex biological questions through comparative proteomics is becoming increasingly attractive to plant biologists. Since the past few decades, the major aim of proteomic studies is to decipher the constituents of a proteome, thus to reveal the basic mechanism of plant responses to various environmental stresses by analyzing changes and the dynamics of changes on the protein level. It is pertinent to mention here that attention has been focused on the determination of the function

and functional network of proteins by proteome analysis after the completion of genome sequences of several organisms. Although sequence analysis of genomic DNA started in the 1990s on a full scale, developed rapidly during the past decade, and made available the entire sequence of genomic DNA for many organisms including higher plants, animals, and human, and the expression of genes can be analyzed at the transcriptional level, the expression of proteins cannot always be analyzed from gene expression because there exists a relatively low correlation (correlation coefficient about 0.5) in quantity between mRNA and protein [40, 41]. Moreover, information on protein posttranslational modification, structure, and protein–protein interaction cannot be provided by the DNA sequence and/or the expression of mRNA. In addition, almost all proteins are posttranslationally modified and then form specific structure and function through protein–protein (ligand) interaction. Therefore, the analysis of proteins assumes great importance. Although proteome research started after the genome sequence analysis was accomplished, the developments over the last few years have been remarkable [41]. The systematic analysis of proteins in plants has greatly helped researchers to understand gene functions through complementation of gene and gene expression analysis in detail. Recently, the development of advanced techniques for revealing coding genes of the organism under study, gene annotation, and functional characterization have added great momentum to plant proteome analysis.

Proteomic analysis is a multistep process that typically involves protein extraction, fractionation, separation, and mass spectrometry (MS). However, a classical proteomics work involves the following two major steps: (i) *separation of proteins step*, usually 2-dimensional gel electrophoresis (2DE), and (ii) *identification of separated proteins step*, usually mass spectrometry.

The following sections will review various gel- and nongel-based approaches that are used in a wide range of biological systems for studying differentially expressed proteins including multidimensional protein identification and labeled or nonlabeled approaches.

15.3.1
Gel-Based Approaches

Gel-based proteomics generates qualitative and quantitative protein behavioral data and as such it provides a core technology to integrate information produced using various "omic" technologies.

15.3.1.1 One- or Two-Dimensional Polyacrylamide Gel Electrophoresis

Depending on the plane of separation, the gel-based approaches for proteome analysis may be one or two dimensional. The 1-dimensional electrophoresis (1DE) is used for most routine protein and nucleic acid separations. The support medium for electrophoresis can be formed into a gel within a tube or it can be layered into flat sheets. In general, the tubes are used for easy 1DE separations.

O'Farrell in 1975 [42] first described the two-dimensional polyacrylamide gel electrophoresis (2D-PAGE). This is the simplest, most popular, and versatile method

of protein separation among a rapidly growing array of comparative proteomic technologies. In fact, 2DE allows for the separation of complex protein and is based on the orthogonal separation of proteins according to their isoelectric points through isoelectric focusing and molecular mass separation using SDS-polyacrylamide gel electrophoresis (PAGE). An SDS-PAGE is run first in one direction and then again at right angles. In the first dimension, an isoelectric focusing (IEF) gel is run and in the second dimension the proteins are separated in SDS-PAGE. A greater number of individually different proteins can be resolved in a highly repeatable fingerprint-like pattern. Two-dimensional gel-based strategies separate intact proteins on the basis of both charge (isoelectric point, p*I*) and mass, and therefore have the ability to resolve multiple charged isoforms (that may result from phosphorylation or other charged posttranslational modifications) and biologically significant proteolytic products.

Advantages of 2DE

i) Represents entire proteome.
ii) Can resolve up to 5000 different proteins simultaneously (≈2000 proteins routinely).
iii) It can detect and quantify <1 ng of protein per spot.
iv) Provides more than a raw list of proteins, and also intensities.
v) Can track posttranslational modifications.
vi) Preset conditions can be manipulated to enhance resolution (pH ranges, size of gel, staining methods, solubility, etc.).
vii) Delivers a map of intact proteins that can be stored and analyzed at will.

Limitations of 2DE

i) Reproducibility and sensitivity are less.
ii) Poor resolution of hydrophobic or membrane-bound and nuclear proteins.
iii) Sample loading/sample size capacity can limit experiments.
iv) Hard to resolve very acidic and/or very basic proteins (pH range from 2.5 to 12), very small, or very large proteins.
v) Difficult to automate process or create accurate databank standards.
vi) Only highly abundant proteins from total cell lysates are visualized and low-abundance proteins of physiological relevance, such as regulators or signaling proteins, are difficult to detect.

The introduction of immobilized pH gradients (IPGs) has largely overcome the major shortcomings listed above for the first dimension of 2DE [43]. A pH gradient formed by mixtures of acrylamide buffers is covalently fixed to the acrylamide matrix during gel polymerization. The gradient does not drift and cannot be distorted. Here, a series of chemically well-defined acrylamide derivatives with the general structure $CH_2{=}CH{-}CO{-}NH{-}R$ (where, R contains either a carboxyl or an amino group) are used that form a series of buffers with different p*K* values ranging between 1 and 13. A true steady-state IEF with increased reproducibility is allowed because of the

generation of extremely stable pH gradients due to occurrence of copolymerization of the reactive end with the acrylamide matrix. With this improved first dimension, not only a substantially wider spectrum of proteins can be resolved throughout the entire pH gradient in one gel but also lower abundance proteins caused by increased sample loading capacity can be detected.

Significant improvements to the 2DE are being made with the advancement of new technologies such as (a) the use of IPG DryStrip technology, (b) the use of semiautomated devices such as the IPGphor in the first dimension, and (c) the use of multiple SDS-PAGE apparatus for running up to 20 different samples in parallel in the second dimension. With the application of fluorescent dyes or isobaric tags, now we can have (a) improved solubilization and (b) separation of hydrophobic proteins, (c) display of low abundance proteins, and (d) reliable protein quantization. In addition, the use of multiplexed fluorescent Cy-Dye staining of different proteome states in difference gel electrophoresis (DIGE) technology has largely eliminated the technical irreproducibility of 2DE.

Unlu *et al.* [44] first introduced the two-dimensional differential gel electrophoresis (2D-DIGE) technology. 2D-DIGE uses three spectrally resolvable fluorescent dyes (Cy2, Cy3, and Cy5) to label up to three samples to be run together on the same 2D gel, adds an essential quantitative component to 2D-GE, and allows for the detection of subtle changes in protein abundance with statistical confidence. As discussed above, a classical 2DE approach lacks the intrinsic gel-to-gel variation that requires several replicate gels of each sample that are not directly overlapped. With the use of multiplexing methods such as fluorescent 2D-DIGE, substantial variability can be reduced by displaying two or more complex protein mixtures labeled with different fluorescent dyes in a single 2D gel. In addition, the use of spectrally resolvable fluorescent dyes also renders 2D-DIGE much more quantitative than colorimetric methods. The detection of proteins in samples in 2D-DIGE has a large dynamic range of 10^4–10^5, and here the dye sensitivity is capable of detecting 0.25–1 ng of sample, thus enabling the detection of relatively low copy-number proteins. Therefore, with this excellent sensitivity, DIGE can be used to analyze relatively small amounts of even very complex cell extracts.

It is pertinent to mention here the other gel-based approach in which metabolic labeling of proteins is done using radioactive isotope-labeled amino acids, and 2DE and recording are done on color negative film by radiographic exposure [45]. Spandidos and Rabbitts [46] described another gel-based subproteome differential display method in which the radiolabelled proteins are used from one source and silver-stained proteins from a second source, which are mixed in a gel in a 1 : 100 ratio, to allow the precise discrimination between members of each subproteome (chromatographic fractions) using commonly available software. In the same year, Gerner *et al.* [47] developed a quantitative proteome profiling method where precise quantitation both of the protein amount and of the ^{35}S incorporated is allowed using a combination of radiolabeling and SYPRO ruby staining of the same gels. In addition, this method also determines the absolute values of cell protein amounts, as well as synthesis and turnover rates.

15.3.2 Nongel-Based Approaches

It is evident from above discussion on gel-based approaches for proteome analysis that most of the classical proteomics approaches suffer from a number of limitations. The identification of proteins by mass spectrometry was made possible by the development of "soft" ionization techniques, namely, matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) developed in the late 1980s in Europe by Michael Karas and Franz Hillenkamp and in the United States by John Fenn, respectively. MS is now firmly entrenched as the method of choice for both protein identification and characterization of posttranslational modifications. In addition, MS has become an increasingly attractive analytical instrument for biologists due in part to new ionization methods and major improvements in mass accuracy, resolution, sensitivity, and ease of use. Therefore, with the introduction of various nongel-based approaches for proteomics studies, we can achieve a dynamic range of analysis (usually 10^3–10^5) and identify low-concentration proteins. In fact, the most of nongel-based approaches digest complex mixtures of proteins in solution where the resulting peptide mixture is fractionated by one or several steps of capillary chromatography and analyzed in a data-dependent manner by MS/MS. We may summarize the major steps in MS as follows: MS consists of (i) an ion source, (ii) the mass analyzer, and (iii) an ion detection system. Analysis of proteins by MS occurs in three major steps: (a) protein ionization and generation of gas-phase ions, (b) separation of ions according to their mass to charge ratio, and (c) detection of ions. In nongel-based approaches such as isotope-coded affinity tag (ICAT) and multidimensional protein identification technology (MudPIT), samples are directly analyzed by MS, whereas in gel-based proteomics (2DE and 2D-DIGE), the protein spots are first excised from the gel and then digested with trypsin. The resulting peptides are then separated by liquid chromatography (LC) or directly analyzed by MS. The experimentally derived peptide masses are correlated with the peptide fingerprints of known proteins in the databases using search engines (e.g., Mascot and Sequest).

15.3.2.1 One-Dimensional LC-MS/MS Technology

Identification of proteins is required for understanding the complex and highly dynamic proteome of a cell/tissue/organ/organism. For this purpose, mass spectroscopy has been widely used. However, mass spectrometers alone cannot resolve more than a certain number of ion signals, therefore, before identification of proteins, reduction of sample complexity by using an advanced separation technique is necessary. Mass spectroscopy coupled with liquid chromatography now has become a method of choice for identification of proteins present in a complex proteomic sample. LC-MS/MS is an advanced technique that combines the separation capabilities of liquid chromatography with the mass analysis capabilities of mass spectrometry.

15.3.2.1.1 Principle In LC-MS/MS, complex protein mixtures are first digested into small peptides that are separated by liquid chromatography. It is important to note that this method is based on peptide separation, instead of protein separation,

because peptides in complex mixtures exhibit a more uniform behavior than individual subclasses of proteins [48]. It is also important that these small peptides can be easily ionized in the mass spectrometer in comparison to the large proteins.

For single-dimensional separation of protein digests, i.e., peptides by liquid chromatography, a nanocolumn packed with reverse-phase C18 resin is used. Peptides bind to C18 chain by hydrophobic interactions. After loading onto the reverse-phase C18 resin nanocolumn, they are directly eluted into the ionization chamber of mass spectrometer.

For ionization, generally electrospray method is used. These ionized peptides are first detected as charged ions that are separated by mass/charge ratio. Peptide with a specific mass/charge is then selected and further fragmented using "collision-induced dissociation" [49, 50]. It takes place in a collision cell filled with N_2 gas with a certain pressure. The selected peptide ion is excited by applying a certain voltage and then it undergoes a collision-induced dissociation by energetic collision with N_2 molecules. After that, they are sent through a second mass spectrometer that scans and detects fragmentation pattern. This CID fragmentation pattern is used to determine the sequence of the peptide and this sequence information is then used to search against databases using computer software for protein identification. This approach is known as MS/MS technique or tandem mass spectroscopy (Figure 15.4).

Advantages of One-Dimensional LC-MS/MS Technology LC-MS/MS is a superior method for protein identification. Identification of proteins in a complex mixture of more than 50 analytes can be achieved without prior purification by this technology (51–53). Its advantages are as follows:

i) Its sensitivity is high because of the use of nanocolumn which can concentrate peptides many folds before detection by MS/MS.
ii) All amount of the sample loaded on a LC-MS/MS system is utilized during ionization process, therefore for detection of a less abundant protein, more amount of sample can be utilized.
iii) Another advantage of LC-MS/MS is its reliability. Confidence level of protein identification is high as it is based on MS/MS sequencing of only one peptide.

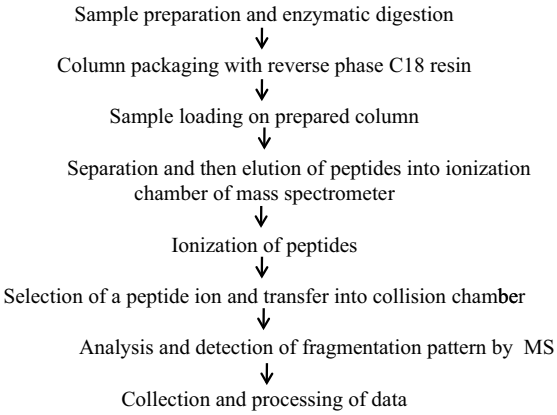

Figure 15.4 Schematic representation of the one-dimensional LC-MS/MS technology.

Limitations of One-Dimensional LC-MS/MS Technology The limitations of this technology are as follows:

i) This technique is routinely used to identify proteins directly from complex mixtures but its sensitivity is limited by the separation capacity of 1D-LC technique.
ii) In LC-MS/MS, data acquisition, database search, and search result analysis may take several hours which is time-consuming.

15.3.2.2 Multidimensional Protein Identification Technology

MudPIT was developed by Washburn *et al.* in 2001 [54]. It is an advanced technology for large-scale analysis of proteome. In general, MudPIT is a combination of two or multidimensional liquid chromatography systems with tandem mass spectrometer.

15.3.2.2.1 **Principle** In this technology, a mixture of proteins is first subjected to reduction, alkylation, and digestion. Reduction breaks cysteine disulfide bonds, alkylation prevents reformation of these bonds, and digestion converts the protein mixture to a mixture of peptides. The digested sample is directly loaded onto a nanocolumn with an internal diameter of 50–100 μm that has a tip with an inner diameter of 2–5 μm [55–58]. The nanocolumn is packed with C18 resin followed by strong cation exchange (SCX) resin. This is known as biphasic column. Desalting of samples containing high salt concentration is required before loading onto this biphasic column. Alternatively, a triphasic column containing C18 resin, SCX resin, and C18 resin in a sequential manner is also generally used. After loading, the column is attached to the tandem mass spectrometer. A high-performance liquid chromatography (HPLC) pump is used to supply different buffers through the column for separation and elution of peptides. In a triphasic column, peptides are desalted in the first step by C18 resin and then they are eluted onto the SCX phase [59]. In SCX, separation is based upon charge. Peptides of similar isoelectric point are sequentially advanced to next C18 resin where separation takes place on the basis of size and hydrophobicity. Thus, peptides are stepwise separated using SCX and C18 resins. After separation and elution from the nanocolumn, peptides are ionized by ESI method and then subjected to the mass spectrometer, where they are separated on the basis of their mass-to-charge ratio (m/z). Selected peptide ions are fragmented via collision-induced dissociation in the tandem mass spectrometer. Tandem mass spectra are generated and are searched against a protein database to determine the peptide sequence and their proteins [53, 60] (Figure 15.5).

Advantages of Multidimensional Protein Identification Technology The use of MudPIT has rapidly increased in proteomics research as it has revolutionized large-scale analysis of complex proteome. It is unbiased, as proteins of extreme values of molecular weights, pI, hydrophobicity, and abundance can be identified with equal sensitivity. MudPIT has been used in a wide range of proteomics experiments [61–66]. These include the following:

i) Identification of protein complexes.
ii) Profiling of organelle/membrane/cell/tissue-specific proteins.

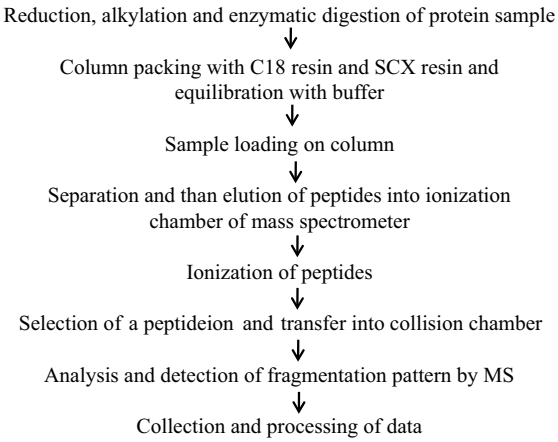

Figure 15.5 Schematic representation of the multidimensional protein identification technology.

iii) Identification of posttranslational modifications.
iv) Quantitative comparison of protein expression level by coupling this technology to labeling methods such as stable isotope labeling, SILAC or iTRAQ [67, 68].

Limitations of Multidimensional Protein Identification Technology The success of MudPIT greatly depends upon the chromatographic separation of mixtures of peptides. The limitations of MudPIT are as follows:

i) Requirement of high-quality nanocolumn and solvents of highest purity.
ii) MudPIT column is a nanocolumn; therefore, it has a limited sample loading capacity.
iii) Successful packing of column for good reproducibility is required.
iv) MudPIT analysis of complex proteome generates huge amount of data. For analysis of such data, advanced computational tools are necessary, and this analysis step can take time from few hours to few days depending upon the sample complexity, the size of database being searched, and the computational tools being used.

15.3.3
Labeled or Nonlabeled Approaches

Mass spectrometry-based methods have become popular not only for qualitative but also for quantitative analysis of a proteome. Information on what types of proteins are expressed in a proteome and what is the level of expression of these proteins is also important.

In classical quantitative proteomics, proteins are separated by one-/two-dimensional polyacrylamide gel electrophoresis and then identified by mass spectrometry [69]. Here, quantification is based upon intensity of staining of a protein. Another technique 2D-DIGE provides more precise quantification as samples to be compared are run together on the same gel; therefore, errors due to separate gel runs get removed [70]. These classical approaches have gel-based limitations such as low-

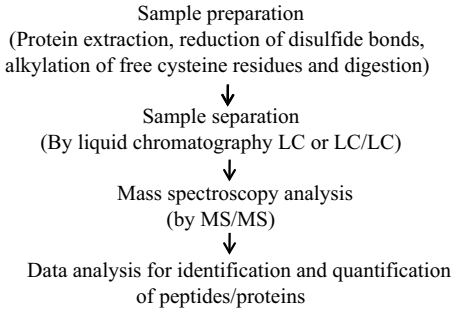

Figure 15.6 Outline of the procedure of the MS-based quantitative methods.

resolution protein separation and difficulty in identification of proteins of extreme molecular weights and p*I* values and that of low solubility [71–73]. These limitations have been overcome by modern mass spectrometry-based methods. Two types of MS-based quantification methods have been developed for extensive comparison of multiple proteomes (Figure 15.6):

1) Labeled quantitative methods
2) Label-free quantitative methods

In labeled quantitative methods, samples to be compared are first separately labeled with different isotopes after which they are pooled together and then they are subjected to sample preparation, separation, and analysis by MS/MS. While in case of label-free quantitative methods, each sample is separately prepared, separated, and analyzed.

15.3.3.1 Principle of Quantification

In label-free quantitative methods, quantification is based on "spectral counting" [74]. Spectral counting is based upon the number of times a particular peptide is identified by MS/MS, which is directly proportional to abundance of corresponding protein present in the sample.

In labeled quantitative methods, during separation by liquid chromatography differentially labeled peptides elute simultaneously, but due to mass difference, two forms of a peptide can be detected by mass spectroscopy. Quantification is done by comparing their signal intensities [75–77]. Intensity ratio of deferentially labeled peptides is calculated and subsequently the fold change in the ratio of peptide and protein is calculated. Thus, relative quantification is performed by labeling approaches.

15.3.3.2 Types of Methods

Labeling approaches include15N/14N metabolic labeling [78], stable isotope labeling by amino acids in cell culture (SILAC) [79], 18O/16O enzymatic labeling, ICAT [75], isotope-coded protein labeling (ICPL) [80], isobaric tags for relative and absolute quantification (iTRAQ) [81], tandem mass tags (TMTs) [82], and other chemical labeling. In case of label-free approaches, normal LC-MS and LC-MS/MS are widely used methods [83, 84].

Although labeling methods have provided high delectability and reproducibility of protein quantification, they have some limitations including complexity in sample

preparation, requirement of high amount of sample, expensive reagents, increased time span and specific computational tools, and importantly incomplete labeling of samples. Therefore, label-free methods being cleaner and relatively cheaper are gaining more interest [78, 85].

15.3.4 Data Mining Tools

Software is used for analysis of a large amount of data generated by modern mass spectroscopy-based techniques. Different search methods are used for peptide identification. These methods can be divided into three types: peptide mass fingerprint, sequence query, and MS/MS ion search. Digestion of a protein using a specific enzyme results in mixture of peptides whose mass spectrum provides a fingerprint of such specificity that protein identification is possible. Therefore, it is known as peptide mass fingerprinting. But it has one drawback that only proteins with already known sequence can be identified. In sequence query method, molecular mass information of peptides is combined with sequence, composition, and fragment ion data. The source of information about sequence is the analysis of a series of peaks of an MS/MS spectrum. This method was developed by Mann and Wilm in 1994 [86]. In MS/MS, ions search data are accepted in different types of peak list formats. A single MS/MS spectrum or a multidimensional LC-MS/MS run containing data from many thousands of peptides may be searched.

Peptide identification algorithms fall into two broad classes: database search and *de novo* search. The former search takes place against a database containing all amino acid sequences assumed to be present in the analyzed sample, whereas the latter infers peptide sequences without knowledge of genomic data. SEQUEST, Mascot, X! Tandem, Phenyx, OMSSA, MyriMatch, Graylag, ByOnic, InsPecT, SIMS, and MassWiz are some database search algorithms used for identification of peptides. For *de novo* sequencing, DeNoS, PEAKS, and Lutefisk algorithms are used.

15.4 Conclusions and Prospects

Advanced new technologies for proteomic analysis have accelerated biological research. Improvement became possible because of the development of advanced separation processes, mass spectrometers, and computer software tools. This has helped us in making new discoveries in the field of proteomics. However, further improvement in proteomics techniques is required in some fields such as quantitative analysis of posttranslational modifications. It will not be wrong to say that there is a huge scope for further improvement of proteomic technology so that the comprehensive analysis of complex biological processes can be done. Because new techniques generate large volume of data in exponential manner, there is need to develop new statistical tools required for finding out logical interpretations of the data. Finally, as these techniques will be developed and popularized, more and more biological information will be dug out.

Plant Tissue Culture and Genetic Transformation for Crop Improvement

Satbir S. Gosal and Manjit S. Kang

Plant tissue culture methods have a wide scope for the creation, conservation, and utilization of genetic variability for the improvement of field, fruit, vegetable, and forest crops and medicinal/aromatic plants. Micropropagation technology, particularly for vegetatively propagated plant species, ensures true-to-type, rapid, and mass multiplication of plants for quick bulking up of new varieties and rejuvenation of old varieties. Cellular techniques, such as anther/microspore culture, somaclonal variation, embryo culture, prototoplast culture, and somatic hybridization, are being exploited to generate useful genetic variability for incremental improvement of field crops. Using anther culture/pollen culture, several cultivars are either under tests or have been released in rice, wheat, barley, maize, rapeseed, and mustard in several countries. Furthermore, the doubled haploid approach is increasingly being used for the rapid development of populations for QTL mapping and construction of genetic linkage maps for traits of interest. Production of secondary metabolites, such as food flavors, food colors, dyes, perfumes, drugs, and scented oils used in aromatherapy, through cell cultures/hairy root cultures, are leading examples of molecular farming/pharming. Cryopreservation of germplasm at the cellular/tissue/organ level in liquid nitrogen at $-196\,^{\circ}C$ is highly rewarding for establishing germplasm banks, especially for vegetatively propagated crops and rare endangered plant species. Tissue culture-based genetic transformation has been commercially exploited for developing transgenic crop varieties in several crops.

16.1
Introduction

Plant tissue culture is a technique of growing plant cells, tissues, and organs in synthetic medium under closely controlled and aseptic conditions. It is based on the concept of totipotency, which refers to the capability of a cell to give rise to a complete plant under suitable cultural conditions. Such a property of cell has far-reaching implications in manipulation of plant cells for rapid multiplication of plants, to cross plants at the level of somatic cells by overcoming limits of crossability, and also to

Improving Crop Resistance to Abiotic Stress, First Edition.

regenerate entire plants after genetic transformation. Suitable explants, that is, organs excised from plants, such as roots, hypocotyls, cotyledons, leaves, shoot apices, nodal segments, anthers, embryos, and seeds, are surface sterilized with a disinfectant like sodium hypochlorite (10–50% w/v for 10–30 min) or with mercuric chloride (0.1% w/v for 5–10 min), thoroughly washed with sterile water and then aseptically cultured in a synthetic medium in culture vessels such as test tubes, jars, and Petri dishes. The cultures incubated at $25 \pm 1\,^{\circ}C$ exhibit growth in 1–3 weeks depending upon the plant species, nature of explant, type of culture medium, kind and concentration of the growth regulators (hormones) used in the medium, and the light intensity in the incubation room.

Several media compositions have been developed for plant tissue culture, but the most commonly used media include [1–4]. Tissue culture medium contains major elements, microelements, vitamins, and amino acids, carbohydrates, and growth regulators (auxins, cytokinins, etc.). Auxins, such as indole acetic acid (IAA), indole butyric acid (IBA), and naphthalene acetic acid (NAA), at concentrations ranging from 0.1 to 5.0 $mg\,l^{-1}$, favor cell elongation and rooting, whereas 2,4-dichlorophenoxyacetic acid (2,4-D) at concentrations of 0.5–4.0 $mg\,l^{-1}$ usually induces callus, that is, homogeneous mass of undifferentiated cells. Likewise, cytokinins, such as 6-furfuryl amino purine (kinetin) and benzyl amino purine (BAP) at concentrations of 0.1–2.0 $mg\,l^{-1}$ cause rapid cell divisions and development of shoot buds/shoots. Solidification of the medium is achieved by adding chemically inert, powdered gelling agents, such as agar, agarose, and gelrite before autoclaving. The medium is poured into culture vessels and sterilized in an autoclave at 121 °C, 15 $lb\,inch^{-2}$ pressure for 20–25 min. Inoculation of explants in the culture vessels is done in Laminar Air Flow Cabinet fitted with HEPA filters (pore size 0.2–0.3 μm) under aseptic conditions. Placement of explants in suitable growth medium under appropriate conditions leads to dedifferentiation, that is, mature cells revert to meristematic state through enhanced DNA/RNA and protein synthesis. The renewed growth in agar-gelled medium gives an unorganized mass of cells, that is, callus. The cells may be cultured in liquid medium that gives a suspension of individual cells called suspension culture. An increased number of cells or calli leads to depletion of medium and thus the growing tissue needs to be transferred after every 3–4 weeks to fresh medium through subculturing. Ultimately, such cells/tissues are to be used to obtain organized structures such as roots, shoots, flower buds, and so on, through the process of organogenesis. Plant tissue and protoplast culture methods offer a rich scope for the creation, conservation, and utilization of genetic variability for the improvement of field crops [5, 6] (see Table 16.1). Various aspects of plant tissue culture in relation to crop improvement are given in Table 16.2.

16.2 Micropropagation

Micropropagation of plants is now one of the best and most successful examples of commercial application of tissue culture technology. Propagation of plants from very

Table 16.1 Plant tissue and protoplast culture techniques in relation to crop improvement.

Technique	Plant material	Remarks	References
Micropropagation	Banana *Musa* spp. (Philippine Lacatan and Grande Naine) plantain (Pelipita and Saba)	Rapidly multiplying cultures from excised shoot tips	[12, 13]
	Strawberry *Fragaria ananassa*	Efficient method for mass production of planting material	[21]
	Eucalyptus tereticornis	*In vitro* clonal propagation through nodal segments	[23]
	Rice *Oryza sativa* L. var. Jaya	Clonal propagation of indica rice through proliferation of axillary shoots	[34]
	Dalbergia sissoo Roxb.	Rapid *in vitro* propagation from mature trees	[24]
	Banana *Musa* spp cv. Grande Naine	Sunlight for micropropagation systems is a way of reducing tissue culture costs	[14]
	Potato *S. tuberosum*	*In vitro* propagation through microtubers	[177]
	Dianthus caryophyllus L. (carnation) cv. scania	*In vitro* propagation through axillary shoot proliferation	[25]
	Sugarcane *Saccharum officinarum* L.	Micropropagation protocol for mass plant production	[7–9, 11]
	Poplar *Populus deltoides*	Protocol for mass production of two important clones, namely, G_3 and G_{48} through induced shoot differentiation of leaf, stem, and root explants collected from adult trees	[26]
	Brahmi *Bacopa monnieri*	Efficient protocol for micropropagation through axillary shoot proliferation	[27]
	Rice *O. sativa* L. var. Mocoi FCA, Itapé P.A., Fortuna INTA, EMBRAPA7-Taim, and CT 6919 and BR IRGA 409	Clonal propagation protocol using shoot tip cultures, and the genetic stability of the micropropagated plants was verified by isozyme analysis	[35]
	Potato *S. tuberosum* L.	A protocol for production of prebasic potato material by microcuttings, obtained from plants with a short period of acclimatization	[18]
	Neem *A. indica*	Macro- and micropropagation protocols	[29]

(*Continued*)

Table 16.1 (*Continued*)

Technique	Plant material	Remarks	References
	Potato (*S. tuberosum* L.) Nif, Clone 122, Agria and Resy	The highest microtuber number (2.8), microtuber yield (278.1 mg) and single microtuber weight (92.2 mg) were obtained in the MS medium containing 2.0 mg BAP/l and 60 g sucrose	[178]
	Potato (*S. tuberosum* L.) cv. Marfona	The use of continuous and semicontinuous bioreactors and their functions at shoot multiplication and microtuberization of potato	[19]
	Banana *Musa sapientum*	Protocol for micropropagation of *M. sapientum* using shoot meristems	[15]
	Grapevine (*Vitis vinifera*)	Best shoot development for the initial culture of rootstock VR043-43 *in vitro* using nodal segments and best microcutting multiplication using QL medium	[30]
	Strawberry *F. ananassa*	Mass propagation via meristem tip culture	[22]
	Sugarcane *S. officinarum* L. cv. CoS 99 259	Spacing of 90 cm × 60 cm was most suitable for transplanting tissue-cultured plantlets	[179]
	Banana *Musa* spp.	Inflorescence apices were found more suitable for rapid *in vitro* propagation	[16]
	Grapevine (*V. vinifera*) cv. Bidaneh Sefid	Micropropagation protocol for quick multiplication	[180]
	Sugarcane *S. officinarum* L. cv. Co 86 032	Setts obtained from micropropagated plantlets resulted in higher seed yields	[181]
	Aloe vera	Micropropagated plants exhibited elevated levels of bioactive compounds	[32]
	Chrysanthemum cinerariifolium (Trev.)	Rapid propagation technology was established and optimized *in vitro*	[33]
	Banana *Musa* spp. cv. Cavendish Dwarf and Valery	Efficient medium for clonal mass propagation (MS + 30 gl^{-1} of sucrose, *N*-phenyl-*N*- 1,2,3-thidiazol 5-yl Urea (0.5 mgl^{-1}) and IAA (2 mgl^{-1}).	[17]
	Grape vine *V. vinifera* L. cv. Perlette	Clonal propagation of grapes for increasing plant material for cultivation	[31]
	Sugarcane *S. officinarum* L.	No variation was detected among the regenerated plants of a particular variety on the basis of RAPD markers, and the profiles of micropropagated clones were comparable to those of the respective donor plants	[182]
	Potato	Successful micropropagation was achieved using nodal segments as explants	[20]
	Scoparia dulcis	A suitable protocol was established through multiple shoot induction from nodal segment and shoot tip explants of this important medicinal herb	[183]

Meristem culture	*Chrysanthemum*	Production of virus free plants	[39]
	Sugarcane	Elimination of yellow leaf virus from infected sugarcane plants	[40]
	Sugarcane	Elimination of sugarcane mosaic virus using chemotherapy and meristem culture	[41]
	Bananas and plantains	Eradication of mosaic disease of bananas and plantains	[42]
	Banana	Eradication of banana bunchy top virus (BBTV) and banana mosaic virus (BMV) from diseased plants	[43]
	Potato	Production of virus-free plantlets	[44]
	Potato	Factors affecting *in vitro* growth of meristem tip-derived plantlets	[45]
	Red raspberry (*Rubus idaeus* L.)	Elimination of apple mosaic virus and raspberry bushy dwarf virus from infected plants	[46]
Somatic embryogenesis	Trifolium repens	Factors influencing coordinated behavior of cells as an embryogenic group	[47]
	Rice	Efficient plant regeneration from protoplasts through somatic embryogenesis	[48]
	Maize	Genotype specificity of somatic embryogenesis and plant regeneration	[53]
	Citrus (*Citrus reticulata* Blanco)	Factors enhancing somatic embryogenesis and plantlet regeneration in mandarin	[57, 58]
	Sugarcane	Factors enhancing somatic embryogenesis and plant regeneration	[51]
	Rice	Influence of antibiotic cefotaxime on somatic embryogenesis and plant regeneration	[49]
	Wheat	Ammonium nitrate improves direct somatic embryogenesis and biolistic transformation of *Triticum aestivum*	[50]
	Sugarcane	Desiccation of callus enhances somatic embryogenesis and subsequent shoot regeneration	[52]
	Maize	Moderate desiccation dramatically improves shoot regeneration from callus	[54]
	Cotton	Highly efficient plant regeneration through somatic embryogenesis in 20 elite commercial cultivars	[55, 56]
Somaclonal variation	*Prunus persica* cvs. Sunhigh, Red haven	Somaclones S156 and S122 resistant to leaf spot, moderately resistant to canker	[87]
	Apple rootstocks (M26, MM106)	S-2 (M26) performed better against *Phytophthora cactorum*	[88]
	Banana Giant Cavendish	Ten somaclones. GCTCV215-1 released for commercial planting	[184]
	Apple cv. Greensleeves	Sixteen somaclones; 21% less symptoms than Greensleeves against fire blight strain T.	[89]

(*Continued*)

Table 16.1 (*Continued*)

Technique	Plant material	Remarks	References
	Sugarcane *S. officinarum* L.	Results confirmed the superiority of two somaclones, one resistant and one tolerant to eyespot disease	[71]
	Potato *S. tuberosum* L.	Somaclones for heat tolerance	[77]
	Potato *S. tuberosum* L cv. Desiree	Somaclones IBP-10, IBP-27, and IBP-30, infected with *Alternaria solani* and *Streptomyces scabiei*, exhibited higher resistance to the pathogen, compared to the susceptible cultivar Desiree	[78]
	Potato cv. Desiree, tomato cv. Amalia leaves, soybean cv. William 82, coffee cv. Robusta	Monomorphism was detected in tomato, coffee, and soybean, indicating the genetic stability of the crops. Potato calli showed variations in the electrophoretic patterns of peroxidase and esterase isoenzymes, indicating somaclonal variation in the crop	[79]
	O. sativa L. cv. CICA-8	Four somaclones showed significantly higher degree of partial resistance compared to the parent cultivar CICA-8	[81]
	Durum wheat (*Triticum durum* Desf.) cv. (Selbera, Sebou, and Kyperounda)	Somaclonal variation thus appears to induce a wide range of modifications among individual components of drought-resistance mechanisms	[185]
	Sugarcane *S. officinarum* L. cv. CP-43/33	The somaclones performed better than the source plant	[73]
	Maize (*Zea mays*)	Somaclones thus derived were tolerant to NaCl	[80]
	Bread wheat (*Triticum aestivum*) cv. (Sakha 8, Sakha 69, Giza 157, Giza 160, Lerma Rojo 64, and Tobari 66)	Somaclones were superior to their original cultivars	[84]
	Wheat (*Triticum aestivum*) cv. Sakha 61	Twenty-one out of the twenty-three somaclones outperformed the original cultivar Sakha 61 in terms of leaf rust resistance and grain yield	[85]
	O. sativa L.	Somaclones were obtained from anther culture of hybrid combinations INCA LP-10/C4 153, Amistad-82/C4 153, and INCA LP-10, as well as from Amistad-82	[82]

	Sugarcane *S. officinarum* L.	Six tissue culture-derived sugarcane somaclones TC-434, TC-435, TC-436, TC-237, and TC-045 from CoC671 and somaclone number TC-338 from Co7219 were evaluated. Somaclone TC-435 gave higher cane yield at 12 mo crop age over CoC 671. Somaclone TC-435 had significantly higher millable cane height and number of internodes than that of the donor parent CoC671	[74]
	Sugarcane *S. officinarum* L.	A new sugarcane variety, Co 94 012, was released in the name of Phule Savitri for cultivation in Maharashtra, India, for Pre and Suru seasons. It is an early, sugar-rich, high-yield variety with high CCS yield. Co 94 012 is a somaclonal variant of CoC 671, with better sucrose content and moderate resistance to red rot (*Glomerella tucumanensis*) and smut diseases (*Ustilago scitaminea*). This is the first sugarcane variety to be released in India through the use of somaclonal variation	[10]
	Alfalfa *Medicago sativa*	An increase in variability was noted in important quantitative and qualitative traits compared to the initial cultivars, including productivity of the above-ground mass and seeds, resistance to fungal diseases, and winter hardiness	[86]
	O. sativa L. cv. Pokkali	The grain yield was significantly high in somaclones BTS 11-1, BTS 28, BTS 24, BTS 9-2(S), BTS-17(S), BTS 10-2, and BTS 11-7, which exhibited higher flag leaf area and moderate leaf area index compared to other somaclones	[83]
	Olive cv. Frangivento	Somaclonal variation could be found in olive plants regenerated through somatic embryogenesis; this appears in mature plants in the field	[186]
	Banana	In banana cultivars (*Musa* × *acuminata*, *Musa* × *balbisiana*), somaclonal variation can be useful in selecting clones with improved agronomic characteristics	[187, 188]
	Dieffenbachia cv. Camouflage, Camille, Star Bright	Potential for new cultivar development by selecting callus-derived somaclonal variants of *Dieffenbachia* was demonstrated	[189]
	Sugarcane *S. officinarum* L.	Development of somaclones resistant to red rot disease using *in vitro* and field selection	[75, 76]
In vitro production of haploid	Wheat	Doubled haploid wheat variety Florin was developed	[97]
	Wheat	A single 2,4-D treatment given to spikes one day after pollination with maize enabled embryos to be recovered from all 19 varieties	[98]

(*Continued*)

Table 16.1 (*Continued*)

Technique	Plant material	Remarks	References
	Rice	Revised medium was used for increasing anther culture efficacy and improved feasibility of using doubled haploids in genetic and breeding research with indica rice	[104]
	Rice	Bicol first F_1 anther culture- derived line from an indica/indica cross in saline-prone areas	[105]
	Rice	An improved method for pollen culture in rice	[106, 107]
	Durum wheat	Dicamba and 2,4-D was best for improving the yield of haploid plants of durum wheat through crosses with maize	[99]
	Maize *Z. mays* L.	Embryogenic induction of microspores within anthers under *in vitro* conditions was the best when a combination of cold treatment, TIBA (0.1 mg l^{-1}) in media and colchicine (0.02% during first 3 days of culture) was applied	[111]
	Citrus (*Citrus clementina*)	Anther culture as a rapid and attractive method of obtaining new triploid varieties in clementine	[110]
	Citrus (*C. clementina*)	Influence of light quality on anther culture of *C. clementina* Hort. ex Tan., cultivar Nules was reported	[111]
	Maize *Z. mays* L.	15, 10, 10, and 3 fertile doubled haploid plants were obtained in cultures treated with paraquat, *t*-BHP, methionine combined with riboflavin, and menadione, respectively	[102]
	Wheat	Simplified wheat × maize haploid production protocol that is 100% effective across all bread wheat cultivars, generating data means of 25% for embryo excision, 90–95% for plantlet regeneration, and between 95 and 100% for doubled haploid ($2n = 6x = 42$, AABBDD) outputs	[100]
	Maize *Z. mays* L.	Maize haploid plants by *in vitro* culture of pollinated ovaries	[128]
	Durum wheat *T. durum*	Novel pretreatment combining mannitol 0.3 M and cold for 7 days had a strong effect on the number of embryos produced and regenerated green plants. 11.55 green plants were produced per 100 000 microspores	[190]
	Tomato *Lycopersicon esculentum* L.	Embryogenesis and plant regeneration by *in vitro* culture of isolated microspores and whole anthers of tomato	[109]

	Rice	The 9 DH lines could provide the basic materials for breeding on Dian-type hybrid rice with both good quality and high blast resistance in the future	[108]
	Maize	Doubled haploids should be induced from F_2 plants rather than from F_1 plants	[103]
Embryo/ovule/ovary culture	*Vigna mungo* × *V. radiata*	Interspecific hybrids between *V. mungo* and *V. radiata* were produced through embryo culture	[143]
	Arachis	Embryo rescue from wide crosses in *Arachis*	[144]
	Moricandia arvensis × *Brassica*	lntergeneric (intersubtribe) hybrids between *M. arvensis* and *Brassica* A and B genome species by ovary culture	[140]
	V. vinifera L	Ovule culture of seedless grapes (*V. vinifera* L.)	[147]
	Brassica × *Sinapis*	Production of intergeneric hybrids between *Brassica* and *Sinapis* species by means of embryo rescue techniques	[141]
	Wheat × Rye	*In vitro* synthesis of white-grained primary hexaploid triticales	[142]
	Populus euphratica Oliv.	Intraspecific hybridization of *P. euphratica* Oliv. using *in vitro* technique	[146]
Protoplast culture and somatic hybridization	Potato *S. brevidens* × *S. tuberosum*	Somatic hybrids were produced by electrofusion	[191]
	Brassica, B. juncea, B. nigra, and *B. carinata* × *B. napus*	Resistance to *Phoma lingam* was expressed in all symmetric hybrids, and in 19 of 24 toxin-selected asymmetric hybrids	[152]
	Potato *S. brevidens* × *S. tuberosum*	Twenty hybrids tested expressed a high level of resistance to PVY	[150]
	Brassica, B. napus × *B. oleracea*	Inoculations *Xanthomonas campestris* pv *campestris* led to identification of four somatic hybrids with high resistance	
	Brassica, B. oleracea × *B. rapa*	Disease assays showed that most somatic hybrids had lower disease severity ratings against bacterial soft rot	[192]
	Citrus, *Citrus sinensis* L. Osbeck × *C. volkameriana Pasquale, C. reticulata Blanco*	Somatic hybrids combined characteristics from both sources and have potential for tolerance to blight and CTV	[153]
	Banana Maçã(*Musa* AAB group) × Lidi *Musa* sp. AA group.	Somatic hybrids were identified by using RAPD markers	[193]

(*Continued*)

Table 16.1 (*Continued*)

Technique	Plant material	Remarks	References
	Citrus mandarin × pummelo, sweet orange × pummelo	Somatic hybrids were confirmed by leaf morphology, ploidy analysis via flow cytometry, and RAPD analysis. Somatic hybrids have been propagated by tissue culture for further evaluation of disease resistance and horticultural performance in field trials	[194]
	Potato Aminca–Cardinal × Cardinal–Nicola	Complete resistance to PVY was noted for one somatic hybrid line (CN2). All other hybrids also showed improved tolerance to *Pythium aphanidermatum* infection during tuber storage or after plant inoculation	[151]
	Potato *S. tuberosum* × *S. tuberosum*	Tetraploid intraspecific somatic hybrids between 16 different diploid breeding lines of *S. tuberosum* L. were produced by PEG-induced fusion	[195]
	Brassica, B. oleracea × *B. rapa*	Calli were screened by RAPD analysis for their hybrid character. This is the first study reporting hybrid formation between two haploid protoplasts	[157]
	B. napus ($2n = 38$) × *Orychophragmus violaceus* ($2n = 24$) *B. napus* ($2n = 38$) × *O. violaceus* ($2n = 24$)	Symmetric fusions of mesophyll protoplasts and subsequent development of *B. napus–O. violaceous* chromosome addition lines	[196]
In vitro production of secondary metabolites	*Capsicum annum*	Accumulation of capsaicin in callus cultures	[159]
	Secondary metabolites, such as vincristine and vinblastine, and recombinant proteins	Plant suspension cells are an *in vitro* system that can be used for recombinant protein production	[160]
	Secondary metabolites	Hairy root culture for mass production of high-value secondary metabolites	[161]
Cryopreservation and *in vitro* germplasm storage	Rice *O. sativa* L.	Rice plants (cv. Taipei 309) were regenerated from different cryopreserved calli and cryopreservation was declared to be a reliable way to store transformation-competent rice lines	[166]

	Potato *S. tuberosum* L	Shoot tips of *in vitro* grown potato (*S. tuberosum* L.) plants were cryopreserved by a modified vitrification method	[167]
	Potato *S. tuberosum* L	*In vitro* plants of potato cultivars 'Superior' and 'Atlantic' were cold acclimated, and axillary buds were precultured, osmoprotected, exposed to PVS-2 solution, plunged into liquid nitrogen, thawed, and finally planted in the regeneration medium. After cryopreservation, vitrified shoot tips resumed growth within a week.	[168]
	Rubus spp. (blackberry and raspberry)	Encapsulation–dehydration and PVS2 vitrification cryopreservation protocols were found successful for preserving diverse *Rubus* germplasm (shoot tips)	[171]
	Arabidopsis	*Arabidopsis* can be successfully cryopreserved using either PVS2 or PVS3 as cryoprotectants prior to rapidly cooling shoot tips in LN	[164]
	Potato *S. tuberosum* L. cv. Dejima and (STN13)	Protocol was tested with 12 selected cultivated varieties and wild species, and the survival percentages obtained ranged between 64.0 and 94.4%	[169]
	Citrus	Up to 98.1% of the plants obtained by cryopreservation were free from HLB bacterium, compared to the sanitation rate of 25.3% yielded by conventional meristem tip culture	[170]
Genetic transformation	Direct gene transfer to plants	Particle mediated genetic transformation	[172]
	Rice	Analysis of transgene integration patterns, expression levels, and stability	[173]
	Various plant species	Various methods for genetic transformation and production of transgenic plants	[174]
	Agrobacterium-mediated transformation of basmati rice (*O. sativa* L.)	Expression of synthetic Cry1AB and Cry1AC genes for the control of European corn borer	[175]
	Transgenic crops	Global status of commercialized biotech/GM crops	[176]

Table 16.2 Various aspects of plant tissue culture.

S. No.	Aspect	Application
1	Micropropagation	True to type, rapid and mass multiplication of plants
2	Meristem culture	Production of disease-free plants
3	Somatic embryogenesis	Production of synthetic seeds and mass cloning of plants
4	Somaclonal variation	Induction of genetic variation particularly in vegetatively propagated species
5	*In vitro* production of haploids	Production of haploids/doubled haploids for early release of varieties
6	Embryo/ovule/ovary culture	Production of distant hybrids/alien gene transfer into cultivated varieties
7	Protoplast culture and somatic hybridization	Production of somatic hybrids and cybrids
8	*In vitro* production of secondary metabolites	Production of secondary metabolites (drugs, flavors, and dyes)
9	Cryopreservation and *in vitro* germplasm storage	Long-term storage of germplasm especially of vegetatively propagated species
10	Genetic transformation	Production of transgenic crop varieties/hybrids and molecular farming

small plant parts (0.2–10 mm) under *in vitro* conditions in the laboratories/polyhouses is called micropropagation. The technique of micropropagation was developed about 50 years back, but its commercial exploitation started only during the 1970s with orchids. Since then, it has seen tremendous expansion globally both in the number of production units and in the number of plants. It is estimated that more than 500 million plants of different plant species are now being produced annually through micropropagation in different parts of the world. Micropropagation industry is environment-friendly and requires little raw material in the form of chemicals. Because of higher labor costs in the developed countries, this industry is now being expanded in developing countries, where plant multiplication can be done at much cheaper rates for the international markets than in the developed countries.

16.2.1 Advantages of Micropropagation

1) It ensures true-to-type plants, that is, identical to mother plant (cloning).
2) Following micropropagation, selected plant species can be multiplied anywhere in the world.
3) It results in rapid and mass multiplication (1–10 per cycle of 2 weeks each) of elite clones/varieties that are otherwise difficult to multiply using conventional methods.
4) It is independent of seasonal and raw material constraints. Thus, the micropropagation industry can function throughout the year.

5) Micropropagation ensures disease-free plants and thus helps in rejuvenation of old clones or varieties.
6) It helps in the national and international exchange of germplasm, avoiding the risk of pathogens and insects.
7) Micropropagated, field-grown plants give higher yield and exhibit better quality.

16.2.2
Steps in Micropropagation

Step-1: **Establishment of Aseptic Cultures**
This is a transitory step, in which *in vivo*-grown plants are made to grow under *in vitro* conditions in the laboratory. Thus, it requires extra care and skill. Small plant parts, usually the shoot tips or nodal buds, are taken and disinfected with an appropriate disinfectant such as sodium hypochlorite or mercuric chloride for a specific period of time, depending upon the disinfectant used and the tissue being disinfected. Plant material is then cultured in a synthetic medium, under aseptic laboratory conditions. The cultures are kept in an incubation room maintained at $25 \pm 1\,^{\circ}C$, with a relative humidity of 60–80% and a light intensity of about 5000 lux, till new shoot buds/shoots appear (3–4 weeks).
Step-2: **Shoot Bud/Shoot Multiplication**
This is the real multiplication phase, in which cultures from the previous cycle are cut or divided and then recultured aseptically in fresh medium in separate culture vessels. This step involves cytokinins. During this step, there is nearly 10 times multiplication per cycle (2 weeks) throughout the year. Therefore, 26 cycles can be completed in a year, generating thousands of propagules. In this step, because of relatively high levels of cytokinins in the culture medium, the roots do not develop; hence, multiplication is generally in the form of shoot buds or shoots.
Step-3: **Induction of Roots and Hardening**
The shoots obtained from Step-2 are transferred to rooting medium to get the root primordia or root formation. Subsequently, hardening of plantlets is done by taking them out of the culture vessels and by washing them under slow-running tap water. The plantlets are then transferred onto water-moist cotton in trays and kept in the incubation room/polyhouse with daily change of tray water for a few days to get the plants acclimatized (Figure 16.1).
Step-4: **Transfer of Plantlets to Soil**
Hardened plantlets, individually or in clumps, are transferred to soil in polythene bags kept in the polyhouse for one and a half months before their delivery to end users.

16.2.3
Significance of Micropropagation

Micropropagation has special significance in the following areas:

1) Production of high-quality, disease-free, and superelite planting material for further seed production, especially in the vegetatively propagated plant species.

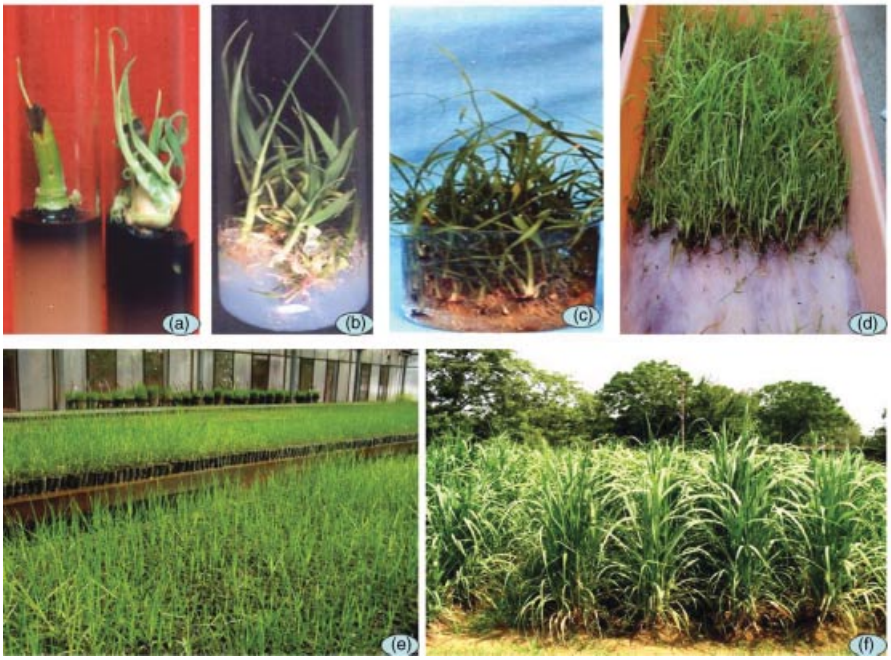

Figure 16.1 Micropropagation of sugarcane. (a) Establishment of shoot cultures *in vitro*. (b) Shoot multiplication. (c) Induction of rooting *in vitro*. (d) Hardening of plantlets. (e) Transfer of plantlets into soil in green house. (f) Micropropagated sugarcane in the field.

2) Rapid spread of new varieties of vegetatively propagated crops such as sugarcane, potato, poplar, and medicinal/aromatic plants for crop diversification.
3) Mass production of ornamental plants, which are otherwise difficult to multiply through conventional methods for domestic and international markets.
4) Rejuvenation of old varieties/clones of vegetatively propagated crops for improving their yield and quality.
5) Mass cloning of rootstocks in horticultural plants such as citrus, peach, and apple.
6) Mass cloning of genetically plus, cross-pollinated, and seed propagated trees.
7) Multiplication of male sterile lines for hybrid seed production or the multiplication of F_1 hybrids and transgenic clones/varieties.
8) During genetic transformation, this technique helps in increasing the plant number of elite events for precise characterization and efficient transfer of regenerated plants to greenhouse.
9) During anther/pollen culture, micropropagation of regenerants helps in minimizing the risk of losing any genotype during their hardening and transfer to soil.

10) Interstate/international exchange of germplasm, avoiding the risk of pathogens and insects.
11) It possesses tremendous potential in keeping our environment clean and green.

Now scores of multimillion-dollar industries around the world propagate a variety of plant species through tissue culture, which allows environment-friendly industries to flourish. The clean planting material can certainly improve the yield potentials of vegetatively propagated crops such as sugarcane, potato, banana, strawberry, sweet potato, cassava, and several ornamental plant species. Micropropropagation protocols for some important crop plants have been developed and are being exploited for commercial plant production. Some of these include sugarcane [7–11], banana [12–17], potato [18–20], strawberry [21, 22], eucalyptus [23], *Dalbergia sissoo* [24], carnation [25], poplar [26], brahmi (*Bacopa monnieri*) [27, 28], neem (*Azadirachta indica*) [29], grapevine [30, 31], Aloe vera [32], *Chrysanthemum* [33], and rice [34, 35]. It is likely that automation of multiplication systems will be commercially feasible within the next few years.

16.3 Meristem Culture

Virus infection in plants reduces both yield and quality. Replacement of virus-infected stock with healthy stock (virus free) has shown up to 300% yield increase [36, 37]. In most of the seed-propagated crops, the gametes serve as sieve against a variety of pathogens and help in production of disease-free seeds, whereas in vegetatively propagated species, the pathogens keep on accumulating generation after generation, which ultimately cause varietal decline. There are no effective chemical methods to control viral diseases. In this regard, meristem culture [38] is a practical approach for producing disease-free plants. Shoot meristems (0.2–0.4 mm) excised from *in vivo*- or *in vitro*-grown plants are aseptically cultured *in vitro* in culture medium under suitable cultural conditions. Meristem-derived plants are screened by using electron microscopy/immunological methods for selecting pathogen-free plants [39]. Disease-free plants are then micropropagated for production of superelite planting material. This technique is well established for the production of disease-free planting material of sugarcane [40, 41], bananas and plantains [42, 43], potato [44, 45], and apple [46].

16.4 Somatic Embryogenesis

Somatic embryogenesis is the process by which somatic cells develop into differentiated plants through characteristic embryological stages without the fusion of gametes [47]. A number of factors, such as genotype of donor plant, medium constitution, auxins, sugars, amino acids, growth retardants, desiccation, and so on, influence the process of somatic embryogenesis and subsequent plant regen-

eration. Embryogenic callus/cell suspension cultures ensure high-frequency plant regeneration upon their transfer to shoot regeneration medium. Therefore, such cultures are preferred for genetic transformation. Furthermore, somatic embryos can be encapsulated in a suitable matrix, containing nutrients, growth regulators, antibiotics, and so on, needed for the development of a complete plant to make what are known as synthetic or artificial seeds that can be stored for several years and can be sown like natural seeds. Frequent somatic embryogenesis has been reported in rice [48, 49], wheat [47, 50], sugarcane [51, 52], maize [53, 54], cotton [55, 56], and citrus [57, 58]. Improvement of somatic embryogenesis [51], coupled with embryo desiccation and encapsulation technology, may lead to the utilization of artificial seeds for mass cloning of plants.

16.5 Somaclonal Variation

Variation among tissues or plants derived from the *in vitro* somatic cell cultures, that is, callus and suspension cultures, is called somaclonal variation. It may be genetic or may result from culture-induced epigenetic changes [59]. The epigenetic changes are expressed at cell culture stage, but these changes usually disappear when plants are regenerated or reproduced sexually. Variation arising out of anther/pollen culture is more precisely known as gametoclonal variation and that through protoplast culture is called protoclonal variation. It, therefore, provides a novel mechanism to generate new genetic variation for crop improvement.

16.5.1 Induction of Somaclonal Variation

Callus cultures are established from suitable explants and multiplied through periodic subculturing (Figure 16.2). Likewise, cell suspension cultures can be established by transferring actively growing callus to constantly agitated liquid medium and can be maintained/multiplied through periodic subculturing. Plants are regenerated usually from long-term maintained (old) callus/cell suspension cultures and transferred to soil and screened for variation, in the glasshouse or field. *In vitro* selection at cellular level can be carried out for some traits by growing cells from cell suspensions and calli on a medium supplemented with elevated levels of various biotic and abiotic stress factors (only the variant cells survive). Using this technique, many million cells (potential plants) can be screened in a single Petri dish, which is practically difficult, if not impossible, to be adapted at whole-plant level in the field. Moreover, *in vitro* selection also reduces the chances of diplontic selection, but it requires high level of correspondence between the trait(s) selected *in vitro* and expressed *in vivo*. Somaclonal variants can be identified through screening, which involves assessment of regenerated plants for characters such as yield that cannot be evaluated at single-cell level or through cell selection that involves application of suitable selection pressure like that of some toxins to permit preferential survival of variant cells.

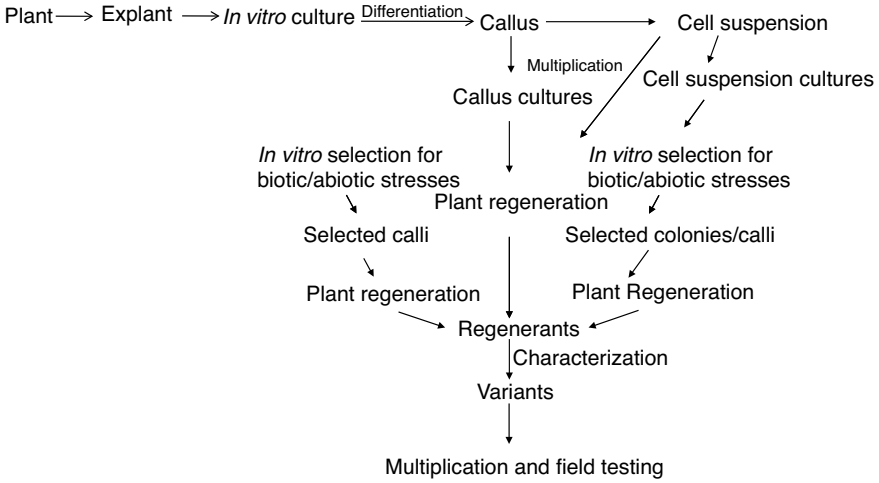

Figure 16.2 Scheme for induction and selection of somaclonal variation in crop plants.

16.5.2
Causes of Somaclonal Variation

Somaclonal variation may be genetic or epigenetic; the genetic variation is heritable, whereas the epigenetic variation, caused by cultural conditions, is not heritable and hence has no significance in sexually propagated plants. Genetic variation may result from the following causes:

- **Chromosomal Changes**
  Chromosomal changes in tissue culture-derived plants have been observed with respect to both chromosome number and structure. Besides polyploidy, aneuploidy (monosomics and trisomics) has been observed in oats, ryegrass, wheat, triticale, and potato. There have been a number of studies of modified chromosome structure in cultured plant cells [60]. Deletions, inversions, translocations, and duplications have been frequently observed in barley, wheat, potato, and maize. While large changes in chromosome structure have been detected, it is likely that less dramatic structural changes that were not detected occur quite frequently. Small changes in chromosome structure could alter expression and genetic transmission of specific genes. In addition, recombination or chromosome breakage may occur in preferential regions or "hot spots" of particular chromosomes, thereby affecting some regions of the genome in a disproportionally higher frequency [61].
- **Mitotic Crossing Over**
  Mitotic crossing over may account for some of the genetic variation that leads to the recovery of homozygous recessive single-gene mutations in some regenerated plants. Dulieu and Barbier [62] regenerated plants from *Nicotiana tabacum* with specific chlorophyll deficiency markers present in heterozygous condition. A high

frequency (9.6%) of variant regenerants at the "a_1" and "y" loci has been ascribed to the combination of deletion and mitotic recombination.

- **Apparent "Point" Mutations**
  Genetic changes resembling single-gene mutations have now been detected in numerous crops. The recessive single-gene mutations are suspected if variant does not express itself in the regenerant (R_0) plant, but the self-fertilized R_1 progeny segregates in an expected 3 : 1 Mendelian ratio for a morphological trait. This type of analysis has been completed for several tomato somaclones and used to map somaclones to specific loci [63]. Such a phenomenon has also been noted in maize, tobacco, rice, and wheat.
- **Cytoplasmic Genetic Changes**
  Cytoplasmic genetic changes involving mitochondrial DNA (mtDNA) have been described in maize by evaluating plants for two cytoplasmic traits [64]. Sensitivity to host-specific toxin of *Drechslera maydis* race T, the causal agent of southern corn leaf blight, is associated with all genotypes containing Texas male sterile (cms-T) cytoplasm. Such traits are tightly linked and controlled by mitochondrial DNA. Gengenbach *et al*. [64] selected *in vitro* for resistance to toxin and regenerated resistant plants with the aim of recovering toxin-resistant cytoplasmic male sterile lines, but among the regenerants, resistance was associated with reversion to male fertility. Restriction endonuclease pattern of mtDNA revealed significant changes in mtDNA. This mutation to male fertility and toxin insensitivity has been shown to be a frameshift mutation in mitochondrial DNA.
- **Deamplifications and Amplifications**
  Deficiencies in ribosomal DNA (rDNA deamplifications), although not associated with change in plant morphology, have been observed at the molecular level in flax, triticale, and potato. On the other hand, gene amplifications, that is, duplications, have been observed in *Nicotiana* [65] and tomato.
- **Transposable Element Activation**
  Activation of otherwise silent controlling elements (mutator genes) has been observed following plant cell cultures of *Nicotiana*, alfalfa, and maize. Chromosome breakage and fusion, which occur in culture, and genomic stress caused by culture conditions are major causes of transposable element activation. Transposable elements are known to cause phenotypic changes in plants and their activation during *in vitro* culture induces somaclonal variation [66].
- **Virus Elimination**
  Virus infection in several instances causes changes in the plant's reaction to other diseases. For example, prior infection with barley yellow dwarf virus causes susceptibility to powdery mildew in oats. Larkin and Scowcroft [59] suggested that the virus elimination during *in vitro* passage could alter the plant's susceptibility to certain fungal diseases and the somaclones exhibited resistance.
- **Methylation/Demethylation of DNA**
  De novo methylation and demethylation events are part of differential genomic changes. Tissue-specific DNA methylation of different sequences has been reported for several plants. Genome activity, that is, transcription, replication,

rearrangement, and the structural organization of chromatin, somehow seems to be related to DNA methylation [67, 68].

- **Altered Expression of Multigene Families**
  It has been postulated that the cultural conditions may regulate the expression of the multigene family in a way that a member gene that previously expressed some agronomically important genes, including those for gliadins, zeins, glutenins, α-amylase, are coded on multigene families. Heritable somaclonal variation has been obtained for gliadin – a storage protein – and β-amylases in wheat [69].

16.5.3
Nature of Somaclonal Variation

Somaclonal variation has been reported in several crops for both qualitative and quantitative traits, including male sterility in maize; improved protein content in rice and triticale; high sucrose content in sugarcane; early tasseling in corn; changed plant height, awns, tiller number, grain color, heading date, gliadin proteins, and α-amylase in wheat; herbicide tolerance in tomato; disease resistance in maize, sugarcane, mustard, and potato; and salt tolerance in rice [70]. However, such somaclonal variations have not been frequently utilized because, in many cases, these include either the already existing types or there were desirable changes accompanied by several undesirable changes.

16.5.4
Significance of Somaclonal Variation in Crop Improvement

Several interesting and potentially useful traits have been recovered using this method in sugarcane [10, 71–76], potato [77–79], maize [80], rice [81–83], wheat [84, 85], alfalfa [86], *Prunus persica* [87], and apple rootstocks [88, 89]. Recovery of novel variants that either do not exist or are rare in the natural gene pool, for example, atrazine resistance in maize, glyphosate resistance in tobacco, improved lysine and methionine contents in cereals, increased seedling vigor in lettuce, jointless pedicels in tomato, and *Fusarium* resistance in alfalfa, are of much significance [63, 76]. Genetic, cytogenetic, and molecular evidence for increased recombination frequency through cell culture has now been provided [90]. Tissue culturing of wide hybrids also helps in breaking undesirable linkages and achieving introgression from alien sources. Several new varieties have been developed through somaclonal variation in tomato, sugarcane, potato, celery, *Brassica*, and sorghum. This simple and cost-effective technique has a huge potential for the improvement of apomictic and vegetatively propagated plant species and, of course, seed-propagated crop plants with a narrow genetic base. In India, a somaclonal variant of a medicinal plant, *Citronella java*, has been released as a commercial variety, B-3, which gives higher yield and oil content than original variety. Likewise, Pusa Jai Kishan is a variety of *B. juncea* that has been released as a somaclonal variant of Varuna variety. However, in several situations, low plant regeneration ability and lack of

correspondence in expression of the trait in field-grown plants are the major problems [91].

16.6 *In Vitro* Production of Haploids

In self-pollinated crops, an inordinately long period is required to assemble desirable gene combinations from different sources in homozygous form. Generally, it takes 8–10 years to develop stable, homozygous, and ready-to-use materials from a fresh cross of two or more parental lines. In cross-pollinated crops, because of inbreeding depression, it becomes difficult to develop vigorous inbreds for hybrid seed production programs. In this regard, haploids possessing gametic chromosome number are very useful for producing instant homozygous true-breeding lines. In addition, haploids constitute an important material for induction and selection of mutants, particularly for recessive genes. In conventional breeding, the early-segregating generation populations involve variation attributable to both additive and nonadditive genetic effects [92], whereas doubled haploid (DH) lines exhibit variation only of additive genetic nature, including additive × additive type of epistatis, which can be easily fixed through a single cycle of selection. The elimination of dominance effects leads to high narrow-sense heritability, and availability of sufficient seed of each DH line allows for replicated testing. Thus, in contrast to relatively large segregating populations in conventional genetic studies, fewer DH lines are required for the purpose of selection of desired recombinants. For instance, in rice, about 150 DH lines derived from F_1, instead of 4000–5000 F_2 plants, are sufficient for selecting desirable genotypes. Production of haploids has also been exploited during wide hybridization for the development of addition and substitution lines. Production of haploids/doubled haploids through anther culture from F_1 rice plants results in true-breeding plants in less than 1 year, which otherwise takes 7–8 generations in conventional methods [93] (Figure 16.3).

16.6.1 Methods of Haploid Production

Four important methods for *in vitro* production of haploids are as follows:

i) Anther culture
ii) Isolated microspore culture
iii) Unpollinated ovary culture
iv) Embryo rescue from wide crosses

16.6.1.1 Anther Culture

Anther/pollen culture is an attractive alternative for developing haploids (sporophytes with gametophytic chromosome number). One of the very popular methods for production of haploids is anther or microspore culture. Incubation of cultures under optimum conditions leads to growth of microspores into sporophytes. The

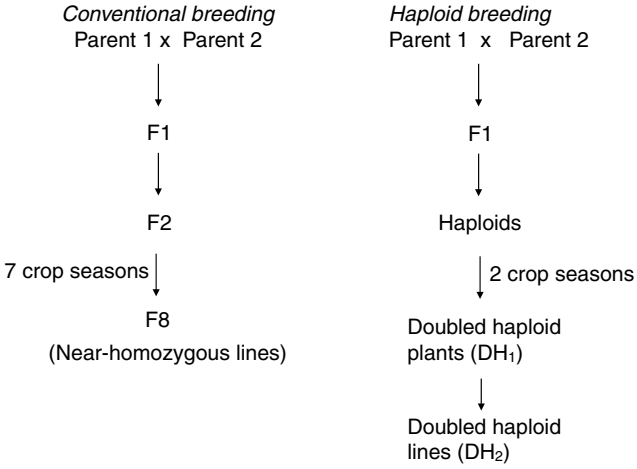

Figure 16.3 Period required to develop homozygous lines through conventional and haploid breeding.

following parameters have been recognized as particularly important for successful anther/microspore culture: (i) growth conditions of donor plant, (ii) genotype of donor plant, (iii) pretreatment of anthers, (iv) developmental stage of anthers/microspores, (v) composition of culture medium, and (vi) physical conditions during culture growth. Anthers are cultured in liquid or on semisolid agar medium [94], where they may directly give rise to embryoids or may lead to callus formation before differentiation. The embryoids develop into haploid plantlets or doubled haploids in some crops (because of spontaneous doubling of chromosomes during callus proliferation). Haploids may be treated with colchicine to obtain fertile, doubled haploid homozygous plants for field testing and selection. The technique of anther culture was first developed in *Datura* by Guha and Maheshwari [95, 96]. Flower buds at an appropriate stage are collected from healthy greenhouse- or field-grown plants. The collected flower buds are usually wrapped in plastic bags and kept in a refrigerator at 4 °C for 7–10 days for cold treatment. Flower buds are surface sterilized with 0.1% $HgCl_2$ for 9–10 min and anthers are carefully dissected out of the flower buds and inoculated in the medium. Cultures are incubated at 25 ± 1 °C under diffused light conditions. In general, the cultured anthers exhibit callusing after 2–6 weeks. About 1 month-old calli are made to regenerate into plants (Figure 16.4).

16.6.1.1.1 **Significance of Anther Culture** Anther culture systems (see Figure 16.5) have been developed for several important crop plants, such as wheat [97–100], maize [101–103], rice [104–108], tomato [109], and citrus [110, 111]. Several cultivars are either under test or have been released for rice, wheat, maize, rapeseed, and mustard in China, Canada, Denmark, the United States, and France [112, 113]. Furthermore, the doubled haploid approach is increasingly being used for rapid development of populations for QTL mapping and construction of genetic linkage maps for traits of interest.

16.6.1.2 **Isolated Microspore Culture**

Microspore culture [114] (Figure 16.6) has several advantages over anther culture because microspores are haploid single cells that can readily be genetically manipulated. Unlike anther culture, microspore culture eliminates the participation of diploid tissues (anther wall and connective tissues). The two methods of pollen isolation are (a) naturally shed pollen in the culture medium after a preculture of anthers and (b) mechanical means by crushing or magnetic stirring. The naturally shed pollen grains are known to result in more calli and plantlets than mechanically isolated pollen of rice, barley, and tobacco. In case of rice, large microspores (50–58 μm) with thin pink colored outer walls produced embryos, whereas the division of small (40 μm) microspores with thick cell walls was not observed [115]. Addition of glutamine, proline at 1 mM concentration, and ficoll 10% (w/v) into the culture medium has shown beneficial effects during the isolated microspore culture in the liquid medium. Most of the factors affecting anther culture also affect the success in pollen culture. Microspore/pollen culture has been an attractive alternative for haploid production in *Brassica napus* [116–119], *B. juncea* [120–123], *Hordeum vulgare* [124], wheat [125], oats [126], and pepper [127].

16.6.1.3 **Ovary Culture**

Induction of haploids from megaspores, also known as gynogenesis, was reported by culturing unpollinated ovaries of *Zea mays* [128]. Subsequently, the technique

has also been extended to other crops, including barley and rice. Genotypic differences have been observed for the development of gynogenic calli. The rate of success also varies with species and is strongly influenced by the genotype. A japonica type of rice genotype is far more responsive than varieties of indica types. The success of ovary culture mainly depends on the development stage of the ovary. Success has been reported with ovaries ranging from uninucleate to mature embryo-sac stages. Regulation of growth regulators to enhance gynogenesis, but to inhibit proliferation of somatic tissues, has been very critical for ovary culture [129]. Rice ovaries failed to enlarge in the absence of MCPA (2-methyl, 4-chlorophenoxyacetic acid). An increase in MCPA concentration from 0.125 to 8 mg l^{-1} favored ovary swelling. In contrast to anther culture, ovary culture is inefficient because there is only one embryo sac per ovary compared to thousands of microspores per anther. However, the rate of induced embryo sacs has generally been higher than for microspores and the frequency of green-plant regeneration has also been higher than from anther cultures. But ovary culture has been successful only in a few species.

16.6.1.4 **Embryo Rescue for Wide Crosses**

Embryo rescuing from wide crosses in some crops serves as an alternative route to haploidy. Moreover, the system is less prone to gametoclonal variation owing to the absence of redifferentiated callus phase. The phenomenon is based on the elimination of a full set of chromosomes of one of the parents during *in vitro* embryo development.

16.6.1.4.1 **Bulbosum Method** This method was first developed for production of haploids in diploid barley by Kasha and Kao [130] (Figure 16.7). The haploids are produced from interspecific crosses between *Hordeum vulgare* (female) and

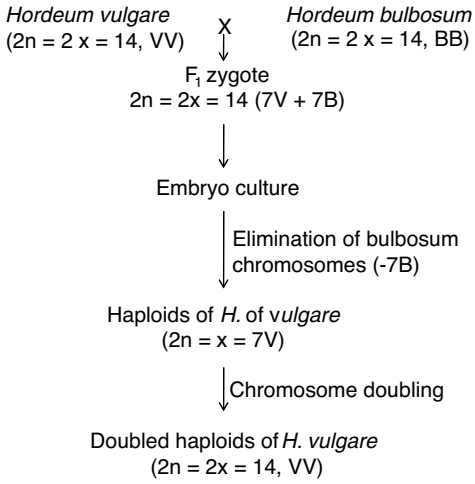

Figure 16.7 Schematic representation of bulbosum method.

H. bulbosum (male). Zygote induction is fairly high and the chromosomes of *H. bulbosum* are rapidly eliminated from the developing embryos. Developing endosperm also aborts after about 2–5 days of growth, which necessitates the rescuing of embryos in order to complete their development. Embryo culture using nutritionally rich medium results in complete haploid plants of *H. vulgare*, and chromosome doubling is induced in the established plants. Barclay [131] extended this method to wheat, in which haploids of wheat were obtained through embryo culture from *Triticum aestivum* cv. Chinese Spring × *H. bulbosum* cross. However, this method is restricted to wheat varieties possessing "kr" crossability genes that are responsible for the elimination of *H. bulbosum* chromosomes.

16.6.1.4.2 **Wheat Haploids from Wheat × Maize Crosses** Zenkteler and Nitzsche [132, 133] were the first to report microscopic early-stage embryos in crosses between wheat and maize. Subsequently, Laurie and Bennet [134, 135] demonstrated the presence of both wheat and maize chromosomes in zygotes and found that maize chromosomes were eliminated during initial cell divisions. Endosperm development ceases early or never occurs, and embryos fail to develop to a size that can be readily rescued. Complete wheat haploid plants using wheat × maize system by employing *in vitro* culture of wheat spikelets, 2 days after pollination, were obtained [98]. This method has been successfully extended to durum wheat [136] and to field-grown bread wheat by daily injecting 2,4-D (125 ppm) into pollinated tillers for 3 days, followed by embryo culturing 15 days after pollination with maize [137, 138].

Haploids produced through any of these methods have been used to produce doubled haploid lines through colchicine treatment. The doubled haploids produced from F_1 plants represent a set of new recombinant lines in homozygous state, which can be used either for commercial cultivation or for further breeding purposes.

16.7 Embryo/Ovule/Ovary Culture for Wide Hybridization

During wide hybridization, when parents are genetically diverse, endosperm degeneration leads to embryo abortion and the failure of the cross. Under such situations, after making desired pollination, developing embryos, ovules, and even ovaries are aseptically excised and cultured *in vitro* using suitable culture medium and physical cultural conditions. The plantlets thus obtained are transferred to greenhouse and characterized using morphological, cytogenetic, biochemical, and molecular approaches. In case of seed sterility, the plantlets are treated with colchicine for production of amphiploids through chromosome doubling. It has been a practical approach [139] to obtain interspecific and intergeneric hybrids in *Brassica* [140, 141], wheat [142], *Vigna* [143], *Arachis* [144], *Lilium* [145], and *Populus* [146]. Ovule culture in grapes has been attempted for developing hybrids, even in seedless grapes [147]. These methods have been successfully used to transfer desirable genes from wild relatives into cultivated varieties of several field and vegetable crops.

16.8
Protoplast Culture and Somatic Hybridization

Somatic hybridization is an effective approach to hybridize sexually incompatible species. Complete fusion of nuclei and cytoplasms of somatic cells from both species leads to formation of somatic hybrid cell and plant. Likewise, the fusion of cytoplasm from two species and nuclear genes from any one leads to the development of a cybrid. The plant cells are surrounded by a thick cell wall that does not allow cells to fuse to get somatic hybrid cell/plant. However, protoplasts can be easily fused and employed in several other experiments aimed at the genetic modification of plants (Figure 16.8). A protoplast is a naked cell without cell wall, surrounded by plasma membrane, and potentially capable of cell wall regeneration, growth, and division. The techniques of isolation, culture, and regeneration of protoplasts have been established in more than 100 plant species, including major field, vegetable, and fruit crops. Protoplast technology (see Figure 16.9) basically involves five steps: (1) isolation of protoplasts, (2) fusion of protoplasts, (3) culturing of protoplasts, (4) regeneration of plants, and (5) characterization of protoplast-derived plants.

Since the production of the first somatic hybrid between *N. glauca* and *N. langsdorfii* in 1972, numerous intraspecific, interspecific, and intergeneric hybrids have been produced. Somatic hybrids fall into two categories, namely, symmetric and asymmetric [148]. Symmetric hybrids consist of complete sets of chromosomes from both the parents, whereas asymmetric hybrids possess full chromosome complement of only one parent. Earlier, efforts were made to obtain somatic hybrids among closely related and cross-compatible species, where somatic hybrids resembled the sexual

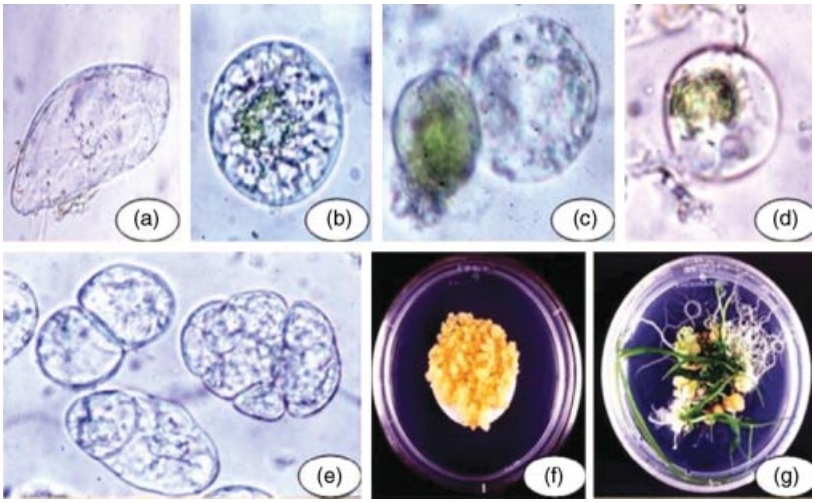

Figure 16.8 Protoplast culture in rice. (a) Somatic cell from cell suspension culture of rice. (b) Isolated protoplast from cell suspension culture. (c) Protoplast aggregation during fusion. (d) Fused protoplasts. (e) Dividing protoplasts during culture. (f) Protoplast-derived colonies on filter membrane. (g) Plant regeneration from protoplast-derived colonies.

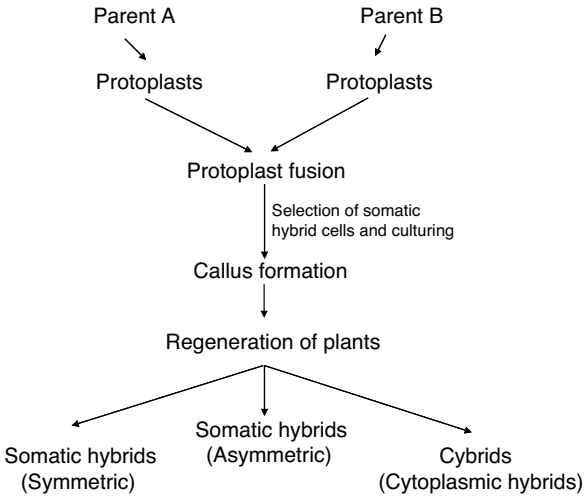

Figure 16.9 Scheme for production of somatic hybrid/cybrid plants.

hybrids. For instance, the somatic hybrid between *B. campestris* and *B. oleracea* resembled *B. napus*. With refinements in the techniques of protoplast isolation, fusion, and culture, people thought to produce novel hybrids by fusing protoplasts from remote species. However, somatic incompatibility has been observed to operate at various levels and different growth patterns have been observed; for example, hybrid cells underwent only few divisions, fusion products grew successfully as undifferentiated cells, and morphogenesis resulted in teratomas (highly abnormal and sterile plants). Asymmetric hybrids carry partial genomes from the donor species. Asymmetrization occurs spontaneously or it can be induced artificially. The final product of protoplast fusion among phylogenetically remote species is usually an asymmetric combination of two genomes, with parts of one or both genomes being lost during the *in vitro* passage. The extent and direction of asymmetrization is largely random, hence unpredictable. Asymmetrization is essential for improving plant regeneration, but it is random and gradual; hence, it may not be potentially desirable at least for the applied objectives. Like nuclear genes, asymmetrization also occurs in cytoplasmic genes. Now, there is growing interest in artificial production of asymmetric cytoplasmic hybrids (cybrids) for a single-step transfer of useful cytoplasmic traits such as male sterility, disease resistance, and herbicide resistance. The protoplasts of the donor species are X-irradiated (9–50 kr) or treated with iodoacetate to inactivate the nuclear genome. In addition, miniprotoplasts (protoplasts lacking nucleus) from donor species are also being increasingly used. In the case of somatic hybrids combining full nuclear genomes, the parental genomes usually remain spatially separated within the nucleus. Effects of spindle-disturbing chemicals such as colchicine, chlorosopropyl-*N*- phenyl-carbamate, and aminoprophosmethyl (APH) are being investigated to induce translocations/recombinations.

16.9
Significance in Crop Improvement

Protoplast culture and somatic cell hybridization, involving fusion of protoplasts from different plant species, are important approaches for combining characteristics even from otherwise sexually incompatible species. Furthermore, cybrids and organelle recombinants, not possible with conventional methods, can also be developed [148]. Therefore, researchers' interest has moved from creation of novel hybrids to the production of cybrids, chromosome transfer, and gene introgression [149]. It is well known that alloplasmic association leads to male sterility as a consequence of interactions between nuclear and mitochondrial elements. Male sterility has been developed by fusing protoplasts of *N. tabacum* with X-irradiated protoplasts of *N. africana*. Likewise, male sterility has been transferred from *Raphanus sativus* into *B. napus*. Moreover, resistance to triazine herbicide has been combined with male sterility by fusing *B. napus* protoplasts from a male-sterile line with *B. napus* protoplasts from a triazine-resistant parent. Cytoplasmic genetic male sterility has also been successfully transferred into rice. Resistances to some diseases such as potato leaf roll virus, PVX, and PVY have been incorporated into *Solanum tuberosum* from *S. brevidens* and *S. phureja* through protoplast fusion [150, 151]. Likewise, resistance against Phoma lingam disease in *Brassica* species [152] and citrus tristeza virus (CTV) in citrus [153] was developed through protoplast fusion. Following protoplast fusion, hybrids of Iris fulva (4x) × Iris laevigata were produced. Iris fulva has unique brown flowers, and this trait could be very useful for flower color improvement in Iris laevigata, which lacks this color [154]. Protoplast-to-plant system developed in basmati rice [155, 156] can be exploited for single-step transfer of male sterility from one line to another for the production of hybrid rice. Pollen protoplasts have also been fused using pollen protoplasts of *B. oleracea* var. italica and haploid mesophyll protoplasts of *B. rapa* [157].

16.10
In Vitro Production of Secondary Metabolites

Several plant species are known to produce secondary metabolites *in vivo* or *in vitro*. These metabolites do not perform vital physiological functions, but some act as potential predators and attract pollinators. Furthermore, these metabolites act as a valuable source of a vast array of chemical compounds, including fragrances, flavors, natural sweeteners, and industrial feedstocks. Cultured cells/organs produce a wide range of secondary products. Mainly three approaches have been followed: (i) the rapid growth of cell suspension cultures in large volumes, (ii) immobilization of plant cells, and (iii) growing hairy root cultures *in vitro*. There are several advantages of the cell culture systems over the conventional cultivation for the production of secondary metabolites, for example, (1) independence from various environmental factors, (2) any plant cell can be multiplied to yield specific metabolite, and (3) culture of cells may prove suitable where plants are difficult or expensive to grow in the field

because of their long life cycles. Since the 1970s, when the possibility of producing useful secondary products in plant cell cultures was first recognized, considerable progress has been made and a number of plant species have been found to produce secondary products, such as shikonin, diosgenin, caffeine, glutathione, capsaicin, and anthraquinone [158–160]. Large-scale production of such compounds (molecular farming) is increasingly becoming popular with the industry where some physical and chemical conditions for growth and product formation have been optimized. Hairy root cultures, which are considered genetically more stable, are now increasingly being used for production of secondary metabolites *in vitro* [161].

16.11 Cryopreservation and *In Vitro* Germplasm Storage

The aim of germplasm conservation is to ensure the ready availability of useful germplasm for scientific research. In seed-propagated crops, seed is extensively used for conservation of germplasm through conventional methods. However, in vegetatively propagated species, where conventional storage techniques are used, it is very difficult to store germplasm on a long-term basis. The conservation of plant parts *in vitro* has a number of advantages over *in vivo* conservation; for example, *in vitro* techniques allow conservation of plant species that are in danger of becoming extinct. *In vitro* storage of vegetatively propagated plants can result in great savings in storage space and time and sterile plants that cannot be reproduced generatively can be maintained *in vitro*. Complete plants have been successfully regenerated from tissues cryopreserved at −196 °C in liquid nitrogen (LN) for several months to years in several crops [162, 163]. This method is now being practically used at several national and international germplasm banks. Successful cryopreservation of plant shoot tips depends upon effective desiccation through osmotic or physical processes. Cryoprotective treatments, which favor survival of small, meristematic, and young leaf cells, are most likely to produce high survival rates after exposure to liquid nitrogen. Furthermore, microscopy techniques have been used to determine the extent of cellular damage and plasmolysis that occur in peppermint (*Mentha piperita*) shoot tips during the process of cryopreservation, using cryoprotectant plant vitrification solution 2 (PVS2) (30% glycerol, 15% dimethyl sulfoxide, 15% ethylene glycol, and 0.4 M sucrose) prior to liquid nitrogen exposure [164]. *Arabidopsis*, which is increasingly being used in genomic studies, can be successfully cryopreserved using either PVS2 or PVS3 as cryoprotectants prior to rapidly cooling shoot tips in LN. PVS3 contains 50% glycerol compared to PVS2 that contains 30% glycerol. PVS3 is less injurious than PVS2. All the shoot tips regrew after LN exposure when cryoprotected with PVS3 for 60 min at 22 °C [165]. The high levels of shoot formation after LN exposure of *Arabidopsis* shoot tips make this a desirable system, in which molecular tools can be used to examine how alterations in biochemical, metabolic, and development processes affect regrowth after cryoprotective treatments. The method has been used for cryopreservation of rice [166], potato [167–169], citrus [170], and blackberry and raspberry [171].

Table 16.3 Tissue culture-based vector and vectorless gene transfer methods in plants.

Vector methods	Vectorless methods
1. *Agrobacterium tumefaciens*	1. Physicochemical uptake of DNA
2. *A. rhizogenes*	2. Liposome encapsulation
3. Sonication-assisted *Agrobacterium* method	3. Electroporation of protoplasts
4. Viral vectors	4. Microinjection
	5. DNA injection into intact plants
	6. Incubation of seeds with DNA
	7. Pollen tube pathway
	8. Use of laser microbeam
	9. Electroporation into tissues/embryos
	10. Silicon carbide fiber method
	11. Particle bombardment

16.12 Genetic Transformation

During the past 20 years, the combined use of recombinant DNA technology, gene transfer methods (Table 16.3), and tissue culture techniques has led to the efficient transformation and production of transgenics in a wide variety of crop plants. In fact, transgenesis has emerged as an additional tool to carry out single-gene breeding or transgenic breeding of crops. Unlike conventional breeding, only the cloned genes of agronomic importance are being introduced without cotransfer of undesirable genes from the donor. The recipient genotype is least disturbed, which eliminates the need for repeated backcrosses. Above all, the transformation method provides access to a large gene pool, as the gene(s) may come from viruses, bacteria, fungi, insects, animals, human beings, unrelated plants, and even from chemical synthesis in the laboratory. Various gene transfer methods [172–175] have been developed for genetic transformation of plants. Among these, *Agrobacterium* and "particle gun" (Figure 16.10) methods are being widely used.

16.12.1 Significance of Plant Genetic Transformation

Rapid and remarkable achievements have been made in the production, characterization, and field evaluation of transgenic plants in several field and fruit crops and forest plant species. Using different gene transfer methods and strategies, transgenics carrying useful agronomic traits have been developed and released in several crops. Transgenic varieties, possessing mainly insect resistance, herbicide resistance, or both, disease resistance, of 10 crops are now being commercially grown in an area of about 134 million ha across 25 countries [176]. Attempts are being made not only to develop transgenic crop varieties resistant to abiotic stresses, such as drought, low and high temperature, salts, and heavy metals but also to develop

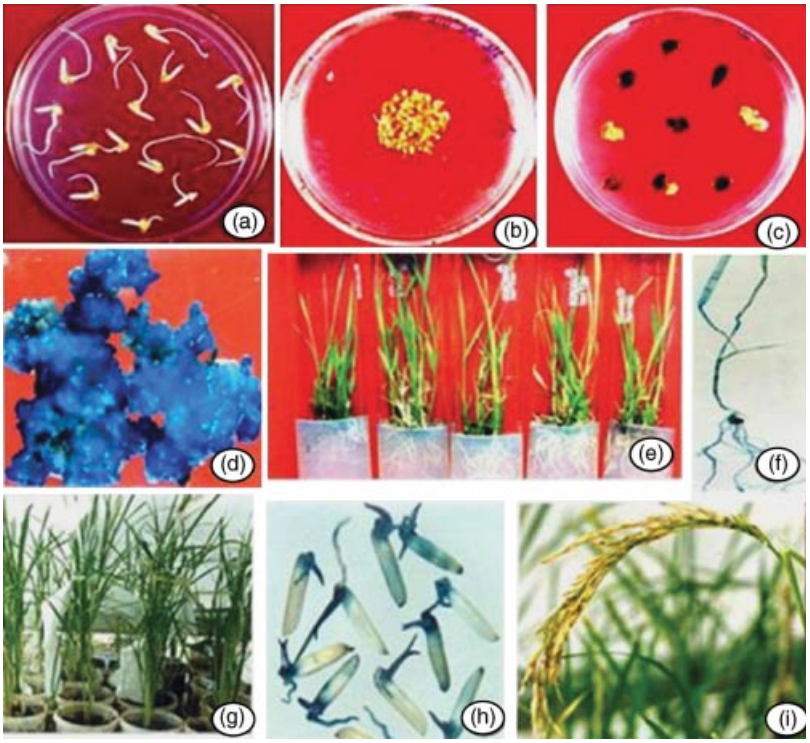

Figure 16.10 Genetic transformation of rice. (a) Germinating mature grains cultured *in vitro*. (b) Scutellar-derived calli placed in the center of target plate. (c) Bombarded calli cultured in selection medium showing blackening of nontransformed calli. (d) GUS expression in the selected callus. (e) Plant regeneration from selected calli. (f) Regenerated plantlet showing GUS exporession. (g) Putative transgenic T_0 plants in the green house. (h) Germinating T_1 grains showing GUS expression. (i) Transgenic plant showing fully fertile mature spike.

transgenic varieties possessing better nutrient use efficiency and better keeping, nutritional, and processing qualities. Genetically modified foods, such as tomato containing high lycopene, flavonols as antioxidants, cavity-fighting apples, golden rice with enhanced vitamin A, golden brassica with provitamin A, canola rich in vitamin E, proteinaceous potatoes, edible vaccines, decaffeinated tea and coffee, and nicotine-free tobacco, are leading examples of genetically engineered crops.

A Systems-Based Molecular Biology Analysis of Resurrection Plants for Crop and Forage Improvement in Arid Environments

John P. Moore and Jill M. Farrant

Resurrection plants represent a remarkable group of plants possessing vegetative tissue capable of surviving water loss to an air-dry state. Many of these species grow in semiarid and arid countries, and a rich diversity is found in Southern Africa. We review the mechanisms proposed to explain how they tolerate desiccation, highlighting the processes that protect them from metabolic disruption, oxidative damage, and mechanical stress during dehydration. Also reviewed are the molecular mechanisms associated with sensing water deficit and activating transcriptional processes associated with desiccation-induced gene expression in these species. Functional genes, which encode protective macromolecules and enzymes, and the systems approaches (transcriptomics and proteomics) utilized are also discussed. The application of resurrection plant studies in the molecular engineering of valuable crop plants and potentially providing new forages is highlighted.

17.1
Introduction

The ability of organisms to survive extreme dehydration (i.e., desiccation), referred to as anhydrobiosis (i.e., life without water), has evolved on multiple occasions in the plant, animal, fungal, and microbial kingdoms. A number of higher plants, tracheophytes, were found to be capable of tolerating desiccation and so these different species became collectively referred to as "resurrection plants" [1, 2]. The name resurrection plant originates from the observation of these plants during rehydration and denotes the seemingly miraculous manner by which the leaves and stems of a desiccated resurrection plant unfolds and regreens upon water availability.

Desiccation tolerance is generally defined as "the ability to survive drying to, or below, the absolute water content of 0.1 g H_2O g^{-1} dry mass (g g^{-1}), this being equivalent to air dryness at 50% relative humidity (20 °C) and a water potential of ≤ -100 MPa [3–5]. This definition arose from studies on anhydrobiosis in desiccation-tolerant (orthodox) seeds. The vegetative tissues of angiosperm resurrection plants dry to equilibrium of the surrounding air, and thus reach water contents of

Improving Crop Resistance to Abiotic Stress, First Edition.

$\leq 0.1\,g\,g^{-1}$. However desiccation tolerance studies are usually performed under glasshouse or simulated field conditions (as opposed to the constant humidity and temperature used for seed experiments). Hence, relative humidity and temperature values recorded in resurrection plant experiments are found to be highly variable. This implies that these conditions could give rise to fluctuations in the water content of tissues supposedly dry. Air-dried seeds have been suggested to contain localized pockets of water [6, 7] and this may be equally true of resurrection plants. An additional issue to consider is that water contents at full turgor can vary among species. In order to compare water contents, scientists in the field have come to use relative water content (RWC) measurements. This measure is determined gravimetrically by oven drying at 70 °C for 48 h and then dividing the obtained value by the gravimetric water content determined at full turgor. Nevertheless, valuable information on the mechanisms employed at different stages of dehydration (measured employing these approaches) in resurrection plants has been obtained.

Vegetative desiccation tolerance in angiosperms is comparatively rare, with approximately 300–400 species being reported as desiccation tolerant. Most of these species occur predominantly in the Southern Hemisphere in arid regions of Africa, South America, and Australia [2, 8]. The phenomenon of desiccation tolerance appears to have evolved independently on a number of occasions during plant evolution [9]. Among the dicotyledonous resurrection plants, there are several members in Schrophulariaceae (approximately 32 species) and Myrothanmaceae (at least 2 species although possibly more), and in the monocotyldeons there are several representatives of the Poaceae (approximately 36 species) and Velloziaceae, Xerophytaceae (approximately 28 species) [1, 2, 10]. The different genera and species of resurrection plants are unified by their common habitat requirements. These species commonly occur in shallow soils on rocky outcrops (also known as inselbergs) in arid subtropical and tropical regions [11]. Rock inselbergs, particularly because of rainfall runoff, expose resurrection plants to frequent cycles of dehydration and rehydration during the year, although the majority of time spent in the dry state is usually in the nonrainy season, which in Southern African region is winter. The exposed nature of these outcrops requires plants growing on them to be able to tolerate desiccation under both hot and cold environmental conditions. A rich diversity of resurrection plants is found in Southern Africa, a region of significant arid and semiarid areas. Several species, including *Myrothamnus flabellifolia*, *Craterostigma plantagineum*, *C. wilmsii*, *Xerophyta viscosa*, *X. humilis*, *Eragrostis nindensis*, and *Sporobolus stapfianus*, have been intensively studied with the goal of identifying the mechanisms responsible for their remarkable tolerance ([12–14], see Figure 17.1). Apart from the strong focus on South African species, very little research has been carried out on other resurrection plants from other countries. For example, resurrection species are found in the Balkans (*Ramonda serbica*), China (*Boea hygrometrica*), Australia (*Sporobolus* and *Eragrostis* spp.), in North and Central America (*Tortula ruralis*), and in South America (*Pleurostima purpurea*) [16–18]. We review the present hypotheses regarding the mechanisms of desiccation tolerance in resurrection plants, including processes associated with protecting against metabolic, oxidative, and mechanical damage due to desiccation. We also discuss

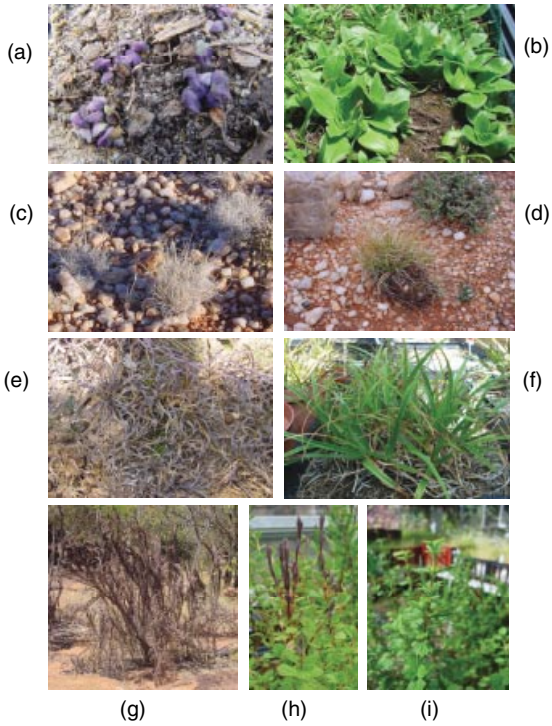

Figure 17.1 South African resurrection plants: *C. plantagineum* in the desiccated (a) and hydrated (b) state; *E. nindensis* in the dehydrated (c) and hydrated (d) state; *X. viscosa* in the desiccated (e) and hydrated (f) state; and *M. flabellifolia* in the desiccated (g), partially rehydrated, (h) and hydrated (i) state.

molecular processes associated with desiccation tolerance and the "new" systems tools that have been applied to study these plants. We conclude by highlighting the utility of research in resurrection plants as applied to improving crop and forage drought tolerance to arid environments.

17.2
Mechanisms to Alleviate Desiccation-Induced Stress

Resurrection plants are exposed to multiple stresses during dehydration and the subsequent rehydration phase. These desiccation-related stresses have been broadly classified into metabolic (including oxidative stress) and mechanical stress categories. Resurrection plants utilize common (interspecies) and unique (species-specific) strategies to alleviate or minimize the effect of these individual stresses to plant growth, reproduction, and survival. Here, we summarize the effects of these stresses on normal plant functioning and the adaptations that resurrection plants possess to counteract them.

17.2.1 Countering Oxidative and Metabolic Stresses by Modifying Photosynthesis and Sugar/Protein Metabolism

In all plants, reactive oxygen species (ROS) form as a natural consequence of metabolic processes involving electron transport [19–21]. Thus, mitochondria and chloroplasts are major sites of ROS production. Photosynthesis, in particular, is very sensitive to water deficit. Electron leakage during photosynthetic electron transport and the formation of singlet oxygen are significantly increased when cells of photosynthetic tissues suffer water loss and this has frequently been cited as a primary cause of damage and resultant plant death in most species [45]. Resurrection plants minimize ROS formation by downregulation of photosynthesis early in dehydration (from 80 to 60% relative water content) [22, 25]. Two mechanisms have evolved in resurrection plants to modify photosynthesis: these are termed poikilochlorophylly and homoiochlorophylly [22, 25].

Poikilochlorophyllous resurrection plants, usually monocotyledons, degrade their chlorophyll and dismantle their thylakoid membranes upon desiccation [22, 25]. This is a highly effective strategy to minimize ROS formation and this may explain why poikilochlorophyllous species appear to remain viable for longer periods than homoiochlorophyllous ones during desiccation [25]. The drawback of this strategy is that reassembly of the photosynthetic apparatus on rehydration requires coordinated transcription and *de novo* translation [26, 28]. Hence, poikilochlorophyllous plants require much longer periods after rehydration to resume normal growth and development. In contrast, homoiochlorophyllous species, commonly dicotyledons, retain most of their chlorophyll and thylakoid membranes intact during desiccation. They utilize various adaptations to prevent ROS production from photoactivated chlorophyll uncoupled from metabolic dissipation mechanisms (thylakoid membranes channeling excited electron to oxygen production) [22, 23, 29]. This is achieved by leaf folding and shading of inner leaves (e.g., the *Craterostigma* spp.) or adaxial surfaces (e.g., *M. flabellifolius* and *M. caffrorum*), utilizing reflective hairs and/or waxes and usually "sunscreen" pigments (anthocyanins and phenols), to reflect light back away from the leaf surface [22, 29, 30].

In addition to water-induced light stress, the progressive loss of water results in metabolic stress related to cytoplasmic crowding. The cytoplasm becomes increasingly viscous, proteins begin to denature, and membrane fusion occurs [3]. It has been proposed that desiccation-tolerant organisms counteract this stress by replacing water with compatible solutes capable of substituting for the hydrogen bonds lost due to dehydration. This water replacement hypothesis presupposes that these molecules are able to stabilize macromolecules in their native configuration during desiccation [31, 32]. Additional stabilization of the subcellular milieu is believed to be achieved via cytosolic vitrification caused by compatible solutes [3, 4, 33]. Solutes believed responsible for replacement and stabilization include (1) sucrose and oligosaccharides [5, 34, 37], (2) proteins (particularly LEA proteins and heat shock proteins) [34, 35], and (3) various compatible solutes such as proline [36]. In the case of sucrose, this is found to accumulate in the leaves and roots of all angiosperm

resurrection plants investigated thus far ([34, 37], reviewed in Ref. [15]). Sucrose is also found to be accumulated in orthodox seeds [3, 5] and this provides confirmatory evidence of an important role this sugar plays in general desiccation tolerance in plants. Recent data show that sucrose accumulates exclusively in the cytoplasmic compartments of leaf and root tissues of resurrection plants [38] and so this further confirms a possible role for this sugar in glass formation and/or stabilization of subcellular structures against desiccation. In addition to sucrose, raffinose and stachyose family oligosaccharides and trehalose have been found to accumulate upon drying in resurrection plants. Trehalose is found only to accumulate to any great extent in *M. flabellifolia*. In seeds, it is widely held that raffinose and stachyose may play an important role in cytosolic stabilization by either, or a combination of, water replacement and/or vitrification [39, 40]. These oligosaccharides are believed to function as (1) facilitators of vitrification and inhibitors of sucrose crystallization, (2) promoters of mechanical stabilization by vacuolar filling, (3) metabolic reserve polymers for excess monosaccharides (utilized in their formation), and (4) carbon sources for rehydration and recovery.

Apart from carbohydrates, proteins are also strongly implicated in desiccation protection in animals, bacteria, fungi, and plants. Particularly the late-embryogenesis abundant or LEA proteins, found at concentrations close to 4% of total cellular protein, were found to accumulate at late stages of seed development [5]. LEA proteins are found in bacteria, nematodes, and tardigrades [41] and are widely present in plants [15]. In plants, they appear to be expressed predominantly in response to desiccation, cold, drought, salt, and osmotic stress [15]. Predicted functions of LEA proteins, based on their rich hydrophilic amino acid content, include (1) water replacement and hydration buffers, (2) ion sequestration, (3) chaperonins and/or heat shock proteins, (4) antiaggregants, and (5) promoters of vitrification [5, 33, 35, 41].

17.2.2
Modulating Antioxidants and Associated Metabolism

Resurrection plants upregulate housekeeping antioxidants, so called because they are present in all plants and are crucial to maintain cellular homeostasis under day-to-day conditions and provide protection against a myriad of abiotic and biotic stresses in order to quench reactive oxygen species. However, they appear to have the additional capacity to maintain function of these antioxidants in the desiccated state and/or quickly resynthesize them upon rehydration. Furthermore, they possess the ability to produce, *de novo*, antioxidants that commonly occur in seeds [34]. The important housekeeping antioxidants, essential for maintenance of redox homeostasis, include the polar glutathione (γ-glutamyl-cysteinylglycine) and ascorbic acid [42], the non-polar soluble tocopherols and β-carotene [43], and enzymes such as superoxide dismutase, ascorbate peroxidase, and other peroxidases, mono- and dehydroascorbate reductases, glutathione reductase, and catalase. It has been shown [14] that the enzymes retain their ability to detoxify reactive oxygen species even below relative water contents of 10%, suggesting that these proteins are stable against denaturation

and desiccation. Common practice when evaluating antioxidant status under desiccation stress is to measure the concentration of individual antioxidant molecules at different stages of dehydration and rehydration. However, the use of antioxidant concentrations alone has limitations, particularly making interpretation ambiguous due to the Gaussian response to stress observed [44]. However, what appears to be a distinguishing feature in resurrection plants is their ability to maintain antioxidant potential in the dry state such that these same antioxidants can be utilized during the early stages of rehydration, thus protecting against the reactive oxygen species associated with reconstitution of full metabolism [14, 15]. Kranner *et al*. [44] have proposed that glutathione is key to the desiccation survival in a variety of desiccation-tolerant systems [44]. It was shown that the half-cell redox potential ($E_{GSSG/2GSH}$) can be used as a marker for plant stress. The authors have demonstrated that longevity of *M. flabellofolius* in the dry state was lost after 8 months when $E_{GSSG/2GSH}$ values became more positive than −160 mV [45], correlating with earlier studies on *M. flabellifolius* [12]. Recently, it was demonstrated that viability loss associated with dry stored *C. wilmsii* (3 months) and *X. humilis* (10 months) coincided with a loss of activity of the enzymes GR, catalase and SOD, even though the $E_{GSSG/2GSH}$ values did not become more positive than −160 mV (Bajic and Farrant, unpublished). Related to glutathione metabolism is ascorbate biosynthesis, due to the Haliwell–Asada antioxidant cycle. It has shown that transcription of a recently discovered gene encoding an enzyme essential to ascorbic acid biosynthesis, in the resurrection plant *X. viscosa*, is upregulated when the plants are dried below 60% relative water content and that mRNA levels remain high in the desiccated plant and during early stages of rehydration. Ascorbate levels in roots and leaves of this plant follow the same trend [46] and we propose that elevated ascorbate levels are maintained during drying and early rehydration by a combination of *de novo* synthesis and regeneration of ascorbate [14, 46]. Further to the standard housekeeping antioxidants, resurrection plants have the ability to induce, *de novo*, antioxidants such as 1- and 2-cys-peroxiredoxins, glyoxylase I family proteins, and zinc metallothionine and metallothionine-like antioxidants in response to desiccation [14, 34, 47, 48]. Polyphenols are unusual antioxidants that have also been shown to play a role in resurrection plants [49]. Moore *et al*. [49] have shown that dry leaves of *M. flabellifolia* contain a high proportion (up to 50% of the leaf dry weight) of 3, 4, 5 tri-*O*-galloylquinic acid that acts as a potent antioxidant [49]. Although this polyphenol is predominantly located in the vacuole, it has been proposed to act as an antioxidant reservoir linked to the cytoplasmic antioxidants and function as a redox buffer [30, 49, 50].

As a final observation, it would appear that the total antioxidant potential, if one combines the extent of upregulation of antioxidant enzymes and potential polyphenol antioxidant capacity and anthocyanin protection, of the homoiochlorophyllous species (*M. flabellifolius* and *Craterostigma* spp.) is greater than that of the poikilochlorophyllous types (*Xerophyta* spp. and *E. nindesis*). This supports the contention that homoiochlorophyllous resurrection plants might need better antioxidant protection against free radical activity than the poikilochlorophyllous ones [14, 23].

17.2.3
Mechanical Stress and Adaptations of Resurrection Plant Cell Walls

There appears to be two general mechanisms employed by angiosperm resurrection plants to avoid mechanical stress: (i) active and reversible wall folding as seen in the *Craterostigma* spp. [51, 52] and (ii) increased vacuolation with water replacement in vacuoles by nonaqueous substances such as in the *Xerophyta* spp. ([23], see Figure 17.2 for ultrastructural changes to resurrection plants). Desiccation induced cell wall folding is essential for structural preservation of tissue [53] and the extent and manner of folding is species specific and depends upon the chemical composition and molecular architecture of the cell wall. A comprehensive biochemical and immunocytological investigation of leaf wall changes during drying and rehydration of *C. wilmsii* has shown that the major difference between dry and hydrated walls lay only in the hemicellulose wall fractions [51, 52].

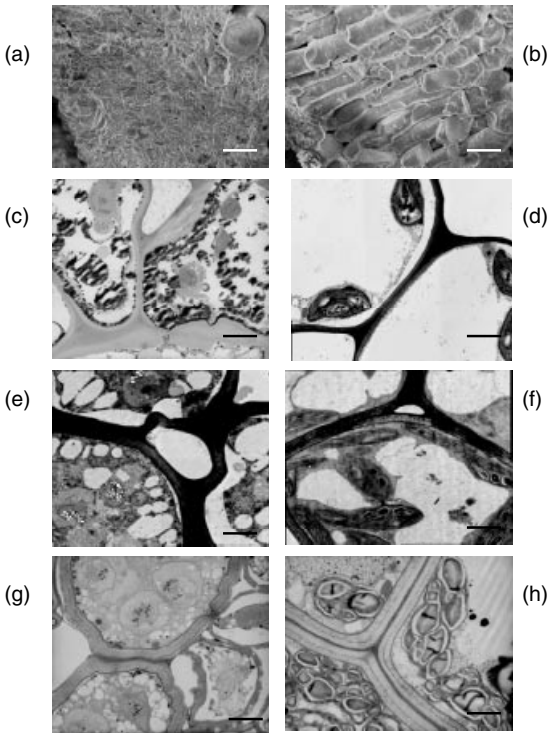

Figure 17.2 Leaf ultrastructure of South African resurrection plants in the hydrated and desiccated states. Scanning electron micrographs of flash frozen leaves *M. flabellifolia* in the desiccated (a) and hydrated (b) state. Transmission electron micrographs of *M. caffrorum* in the dehydrated (c) and hydrated (d) state, of *X. viscosa* in the desiccated (e) and hydrated (f), and of *E. nindensis* in the desiccated (g) and hydrated (h) state. Scale bars: (a) and (b) = 40 μm; (c–h) = 3 μm.

We have proposed that cleavage, or partial cleavage, of the long-chained XG units during drying into shorter, more flexible ones allows for wall folding. Ca^{2+} ions play an important role in cross-linking wall polymers, such as acid pectins, and we propose that this serves to stabilize walls in the dry state and, more importantly, prevent mechanical stress of rehydration. *C. wilmsii* is a small plant, and rehydration is rapid and if walls hydrate and unfold before cell volume is regained, plasmalemma tearing and further subcellular damage could occur [52]. Jones and McQueen-Mason [54] have shown an increase in abundance of an α-expansin transcript during drying and rehydration in leaves of *C. plantigineum* that correlated with changes in wall extensibility in that species [54]. Expansins are proposed to facilitate a complementary mechanism, whereby wall folding might be facilitated in the *Craterostigma* spp. [54].

In *M. flabellifolius* [55], wall folding occurs in the epidermis (around seemingly less flexible stomata and gland cells) and in the adjacent mesophyll cells [30]. In this species, there were no significant changes in wall components during drying, but walls contained an unusually high amount of arabinose. These arabinans were associated with pectin, presumably as arabinan polymers, and also in arabinogalactan proteins. Arabinose polymers are highly mobile and allow wall flexibility and have a high water absorbing capacity [55], which would be important for rehydration. We propose that arabinans are constitutively synthesized in leaf cell walls of *M. flabellifolius* and that their presence as "pectic plasticizers" for dehydration–rehydration cycles is crucial in this species [55].

Wall folding occurs in mesophyll cells of the grasses *E. nindensis* and *S. stapfianus*, but the biochemical nature of wall changes has not been elucidated. Interestingly, though, when tensilometry studies were performed to compare cell wall properties of the resurrection grass *E. nindensis* with three desiccation-sensitive *Eragrostis* species with differing degrees of "drought tolerance" [56], it was found that leaf tensile strength increased with degree of drought, but not desiccation tolerance [56]. Among the sensitive species, vascular bundle size and degree of lignification correlated with increased mechanical properties and water loss. However, in the resurrection species, *E. nindensis*, there was no such change in tensile properties despite the structural features of the leaves being similar to those of drought-tolerant *E. curvula* [57].

Replacement of water in vacuoles within dry tissues of resurrection plants was first suggested on the basis of ultrastructural observations that vacuoles continue to take up a large proportion of the cytoplasmic space despite the fact that there was no longer bulk water available in tissues, the remaining water being purely structure associated [14, 23, 30, 58]. A thorough biochemical analysis of *M. flabellifolius* [30, 49] revealed that the vacuoles (both hydrated and dry) contained the 3,4,5 tri-*o*-galloylquinic acid and that this polyphenolic increased upon drying to fill the vacuole and stabilize the subcellular milieu against mechanical stress. The content of vacuoles from desiccated leaves of *E. nindensis* was analyzed after nonaqueous extraction and was shown to contain proline, sucrose, and protein in equal proportions [58]. Analysis of metabolite changes in *Mohria caffrorum* showed significant fold change increases in glycerol and monohexadecanoglycerol during drying, and since these molecules are believed to be cytotoxic in large quantities, it was proposed that they accumulated

in vacuoles within the dry leaves [29]. Further studies using metabolomic technologies are underway, focused on investigating the cell wall and vacuolar content of a variety of resurrection plants.

17.3
Molecular Biology and Systems Biology of Desiccation Tolerance

A little over a decade ago, knowledge of regulatory networks controlling drought responses in plants was limited, with almost no information on signal transduction [59]. More than a decade later, while much of the signal transduction pathway in plant drought stress response has been elucidated in model plants such as *Arabidopsis*, corresponding information is still fragmentary in resurrection plants. The scarcity of information may be a consequence of the fact that of the 300–400 known resurrection plants, the molecular genetic basis of desiccation tolerance has been studied in relatively few species, namely, the mosses *S. lepidophylla* [60] and *T. ruralis* [61], the monocots *S. stapfianus* [62], *X. viscosa* [22], and *X. humilis* [48], and the dicot *C. plantagineum* [13]. In *C. plantagineum*, the synthesis of phospholipid-based signaling molecules is known as one of the earliest events in the perception of water stress. Phospholipase D (PLD) activity is induced within minutes by dehydration stress, but not by ABA [63]. PLD catalyzes the hydrolysis of phospholipids to form phosphatidic acid (PA), which in turn can regulate other components of the stress signaling pathway such as protein kinases or small GTP binding proteins. Two PLD genes, *CpPLD-1* and *CpPLD-2*, have been isolated from *C. plantagineum* [63]. The constitutively expressed *CpPLD-1* transcript is thought to be involved in early responses to dehydration by producing PA as a second messenger that transmits the stress signal, while the dehydration-induced *CpPLD-2* may be involved in phospholipid metabolism and in the rearrangement of lipids within membranes that occurs as a result of desiccation. While little is known about the early events in the perception of desiccation within resurrection plants, much more is known about downstream events in the dehydration response signaling pathway, with many genes having been characterized. Genes that are expressed in response to drought stress in resurrection plants are classified into two main types: those that control the expression of other genes such as transcription factors and regulatory RNAs, and those that encode products with putative protective functions.

17.3.1
Transcription Factors: the Magic Bullet for Plant Desiccation Tolerance?

Several classes of drought-induced transcription factors have been isolated from *C. plantagineum*; namely, MYBs, homeodomain-leucine zipper (HD-Zip) family, and a novel zinc finger ([63–67], see Table 17.1). Two Myb-related genes, *CpMyb7* and C*pMyb10*, show differential expression and regulation in response to desiccation and ABA in different tissues of *C. plantagineum* [67]. *CpMYB10* transcription is also induced by cycloheximide treatment, suggesting that *CpMYB10* expression is

Table 17.1 Functional studies and overexpression experiments performed on a number of regulatory genes from resurrection plants.

Gene	Source	Functional studies
CpMyb7 and CpMyb10	*C. plantagineum*	Show differential expression and regulation in response to desiccation and abscisic acid in different tissues of *C. plantagineum*. *CpMYB10* transcription is induced by cycloheximide treatment, expression is repressed under watered conditions, and binds to the promoter of *CDeT11-24* (a possible LEA target gene)
CpHB-7	*C. plantagineum*	The HD-Zip transcription factor family act in different pathways of the dehydration response; some mediated by abscisic acid, while others are independent of abscisic acid
CpR18	*C. plantagineum*	The C_3H-type zinc finger transcription factor CpR18 binds to a 29-bp promoter region of the LEA-like *CDeT27-45* gene that is essential for transcriptional activation by abscisic acid in *C. plantagineum*.
CpbZIP1	*C. plantagineum*	A bZIP transcription factor (CpbZIP1) and three highly conserved histone H3 proteins have been shown to bind to the promoter of the dehydration-induced group 4 LEA gene, *CpC2*. A repressor function, possibly by inhibition of other transcription factors from binding to the *CpC2* promoter, has been suggested

CDT-1	*C. plantagineum*	It was also shown that *CDT-1* has the ability to code for an siRNA and that it directs the synthesis of a double-stranded 21-bp siRNA necessary for induction of desiccation tolerance	

Gene	Source	Target	Results
CpHB-7 *Homeodomain leucine zipper* transcription factor	*C. plantagineum*	Tobacco	Overexpression resulted in early germination, increased growth rate, reduced abscisic acid sensitivity, germination sensitivity, and stomatal closure. Transgenic plants show increased salt tolerance
		Arabidopsis	Overexpression resulted in early germination, reduced abscisic acid sensitivity, stomatal closure
CpMYB10 *Myb* transcription factor	*C. plantagineum*	*Arabidopsis*	Overexpression resulted in abscisic acid hypersensitivity, glucose insensitivity, and drought and salt tolerance
CDT-1 Regulatory RNA	*C. plantagineum*	*C. plantagineum*	Constitutive desiccation tolerance in callus tissue. abscisic acid insensitive
XvSAP1 unknown	*X. viscosa*	*Arabidopsis*	Overexpression resulted in improved salinity, osmotic, and high-temperature stress

repressed under watered conditions by other (unknown) regulatory factors or that *CpMYB10* transcript is protected from degradation by inhibition of labile ribonucleases [67]. Transgenic *Arabidopsis* plants overexpressing C*pMyb10* displayed increased tolerance to drought and salt stress [68]. Interestingly, these plants also showed ABA hypersensitivity and glucose insensitivity, suggesting that C*pMyb10* is involved in mediating ABA and glucose signaling responses in *Arabidopsis* as well as the response to drought stress. Recombinant CpMYB10 protein is able to bind to specific MYB response elements within the promoter of *CDeT11-24* (a possible LEA target gene) and to elements within its own promoter, suggesting that CpMYB10 may autoregulate its expression. Several drought-regulated HD-Zip genes have been isolated from *C. plantagineum*, with some being inducible by both dehydration and exogenously applied ABA, while others are induced by dehydration stress only [64, 69]. These results demonstrate that members of the HD-Zip transcription factor family act in different pathways of the dehydration response; some are mediated by ABA, while others are independent of ABA. In both desiccation-tolerant and desiccation-sensitive plants, the expression of drought-responsive genes is mediated by both ABA-independent and ABA-dependent signal transduction pathways. Transgenic tobacco and *Arabidopsis* plants that ectopically express the HD-Zip transcription factor, *CpHB-7*, display reduced sensitivity toward ABA during seed germination and stomatal closure [65]. This suggests that CpHB-7 modifies ABA-responsive gene expression in these transgenic plants at the transcriptional level as a negative regulator. The ABA- and dehydration-responsive dehydrin gene, *CDeT6-19*, has been identified as one of the potential target genes of CpHB-7 [65]. The C_3H-type zinc finger transcription factor CpR18 binds to a 29-bp promoter region of the LEA-like *CDeT27-45* gene that is essential for transcriptional activation by ABA in *C. plantagineum* [66]. CpR18 contains an acidic SAP domain and two conserved motifs, one of which is rich in basic residues and is predicted to form a helix–loop–helix structure. CpR18 is capable of activating reporter gene expression in tobacco protoplasts by binding to the AGCCC element within the CDeT27-45 promoter. A bZIP transcription factor (CpbZIP1) and three highly conserved histone H3 proteins have been shown to bind to the promoter of the dehydration-induced group 4 LEA gene, *CpC2* [70]. *CpbZIP1* belongs to the group S of bZIP genes possessing a conserved small upstream open reading frame within the 5′-leader sequence that may be involved in regulating gene expression at the translational level. Although the exact function of CpbZIP1 is unknown, a repressor function, possibly by inhibition of other transcription factors from binding to the *CpC2* promoter, has been suggested. Two of the CpHistone H3 proteins are constitutively expressed histone H3 variants that are thought to regulate gene expression through histone modification.

17.3.2
A Role for Small RNAs as Regulators

Research over the last few years has highlighted the significance of small RNAs in regulating plant responses to abiotic stress [71]. Furini *et al.* [72] characterized the dehydration- and ABA-inducible gene *CDT-1* from *C. plantagineum* [72]. Overexpres-

sion of *CDT-1* resulted in constitutive expression of dehydration- and ABA-responsive transcripts and contributed to desiccation tolerance of *C. plantagineum* callus tissue in the absence of ABA treatment. The *CDT-1* gene lacks significant open reading frames, and appears to be naturally expressed in both sense and antisense orientations. *CDT-1* and other functionally related gene members [73] have features of short interspersed retrotransposon elements, and are hypothesized to act as regulatory noncoding RNA molecules. Recently, it has been shown that translation of the *CDT-1* transcript is not required for the induction of desiccation tolerance since *C. plantagineum* calli transformed with mutated versions of the *CDT-1* gene are constitutively desiccation tolerant [74]. The information necessary for induction of desiccation tolerance is contained within the 488-bp region at the 3′ end of the *CDT-1* gene. It was also shown that *CDT-1* has the ability to code for a small interfering RNA (siRNA) and that it directs the synthesis of a double-stranded 21-bp siRNA. Expression of the siRNA is capable of inducing desiccation tolerance in callus tissue of *C. plantagineum*. Thus, it has been demonstrated that retrotransposons and siRNA play a role in the evolution of desiccation tolerance in *C. plantagineum*. Whether this is also the case in other resurrection plants remains to be seen. *CDT-1* and its closely related gene members appear to be unique to *C. plantagineum* [73]. However, it is likely that more regulatory RNAs involved in desiccation tolerance will be discovered. Regulation of gene expression by small RNAs allows plants the flexibility to modulate stress responses and adapt to diverse and extreme habitats [71].

17.3.3
Functional Genes Encoding for LEA Proteins

The ability of resurrection plants to survive desiccation depends on the accumulation of protective proteins such as the late-embryogenesis abundant proteins. LEA proteins have been classified into 18 superfamilies on the basis of sequence homology [75]. Members of some LEA superfamilies, notably group 3 and group 4, share strong conservation of structural motifs across diverse plant species including resurrection and desiccation-sensitive plants. Many of these LEA genes are activated under mild dehydration stress conditions (>65% RWC) in both desiccation-sensitive and -tolerant tissues, and are proposed to protect plants only at higher water contents [34]. However, only genes belonging to LEA-1, -6, and -9 superfamilies are significantly expressed during seed development. These LEA genes are thought to play a role in defense against severe water loss such as that experienced by orthodox seeds during maturation or by resurrection plants during desiccation [34]. Several protective functions have been predicted for LEA proteins including a role in the unwinding or repair of DNA, forming cytoskeletal filaments to counteract the physical stresses imposed by desiccation, and acting as molecular chaperones [76]. Alternatively, LEA proteins, possibly in combination with compatible solutes and/or sugars, may replace water during desiccation and thus maintain the hydration shell of proteins and other molecules. Recently, it has been shown that LEA proteins can act synergistically with sugars such as trehalose to prevent protein aggregation during desiccation [41]. The expression of at least 16 different LEA genes,

representing seven LEA superfamilies, is activated during desiccation in *X. humilis* leaves [48]. The concurrent induction of multiple LEA genes during dehydration suggests that these LEAs may interact to stabilize and protect other proteins and membranes, or that different LEAs are specifically targeted at different organelles or cellular structures to exert their protective function. Two LEA proteins from *C. plantagineum*, CDeT11-24 and CDeT6-19, have recently been shown to be phosphorylated in both leaf and root tissues during desiccation [77]. Phosphorylation is believed to be required for the function of these proteins that is proposed to protect the catalytic activities of enzymes by altering the stability or specificity of protein–protein interactions [77]. LEAs may also play a role in recovery during rehydration in *T. ruralis* [61]. It has been proposed that in rehydrating *T. ruralis* gametophytes, LEA proteins may stabilize membranes or perhaps function in the transport of lipids for reconstitution of damaged membranes [78].

17.3.4
Functional Genes Encoding for Antioxidant Enzymes

Antioxidant enzymes such as superoxide dismutase, glutathione reductase, and ascorbate peroxidase are considered as general "housekeeping" protectants because they are not only expressed specifically in resurrection plants but are also induced in response to various abiotic stresses in desiccation-sensitive organisms [34]. However, there are some novel antioxidants that appear to be specific to desiccation tolerance. Several members of the aldehyde dehydrogenase (ALDH) have been identified both in seeds during maturation drying and in dehydrated vegetative tissues of resurrection plants. Velasco *et al.* [79] demonstrated that mRNA and protein levels of GAPDHc, a member of the ALDH11 (GAPDH) family, increased in response to desiccation in the leaves of *C. plantagineum* [77]. Recently, Kirch *et al.* [80] showed that the ABA- and dehydration-induced Cp-ALDH protein, an ALDH3 protein family homologue from *C. plantagineum*, was capable of oxidizing toxic nonanal, propionaldehyde, and acetaldehyde [80]. In *T. ruralis*, the *ALDH21A1* gene is thought to play an important role in the detoxification of aldehydes generated in response to desiccation and salinity stress, and to oxidize a novel class of stress-induced aldehydes [81]. Another antioxidant enzyme, the seed-specific 1-cys-peroxiredoxin, has been previously shown to be abundantly expressed during desiccation in the leaves of *X. humilis* and *X. viscosa* [47]. Interestingly, a 1-cys peroxiredoxin is also expressed not only during dehydration but also during rehydration of *T. ruralis* [82].

17.3.5
Functional Proteomic Studies of Desiccation Tolerance

Transcriptomic approaches have identified many mRNAs that are induced by dehydration and encode proteins that play important roles in desiccation tolerance in resurrection plants. However, there have been few studies of the proteome of resurrection plants during dehydration and/or rehydration (see Table 17.2). The importance of proteomic studies is highlighted by the fact that, in plants, there only

Table 17.2 Transcriptomic and proteomic studies performed on a variety of resurrection plants to elucidate mechanisms of their tolerance to desiccation.

Division	Species	Transcriptomic and/or proteomic study
Bryophyte	*T. ruralis*	Approximately 10 000 ESTs were obtained from drying and rehydrating gametophytes, including LEA genes involved in protection and repair [61, 86]
	T. ruralis	cDNA libraries enriched with ESTs from slow drying and rehydrating gametophytes revealed genes involved in metabolic recovery, signaling, proteosomal processing, and splicing [94]
Lycophyte	*Selaginella lepidophylla*	EST library corresponding to approximately 800 genes compared to 1300 genes from desiccation-sensitive *S. moellendorfii*. Genes identified that are involved in transport, cytoskeleton, phenylpropanoid biosynthesis, LEA proteins, ELIPs, and HSPs [60]
Angiosperm	*S. stapfianus*	144 cDNA upregulated genes in dried leaves; mostly LEA genes, defense, and detoxification genes [95]
	X. humilis	Normalized cDNA library (about 10 000 clones) from dried roots and leaves containing 424 sequenced and arrayed cDNA. Identification of LEA genes, antioxidant and signaling genes upregulated, and metabolism and growth genes downregulated [48]
	X. viscosa	Identification of water stress-induced photosynthesis-associated proteins, chaperones, RNA-binding protein, 2-Cys peroxiredoxin, and protein phosphatase 2C [28]
	B. hygrometrica	Water stress induces polypeptides involved in photosynthesis, glutathione metabolism, and phenolic metabolism [85]
	C. plantagineum	Enriched phosphoproteins correspond to chlorophyll a/b binding protein, rubisco, 14-3-3 proteins, HSPs, elongation factor 1, eukaryotic initiation factor [77]

appears to be approximately 50% correlation between the abundance of proteins and their corresponding mRNA levels. Similarly, a high percentage (40–55%) of drought-induced proteins do not show an increase in transcript abundance during dehydration in poplar. Thus, there is a clear need for proteomic studies in resurrection plants in order to understand the mechanisms of desiccation tolerance. A two-dimensional (2D) SDS-PAGE analysis of the *S. stapfianus* leaf demonstrated that the protein complement changes during the induction of desiccation tolerance [83]. 2D SDS-PAGE was also used to study *de novo* protein synthesis during rehydration in *T. ruralis* [84] and in *C. plantagineum* [77]. However, in all three studies, no protein identification was attempted. Recently, changes in the leaf proteomes of resurrection plants during desiccation were examined in *X. viscose* [28] and in *B. hygrometrica* [85] using quantitative 2D SDS-PAGE analysis. Several novel gene products, not previously isolated in transcriptomic studies, were identified as being upregulated during

dehydration. In detached *B. hygroscopica* leaf tissue, dehydration-induced proteins include an ABC transporter and a vacuolar H^+-ATPase that may be involved in protection against osmotic stress, a glutathione peroxidase-like protein that may be involved in oxidative stress protection, and a polyphenol oxidase that may prevent proteolytic activity [85]. In severely dehydration-stressed *X. viscosa* leaf tissue (35% RWC), proteins that increase in abundance include a chloroplast FtsH protease, GDP-mannose-3′,5′-epimerase, alcohol dehydrogenase, and protein phosphatase type 2C, VDAC1.1, and 2-cys peroxiredoxin that may be involved in antioxidant defense [28]. Of particular interest are proteins synthesized *de novo* upon dehydration (i.e., absent in hydrated tissues). These include a dnaK-type molecular chaperone, RNA binding protein, phosphopyruvate hydratase, and desiccation-related protein. A major hindrance to proteomic analysis in resurrection plants is the lack of a large genomic or EST database such as those available for organisms with completely sequenced genomes. For both *X. viscosa* [28] and *B. hygroscopica* [85], this has resulted in low success rate (~30%) in protein identification when searching against the NCBI nonredundant database. Although large EST collections (containing more than 10 000 ESTs and representing several thousand genes) are available for *T. ruralis* [86] and *X. humilis* [48], this number is probably still too low to increase the protein identification success rate significantly for proteomics study. For that, a much larger EST collection would be needed. New high-through put sequencing technology allows many more genes to be sequenced in a relatively short time (up to 100 Mbp per one 7–8 h instrument run). The technology can be adapted for gene discovery from cDNA [87] or small RNA [88] libraries.

17.4
Applications for Engineering Drought Tolerance in Crops and Forages

The aim of the study of desiccation tolerance in resurrection plants is to engineer agronomically valuable desiccation-sensitive crop plants for increased tolerance [89, 90]. Over 100 dehydration-induced genes from a number of resurrection plants have now been characterized [48]. However, very few of these genes have been introduced into desiccation-sensitive plants and tested for improving drought tolerance (see Table 17.1). The problem is that overexpressing single genes has proven a flawed strategy for producing drought-tolerant plants. Many of these transgenic plants show side effects, including, abscisic acid hypersensitivity or insensitivity, impaired germination ability, modified stomatal activity, glucose insensitivity, and constitute desiccation tolerance (see Table 17.1). Although some results have proven promising, such as plants showing improved salt, osmotic, and temperature stress, we still have a very unclear understanding of the reasons behind this (see Table 17.1). Limited information is available on the feasibility of transferring resurrection genes to a crop plant system and equally whether such genes will be useful in an agricultural scenario. Yield under drought stress is possibly a greater consideration than survivability, which is what resurrection plants are adapted for. Nevertheless, progress in crop improvement will be possible only with a multifaceted

approach using systems biology and molecular genetics (see review [15]), so that multiple high-impact "resurrection plant" genes can be coordinately expressed in model crop systems for drought tolerance. This approach requires data acquisition using genomics (the genome sequence of one or two model resurrection plants would be invaluable here), transcriptomics, proteomics, and metabolomics that needs to be coupled to multivariate data analysis methods (see review [15]). An alternative approach for resurrection plants is to employ them as forages in arid countries such as India and South Africa. Many resurrection plants are grasses and early surveys of resurrection grasses in India have identified these as potential forages [91, 92]. This strategy avoids the problem of "molecular reengineering" of established crops as here the objective is to convert an already desiccation-tolerant species into valuable forage by genetically enhancing nutritional value. Genetic engineering, tissue culture, and transformation technology are still fairly rudimentary in resurrection plants, but progress is being made [90, 93]. This strategy might pose a valuable alternative strategy for utilizing indigenous resources, such as resurrection plants, as drought-tolerant forages, because only a few genes, for enhanced nutritional value, need to be transferred. However, much more research is needed to confirm the reliability and validity of these approaches.

17.5
Concluding Remarks and Future Directions

The research to date outlined highlights not only a number of key differences among resurrection plants in their responses to desiccation but also some important similarities. As more transcriptomic, proteomic, and, in particular, metabolomic studies are conducted on these remarkable plants, it is likely that more of these commonalities will be discovered or confirmed. It is expected, for instance, that more studies will confirm the proposition that the evolution of desiccation tolerance in vegetative tissues is derived from a specific program of gene expression vital for orthodox seed development [34]. Data (J.M. Farrant, unpublished) is emerging that support the hypothesis that resurrection plants evolved through "vegetative tissue localized" activation of an existing seed desiccation program coupled to environmental regulation. Desiccation tolerance is a complex phenomenon and involves multiple factors, probably much more intricately connected than as outlined in the summary put forward in this chapter. More information is urgently needed both on pre- and posttranscriptional and -translational control mechanisms and on all protective proteins and metabolites that are critical for tolerance to emerge. A more holistic analysis of desiccation tolerance in resurrection plants is required, extending from leaves to roots and other organs, providing an integrative analysis. An integrated approach whereby genomic, transcriptomic, proteomic, and metabolomic data are collected from a few key "model" resurrection plants will allow for the prioritization of vital tolerance factors. This would allow for the engineering of multiple "high-impact" genes (regulatory or functional) using inducible expression systems into crop plants for improved tolerance. An alternative approach is to reactivate seed-

specific gene expression systems in vegetative tissues of crops, thereby "unlocking" innate tolerance processes and coupling these to environmental stress cues. It is hoped that such approaches will enable us to eventually obtain a clear picture of the desiccation tolerance phenomenon as it pertains to the vegetative tissues of angiosperm resurrection plants.

Molecular Breeding for Enhancing Abiotic Stress Tolerance Using Halophytes

Ajay Parida, Suja George, and K. Kavita

Halophytes are plants that survive in environments where the salt concentration is around 200 mM NaCl. The tolerance of halophytes to salinity relies on controlled uptake and compartmentalization of Na^+ and the synthesis of compatible solutes. Identification and isolation of novel genes by genomic approaches will advance the understanding of mechanisms of high salt tolerance. Plant stress tolerance can be improved by manipulating stress-associated genes and proteins and/or overexpression of stress-associated metabolites. Here, we discuss the role of possible genes in stress mitigation and tolerance in halophytes and their overexpression to generate stress-tolerant crop plants.

18.1
Introduction

Abiotic stress limits crop productivity and their effect on plants in both natural and agricultural settings is a topic that is receiving increasing attention. Salt and drought are the two major abiotic stresses causing yield losses in crop plants. Seven percent of the land's surface and five percent of cultivated lands are affected by salinity [1], with salt stress being one of the most serious environmental factors limiting the productivity of crop plants [2]. Extensive research in plant salt tolerance has been carried out, with the aim of improving the tolerance of crop plants. Salt tolerance is the ability of plants to grow and complete their life cycle on a substrate that contains high concentrations of soluble salt. Plants have been categorized into halophytes and glycophytes depending upon their behavior in saline environments [1]. Plants that can survive on high concentrations of salt in the rhizosphere and grow well are called halophytes. Depending on their salt-tolerating capacity, halophytes are either obligate or characterized by low morphological and taxonomical diversity with relative growth rates increasing up to 50% sea water or facultative and found in less saline habitats along the border between saline and nonsaline upland and characterized by broader physiological diversity that enables them to cope with saline and nonsaline conditions [3].

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

Classification of halophytes has been based on the characteristics of natural saline habitats [3, 4], the chemical composition of the shoots [5], or the ability to secrete ions [6]. Saline habitats do differ in many regards (e.g., soil water content) and differences do exist among species in the balance of Na^+ and K^+ in shoot tissues [7]. The halophytes have been discussed over the past three decades including review on general physiology of halophytes [1, 8], ecophysiology [4, 6, 9–11], photosynthesis [12], response to oxidative stress [13], flooding tolerance, and salinity tolerance [14].

18.1.1
Halophytes and their Adaptations to Salinity

Halophytes have the capacity to tolerate extreme salinity because of very special anatomical and morphological adaptations or avoidance mechanisms [15]. Sodium secretion through specialized cells is a strategy used by many halophytic plants [16]. Salts may, however, also be released through the cuticle or in guttation fluid. In addition, they may be retransported back to the roots and soil via the phloem or become concentrated in salt hairs [17]. Halophytes become succulent in response to increasing salinity, and such influential changes seem to integral to halophytic development [3]. Dropping off salt-saturated organs also removes large quantities of salt from some halophytes [18].

Halophytes utilize various physiological and biochemical mechanisms that include (1) exclusion of Na^+ at the soil root boundary and therefore from all tissues; (2) exclusion of Na^+ from the xylem and therefore from leaf, thus preventing disruption of photosynthesis; (3) inclusion of Na^+ and synthesis of compatible solutes to maintain osmotic adjustment; (4) inclusion of Na^+ and its subsequent sequestration in vacuoles [19]; and (5) inclusion of Na^+ and its eventual elimination through secretion by leaves [20].

Halophytes store about 90% of Na^+ in the shoot, at least 80% in the leaves, while the root system has a much lower Na^+ concentration compared to the aerial parts of the plant [20]. It has been found that although halophytes accumulate large amounts of Na^+ in the cells, the concentration of NaCl in the cytosol is maintained within nontoxic limits by the compartmentation of NaCl in vacuoles [21]. Induction of the CAM pathway, which increases water use efficiency, is also reported in some halophytes [22]. However, individual halophytes utilize different salt tolerance traits in different situations. Since a wide range of salt tolerance mechanisms are employed by halophytes, the precise combination of one or more mechanisms used to tolerate salinity varies between and across species and makes the study of salinity tolerance more complex.

18.1.2
Halophytes as a Source for Gene Mining

The mechanism of salinity tolerance is a very complex phenomenon. Studies have shown that components of various pathways are involved in imparting the salinity tolerance to the plants. Understanding the molecular basis of the salt stress signaling

and tolerance mechanisms is essential to breeding and genetic engineering of salt-tolerant plants [23]. Genetically engineering the plants by introducing and/or overexpressing selected genes seems to be a viable option to hasten the breeding of "improved" plants, while the introgression of genomic portions (QTL) involved in stress tolerance often brings along undesirable agronomic characteristics from the donor parents. Intuitively, genetic engineering would be a faster way to insert beneficial genes than through conventional or molecular breeding. Also, it would be the only option when genes of interest originate from cross barrier species, distant relatives, or from nonplant sources. Attempts on plant stress tolerance can be made by manipulating stress-associated genes and proteins and/or overexpression of stress-associated metabolites that would confer increased tolerance to salt or drought.

Halophytic plants are a very important genetic resource for the isolation of novel promoters and/or genes that are involved in the adaptation to salinity that could be transferred to salt-sensitive glycophytes. Identification and isolation of novel genes by genomic approaches will advance the understanding of these mechanisms [24]. Hence, different efforts in large-scale EST sequencing and analysis have been made in a number of dicotyledonous halophytes, such as *Suaeda salsa* [25], *Thellungiella halophila* [26], *Mesembryanthemum crystallinum* [27], *Aegiceras corniculatum* [28], *Avicennia marina* [29], *Tamarix hispida* [30], and *Limonium sinense* [31], and monocotyledonous halophytes such as *Leymus chinensis* [32], *Puccinellia tenuiflora* [33], *Lolium temulentum* [34], *Aeluropus littoralis* [35], and *Spartina alterniflora* [36].

This chapter summarizes the involvement of various genes in sensing and response to salt stress in halophytes according to their putative functions such as (1) genes for reestablishing ionic homeostasis or preventing damage, (2) genes with an osmotic or unknown protective function, and (3) genes for signal transduction. This paper focuses on the different genes explored from halophytes for the genetic enhancement of crop plants for abiotic stress tolerance using transgenic approach.

18.2
Genes for Reestablishing Ionic Homeostasis/Preventing Damage

Excessive intracellular or extracellular Na^+ triggers a cytoplasmic Ca^{2+} signal that involves an SOS pathway. This leads to enhanced expression of transporters for ions such as Na^+, K^+, and H^+. Na^+/H^+ antiporter located in the plasma membrane excludes Na^+ from the cells [37]. The compartmentalization of Na^+ into vacuoles provides an efficient mechanism for averting the toxic effects of Na^+ in the cytosol. The transport of Na^+ into vacuoles mediated by vacuolar Na^+/H^+ antiporters is driven by the electrochemical gradient of protons. The proton-motive force generated by the vacuolar ATPase (V-ATPase) and vacuolar pyrophosphatase (V-PPase) can drive secondary transporters, such as the Na^+/H^+ antiporter and the Ca^{2+}/H^+ antiporter, as well as organic acids, sugars, and other compound transporters to maintain cell turgor.

18.2.1
Vacuolar Na^+/H^+ Antiporter

Salt-tolerant plants such as halophytes efficiently sequester Na^+ into vacuoles, to maintain low cytosolic concentrations of Na^+ and thus allow antiporter genes to be isolated from halophytes and transformed into transgenic plants. In transgenic systems, it was found that vacuolar antiporters from glycophytes and halophytes confer salt tolerance to varying limits. Genes encoding vacuole-type Na^+/H^+ antiporters have been isolated from a number of halophytes such as *Atriplex gmelini* (AgNHX1) [38], *M. crystallinum* (McNHX1) [39], *A. dimorphostegia* (AdNHX1) [40], *Chenopodium glaucum* (CgNHX1) [41], *S. salsa* (*SsNHX*1) [42], *Porteresia coarctata* (PcNHX1) [43], and *Salicornia brachiata* (SbNHX1) [44]. A recent study identified six putative vacuolar Na^+/H^+ antiporter genes in *P. euphratica* (PeNHX1–6), a salt-resistant tree species [45].

Overexpression of *SsNHX*1 [46] and *AgNHX1* [47] in rice markedly enhanced the tolerance to salt stress (300 mM NaCl). Increased Na^+/H^+ antiport activity in the transgenic plants caused larger amounts of Na^+ to be excluded into vacuoles in individual cells, thus rendering the transgenic rice plants more tolerant to salinity [46, 47]. But another study reported that overexpression of *NHX1* genes from both glycophytic (*OsNHX1*) and halophytic (*AdNHX1, CgNHX1*) species led to similar degree of salt tolerance in transgenic rice plants [41]. The better salt tolerance in halophytes might result from a different regulation system of *NHX1* genes or mechanisms other than vacuolar Na^+ pump [48].

18.2.2
Plasma Membrane Na^+/H^+ Antiporter

In addition to Na^+ influx control and vacuolar compartmentation, Na^+ efflux is also important in maintaining a low Na^+ concentration in the cytoplasm. Unlike animal cells, which have Na^+/K^+ ATPases, or fungal and perhaps some algal cells, which have Na^+ ATPases for Na^+ efflux, plant cells do not appear to contain Na^+ ATPases. In higher plants, the main mechanism for Na^+ extrusion is powered by the operation of the plasma membrane H^+ ATPase. H^+ ATPase allows the operation of plasma membrane Na^+/H^+ antiporter that couples the downhill movement of H^+ into the cell along its electrochemical gradient to the extrusion of Na^+ against its electrochemical gradient [49]. Na^+/H^+ antiporter activity has been reported to occur across the plasma membrane of *A. nummularia* [50]. In *A. thaliana* salt overly sensitive 1 (SOS1) is a plasma membrane Na^+/H^+ antiporter that retrieves and loads Na^+ ions from and into the xylem [51]. A comparison of *SOS1* transcript in unstressed plants of *A. thaliana* and *T. halophila* revealed that the two species had similar levels of *SOS1* transcript in their shoots, while *T. halophila* possessed threefold more *SOS1* transcript in its roots than *A. thaliana* under control conditions. *A. thaliana* plants that overexpress *SOS1* are more tolerant to salt because of this Na^+ retrieval [52]. In *T. halophila*, the salt-mediated induction of shoot *ThSOS1* expression coupled with high basal root *ThSOS1* expression is likely to be a crucial factor in tightly controlling the extent of shoot Na^+ accumulation [53].

18.2.3
Vacuolar Pyrophosphatase

The vacuolar H^+-PPase is a single subunit protein located in the vacuolar membrane [54]. It pumps H^+ from the cytoplasm into vacuoles with PPi-dependent H^+ transport. Theoretically, overexpression of H^+-PPase should enhance the ability to form the pH gradient between the cytoplasm and the vacuoles, resulting in a stronger proton-motive force for the Na^+/H^+ antiporter, Ca^{2+}/H^+ antiporter, and other secondary transporters. Overexpression of H^+-PPase genes from *T. halophila* (TsVP) enhanced the salt tolerance of tobacco [55] and cotton [56]. The transgenic lines had higher H^+-PPase hydrolytic activity and the plants accumulated more Na^+ under salt stress conditions [55, 56]. A comparison of promoters of vacuolar H^+-PPase genes from *T. halophila* (TsVP1) and *Arabidopsis* (AVP1) indicated that these two promoters had seven similar motifs at similar positions. But analysis of transgenic plants expressing GUS reporter gene under the control of these promoters indicated that TsVP1 promoter was responsible for strong reporter gene activity in almost all tissues except the seeds, and the activity was induced in both shoots and roots, especially in the root tips, when treated with salt stress. Such induction was not found in transgenic *Arabidopsis* with the AVP1 promoter. Deletion analysis revealed the presence of enhancer elements in TsVP1 promoter that increased gene expression levels [57]. These results point out the importance of cloning stress tolerance genes under stress-inducible promoters for improved tolerance.

18.2.4
Potassium Transporters

Salt tolerance requires not only the adaptation to sodium toxicity but also the acquisition of potassium whose uptake is affected by high external sodium concentration. Therefore, potassium transport systems involving good selectivity of potassium over sodium can also be considered an important salt tolerance determinant [58]. In some halophytes, salinity increases the K^+ concentration of the tissue. K^+ transport is mediated by K^+ channels and high-affinity K^+ transporters both in the plasmalemma and in the tonoplast of plant cells [59]. The K^+ channels and transporters may regulate Na^+ transport – either directly because they may be incompletely selective for K^+ and transport Na^+ when presented with a high Na^+ concentration or a high Na^+/K^+ ratio or indirectly because they may buffer the cell against Na^+ uptake by maintaining rigorous K^+ homeostasis.

The families in K^+ transporters include HAK/KUP/KT and HKT transporters. These transporters control K^+ uptake and K^+/Na^+ selectivity. In *M. crystallinum*, HAK-type proteins mediates the transport of K^+, Rb^+, and Cs^+ but not that of Na^+. McHAKs seem to have a role in mediating root K^+ uptake and that could be involved in plant long-distance K^+ transport through loading and/or unloading in the vasculature [60]. The capacity of HKT to mediate Na^+ uptake in some species makes it a candidate that could have a major function for maintaining or breaking ion

homeostasis under saline conditions. Unlike the HAK transporters, transporters in the HKT family display different ion selectivity and transport mechanisms.

McHKT1, isolated from *M. crystallinum*, is a potassium transporter localized in the plasma membrane of cells of both the leaves and the roots. The expression of *McHKT1* is upregulated after a sudden increase in external salinity (400 mm NaCl) [61], as is the expression of SOS1 and some HAK transporters. The decreased storage of Na^+ in the root and enhanced transport to the shoot, with the upregulation of *Mc*HKT1, suggested to contribute to storage of Na^+ in the leaves in ice plant [61]. In *Xenopus* oocytes, *Mc*HKT1 transports Na^+ and K^+ equally [61]. In *S. salsa*, *SsHKT1* transcript was developmentally controlled and significantly upregulated by K^+ deprivation and NaCl treatment suggesting its role in ion homeostasis and salt tolerance [62]. An AKT1-type K(+) channel gene from *Puccinellia tenuiflora*, a salt-tolerant plant, was found to be localized in the plasma membrane and preferentially expressed in the roots. The expression of PutAKT1 was induced by K(+)-starvation stress in the roots and was not downregulated by the presence of excess Na(+). *Arabidopsis* plants overexpressing PutAKT1 showed enhanced salt tolerance compared to wild-type plants. PutAKT1 transgenic plants also showed a decrease in Na(+) accumulation both in the shoot and in the root. It is possible that PutAKT1 is involved in mediating K(+) uptake (i) both in low- and in high-affinity K(+) uptake range and (ii) unlike its homologues in rice, even under salt stress condition [63]. Evidence from the range of studies discussed indicates that there may be considerable variation in the transporters involved in the uptake of Na^+, not only between glycophytes and halophytes but also between species of halophyte and even at different external salt concentrations. In *M. crystallinum* coordinate regulation of multiplicity of channels, transporters, symporters, and antiporters results in irreversible transport of NaCl from root to shoot, accumulation in leaves, and sequestration of Na^+ into the vacuoles of cells in the leaves and shoot [61].

18.2.5
ROS Scavengers

The accumulation of ROS during salt stress is mainly attributed to the inhibition of photosynthesis and a decline in CO_2 fixation. Some of the ROS are highly toxic and need to be detoxified rapidly. In order to control the level of ROS and protect the cells from oxidative injury, plants have developed a complex antioxidant defense system to scavenge the ROS. These antioxidant systems include various enzymes and nonenzymatic metabolites that may also play a significant role in ROS signaling in plants [64]. A number of transgenic improvements in abiotic stress tolerance have been achieved through detoxification strategy. These include transgenic plants overexpressing enzymes involved in oxidative protection, such as glutathione peroxidase, superoxide dismutase, ascorbate peroxidases, and glutathione reductases. In *Bruguiera parviflora*, salt treatment preferentially enhanced both the content of H_2O_2 and the activity of ascorbate peroxidase (APX), guaiacol peroxidase (GPX), glutathione reductase (GR), and superoxide dismutase (SOD), while induc-

ing a decrease in total ascorbate and glutathione (GSH^+GSSG) content and in catalase (CAT) activity [65]. Expression of cytosolic Cu/Zn SOD in *B. gymnorrhiza* was increased after NaCl treatment and also in the presence of mannitol and abscisic acid (ABA) [66]. In *A. marina*, the mRNA transcripts of Cu/Zn SOD (Sod1), catalase (Cat1) [67], and ascorbate peroxidase (AmAPX1) [68] were upregulated under both salinity and oxidative stress. Overexpression of *A. marina* cytosolic copper/zinc SOD conferred enhanced tolerance to both salt and drought treatments in transgenic rice [69].

18.2.6
Genes with an Osmotic/Protective Function

Compatible solutes or osmolytes would be essential for coordinated regulation of vacuolar and cytoplasmic volumes. Compatible solutes are nontoxic solutes that could increase in high concentrations in the cytosol and be compatible with metabolic activity. They would be important to adapt plants to drought, as they could enhance osmotic adjustment and allow turgor maintenance of cells that would otherwise dehydrate. In addition, certain solutes have a metabolic protective role. They could stabilize soluble or membrane proteins and thus maintain growth at high salinity, and the term osmoprotectant has arisen for this function. There are four main classes of solutes that could have an osmotic or protective role: N-containing solutes such as proline and glycine betaine; sugars such as sucrose and raffinose; straight-chain polyhydric alcohols (polyols) such as mannitol and sorbitol; and cyclic polyhydric alcohols (cyclic polyols) [70].

Many crops lack the ability to synthesize the special osmoprotectants that are naturally accumulated by stress-tolerant organisms. It is believed that osmoregulation would be the best strategy for abiotic stress tolerance, especially if osmoregulatory genes could be triggered in response to drought and salinity. Therefore, a widely adopted strategy has been to engineer crops with such osmolytes for abiotic stress tolerance.

18.2.7
Amines

Glycine-betaine (GB) highly accumulates as a compatible solute in certain plants and has been considered to play a role in the protection from salt stress. In plants, glycine-betaine is synthesized from choline in two steps, the first being catalyzed by choline monooxygenase (CMO) that requires phosphoethanolamine *N*-methyltransferase (PEAMT) and *S*-adenosyl-L-methionine (SAM) leading to synthesis of betaine-aldehyde, which is further oxidized by betaine-aldehyde dehydrogenase (BADH). CMO has been cloned and characterized from halophytes such as *Beta vulgaris* subsp. *maritime* (*BvCMO*) [71], *A. hortensis* (*AhCMO*) [72], *A. prostrata* (ApCMO) [73], and *A. nummularia* (*AmCMO*) [74]. CMO expression was highly induced upon salt treatment in *A. hortensis* [75] and *A. prostrata* [73]. Drought stress also induced the expression of *AhCMO*, but with ABA treatment *AhCMO* was induced only slight-

ly [75]. ABA treatment did not induce *ApCMO* in *A. prostrate* showing that *ApCMO* mRNA does not depend upon exogenous ABA [73].

Metabolic engineering of GlyBet in all the plants suffered from one feature: the GlyBet level in transformants is lower than that in the natural accumulator to adjust the osmotic pressure *in vivo* [76]. The transport of choline into the chloroplast constrains GlyBet accumulation in CMO^+ tobacco [77]. If supplied with extraneous substrate, transgenic plants would then synthesize enough GlyBet and greatly promote stress tolerance [78, 79]. Overexpression of *AhCMO* improved drought tolerance in transgenic tobacco and the transgenic plants also performed better under salt stress [75]. Transplastomic tobacco plants overexpressing BvCMO gene exhibited increased tolerance to salt and drought stress. Accumulation of GlyBet in transplastomic plants enhances the net photosynthetic rate and apparent quantum yield of photosynthesis under salt stress condition [80].

BADH gene has been isolated and characterized from halophytes such as *A. hortensis* (*AhBADH*) [81], *A. marina* (*AmBADH*) [82], and *S. liaotungensis* (*SlBADH*) [40]. Overexpression of *AhBADH* gene into rice [83], wheat [84], and white clover [85] and *SlBADH* into tobacco plants [40] improved salt tolerance. Cotargeting multiple steps in the same pathway was found to be a successful strategy for overexpressing glycine-betaines in plants. A study by Yilmaz and Bülow [86] reported that salt tolerance can be enhanced by genetic engineering of tobacco plants with the betaine aldehyde–choline dehydrogenase fusion protein.

18.2.8 Proline

Among compatible osmolytes, proline accumulates in many plants in response to abiotic stress [87]. Proline accumulation was correlated with improved plant performance under salt stress. In plants, the proline biosynthetic pathway from glutamate proceeds through the action of a determining enzyme, Δ1-pyrroline-5-carboxylate synthetase (P5CS). Proline catabolism is catalyzed by proline dehydrogenases (PDHs). Stress-induced increase in proline content is caused by concerted induction of proline biosynthesis genes and by repression of proline catabolism genes [87]. Undetectable level of PDH transcripts after NaCl stress in *T. halophila* resulted in reduced capacity for proline catabolism in *T. halophila*. Higher proline accumulation in *T. halophila* suggests that changes in *T. halophila* PDH expression could cause significant increases in free proline levels. Increased accumulation of proline leads to improved salt stress tolerance and is possibly a reason for improved salt stress tolerance of *T. halophila* in comparison to *A. thaliana* [53]. Increased levels of proline accumulation have also been observed in salt-stressed calli of *S. nudiflora* suggesting that proline protects the callus cells from membrane damage caused by free radicals formed during salt stress [88]. The ability of NaCl to improve the performance of *Sesuvium portulacastrum* under mannitol-induced water stress may be due to its effect on osmotic adjustment through Na^+ and proline accumulation, which is coupled with an improvement in photosynthetic activity [89].

18.2.9
Polyols

Accumulation of polyols, either straight-chain metabolites such as mannitol and sorbitol or cyclic polyols such as *myo*-inositol or its methylated derivatives such as pinitol is correlated with tolerance to drought and/or salinity [90]. Many naturally occurring salt or drought-tolerant plants accumulate such compounds during stress. These metabolites are considered compatible solutes that act by providing osmotic adjustment and by lowering the osmotic potential, thus increasing the water retention capacity of the plant [91]. *Myo*-inositol, the precursor of pinitol, is synthesized through L-*myo*-inositol 1-phosphate synthase (MIPS) coded by the *INO1* gene. The enzymatic product of MIPS is specifically dephosphorylated by a Mg^{++}-dependent L-*myo*-inositol 1-phosphate phosphatase to form free inositol. Inositol is methylated to pinitol by the inositol methyl transferase coded by an *IMT1* gene in an *S*-adenosyl methionine (SAM)-dependent reaction [90]. *IMT1* gene in halophytes has been cloned and characterized from *M. crystallinum* [90] and *P. coarctata* [92]. The transcript and protein content of *PcIMT1* was substantially upregulated in salinity and ABA in *P. coarctata*. The halophytic ice plant accumulates predominantly D pinitol under salinity and low-temperature stresses.

Several halophytic and nonhalophytic species are reported to contain pinitol as the major soluble carbohydrate in their leaves. The halophytic wild rice *P. coarctata* harbors a unique salt-tolerant MIPS coded by *PcINO1* that is able to generate *myo*-inositol even at high salt concentration, and the inositol pool in the plant is well maintained during salinity [93, 94]. Overexpression of *PcINO1* has been reported to confer salt-tolerant phenotype with unabated photosynthetic functions to transformed tobacco plants. In *M. crystallinum*, *McINO1* is induced upon salt stress but in *A. thaliana AtINO1* is not induced by salt stress [95]. A coordinated functioning of both the *INO1* gene and the *IMT1* gene is expected to be operative during salt stress in *M. crystallinum* [95] and *P. coarctata* [92] for synthesis of pinitol.

18.3
Genes for Signal Transduction

Candidate genes controlling growth are probably involved in signaling pathways and respond to hormones, transcription factors, protein kinases, protein phosphatases, and other signaling molecules. Transcription factors are proteins that respond to environmental stimuli through a signaling cascade and bind to specific regulatory sites upstream of constituent genes in a regulatory network by direct physical interaction or in combination with other proteins. Consequently, an alteration of the expression of transcription factor genes results in dramatic differences in the expression of multiple genes in a plant [96]. NAC proteins form a large family of plant-specific DNA binding transcription factors that are gaining importance in recent times with respect to understanding plant development and adaptation. In *A. marina*, *AmNAC1* transcript expression was upregulated by NaCl and ABA treatment [97].

The zinc finger proteins (ZPT2) have been previously used as candidates to show how a subset of transcription factors might be involved in the water stress response at the level of transcriptional regulation [98]. In *T. halophila*, *ThZF1*, encoding a plant-specific transcription factor, is induced at the transcription level by both drought and salt [99]. Overexpression of *AhDREB1* of *A. hortensis* improved the salt tolerance in transgenic tobacco through functioning as a regulatory molecule in response to salt stress [100]. Recently, a novel zinc finger gene designated AlSAP was isolated from the halophyte grass *A. littoralis*. Sequence homology analysis showed that the AlSAP protein is characterized by the presence of two conserved zinc finger domains A20 and AN1. AlSAP was found to be induced not only by various abiotic stresses such as salt, osmotic pressure, heat, and cold but also by abscisic acid and salicylic acid (SA). Tobacco plants expressing the AlSAP gene exhibited an enhanced tolerance to high-salinity stress. Moreover, the transgenic plants were able to complete their life cycle and to produce viable seeds under high salt conditions, while the wild-type plants died at the vegetative stage [101]. Such studies characterizing novel genes add on to the available information on salt tolerance mechanisms in halophytes.

18.4 Conclusions

Halophytes are a diverse group of plants with varying degrees of salt tolerance, yet they appear to share in common the ability to sequester NaCl in cell vacuoles as the major plant osmoticum. Efforts to produce salt-tolerant crops were aimed mainly at increasing the salt exclusion capacity of glycophytes. However, these efforts have not produced breakthroughs in salt tolerance [102]. Progress in producing highly tolerant crops may require a change in strategy, to attempt to introduce halophyte genes directly into glycophytes [103]. This chapter focuses on the combination of the genes that impart salt tolerance in halophytes and hence their use in the genetic engineering of salt-tolerant crops. Thus, engineering for accumulation of salt in vacuolated cells, together with the active extrusion of Na^+ from nonvacuolated cells (i.e., young and meristematic tissue) will allow the maintenance of a high cytosolic K^+/Na^+ ratio. This in combination with the enhanced production of compatible solutes will generate transgenic crop plants that can tolerate and grow in high soil salt concentrations.

Helicases in Improving Abiotic Stress Tolerance in Crop Plants

Narendra Tuteja, Sarvajeet Singh Gill, and Renu Tuteja

Abiotic stress conditions adversely affect plant growth and limit agricultural production worldwide. Minimizing these losses is a major area of concern for all countries. Salinity, drought, and cold are among the major environmental stresses that greatly influence the growth, development, survival, and yield of plants. Several genes including the genes for helicases are known to express under the influence of various abiotic stresses. The helicases are ubiquitous enzymes that catalyze the unwinding of energetically stable duplex DNA (DNA helicases) or duplex RNA secondary structures (RNA helicases). Most helicases are members of DEAD-box protein superfamily that play essential roles in basic cellular processes regulating plant growth and development, such as DNA replication, repair, recombination, transcription, ribosome biogenesis, and translation initiation. It seems, therefore, that DEAD-box helicase might also be playing an important role in stabilizing growth in plants under stress conditions by regulating some stress-induced pathways. There are now few reports on the upregulation of DEAD-box helicases in response to abiotic stresses. The exact mechanism of helicase-mediated tolerance of stress has not yet been understood. There could be two possible sites of action for the helicases: (i) at the level of transcription or translation to enhance or stabilize protein synthesis or (ii) in an association with DNA multisubunit protein complexes to alter gene expression. Here, we have described all the known plant helicases, which play a role in stress responses. The exploitation of abiotic stress-responsive helicase genes of new pathways of RNA and DNA unwinding will be helpful for engineering stress-tolerant crop plants.

19.1
Introduction

Stress is fundamentally a mechanical concept, defined by engineers and physical scientists as a force per unit area applied to an object. It is difficult to define stress so accurately in a biological sense. The most useful definition of biological stress is an "adverse force or influence that tends to inhibit normal system from functioning" [1].

Improving Crop Resistance to Abiotic Stress, First Edition.

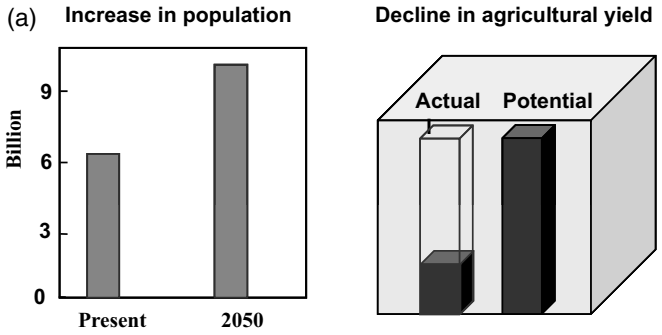
World population is increasing continuously and in 2050 it may reach more than 9 billion (http://www.unfpa.org/swp/200/); on the other hand, the crops' productivity is decreasing because of many negative factors including stresses (Figure 19.1a). Also, the demand for oilseeds, wheat, rice, pulses, and so on is going to much increase in near future (Table 19.1). Because of these factors, in future there may be danger to food security; therefore, it is important to develop stress-tolerant crops. Plants being immobile in nature have to bear a wide range of environmental stresses. They can respond to stress in several ways and have evolved mechanisms by which to increase their tolerance of these stresses through both physical adaptation and interactive molecular and cellular changes that begin after onset of stress [2]. Stresses can be broadly classified into two classes, namely, abiotic and biotic (Figure 19.1b). Low temperature, drought, and high salinity are common abiotic stress conditions.



(b)

Abiotic
1. Heat
2. Cold
3. Drought
4. Salinity
5. Wind
6. Waterlogging
7. Ozone
8. Heavy metals
9. Wounding
10. Nutrient loss
11. Excess light
12. Anoxia/Hypoxia
13. Genotoxic

Biotic (imposed by other organisms)
1. Pathogens (B,F,V)
2. Herbivores
3. Weeds
4. Insects
6. Nematodes
7. Mycoplasma

It is necessary to obtain stress-tolerant crops to cope with the upcoming problem of food security

Figure 19.1 (a) Population of the world is increasing, while the crop production is decreasing due to the negative impact of different stresses. (b) Different types of abiotic and biotic stresses and their negative effect leading to declining agricultural production. To cope up with the impending danger to food security, it is important to develop stress-tolerant crops.

Table 19.1 Target productivity requirement to meet the demand in 2020.

Food items	2009 Production (mt)	Demand 2020	Increase required
Oilseeds	30	8.5	243%
Pulses	35	~15	140%
Wheat	110	80	38%
Rice	130	~100	30%
Total cereals	285	220	30%

Source: FAO, 2009.

Biotic stresses include diseases caused by various pathogens. Overall, the environmental stresses adversely affect plant growth and productivity.

Abiotic stress in plants induces changes in the expression of many important genes, which affect the plant growth and development. Plants are continuously exposed to a plethora of different signals, which prevent them from reaching their full genetic potential. All these stress conditions adversely affect plant growth and limit agricultural production worldwide. To increase their tolerance, plants have developed mechanisms that involve both physical adaptation and interactive molecular and cellular changes. The responses to abiotic stresses are multigenic and the molecular mechanisms underlying these are not very well understood. The extracellular stress signal is first perceived by the membrane receptors and it then activates a large and complex signaling cascade intracellularly, including the generation of secondary signal molecules. The signal cascade results in the expression of multiple stress-responsive genes, the products of which can provide the stress tolerance directly or indirectly. Overall, the stress response could be a coordinated action of many genes, which may crosstalk with each other. Because the abiotic stresses affect the cellular gene expression machinery, it is possible that molecules involved in nucleic acid metabolism including helicase are likely to be the target. DNA helicases are motor proteins that catalyze the unwinding of duplex DNA in an ATP-dependent manner and thereby play an important role in most of the basic genetic processes including replication, repair, recombination, transcription, and translation [3–6] (Figure 19.2a). Usually, they need single-stranded (ss) DNA or ss/dsDNA junction as loading zone and translocate on DNA either in the 3′–5′ or in the 5′–3′ direction [3, 4].

All the helicases are also associated with intrinsic DNA-dependent ATPase activity, which provides energy for the helicase action [7, 8]. RNA helicases catalyze the ATP-dependent unwinding of local RNA secondary structures and play a broader role in remodeling RNA structures [9–12]. Many helicases share a core region (~200–700 amino acids) of highly conserved nine sequence motifs (designated Q, I, Ia, Ib, II, III, IV, V, and VI) and belong to the rapidly growing DEAD-box or DEAH-box protein family, which is conserved from bacteria to humans [6, 9–12] (Figure 19.2b). These conserved motifs are involved in different activities such as ATP-binding and hydrolysis, Mg^{2+} binding, DNA or RNA binding, unwinding, and so on (Figure 19.2b). Multiple DNA helicases are present in single cell in each system because of different structural requirement of the substrate at various stages of DNA

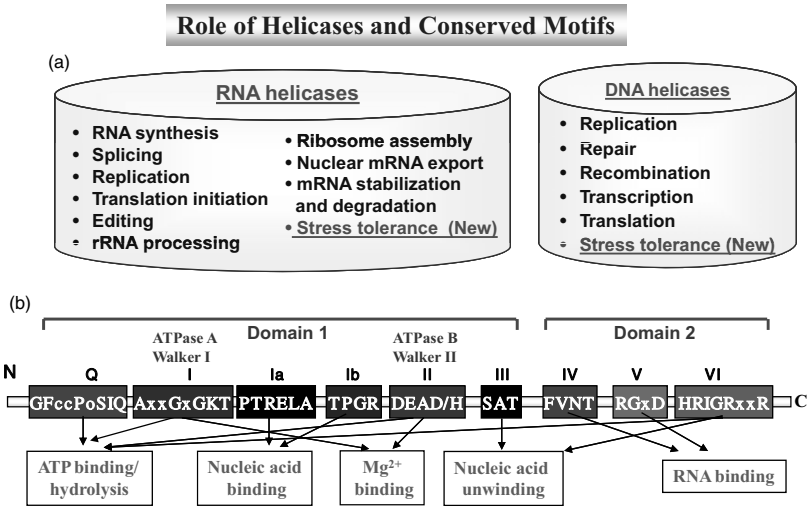


Figure 19.2 (a) Role of RNA and DNA helicases in different processes of nucleic acid metabolism. A new function in stress tolerance is also mentioned. (b) Helicase-conserved motif structure of DEAD and DEAH helicase family of proteins. Helicases are characterized by the presence of an Asp-Glu-Ala-Asp (DEAD) or an Asp-Glu-Ala-His (DEAH) motif (shown as motif II here). Both families of helicases contain amino-terminal (N) and carboxy-terminal domains (domain 1 and domain 2, respectively) and nine characteristic motifs (Q, I, Ia, Ib, and II–VI) within these. The known or proposed functions of each motif are shown.

transaction [3, 4, 13]. For example, at least 14 different DNA helicases have been reported from *Escherichia coli*, 6 from bacteriophages, 12 from viruses, 15 from yeast, 11 from calf thymus, and 34 from humans [5]. However, the exact biological roles of only few DNA helicases have been defined [3, 4, 6]. Still very little is known about DNA helicases from plant system. Till to date only 11 biochemically active DNA helicases have been reported in the purified form from plants [5, 14]. In plants, the exact role of plant DEAD-box helicases has not been defined properly. Recently, there have been some indications of a new role of helicases in stress-regulated processes.

19.2 Stress-Regulated Helicases

Many important crops and fruits that originated from the tropics or subtropics, such as rice, maize, tomato, banana, and orange, are injured or killed by exposure to low, nonfreezing temperature in the range of 0–12 °C [15, 16]. Low temperature is an important environmental factor that greatly influences the growth, development, survival, and distribution of plants [17]. Plant response to chilling are multigenic and the molecular mechanism of chilling sensitivity or resistance is not well understood [18]. Low temperature induces the expression of a diverse array of genes [19]. The product of these genes helps plants to adapt to subsequent freezing stress.

DEAD/H-box helicase genes were reported to induce under chilling and freezing stress [20, 21]. Although multiple DNA helicases have also been isolated from plants [5, 14], the molecular and biochemical characterization of the plant stress-induced DNA helicase(s) has not been achieved. Though the involvement of RNA helicase genes in response to stress has been reported from nonplant systems [22–24], the role of DNA helicases in stress has not been well studied. Analysis of genes whose expression is induced under stress condition is important to understand the mechanism of abiotic stress tolerance and possibly to use it for breeding stress-tolerant plants. However, the functions of DNA/RNA helicases are poorly understood in plants [25, 26]. Among all the sequenced genomes including those of humans, fly, worm, and yeast, *Arabidopsis* has the largest number of DEAD/H-box helicase genes [26–28]. There are 94 helicases reported from *Arabidopsis* (TAIR) that are regulated with stress. The Affymetrix 22 K ATH1 oligonucleotide expression data were obtained from the Genevestigator Response Viewer (https://www.genevestigator.com) [29] available as an external link in TAIR database.

19.3
Expression Profiling of *Arabidopsis* Helicase Genes under Abiotic Stress

The log2 fold expression values for 113 genes in various stresses such as anoxia, cold (3 independent replicates), drought, genotoxic, heat (2 independent replicates), hypoxia, osmotic, oxidative, salt, and wounding were imported into the Genesis software. The hierarchical clustering of 113 different transcriptomes revealed expression patterns for helicase genes under 10 different stress conditions. A dendrogram was constructed after integrating together the similar expression of genes into rows to form a cluster. The heat map resulting from the clustering analysis showed high expression of large set of helicases under anoxia, cold, and heat stresses. The expression analysis revealed overexpression of SDE3, RH55, chromatin remodeling 31, three genes for helicase domain-containing proteins, RH18 and RH11, in drought stress; RecQl3, helicase-related, CHR31 and MCM8 in genotoxic stress; MEE29, RH42, helicase domain-containing protein, SNF2, RH55, and MER3 in hypoxia. In osmotic stress, MEE29, RH55, CHR31, and RH45 showed increased expression, while in oxidative stress SDE3, helicase domain-containing protein, RH28, RNA helicase DRH1, and RH37 were overexpressed. The genes that showed high expression in salt stress were MEE29, SNF2 domain-containing protein, RH55, CHR31, CHR9, EDA16, RH30, RH40, and RNA helicase DRH1. In wounding stress, SNF2, CHR42, MER3, and PIF1 showed increased expression levels [28].

Since RNA molecules are more prone to forming stable nonfunctional secondary structures, their proper functioning requires RNA chaperones [28]. DEAD/H-box RNA helicases are the best candidates for RNA chaperones because these proteins can use energy derived from ATP hydrolysis to actively disrupt misfolded RNA structures so that correct folding can occur [28].

Kujat and Owttrim [30] reported that in photosynthetic organisms light-driven shift in redox potential acted as a sensor that initiates alteration in gene expression at

the level of both transcription and translation. This study provides evidence that the expression of a cyanobacterial RNA helicase gene *crhR* is controlled at the level of transcription and RNA stability by a complex series of mechanisms that are redox regulated. RNA helicase would not be directly involved in photosynthetic reaction *per se* to coordinate regulation of crhR expression implying that modulation of RNA secondary structure is required to elicit electron flow. CrhR-induced RNA unwinding activity could remove secondary structures that inhibit efficient translation of mRNAs whose products are required under these conditions. Whether crhR has specific RNA targets such as redox-induced mRNA, enhancing translation or assembly of ribonucleoprotein complex, or RNA turnover, remains to be explored [30].

19.3.1
Arabidopsis FL25A4 Helicase

Using biotinylated CAP trapper method, full-length cDNA libraries from *Arabidopsis* plants grown under different conditions such as drought treated, cold treated, or unstressed were constructed. By cDNA microarray analysis of 1300 *Arabidopsis* genes, Seki *et al*. [31] reported a DEAD-box helicase gene (accession number AB050574) as a cold stress-inducible gene suggesting a new role of helicases in stress signaling [25], but it has not been characterized further.

19.3.2
Arabidopsis LOS4 Helicase (AtRH38)

During a genetic screening for *Arabidopsis* mutants with deregulated expression of the *RD29A-LUC* reporter gene, a mutant named *los4-1* was isolated, which showed a reduced *RD29A-LUC* expression in response to cold, but not ABA or high salt. Northern blot analysis indicated that the mutation also decreases expression of endogenous RD29A and other COR/RD genes under cold stress. The CBF gene shows reduced or delayed cold induction in *los4-1* mutant plants. Unexpectedly, *los4-1* mutant plants are very sensitive to chilling temperature in dark. The constitutive expression of the CBF-3 gene reverses the chilling sensitivity of *los4-1* mutant plants. LOS4 gene was isolated by map-based cloning and found to encode for a DEAD-box RNA helicase protein (AtRH38) that is localized both in cytoplasm and in nucleus [21]. A novel *Arabidopsis* mutant (cryophyte) was isolated as having an enhanced cold induction of CBF2 and its downstream genes. Compared to wild type, mutant plants flower earlier and are smaller in size. The gene in this mutant was found to be a DEAD-box RNA helicase identical to LOS4 (low expression of osmotically responsive gene). Cryophyte was given the name *los4-2*. It has an RNA-dependent ATPase activity, and *los4-2* mutants are defective in mRNA export (Table 19.2). Consistent with its role in mRNA export, the LOS4 protein appears highly enriched at the nuclear rim. The *los4-2* and *los4-1* mutation affect cold response but in an opposite way. The *los4-1* plants appear to be sensitive to chilling stress, while *los4-2* show chilling resistance compared to the wild type. The *los4-2* mutant disrupts RNA export at warm

Table 19.2 Stress upregulated helicases from plants.

and high temperature but not at low temperature, while *los4-1* impairs mRNA export at warm and low temperature. So, *los4-1* appears to be a heat-sensitive allele that may even enhance mRNA export at low temperature, whereas *los4-1* appears to be a constitutive allele that affects mRNA export in both low and warm temperatures. Analysis of mRNA export-defective mutant cryophyte/*los4-2* has provided an uncommon opportunity to understand the contribution of mRNA export to higher plant development and stress response [32]. Overall, LOS4 helicase confers freezing tolerance by regulating mRNA export from the nucleus to the cytoplasm under cold stress conditions [21, 32, 33]. LOS4 helicase is also involved in many physiological processes such as germination (ABA hypersensitivity of los4-2) and plant development (los4 mutant flowers earlier), in addition to its role in low-temperature responses [32].

19.3.3
Sorghum HVD1 Helicase

In sorghum [34], a salt-responsive transcript HVD1 (*Hordeum vulgare* DEAD-box protein), encoding a putative ATP-dependent DEAD-box RNA helicase, was reported (Table 19.2). The transcript accumulation was induced under salt stress, cold stress, and ABA treatment. In addition to the conserved helicase domain, the encoded protein contained five repeats of RGG known as RNA recognition motif, at its hydrophilic C terminus. The transcript also dramatically increased during recovery from salt stress. The protein was found to localize in chloroplast by immunogold labeling. Thus, it was anticipated that HVD1 protein regulates the function of transcript(s) concerned with salt tolerance or important metabolism such as photosynthesis, in chloroplast. cDNA is essential for functional analysis of plant genes.

19.3.4
Pea DNA Helicase 45

It exhibits striking homology to eukaryotic translation initiation factor 4A (eIF4A) and contains ATP-dependent DNA and RNA helicase activity and DNA-dependent ATPase activity [35]. It is also reported that the pea DNA helicase 45 (*PDH45*) mRNA is upregulated in pea seedling in response to high salt (200 mM of NaCl), and when this gene was transferred to tobacco it provided the salinity stress tolerance [36]. This response was specific to Na^+ ion stress because treatment with Li^+ did not induce the transcript. This study was the first direct evidence of the possible role of a helicase in promoting the salinity stress tolerance in plants. The *PDH45* transcript was also upregulated in response to other abiotic stresses (dehydration, wounding, and low temperature), which suggested that the transcript increase could be due to water stress resulting from salinity- and mannitol-induced desiccation [36]. The induction of *PDH45* transcript was observed to be induced by the phytohormone, ABA, which suggested that the stress effect may take place through ABA-mediated pathways. The exact mechanism of PDH45-mediated tolerance to salinity stress is not understood. This protein may act at translational level or may associate with DNA multisubunit protein complex to alter gene expression [36].

19.3.5
Pea DNA Helicase 47 (PDH47)

The pea DNA helicase 47 (PDH47) also belongs to DEAD-box protein family and shows 93% homology to tobacco eIF4A. The purified recombinant protein (47 kDa) was reported to contain ATP-dependent DNA helicase and DNA-dependent ATPase activities. These activities are upregulated after phosphorylation of PDH47 at Ser and Thr residues with protein kinase C. Using Western blot analysis and *in vivo* immunostaining followed by confocal microscopy, PDH47 is localized in the nucleus and cytosol. The level of transcript of *PDH47* is more in shoot than in root. The transcript was induced in both shoot and root under cold (4 °C) and salinity (300 mM of NaCl) stress, but there was no change in response to drought stress. It is a unique bipolar helicase that contains both the 3′–5′ and 5′–3′ directional helicase activities. The anti-PDH47 antibodies immunodeplete the activities of PDH47 and inhibit *in vitro* translation of protein. Furthermore, the PDH47 protein showed induction of protein synthesis [37].

19.3.6
Arabidopsis STRS1 and STRS2

Two DEAD-box RNA helicases from *Arabidopsis* were reported to be downregulated by multiple abiotic stresses. However, the mutations in their coded genes resulted in increased tolerance to salt, osmotic, and heat stresses (Table 19.2). This suggested that these helicases suppress responses to abiotic stress. The genes were, therefore, named stress response suppressor 1 (STRS1; At1g31970) and STRS2 (At5g08620) [38]. These mutants showed greater tolerance than wild type to multiple abiotic stresses and also showed more highly induced expression of genes encoding stress-responsive transcription factors and their downstream target genes. The ABA is observed to reduce the expression of the STRS genes, but the STRSs were reported to be regulated by both ABA-dependent and -independent stress signaling networks. Overall, this study indicated the importance of RNA metabolism in the control of stress-responsive gene expression.

19.3.7
Dogbane AvDH1 Helicase

The AvDH1 helicase is a salt-responsive gene isolated from the halophyte dogbane (*Apocynum venetum*). It also contained the nine conserved helicase motifs of the DEAD-box protein family. The purified recombinant protein contains ATP-dependent DNA and RNA helicase activities and DNA- or RNA-dependent ATPase activities. The *AvDH1* gene was reported to be present as a single copy in the dogbane genome. This gene was found to be upregulated in response to NaCl and not in drought and abscisic acid. The AvDH1 transcript was also induced by cold stress, but its accumulation was first increased then decreased with time [39].

19.3.8
Alfalfa MH1 Helicase

The cDNA of this helicase was cloned from *Medicago sativa* (alfalfa) and was found to be homologous to PDH45, and was named M. sativa helicase 1 (MH1). The *MH1* gene was found to be expressed in roots, stems, and leaves, and was upregulated in response to mannitol (drought), NaCl, or H_2O_2 treatments (Table 19.2). The expression of *MH1* in *Arabidopsis thaliana* conferred tolerance to drought and salinity to the transgenic plants. The enhanced stress tolerance in MH1-expressing *Arabidopsis* was observed to be correlated with an increase in superoxide dismutase (SOD) and ascorbate peroxidase (APX) activities and proline content. The findings suggested that MH1may function in abiotic stress by elevating the capacities for reactive oxygen species (ROS) scavenging and osmotic adjustment [40].

19.3.9
Arabidopsis AtRH9 and AtRH25

Two *Arabidopsis* helicases, AtRH9 (At3g22310) and AtRH25 (At5g08620), were selected by Kim *et al.* [41] to study the basis of the observation that these two DEAD-box RNA helicases were among the genes highly upregulated in the transcriptome of *Arabidopsis* plants subjected to cold stress [42]. Both these helicases were found to be upregulated in response to cold stress, whereas their transcript levels were downregulated by salt or drought stress (Table 19.2). Phenotypic analysis of the overexpression of AtRH9 or AtRH25 transgenic plants showed the retarded seed germination of *Arabidopsis* plants under salt stress conditions. AtRH25, but not AtRH9, was also reported to enhance freezing tolerance in *Arabidopsis* plants [41].

19.3.10
Soybean GmRH

A novel RNA helicase GmRH has been isolated from soybean and characterized by Chung *et al.* [43]. This helicase was shown to contain a bipartite lysine-rich nuclear localization signal (NLS) to ward the N-terminal variable region of GmRH. The soybean genome was reported to contain two copies of *GmRH* gene. The gene was reported to be upregulated in response to low-temperature or high-salinity stress, but not in response to abscisic acid or drought stress. The GmRH recombinant protein contained dsRNA unwinding activity independent of ATP *in vitro*. The authors proposed that GmRH might play an important role in RNA processing during low-temperature and high-salinity stresses in plants (Table 19.2).

19.3.11
Pea MCM6 Single-Subunit DNA Helicase

The eukaryotic prereplicative complex (Pre-RC), including heterohexameric mini-chromosome maintenance (MCM2–7) proteins, ensures that the DNA in genome is

replicated only once per cell division cycle. The MCM complex provides DNA unwinding function during the DNA replication. However, the unwinding function in the single subunit of MCM and its role in abiotic stress tolerance were not reported so far in any systems. Recently, we have shown the first direct evidence of the identification of a DNA unwinding activity in a single-subunit (MCM6) of the MCM complex of pea [44]. The pea MCM6 single subunit is also reported to form a homohexamer that actually functions as a DNA helicase (Table 19.2). The DNA helicase activity is in 3′–5′ direction and the activity is found to be stimulated by replication fork-like structure of the substrate [44]. Since MCM proteins play an essential role in cell division and most likely are affected during stress conditions, their overexpression in plants may help in stress tolerance. Furthermore, we have tested its role in salinity stress tolerance. Recently, we have reported that (a) the MCM6 transcript is upregulated in pea plant in response to high-salinity and cold stress and not with ABA, drought, and heat stress (Table 19.2); (b) MCM6 overexpression driven by a constitutive cauliflower mosaic virus-35S promoter in tobacco plants confers salinity tolerance. The T_1 transgenic plants were able to grow to maturity and set normal viable seeds under continuous salinity stress, without yield penalty. It was observed that in salt-grown T_1 transgenic plants, the Na^+ ions is mostly accumulated in mature leaves and not in seeds of T_1 transgenic lines compared to the wild-type (WT) plants. T_1 transgenic plants exhibited better growth status under salinity stress conditions in comparison to WT plants. Furthermore, the T_1 transgenic plants maintained significantly higher levels of leaf chlorophyll content, net photosynthetic rate, and therefore higher dry matter accumulation and yield with 200 mM of NaCl compared to WT plants. Tolerance index data showed better salt tolerance potential of T_1 transgenic plants in comparison to WT. These findings provide first direct evidence that overexpression of single-subunit MCM6 confers salinity stress tolerance without yield loss [45]. The possible mechanism of salinity tolerance is discussed. These findings suggest that DNA replication machinery can be exploited for promoting stress tolerance in crop plants.

19.4
Possible Mechanisms of Helicase Action During Stress

The exact mechanism of helicase-mediated tolerance of stress has not yet been understood. There could be two possible sites of action for the helicases: (i) at the level of transcription or translation to enhance or stabilize protein synthesis or (ii) in an association with DNA multisubunit protein complexes to alter gene expression. It is evident that mRNA and protein synthesis are very sensitive to stress, so factors involved in transcription and translation are potential targets of salt toxicity in plants. In bacteria, the toxic effect of Na^+ is mainly in translation rather than in RNA synthesis. The mechanisms of translation initiation are conserved among eukaryotes and the regulation of translation occurs at the step of initiation. The RNA helicase activity of DEAD-box proteins could facilitate transcription by altering the structure of nascent RNA, a process that can stimulate reinitiation and/or elongation.

The initiation step of translation is impaired after cold shock and the reactivation of translation machinery might represent a bottleneck during cold adaptation. RNA helicases not only remove RNA secondary structure but also protect mRNA from degradation in particular under condition where transcription and translation are uncoupled as a result of inefficient translation initiation [46].

There are also temperature-dependent changes in the cellular ribosome profile. Upon cold shock, the number of polysomes existing at optimal temperature decreases in favor of increasing amounts of monosomes, 70 S particles, and free ribosomal 30 S and 50 S subunits. This effect has been suggested to result from a cold-induced block in translation initiation. As a consequence, additional mRNA structuring may occur that would further complicate protein biosynthesis at low temperature [47]. There is a temperature-dependent alteration of mRNA structures affecting ribosomal protein synthesis. The mRNA secondary structures at the 5′ untranslated region (5′UTR) can mask the ribosomal binding site, and at 3′UTR can mask the stop codon, which finally

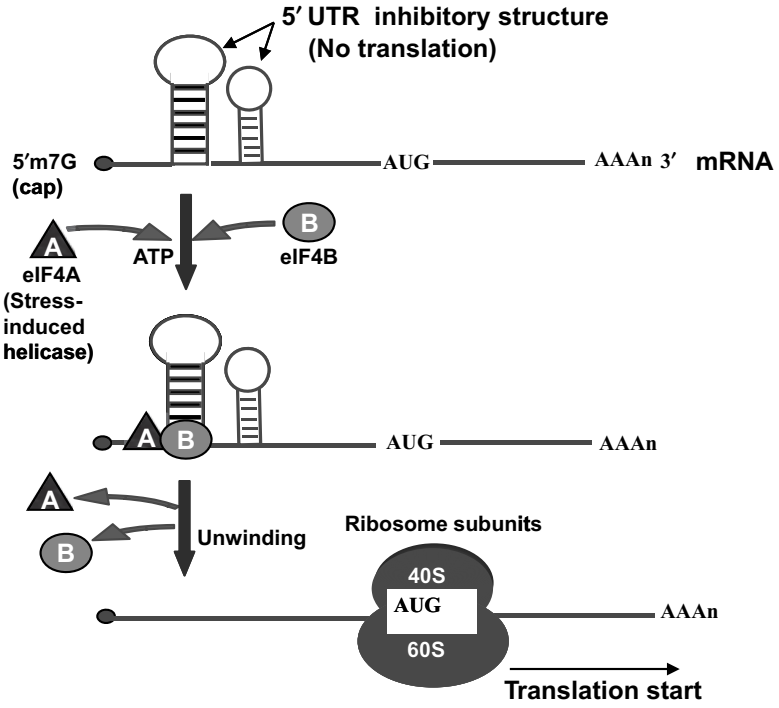

Figure 19.3 Hypothetical model for the possible mechanism of stress tolerance by a helicase. The eIF4A is a prototypic member of the DEAD-box RNA helicase family. Stresses may enhance formation of the inhibitory secondary structure at the 5′UTR of mRNAs of many essential genes. The eIF4A is responsible for removal of the secondary structure of the mRNA. eIF4A, along with eIF4B, binds to 5′UTR and unwinds the inhibitory secondary structure in an ATP-dependent manner. This facilitates the binding of ribosome. After this, ribosome scans for the start codon (AUG) and protein synthesis begins normally, which was inhibited due to negative impact of the stress.

leads to impairment of protein translation initiation. The stress-induced helicases may resolve these inhibitory structures during stress adaptation.

The possible mechanism of helicase action during stress is depicted in Figure 19.3. In response to stress, the extra secondary structures could be formed in the 50-untranslated region in mRNA of many essential genes, which could be inhibitory for translation. These inhibitory secondary structures need to resolve in order to have active translation, as otherwise these RNAs will act as nonfunctional RNAs where protein synthesis cannot proceed. The stress-induced RNA helicase(s) recognized these nonfunctional RNAs and unwound to resolve the secondary structures, which permit the translation initiation to proceed (Figure 19.3). Overall, these stress-induced helicases help in recovering the functions of the genes for stress adaptation, which were stopped previously because of the negative impact of the stress.

The involvement of DEAD-box helicases in various metabolic processes in plant cells might have general implications. In plants, the role of these helicases in stress responses is just beginning to be understood. The overexpression of stress-induced DEAD-box helicase(s) can provide an example of the exploitation of DNA/RNA metabolism pathways for engineering stress-tolerant crop plants. Overall, DEAD-box helicases are conserved and have emerged as new molecules to understand stress signaling in plants. A few studies of stress-induced DNA and RNA helicases suggested that salinity stress affects the stability of nucleic acid base pairing. Therefore, the exploitation of salinity stress-responsive genes of new pathways, including DNA/RNA metabolism, will be useful in elucidating the less-known stress signaling networks and will also be helpful for engineering salinity-tolerant crop plants.

Transcription Factors: Improving Abiotic Stress Tolerance in Plants

Pil Joon Seo, Jae-Hoon Jung, and Chung-Mo Park

Perception of environmental cues and downstream cellular signaling schemes are critical for plant adaptation and survival under abiotic stress conditions. Gene transcription is a primary regulatory scheme that induces massive biological processes and traits in response to incoming signals. In this regard, transcription factors play a critical role in gene regulatory networks governing cellular and organismal responses to developmental signals, including those mediated by growth hormonal regulators, and environmental fluctuations, such as cold or low temperatures, high salinity, and drought. Numerous transcription factors and their target genes have been identified, and underlying molecular mechanisms have been explored in a variety of plant species, mostly in *Arabidopsis* and rice. Furthermore, it has been shown that there are extensive signaling crosstalks among different environmental signals. Therefore, understanding the roles of major transcription factors in stress adaptation responses and their signaling interactions is important for genetic engineering of crop plants to improve stress tolerance. In this chapter, transcriptional signaling cascades under various abiotic stress conditions, roles of transcription factors, and their regulatory schemes are discussed.

20.1
Introduction

Gene expression regulation is a fundamental step in modulating plant growth and developmental processes and environmental adaptation responses. Gene transcription is regulated by transcription factors, which perceive developmental and environmental cues. Therefore, understanding transcription factor activities and underlying molecular mechanisms provides information on molecular and physiological changes occurring in plant responses to various abiotic stress conditions [1, 2].

Gene transcriptional regulation is established by coordinate interactions between *cis*-acting elements of gene promoters and transcription factors. The *cis*-acting elements determine the type, affinity, and arrangement of transcription factors and

associated regulatory proteins [3]. Transcription factors also have differential DNA binding affinities, transcriptional activation/repression activities, and capacities of protein–protein interaction, suggesting that elaborate combinatorial interactions between transcription factors and gene promoters allow precise control of gene transcription [3, 4].

Transcription factors are usually defined as sequence-specific DNA binding proteins, which are capable of activating or suppressing gene transcription [3]. Transcription factors have a modular structure, which consists of DNA binding domain (BD), protein–protein interaction domain, and transcriptional regulation domain [1]. DNA binding domain facilitates binding of transcription factors to specific DNA sequences. According to the structural features of DNA biding domains, transcription factors are grouped into families [5]. Approximately, 64 DNA binding domains have been defined in *Arabidopsis* transcription factors [4, 5]. Protein–protein interaction domains are responsible for interactions with both its own and diverse transcription factors and its isoforms, contributing to regulational diversity and specificity. Gene transcriptional regulation domains function in harmony with regulatory proteins that interact with RNA polymerase [1]. These domains determine the efficiency of assembly of basal transcriptional complex and binding to RNA polymerase II [1]. Their activities are resulted from acidic or hydrophobic residues residing in the domains [3].

Transcription factors are regulated by diverse environmental and developmental signals to activate/suppress target genes involved in stress adaptation and developmental optimization, and thus they are important and efficient signaling mediators between external/internal signals and plant responses [6, 7]. Signaling network is a dense web of numerous regulatory proteins and responsive genes. Therefore, it is not surprising that individual transcription factors belonging to the same family are differently regulated by incoming signals. In addition, those belonging to different transcription factor families often share same targets, indicating that complex networks and crosstalks are established by transcription factors [7, 8].

In this chapter, we will emphasize transcriptional regulation of abiotic stress responses. We will also cover general interactions between transcription factors and *cis*-elements that are involved in abiotic stress responses and roles of various transcription factors in establishing abiotic stress resistance with concrete examples. Furthermore, functional mechanisms underlying transcription factor activities are also discussed.

20.2 Abiotic Stress Responses

Drought and salt stresses, together with cold stress, greatly affect agronomic yield and productivity. Perception of environmental stresses and downstream signaling cascades to activate adaptive stress responses are key steps to acquire stress resistance [7, 9, 10]. Various abiotic stresses impose both general and specific effects

on plant growth and development. Molecular and genetic studies, in particular with model plants *Arabidopsis* and rice, have elucidated diverse mechanisms and signaling networks that are involved in stress signaling and responses.

Many transcriptional regulators have been identified by transcriptome analysis. It has been found that transcription factor genes constitute a significant proportion of stress-inducible genes, suggesting that gene transcriptional regulation of stress responses is a crucial mechanism for stress adaptation [8]. These transcriptional regulators include diverse transcription factor family members, such as basic helix–loop–helix (bHLH), basic leucine zipper (bZIP), APETALA2/ETHYLENE-RESPONSIVE ELEMENT BINDING FACTOR (AP2/ERF), homeodomain, MYB, *N*AM/*A*TAF1,2/*C*UC2 (NAC), WRKY, and zinc finger transcription factors [7].

Transcription factors establish complicated signaling cascades in abiotic stress responses. These signaling cascades are classified on the basis of several criteria. A substantial proportion of the genes induced by osmotic stresses, such as salt, cold, and drought, are also regulated by abscisic acid (ABA) [7]. Accordingly, involvement of ABA is used as an important criterion in dividing stress signaling pathways. ABA dependence of stress response is investigated by ABA-deficient *aba* mutants and ABA-signaling mutants, such as *abi* (ABA-insensitive). A number of genes are completely independent of ABA, indicating that both ABA-dependent and ABA-independent pathways mediate stress adaptation responses [11]. It has been found that while more than half of the drought-inducible genes are also induced by high salt and/or ABA, only 10% of them are regulated by cold stress [11]. Responses to drought, high salt, and ABA are highly linked through extensive crosstalks, but cold stress responses are relatively separated from ABA signaling [11].

Signaling cascades governing stress responses can be understood by examining the interactions of transcription factors with *cis*-acting elements. Transcription factors regulate their target genes through direct binding to target gene promoters. In this regard, promoter analysis provides clues as to the interdependence and/or independence between different abiotic stress signaling pathways [6, 7]. Promoters of abiotic stress-responsive genes usually contain C-repeat/dehydration responsive element (CRT/DRE), ABA-responsive element (ABRE), and recognition sequences of MYC and MYB transcription factors [7]. The ABRE (PyACGTGGC) functions as a *cis*-acting element in many ABA-responsive genes [12]. High salt and drought stresses induce ABA accumulation, which activates osmotic stress responses. Therefore, most of high salt- and drought-inducible genes contain the ABRE in their promoters. ABA-dependent signaling usually activates bZIP transcription factors, including ABRE-binding factors/AREB-binding proteins (ABFs/AREBs), which induce stress-responsive genes by directly binding to the ABRE [12]. Interactions of MYB and MYC transcription factors with its recognition sequences also constitute ABA-dependent signaling [13].

While ABA-dependent stress-responsive genes are regulated through the ABRE, ABA-independent stress-responsive genes are regulated mainly via the DRE *cis*-acting element (TACCGACAT) [7, 14]. The C-repeat binding factor/DRE-binding protein (CBF/DREB) transcription factors belonging to the AP2/ERF family bind

specifically to the DRE *cis*-acting element to activate stress-responsive genes [6]. Compared to high salt and drought stresses, cold stress is relatively independent of ABA signaling pathways [11, 14]. Mutations harboring ABA-mediated *RESPONSIVE TO DESICCATION 29A* (*RD29A*) induction increase salt and drought tolerance but not cold, implying that cold stress responses are partially separated from ABA-mediated osmotic stress responses [7, 14]. ABA accumulation in response to cold stress is still controversial. Although ABA contributes to regulation of cold-responsive gene expression and freezing tolerance, its effects is not great as those of high salt and drought stresses. These observations may be due to the existence of DRE *cis*-acting element-mediated ABA-independent signaling pathway in cold stress responses [6] (Figure 20.1).

Interactions and convergence of signalings are largely mediated through *cis*-acting elements. The promoter of the *RD29A* gene contains four DRE-like sequences and one ABRE. As inferred from the presence of a series of distinct *cis*-acting elements in the gene promoter, the *RD29A* gene is induced by ABA, dehydration, and cold, supporting the view that the *cis*-acting elements existing in the gene promoter are one

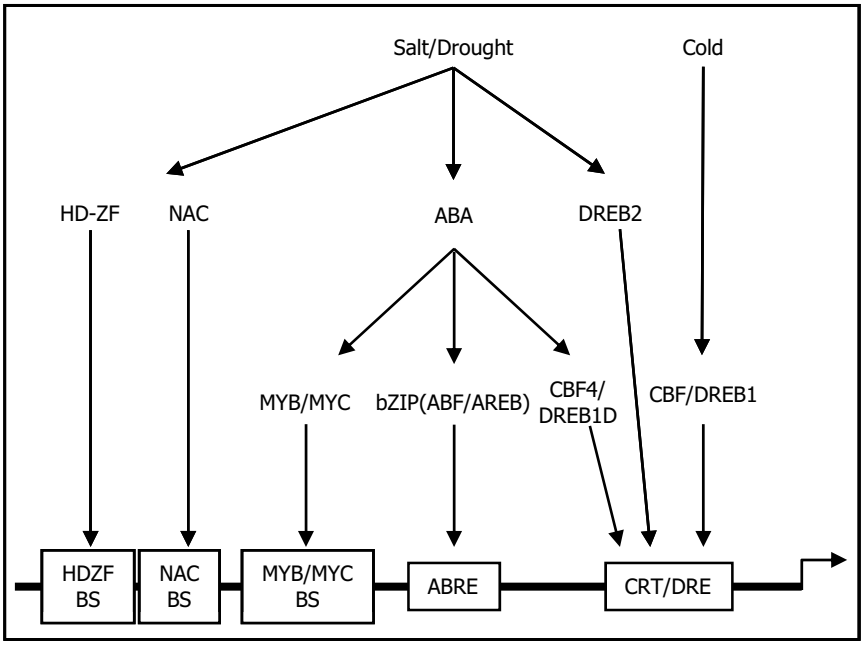

Figure 20.1 The *trans*-acting regulators and *cis*-acting elements involved in abiotic stress signaling. Specific interactions between stress-inducible transcription factors and *cis*-acting elements determine specificity and strength of downstream signaling. Note that multiple *trans*-acting regulators bind to a *cis*-acting element either cooperatively or competitively to fine-tune downstream signaling. This entails that there are extensive signaling crosstalks between different stress signalings.

of the major sites for signal convergence [7, 14]. Consistent with this view, the gene induction patterns in response to dehydration and cold stresses are maintained in the ABA biosynthetic and signaling mutants, indicating that the *RD29A* gene integrates both the ABA-dependent and the ABA-independent signals via the interaction of *cis*-acting elements [7, 14].

Interactions between *cis*-elements are also important for a proper regulation of stress-inducible genes. The DRE *cis*-acting element is sufficient for stress-responsive gene induction. While ABA is required for full induction of the DRE, it cannot directly activate the DRE [11]. It is suspected that interactions between the DRE and ABREs are important for full activation of target genes [11]. As described above, the *RD29A* gene promoter contains four DRE-like sequences and one ABRE. Although single ABRE cannot efficiently perceive ABA signals, the DRE–ABRE interactions seem to be necessary to mediate webs of ABA signalings [11].

Plants are frequently exposed to more than one stress under given growth conditions. Therefore, plants evolved complicated mechanisms to resist various environmental stresses through extensive crosstalks and feedbacks [6]. In other word, improvement of resistance to one stress can induce tolerant response to other stresses. We will further categorize transcription factors according to stress signaling involved. However, signaling crosstalks and interrelationship should be considered.

20.3
Transcription Factors in Stress Adaptation

20.3.1
Drought Stress

Several genes involved in ABA biosynthesis are induced by drought stress [7, 15]. The ABA biosynthetic genes encoding 9-*cis*-epoxycarotenoid dioxygenase (NCED) are transcriptionally regulated by drought stress, supporting the view that ABA is intimately linked to drought stress responses [16]. As a result, a significant proportion of drought inducible genes is also induced by ABA.

The bZIP transcription factors ABFs/AREBs are the best characterized transcription factors that function in drought stress response via ABA-dependent signaling [7, 12]. The ABF1, ABF2/AREB1, ABF3, ABF4/AREB2, and ABEB3 transcription factors require ABA to activate their own activity through ABA-dependent phosphorylation. Therefore, they exhibit reduced activity in the *aba* and *abi* mutants, but increased activity in the ABA-hypersensitive *era1* mutant [17]. Although loss-of-function mutants do not have any obvious phenotypes, constitutive expression of either *ABF3* or *ABF4*/*AREB2* leads to ABA hypersensitivity, reduced transpiration, stomatal closure, enhanced drought resistance, and altered expression of ABRE-containing genes, such as *RD29B*, *ABI1*, and *ABI2* [12].

There are additional pathways to regulate drought stress responses in an ABA-dependent manner. Although the *RD22* gene is induced by ABA and drought stress,

the ABRE does not exist in the *RD22* gene promoter. Instead, MYC and MYB transcription factors cooperatively regulate drought stress responses [13]. The AtMYC2 (RD22BP1) and AtMYB2 transcription factors bind directly to the *cis*-acting element present in the *RD22* gene promoter [13].

Additional MYB transcription factors also serve as drought stress regulators in *Arabidopsis*. The MYB96 transcription factor coordinately regulates stomatal aperture, shoot growth, lateral root development, and expression of the *RD22* gene and a subset of *GH3* genes to optimize plant growth under drought conditions [18]. Accordingly, while transgenic plants overexpressing the *MYB96* gene exhibit enhanced drought tolerance, the *myb96-1* knockout mutant is susceptible to drought stress [18]. The MYB44 transcription factor also regulates stomatal aperture in response to ABA, drought, and high salinity. Transgenic plants overexpressing the *MYB44* gene exhibit enhanced tolerance to drought and high salt stresses, stomatal closure, and reduced water loss [19]. Microarray analysis have shown that a group of protein phosphatase 2C (PP2Cs) genes is negatively regulated by MYB44, resulting in constitutive activation of ABA signaling [19].

Two R2R3-type MYB transcription factors, MYB60 and MYB61, have been identified as stomatal movement regulator. The *MYB60* gene is expressed specifically in guard cells and repressed in response to drought stress. Consistent with this, loss-of-function mutants of the *MYB60* gene show reduced stomatal aperture and enhanced drought resistance [20]. The *MYB61* gene is also expressed specifically in guard cells and controls stomatal aperture according to light/dark responses, suggesting a specific role of the MYB transcription factors in regulation of stomatal function [21].

A WRKY transcription factor is also involved in ABA-mediated drought tolerance response. Loss-of-function mutants of *AtWRKY63* are less sensitive to ABA in stomatal closure. In addition, drought resistance in the mutants is reduced [22]. AtWRKY63 regulates the *ABF2*/*AREB1* gene transcription by binding to the W-box existing in the gene promoter and affects expression of the *RD29A* and *COR47* genes [22].

Nuclear Factor (NF) is a transcription factor with high DNA binding affinity to the CCAAT box [23]. A subunit of NF-Y (NF-YA) confers the specific binding capacity to DNA by forming a trimeric complex (NF-YA, NF-YB, and NF-YC) [24]. Among the 10 members of NF-YAs, the *NFYA5* gene is induced by drought stress via an ABA-dependent signaling [23]. In addition, miR169 regulates the *NFYA5* transcript. The miR169 expression is downregulated by drought stress via ABA-dependent pathways, upregulating the *NFYA5* gene. Accordingly, whereas transgenic plants overexpressing *NFYA5* exhibit enhanced drought tolerance, the *nfya5* mutant and miR169-overproducing transgenic plants show higher susceptibility to drought stress with elevated water loss [23]. Related transcription factors NFYB1 and LEC1, members of the NFYB family, also confer drought tolerance, implying that physiological pathways mediated by NFs also play an important role in regulating drought tolerance [25, 26].

NAC domain-containing transcription factors constitute both ABA-dependent and ABA-independent pathways. The *RD26* gene is induced by ABA and drought stress,

implying that RD26 may function in an ABA-dependent manner. A microarray analysis has shown that the RD26 transcription factor largely affects expression of stress- and ABA-responsive genes. As a result, while the 35S:*RD26* transgenic plants are highly sensitive to ABA, loss-of-function mutants are insensitive to ABA [27].

In contrast, three NAC transcription factors, ANAC019, ANAC055, and ANAC072, have been identified as regulators of drought stress responses independent of ABA. The transcription factor genes are highly induced by drought stress and high salinity. They bind directly to the NAC recognition sequence motif (CATGTG) existing both in the 63-bp region of the *EARLY RESPONSIVE TO DEHYDRATION STRESS 1* (*ERD1*) gene promoter [28] and in the diverse stress-responsive gene promoters. Overexpression of *ANAC019*, *ANAC055*, or *ANAC072* leads to upregulation of stress-responsive genes and enhanced drought tolerance [28]. The ZINC FINGER HOMEODOMAIN 1 (ZFHD1) transcription factor also binds directly to the *rps1* site 1-like sequence (CACTAAATTGTCAC) in the *ERD1* gene promoter. The *ZFHD1* gene is induced by ABA, drought, and high salinity. Overexpressing the *ZFHD1* gene induces expression of several stress-responsive genes and enhanced resistance to drought stress [29]. Notably, the ANAC and ZFHD1 transcription factors interact with each other to activate the *ERD1* gene, constituting an ABA-independent signaling pathway.

Consistent with this, several genes are still induced by drought stress in the *aba* biosynthetic mutants, suggesting that ABA-independent pathways also play a role in drought stress responses [14]. The *CBF1*-overexpressing transgenic plants are also resistant to drought and salt stresses, suggesting that genes containing the DRE in their promoters may also be regulated by drought and salt stresses [7]. The *COR* genes induced by CBFs may also play a protective function under drought stress conditions. While the *DREB1* genes are induced specifically by cold stress, the *DREB2* genes are regulated by drought and high salt stresses but not by cold stress [14]. The *DREB2* genes may confer drought tolerance by inducing the genes containing the DRE motifs in their promoters [14].

20.3.2
Salt Stress

High salinity causes hyperosmotic and hyperionic stresses to plants. In terms of water potential, basic physiology of high salinity and drought stress is highly overlapped with each other. Therefore, research on salt stress responses has been oriented to those ion-specific stress responses that repair cellular imbalance of K^+ and Na^+ ions. Briefly, various ion pumps, transporters, and channels are involved in maintaining sodium ion homeostasis. A representative example is the salt overly sensitive (SOS) pathway. It participates in the regulation of ion homeostasis. The *SOS3* gene encodes a CALCINEURIN B-LIKE (CBL) protein, which senses cytosolic Ca^{2+} by directly binding to ions. The SOS2 protein is serine/threonine protein kinase, which is activated by SOS3 in a calcium-dependent manner. The SOS1 protein is a Na^+/H^+ antiporter and is phosphorylated by the SOS3–SOS2 complex, which eventually causes reduction of cytosolic Na^+ concentration [9, 30].

Transcriptional regulation of salt stress responses is quite similar to that of drought stress responses [7, 8]. Accumulation of ABA is induced under high salinity and subsequently activates ABA-responsive genes. Interaction of bZIP transcription factors with the ABRE *cis*-acting elements is a major regulatory scheme in the salt stress responses. Several MYB and MYC transcription factors, which play roles in drought stress responses, are also involved in salt stress responses [31].

Some transcription factors have been identified as key players in salt stress-specific responses. It has been reported that A NAC domain-containing transcription factor regulates salt stress response and lateral root development through signaling interaction with growth hormones. A gene encoding the NAC2 transcription factor is highly induced by high salinity. It has been proven that it is also influenced by ethylene and auxin signalings [32]. Notably, ETHYLENE INSENSITIVE 2 (EIN2) converges ethylene and auxin signals and positively regulates the *NAC2* gene [32]. As a result, *NAC2* expression is completely blocked in the *ein2* mutant. The NAC2-mediated promotion of lateral root formation reflects an adaptive stress response under salt salinity [32].

A few WRKY transcription factors have been reported as specific mediators of salt stress responses. Expression of the *WRKY25* and *WRKY33* transcription factor genes is induced by high salt. Analysis of the induction patterns indicates that *WRKY33* expression partially depends on ABA but is independent of SOS. Transgenic plants overexpressing either the *WRKY25* or the *WRKY33* gene are tolerant to high salt stress. In contrast, the *wrky25wrky33* double mutant is sensitive to high salinity [33].

The AP2/ERF transcription factors are also involved in salt stress responses. Transcription of the *CBF4/DREB1D* gene is induced by osmotic stress [14]. Because the CBF/DREB transcription factors bind to the CRT/DRE sequence, it seems that most of the CBF/DREB-mediated signals are converged at the gene promoters containing the CRT/DRE sequence [34]. The *DWARF AND DELAYED FLOWERING 1* (*DDF1*) gene encoding an AP2 transcription factor, belonging to the CBF/DREB1 subfamily, regulates primarily the *GA 2-OXIDASE 7* gene (*GA2ox7*) [35]. The GA2ox7 protein is a C_{20}-GA deactivating enzyme. The *DDF1* gene is induced strongly by high salt stress, which subsequently upregulates the *GA2ox7* gene by directly binding to the DRE-like motifs (GCCGAC/ATCGAC) possibly via an ABA-independent manner [35]. This signaling supports the growth repression under high salinity. In addition to *GA2ox7*, other salt stress-responsive genes, such as *RD29A*, *COR15A*, and *KIN*, are also upregulated in 35S:*DDF1* transgenic plants, conferring resistance to salt stress [35].

20.3.3
Cold Stress

Temperate plants develop freezing tolerance through sustained experience of low but nonfreezing temperatures [9]. Cold acclimation responses include rapid induction of many transcriptional activator genes, such as those encoding the CBFs/DREBs transcription factors, reduction of growth, and modulation of metabolic activity [36, 37]. Changes in transcriptome have been intensively investigated and analyzed. The *CBF1/DREB1B*, *CBF2/DREB1C*, and *CBF3/DREB1A* genes, which play a

central role in cold acclimation process, have been identified through this approach [38, 39]. These genes are rapidly induced upon exposure to cold within 15 min, and constitutive expression of these genes enhances freezing resistance [38, 40]. The DREB/CBF transcription factors directly regulate the *COR* genes via the DRE *cis*-acting elements in respond to cold stress independent of ABA. *Arabidopsis COR* genes (*COR6.6*, *COR15a*, *COR47*, and *COR78/RD29a*) encoding LEA-like proteins are critical for development of freezing tolerance and cold acclimation.

INDUCER OF CBF EXPRESSION 1 (ICE1) is a MYC-like bHLH transcription factor and binds directly to the MYC recognition sequence present in the *CBF3* gene promoter [41]. An R2R3-type MYB transcription factor MYB15 is also involved in the regulation of the *CBF3* gene through interaction with ICE1 [42]. It is highly possible that other bHLH and MYB transcription factors regulate the *CBF1* and *CBF2* expression. Transcriptional regulation of *CBF*s by ICE1 is not ordinary. Considering the rapid induction of *CBF*s upon exposure to cold, ICE1 should be present in the nucleus under normal growth condition and its conformation or interaction with other binding partners would be modified in response to cold, which in turn regulates expression of the *CBF3* and *COR* genes in inducing freezing tolerance [36]. To date, the ICE1–CBF–COR regulon is a major cold stress signaling pathway, which regulates a wide array of cold-responsive genes and thus induces freezing tolerance (Figure 20.2). Sensors, which are responsible for activation of the major pathway remain to be elucidated.

The *CBF* genes are also regulated by negative regulators. The ZAT12 transcription factor is a zinc finger protein that contains EAR-motif sequence that may function as a transcriptional repression domain [43, 44]. The ZAT12 transcription factor is

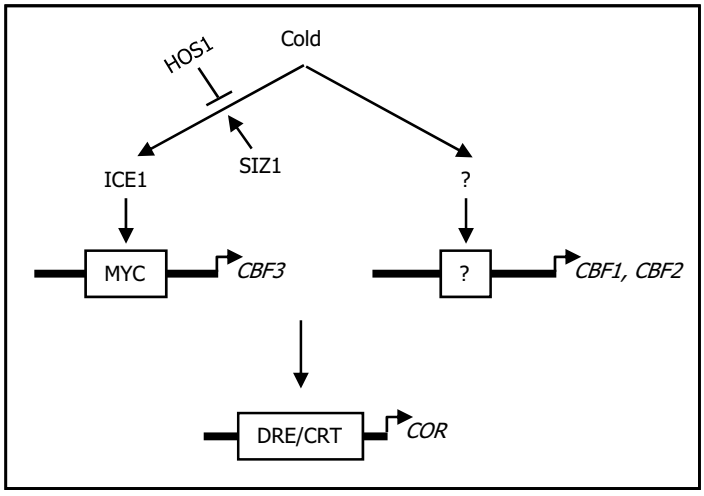

Figure 20.2 Transcriptional regulatory networks in cold stress signaling. HOS1 E3 ligase-mediated process regulates a key transcription factor ICE1 at the protein level. Protein sumoylation is also linked to the ubiquitination pathway.

involved in regulation of the *CBF* expression in response to cold stress. In addition, constitutive expression of *CBF2* suppresses the expression of *CBF1* and *CBF3*, establishing a negative feedback loop [45].

Because of its importance, CBF orthologues have been identified and functionally characterized in other plant species. *Arabidopsis* transgenic plants overexpressing the rice *OsDREB1A* gene exhibit phenotypes similar to those overexpressing the *Arabidopsis DREB1A* gene, indicating that this transcription factor is conserved in both monocot and dicot [46]. *Lycopersicum esculentum* contains three *CBF* genes in a tandem array [47]. Constitutive expression of *LeCBF1* in *Arabidopsis* also confers freezing tolerance and regulates cold-responsive genes [47]. *Brassica napus* also has four orthologues of the *Arabidopsis CBF* genes. Wheat and rye are suspected to have the AP2 transcription factor, which is homologous to *Arabidopsis* CBF, suggesting that the CBF regulon is conserved in diverse plant species [48, 49].

Several cold-responsive genes do not contain the DRE in their promoters, suggesting that *cis*-acting elements other than the DRE are also involved in cold-responsive gene expression [50]. Moreover, constitutive expression of *CBF* genes does not lead to full cold acclimation in *Arabidopsis*, supporting the view that additional signaling pathways participate in cold acclimation and responses. The *HIGH EXPRESSION OF OSMOTICALLY RESPONSIVE GENE 9* (*HOS9*) gene encodes a homeodomain-containing transcription factor localized in the nucleus. The *hos9-1* mutant shows reduced freezing tolerance without alterations in *CBF* gene regulation. The *HOS9* gene is unaltered by cold, suggesting that it may have a role in basal freezing tolerance response [51]. Although molecular function is unknown, the ESKIMO1 (ESK1) protein also regulates freezing tolerance by inducing proline accumulation. Loss-of-function mutant of *ESK1* exhibits enhanced and constitutive freezing tolerance. Genes affected by the *esk1* mutation are largely independent of CBF pathway, supporting the view that CBF-independent pathways are also involved in cold adaptation and freezing tolerance. Transcription factors in ABA-dependent pathways have also been investigated. It seems that bZIP, MYC, and MYB transcription factor family members may participate in the regulation of cold-responsive gene expression [13, 52–54].

Overall, cold-regulated genes include those encoding COLD-REGULATED (COR), LOW-TEMPERATURE-INDUCED (LTI), COLD-INDUCIBLE (KIN), and EARLY DEHYDRATION RESPONSIBLE (ERD). These genes are regulated through interactions of the transcription factors with *cis*-acting elements in the gene promoters. Interactions between DREB/CBF transcription factors and DRE/CRT elements establish an ABA-independent pathway. In contrast, bZIP interactions with ABRE, MYB interactions with its recognition sequence (TGGTTAG), and MYC interactions with its recognition sequence (CACATG) constitute ABA-dependent pathways.

20.3.4 Heat Stress

Ambient temperatures above optimal ranges are sensed as heat stress in eukaryotes. Heat stress disturbs cellular homeostasis and causes severe growth retardation, arrested development, and death in many cases. Most of the higher plants are unable

to survive from extended exposure to temperatures above 45 °C [55]. As plants are sessile, they have evolved a complex set of defensive mechanisms against stressful high temperatures, which minimizes damage and protects cellular homeostasis.

Prior treatment with high temperatures often induces thermotolerance to lethal temperatures. This heat acclimation involves accumulation of a group of heat shock proteins (HSPs), which act as molecular chaperones by facilitating refolding of denatured proteins and removing misfolded proteins [56, 57]. Induction of HSP accumulation is regulated primarily at the transcriptional level by heat shock transcription factors (HSFs), which bind specifically to the heat shock element (HSE) "GAANNTTC" existing in the promoters of *HSP* genes [58].

HSFs are central components in heat stress signaling that sense temperature changes to regulate genes involved in heat shock response. Similar to many other transcription factors, HSFs have a modular structure. The highly conserved N-terminal DNA binding domain is characterized by an HLH motif and an adjacent oligomerization domain (OD) having a hydrophobic heptad repeat pattern [59, 60]. These structural components are also important for heat stress-dependent activation that converts inactive HSF monomers to trimeric forms, which bind specifically to the HSE element in the promoters of HSF-responsive genes [61].

Plants contain a small family of *HSF* genes. More than 20 HSF members have been defined in *Arabidopsis* and tomato [59, 60]. This is in contrast to what has been observed in other eukaryotes. For example, vertebrates have only three HSF members, and yeast and *Drosophila* have a single HSF in each case [62]. On the basis of the structural details of the oligomerization domains, plant HSFs are grouped into three conserved evolutionary classes: A, B, and C. In tomato, HSFA1a and HSFB1 belong to class A, which form a regulatory network acting as master regulators of heat stress-responsive genes [60, 62]. The *HSFA1a* gene is constitutively expressed and mediates heat stress-induced expression of *HSFA2* and *HSFB1* [63]. HSFA1a also functions as a nuclear retention factor and as a coactivator of *HSFA2* by forming HSFA1a–HSFA2 heterooligomeric complexes.

It is notable that HSFs belonging to class B or class C have no evident activities as transcription activators of their own. HSFB1 has been identified as a coactivator cooperating with class A HSF members and other transcription factors [64–66].

Genome-wide transcriptome analysis of *HSFA1a*, *HSFA1b*, and *HSFA2* knockout mutants in *Arabidopsis* suggests that HSFA1a and HSFA1b play important roles in the initial phase of heat stress response, but HSFA2 functions under prolonged heat stress conditions and in the later recovery phase [67–69]. The heat stress-induced expression of *HSFA2* in *Arabidopsis* is uninfluenced by HSFA1a or HSFA1b [67]. The *HSFA2* gene is also induced by high light intensity and H_2O_2 [69]. It is also closely related to the regulation of *ASCORBATE PEROXIDASE 2* (*APX2*) encoding a key enzyme in oxidative stress response, indicating that HSFA2 plays diverse roles under various environmental stresses. The heat stress induction of *Arabidopsis HSFA3* is regulated directly by DREB2A, a transcription factor functioning in drought stress responses [70]. Accordingly, the DRE has been identified in the promoters of a cluster of heat-inducible genes [71]. It has been

proven that the heat-induced DREB2A transcription factor binds to the DRE present in the *HSFA3* gene promoter [72, 73].

Additional heat-inducible transcription factors are also involved in thermotolerance. Under heat stress conditions, the *NF-X1* (*NUCLEAR TRANSCRIPTION FACTOR X-BOX BINDING 1*) gene shows an induction pattern similar to that of genes having DREs in their promoters. The NF-X1 transcription factor promotes tolerance to heat and salt stresses [71]. The transcriptional coactivator MBF1c (MULTIPROTEIN BRIDGING FACTOR 1C), which is involved in multiple stress responses, accumulates rapidly after exposure to heat stress. In contrast, MBF1c is not required for the expression of the *HSFA2* gene and other *HSP* genes [74]. The *Arabidopsis bZIP28* gene encoding a putative membrane-tethered transcription factor is induced in response to heat stress, and a *bZIP28* null mutant exhibits a heat-sensitive phenotype [75]. Upon exposure to heat, the bZIP28 protein, which is localized to the endoplasmic reticulum membranes, undergoes proteolysis to release a nuclear form. Although direct target genes have not been determined, heat-inducible expression of a gene *Bip2* encoding an endoplasmic reticulum chaperone and a small HSP gene *HSP26.5-P* is altered in the mutant.

20.4
Regulation of Transcription Factor Activities

Transcription factor should act in appropriate tissues or cells at appropriate times by directly binding to target DNA sequences. They also interact with other regulatory factors, such as transcriptional regulators. Temporal and spatial regulation of transcription factor activities is also important for understanding molecular mechanisms underlying abiotic stress signaling and responses. Transcription factors are regulated at multiple steps, such as gene transcription, posttranscriptional RNA processing, posttranslational modification, protein–protein interactions, and controlled protein turnover.

20.4.1
Transcriptional Control

Gene transcription is a primary step to regulate transcription factor activities. It usually determines tissue-specific expression, stage-dependent expression, and signal-inducible expression. Gene regulation under diverse environmental conditions is mediated by intensive transcriptional regulatory cascades [76]. Early-response genes are induced rapidly within minutes after exposure to stress conditions. Notably, a large portion of the early-response genes encodes transcription factors, suggesting that transcriptional regulation is a central regulatory scheme in earlier steps of stress adaptive responses [8, 10]. Transcriptional regulation also facilitates additional steps of gene regulations, such as posttranscriptional, translational, and even posttranslational control of transcription factor genes.

20.4.2 Posttranscriptional Modification

Posttranscriptional regulation is exerted at the RNA level. Recent studies suggest that it plays an essential role in acquisition of abiotic tolerance. Posttranscriptional regulation is exerted at variable steps, such as alternative splicing, controlled mRNA processing, mRNA silencing, nucleocytoplasmic transport, and accessibility to translational apparatus. In this section, we more focus on alternative splicing and mRNA silencing.

RNA splicing is the excision of intron sequences from pre-mRNA mediated by spliceosome. Alternative splicing (AS) generates multiple mRNAs from a single primary transcript through alternative selection of splice sites in the pre-mRNA [77, 78]. It has been reported that 95% of human genes having multiple exons undergo AS [79]. In plants, over 35% of *Arabidopsis* and rice genes are considered to be alternatively spliced [80–82], indicating that AS is widespread in eukaryotes. AS occurs through exon skipping, alternative selection of 5′ and 3′ splice sites, and intron retention. Such molecular events produce a small group of protein isoforms, which possess differential activities. Alternatively, some of them are degraded through nonsense-mediated decay (NMD) [83, 84]. Exon skipping is the most frequently observed AS mechanisms. In contrast, intron retention is rarely observed in animals. It is notable that intron retention is the most frequently occurring AS event in *Arabidopsis* and rice [85, 86].

It seems that AS affects preferentially a certain class of genes that is mostly involved in signal transduction or encodes specific enzymes, receptors, and transcription factors [85, 87]. The wheat *WDREB2* gene, an *Arabidopsis DREB2* homologue, produces three differential transcripts through exon skipping under stress conditions. The three isoforms have different accumulation patterns, and relative ratio of the transcript isoforms is regulated via an ABA-dependent pathway under drought and salt stresses and an ABA-independent pathway at low temperatures [88]. A subgroup of MYB transcription factor genes in *Arabidopsis* and rice produces alternatively spliced transcripts, accumulation of which is influenced by various phytohormones and stress signals. AS of the *MYB* genes results in three (rice) or four (*Arabidopsis*) distinctively spliced transcripts for each gene, producing putative proteins differing by numbers of MYB repeats and probably by their binding affinities to gene promoters [89]. Durum wheat genes encoding a putative ribokinase and a C3H2C3 RING finger protein undergoes AS, in which a subset of introns are retained under stress conditions [90].

AS of genes encoding nuclear splicing factors is also influenced by abiotic stresses. Nineteen genes encoding serine-/arginine-rich proteins, which are classified as RNA binding proteins with a role as a splicing regulator in eukaryotes, have been identified in *Arabidopsis*, and most of them undergo AS in response to environmental stimuli [91, 92]. *STABILIZED1* (*STA1*), a gene encoding a pre-mRNA splicing factor, is induced under cold stress conditions in *Arabidopsis*. The *sta1-1* mutant has defect in the splicing of *COR15A* mRNA, resulting in hypersensitivity to chilling and salt stresses and ABA [93]. Regulation of AS of a specific gene and subsequent regulation

of AS of other genes may contribute to enhancement and amplification of abiotic stress signal transduction cascades.

Small noncoding RNAs consisting of 20–25 nucleotides (nts), such as microRNAs (miRNAs) and small interfering RNAs (siRNAs), emerge as essential players in posttranscriptional control of gene expression. They are processed from double-stranded RNA (dsRNA) precursors by specific RNases belonging to the DICER-LIKE (DCL) family. One strand of the processed duplex form is then combined with the AGONAUTE (AGO) protein that form RNA-induced silencing complex (RISC). The RISC ribonucleoprotein complex recognizes target mRNAs that contain a complementary sequence to the small RNA and subsequently silences them by either guiding RNA degradation or repressing translation of target mRNAs [94–96].

A large group of small RNAs has been identified primarily by computational identification of small RNAs and their corresponding mRNA targets [97, 98]. Recently, microarray-based large-scale analysis and computational transcriptome analysis have shown that numerous miRNAs are differentially accumulated in response to cold, dehydration, high salinity, and nutrient starvation [99, 100]. Notably, the genetic loci encoding these miRNAs contain stress-related *cis*-acting elements in their promoter regions, suggesting that RNA silencing by small RNAs is an important gene regulatory scheme in plant stress responses.

Although most small RNAs target transcription factor genes, those functioning in plant responses to abiotic stress and nutrient deficiency frequently regulate genes encoding enzymes and transporters involved in plant metabolism [101, 102]. In *Arabidopsis*, miR393 negatively regulates several genes encoding F-box protein, such as *TIR1* and *AFB*s, to acquire resistance to pathogen infection [103]. miR393 abundance is increased by diverse abiotic stress conditions, and accordingly transcript levels of its targets are reduced under identical conditions [98]. While abiotic stress-mediated miRNA regulation is widely documented, miRNA regulation of transcription factor genes is still elusive.

An additional class of small RNAs, referred to as natural antisense transcripts (NAT)-generated siRNAs (nat-siRNAs), has recently been proven to function in plant stress responses [104]. The nat-siRNAs are produced from dsRNA formed by intermolecular association of NATs and complementary transcripts. For example, accumulation of proline under salt stress conditions is regulated by a nat-siRNA-mediated pathway. The *P5CDH* (*D-PYRROLINE-5-CARBOXYLATE DSHYDROGENASE*) gene encoding proline catabolic enzyme is constitutively expressed under normal conditions [104]. The *SRO5* (*SIMILAR TO RADICAL-INDUCED CELL DEATH ONE 5*) gene is transcribed from the identical *P5CDH* locus, but in an opposite direction. Salt stress induces expression of both genes, leading to accumulation of partially complementary dsRNA formed by base pairing of the two transcripts. This dsRNA is subsequently cleaved by DCL, generating two siRNAs consisting of 24 nts and 21 nts. These siRNAs trigger silencing of the *P5CDH* gene by mRNA cleavage and lead to partial inhibition of proline catabolism. This salt-dependent control of proline accumulation via the nat-siRNA and P5CDH pathways allows better tolerance to salt stress. More than 2000 NATs are predicted by bioinformatic analyses in *Arabidopsis* [105, 106]. Therefore, it is expected that

nat-siRNA-mediated regulation is a genome-scale mechanism modulating environmental stress responses in plants.

20.4.3 Posttranslational Modification

Several transcription factors require posttranslational modifications for their activation. Simple overexpression of these transcription factor genes does not induce any physiological responses. For example, transgenic plants overexpressing membrane-bound transcription factor (MTFs) genes do not exhibit phenotypic alterations [17, 107]. It has been shown that these transcription factors should be modified posttranslationally to obtain specific activities.

20.4.3.1 Membrane-Bound Transcription Factors

Regulation of subcellular localization is a fundamental mechanism that activates transcription factors. Transcription factors exert its activity in the nucleus. However, some transcription factors are present in dormant forms in the cytoplasm. Biochemical modifications and interactions with certain partners induce their nuclear translocation [108, 109].

The plasma membrane is the primary site that perceives external signals, such as signal peptides, growth hormones, and ligands. Many membrane-bound proteins are intimately related to signal perception and signaling transduction from the plasma membranes to the nucleus. It has been reported that a group of transcription factors are membrane-associated in plants. The MTFs are stored in dormant forms in association with intracellular membranes, such as the plasma membranes, nuclear membranes, and ER membranes [110]. Upon stimulation by intrinsic and extrinsic signals, they are proteolytically activated via either regulated intramembrane proteolysis (RIP) mediated by membrane-bound protease or regulated ubiquitin/proteasome-dependent processing (RUP) modulated by proteasomic activity. The processed MTF forms are translocated into the nucleus, where they regulate expression of target genes as ordinary transcription factors (Figure 20.3).

Several *Arabidopsis* NAC and bZIP transcription factors have been shown to be associated with the plasma membranes and ER membranes, respectively [110]. These MTFs are type II membrane proteins with their N-termini oriented toward the cytoplasm. They are activated by specific membrane-associated proteases, such as the SITE-1-PROTEASE (S1P) and S2P, via the RIP mechanism [110]. Notably, most of the MTFs are involved in diverse abiotic stress responses. A genome-wide screening has revealed that at least 13 members of the NAC transcription factors are membrane-tethered, which are collectively termed as NTLs (*NT*M1-*L*ike), in *Arabidopsis* [111]. These transcription factors do not induce any phenotypic alteration when full-size forms are overexpressed. Instead, overexpression of processed, nuclear forms induces specific physiological changes, indicating that release from the membrane is critical for their activities. Roles of several NTLs have been explored in plant responses to high salinity, osmotic stress, and cold. NTL6 is proteolytically activated by cold-induced membrane rigidification, and the activated NTL6 form regulates

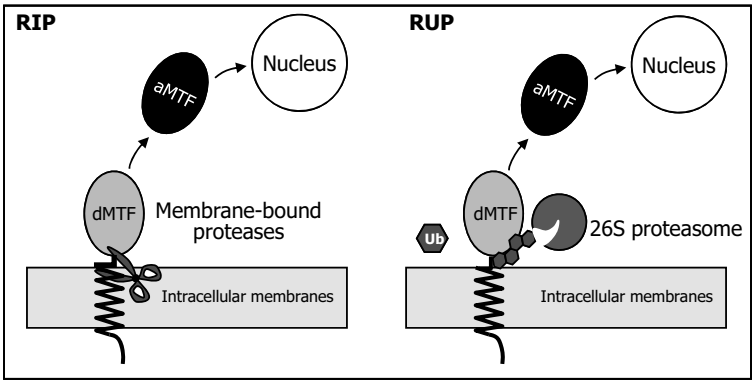

Figure 20.3 Proteolytic activation schemes of membrane-bound transcription factors. The membrane-bound, dormant MTF (dMTF) is released from the membranes by either RIP or RUP. The activated MTF (aMTF) enters the nucleus. Adapted from Seo *et al.* [110].

directly a subset of *PATHOGENESIS-RELATED* (*PR*) genes [112]. NTL8 mediates salt regulation of flowering initiation and seed germination [113, 114]. In addition, NTL9 regulates leaf senescence in response to osmotic stress [115]. Several bZIP MTFs, including bZIP60 and bZIP28, have been shown to play a role in ER stress responses [116–118]. bZIP17 participates in plant responses to salt stress. It is now widely accepted that sequestration of transcription factors from the nucleus provides a way of quick transcriptional responses to environmental fluctuations by skipping the transcription and translation steps.

Extensive genome-wide analyses of the *Arabidopsis* and rice genomes have predicted that at least 190 TFs, constituting approximately 10% of the all plant transcription factors, are physically associated with intracellular membranes [111]. These observations support the hypothesis that membrane biology is a critical component of transcriptional regulatory networks in plants.

20.4.3.2 **Phosphorylation**

Biochemical modifications greatly alter transcription factor activities. Phosphorylation is recognized as a major posttranslational modification of transcription factors that regulate their subcellular localization and transcriptional activation [119–121].

Snf1-related protein kinase (SnRK) is a representative serine/threonine protein kinase family, which positively regulates ABA-dependent signaling [122]. The *Arabidopsis* genome contains 38 SnRKs, of which SnRK2 consists of 10 members [122]. SnRK2.2 and SnRK2.3 redundantly regulate ABA signaling, such as seed germination and seedling growth, by phosphorylating ABFs/AREBs [123]. In addition, SnRK2.6 (OST1/SnRK2E) is involved in regulation of stomatal aperture and transpiration, and SnRK2.8 (SRK2C/OSKL4) regulates drought tolerance without affecting stomatal aperture [73, 124]. As a result, transgenic plants overexpressing either SnRK2.6 or SnRK2.8 exhibit enhanced drought tolerance [73, 124]. Consistent with this, transgenic plants expressing a constitutively phosphor-

ylated AREB1 show ABA-responsive phenotypes even without exogenous application of ABA, supporting that protein phosphorylation is a crucial regulatory scheme of osmotic stress resistance [17].

SnRK2-mediated osmotic stress responses are further modulated by ABA perception machinery. Type 2C protein phosphatase (PP2C) induces stomatal closure and drought stress responses by inactivating SnRK2s [125]. Expression of more than 90% of ABA-responsive genes is abolished in the *abi1-1* mutant, supporting a central role of PP2C in ABA signaling [126]. Interactions of PP2Cs with SnRK2s have been studied using potential ABA receptors [127, 128]. The ABA-bound PYR1 (PYROBACTIN RESISTANCE PROTEIN 1) protein disrupts the interaction between SnRK and PP2C by directly docking the active site of PP2C. Inhibition of the PP2C-mediated dephosphorylation of SnRK by PYR1 activates downstream events of ABA signal transduction cascades [127–130].

Several calcium-sensing proteins also participate in ABA signaling. The CBL-interacting protein kinase CIPK15/PKS3 interacts with ABI1 and ABI2, which play a central role in ABA signaling [131]. In addition, the kinase also phosphorylates the AP2/ERF-type transcription factor ERF7 that negatively modulates ABA signaling [132]. The calcium-dependent protein kinases (CDPKs), which constitute 34 members, have also been identified as ABA signaling regulators. The CPK32 kinase interacts with the ABF4 transcription factor, and overexpression of *CPK32* leads to ABA-hypersensitive phenotypes [133]. Likewise, the CPK4 and CPK11 activities are also stimulated by ABA. The *cpk4 cpk11* double mutant shows reduced ABA and stress responsiveness and reduced resistance to salt stress. In contrast, transgenic plants overexpressing either *CPK4* or *CPK11* exhibit slightly enhanced resistance to salt and drought stresses. The CPK4 and CPK11 kinases phosphorylate the ABF1 and ABF4 transcription factors and positively regulate Ca^{2+}-mediated ABA signaling [134].

20.4.3.3 **Ubiquitination**

Ubiquitin is widely known as a ubiquitous protein modifier that guides target proteins to proteasome-dependent degradation. Proteins designated for degradation are modified by covalent attachment of ubiquitin polymers [135]. Ubiquitinated protein is degraded by the 26S proteasome [136]. For protein ubiquitination, a series of enzymes function in sequence. The ubiquitin-activating enzyme (E1) catalyzes formation of thioester bond between ubiquitin and itself using ATP as energy source. The activated ubiquitin is transferred to an ubiquitin-conjugating enzyme (E2). Finally, the ubiquitin ligase (E3) facilitates formation of isopeptide bond between the activated ubiquitin and the protein substrates [136]. The E3 ligase interacts with both E2 enzyme complex and substrates to determine target specificity [137]. The majority of the enzymes involved in the ubiquitination process consist of E3 ligases, and a large portion of E3 ligases is the REALLY INTERESTING NEW GENE (RING) type [138]. Ubiquitination-mediated regulation of transcription factors is frequently found in plant response to abiotic stresses.

The SALT- AND DROUGHT-INDUCIBLE RING FINGER 1 (SDIR1) E3 ligase that is involved in drought and salt stress signaling and depends on ABA [139]. The *SDIR1* gene is induced by drought and salt stresses, and its overexpression leads to ABA- and

osmotic stress-hypersensitivity, which results in enhanced drought tolerance. In addition, expression of ABA- and stress-responsive genes is profoundly altered in loss-of-function mutants of *SDIR1* that exhibit ABA insensitivity. Although its direct targets have not been identified, SDIR1-mediated signaling affects expression of the *ABI3* and *ABI5* genes and resistance to drought and salt stresses [139].

Among the four ABI3-INTERACTING PROTEINS (AIPs) identified through yeast two-hybrid assays [140], AIP2 functions as a ubiquitin E3 ligase that degrades ABI3 [141]. As inferred from the interactions between ABI3 and AIP2, protein stability of the ABI3 transcription factor is increased in the *aip2-1* mutant but decreased in *AIP2* overexpressors. Accordingly, the *aip2-1* mutant, in which the ABI3 transcription factor accumulates, exhibits hypersensitive responses to ABA, supporting that AIP2 negatively regulates ABI3-mediated ABA signaling [141].

The ABI5 transcription factor is also regulated by ubiquitin-mediated degradation in nuclear bodies [138]. The RING-type E3 ligase KEEP ON GOING (KEG) negatively regulates the ABI5 transcription factor. While the ABI5 proteins accumulate in loss-of-function mutant of *KEG*, transgenic plants overexpressing *KEG* are insensitive to ABA and high salt. In the absence of ABA, KEG maintains the ABI5 transcription factor at a low level. However, in the presence of ABA, the KEG protein is degraded through autoubiquitination, which increases ABI5 protein stability and activity [142]. Notably, protein phosphorylation accelerates degradation of the KEG protein in response to ABA [142].

The DREB2A transcription factor is negatively regulated by DREB2A-INTERACTING PROTEIN 1 (DRIP1) and DRIP2. Overexpression of *DRIP1* leads to delayed induction of DREB2A-regulated genes. In contrast, expression of genes regulated by DREB2A and drought stress is greatly induced in the *drip1-1drip2-1* double mutant. DRIP1 is a potential C3HC4 RING-type E3 ligase and mediates ubiquitination of the DREB2A protein, further supporting the significance of ubiquitination in ABA responses [143].

The ubiquitin/26S proteasome pathway is also implicated in cold stress signaling. The *HOS1* gene encodes a RING finger protein acting as a ubiquitin E3 ligase enzyme. HOS1 is present in the cytoplasm under normal growth conditions. However, it is translocated to the nucleus in response to cold. Notably, HOS1 physically interacts with ICE1 in the nucleus [144]. The HOS1 protein degrades the ICE1 transcription factor through the ubiquitination process and fine-tunes expression of the *CBF/DREB1* gene under cold stress. As a result, cold stress-responsive genes are induced in the *hos1* mutant, and cold stress resistance is enhanced. On the other hand, overexpression of *HOS1* suppresses the *CBF* gene and reduces freezing tolerance, indicating that HOS1-mediated ubiquitination is a crucial negative regulation mechanism in cold stress signaling [144].

20.4.3.4 **Sumoylation**

Sumoylation is emerging as one of the major posttranslational modification processes. Small ubiquitin-related modifier (SUMO) is reversibly conjugated to protein substrates, and SUMO conjugation/deconjugation is conserved in eukaryotes [145]. Sumoylation is very similar to ubiquitination process. Indeed, E1, E2, and E3

enzymes, analogous to those mediating ubiquitination, are involved in sumoylation [146]. Sumoylation regulates subcellular localization and enzymatic activity of substrate proteins and functions in innate immunity and DNA repair. Notably, SUMO conjugation also modulates activities of transcription factors in response to developmental and environmental cues [145].

Among the 8 SUMO isoforms, only SUMO1 and SUMO2 isoforms are conjugated to target proteins in response to environmental stresses, and stress-mediated SUMO conjugation is brought mainly by AtSIZ1 [147–150]. AtSIZ1-mediated ICE1 sumoylation induces expression of the *CBF3/DREB1A* gene and thus enhances freezing tolerance in *Arabidopsis*. Consistent with this, the *siz1-2* and *siz1-3* mutants exhibit freezing-sensitive phenotypes. Sumoylation of ICE1 at K393 inhibits ubiquitination that is possibly mediated by the HOS1 E3 ligase [150]. Therefore, AtSIZ1-mediated sumoylation stabilizes the ICE1 protein and thus confers freezing tolerance [145].

AtSIZ1 also negatively regulates ABA signaling. Expression of ABA-responsive genes containing the ABREs in their promoters is upregulated in the *siz1-2* and *siz1-3* mutants that exhibit hypersensitive responses to ABA [151]. ABA hypersensitivity of the *siz1* mutants is caused by accumulation of a bZIP transcription factor ABI5. However, the hypersensitive response is compromised in the *siz1 abi5-4* double mutant, indicating that SIZ1 negatively regulates ABI5-mediated ABA signaling. The SIZ1-mediated ABI5 sumoylation at K391 inactivates the transcription factor activity independent of AFP and KEG-mediated degradation [151].

Sumoylation and ubiquitination regulate target proteins either in a cooperative manner or in a competitive manner to maintain protein function and activity to an appropriate level. Unlike ubiquitin-mediated degradation, reversible mechanism of sumoylation/desumoylation serves as a switch system in regulating transcription factor activities under stress conditions [146]. Accordingly, SUMO proteases, which cleave the linkages between SUMO and substrates, have been identified as stress response regulators [152]. The OVERLY TOLERANT TO SALT 1 (OTS1) and OTS2 proteins are such SUMO proteases, which participate in salt stress responses. While the *ots1 ots2* double mutant is sensitive to high salinity because of high-level accumulation of SUMO-conjugated proteins, *OTS1* overexpression leads to an enhanced salt tolerance [152]. Although identification of OTS1/2 substrates is elusive, OTS1/2-mediated pathway is an attractive target for genetic engineering of salt-tolerant crops.

20.4.4
Protein–Protein Interactions

Dynamic protein dimerization plays a critical role in the regulation of transcription factor activities. A number of transcription factors function as dimers to assure DNA binding specificity. For example, bZIP transcription factors form both homodimers and heterodimers via the coiled coil motifs [153, 154]. DNA binding affinity and transcriptional regulation activity vary within a transcription factor family. Thus, dynamic formation of homodimers and heterodimers modulates specific activities and functional diversities of transcription factors [154].

This regulatory mechanism is also observed widely in transcription factors mediating abiotic stress responses. The AtMYC2 and AtMYB2 transcription factors coordinately regulate the *RD22* gene, supporting that dimer formation of transcription factors is important for controlling the target genes [13].

NAC transcription factors, such as ANAC019, ANAC055, and ANAC072, regulate stress-responsive genes by binding directly to NAC recognition sequences in the gene promoters. As a result, overexpression of individual ANAC transcription factors affects expression of stress-responsive genes and induces drought tolerance. Although the *ERD1* gene promoter contains NAC recognition sequences, overexpression of the ANAC transcription factors does not fully induce the *ERD1* gene. It has been found that the ANAC transcription factors require the binding partner ZFHD1 for regulation of the *ERD1* gene [29]. Coordinate action of the ANAC and ZFHD1 proteins modulates expression of the *ERD1* gene to obtain developmental balances [29].

An exquisite regulatory scheme has recently been proposed to modulate transcription factor activities. A group of small peptides have limited sequence similarities to specific transcription factors. Although they possess protein dimerization motifs, they lack DNA binding domain or transcriptional regulation domain. It has been demonstrated that they form nonfunctional heterodimers with specific transcription factors and thus exclude the target transcription factor from DNA binding [155]. Genome-scale identification of small proteins having similar structural organization in the databases suggests that small peptide-mediated transcription control would be a regulatory mechanism widespread in plants [156]. To date, although such small proteins have not been reported in abiotic stress responses, it would certainly be a way of modulating transcriptional regulatory activities of a number of transcription factors functioning under stress conditions (Figure 20.4).

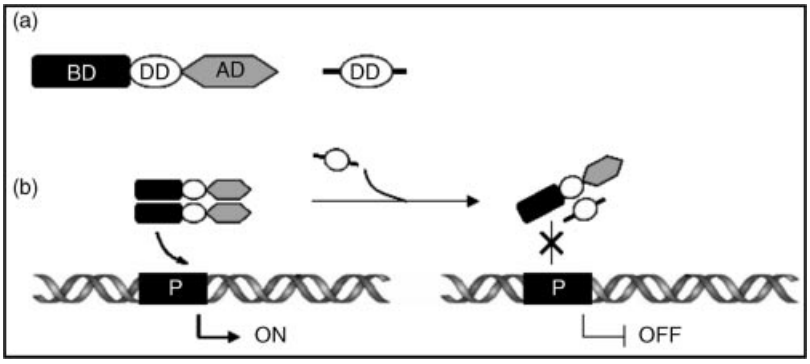

Figure 20.4 Small interfering peptide (siPEP)-mediated suppression of transcription factor activity. (a) Structural organization. The siPEP has a sequence similarity to a specific transcription factor. Although the former has the dimerization domain, it lacks other functional domains, such as DNA binding domain and activation domain, which are required for transcriptional regulation. (b) Competitive inhibition of transcription factor by siPEP. The siPEP forms nonfunctional heterodimers and thus competitively inhibits the formation of functional homodimers. The nonfunctional heterodimers possess reduced affinity to the promoter (P) sequence. Reprinted from [156] with kind permission by Chung-Mo Park.

20.4.5
Epigenetic Regulation

Genomic DNA is packed in a highly condensed structure in the nucleus. A group of nucleoproteins extensively interact with genomic DNA to establish the chromatin structure. Transcription factors bind target DNA sequences within chromatin to modulate gene expression. Chromatin structure, therefore, affects accessibility of transcription factor to their DNA target sites. Transcription factors easily access the naked DNA and open chromatin structure. In contrast, it is difficult for transcription factors to access the heterochromatin structure, suggesting the regulation of transcription factor activity by chromatin structure modification.

Changes in chromatin structure triggered by histone modifications constitute a crucial regulatory mechanism by which a wide spectrum of genes are expressed. Histone acetylation is dynamically regulated by histone acetyltransferases (HATs) and histone deacetylases (HDACs). Histone methylation is modulated by histone methyltransferases (HMTs) and histone demethylases (HDMs). Some of the histone modifying enzymes are involved in abiotic stress responses. The *Arabidopsis* GCN5 protein is an HAT enzyme that regulates cold stress responses [157]. GCN5 physically interacts with transcriptional machinery adapter proteins Ada2a and Ada2b. Remarkably, Ada2b-deficient mutants show enhanced freezing tolerance [158], suggesting that the HAT complex may directly or indirectly repress a signaling step that regulates freezing tolerance. It has also been reported that overexpression of the *Arabidopsis* HDAC homologue AtHD2C leads to enhanced resistance to salt and drought stresses [159].

The *hos15* mutant is hypersensitive to freezing stress. A WD40-repeat protein HOS15 is a component of protein complex involved in histone deacetylation and interacts specifically with histone H4, which results in deacetylation of histone H4. In the *hos15-1* mutant, acetylated histone H4 accumulates. The *RD29A* gene is greatly induced under cold condition possibly by hyperacetylation of histones. Additional genes influenced by the *hos15* mutation may also affect freezing sensitivity, supporting the view that histone acetylation/deacetylation is involved in cold adaptation responses [160].

In *Arabidopsis* H3, four acetylation sites (H3K9, H3K14, H3K18, and H3K23) and four methylation sites (H3K4, H3K9, H3K27, and H3K36) have been identified [161]. Such histone modification would also be widespread in plant stress responses. It has also been reported that distribution of H3 phosphorylation and H4 acetylation is dynamically regulated by abiotic stresses in various plant species, such as rye, barley, tobacco, and *Arabidopsis* [162, 163]. In addition, acetylation and methylation of histone H3 N-tail and nucleosome occupancy in the *RD29A*, *RD29B*, *RD20*, and *RAP2.4* genes are altered under drought stress conditions [164]. Under drought stress conditions, trimethylation of H3K4 and acetylation of H3K9 are induced, and certain genes are activated, and acetylation of H3K23 and H3K27 also occurs in the *RD29B* and *RD20* gene sequences [164, 165]. In addition, nucleosome density in the promoter regions of the *RD29A* and *RD29B* genes is lower than that

in the coding regions without nucleosome loss, facilitating rapid binding of transcription factors to the DRE and ABRE *cis*-acting elements [165]. Trimethylation of H3K27, which acts as a negative regulatory marker for gene expression, is decreased in cold-responsive genes, such as *COR15A* and *GALACTINOL SYTHASE 3* (*GOLS3*), under cold stress conditions, supporting the role of histone modification in abiotic stress responses [166].

The high-mobility group (HMG) proteins are the second most abundant proteins among the chromosomal proteins. They are involved in regulation of transcription and recombination. They also induce transient changes in chromatin structure [167, 168]. There are two groups of HMG proteins in plants [169]: HMGA having AT-hook DNA binding motif and HMGB having HMG-box domain. They interact with nucleosomes and transcription factors, supporting a role of HMG in gene transcriptional regulation [169]. Indeed, several plant HMGB proteins specifically interact with the bZIP and Dof transcription factors and assist their binding to target DNA sequences [170, 171].

There are 7 HMGB proteins in the *Arabidopsis* genome. At least a few of them are critical for stress responses [169]. The *HMGB1/2/3* genes are downregulated in response to high salinity, and transgenic plants overexpressing either *HMGB1* or *HMGB2* have alterations in seed germination under high salinity [169, 172]. However, molecular mechanisms underlying the HMGB regulation of stress responses have not been elucidated.

The switch (SWI)/sucrose nonfermenting (SNF) complex is a multisubunit DNA-dependent ATPase that is involved in chromatin remodeling [173]. It is also regulated by environmental stresses and subsequently regulates expression of stress-responsive genes. It has been observed that SWI3B interacts with PP2C and HYPERSENSITIVE TO ABA1 (HAB1) [174]. ABA inhibits binding of HAB1 to the gene promoters of *RD29B* and *RAB18*, and SWI/SNF chromatin-remodeling complex contributes to ABA responses. Consistently, the *swi3b* mutant exhibits insensitive responses to ABA [174].

20.5 Conclusions and Prospects

Understanding transcriptional cascades in stress signaling provides an excellent opportunity for stress-resistant crop production by genetic engineering. Transcription factors are most appropriate targets for genetic engineering to develop stress-resistant crops. A group of stress-responsive genes are coordinately regulated by introducing a transcription factor.

There are inevitable problems to be resolved in plant genetic engineering. In many cases, overexpression of stress-inducible genes leads to growth and developmental defects. To overcome this problem, inducible promoter would be an appropriate choice. Most of the genes are coordinately regulated by diverse signals through a web of signaling crosstalks, necessitating that multiple growth and developmental traits

are carefully considered before engineering genes of interests. One critical factor to be considered is gene promoter. Basically, any endogenous gene promoter in plants can be used to drive gene expression. Overexpression of the *DREB1A* gene in transgenic plants could activate a number of stress-tolerant genes, which results in enhanced resistance to drought, high salt, and freezing stresses. While the *DREB1A* gene expression driven by the cauliflower mosaic virus (CaMV) 35S promoter results in severe growth retardation under normal growing conditions, expression of a *DREB1A* gene expression construct fused to the *RD29A* gene promoter only slightly influences plant growth [175].

Heterologous expression of useful genes may confer advantages in acquiring resistance to environmental stresses. Overexpression of either *CBF3* or *ABF3* gene in *Arabidopsis* causes growth inhibition under normal growth condition. Interestingly, transgenic rice overexpressing the *Arabidopsis CBF3* gene exhibits enhanced resistance to drought and high salinity without causing growth defects and phenotypic alterations [176]. It may be due to mismatching of the targets in the heterologous organisms and/or differential transcriptional activation strengths of the transcription factor in *Arabidopsis* and rice [176].

Information on regulatory mechanisms controlling transcription factor activities certainly provides novel insights into genetic engineering of stress-resistant crops. Overexpression of certain transcription factors does not always lead to expected phenotypic alterations and traits. In many cases, additional modification is required, as observed with the ABFs/AREBs and MTF transcription factors. Overexpression of ABFs/AREBs does not lead to phenotypic alterations unless they are phosphorylated [12]. In addition, MTF should be expressed as a truncated form, which is localized into the nucleus [110].

Generation of knockout mutation in crops is extremely difficult because of large size of genomes and polyploidy. In this view, small peptides (siPEPs) would be of choice to selectively suppress specific transcription factors. A large number of transcription factors act as homodimers. Therefore, overexpression of a small interfering protein (peptide) containing the dimerization domain (DD), but lacking the DNA binding domain, may lead to competitive inhibition of functional homodimer formation by forming nonfunctional heterodimers.

Make Your Best – MYB Transcription Factors for Improving Abiotic Stress Tolerance in Crops

Andrea Pitzschke

Too hot, too dry, too cold, and too bright. Field crops grow and reproduce in a dynamic and unpredictably changing environment. Adverse climate conditions severely impair plant growth and development. In the face of the growing world population and the climate change, humanity cannot take food production for granted. There is an increasing demand for crops with improved stress tolerance and yield. Understanding the molecular mechanisms that mediate stress adaptation and applying this knowledge to engineering stress-resistant crops is therefore a key to ensure world food security.

MYB domain-containing proteins form a family of transcription factors involved in a diversity of stress-related responses in plants. Interfering with the activity of individual family members often correlates with altered stress tolerance. MYB transcription factors have been thoroughly studied and functionally characterized not only in the model plant *Arabidopsis thaliana* but also in other plant species. Heterologous expression approaches and phylogenetic analyses indicate a good degree of functional conservation.

This conservation will facilitate knowledge transfer, and thus tomorrow's farmers may benefit from today's discoveries in *Arabidopsis*. This chapter reviews the role of MYB transcription factors in abiotic stress signaling. While selected examples from *Arabidopsis* are described, emphasis is given to MYB proteins in field crops. The potentials and limitations of using heterologous expression approaches for genetic engineering of crops with improved stress tolerance are discussed. One part is devoted to mechanisms that regulate MYB protein abundance and activity. A list of valuable data resources (transcription factor databases, transcriptome studies) shall provide fast access to detailed information and bioinformatics tools for researchers interested in a particular plant species.

Improving Crop Resistance to Abiotic Stress, First Edition.

21.1 Introduction

21.1.1 Abiotic Stress

As sessile organisms, plants have to endure any condition posed by their environment. Environmental stress is estimated to account for 60–70% of crop yield loss [1]. Owing to global warming, abiotic stresses are gaining even more importance as major constraints on worldwide crop production. The most widespread types of abiotic challenges occurring in the field are drought, osmotic, cold, and heat stresses. In addition, other stresses such as those triggered by ozone and ultraviolet (UV) light are a growing problem. Over the past decades, intensive research has been dedicated to disentangle the molecular mechanisms and identify key regulators of stress adaptation.

Plant stress responses have been most intensively studied in the model plant *Arabidopsis thaliana* and to various extents also in other species. Principal stress adaptation strategies such as osmolyte accumulation under high-salt conditions, production of anthocyanins as UV protectants, and the underlying signaling mechanisms, appear to be largely conserved between species.

21.1.2 Abscisic Acid – A Stress Signaling Hormone

Many stress-related signaling pathways are involve in the production of and regulation by abscisic acid (ABA) [2, 3]. The importance of this plant hormone as mediator of a variety of stress adaptation mechanisms is mirrored by the fact that many mutants displaying an altered stress tolerance also show abnormalities in ABA sensitivity or biosynthesis. As regulator of stomatal aperture, ABA directly controls the plant's water balance.

21.1.3 (Dis)Similarities of Stress Responses

Although any kind of environmental challenge requires a specific adaptation response, the molecular events triggered by diverse abiotic stresses significantly overlap. This is, for example, evidenced in studies comparing transcriptome changes upon cold, salt, or heat treatment in *Arabidopsis* [4], as well as upon cold, drought, or salt treatment in chickpea [5]. Accordingly, a number of mutants and transgenic plants exhibit altered tolerance to, for example, salt, cold, and drought [4, 6].

Often, enhanced stress tolerance is accompanied by a poor growth or seed yield. This may be explained by the relatively high energy cost required for maintaining a permanent "stress awareness." For instance, the *Arabidopsis eskimo* mutant not only tolerates drought, cold, and osmotic stress but also produces fewer seeds [6]. Likewise, enhanced stress tolerance conferred by overexpression of a number of

MYB genes in various plant species is reflected by severe dwarfism [7–10]. An increasing understanding of stress-related signaling mechanisms shall pave the way for improving stress tolerance in crops while maintaining normal plant growth under nonstress conditions.

21.2
Signal Transduction and Amplification

21.2.1
Principle of Signaling Pathways

Plant growth under adverse conditions is a challenging task that requires the establishment of effective stress signaling pathways and networks. Stress adaptation follows a general scheme: (1) stress perception; (2) transduction of the "stress signal" to cytoplasmic components, for example, through modification of receptor binding intracellular proteins; (3) transduction of information into the nucleus; and (4) transcriptional reprogramming, followed by synthesis of stress proteins (e.g., HSPs in heat stress), altered enzyme activities, and metabolic changes (e.g., osmoprotectants upon salt stress, anthocyanins as UV protectants, etc.). Up to now, most signaling pathways are far from being known in their entirety.

21.2.2
Protein Signaling Cascades

Cellular signaling is not only a one-to-one transduction from protein to protein but also involves concomitant amplification of the stress information. Such amplification can be achieved through modification of (a homo- or heterogeneous pool of) multiple target proteins by a single molecule of regulatory enzyme. Prominent players in such catalysis-based signal amplification in the early stress response are protein kinases, such as those of the SERK [11], CDPKs [12], and MAPK family [13–15].

21.2.2.1 **MAPK Cascades**

A highly efficient and specific funneling and amplification of perceived stress signals is achieved if regulatory enzymes are linked in a cascade. Here, mitogen-activated protein kinase (MAPK) cascades are prominent examples. MAPK cascades are signaling modules conserved in eukaryotic species. These cascades minimally consist of three types of kinases, encoded by the gene families of MAPK kinase kinases, MAPK kinases, and MAPKs. MAPK modules serve as both signal transduction and signal amplification: an MAPK kinase kinase phosphorylates multiple molecules of its target MAPK kinase, which in turn phosphorylates and thereby activates a pool of MAPK molecules. The active MAPK then passes on the signal through phosphorylation of downstream targets, including transcription factors. Thus, by altering the properties/activities of target transcription factors, MAPK cascades translate signal perception into altered gene expression. Genetic and

biochemical studies implicate MAPK signaling modules both in biotic and abiotic stress responses and in stomata development [13, 15, 16].

21.2.3 Transcription Factors

Transcription factors that accumulate or are stimulated by an upstream kinase or other regulatory protein subsequently further amplify the perceived stress signal. Few molecules of active transcription factor can drive massive accumulation of target gene transcripts whose translation can yield thousands of thousands of molecules of the respective protein. Thus, transcription factors may be considered as "master switches." Often, their activity is tightly controlled, so as to prevent expression of target genes when there is no demand. Many transcription factors accumulate or are activated at a particular development stage or in a stress-dependent manner. Undoubtedly, transcription factors are very attractive proteins for genetic manipulation to generate stress-resistant crops. Plant transcription factors, according to the type of DNA binding domain, are classified into several families. Many families have been shown to be involved in stress responses. Examples of stress-related transcription factors can be found in all main transcription factor families, including bZIP proteins, WRKY, AP2, NAC, C_2H_2 zinc finger, and MYB proteins [17].

While members of the WRKY family are prominent regulators of biotic stress responses, those of the MYB family primarily act in the signaling of abiotic stresses. In the subsequent chapters, focus will be on MYB transcription factors and their role as regulators of the abiotic stress response and on their potential for engineering crops with improved stress tolerance. Table 21.1 provides an overview of all MYB genes discussed in the chapter, including information on expression and stress-related phenotypes of mutants and overexpressing plants.

21.2.3.1 MYB Transcription Factors – Structure and Phylogeny

MYB proteins form one of the largest families of transcription factors in plants [18], characterized by the conserved DNA binding domain, the MYB domain. The name is derived from the first MYB gene identified, the oncogene v-MYB from the avian *my*elo*b*lastosis virus. MYB proteins are found in animals, fungi, and plants. In animals, they control the development of various types of cancer [19]. The MYB DNA binding domain generally consists of up to three imperfect repeats, R1, R2, and R3, each consisting of 51–53 amino acids.

MYB genes in plants form three major subfamilies, depending on the number of repeats: according to a nomenclature suggested by Stracke *et al.* [20], 1-, 2-, and 3R repeat-containing plant MYB proteins are referred to as MYB1R (Myb-related), R2R3, and MYB3R factors. The largest group, R2R3-type MYB proteins, is exclusively found in plants. Members of this group mainly regulate plant-specific processes [20].

The richest pool of plant MYB research data has been generated in *A. thaliana* and has been reviewed previously [21]. The *Arabidopsis* genome encodes for 126 MYB and

Table 21.1 Overview of plant MYB transcription factors discussed in the chapter.

Species	Gene name/ID	Closest homologue (*A. thaliana*, rice)[a)]	Gene expression (+, induced; −, repressed)	Phenotype (+, enhanced; −, reduced tolerance; o/e, overexpression; k.o., knockout)	Comment	References

a) Closest homologue using NCBI BlastP.

64 MYB-related proteins [22]. Until now, to approximately half of all *Arabidopsis* MYB proteins, a functional role could be ascribed [21]. *Arabidopsis* MYB factors regulate a diversity of processes, including primary and secondary metabolism, cell fate and identity, and development and stress responses. The identification and functional characterization of MYB proteins in crops is on the rise, and a picture of MYB transcription factors as key players in plant stress management is emerging.

21.3
MYB Proteins in the Model – Abiotic Stress Signaling in *Arabidopsis*

21.3.1
AtMYB2: the Pioneer and Its Partner

The involvement of MYB proteins in the plant response to abiotic stress was first reported in 1997 [23]. In *Arabidopsis*, AtMYB2, a MYB-related protein, and AtMYC2, a bHLH transcription factor, function as transcriptional activators in ABA-inducible gene expression under drought stress. Coordinately, they activate the expression of the drought stress marker gene *AtRd22* through direct binding to *AtRd22* promoter elements [10, 23]; AtMYB2 and AtMYC2 are synthesized *after* the accumulation of endogenous ABA, pointing to a role at a late stage in the stress response. Overexpression of these transcription factors in *Arabidopsis* resulted in ABA hypersensitivity and an enhanced tolerance to osmotic stress [10]. Accordingly, several ABA-inducible genes are among the candidate target genes identified by microarray analysis of *AtMYC2/AtMYB2* overexpressing plants [10]. Although *AtMYC2* overexpressing plants under normal conditions are indistinguishable from wild type, *AtMYB2* and *AtMYC2/AtMYB2* overexpression results in growth retardation.

Meanwhile, *Arabidopsis* drought stress-related MYB proteins have been characterized further. Apparently, they are involved in several aspects of the desiccation response, both as tolerance enhancing and as tolerance repressing factors.

21.3.2
Arabidopsis MYB Proteins as Stomatal Regulators

Stomata are the major sites of gas exchange. Adequate stomatal movement is pivotal to allow CO_2 uptake for photosynthesis on the one hand and to restrict excessive water loss on the other hand. Stomatal pore aperture is mediated by turgor-driven volume exchanges of two surrounding guard cells [24]. Both opening and closing of stomata is regulated by the stress hormone ABA and has been reviewed previously [25]. Briefly, ABA-stimulated accumulation of reactive oxygen species induces stomatal closure via activation of plasma membrane calcium channels. Complementarily, ABA inhibits stomatal opening through downregulation of K^+_{in} channels and H^+-ATPases.

The first plant transcription factor reported to regulate stomatal movement was a MYB protein *Arabidopsis* AtMYB60 [26]. AtMYB60 is specifically expressed in guard cells, and its expression decreases during drought. Loss-of-function mutants show constitutive reduction of stomatal opening and an enhanced drought tolerance. Microarray analysis showed only few genes to be differentially expressed in these mutants, and many are associated with stress responses. The stomata-specific gene expression and the fact that lack of functional AtMYB60, at least in the homologous system (*Arabidopsis*) is affecting only stress-associated pathways and not interfering with growth and development point to a highly specific role. Identifying potential AtMYB60 orthologues in other plant species and repressing their expression would be a targeted and promising strategy to engineer stomatal activity to help crops survive desiccation.

At least three more genes, *AtMYB15* [27], *AtMYB44*, and *AtMYB96* [28], are implicated in drought stress response through stomatal regulation in *Arabidopsis*. *AtMYB15* is expressed in stomatal guard cells. Its expression is induced by ABA, drought, or salt treatments. *AtMYB15* overexpressing lines are hypersensitivity to exogenous ABA and display an improved tolerance to drought and salt stresses. ABA-induced induction of ABA biosynthesis, ABA signaling, and ABA-responsive genes is enhanced in these lines.

Overexpression of *AtMYB44* enhances ABA sensitivity in stomatal closure [29]. *AtMYB44* is an immediate stress-responsive gene whose expression is regulated via a MAPK pathway (see Section 21.6.3.2).

AtMYB96 is primarily expressed in the root. An activation-tagged *myb96* overexpressing mutant (MYB96ox) exhibited an enhanced drought resistance, accompanied by a reduction in stomatal opening upon ABA or drought exposure. The opposite was observed in a *myb96* T-DNA insertional knockout mutant [28]. Stomatal densities were not affected in either of these mutant lines, showing that AtMYB96 regulates specifically stomatal opening.

In addition, AtMYB96ox mutants exhibit dwarfed growth with altered leaf shape and reduced lateral roots. Thus, in contrast to *Atmyb60* knockout mutants, enhanced drought resistance in *AtMYB96*ox mutants is gained at the expense of reduced growth. This growth impairment might in addition be explained by the energy cost paid to an alerted state toward biotic stress: *AtMYB96*ox plants have elevated levels of biotic stress genes and are more resistant to infection with the biotrophic pathogen *Pseudomonas syringae* [9].

21.4 Desiccation, Cold, and Osmotic Stress in Crops

21.4.1 Wheat

Also in other plant species, abiotic stress responses are controlled through multiple MYB proteins. In wheat, 203 MYB and 116 MYB-related genes have been

identified [30], and experimental evidence implicates several family members in stress signaling. Aiming at improving wheat harvest yield, the challenge is now to pick the most relevant candidates (see also Section 21.7).

Upon wheat desiccation, *TaMYB2*, *MYB4*, and *MYB5* are induced (treatment with 30% PEG), while another gene, *TaMYB1*, is repressed [31]. Whether the opposite responsiveness of *TaMYB1* versus *TaMYB2*, *TaMYB4*, *TaMYB5* is due to a crosstalk between the four genes is an interesting question. Another salt stress-induced MYB gene in wheat, *TaMYB32*, was isolated and mapped [32]. All five genes mentioned above still await functional characterization. TaMYB2 might be particularly interesting: its closest homologue in *Arabidopsis* is AtMYB15, a drought-inducible gene that is expressed in stomatal guard cells [27] (see above). It will be interesting to see whether TaMYB2 also displays guard cell-specific expression and, more important, whether similar to AtMYB15 [28], TaMYB2 overexpression also confers salt and drought stress tolerance.

A study examining the expression levels of 10 MYB genes in two recombinant inbred wheat lines that have contrasting salt and drought tolerance revealed four genes responding to short-term salt treatment [33]. One of these genes, *TaMYBsdu1*, is upregulated in leaves and roots under long-term drought stress. Moreover, *TaMYBsdu1* expression is more strongly induced upon salt treatment in the tolerant than in the susceptible genotype. *TaMYBsdu1* could be an important regulator in wheat adaptation to both salt and drought stresses [33]. Its closest homologues in rice and *Arabidopsis* are a MYB protein of unknown function and *AtMYB20/AtMYB85*, respectively. Interestingly, *AtMYB85* expression is upregulated and *AtMYB20* expression downregulated by salt and drought stresses [34, 35]. Neither AtMYB20 nor AtMYB85 loss- or gain-of-function mutants/transgenic plants have been analyzed yet.

21.4.2 Rice

Plants growing in temperate zones have developed a strategy, termed cold acclimation, to withstand subfreezing conditions. Cold acclimation involves the orchestrated action of numerous genes whose expression is controlled by a small number of transcription factors directly responding to the temperature stimulus. Substantial research data exist for several MYB genes to be involved in low-temperature signaling in *Arabidopsis* [21]. Also, in crops evidence for a role of MYB genes in cold adaptation is growing.

Cold is one if not *the* limiting factor in rice production. Particularly at the seedling stage, rice is very sensitive to chilling. Once again, MYB proteins are playing at the front in stress management.

OsMYBS3 is a single MYB domain-containing protein that had been previously implicated in sugar signaling in rice [36]. Sound evidence exists for an additional role of this protein as mediator of cold adaptation [37]: *OsMYBS3* expression is induced by cold. Loss-of-function results in a cold-hypersensitive phenotype, while transgenic rice constitutively overexpressing *OsMYBS3* is more cold tolerant (4 °C for at least 1 week). Thus, *OsMYBS3* appears to be sufficient and necessary for cold tolerance

in rice. Transcriptome profiling of loss- and gain-of-function plants revealed putative OsMYBS3 target genes, including various stress-responsive genes. Interestingly, OsMYBS3 was found to repress the well-known DREB1/CBF-dependent cold signaling pathway. The different kinetics of cold-induced DREB1 (rapid) and OsMYBS3 (slow) expression suggests that distinct pathways act sequentially and complementarily for adapting short- and long-term cold stress in rice [37]. The closest *OsMYBS3* homologue in *Arabidopsis*, At5g47390, is also induced by salt, as well as by ABA and CdCl2 [22], indicating a functional similarity. More important, the enhanced cold tolerance of *OsMYBS3* overexpressing plants is *not* accompanied by yield penalty in normal field conditions [37], making *OsMYBS3* particularly attractive for improving cold tolerance in other crops (Table 21.3).

Equally promising is another cold-inducible *MYB* gene from rice, *OsMYB4*. Constitutive overexpression of *OsMYB4* in *Arabidopsis* conferred enhanced tolerance to several abiotic stresses [8], suggesting that the function is evolutionarily conserved. In fact, it was found later that ectopic expression of *OsMYB4* also improves drought and cold resistance in apple [7]. Despite its promising potential for genetic engineering of other stress-resistant crops, *OsMYB4* will have to be expressed in a more controllable manner (see Section 21.8): both *Arabidopsis* and apple plants constitutively expressing *OsMYB4* showed reduced growth under normal conditions [7, 8]. So far, no studies on *OsMYB4* overexpressing or mutant plants in the homologous system, that is, rice, have been reported.

The rice MYB protein OsMYB3R-2 has also been implicated in the cold response [38]. OsMYB3R-2 specifically binds a mitosis-specific activator *cis*-element, found in the promoters of cyclin-genes. Upon cold treatment, transgenic rice plants overexpressing OsMYB3R-2 have higher transcript levels of several G2/M phase-specific genes. Moreover, these plants display an enhanced cold tolerance, accompanied with elevated levels of the osmoprotectant proline. Therefore, OsMYB3R-2 was proposed to mediate a cold resistance mechanism through regulation of the cell cycle [38].

21.4.2.1 Thirty-Seven Priority Candidates for Cold Signaling in Rice

The above examples might only be the tip of the iceberg in MYB-regulated rice chilling response. A genome-wide, physiological and whole-plant-level analysis reported by Yun *et al.* [39] provides a more holistic view of the chilling stress response mechanism in rice.

Within a 96-h duration at which rice seedlings were exposed to 10 °C, 8668 genes showed altered expression. The majority of chilling-induced transcription factors were activated during the initial 24 h. Among these potential main determinants in orchestrating the rice cold response are 37 members of the MYB gene family.

21.4.3 Soybean

In soybean, there are at least 156 MYB genes [40]. For 43 of these, altered expression in response to treatment with ABA, salt, drought, and cold stress was observed. Three candidates, GmMYB76, GmMYB92, and GmMYB177, were studied in more detail.

Table 21.2 (a) Transcriptional profiling studies on abiotic stress responses in crops and (b) useful bioinformatic tools and databases on transcription factors in *Arabidopsis* and field crops.

Table 21.3 Highly attractive MYB genes for genetic engineering, also in heterologous plant species. Research data so far indicate that tolerance is *not* at the expense of growth, development, or seed yield.

Strategy	Reported effect	Studied so far in species
OsMYB3 overexpression	Cold tolerance	Rice
Snapdragon *MYB/MYC* overexpression	Anticancer effect due to anthocyanin accumulation in fruit	Tomato
IbMYB1 overexpression	Potential health-promoting effect due to anthocyanin accumulation	Sweet potato
AtMYB60 inhibition	Drought tolerance, anthocyanin synthesis	*A. thaliana*, lettuce
GmMYB76 or *GmMYB177* overexpression	Salt and freezing tolerance	*A. thaliana*

They exhibit different dimerization characteristics and DNA binding preferences. Overexpression of *GmMYB76* or *GmMYB177*, but not *GmMYB92*, in *Arabidopsis* resulted in an improved salt and freezing tolerance [40]. Together, this study suggests a nonredundant function for these three MYB genes in the plant stress response. The remaining 40 stress-responsive *MYB* genes are further attractive candidates for stress tolerance improvement through genetic engineering.

21.5 Colorful MYB Proteins and Their Merits

Excessive UV radiation triggers the production of reactive oxygen species, followed by cell death. Many plant species produce flavonols and anthocyanins as effective UV protectants. Pigmented anthocyanin compounds also play an important reproductive role as attractants for pollinating insects. On the other hand, accumulation of anthocyanins can prevent plants from excessive herbivory insect attack [41].

For the human diet, the health-promoting effect of anthocyanins is of great interest. Flavonols/anthocyanins offer protection against certain cancers, cardiovascular disease, and age-related degenerative diseases; they have anti-inflammatory activity, promote visual acuity, and hinder obesity and diabetes [42].

The identification and characterization of key regulators in flavonol production in crops may therefore speed up the development of plants with enhanced UV tolerance, improved pollination, and elevated nutritional/health value.

Anthocyanin biosynthesis is controlled by a distinct clade of R2R3 MYB transcription factors [43]. In *Arabidopsis*, a number of MYB factors are involved in the regulation of the phenylpropanoid pathway, mediating anthocyanin and flavonol biosynthesis [21]. This pathway appears to be also regulated by multiple MYB factors in other plant species, including, for instance, apple [44–46], strawberry [47], grapevine [48], persimmon fruit [49], tomato [50], and sweet potato [51].

21.5.1
MYB Proteins for the Human Health

In an impressive scientific report [42], the huge potential of MYB proteins for the engineering of crops with health-promoting activity was demonstrated: ectopic expression of a bHLH and a MYB transcription factor, which had earlier been found to interact to induce anthocyanin biosynthesis in snapdragon [52], in tomato gave rise to fruits with substantially elevated anthocyanin levels. The anthocyanin production in these dark-colored transgenic tomato fruits correlated with a massive increase in antioxidant capacity. Strikingly, cancer-susceptible mice, which were fed with these fruits, attained a longer life span [42]. MYB proteins may therefore open novel approaches for human medicine. Particularly in countries with limited access to a balanced and healthy diet, anthocyanin-accumulating crops may provide a solution.

21.5.2
Anthocyanin Production in Grapevine

For winemakers, sun can be both a blessing and a curse. Quality and quantity of sun is a major determinant in flavor development in ripening wine berries. However, high light and the associated UV radiation are critical challenges for wine plants. A number of wine MYB transcription factors have been identified and characterized to various extents: *VvMYBF1* controls flavonol synthesis through activation of the flavonol synthase gene *VvFLS*. Overexpression of *VvMYBF1* in *Arabidopsis* complements the flavonol-deficient phenotype of *Atmyb12*. This finding highlights the strong conservation and interspecies compatibility of plant MYB proteins [48].

VvMYBPA1 was the first transcription factor found to be involved in the regulation of protocyanin production during seed development in grapevine [53]. Later on, a second gene with high sequence similarity, *VvMYBPA2*, was identified. *VvMYBPA2* is expressed in berries and leaves. The proanthocyanidin profiles in grapevine hairy roots ectopically expressing *VvMYBPA1* or *VvMYBPA2* were altered. Transcriptomic studies of transformed grapevine organs ectopically expressing *VvMYBPA1* or *VvMYBPA2* revealed putative target genes, including several enzymes of the flavonoid pathway [54]. Considering the UV-protective role of anthocyanins and the high light conditions often encountered in vineyards, it will be a worthy experiment to assess the UV tolerance in *VvMYBPA1/2* overexpressing organs or plants.

21.5.3
A Red and Rich Sweet Potato

Purple-fleshed sweet potatoes owe their color – at least partially – to the activity of a MYB transcription factor, IbMYB1 [51]. Transcript levels of this gene are particularly high in the roots of the purple-fleshed variety. *IbMYB* overexpression leads to a drastic

increase in anthocyanin levels through induction of all structural anthocyanin genes, both in sweet potato and in heterologous plant species (*Arabidopsis*). IbMYB1 might therefore be applicable to the production of anthocyanins as nutritive value [55], but it might also serve as a UV protectant in other plant species.

21.5.4
Negative Control of Anthocyanin Production

The above-described proteins, along with a number of other MYB factors from diverse species [43], are all positive regulators of the phenylpropanoid pathway. In contrast, *Arabidopsis AtMYB4* acts as a repressor by inhibiting the expression of a rate-limiting enzyme in this pathway. Accordingly, *Atmyb4* mutants accumulate sinapate esters (major soluble phenylpropanoid metabolites) and exhibit an enhanced UV tolerance, while overexpression – in *Arabidopsis* and tobacco – diminishes sinapate ester levels and results in UV hypersensitivity. The transcriptional repressing effect of AtMYB4 is conferred by a repressor domain located in the C-terminus of the protein [56].

Similar motifs are found in and apparently confer a repressing effect on a small number of other MYB proteins. FaMYB1, which had been isolated from ripening strawberry, represses transcription of anthocyanin-related genes [47]. Heterologous overexpression of FaMYB1 in tobacco represses flavonol and anthocyanin synthesis [47]. Thus, the putative repressor motif contained in FaMYB1 is apparently also functional in the (distant) heterologous species.

21.5.5
Anthocyanins, UV Protection, and the Crosstalk with Other Stressors

Apart from their role as major contributors to UV protection and as attractants for pollinating insects, phenylpropanoid-regulating MYB factors might have a huge yet mainly undiscovered potential; a recent study on the involvement of MdMYB10, a regulator of anthocyanin production in apple fruit [45], in osmotic stress protection is promising: overexpression of *MdMYB10* in *Arabidopsis* resulted in improved growth under high-sorbitol conditions. Accordingly, levels of anthocyanins and osmoprotectants were elevated in these plants [57]. A possible two-sided regulation of both phenylpropanoid pathway and seemingly rather distant stress responses by a single MYB factor is indicated by *Arabidopsis* AtMYB60. The gene is repressed upon UV radiation (www.genevestigator.ethz.ch [58]). *myb60* mutants are more drought tolerant, which is due to a constitutive reduction in stomatal opening (see above section) [26]. Interestingly, when overexpressed in lettuce, AtMYB60 acts as transcriptional repressor of anthocyanin biosynthesis [59]. Recently, also enhanced anthocyanin levels have been reported for AtMYB96 activation-tagged *Arabidopsis* mutants, which are more tolerant to drought [9] and pathogen infection [28]. So far, the salt/drought/temperature tolerance of mutants and transgenic plants with altered content or activity of MYB transcription factors involved in phenylpropanoid biosynthesis has hardly been tested. This is worthy of future study.

21.6
Regulating the Regulators

Members of the MYB factor family not only take an active part in gene regulation, but many are also subject to transcriptional regulation themselves (summarized in Table 21.1). In addition, MYB transcription factors are controlled at the posttranscriptional and posttranslational levels. This is indicative of a sophisticated network fine-tuning MYB-mediated cellular effects. Under acute conditions, plants must be able to quickly prioritize stress responses at the expense of growth. Posttranslational regulation of MYB proteins may serve the immediate response, while their stress-induced transcriptional accumulation is likely to mediate long-term stress adaptation. The major mechanisms controlling MYB expression and activity are described next.

21.6.1
Transcriptional Regulation of MYB Genes

Many MYB factor-encoding genes are expressed in a stimulus-dependent manner. As exemplified in the previous sections, transcript accumulation of individual MYB genes under certain stress conditions has often (successfully) been taken as indicative of the process controlled by the respective proteins. Some MYB transcript levels are altered in response to a diversity of small selection of stimuli or to one type of stress exclusively (www.genevestigator.ethz.ch). A comprehensive survey of transcript abundance of *Arabidopsis MYB* genes in response to various hormone and abiotic stress treatments, as well as a phylogenetic comparison with rice, has highlighted the complex regulation of this gene family in both species [22]. An overview of MYB genes and their response to abiotic stresses can be found in Table 21.1. Transcriptome profiling of plant stress responses and their applicability for MYB research are described in detail in Section 21.7.1.

21.6.2
miRNAs

In *Arabidopsis*, a number of *MYB* genes are targeted by microRNAs. miR159 appears to be a key regulator, controlling at least four AtMYB proteins that are involved in anther and pollen development [21]. Similar posttranscriptional regulatory mechanisms of MYB proteins are likely to exist in other plant species. The identification of miRNAs targeting multiple MYB proteins in crops is a challenging but promising task. Manipulation of miRNAs is a useful tool to repress related, that is, potentially functionally redundant MYB proteins that negatively control stress tolerance. Interesting candidates in this respect are *AtMYB60* and its putative orthologues (see Section 21.3.2).

21.6.3
Posttranslational Regulation of MYB Proteins

Under acute stress conditions, plants need to respond rapidly. Cell damage has to be immediately prevented, even before *de novo* synthesis of signaling components is

accomplished. This can be achieved through posttranslational modification of inactive transcription factors already residing in the cell. Moreover, cells also employ this strategy to quickly inactivate signaling components. Examples of posttranslationally modified proteins can be found in all plant transcription factor families.

Particularly under the aspect of employing transcription factors for genetic engineering of plants, possible posttranslational modifications and their effects on protein activity should be considered. Once again, knowledge about modifications of MYB proteins in (the better-studied) *Arabidopsis* may in some cases be applied to their closest homologues in other species. Major types of posttranslational modification are outlined in the following sections.

21.6.3.1 **SUMOylation**

SUMOylation is a type of posttranslationial modification in which the small ubiquitin-related modifier (SUMO) is reversibly and covalently conjugated to a lysine residue in a substrate protein. This process involves three biochemical steps, SUMO E1 activation, E2 conjugation, and E3 ligation, and is reversed through the action of ubiquitin-like SUMO-specific proteases. SUMOylation can lead to changes in protein–protein interactions, resulting in an altered activity, stability, or localization of substrate proteins [60–62]. Bioinformatic, genetic, and biochemical analyses of *Arabidopsis*, rice, tomato, and *Medicago* indicate that components of the SUMO conjugation and deconjugation systems are conserved in plants [63].

At present, knowledge on SUMOylated proteins in plants is very limited. Putative SUMOylation target motifs (characterized by the minimal consensus motif ΨKXE/D, where Ψ is a large hydrophobic residue; X, any amino acid; E/D, glutamate or aspartate) are found in several plant proteins, including a number of MYB transcription factors. Modification through SUMOylation has been reported for the MYB protein AtLAF1. Disruption of the AtLAF1 SUMO motif resulted in an altered nuclear distribution [64]. However, the functional relevance is still unclear.

A sophisticated mutual regulation between MYB factors and SUMOylation was reported by Miura *et al.* [63]: the *Arabidopsis* MYB-like protein AtPHR1 is a SUMOylation target of the SUMO E3 ligase AtSIZ1, involved in the phosphate starvation response. In turn, SUMOylated AtPHR1 functions as the transcriptional activator of At*SIZ1*.

Another plant SUMO target MYB protein, AtMYB30, has been studied thoroughly *in vitro*, and three SUMOylated lysine residues, located at the C-terminus, have been identified [65]. The experimental system reported by the authors can be applied to test candidate proteins, from any species of interest, for SUMOylation. In this context, it is interesting to note that a few MYB proteins from other plant species display homology to the SUMOylation-site-spanning region of AtMYB30, and at least some of the SUMOylation motifs are conserved (Pitzschke, unpublished).

21.6.3.2 **Phosphorylation**

Phosphorylation is a means of reversible modification that can change the properties of a protein. Protein kinases attach phosphate groups to serine, thereonin, or tyrosine residues of target substrates, while protein phosphatases reverse this process. A fascinating stress-related transcription factor involved in stress and MYB regulation

is the bZIP protein AtVIP1. AtVIP1 has been shown to be a target of the stress-activated kinase AtMPK3 [66]. Upon phosphorylation, AtVIP1 migrates into the nucleus where it activates the expression of stress genes, including AtMYB44. Thus, AtVIP1 directly links MAPK activation to transcriptional reprogramming. Moreover, it further amplifies the stress signal perceived from the MAPK cascade by driving expression of further transcription factors, which in turn modify expression of subsequent target genes [67]. Interestingly, both At*mpk3* [68] and At*myb44* mutants [29] are impaired in ABA-dependent stomatal closure. Whether this defect in At*mpk3* is primarily due to a nonfunctional VIP1–MYB44 pathway is yet to be determined.

Rather than being transcriptionally regulated through MAPKs, some MYB proteins are likely to be directly modified by MAPKs: several MYB proteins are among the candidates identified through a proteomic approach using high-density protein microarrays to determine phosphorylation targets of *Arabidopsis* MAPKs [69]. A MAPK phosphorylation-controlled MYB factor has been reported from pine. PtMYB4 has a potential role in xylem differentiation. Phosphorylation had no effect on (*in vitro*) DNA binding activity of PtMYB4, but it altered its capacity to promote transcription [70].

21.7
Databases and Transcriptome Studies – Resources for MYB Research

Omics-based approaches are promising tools for identifying candidate key regulators in the stress response. A number of links to transcriptome profiles and databases relevant for abiotic stress/MYB research in crops are listed in Table 21.2.

21.7.1
Transcriptomic Profiling of Abiotic Stress Responses in Crops

The characterization of many stress-related plant MYB genes has been preceded by isolation of candidate genes from transcriptome studies. From the vastly increasing information extracted from transcriptomic approaches, combined with large-scale EST sequencing in crops and phylogenetic studies, a global picture is emerging. These rich sources of data, handled in a smart manner, can elucidate stress-specific/cross-species similarities and thus aid the development of more directed approaches toward generating multiple stress-resistant crops. A targeted search for stress signaling components can, for example, be performed by screening published microarrays for genes differentially expressed upon a certain stimulus. This will reveal not only MYB genes as putative regulators, but also their possible downstream targets (i.e., those whose promoters contain MYB binding sites).

A promising and targeted approach to identify MYB factors (and other key components) potentially involved in abiotic stress resistance is the comparison of transcription profiles between non- and stress-exposed plants or between stress-susceptible and -tolerant cultivars.

The latter has, for example, been applied in tomato, where a *MYB* gene is among the transcription factors that show altered expression specifically in drought-tolerant genotypes [71]. Likewise, in wheat *TaMYBsdu1*was found through comparison of expression profiles in wheat cultivars exhibiting contrasting salt and drought tolerance (see above) [33]. Similarly, *IbMYB* was identified as a gene particularly highly expressed in purple-fleshed sweet potato (see above) [55].

Changes in expression profiles in response to stresses have been studied in numerous plant species. Not surprisingly, MYB transcription factors are on the "candidate lists" that arose from such screens. A selection of transcriptome studies is given below, stressing the versatility of such approaches.

By means of microarray analysis of cold-treated rice plants, a number of candidates, including MYB-encoding genes, involved in the chilling response, were identified [39]. Transcript and metabolic profiling data are now also available for common bean, an important legume for human consumption. Phosphorus deficiency is a major limiting factor for nitrogen fixation and is widespread in areas where common bean is grown. From the comparison of P-deficient versus control nodules, a number of candidate genes, including 37 transcription factors, 3 of which are annotated as MYB genes, were identified [72]. In *Arabidopsis*, at least two MYB proteins are involved in the phosphate starvation response (AtPHR1 and *AtMYB62*) [73, 74], once again stressing functional conservation. Given their widespread cultivation, excellent characteristics for the human diet (protein rich!), and the suitability for enriching nitrogen content in soil, leguminous plants are very attractive for research aimed at improving yield/stress tolerance. It is reasonable to assume that MYB proteins act in abiotic stress signaling in probably all legume species. In this context, a database of gene expression profiles of salt-treated roots in *Medicago truncatula* (http://bioinformatics.cau.edu.cn/MtED/) is worth mentioning. This database provides a number of useful bioinformatics tools and is intended to help in selecting gene markers to improve abiotic stress resistance in legumes [70].

A heterologous oligonucleotide microarray approach leads to the identification of drought-induced genes in banana. [75]. Many of these, including MYB genes, displayed homology to genes underlying QTL for drought and cold tolerance in rice. Similar experimental approaches may speed up the discovery of key regulators in abiotic stress signaling in other crop species. First attempts toward microarray studies for the identification of abiotic stress-responsive genes in sunflower have been reported [76].

Despite the merits of microarray studies, one has to be cautious with data interpretation. On the one hand, transcript abundance does not always correlate with protein abundance or activity. On the other hand, most expression studies cover only one or few time points; therefore, genes with transient transcript accumulation might be missed. Even if a stress persists, regulatory proteins (such as MYBs) may not have to be synthesized continuously. Rather, once they have initiated downstream signaling through induction of their target genes, subsequent signaling components "take over." Transient accumulation of MYB transcription factors is also a means of preventing "spillover."

The fine-tuning of MYB-mediated signaling is exemplified by AtMYB4. AtMYB4 negatively regulates the expression of a rate-limiting enzyme in the phenylpropanoid biosynthesis (see above). The repressing effect exerted by AtMYB4 occurs in a dose-dependent manner. Moreover, upon UV exposure, *AtMYB4* expression is down-regulated, indicating that derepression is an important step in acclimation to UV [56].

21.7.2
Transcription Factor Databases

Another milestone in plant stress research was the development of transcription factor databases (TFDB) (see Table 21.2). These have become available for *A. thaliana*, polar rice, *Chlamydomonas reinhardtii*, and *Ostreococcus tauri* [77]. A similar fruitful database and excellent tool providing a more substantial idea on the complexity of the MYB (and other transcription factors) family also exists for wheat [30]. This tool integrates information on 203 MYB and 116 MYB-related genes.

Another example is the database LegumeTFDB, integrating a diversity of information for transcription factors of *Glycine max*, *Leonurus japonicus*, and *M. truncatula*. Hyperlinks to available expression profiles as well as information on *cis*-elements in transcription factor promoters will further aid the identification of stress-related MYB proteins. [78]. For instance, the database can be searched for all TF genes, in a given species, in a given TF family, whose promoters carry a stress-associated *cis*-element(s) of choice. Questioning this database for members of the *G. max MYB* gene family (333 members) that contain MYBR *cis*-element(s) returns 87 hits. In contrast, the larger family of AP2_EREBP transcription factors (405 members) contains proportionally fewer MYBR elements (87/405) (Pitzschke, own observation). The overrepresentation of MYBR elements in promoters of *MYB* genes might be indicative of a sophisticated crosstalk between several MYB members. In addition, autoregulation (a MYB protein regulating its own expression) is also a likely explanation.

21.8
Genetic Engineering, Limitations, Optimizations, Practical Considerations

For the genetic engineering of stress-resistant plants, "simply" overexpressing a transcription factor of interest might often not lead to the anticipated result. Two reasons of failure and means to circumvent these problems are outlined as follows:

1) Overabundance of the transcription factor can have adverse side effects.
2) Posttranslational modification is required for full activity.

1) Most transcription factors carry a nuclear localization signal. Both bioinformatic and *in vivo* studies document that the majority indeed localize to the nucleus, that is, the subcellular site of action. Overexpression of a transcription factor of interest that constitutively localizes to the nucleus and that does not

require posttranslational modification or additional (limiting) transcription factors for reaching full activity might result in hyperactivation of stress genes to an undesirable extent, particularly if growth retardation or developmental defects are the price of enhanced stress resistance conferred by constitutive expression of stress genes. This is exemplified by the dwarfed phenotype of *Arabidopsis AtMYB96* overexpressing plants [28]. Moreover, in several cases attempts to generate transgenic plants constitutively overexpressing *MYB* genes were unsuccessful, possibly due to the toxicity of excessive amounts of the protein (Pitzschke, unpublished) [65].

Here, a more controlled approach might be the method of choice. To minimize negative effects on plant growth due to the use of a constitutive promoter, the use of stress-inducible promoters (*rd29A*, *COR15A*) to drive ectopic expression of transcription factors was previously reported [79, 80]. Alternatively, a chemical-inducible, ecdysone receptor-based system suitable for field applications [81] may be used.

2) In some cases, transcription factors need to be posttranslationally modified to achieve full activity. Such modification can alter the stability, localization, dimerization properties, DNA binding activity, or *cis*-motif preference (see Section 21.6.3). If the site and type of modification is known, protein variants carrying single amino acid exchanges (e.g., mimicking a constitutively phosphorylated state of a transcription factor) should be considered. This strategy has been successfully pursued for PtMYB4 from pine [70] and the MYB44-regulating bZIP protein VIP1 [66]).

21.9 Outlook

The high functional conservation of MYB transcription factors across species will accelerate the process of engineering crops with improved stress tolerance. As many studies have shown, overexpression in heterologous plant species can indeed produce the anticipated stress phenotype.

However, interfering with MYB transcription factor activity has its limitations that one should be aware of: enhanced tolerance to one type of stress might be associated with a reduced tolerance to other stress types. For instance, *Arabidopsis* mutants lacking a functional MYB gene, AtBOS1 (AtMYB108), are more tolerant to infection by a nectrotrophic pathogen (*Botryotinia cinerea*), but have a reduced resistance to drought, salt, and oxidative stress. [82]. Therefore, in-depth studies of a range of stress responses will have to be carried out before engineered plants are ready for the field.

Transporters and Abiotic Stress Tolerance in Plants

Vandna Rai, Narendra Tuteja, and Teruhiro Takabe

Salt and drought are important factors in reducing the crop yields. Transporters play significant roles for stress tolerance in plants. After completion of gene sequencing of rice and *Arabidopsis*, rapid progresses in plant transporters have been made. Here, recent progresses in the plant transporters such as NHX, HKT, sucrose transporters and amino acid transporters for abiotic stress tolerance are discussed. Recently, whole-genome expression profiling has been done to get the information on the roles of transporters under drought and salt stress conditions. Salt- and/or drought-tolerant and sensitive rice varieties, as well as expression profiling for *Arabidopsis* transporters, were used to obtain the important genes for salt/drought stresses. Recent progress on these approaches has also been discussed.

22.1
Introduction

World population is increasing at an alarming rate to reach about 9 billion by the end of 2050. On the other hand, increase in food productivity is hampered by worsening environmental problems. Salt and drought are major factors in decreasing crop production on irrigated land worldwide. A recent estimate by FAO suggested that around 6% of the world's total land area and 20% of irrigated land are affected by high salinity [1]. In India, 9 million ha of rice area is affected by salinity, leading to a considerable loss of grain yield. Thus, there is an urgent need to develop varieties that can grow well in saline environments to enable the farmers to reap good harvests. However, there are only few instances where salt-tolerant cultivars have been developed. The reason for this is that salt stress is a very complex trait, has many components, and is caused by the coordinated action of multiple stress-responsive genes. Recent progress in genetic approach is remarkable. Analysis of various genomes suggested that 10% of all the proteins functions as transporters, and in *E. coli* 42% of proteins are transporters. About 200 families of

Improving Crop Resistance to Abiotic Stress, First Edition.

transporters are reported, among which ABC is the largest family. Here, transcriptome and functional analysis of plant transporters in salt and drought stresses will be described.

22.2 Basic Description of Transporters

Transporters vary in their structure and size from small organic molecules and peptides to multisubunit complexes. Membrane transport proteins are divided into three categories: pump, channel, and secondary transporters. Two modes of transport across membranes are known: one is the simple diffusion where no carriers are involved and the other is carrier-mediated diffusion. There are two modes of mediated diffusion, one is passive transport and other is active transport (Figure 22.1). Passive transport is energy independent and occurs following the concentration gradient as mobile carriers (valinomycin, nigericin, dinitrophenol, etc.), protein translocators (porins, erythrocyte glucose transporter), channel-forming ionophores (gramicidin), voltage-gated channels (Na^+, K^+, and Ca^{2+} channels), ligand-gated channels, and mechanosensitive channels. Another is an active transport that is energy dependent and occurs against concentration gradient. It is the primary active

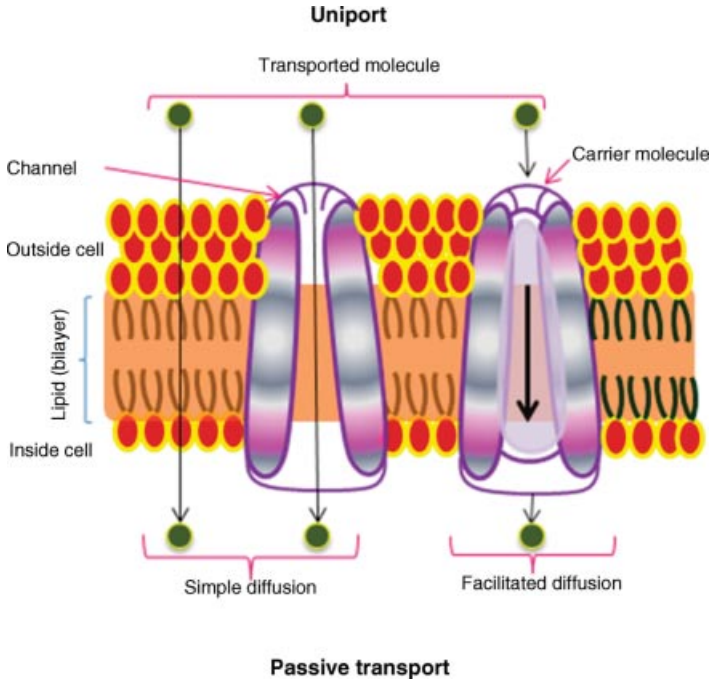

Figure 22.1 Mechanism for passive transport.

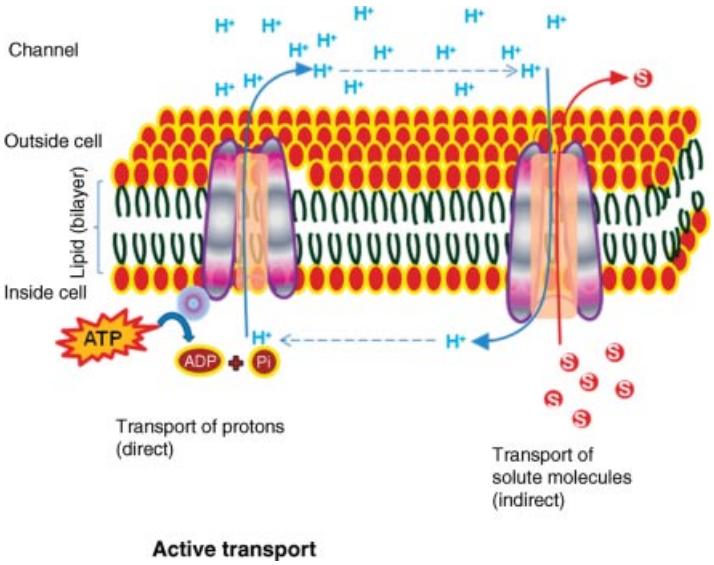

Figure 22.2 Mechanism for energy-dependent transport.

transport that utilizes energy of ATP hydrolysis that includes P-type ATPases (H^+/K^+-ATPases, Ca^{2+}-ATPase), V-ATPases, and F_1F_0-ATPases (Na^+-ATPase, H^+-ATPase) (Figure 22.2). The main roles of the ATP-dependent (pump) proteins include transport of molecules in specific directions independent of the environmental situation and transport of ions to form a concentration gradient (active transport). The secondary transporter system works through concentration gradient dependent on cotransporter molecules (Figure 22.3). More than 100 species of secondary transporter gene families are described [2]. Compared to those in the pump and

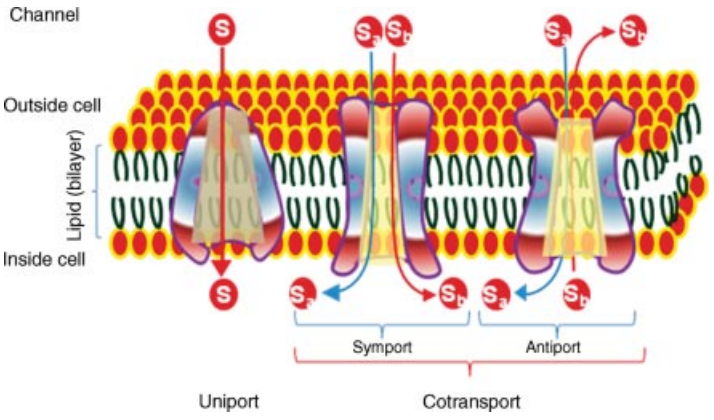

Figure 22.3 Mechanism for secondary transporters.

channel systems, the genes involved in the secondary transporter system are most divergent in plants. In plant system, many cations, anions, metals, and drugs are cotransported with H^+ ions. Only few transporters use Na^+ ions as cotransporter molecules for efflux of ions from the cytoplasm, so plants do not need sodium uptake. For secondary transport, different types are known, such as symporters (two solutes move in same direction, lac permease, Na^+/glucose transporter), antiporters (two solutes move in opposite directions, Na^+/H^+ antiporter), and uniporters (mitochondrial Ca^{2+} transporter). Ion channels have the "gates" in the membranes that help in opening or closing of gates with response to signals such as mechanical or electrical stimulation and ligand binding. Many channel genes for ion homeostasis and signal transduction (CytB and MscS) are found in plants. The MIP (major intrinsic protein) gene family encoding water transport proteins are well developed in plants. MIP proteins are abundant in the plasma membrane (15–20% of total membrane protein) and vacuoles (30–50% of total membrane protein) of plants. Therefore, a high level of water transport is carried out at plant cell membranes.

22.3 Role of Transporters for Salt Tolerance in Plants

22.3.1 Na^+ Transporter

Plant salinity tolerance is a function of Na^+ exclusion, tissue tolerance to Na^+, and osmotic tolerance [3] and depends to a varying extent on each of these three components, even within a single species [4]. Water and ions (primarily Na^+, K^+, and Cl^-) transport is the key to these three mechanisms of salinity tolerance for transport both into and throughout the plant as this transport is highly interconnected with salinity tolerance (Figure 22.4). For saline soils, NaCl is the dominant salt and both Na^+ and Cl^- are metabolically toxic to plants at high concentrations in the cytoplasm.

An extensive study was done on model plant *Arabidopsis* for salinity stress and many genes were found out for salt tolerance that consisted of a group of transporters, including AtNHX1, AtSOS1, and AtHKT1 [5–12]. The *AtNHX1* gene was identified by sequence homology to the *Nhx1* gene in *Saccharomyces cerevisiae*. The AtNHX1 transporter functions in Na^+ sequestration into the vacuole during salinity stress to maintain a high K^+/Na^+ ratio in the cytosol [6, 7]. The salt overly sensitive 1 (*SOS1*) gene, which has been identified in a genetic screen [8], encodes a membrane protein that is homologous to plasma membrane Na^+/H^+ antiporters from bacteria and fungi [13]. Mutant analyses of *sos1* plants have led to a working model of the SOS1 transporter under salinity stress, where SOS1 prevents Na^+ level in xylem sap by unloading/loading of Na^+ into xylem vessels decided by the strength of salinity stress, and influenced Na^+ transport from roots to shoots [13]. SOS1 also functions in direct Na^+ extrusion to outer environment from the root tip where meristematic cells do not have large vacuoles for Na^+ sequestration [13]. Direct Na^+ extrusion by

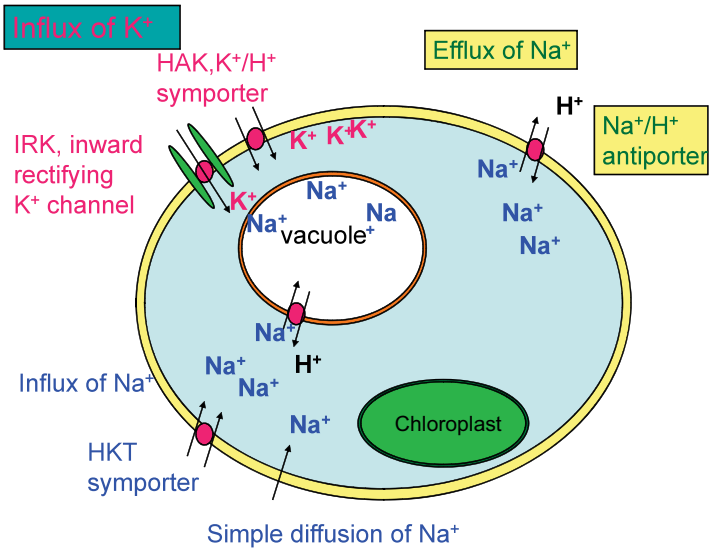

Figure 22.4 Plant cell showing NHX and HKT type of transporters function.

SOS1 from mature epidermal zones of *Arabidopsis* roots was also suggested [14]. *AtHKT1;1* was identified as an *Arabidopsis* homologue of the wheat *TaHKT2;1* [9, 15]. When expressed in heterologous systems such as *S. cerevisiae* and *Xenopus laevis* oocytes, AtHKT1;1 prefers selective Na^+ transport. The disruption of the *AtHKT1;1* gene makes plants hypersensitive to Na^+ resulting in severe leaf chlorosis and Na^+ overaccumulation in shoots under saline conditions [10, 16–19]. For some species such as rice and wheat, the concentrations of Na^+, but not Cl^-, in shoot or root are negatively correlated with salt tolerance [20–23], while the reverse is true for other species. In soybean, leaf Cl^- was negatively correlated with salt tolerance, but there was no significant correlation for leaf Na^+ [24].

22.3.1.1 Uptake of Na^+ to the Root

Na^+ uptake is mediated by Ca^{2+}-sensitive and -insensitive processes. Addition of up to 10 mm Ca^{2+} to the external solution will (generally) reduce the toxic effects of Na^+ [24], probably due to the inhibition of unidirectional Na^+ influx by Ca^{2+}. Ca^{2+}-sensitive Na^+ influx likely occurs through nonselective cation channels (NSCCs) [25]. Many candidates for NSCCs are present, such as cyclic nucleotide-gated channels (CNGCs) [26] and glutamate-activated channels (GLRs), but still the genetic nature of NSCCs is not well known.

22.3.2 K^+ Transporter

Potassium (K^+) is an essential macronutrient that is required for diverse cellular processes, such as osmotic regulation, maintenance of membrane potential, enzyme

activity, protein and starch synthesis, respiration, and photosynthesis. Various studies have indicated that increasing cytosolic K^+ levels relative to Na^+, thus increasing the K^+/Na^+ ratio, is crucial for Na^+ tolerance in plants, and maintaining high K^+/Na^+ ratio in shoots is highly correlated with salinity tolerance in glycophytes [17, 28]. Physiological experiments have shown that the K^+ content in glycophytes can reach 1.5–5% of the dry weight, and the majority of K^+ absorbed in roots are transported to shoots, which is a major limiting factor of the shoot growth and yields of crop plants. Since excessive Na^+ ions inhibit various important cellular processes, many of which are directly correlated with K^+ transport and essential functions of K^+, it is not surprising to see that K^+ alleviates toxic effects of Na^+ and that a high K^+/Na^+ ratio in shoots, especially in leaves, is preferred by glycophytes.

Plant cells utilize K^+ as a major osmotically active solute to maintain turgor and drive irreversible cell expansion and reversible changes in cell volume. Potassium is a major factor in resistance to drought, salinity, and fungal diseases [29]. Plants possess a large number of genes encoding K^+ transporters, including high-affinity transporters and ion channels [10]. The K^+ channels contribute to more than 50% of the nutritional K^+ uptake under most field conditions [30]. *Arabidopsis thaliana* AKT1 (*Arabidopsis* K^+ transporter 1) was reported to be channel mediated that is regulated by voltage (a process known as gating in which the channels open and close), and in this case to favor channel opening at negative voltages that promote net K^+ influx. AKT1 and its relatives are members of the Kv-like (Shaker-like) family of channel proteins that form functional units as tetrameric assemblies around a central pore [31, 32]. Other channels such as SKOR and GORK facilitate K^+ flux outward across the plant plasma membrane. In the root, SKOR is primarily localized to xylem parenchyma cells and is thought to enable the efflux of K^+ from these cells into the xylem for transport to the shoot [33]. GORK contributes to stomatal closure, which is important for plant adaptation to environmental change [34]. Membrane depolarization is required for potassium ion flux through SKOR and GORK. Both SKOR and GORK share the same basic structural features of the inward-rectifying K^+ channels, including AKT1 and KAT1 (K^+ channel of *A. thaliana* 1), although their gating characteristics differ profoundly.

22.3.3 Cl^- Transporters

Mechanisms of Cl^- transport in plants are not well known; however, it is very important to minimize Cl^- toxicity for salt tolerance. Key aspects of Cl^- transport that contribute to salt tolerance in some species include reduced net xylem loading, intracellular compartmentation and greater efflux of Cl^- from roots. Candidate genes for anion transporters are identified that may be contributing to Cl^- movement within plants during salinity [35]. The initial uptake of Cl^- (and Na^+) at the root–soil interface would control the transport of these ions to shoots. NaCl-induced efflux of Cl^- has been observed in several species, for example, in the halophyte *Diplachne fusca* [36], barley [37, 38], sorghum [39], and *Arabidopsis* [40]. Genotypic differences in Cl^- efflux have also been observed. In a recent study, using scanning ion-selective

electrodes, roots of salt-tolerant *Populus euphratica* treated with 100 mm NaCl for 15 days exhibited a significant net efflux of Cl^- at 400–1200 mM from the apex [41]. Under the same conditions, no efflux of Cl^- was observed in the salt-sensitive *Populus popularis* and responses were NaCl specific (and not a result of hyperosmotic stress). The conclusion from this study was that Cl^- (and Na^+) extrusion from *P. euphratica* roots contributed to ion homoeostasis under saline conditions [41].

22.3.3.1 Intercellular Compartmentation of Cl^- is One Way to Cope with High Cl^- Toxicity

Compartmentalization of Cl^- between different cell types in both roots and shoots contributes to salt tolerance in some species. In leaves, Cl^- is preferentially accumulated in the epidermis, reducing Cl^- toxicity in mesophyll cells that are more important for photosynthesis. A salt-tolerant cultivar of barley was more effective in excluding Cl^- from mesophyll cells, compared to a more sensitive barley cultivar [42]. In a study comparing a salt-tolerant barley cultivar with a salt-sensitive durum wheat, Cl^- was preferentially accumulated in the epidermis compared to the mesophyll, but to a similar extent in both species [43]; thus, allocation of Cl^- to particular cell types might not be a major factor contributing to salt tolerance. Further work with other genotypes that have similar shoot Cl^- concentrations, but differ in salt tolerance, could help determine if partitioning of Cl^- in epidermal cells, away from the mesophyll, contributes to salt tolerance. Another form of intercellular compartmentation of Cl^- in leaves is the accumulation of Cl^- in salt glands or bladders. These highly specialized cell structures are unique to some halophytes, which can accumulate Cl^- (and Na^+) in salt glands on leaf surfaces to lower internal leaf ion concentrations. Cl^- secretion via salt glands can be significant, with approximately 20% of leaf Cl^- excreted from salt glands of *L. fusca* at 100 mM NaCl [44]. A cation-chloride cotransporter (CCC) was localized to leaf trichomes and hydathodes in *Arabidopsis* [45] and was recently identified in salt-tolerant indica rice [46]. However, the exact role of these transporters in Cl^- transport is still not very clear. At the root level, Cl^- transport across different cell types from the cortex to the xylem could affect the total flux of Cl^- to the shoot [47].

Intracellular compartmentation of Cl^- is also important since low shoot concentrations of Cl^- and Na^+ are not always correlated with salt tolerance. Most species can "exclude" Cl^- and Na^+ up to 90–98%, [48], but salt tolerance is improved by efficient sequestration of Cl^- and Na^+ in vacuoles to prevent toxic level accumulation in the cytoplasm. Halophytes have mechanism for controlled uptake of Cl^- (and other ions) to maintain turgor-related growth and this relies on the effective sequestration of Cl^- into vacuoles [49, 50].

Plant cell vacuoles have capacity to accumulate up to 500 mM Cl^- [51]. In the halophyte *Suaeda maritima* growing at 200 mM NaCl, Cl^- concentrations ranged from 86 to 95 mM (cytoplasm), 430 to 465 mM (vacuole), and 111 to 130 mM (cell wall), with similar values found for Na^+ [52]. Using the fluorescent dye lucigenin, initial Cl^- transport into tonoplast vesicles from the salt-tolerant ice plant (*Mesembryanthemum crystallinum*) followed saturation kinetics, with a K_m of about 17 mM [53]. This K_m is significantly higher than those found for less salt-tolerant

species, for example, red beet (6.5 mM) [54]. The vacuolar Cl^- transport in the halophytic ice plant saturates at higher Cl^- concentrations than that for less salt-tolerant species [53]. In *Atriplex gmelini*, Cl^- concentrations of isolated vacuoles were 260 mM, which was almost the same as that measured in protoplasts, suggesting that for this halophyte, most of the leaf Cl^- (and Na^+) is compartmentalized into vacuoles [55]. For some species, there is indirect evidence that more efficient vacuolar sequestration of Cl^- is associated with salt tolerance as salt-tolerant genotypes of citrus, grapevine, and *Lotus* with low shoot Cl^- actually have higher root Cl^- concentrations compared to the more sensitive genotypes [47], suggesting more efficient compartmentation of Cl^- in root vacuoles for the tolerant genotypes. The efficient intracellular compartmentation of Cl^- is linked to salt tolerance. In a comparison between two maize genotypes that differ in salt tolerance, the more salt-sensitive genotype had consistently higher root cytoplasmic Cl^- concentrations than the tolerant genotype (based on ^{36}Cl flux analysis and electron microscopy) [52]. The estimates of cytoplasmic Cl^- concentrations were surprisingly high, with approximately 563 mM in the sensitive genotype and 360 mM for the tolerant genotype (measured at 100 mM NaCl) [52]. These values are consistent with other published estimates, as cytoplasmic Cl^- was also predicted to be about 350 mM for barley at 100 mM NaCl [38]. High ion concentrations in the cell wall may result in reduced turgor, leading to reduced shoot growth in the more sensitive genotype.

22.4 Amino Acid Transporters

One of the metabolic adaptations to high salinity in plants is the accumulation of compatible solutes [56]. Glycine betaine and proline are potent compatible solutes that are produced widely under salt/drought stress in flowering plants, such as Gramineae, Amaranthaceae, Malvaceae, and Compositae [57]. Within the amino acid transporter (ATF) superfamily, the amino acid permeases (AAPs) mediate proton-coupled uptake of structurally diverse amino acids, including proline. Proline transporters (ProTs) preferentially transport proline but no other amino acids [58, 59]. However, ProTs from tomato (LeProTs) were subsequently shown to transport both betaine and proline, although tomato is a betaine nonaccumulating plant [60, 61]. The homologous transporters were isolated from betaine accumulating mangrove *Avicennia marina* and were shown to transport betaine and proline [62]. So far, functional properties of ProTs have been reported in betaine nonaccumulating plants; *A. thaliana* (AtProT1–3) [58, 61], tomato (LeProT1–3) [60], and rice (OsProT1) [63], and betaine accumulating plants; and mangrove (AmBet/ProT1–2) [62], sugar beet (BvBet/ProT1) [64], and barley (HvProT1-2) [65, 66]. Among them, the selectivity of rice ProT for betaine remains uninvestigated [63], and the barley HvProT1 was reported to recognize proline, but not betaine [65]. All other transporters mediate transport of both betaine and proline.

Betainet is a small, nontoxic molecule that increases the osmotic potential of the cytoplasm without disturbing metabolism by stabilizing protein and membrane

structure against the damaging effect of high salinity [67]. Since betaine is a stable metabolic end product and not degraded in plants [68], accumulation patterns of betaine at cellular and plant levels are regulated by the synthesis and transport of betaine. In higher plants, betaine is synthesized by a two-step oxidation of choline [69]. The first step (choline, betaine aldehyde) is catalyzed by ferredox-independent choline monooxygenase in Amaranthaceae (e.g., spinach), while its corresponding enzyme in Gramineae (e.g., barley) has not been found [70, 71]. The last step is catalyzed by NAD^+-linked betaine aldehyde dehydrogenase (BADH) [72–74]. In Amaranthaceae, both steps are shown to be strictly localized in chloroplast stroma [75]. On the other hand, in barley, two *BADH* proteins are localized in peroxisomes and cytosol, respectively [76–78]. The accumulation of betaine is one of the adaptive strategies to adverse salt stress conditions [79, 80].

When betaine was applied exogenously to old leaves, it was translocated preferentially into young leaves and roots [64]. In response to salt stress, betaine levels increased in all tissues, but most significantly increased in young leaves. Expression of betaine transporter (BvBet/ProT1) was more strongly induced in old leaves than in young leaves, indicating importance of long-distance translocation of betaine [64].

γ-Aminobutyric acid (GABA) is a four-carbon nonprotein amino acid present in prokaryotes and eukaryotes. One *AtGAT1* (At1g08230) code for an H^+-driven, high-affinity GABA transporter from *Arabidopsis* was identified [81]. AtGAT1 did not transport betaine and proline. *AtGAT1* expression was highest in flowers and under conditions of elevated GABA concentrations such as wounding or senescence. GABA level increased under various stress conditions, such as low temperature, mechanical stimulation, and oxygen deficiency [82].

22.5 Sucrose Transporters

Sugars are essential as major energy source, substrates for polymer synthesis, storage compounds, and carbon precursors that are required for a large number of metabolic reactions in plants. Several transporters are required for distribution of sugars not only in the cells but also for long-distance transport [83]. Salinity stress enhances sugar accumulation in melon fruits [84]. In plants, soluble sugars are present in the form of glucose, fructose, and sucrose. Sucrose can be directly transported into sink cells or tissue or can be taken up by sucrose transporters or hexose transporters [85]. Under abiotic stress conditions, galactinol and raffinose accumulate in plant cells [86]. Overexpression of *GolS2*, an abiotic stress-inducible gene, increases galactinol and raffinose concentrations and improves abiotic stress tolerance in *Arabidopsis* [86]. It showed that sugars might also function as osmoprotectants; however, not much is known about their physiological function under abiotic stresses. The expression of genes is induced under abiotic stress conditions not only for sugar synthases but also for sugar transporters [87], and sugars might be transported to specific tissues or organelles under abiotic stress conditions [88]. Facilitated diffusion and secondary active transporters for sugars were found in plants [89–91]. They are mainly

secondary active transporters [88, 92–94], and in many cases the activities of secondary active transporters in plants depend on proton gradients. A plant sugar transporter from *Arabidopsis* STP1 was isolated and was observed to be a proton/hexose symporter localized at the plasma membrane. Two proton-dependent antiporters involved in glucose influx across the tonoplast were identified in *Arabidopsis* [88, 94]. From *Arabidopsis*, an abiotic stress-inducible transporter for monosaccharides from ERD6 family was isolated and named ESL1 [89]. Expression of *ESL1* was found to be induced under drought and high-salinity conditions and also with exogenous application of abscisic acid. *ESL1* is mainly expressed in pericycle and xylem parenchyma cells and was detected at tonoplast in transgenic *Arabidopsis* plants and tobacco BY-2 cells. The K_m for glucose uptake activity of mutated ESL1 in the transgenic BY-2 cells was extraordinarily high, and the transport activity was independent of a proton gradient, indicating that ESL1 is a low-affinity, facilitated diffusion transporter. It was reported that ESL1 might function coordinately with the vacuolar invertase to regulate osmotic pressure by affecting the accumulation of sugar in plant cells [89].

22.6 Transporters in Rice and *Arabidopsis*

When a comparison is made between numbers of membrane transporter genes in *Arabidopsis* and rice, many transporter genes are found to be similar in these plants; *Arabidopsis* has a more diverse array of genes for multiefflux transport and for response to stress signals, and rice has more secondary transporter genes for carbohydrate and nutrient transport [2]. In rice, a total of 1200 membrane transporters are identified, among which 800 are secondary transporters, 180 are pumps, and 120 are channel transporters. In pumps, 153 are ABC and 57 are P-ATPase kinds of transporters; in channels, MIPs are maximum 38, Hsp are 23, 14 CIC, and annexins 10; and in secondary transporters, MFS are 145, MC 56, DMT 57, CpA2 16, and CACA 23 [2]. Whole-genome expression profiling was examined to find out transporters under salt and drought stress conditions in indica rice.

Microarrays were used to identify differentially expressed genes of rice in response to salt stress for shoots [95] and roots [96] and to compare rice with other cereals [97]. Problem with these approaches was that they also identified many false positives because of treatment and the use of different species. To minimize these risks, the use of cultivars with different salt sensitivity for comparative transcriptomics studies was used for salt and drought stress [98]. For salinity, CSR-11 (salt tolerant) and VSR-156 (salt sensitive), as well as for drought Vandana (tolerant) and IR-64 (sensitive), were used to identify transporters involved in both stresses. Expression profiling was done and presented as heat map (Figure 22.4) with a list of 72 genes that included all the transporters expressed differentially. *Arabidopsis* microarray data for salinity stress and drought stress were used. All differentially expressed transporters were extracted after analysis ($p < 0.05$) and with a fold change >2. False discovery rates were kept at <2% and heat map for 127 genes for transporters was presented (Figure 22.5). Venn

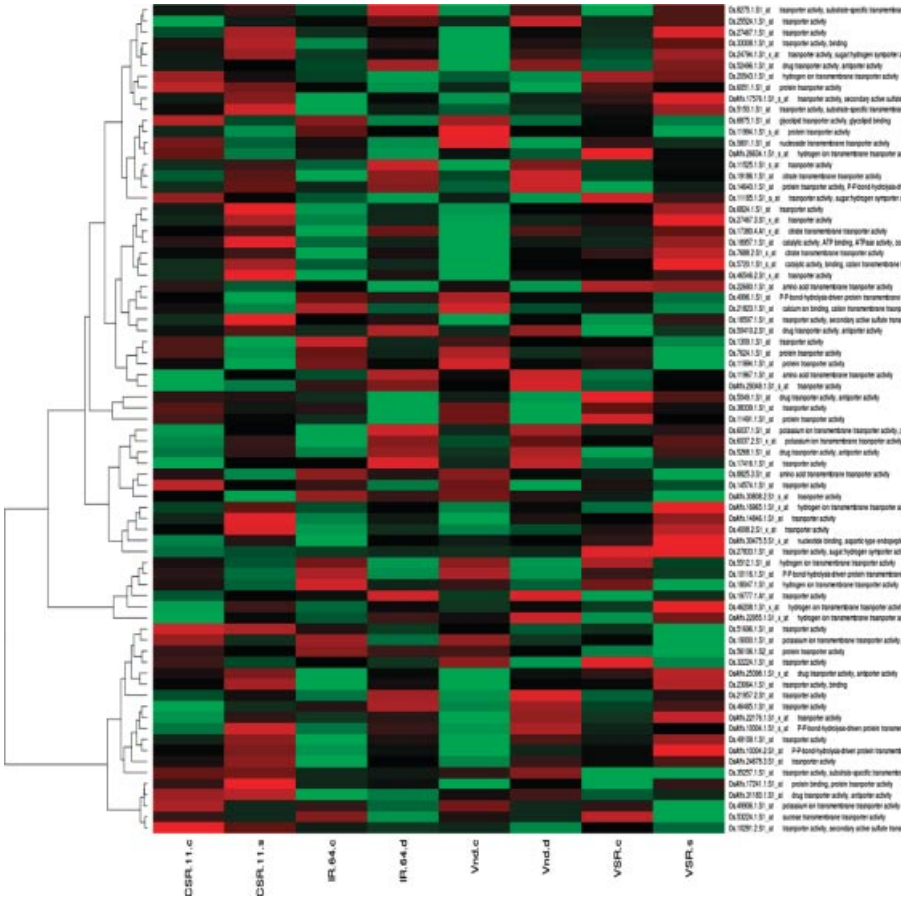

Figure 22.5 The expression profiling of transporters differentially expressed under salt-tolerant (CSR-11), salt-sensitive (VSR), drought-tolerant (Vandana), and drought-sensitive (IR-64) conditions using hierarchical clustering of 70 genes.

diagram (Figure 22.6) for comparing the number of expressed genes under salt and drought conditions showed that 52 genes were common to both stresses that include mainly metal ion, peptide, amino acids Na^+/H^+, sugar, cadmium/zinc, peptide, cation transporter HKT1, phosphatidylinositol transfer-like protein III, aquaporin TIP2.2, and high-affinity cationic amino acid transporters. QTL analyses using rice (*Oryza sativa*) plants identified a gene contributing to salt tolerance of an indica rice cultivar Nona Bokra. The gene encoded a Na^+ transporter, named SKC1 or OsHKT1;5 [28], which is an orthologue of AtHKT1;1. OsHKT1;5 was found to function in Na^+ exclusion from xylem [28]. Two major QTL controlling Na^+ exclusion from leaves in wheat were also identified, which conferred salt tolerance encoding the AtHKT1;1 orthologues HKT1;4 and HKT1;5 [99, 100]. The common requirement of a HKT-mediated Na^+ exclusion from the xylem in *Arabidopsis*, rice, and wheat

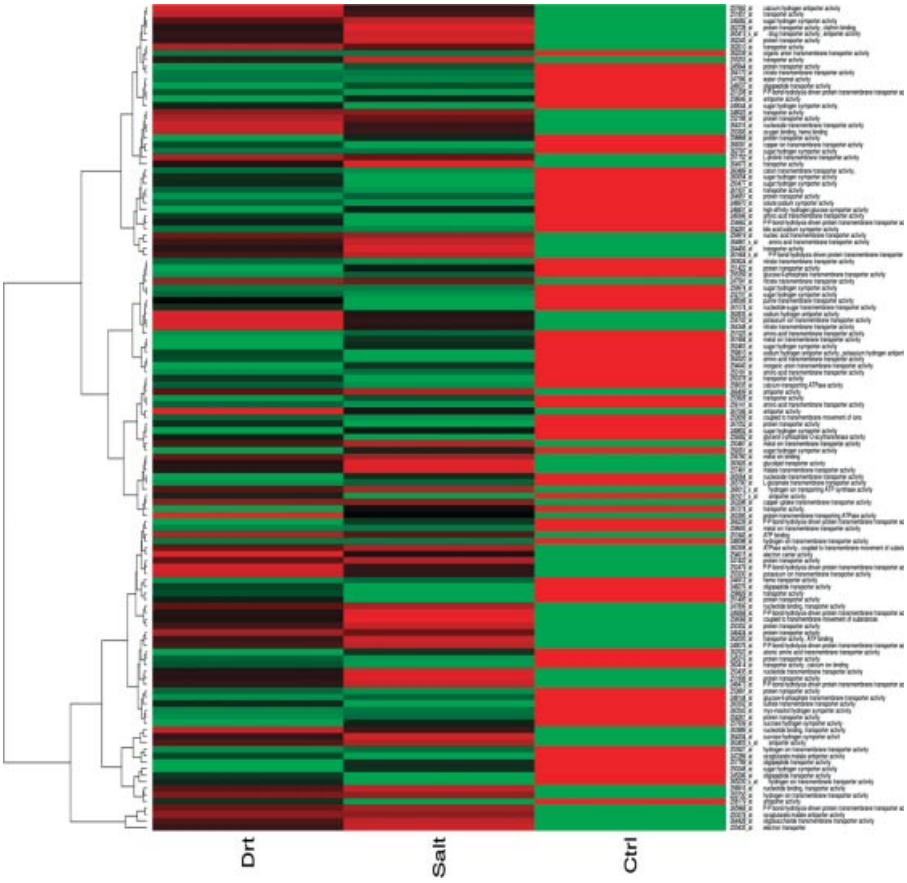

Figure 22.6 The expression profiling of transporters differentially expressed under salt and drought conditions in *Arabidopsis* using hierarchical clustering of 127 genes.

recommended that this is a widely conserved primary salt tolerance mechanism in glycophytes [101]. Rice, a monocot model, contains nine HKT-like genes, which is different from dicot model plant *Arabidopsis* that has a single AtHKT1 [102]. In the case of *Arabidopsis*, 40 genes were common to salt and drought stress conditions (Figure 22.7), which were mainly water channels, ABC transporters, amino acid transmembrane transporter, sugar:hydrogen ion symporter, oligopeptide transporter, antiporter/glucose-6-phosphate transmembrane transporter, oligopeptide transporter, oxoglutarate:malate antiporter, copper ion transmembrane transporter, coupled to transmembrane movement of ions, and sodium:hydrogen antiporter.

The rice genome size (430 Mb) is more than three times that of *Arabidopsis* (125 Mb), but the total number of membrane transporter proteins (1200) is only 1.20 times that in *Arabidopsis* (1000). The total number of differentially expressed transporters under salt and drought stress is 135 in rice, while it was 145 in *Arabidopsis*. Being a wild plant, *Arabidopsis* lives under diverse soil conditions and under environmental

stress, whereas rice is a cultivated crop plant grown under more stable environmental conditions. Therefore, *Arabidopsis* has diverged more than the rice to form transporter systems involved in multiefflux and stress response signaling. However, rice has more pump and secondary transporter genes (ABC, P-type ATPase, MFS, and POT) for carbohydrate and nutrient transport systems [2]. Amino acid (AAAP), ammonia (Amt), sulfate (SulP), metal ion (ZIP), Ca^{2+} (CaCA), and K^+ transport protein gene families (VIC, KUP) are specifically diverged in rice due to nutrient acquisition growth in subtropical plants. It was found that HKT transporters, HKT6, 8, 11, 12, 14, 16, and 17, are differentially expressed. The genome of the japonica rice cultivar Nipponbare has been reported to contain nine *OsHKT* genes with two of them being nonfunctional [102]. Among the remaining seven OsHKT transporters, OsHKT1;5 was found to be an AtHKT1;1 orthologue [102]. A phylogenetic analysis using the amino acid sequences of HKT transporters has shown that the HKT transporters are of two major subfamilies, class I and class II [103]. Remarkable differences between these two classes of HKT transporters were found in the structure of the putative selectivity pore-forming regions and the selectivity for K^+ characterized in heterologous expression systems. HKT transporters are members of a large K^+ transporter family, the HKT/Trk/Ktr family, which retains four selectivity pore-forming regions (p-loops) that show similarity to a bacterial K^+ channel [104, 105]. It was found that a serine to glycine replacement in the first p-loop region of AtHKT1;1 and OsHKT2;1 transporters that show a poor K^+ permeability conferred a robust K^+ permeability, while a glycine to serine replacement abolished the robust K^+ permeability from typical class II transporters TaHKT2;1 and OsHKT2;2 [106]. The OsHKT2;1 transporter is an unusual class II HKT transporter. It is clearly classified into the HKT2 transporter subfamily in sequence analyses [103]. The OsHKT2;1 is a SGGG type, but not a class II representative GGGG-type transporter, and shows a strong preference for Na^+-selective transport in yeast and *X. laevis* oocytes, comparable to typical class I HKT transporters [2, 11].

22.7 Conclusions

The outline above indicates the importance of plant transporters for abiotic stresses. Genomics, proteomics, and molecular functional approaches, coupled with a strong bioinformatics capability, now can be used efficiently for the study of plant transporters involved in abiotic stresses. This understanding of plant transporters can be used for the manipulation of the responses or their transfer to important cereal crop species through conventional, marker-assisted, or transgenic approaches.

Potassium and Sodium Transporters: Improving Salinity Tolerance in Plants

Toshio Yamaguchi, Nobuyuki Uozumi, and Tomoaki Horie

Crop productivity can be greatly affected by soil salinity since high concentrations of Na^+ cause osmotic stress and ion-specific cytotoxicity in most plant species. Plants have developed multiple mechanisms to alleviate Na^+ stresses, which include exporting Na^+ from the cells, compartmentation to vacuoles, and preventing Na^+ from being transported to photosynthetic organs such as leaves. Recent advancements in molecular and genetic studies have led to the identification of several classes of ion transporters that are involved in these processes and have extended our understanding of the molecular mechanisms that plants use to circumvent Na^+ toxicity. Among these, the NHX-type tonoplast cation/H^+ antiporters, the HKT-type plasma membrane Na^+(K^+) transporters, and the SOS1-type plasma membrane Na^+/H^+ antiporters have drawn particular attention due to their physiological significance under salinity stress. Moreover, ectopic tissue-specific overexpression of these molecules has provided promising evidence for the utility of a transgenic approach toward improving crop salinity tolerance using genes encoding Na^+ transporters.

23.1
Introduction

Soil salinity imposes severe deleterious effects on crop productivity in most plant species, mainly through osmotic stress and ion (Na^+)-specific toxicity [1–3]. The accumulation of sodium cations (Na^+) in the cytosol causes serious damage via inhibition of essential cellular processes, including protein synthesis [4] and vital enzyme reactions [5, 6]. Moreover, since photosynthetic processes have been shown to be susceptible to salinity [7], it is important that photosynthetic organs are protected from overaccumulation of Na^+ in order to maintain efficient carbon

Improving Crop Resistance to Abiotic Stress, First Edition.

fixation and biomass production [8]. Na^+ is not an essential mineral ion in plants, and removal of excessive Na^+ from the cells is necessary to reduce Na^+ toxicity. Recent studies have revealed that some classes of Na^+ transporters play crucial roles in Na^+ homeostasis during salinity stress [9–11]. Among them, the *Arabidopsis* plasma membrane Na^+/H^+ antiporter SOS1 (salt overly sensitive 1), the Na^+ transporter AtHKT1;1, and the tonoplast Na^+/H^+ antiporter AtNHX1 have drawn particular interest due to their capacity to transport Na^+, and their molecular functions and physiological roles have been extensively studied. These Na^+ transporters have been described in a number of plant species, and they have been found to contribute to Na^+ extrusion, limited Na^+ accumulation in leaves, and monovalent cation sequestration in plant vacuoles to alleviate sodium stress under saline conditions. In addition, some of these transporters have been shown to improve salinity tolerance of crop plants when their encoding gene is overexpressed.

In this chapter, we will provide an overview of the molecular properties, regulation mechanisms, and physiological roles of distinct classes of transporters that are involved in plant Na^+ tolerance, with particular emphasis on NHX-, HKT-, and SOS1-type transporters. We will also summarize the advances in transgenic approaches using these molecules and discuss the potential for using other K^+ or Na^+ transporters in the improvement of plant salinity tolerance.

23.2 NHX Transporters

23.2.1 Overview

One of the mechanisms that plant cells use to cope with Na^+ stress is compartmentation of Na^+ into the vacuoles, and many reports have indicated that Na^+/H^+-exchanging NHX transporters are involved in this process (Figure 23.1) [2]. The plant Na^+/H^+ exchanger NHX was first identified in *Arabidopsis* via a complementation study using the *Δnhx1* yeast mutant [12], and NHX-type transporters have since been identified in a wide variety of plant species [13–16]. In general, plant genomes contain genes encoding more than one type of NHX isoform; for example, six NHX isoforms have been identified in *Arabidopsis*, rice, and maize (AtNHX1–6, OsNHX1–6, and ZmNHX1–6, respectively), four isoforms in tomato (LeNHX1–4), and at least two isoforms in Japanese morning glory (*Ipomoea nil*; InNHX1-2). Most of the NHX proteins studied to date have been shown to localize to the endomembranes including the tonoplast (see below) and mediate Na^+/H^+ and K^+/H^+ antiport across the membrane by utilizing the H^+ gradient as a driving force, as demonstrated using a yeast heterologous expression system [12, 17–20], isolated plant vacuoles [21], and proteoliposomes containing purified NHX proteins [22, 23].

Phylogenetic analysis has revealed that NHX family transporters belong to the cation/proton antiporter 1 (CPA1) family according to the transporter classification (TC) system [24]. The NHX family includes a distinct subfamily called the IC-NHE/NHX

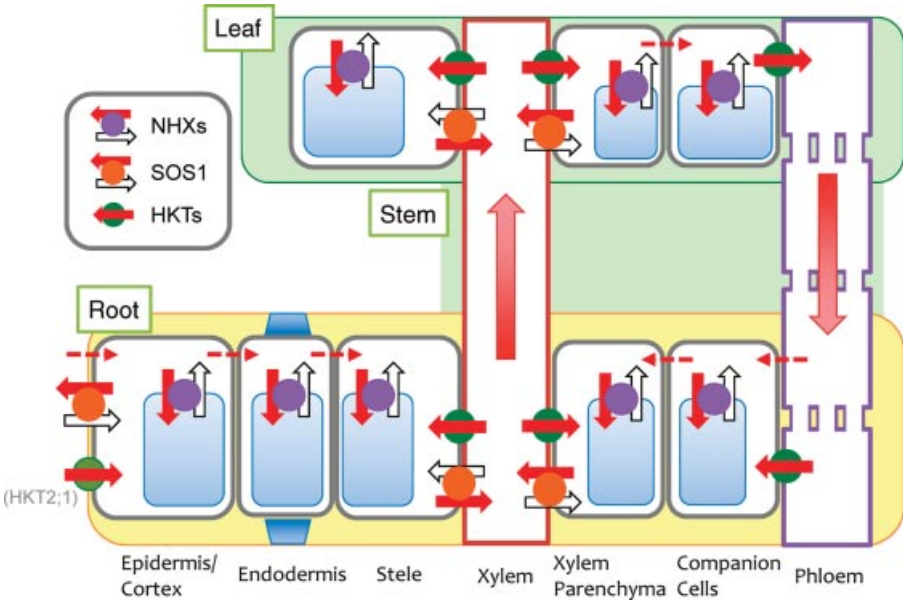

Figure 23.1 Na^+ movement in plant tissues and the involvement of NHX-, SOS1-, and HKT-type transporters in Na^+ detoxification under salinity stress. Na^+ entering through the plasma membrane of the root epidermis is exported out of the cells by SOS1-type transporters or compartmentalized into the vacuole via NHX-type transporters in order to maintain a low cytosolic Na^+ concentration [18, 19, 21, 25, 111, 112, 115, 117]. Excess Na^+ that reaches stele through radial movement is loaded into the xylem via SOS1-type transporters [116]. HKT-type transporters in xylem parenchyma cells function in removing Na^+ from the xylem stream to protect shoots from overaccumulating Na^+ and also in loading Na^+ into the phloem for transporting it back to the roots (Na^+ recirculation) [64, 65, 67, 70, 85–88, 90, 104]. A low cytosolic Na^+ concentration in leaves is achieved through the actions of SOS1- and NHX-type transporters. Note that HKT2;1 transporters have been shown to be a Na^+ influx transporter in wheat [98] and rice [102] when extracellular K^+ availability is limited.

family composed of intracellular (IC) cation/H^+ antiporters [14]. The members of IC-NHE/NHX subfamily can be further subdivided into two groups, namely, class I and class II [14, 15], although the functional relevance of this subdivision is yet to be studied. The tonoplast localization of class I NHXs in various plant species has been well documented using subcellular fractionation [17, 25–28], transient or stable expression of GFP fusion proteins [17, 19, 29, 30], and immunomicroscopic analysis [28]. On the other hand, subcellular localization of a class II NHX was studied by expressing a GFP fusion protein of LeNHX2 in onion epidermal cells, and it indicated a nonvacuolar vesicular localization reminiscent of yeast ScNHX1 [12, 31, 32].

The spatial localization pattern of *NHX* transcripts has been studied in several plant species, indicating diverse expression patterns of NHX isoforms. In rice, *OsNHX1* expression was found in whole tissues, although the expression was higher in shoots than in roots [17]. *MNhx* transcripts of the ice plant *Mesembryanthemum*

crystallinum were found in leaves, stems, flowers, seedpods, weakly in roots [33]. In *Arabidopsis*, *AtNHX1* and *AtNHX2* were the most abundant isoforms and transcripts were widespread across roots and shoots, whereas expression of *AtNHX3* and *AtNHX4* was almost exclusively detected in flowers and roots, albeit in lower amounts than that of *AtNHX1* and *AtNHX2* [18, 19]. *AtNHX5* transcripts were found in all organs tested, although the expression level was lower than that of *AtNHX1* or *AtNHX2* [18, 19]. The expression of *AtNHX6* was found in roots and shoots, but the amount of transcripts was very low [19]. *InNHX1* and *InNHX2* genes of *I. nil* were expressed in virtually all organs tested. *InNHX1* expression is extensively induced in floral organs (particularly in flower limbs at 12 h before flowering), with induction being necessary for flower color change during maturation [20, 29]. It might be too early to generalize, but these results imply the possibility that some NHX isoforms are ubiquitously expressed and play housekeeping roles, while other isoforms have specific expression patterns for more specialized roles in the tissues where they are expressed.

Hydropathy profiling of NHX proteins suggests the presence of 10–12 transmembrane segments and a relatively long C-terminal hydrophilic tail [34]. At present, the structural properties of NHXs have been studied only for AtNHX1, and two distinct topology models have been proposed. The first topology model was proposed based on the results of protease protection assays of yeast vacuoles expressing AtNHX1 proteins with triple hemagglutinin ($3 \times$ HA) epitope tags inserted into the hydrophilic loops [34]. The proposed model was unlike any model for known Na^+/H^+ antiporters and consisted of nine transmembrane segments with three membrane-associated hydrophobic regions that would not span a membrane (TM3, 5, and 6) and a C-terminal hydrophilic tail facing the vacuolar lumen [34]. The C-terminus hydrophilic region of Na^+/H^+ antiporters had been shown to be involved in the regulation of transport activity in mammalian NHE1 [35, 36] and ApNhaP from the cyanobacterium *Aphanothece halophytica* [37]. In both cases, the C-terminal tails were exposed to the cytoplasm and were therefore considered to be involved in sensing of the cytoplasmic pH and cation environment. The regulation of transport activity via the C-terminus has also been suggested for AtNHX1; truncation of the C-terminus region of AtNHX1 resulted in increased Na^+ transport without affecting K^+ transport activity in yeast, suggesting that the C-terminal tail plays a role in modulating cation selectivity of AtNHX1 [34]. However, it should be noted that regulation of transport activity according to this model is supposed to occur from the inside of the vacuole rather than from the cytosolic side, as in the case of the NHE1 and ApNhaP antiporters. In addition, it has been shown that another regulatory protein is involved in the regulation of AtNHX1 activity via the C-terminus. Yeast two-hybrid screening identified a calmodulin-like protein, AtCaM15, as a protein interacting with the AtNHX1 C-terminus. This was confirmed by a pull-down assay using a yeast expression system and affinity purified recombinant proteins [38]. Coexpression of AtCaM15 with AtNHX1 decreased Na^+ transport activity in yeast vacuoles, which suggested the involvement of AtCaM15 in the modulation of AtNHX1 cation selectivity. AtCaM15 was found inside the vacuoles of yeast and plant cells overexpressing AtCaM15, which further supports the above topology

model. Interestingly, it was shown that the interaction between AtCaM15 and AtNHX1 was enhanced as the pH became more acidic. These results indicate that, at physiological conditions, AtCaM15 would be bound to the AtNHX1 C-terminus and AtNHX1 would favor K^+/H^+ antiport over Na^+/H^+ antiport due to the acidic vacuolar luminal pH [38]. In addition, there are several reports that have shown increased vacuolar pH under salinity stress [39, 40]. Such a pH change would cause disassociation of AtCaM15 and AtNHX1, leading to increased Na^+/H^+ antiport and compartmentation of Na^+ into the vacuoles under salinity stress.

Another topology model has been proposed on the basis of *in vitro* translation experiments using truncated *AtNHX1* genes. Sato and Sakaguchi [41] showed that several transmembrane segments of AtNHX1 retain topogenic properties similar to human NHE1 and suggested that AtNHX1 has a topology similar to human NHE1, consisting of 11 transmembrane segments and an intramembranous hydrophobic region (TM9) with the C-terminal tail exposed to the cytoplasm [41, 42].

23.2.2 Physiological Roles of NHXs

It has been well established that NHX isoforms mediate Na^+/H^+ and K^+/H^+ antiport and compartmentation of Na^+ and K^+ into the vacuole (or intracellular vesicles) at a cellular level (Figure 23.1); however, there are few experimental data to clarify the physiological roles of NHX isoforms. The physiological roles of *NHX* isoforms can be deduced from their spatial expression patterns (described above) and, more important, from the stress-specific induction of each *NHX* isoform. Although most of the *NHX* isoforms have been shown to be expressed under nonstress conditions to some extent, the stress-specific expression of several isoforms has also been reported. *AtNHX1*, *AtNHX2*, and *AtNHX5* were induced by salt and osmotic stresses [19, 43], indicating the potential roles of NHX isoforms under these stresses. Rice *OsNHX1* expression is also induced by salt and osmotic stress, although the induction by osmotic stress was less than that by salt, indicating that ionic stress is mainly responsible for this induction [17]. The induction of *NHX* transcripts by salt stress has also been observed for *MNhx* in the ice plant and *InNHX2* in Japanese morning glory [29, 33]. These results suggest a general role for NHXs under salt stress and, in some cases, under osmotic stress.

In addition to its role in stress response, the involvement of an NHX isoform, InNHX1, in Japanese morning glory in the regulation of vacuolar pH has been well documented; a natural variant of *I. nil* that has a transposon insertion in the *InNHX1* locus shows a marked reduction in vacuolar pH of flower petal cells compared to wild type, resulting in purple flower coloration in the mutant as opposed to the blue wild-type flowers. Furthermore, specific induction of *InNHX1* during flower opening has been observed in wild-type petals [20]. Developmental stage-specific induction has also been observed in grape (*Vitis vinifera*) *VvNHX1* during fruit maturation [44]. These results indicate the involvement of NHX isoforms in diverse physiological roles, including cellular ion homeostasis, stress tolerance, and even organ development.

Characterization of a T-DNA insertion mutant of AtNHX1 (*atnhx1*) revealed that this line is indeed susceptible to salinity, as the detrimental effects of sublethal concentrations of NaCl on seedling establishment and leaf size were significantly higher in the *atnhx1* mutant than in the wild type [21]. Furthermore, the leaf epidermal cells of the mature *atnhx1* mutant were much smaller than those of the wild type at an equivalent developmental stage (i.e., equivalent age and position). It should be noted that this reduction in leaf cell size completely disappeared when *AtNHX1* was overexpressed in the *atnhx1* mutant. Vacuoles isolated from the leaves of the *atnhx1* mutant showed almost no Na^+/H^+ and K^+/H^+ activities despite the other five isoform genes being intact, suggesting that AtNHX1 is the predominant isoform in *Arabidopsis* leaves. These results indicate that AtNHX1 is also involved in leaf cell expansion, probably via regulating cation accumulation in the vacuole, which plays a central role in providing turgor necessary for cell expansion. Interestingly, the transcriptional profiling of wild type and *atnhx1* revealed that the loss of a functional *AtNHX1* had a large impact on the expression of other genes involved in ion homeostasis, vesicular trafficking, and protein targeting, suggesting that AtNHX1 has important roles in these processes [45]. The exact mechanisms leading to these alterations in gene expression are unknown at present. However, these results might indicate that cation and pH homeostasis mediated by NHX isoforms plays key roles in a number of cellular processes in addition to stress tolerance.

The physiological role of another NHX isoform, tomato *LeNHX2*, has also been studied by RNAi-mediated gene silencing, and it was found that the degree of gene silencing showed a strong correlation with plant growth and development under normal growth conditions: strongly silenced T0 lines showed poor growth compared to nontransgenic plants and also failed to produce fruits or seeds [31]. Furthermore, growth analysis with moderately silenced plants under saline conditions revealed that silenced plants were more susceptible to Na^+ compared to nontransgenic plants [31]. Although the exact mechanisms behind these phenotypes remain elusive, these results indicate the physiological significance of *LeNHX2* in the growth and development of tomato plants.

23.2.3
Transgenic Approaches to Increasing Salinity Tolerance Using NHX Genes

It has been shown that overexpression of *NHX* isoforms using constitutive promoters increases salinity tolerance of the host plant in all cases except one [46]. The first successful case reported by Apse *et al.* [25] demonstrated that overexpression of *AtNHX1* markedly increased salinity tolerance in *Arabidopsis*. The transgenic plant also showed increased vacuolar Na^+/H^+ antiport activity and cellular Na^+ sequestration, indicating that overexpression of *AtNHX1* increased the plant's ability to detoxify cellular Na^+ by compartmentation into the vacuole [25]. Overexpression of *AtNHX1* has been successfully employed to increase salt tolerance in tomato [47] and *Brassica napus* [48] without affecting their crop qualities. Enhancement of salt tolerance by overexpression of the *AtNHX1* gene has also been observed in other plant species including wheat (*Triticum aestivum* L.) [49], buckwheat (*Fagopyrum*

esculentum) [50], tall fescue (*Festuca arundinacea*) [51], and cotton (*Gossypium hirsutum* L.) [52]. In addition, *AtNHX3* and *AtNHX5* have been shown to increase salt tolerance when overexpressed in sugar beet (*Beta vulgaris*) [53] and Torenia (*Torenia fournieri*) [54], respectively. NHX isoforms from other plant species have also been utilized to increase salt tolerance through overexpression, either in the plant species of their origin or in heterologous host species. For example, enhanced salt tolerance in rice has been successfully achieved by introducing an additional copy of the endogenous *OsNHX1* gene [17], as well as several *NHX* isoform genes from halophytic species, namely, *Chenopodium glaucum* [55], *Pennisetum glaucum* [56], and *Atriplex gmelini* [57]. In addition, it has been shown that the overexpression of the *MdNHX1* gene from the salt-tolerant rootstock of apple (*Malus* × *domestica* Borkh.) conferred Na^+ tolerance to a salt-sensitive variety of apple [58]. These observations illustrate the effectiveness of the overexpression of *NHX* isoforms to produce salt-tolerant crops.

It should be noted, however, that there are some arguments regarding the mechanisms by which these transgenic plants circumvent Na^+ cytotoxicity. Although most of the above transgenic plants showed increased accumulation of Na^+ compared to their parental plants under saline conditions, there were some cases where transgenics exhibited no significant increase in Na^+ content, even though they did display increased salinity tolerance [31, 59]. In one such case, an *Arabidopsis* plant overexpressing *LeNHX2* showed increased K^+ accumulation, while Na^+ accumulation was less than that of the wild type [31]. Increased K^+ content was also observed in sugar beet overexpressing *AtNHX3* [53]. These results might suggest that the acquisition of salt tolerance by *NHX* overexpression may be attributed to, at least in some cases, the alteration of cellular K^+ homeostasis rather than increased compartmentation of Na^+ into the vacuole.

23.3 HKT Transporters

23.3.1 Overview

The first HKT-type transporter was identified in wheat (*T. aestivum*; TaHKT2;1, originally named HKT1). The nomenclature "HKT" is based on the initial description of the transporter's high affinity for K^+ transport (*h*igh-affinity K^+ *t*ransporter) [60]. However, subsequent detailed biophysical transport analyses revealed that TaHKT2;1 shows unique selectivity for Na^+, such that TaHKT2;1 mediates high-affinity Na^+/K^+ symport when the extracellular concentration of K^+ is higher than Na^+, but low-affinity Na^+-selective uniport is preferred when the Na^+ concentration far exceeds that of K^+ [61, 62]. HKT transporters have been isolated from a wide variety of plant species to date, including the halophyte *M. crystallinum* [63], and the ion selectivity of those HKT transporters has been well characterized, indicating that HKT transporters in general mediate robust Na^+ transport [9, 10].

Several plant HKT transporters including AtHKT1;1 from *Arabidopsis* have been shown to exhibit very poor K^+ permeability, preferring Na^+-selective uniport in eukaryotic heterologous cells [64–66]. Experimental approaches to determine the membrane structure of AtHKT1;1 have provided evidence for a four transmembrane–pore–transmembrane topology model [67], which is conserved in the K^+-conducting pore region of HKT/Trk/Ktr transporters as well as the K^+ channels of prokaryotic and eukaryotic cells [68, 69]. Heterologous expression studies of the Na^+-selective transporters *AtHKT1;1* and *OsHKT2;1*, and the K^+-transporting *TaHKT2;1* and *OsHKT2;2*, in combination with domain swapping and site-directed mutagenesis have revealed that a glycine residue (G) at the filter position in four putative p-loops is critical for robust K^+ permeability and more Na^+-selective HKT transporters retain a serine residue (S) at the filter position of the first pore region (SGGG type) in contrast to K^+-transporting HKT transporters that conserve the glycine residues in all four pore regions (GGGG type) [70]. Moreover, ion transport analyses of the bacterial KtrAB K^+ transporter from *Vibrio alginolyticus* have demonstrated that the glycines at the four filter positions are essential for robust K^+ permeability [71]. Together, these analyses support the p-loop hypothesis put forward for the HKT/Trk/Ktr transporters [68, 69]. Phylogenetic analysis of various HKT amino acid sequences has indicated the existence of at least two major subfamilies, namely, class I and class II [9, 10, 72]. One of the characteristics of class I HKT transporters is higher selectivity for Na^+ than other cations, which contrasts with class II HKT transporters that show robust permeability for both Na^+ and K^+. Differences in cation specificity between class I and class II HKT transporters show a close correlation with the glycine residues at the filter positions in the pore regions. Among the amino acid sequences of HKT transporters that are publicly available thus far, the filter positions of all class I HKT transporters are SGGG, as in AtHKT1;1 and OsHKT2;1 [65, 70], except for VvHKT1;2 from *V. vinifera*, which has the aspartic acid residue (D) in the second p-loop (SDGG type) [10]. Conversely, all class II HKT transporters, except for OsHKT2;1, conserve glycine residues at the filter positions, as in the cases of TaHKT2;1 and OsHKT2;2 (GGGG) [9, 10]. OsHKT2;1 is a unique class II transporter that exhibits class I transporter-like features, SGGG-type filter composition, and more Na^+-selective transport [65, 70]. Note that independent analyses have indicated that OsHKT2;1 shows broader selectivity to alkali monovalent cations in heterologous cells [66, 73]. More recent reports, however, have demonstrated that the Na^+-selective transport by OsHKT2;1 and Na^+/K^+ symport by OsHKT2;2 observed in heterologous cells [65, 70, 74] are consistently reproduced in the homologous plant cell system of cultured tobacco BY2 cells (*Nicotiana tabacum* L. cv Bright Yellow 2 cells) [75]. It has been shown that SGGG-type HKT transporters from *Eucalyptus camaldulensis* and *M. crystallinum* are permeable to K^+ when expressed in heterologous systems [63, 76]. Conserved positively charged residues and negatively charged residues have been identified as residues essential for the function of *Synechocystis* Ktr transporters and plant HKT transporters [77–79]. In particular, the electrostatic interaction present in HKT/Trk/Ktr transporters is proposed to be one of the determinants for ion conductivity resulting in the difference between ion channels and transporters [77, 80]. Several

other residues that are important for ion conductivity have also been found in the *Vibrio* Ktr transporter [81, 82].

23.3.2 Physiological Roles of HKTs

A. thaliana plants retains a single *HKT* gene, *AtHKT1;1*, in the genome [64]. Given that genetic suppressor screening using *sos3* (*salt overly sensitive 3*) mutant plants revealed that *AtHKT1;1* gene disruption rescues salt hypersensitivity of *sos3* plants, AtHKT1;1 was initially proposed to be a major pathway for Na^+ entry into roots during salinity stress [83]. Several subsequent reports, however, demonstrated that independent *athkt1;1* mutant lines displayed hypersensitivity to Na^+, accompanied by leaf chlorosis due to overaccumulation of Na^+ in the aerial organs, while maintaining lower root Na^+ concentrations compared to wild-type plants [84–89]. These reports proposed an essential physiological function of AtHKT1;1 in the salinity resistance mechanism in stelar cells in contrast to the proposed function from the *sos3* suppressor screening [83]. Berthomieu *et al.* proposed a "Na^+ recirculation" model, where AtHKT1;1 loads Na^+ into the phloem and Na^+ ions are transferred from shoot to root via the downward phloem stream, thereby preventing overaccumulation of Na^+ in the shoots (Figure 23.1) [85]. On the other hand, since localization of AtHKT1;1 has been observed at the plasma membrane in xylem parenchyma cells, a Na^+ unloading model, which similarly prevents overaccumulation of Na^+ in shoots, especially in leaves, was proposed (Figure 23.1) [84, 87–89]. Note that the role of AtHKT1;1 in the phloem needs to be further investigated as independent laboratories have drawn different conclusions; a significant effect of *AtHKT1;1* mutations on phloem sap under salt stress was found in one study [87], similar to the findings of Berthomieu *et al.* [85], but Na^+ recirculation was concluded not to occur based on $^{22}Na^+$ flux measurements in another study [89]. Further investigation will be needed to figure out the precise physiological function of AtHKT1;1 in stelar cells as a positive salinity resistance determinant. The discrepancies in the proposed functions of AtHKT1;1 *in vivo*, derived from the studies of *sos3 athkt1;1* double mutants and *athkt1;1* single mutants, have not yet been completely reconciled. However, one possible explanation has been proposed, in which the effect of *AtHKT1;1* mutations becomes predominant under higher Ca^{2+} conditions in *sos3 athkt1;1* double mutant plants, such that the plants display *athkt1;1*-derived salt hypersensitivity that suppresses *sos3*-mediated phenotypes [88].

An interesting indirect relationship between AtHKT1;1-mediated Na^+ removal and K^+ homeostasis across xylem vessels has been proposed in the xylem Na^+ unloading model [87]. AtHKT1;1-mediated Na^+ removal into xylem parenchyma cells would cause depolarization of the cells, which in turn triggers K^+ loading into xylem vessels, resulting in maintenance of high K^+/Na^+ ratios in the leaves. This working hypothesis is consistent with similar HKT transporter-mediated mechanisms in crop plants, which are described below (for details, see Refs [9, 10]).

Xylem Na^+ unloading by class I HKT transporters has also been demonstrated to occur in the monocot crop plants rice and wheat. The *SKC1* locus, one of the major

QTL for salt tolerance identified by crossing a salt-tolerant rice cultivar Nona Bokra with a salt-sensitive cultivar Koshihikari, has been found to control Na^+/K^+ content in the xylem sap, and it encodes a class I HKT transporter (OsHKT1;5) [90]. A comparison of *OsHKT1;5* sequences highlighted several point mutations between Nona Bokra-derived and Koshihikari-derived *OsHKT1;5* transporter genes, which were eventually found to be a cause of the difference in the Na^+ transport activity of the two OsHKT1;5 transporters such that Nona Bokra-derived OsHKT1;5 exhibits significantly higher Na^+ transport activity. Moreover, the Nona Bokra-derived OsHKT1;5 was shown to maintain lower Na^+ but higher K^+ contents in the xylem sap during salinity stress, indicating that Nona Bokra plants have the ability to retrieve more Na^+ from xylem vessels under salt stress [90].

Several genetic loci related to salinity tolerance have been found in wheat species, namely, the *Kna1* locus in *T. aestivum* [91] and the *Nax1* and *Nax2* loci in *T. monococcum* [92, 93], which have been shown to be involved in the maintenance of a high K^+/Na^+ ratio in leaves. The *Nax1* and *Nax2* loci were shown to play important roles in preventing root-to-shoot Na^+ transport by excluding Na^+ from the xylem [94]. Interestingly, the *Nax1* locus has been demonstrated to be a leaf-located mechanism controlling the Na^+ content of leaves by excluding Na^+ from the xylem of the leaf sheath, thus preventing Na^+ overaccumulation in the leaf blade. It has since been suggested that the *Nax1* locus encodes the TmHKT1;4 transporter, a class I HKT transporter [95]. In addition, the *Nax2* and *Kna1* loci are proposed to harbor the same gene, *HKT1;5* (*TmHKT1;5* and *TaHKT1;5*, respectively), which also encodes a class I transporter [96]. Together with the results from analyses of the *AtHKT1;1* gene, these results indicate that xylem Na^+ unloading is a common essential mechanism of salinity tolerance in these plants. Genetic studies of wheat class I HKT transporters implies that both HKT1;4 and HKT1;5 transporters might be necessary to exert complete salinity resistance in crop plants [95]. Studies of the molecular and physiological functions of HKT1;4, including OsHKT1;4 from rice, will be important to fully understand class I HKT transporter-mediated salinity resistance in plants.

Physiological functions of the class II HKT transporters have been less reported compared to class I HKT transporters. Several independent studies have demonstrated that mRNA accumulation of class II *HKT* genes in rice, wheat, and barley, including *OsHKT2;1* and *TaHKT2;1*, is induced under K^+-limiting conditions [65, 74, 97], which implies an essential role for these genes in K^+ homeostasis. In addition, the *TaHKT2;1* gene was found to be expressed in root cortical cells [60]. However, given that the *TaHKT2;1* gene knockdown wheat plants were shown to exhibit reduced root Na^+ influx and increased Na^+ sensitivity without showing any significant effect on K^+ uptake, TaHKT2;1 has been suggested to play a major role in Na^+ uptake in K^+-starved roots with a lesser contribution to K^+ uptake [98]. The K^+ uptake system in plants is suggested to be composed of multiple pathways [99–101]. Another possibility that should therefore be considered is that other high-affinity K^+ transport systems would mask the effect of gene knockdown/knockout of K^+-transporting class II HKT transporters. Whether class II HKT transporters might contribute to high-affinity K^+ uptake in plants remains to be elucidated.

OsHKT2;1 is an atypical member of the class II HKT transporters that retains SGGG filter amino acids and more Na^+-selective transport, as in class I HKT transporters [65, 70, 74, 75]. It has been demonstrated that independent null mutations of the *OsHKT2;1* gene cause a reduction in the shoot biomass of the rice mutant lines compared to wild-type plants under conditions with low Na^+ and no added K^+ [102]. Together with evidence for the lack of major Na^+ absorption ability in roots of K^+-starved *oshkt2;1* mutant plants, the OsHKT2;1 transporter has been assigned to play an indispensable role in K^+ starvation-induced nutritional Na^+ uptake and distribution in rice plants to maintain growth under low K^+ availability (Figure 23.1) [102].

In the japonica rice cultivar Nipponbare, only two GGGG-type class II OsHKT transporters, OsHKT2;3 and OsHKT2;4, were found to exist [74]. OsHKT2;3 and OsHKT2;4 are highly identical proteins (more than 93% identity at the amino acid sequence level). OsHKT2;4 has recently been found to display broad permeability to not only K^+ and Na^+ but also divalent cations including Ca^{2+} and Mg^{2+} [103]. Together with the evidence of the root hair plasma membrane localization of OsHKT2;4, a novel physiological role for OsHKT2;4 in Ca^{2+}-linked processes including Ca^{2+} uptake has been proposed [103]. However, evidence for the role of OsHKT2;4 in Ca^{2+} homeostasis *in vivo* in rice plants (e.g., using the *oshkt2;4* rice mutant) is required to confirm this hypothesis.

23.3.3
Transgenic Approaches to Increasing Salinity Tolerance Using Class I HKT Genes

Since the function of known class I HKT transporters is uptake of Na^+ into the cell, ectopic overexpression of this class of transporter genes using constitutive promoters might not be a recommended approach for improving salt tolerance in plants. In fact, overexpression of *AtHKT1;1* using the 35S promoter has been shown to lead to an increase in Na^+ susceptibility due to Na^+ overaccumulation in shoots [104]. Recently, Møller *et al.* demonstrated that the targeted expression of the *AtHKT1;1* gene in root stelar cells (including xylem parenchyma cells) using an enhancer trap system successfully increased Na^+ tolerance of *Arabidopsis* plants [104]. Patch clamp analysis revealed that the Na^+ influx capacities of transgenic root cells were markedly increased. Moreover, the root-to-shoot transfer of Na^+ was significantly decreased in transgenic plants (determined using $^{22}Na^+$ tracer), which is consistent with the finding that the Na^+ content in transgenic plants was lower in shoots but higher in roots compared to control plants [104]. Interestingly, the highest Na^+ accumulation was found in root cortical cells with minor accumulation in stelar cells, suggesting a radial movement of Na^+. Note that cortical cells are highly vacuolated and considered to have a large capacity to sequester Na^+, probably via vacuolar $Na^+(K^+)/H^+$ antiporters (for details, see Section 23.2). These results suggest that overexpression of AtHKT1;1 in root stelar cells enhanced retrieval of Na^+ from the xylem stream to stelar cells, which indirectly enhanced Na^+ sequestration in the vacuoles of cortical cells, resulting in protection of shoots from Na^+ overaccumulation [104]. Similar tissue-specific expression systems have been utilized to express *AtHKT1;1* in root

cortical/epidermal cells of *Arabidopsis* and cortical cells of rice. Interestingly, both attempts increased salt tolerance in the transgenic plants [105]. Overexpression of *AtHKT1;1* in root cortical cells enhanced the expression level of endogenous class I *HKT* genes (*AtHKT1;1* and *OsHKT1;5* for *Arabidopsis* and rice, respectively), thereby increasing Na^+ retrieval from the xylem and sequestration to the vacuole in cortical cells simultaneously [105]. Together, these tissue-specific *AtHKT1;1* expression analyses have indicated that enhancing the activity for Na^+ reabsorption from the xylem vessels is a powerful approach for increasing plant salinity tolerance.

23.4 SOS1 Transporters

23.4.1 Overview

In addition to compartmentation of Na^+ in the intracellular compartments, exclusion of Na^+ from the cytosol across the plasma membrane is also an important mechanism to alleviate cellular Na^+ toxicity in plants [1]. Earlier studies demonstrated the presence of Na^+/H^+ antiport activity at the plasma membrane in a number of plant species, including tomato [106, 107], barley [108], wheat [109], and red beet [110], and this activity was presumed to be responsible for Na^+ efflux from the cell [1]. The SOS1 transporter is one of the best-characterized class of transporters that show Na^+ efflux activity in land plants. The *SOS1* gene was first identified by genetic screening as an essential gene that contributes to salt tolerance in *Arabidopsis* [111]. Genetic mapping and positional cloning revealed that the *Arabidopsis SOS1* gene (also named *AtNHX7*, but hereafter referred to as *AtSOS1*) encodes a large putative membrane protein (127 kDa, 1146 aa) that shares substantial similarities to several known Na^+/H^+ antiporters, including the mammalian NHE1 and the bacterial NhaA [112]. Detailed phylogenetic analysis with other cation/H^+ antiporters showed that AtSOS1 is categorized into the CPA1 family along with NHEs and NHXs, although it is more closely related to bacterial NhaP antiporters [15, 112, 113]. An analysis of the subcellular distribution by overexpressing AtSOS1-GFP fusion proteins in *Arabidopsis* plants indicated that AtSOS1 is localized in the plasma membrane, which was further supported by results of subcellular fractionation [114]. Promoter–GUS analysis has revealed that the *AtSOS1* transcript is predominantly found in the epidermal tissues of root tips and xylem parenchyma cells of roots, stems, and leaves [115]. *AtSOS1* mRNA expression is specifically induced in shoots and roots by salt treatment, but not by cold or ABA treatment [112]. Interestingly, the induction of *AtSOS1* expression appears to be under the control of other *AtSOS* genes, namely, *AtSOS2* (encoding a serine/threonine protein kinase) and *AtSOS3* (encoding a calcium binding protein) since induction of *AtSOS1* expression by salt treatment in *atsos2* and *atsos3* mutant plants is partially and almost completely abolished, respectively [112]. In addition, it seems that the mRNA stability of *AtSOS1* is also regulated by salinity stress since the amount of *AtSOS1*

transcripts in transgenic *Arabidopsis* plants harboring an additional copy of the *AtSOS1* ORF under the control of a constitutive promoter was significantly increased under saline conditions compared to nonstress conditions [116]. Hydropathy prediction indicated that the AtSOS1 protein consists of 12 putative transmembrane segments and a long C-terminal hydrophilic tail [112], although detailed structural properties of AtSOS1 remain to be studied.

It has been shown that AtSOS1 is able to complement the Na^+ sensitivity of yeast mutants lacking functional genes for plasma membrane Na^+-ATPases (Ena1–4) and two Na^+/H^+ antiporters localized to the plasma membrane (Nha1) or prevacuole (Nhx1) [115]. Interestingly, phenotypes not directly related to Na^+ efflux (i.e., sensitivity to high external K^+ of the *nha1* mutant and hygromycin B sensitivity of the *nhx1* mutant) were not rescued by the expression of *AtSOS1*, suggesting that AtSOS1 is a Na^+-specific transporter [115]. Transport activity of endogenous AtSOS1 was demonstrated by comparing the Na^+/H^+ antiport activities of highly purified plasma membrane vesicles from the leaves of wild-type and *atsos1* mutant *Arabidopsis* plants pretreated with NaCl; the Na^+/H^+ antiport activity of plasma membrane vesicles of the *atsos1* mutant was significantly lower than that of wild type [117]. Further study using a similar approach characterized AtSOS1 both as a low-affinity Na^+/H^+ antiporter (apparent $K_m = 22.8$ mM) that does not accept K^+ or Li^+ as substrates and as an electroneutral transporter [114].

It should be noted that AtSOS1 requires AtSOS2 and AtSOS3 to be fully activated since AtSOS1 activities of plasma membrane vesicles from *atsos2* and *atsos3* mutant plants were similar to the *atsos1* mutant [117]. Moreover, the addition of constitutively active AtSOS2 proteins was found to significantly increase Na^+/H^+ antiport activities [117]. A separate study using a yeast heterologous expression system showed that AtSOS1 could be directly phosphorylated by AtSOS2 kinase [118], and this phosphorylation by AtSOS2 is enhanced when AtSOS3, which is known to form a complex with AtSOS2 [119], coexisted. Furthermore, it has been shown that AtSOS3 is able to recruit AtSOS2 protein to the plasma membrane [118]. On the basis of these results, AtSOS1 is known to be a part of the so-called "SOS pathway," in which AtSOS3 delivers otherwise cytosolic AtSOS2 kinase to the plasma membrane, where AtSOS2 activates its target AtSOS1 by phosphorylation [114, 118].

SOS1 orthologues have been isolated from several plants, including rice [120], wheat [121], tomato [122], and halophytic *Thellungiella salsuginea* (formerly *T. halophila*) [123]. All these SOS1 orthologues are shown to at least have the ability to rescue mutant yeast or *Escherichia coli* that are deficient in Na^+ export, and recent RNAi studies in tomato and *T. salsuginea* have indicated that SOS1 plays major roles in salt tolerance in these plant species [122, 124–126] (see below).

In addition to the above orthologues, a *SOS1*-like gene, *AtNHX8*, has been identified in *Arabidopsis*. AtNHX8 is the closest homologue of AtSOS1 and shares more than 88% similarity in the hydrophobic region but lacks approximately half the hydrophilic tail at the C-terminus (83 kDa, 756 aa). Detailed characterization using a heterologous yeast expression system and *atnhx8* null mutant plants indicate that despite its high sequence similarity to AtSOS1, the *AtNHX8* gene likely encodes a Li^+/H^+ antiporter rather than a Na^+/H^+ antiporter [127].

23.4.2 Physiological Roles of SOS1

The physiological significance of AtSOS1 in saline environments has been well established in *Arabidopsis*, as *atsos1* null alleles exhibit intense salt sensitivity [111, 112]. The *atsos1* mutant has been shown to accumulate a higher amount of Na^+ compared to wild-type plants under severe salt stress, with the difference in Na^+ accumulation being more apparent in roots than in shoots [115]. Given that AtSOS1 expression is found predominantly in the epidermis of *Arabidopsis* root tips and increases with Na^+ stress, and that its proposed function is as a Na^+/H^+ antiporter at the plasma membrane (see above), it has been suggested that AtSOS1 plays a critical role in Na^+ efflux from root cells, which limits net Na^+ entry (Figure 23.1) [115, 117]. The results from proton flux measurements have indicated that SOS1 is involved in Na^+-dependent H^+ influx at the meristem zone of *Arabidopsis* roots, supporting this view [128].

It has been suggested that AtSOS1 is also involved in the long-distance transport of Na^+. The Na^+ accumulation in shoots of *atsos1* mutant plants was less than that of wild-type plants under moderate salt stress when cultivated in hydroponic or high humidity conditions [116, 129]. This observation, together with the xylem parenchyma cell-specific expression pattern of the *AtSOS1* transcript [116], prompted the suggestion that AtSOS1 might play a role in loading of Na^+ into the xylem stream under moderate salt stress and no or low transpiration (Figure 23.1), although its physiological significance in *Arabidopsis* is yet to be determined.

A recent RNAi study in tomato (*Solanum lycopersicum*) [122] has revealed another role for SOS1 transporters under salinity stress. The *SlSOS1*-silenced line showed increased Na^+ content in roots and leaves compared to wild type under salt stress, consistent with the suggested role for AtSOS1 in *Arabidopsis*, but stems of silenced plants accumulated less Na^+ compared to the wild type [122, 124]. These results indicated that SlSOS1 plays a key role in the retention of Na^+ in the stem in tomato. Although direct evidence is not available at this point, the authors hypothesized that SlSOS1 might function in Na^+ efflux from the leaf cells to the xylem stream to protect the photosynthetic organs (Figure 23.1), and the higher leaf/root Na^+ and lower stem Na^+ concentrations observed in silenced plants were the consequence of a loss of this process, while the xylem unloading of Na^+ mediated by HKT1 remained intact [122, 124].

An RNAi suppression study has also revealed a critical role of SOS1 in *T. salsuginea*, which is an extremely salt-tolerant species closely related to *Arabidopsis*. The silenced plants exhibited faster Na^+ accumulation under saline conditions and slower Na^+ efflux after removal of salt, indicating that SOS1 plays a similar role in Na^+ efflux in roots as observed in *Arabidopsis* [125]. Propidium iodide staining detected cell death in the silenced plants, initially occurring at the elongating zone of the roots and expanding to older tissues as the salt stress continued, indicating that SOS1 protects these susceptible regions from Na^+ accumulation by excluding it at the root tip, where SOS1 is most abundantly expressed [125]. The expression level of *SOS1* in wild-type *T. salsuginea* was reported to be 10 times higher than that of *Arabidopsis* under saline conditions [125]. Furthermore, the suppression of *SOS1* expression

resulted in a loss of its halophytic nature, as root growth inhibition and partial chlorosis were observed at 200 mM NaCl, conditions under which *T. salsuginea* plants can usually grow without symptoms but are toxic to *Arabidopsis* [125]. These results indicate that SOS1 plays a key role in the halophytism of *T. salsuginea* [125].

Besides its critical roles in salt tolerance, SOS1 appears to be involved in several other cellular processes that do not seem to be directly related to Na^+ transport. A recent study using fluorescent probes reported that the loss of a functional *AtSOS1* gene resulted in altered pH homeostasis, both in the cytosol and in the vacuole of root cells [130]. Since AtSOS1 expression has not been found in the tonoplast membrane, the change in the vacuolar pH homeostasis is likely to be an indirect consequence of the alteration in plasma membrane H^+ flux, which has also been demonstrated by the electrophysiological study of *atsos1* [131]. In addition, fragmentation of the vacuoles and defects in endocytosis under salinity stress have been observed in *atsos1* mutants [130]. This is probably related to the altered cellular pH homeostasis, as modulations of H^+-translocating protein activities often affect intracellular membrane trafficking [113, 132–134]. In addition, SOS1 appears to play a role in protecting the root plasma membrane K^+ uptake under salinity stress since inhibition of root K^+ permeability under moderate salinity stress and growth under K^+-limiting conditions were observed in *atsos1* but not in wild-type plants [135].

23.4.3
Transgenic Approaches to Increasing Salinity Tolerance Using SOS1 Genes

It has been shown that ectopic expression of *AtSOS1* using the 35S promoter in *Arabidopsis* confers resistance to salinity stress, as less growth inhibition was observed in transgenic plants compared to nontransgenic plants under salinity stress [46, 116]. Transgenic plants and undifferentiated calli also exhibited less accumulation of Na^+, suggesting that enhancement of salinity tolerance by overexpression of AtSOS1 could be due to the limitation of Na^+ accumulation, which occurs through increased Na^+ efflux via AtSOS1 [116]. Similar growth improvements under saline conditions have also been observed in *Arabidopsis* plants that overexpress the *T. salsuginea SOS1* [125] or *OsSOS1* [120]. These results indicate that overexpression of a *SOS1* gene could be a valid approach to improve the salinity tolerance of crop plants.

23.5
Other Molecules that are Potentially Useful for Improving Salt Tolerance

23.5.1
HAK/KUP/KT Transporters

K^+ is an essential macronutrient for growth and the most abundant cation in plant cells. K^+ ions play vital roles in many homeostatic processes including osmoregulation, maintenance of membrane potential, and photosynthesis [100, 136]. K^+ is also an important factor in determining salt tolerance since K^+ absorption is

competitively blocked by Na^+ and K^+ alleviates the toxic effects of Na^+ [9–11]. Therefore, one potential strategy to engineer salt-tolerant plants is to enhance K^+ acquisition during salinity stress. Recently, the relatively Na^+-insensitive K^+ transport function of the OsHAK5 transporter from rice was identified in heterologous *E. coli* and yeast cells, and attempts have been made to utilize this as a tool to increase salinity tolerance in plant cells [137]. OsHAK transporters are members of the HAK/KUP/KT transporter family that constitutes a major K^+ transporter family in plants [100]. Constitutive expression of OsHAK5 in cultured tobacco BY2 cells was found to increase K^+ accumulation but decrease Na^+ accumulation during salt stress compared to control cells, conferring increased salt tolerance to the BY2 cells [137]. The study suggested that enhanced K^+ acquisition would also lead to a decrease in Na^+ accumulation, presumably due to depolarization of the membrane potential through increased K^+ uptake. These results indicate that the plasma membrane localized Na^+-insensitive K^+ transporters could be a tool to produce salt-tolerant plants. Further evaluation of the effect of OsHAK5 expression on plant salt tolerance will be needed at the individual plant level, in addition to identification of similar Na^+-insensitive K^+ transporters/channels.

23.5.2 ENA1/PMR2A

Fungi, including budding yeast (*Saccharomyces cerevisiae*), have a plasma membrane Na^+-ATPase that mediates Na^+ efflux as a major means of resisting salt stress [138, 139]. Although *S. cerevisiae* retains a tandem array of P-type Na^+-ATPase genes, only the *ENA1/PMR2A* gene encoding Ena1p was found to be strongly induced by salt stress [140, 141]. Ena1p tagged with the triple hemagglutinin tag (Ena1p-3HA) was expressed in cultured tobacco BY2 cells [142]. Ena1p-3HA expressing BY2 cells showed increased NaCl and LiCl tolerance by maintaining lower levels of Na^+ and Li^+ than control cells under salt stress conditions [142]. These results indicate that Ena1p is a candidate for increasing plant salt tolerance. ENA1-like P-type ATPases have been found in a primitive moss *Physcomitrella patens* [143]. PpENA1 was demonstrated to be a Na^+ pump and was suggested to play an important role in extruding Na^+ under salt stress as a mechanism for the moss to resist Na^+ toxicity [143]. It seems likely that such Na^+ pump activity was lost in flowering plants during evolution, and it might suggest that the Na^+ pump system is a not favorable mechanism due to the energy-consuming nature of the Na^+ pump. Further study using Ena1p expressing transgenic plants in combination with tissue-specific promoters will be necessary to evaluate the utility of the Na^+-ATPase for increasing plant salt tolerance.

23.6 Conclusions

Merely two decades ago, there was no evidence for Na^+ influx/efflux or a Na^+ circulation system in plants because of Na^+ being a nonessential element for plant

growth and development. Since the cloning of *HKT*, *SOS1*, *NHX*, and *HAK/KUP/KT* transporter genes from higher plants, numerous Na^+ transporters have been characterized. A large number of studies have provided evidence that these transporters play crucial roles in plants, and these studies have revealed the detailed mechanisms involved in the removal of Na^+ from cells to prevent cytotoxicity. Moreover, these studies have shed light on the potential for developing engineered elite traits using ion transporter genes. Further progress in identifying and characterizing the transporters involved in Na^+/K^+ homeostasis can be expected to increase our understanding of the mechanisms underlying this process in addition to aiding the development of tools for improving salinity tolerance in plants.

Piriformospora indica, A Root Endophytic Fungus, Enhances Abiotic Stress Tolerance of the Host Plant

Manoj Kumar, Ruby Sharma, Abhimanyu Jogawat, Pratap Singh, Meenakshi Dua, Sarvajeet Singh Gill, Dipesh Kumar Trivedi, Narendra Tuteja, Ajit Kumar Verma, Ralf Oelmuller, and Atul Kumar Johri

Piriformospora indica is an endophytic fungus that colonizes the roots of both monocot and dicot plants including members of the family Brassicaceae, which are nonhost for arbuscular mycorrhizal fungi (AMF) and can also be grown axenically. Like the AMF, *P. indica* was found to be involved in the enhancement of plant tolerance against abiotic stress. Growth promotion in plant is a characteristic effect of the fungal colonization, which can also be observed under the stress conditions. *P. indica* modulates the defense system and alters the metabolism to compensate the loss in photosynthesis and prevent oxidative damage caused by stress. Primarily, *P. indica* induces the defense system, especially the ascorbate–glutathione (ASH-GSH) cycle, and maintains a high antioxidative environment during salt and drought stress. *P. indica* also induces sevaral antioxidative enzymes during salt and drought stress that are involved in detoxification of reactive oxygen species (ROS) such as superoxide dismutase (SOD), catalase (CAT), ascorbate peroxidase (APX), glutathione reductase (GR), peroxidase (POD), monodehydroascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR), and so on. *P. indica* also increases the level of osmolytes such as polyamine and proline in response to salinity and drought stress. Interplay of antioxidative environment mediated by ASH, osmolytes (polyamine, proline, etc.), and strong activity of antioxidative enzyme system leads to maintenance of plastid integrity and therefore enhanced photosynthetic efficiency in colonized plant during abiotic stress. In addition, *P. indica* also induces salt and drought stress-responsive genes of the plant, which may play an important role in enhanced abiotic stress tolerance of crop plants.

24.1
Introduction

The unfavorable environmental parameters, such as drought, salinity, cold, freezing, high temperature, water logging, high light intensity, UV irradiation, nutrient imbalances, metal toxicities, nutrient deficiencies, climate change, and so on are

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

termed as abiotic stress. Only 10% of the world's arable land is free of stress. Abiotic stresses have become an integral part of crop production. In general, plants suffer from dehydration or osmotic stress under drought, salinity, and low-temperature condition, which causes reduced availability of water (dehydration) for cellular function and maintenance of cellular turgor pressure. Prolonged period of dehydration leads to high production of ROS in the chloroplasts, causing irreversible photoinhibition and cellular damage. Because of cellular damage, mainly the cell membrane integrity is disturbed, and therefore plant roots are unable to absorb minerals efficiently, causing nutritional stress [1]. Plants respond to stress as individual cell and synergistically as a whole organism. Generally, stress signal is first perceived by receptors of the plant cells. Following this, the signal information is transduced, resulting in activation of various stress-responsive genes. The products of these stress genes ultimately lead to a stress tolerance response or plant adaptation and help the plant to survive and surpass unfavorable conditions [2, 3]. The response could also result in growth inhibition or cell death, which would depend on the number and type of the genes, those that are up- or downregulated in response to the stress. The overall stress response of a plant is a coordinated action of several genes encoding signaling proteins/factors, including protein modifiers (methylation, ubiquitination, glycosylation, etc.), adapters, scaffolds, and antioxidative system [2, 3]. Furthermore, plant growth-promoting fungi (PGPF) such as arbuscular mycorrhizal fungi (AMF), ectomycorrhizae, and other endophytic fungi [4], as well as plant growth-promoting rhizobacteria (PGPR) [5] or plant growth-promoting bacteria (PGPB) [6], confer abiotic tolerance and decreased yield losses in cultivated crop plants. AMF can act as a biofertilizer, bioprotectant, and biodegrader [7] and, in turn, modulate stress responses and increase the lowest limit of tolerance of the plant to abiotic stresses. Several studies are available on the impact of AMF on plant's abiotic stress tolerance, suggesting that AMF play a comprehensive role in plant's stress tolerance, and colonization of AMF induces a molecular signaling cascade that affects stomatal conductance, transpiration, photosynthesis, leaf dehydration, root hydration, hydraulic conductivity, growth, nutrient uptake, low weight metabolites (e.g., sugars, glycerol, amino acids, and sugar alcohols), and morphology. However, application of AMF in sustainable agriculture is limited due to unavailability of axenic culture and its host specificity, as AMF cannot colonize a group of important crop plants.

A recently discovered root endophytic fungus of the Sebacinaceae family, *Piriformospora indica*, can colonize the roots of many plant species, including *Arabidopsis* [8–19]. Infestation of *P. indica* can be intercellular or intracellular (Figure 24.1); however, unlike AMF, they do not form arbuscular structures in plant cells [10]. There are several reports which suggest that *P. indica* can mimic the effect of AMF colonization to plants; besides, this fungus is axenically cultivable and has a broad host spectrum. *P. indica* can provide several benefits to host plants, such as better tolerance to biotic (diseases) and abiotic stresses, for example, drought and salinity stress, and improved plant fitness by increasing growth performance under normal and stress conditions [18, 20]. The ability of *P. indica* to promote plant growth, higher seed yield, seed oil content, and so on of various host plants under conditions that are

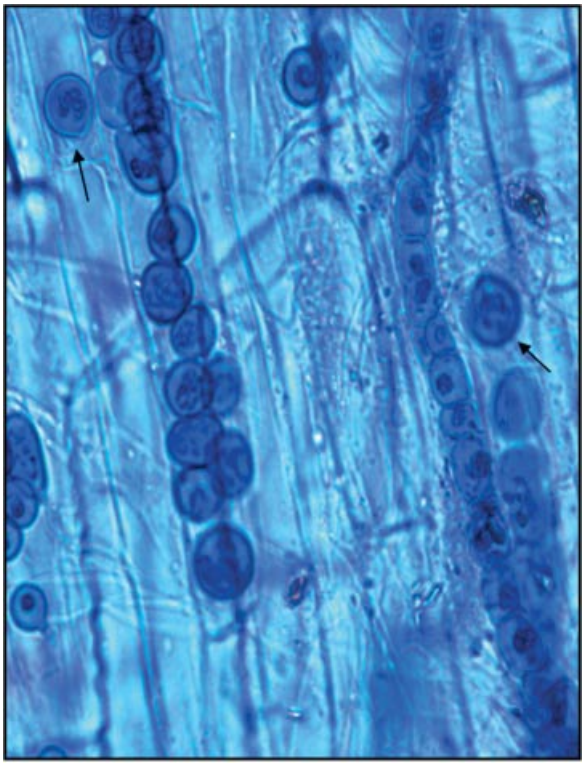

Figure 24.1 Trypan blue staining of maize plant roots showing intracellular *P. indica* chlamydospores (black arrow) observed at day 10. The fungus forms intercellular and intracellular pear-shaped chlamydospores within root. Fungus grows into cortex tissue but does not colonize vascular tissue of the root and never colonizes the shoot tissue. Adapted from Ref. [9], reprinted with permission from the Society for General Microbiology © 2009.

not optimal for the plants is well documented [8, 11, 18, 21, 22]. It can act as a bioprotector and facilitate hardening of micropropagated plants that are transferred to soil and the natural environment [23, 24]. It also has a stimulatory effect on adventitious root formation in ornamental stem cuttings. There are also studies showing that culture filtrates of the fungus are rich in nutrients and can promote growth yield [22]. However, the exact nature of plant growth promotional effects is still unclear [25, 26]. *P. indica* was reported to activate both nitrate reductase that plays a major role in nitrate acquisition and a starch-degrading enzyme, glucan-water dikinase, involved in early events of starch degradation in the plants such as tobacco and *Arabidopsis* [15]. Root infestation resulted in promotion of plant growth and yield. In this chapter, we have emphasized the effect of *P. indica* colonization on the abiotic stress tolerance and the mechanism for these stress tolerance in colonized plants. Colonization may lead to activation of various genes involved in stress acclimation and their roles in maintenance of cell homeostasis and activation of antioxidant system are also discussed.

24.2
Role of *P. indica* in Salt Tolerance

Soil salinity is a major threat to crop yield and a widespread problem. Around 7% of the global land surface is covered with saline soil [27]. Out of 1.5 billion ha of cultivated land, about 77 million ha (5%) is affected by excess salt content mainly induced by irrigation with groundwater of high salt content [28]. At present, it is a well-known fact that crop yield is low in saline soil, mainly due to decrease in efficient nutrient uptake, plant water holding capacity, and adverse effect on photosynthesis. Salinity and drought exert their influence on a cell mainly by disrupting the ionic and osmotic equilibrium [3]. Thus, excess of Na^+ ions and osmotic changes in the form of turgor pressure are the initial triggers, leading to a cascade of events that can be grouped into ionic and osmotic signaling pathways, the outcome of which is ionic and osmotic homeostasis, resulting in stress tolerance. Many crop species are extremely sensitive to soil salinity and are known as glycophytes, whereas salt-tolerant plants are known as halophytes. In general, glycophytes cannot grow at 100 mM of NaCl, whereas halophytes can grow at salinities over 250 mM of NaCl. The salinity-sensitive plants restrict the uptake of salt and strive to maintain an osmotic equilibrium by the synthesis of compatible solutes, such as amino acids and sugars. The salinity-tolerant plants have the capacity to sequester and accumulate salt in the cell vacuoles, thus preventing the buildup of salt in the cytosol and maintaining a high cytosolic K^+/Na^+ ratio in their cells. Recent studies suggested that *P. indica* could enhance the ability of plants to cope with salt stress. Waller *et al.* [18] have shown that *P. indica* colonization enhanced salt tolerance of barley plants. The detrimental effect of moderate salt stress was completely abolished by *P. indica* with a higher biomass gain. This effect of enhancement of salt tolerance by *P. indica* was similar to that of AMF. However, AMF-induced salt tolerance is due to improvement in plant nutrient uptake and ion balance, protecting enzyme activity and facilitating water uptake.

Earlier studies suggested salt-induced increase in lipid peroxidation and reduction in metabolic heat production [31] in salt-sensitive plants, while they remained unchanged in salt-tolerant cultivars. Baltruschat *et al.* [32] assessed the impact of *P. indica* colonization on biochemical markers for salt stress, such as metabolic activity, fatty acid composition, lipid peroxidation, and marked reduction in metabolic heat production in salt-sensitive barley plants. Reduction in plant metabolic activity is recognized in salt-stressed plants. Salt-induced responses, that is, heat emission and ethane production in *P. indica*-colonized salt-sensitive plant, resemble those of salinity-tolerant plants because *P. indica* increases the metabolic activity in leaves of salt-stressed plant and therefore recompenses the salt-induced inhibition of metabolic activity. Calorimetric studies indicated that the rate of metabolic activity increased in leaves of *P. indica*-infected plants after salt treatment. Prior studies have also shown that the extent of natural herbicide resistance of wild oat biotypes is tightly correlated with the rate of heat production upon herbicide exposure, owing to the activation of metabolic pathways required for defense responses [33]. This suggests that enhanced tolerance to salt stress can be associated with higher metabolic activity in *P. indica* colonized plants [32]. Salt stress can induce ionic stress and osmotic stress

in plant cell, leading to enhanced accumulation of ROS that are harmful to plant cell at high concentration. On the one hand, ROS accumulation can be toxic to living cells, causing oxidative damage to DNA, lipids, and proteins, and on the other hand, ROS can act as signaling molecules for stress responses. Several studies have demonstrated that tolerance of plants to salt stress is associated with the induction of antioxidant enzymes [34–36]. Recent reports suggest that *P. indica* induces antioxidative environment in the cell by altering the activities of different enzymes involved in ROS-scavenging system [9, 37]. Exogenously applied unsaturated fatty acids can protect barley plants during NaCl-induced stress [38]. Lipid desaturation could be an important component of plant tolerance in response to salt stress. *P. indica* colonization leads to a significant reduction in the proportion of oleic acid in barley leaves and also induces changes in fatty acid composition similar to those induced by salinity [32]. Such effects on the fatty acid composition of host plants may display a symbiotic adaptive strategy mediated by the endophyte to cope with salt stress in hostile environments [37]. Owing to its original habitat, *P. indica* might induce similar effects on fatty acid composition of the host plants [32].

It has been shown that *P. indica* is able to produce auxin when associated with plant roots [39] or changes in phytohormone synthesis and perception in plants [40–42]. Exogenous auxin has been found to transiently increase the concentration of ROS and then prevent hydrogen peroxide (H_2O_2) release in response to oxidative stress (caused by paraquat) and enhanced APX activity, while decreasing CAT activity [43, 44]. In a recent study, it was found that *P. indica* increases the level of osmolytes such as polyamines and amino acid proline (unpublished data) in colonized plants. This increase in polyamine content is due to the upregulation of methionine synthase in colonized plant, which plays a crucial role in biosynthesis of polyamines and ethylene [10]. A well-known adaptive response of plants under salt stress is the synthesis and accumulation of low molecular weight organic compounds in the cytosol and organelles, which are collectively known as compatible osmolytes because they accumulate and function without perturbing intracellular biochemistry. Transgenic tobacco plants overproducing polyamines also have enhanced tolerance toward salt stress, and salt treatment induces antioxidant enzymes such as APX, SOD, and glutathione *S*-transferase (GST) more significantly in these transgenic plants than in wild-type controls [45]. The major function of osmolytes is osmotic adjustment to counteract higher inorganic salt in vacuole and root medium, protection of membrane, and stabilization of proteins. The osmolyte proline protects membranes and proteins against the adverse effects of high concentrations of inorganic ions and temperature extremes. Proline may also function as a protein-compatible hydrotrope and as a hydroxyl radical ($OH^{\bullet}$) scavenger [46].

In a previous study, Waller *et al*. [18] has reported that *P. indica* enhances the level of antioxidant buffer ascorbate and induces dehydroascorbate reductase activity in colonized plant. Ascorbic acid is directly involved in detoxification of H_2O_2 by coupling with glutathione cycle or NADH. Moreover, it acts directly to neutralize oxygen free radicals [47]. During early stage of salt exposure, *P. indica* maintains the redox balance ascorbate and increases its concentration in colo-

nized plant; however, over time, the concentration decreases in both the salt-treated colonized and the control plants. Several studies suggested that the tolerance of plant to salt stress is associated with the capability of detoxification of ROS, which is directly related to the induction of antioxidant enzymes [32]. Overexpression of CAT, APX, or DHAR in transgenic plants enhanced tolerance to salt stress [48, 49]. However, *Arabidopsis* double-mutant plants deficient in cytosolic and thylakoid APX also show enhanced tolerance to salinity, suggesting that ROS such as H_2O_2 could be responsible for activation of an abiotic stress signal that leads to enhanced stress tolerance [50]. Exposure to NaCl increases the activities of antioxidant enzymes CAT, APX, DHAR, MDHAR, and GR, but this initial induction of activity cannot sustain and decreases over time. However, in the presence of *P. indica*, the decrease in the enzyme activity is less pronounced and delayed. The elevated levels of GR, MDHAR, and DHAR activities affect the ascorbate level during salt exposure in *P. indica* colonized plant. Ratio of ascorbate to DHA decreased in the salt-sensitive *Lycopersicon esculentum* under salt stress and increased in the salt-tolerant *L. pennellii* [51]. Earlier, investigations have shown that ascorbate content decreased in salt-sensitive and salt-tolerant pea cultivars as well, but the decline was greater in the salt-sensitive plants [34]. The importance of ascorbate in cellular protection under salt stress has also been demonstrated in an ascorbate-deficient *Arabidopsis* mutant. Impaired in the ascorbate-glutathione cycle, this mutant accumulated high amounts of ROS and showed increased sensitivity to salt stress [52]. Constant exogenous application of ascorbate increased resistance to salt stress and attenuated the salt-induced oxidative burst [53]. Alternatively, ascorbate can improve the tolerance of barley to high salinity via processes related to root growth. Ascorbic acid and high ratio of reduced to oxidized ascorbate accelerate root elongation and increase root biomass [54].

Under salt stress condition, MDHAR activity remained elevated in roots of both salt-sensitive and -tolerant plants. *P. indica* maintains a sustainably higher CAT and APX activity in salt-sensitive plants during salt exposure. CAT activation is a well-known marker of oxidative stress and catalyzes the degradation of hydrogen peroxide into water and thus reduces the oxidative damage to cell. APX is an integral component of glutathione-ascorbate cycle and it detoxifies peroxides such as hydrogen peroxide into water using the ascorbate as substrate. Furthermore, it was found that during the interaction with *P. indica*, enhanced glutathione pool was observed in the plant leaves [18]. As glutathione is a key component in the glutathione-ascorbate cycle, it can suppress the effect of ROS on leaves and, consequently, on photosynthesis. The exact mechanism responsible for *P. indica*-mediated upregulation of the plant antioxidant system is not yet known. The hormonal signaling in the enhancement of salt tolerance of the plant in *P. indica* colonized plant cannot be rule out. *Sebacina vermifera*, an endophyte closely related to *P. indica*, downregulates ethylene production in *Nicotiana attenuata* [40]. During the interaction, induction of methionin synthase takes place, and thus an increased level of ethylene has been observed in plant root. Ethylene signaling may be required for the plant salt tolerance and it may induce some antioxidant enzyme during heat stress. However, the function of phytohormones in salt tolerance has not been clear yet.

24.3 Role of *P. indica* in Drought Tolerance

Water deficit stress is known as drought stress, which reduces agricultural production mainly by disrupting the osmotic equilibrium and membrane structure of the cell. Climate models have indicated that drought stress will become more frequent because of the long-term effects of global warming, which highlights the urgent need to develop adaptive agricultural strategies for a changing environment. Actually, the water stress within the lipid bilayer results in displacement of membrane proteins, which contributes to loss of membrane integrity, selectivity, disruption of cellular compartmentalization, and loss of membrane-based enzyme activity. The high concentration of cellular electrolytes due to the dehydration of the protoplasm may also cause disruption of the cellular metabolism. To avoid drought stress, plants close their stomata, repress cell growth and photosynthesis, activate respiration, reduce leaf expansion, and start shedding older leaves to reduce the transpiration area [1]. The components of drought and salt stress crosstalk as both these stresses ultimately result in dehydration of the cell and osmotic imbalance. Overall, drought stress signaling encompasses three important parameters [55]: (a) reinstating the osmotic and the ionic equilibrium of the cell to maintain cellular homeostasis under the condition of stress, (b) control and repair of stress damage by detoxification, and (c) signaling to coordinate cell division to meet the requirements of the plant under stress.

Recent works suggest that *P. indica* is involved not only in salt stress tolerance but also in drought stress tolerance. Sherameti *et al.* [56] has shown that *P. indica* enhances drought tolerance of *Arabidopsis*. Furthermore, the authors found that after exposure for 84 h to drought stress at the seedling stage, none of the uncolonized plant recovered and survived, while about 50% of the *P. indica*-colonized plant produced seeds. *P. indica* is also found to be involved in enhancing the drought stress tolerance of other plants, such as maize, mustard, cabbages, cress, and tobacco. The primary visible effect of *P. indica*-induced drought tolerance on the plant is shoot growth. In another study on Chinese cabbage, no visible effect of drought was seen [57]. Like salt stress, drought stress also induces strong oxidative stress and generates ROS in plant. ROS act upon the polyunsaturated lipids of membrane and thereby form malondialdehyde (MDA). The production of this aldehyde is used as a biomarker to measure the level of oxidative stress. Drought stress promotes MDA accumulation in the leaves, while *P. indica* colonized plant contains a lower amount of MDA, suggesting that *P. indica* prevents the colonized plant from oxidative stress. Furthermore, *P. indica* induces the antioxidant enzyme activity in plant leaf during the drought stress. Three enzymes, SOD, CAT, and POD, were found induced in the colonized plant. The induction of CAT is somewhat different; it is found induced in both control and colonized plants, but the induction is higher in colonized plant. PODs are a large family of enzymes that detoxify hydrogen peroxide, organic hydroperoxides, or lipid peroxides to generate alcohols. PODs contain a heme cofactor in their active sites that is synthesized in the plastid. In addition, PODs contain redox-active cysteine residues that directly

measure the redox potential in cell or organelle. The most important organelle in the leaf that controls the redox potential in the cell is plastid. These enzymes can play an important role in the detoxification of ROS. Hence, one can understand why the amount of MDA is reduced in colonized plant.

P. indica induces not only the antioxidative enzymes but also the antioxidative molecules such as ascorbate under the drought stress. The fungus induces the accumulation of ascorbate in root and shoot, especially leaves of the plant, and maintains a higher antioxidative environment in plant cell. At the molecular level, fungus induces monodehydroascorbate reductase 2 (MDHAR2) and dehydroascorbate reductase 5 (DHAR5) in the colonized plant [58]. MDHAR2 and DHAR5 are the important part of the ascorbate–glutathione cycle that maintains ascorbate in its reduced state. MDHAR2 converts MDHA into the ascorbate using NADH, while DHAR5 converts DHA into ascorbate using its integral part, the glutathione cycle, and finally gives an antioxidative environment to the cell mediated by ascorbate. The importance of these two genes was analyzed using the knockdown (KO) lines of *Arabidopsis*, and it was found that growth, flower development, and seed production were not promoted by fungus and were inhibited under drought stress. This indicates that both the enzymes are crucial for the plant to respond to the fungus and the fungus-mediated growth promotion and cannot be fully replaced by other members of the gene family [58]. It has been demonstrated that loss of benefits for the plants could be caused by a shift from mutualism to parasitism, a phenomenon that occurred due to an uncontrolled growth of fungal hyphae in the roots [59]. During the drought stress, KO lines were found over colonized root, indicating that these mutants were less protected against the fungal colonization. Furthermore, an antifungal protein PDF1.2, which is not expressed in uncolonized root, but expressed at a detectable level in colonized root, is several times upregulated in KO lines, where interaction shifts from mutualism to parasitism. This suggests that these two genes of ascorbate-glutathione cycle contribute to the repression of defense gene expression against *P. indica* under drought stress condition [58]. Taking all the studies into consideration, activation of antioxidative system in leaves is a major target of the fungus and plastids are the main targets of drought stress in leaves.

The most crucial adverse effect of drought stress is the reduction in photosynthetic efficiency, pigment content, and proteins of the photosynthetic machinery and the biosynthetic pathways in the stroma of the plastids. *P. indica* does not target specific photosynthesis genes or proteins to establish drought tolerance, but creates preventive atmosphere in the cells that stabilizes plastid function by inducing different antioxidative enzymes. However, chloroplast is a major organelle site for antioxidative activity in the cells where SOD, APX, PODs, MDHAR, and DHAR are localized [60], and induction of these enzymes in the leaves may stabilize the plastid structure and detoxify the ROS during the drought-induced oxidative stress. The ultimate/crucial effect of *P. indica* colonization on leaves under drought condition is the increase in chlorophyll content. Drought stress also has a strong effect on photosynthesis. The photosynthetic efficiency ($F_{\text{variable}}/F_{\text{maximum}}$, F_v/F_m) values around 0.83 reflected the potential fluorescence quantum efficiency of photosystem II, which are sensitive indicators of plant photosynthesis performance [61], and the

values lower than 0.83 indicated the exposure of stress [62]. Drought stress decreases the F_v/F_m values in uncolonized plant, but colonization of fungus compensates the loss in F_v/F_m values and is equal to that of unstressed plant. The difference in the F_v/F_m values clearly demonstrates the beneficial effect of the fungus on photosynthetic efficiency under drought stress [56, 57]. Besides, *P. indica* impeded the drought-induced decline in photosynthetic efficiency and degradation of chlorophylls and thylakoid proteins [57]. Interestingly, *P. indica* does not influence any specific photosynthetic genes or protein that may lead to an increase in photosynthetic efficiency, but a plastid-localized CAS protein appears to be a specific target in the chloroplast during the drought stress. CAS protein is identified as a chloroplast-localized Ca^{2+}-sensing receptor protein that is crucial for proper stomatal regulation in response to elevations of external Ca^{2+}. CAS fulfils this role through modulation of the cytoplasmic Ca^{2+} concentration under stress condition and is also involved in signaling [63]. Drought stress induces the mRNA and protein level in the leaves and it is likely that the fungus counteracts drought stress by elevating cytoplasmic calcium transients, which finally results in stomata closure in the guard cells. A large number of genes involved in drought tolerance are more quickly and strongly upregulated in *P. indica*-colonized *Arabidopsis* leaves upon exposure to drought stress. This result was further validated when a *P. indica*-insensitive *Arabidopsis* mutant (*pii*) was found less tolerant to drought stress and did not upregulate the stress-related genes in the presence of *P. indica*. Hence, *P. indica*-mediated drought tolerance to *Arabidopsis* is associated with the priming of the expression of rather diverse set of stress-related genes in the leaves [42, 56].

These stress-related genes are involved in rather different cellular processes. Phospholipase Dδ (PLDδ) is involved in phospholipid metabolism at the plasma membrane; calcineurin B-like protein 1 (CBL1)/CBL-interacting protein kinase 3 (CIPK3) is involved in cytoplasmic signaling; histone acetyltransferase (HAT), dehydration response element binding protein 2A (DREB2A), and ANAC072 control the gene expression in the nucleus; and other proteins such as salt and drought ring finger 1 (SDIR1) and early response to dehydration 1 (ERD1) have a role in protein degradation and response to dehydration 29A (RD29A) with cytoplasmic function. RD29A and ERD1 are the reporters of drought stress responses. ERD1 is a plastid-localized caseinolytic protease that is induced by dehydration or cold stress. PLDδ is associated with the plasma membrane and specifically induced under drought stress. This plasma membrane-bound PLDδ is activated in response to hydrogen peroxide and the resulting phosphatidic acid (PA) functions to decrease hydrogen peroxide-promoted programmed cell death [64]. DREB2A is a transcription factor that specifically interacts with *cis*-acting, dehydration-responsive elements involved in drought stress-responsive gene expression in *Arabidopsis*. Intact DREB2A expression does not activate downstream genes under normal growth condition, which suggests that this transcription factor requires posttranslational modification for activation. However, the activation mechanism has not yet been clarified, but a constitutive active form of DREB2A showed improved drought stress tolerance in *Arabidopsis* [65]. SDIR1 is an E3 ubiquitin ligase localized in intracellular membranes of all tissues of *Arabidopsis* and is a positive regulator of ABA signaling, induced by drought and salt

stress but not by ABA. Overexpression of SDIR1 is involved in an ABA-dependent pathway leading to stress tolerance [66].

Calcium (Ca^{2+}) signaling is an important part of the early signaling system in plant response to various stimuli [67, 68]. Alterations occurred in cytosolic-free Ca^{2+} ($[Ca^{2+}]$cyt) in response to abiotic signals [69], such as drought [70]. Ca^{2+} acts as a secondary messenger in plant cells and links different input signals to many diverse and specific responses [68]. The Ca^{2+} signaling system is based on multifactorial processes that start with a specific Ca^{2+} signature and the availability of a specific set of Ca^{2+} sensors and end with target genes and proteins that activate precise downstream events [69, 71]. The source of the Ca^{2+} contributing to the rise in $[Ca^{2+}]$cyt (apoplasts or internal stores or both) is crucial for the physiological responses [70, 72]. Sun *et al.* [57] found that the expression levels of the drought-related genes DREB2A, CBL1, ANAC072, and RD29A were upregulated in the drought-stressed leaves of *P. indica* colonized plants. Furthermore, the CAS mRNA level of the thylakoid membrane-associated Ca^{2+}-sensing regulator and the amount of the CAS protein were also found to be increased. Thus, Ca^{2+} signaling is involved in *P. indica*-induced drought stress tolerance in plants. CBL1 is an important player in Ca^{2+} signaling and integrates plant responses to abiotic stresses, including drought stress ABA-independent pathways. Besides CBL1, a calcium sensor-associated kinase, CIPK3, has multiple functions in stress responses and might be a crosstalk node in stress and ABA signaling pathway [73]. Interestingly, CIPK3 primarily modulates cold- and salt-induced gene expression but not drought-induced gene expression; however, the level was earlier upregulated in *P. indica* colonized seedlings during the drought stress. Another transcription factor DREB1B, involved in dehydration and cold responses, works on the recruitment by HAT. Thus, *P. indica* might control gene expression more generally by regulating crucial factors involved in histone acetylation. The earlier upregulation of the genes involved in stress responses in *P. indica*-colonized plants is the modulation of the defense system by molecular signaling, which finally resulted in the prevention of water loss, balanced shift of metabolism, and functional and structural integration of the organelles and cell.

24.4 Conclusions

P. indica is a root endophytic fungus that has a broad host spectrum, including the monocot, dicot, and Brassicaceae family, which are not colonized by the mycorrhizal fungus. This interaction provides a critical linkage between the plant root and the soil. As a result, *P. indica* colonized plants are often more competitive and better able to tolerate environmental stress than the uncolonized plants. Plant responses to colonization by *P. indica* can range from growth promotion to multistress tolerance. Growth promotion in plant is the characteristic effect of the fungal colonization and visible under stress condition. This growth promotion may be due to the nutritional transfer by the fungus to the plant and phytohormone signaling mediated by auxin and cytokinine secreted by colonized fungus. On the basis of the reports available, we

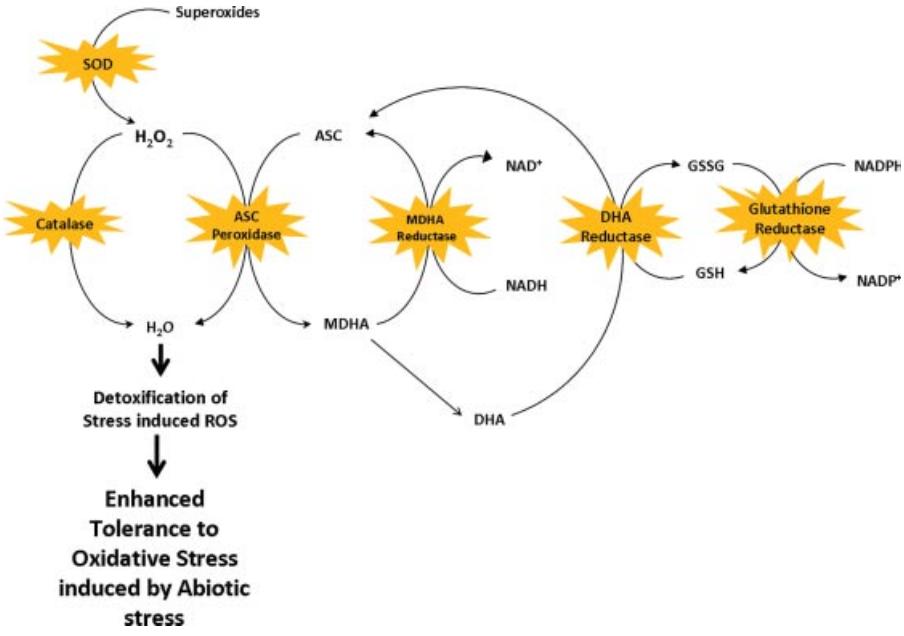

Figure 24.2 Couples series of redox reaction involved with scavenging of H2O2 of glutathione–ascorbate cycle in the plant cell. *P. indica* influences nzymes' expression and activity of the cycle (shown in exploding star) and leads to induction in ROS scavenging capacity in the cell. SOD (superoxide dismutase), ASC peroxidase (ascorbate peroxidase), MDHA reductase (monodehydroascorbate reductase), and DHA reductase (didehydroascorbate reductase) are the important enzymes playing crucial role in detoxification of stress-induced ROS and are differentially induced in *P. indica*-colonized plant during the abiotic stress.

proposed a diagrammatic representation of ROS-scavenging system of plant (Figure 24.2), showing how *P. indica* influences the glutathione–ascorbate cycle that resulted in enhanced oxidative stress tolerance under the abiotic stresses. *P. indica* modulates the defense system and alters the metabolism to compensate the loss in photosynthesis and prevention of oxidative damage due to stress. As the role of *P. indica* in abiotic stress tolerance has been shown under the controlled green house conditions, therefore we suggest the use of *P. indica* can also be tested in the agriculture field. We, further, suggest that this endophytic fungus is a good candidate for the application in sustainable agriculture to help crop plants overcome salt, drought, and other abiotic stresses.

Acknowledgments

We thank Ms. Madhunita Bakshi for critical reading and scientific corrections. We (AKJ, NT) also thank the Department of Science and Technology, Council of Scientific

and Industrial Research, Government of India, for providing the financial help. MK, PS, and AJ are also very thankful to the Indian Council of Medical Research and CSIR, Government of India, for granting them research fellowship.

The Micromics Revolution: MicroRNA-Mediated Approaches to Develop Stress-Resistant Crops

Camilo López and Álvaro L. Pérez-Quintero

In the past two decades, small silencing RNAs (ssRNAs or sRNAs) have emerged as one of the most exciting and revolutionary discoveries in molecular biology. ssRNAs are noncoding molecules used by eukaryotes in transcriptional and posttranscriptional gene silencing, endogenous mechanisms for gene regulation and defense against invasive nucleic acids. MicroRNAs (miRNAs), a type of ssRNAs, play a pivotal role in endogenous regulation of gene expression via cleavage or translational repression of complementary "target" mRNA molecules. Plant miRNAs were first described in *Arabidopsis* in 2002 and now have been identified in more than 120 plant species (including crops and model species); thus, plant miRNA research is one of the fastest growing fields in molecular biology. The first families of miRNAs identified were known to mainly target transcription factors and were involved in growth and development regulation. The initial tools for miRNA identification were often time consuming, expensive, and difficult. In the last few years, various "omics" approaches have been developed to study miRNAs, allowing the spread of miRNA studies to a larger number of plants and the discovery of novel miRNAs and their functions. Notably, various miRNAs are now known to play a role in biotic and abiotic stress, which has led researchers to consider them as a promising tool to develop stress-resistant crops. In this chapter, we review the role miRNAs play in the way plants react to biotic and abiotic stress. We highlight the new methodologies being used to discover miRNAs and to understand their functions in plant responses to environmental stimuli. We also discuss and emphasize the possibilities of generating crop plants with increased stress tolerance using microRNA-mediated technologies.

25.1
Introduction: Silent Molecules Scream Out Loud

There is a clear reason why RNA is at the core of the central dogma of molecular biology. Although it was once regarded as a simple mediator between DNA and

Improving Crop Resistance to Abiotic Stress, First Edition.

protein, we now recognize its role in various cellular processes and its importance as being a possible precursor to all life forms. In the past 20 years, a new breakthrough in the "RNA world" has significantly changed not only our perception of the RNA's role in the cell but also our general ideas on genetics and molecular biology: the small silencing RNAs (ssRNAs).

The story begins in 1990 when plants from the genus *Petunia* were genetically transformed with a chalcone synthase gene expecting to obtain deep purple flowers but getting instead completely white flowers. The phenomenon was called cosupression and could not be fully explained at that moment [1, 2]. This silencing phenomenon was then described in plants as well as in animals and fungi, receiving names such as RNA interference (RNAi), quelling, and posttranscriptional gene silencing (PTGS) [3–5].

We now know that gene silencing is present in most groups of eukaryotes and it is governed by small silencing RNAs (ssRNAs). ssRNAs are 18–30 nucleotides (nt) long molecules that interact with complementary nucleic acids and are involved in the control of gene expression, defense against invasive nucleic acids and transposons, heterochromatin regulation, and epigenetic modifications [6]. All ssRNAs share some similarities in their biogenesis and their action mechanism. They originate from exogenous or endogenous double-stranded RNAs (dsRNAs) that are processed by RNase enzymes, Drosha, Dicer, and/or Dicer-like (DCL), to their final functional size, and then interact directly with Argonaute (AGO) proteins that associate with other proteins forming the RNA-induced silencing complex (RISC). Alternatively, they can also be incorporated into the RNA-induced transcriptional silencing (RITS) complex. Both complexes will use the ssRNA as a template to recognize and modify complementary nucleic acids [7–9].

Among the different classes of ssRNAs, microRNAs (miRNAs) (~21–22 nt) and small interference RNAs (siRNAs) (21–24 nt) have been extensively studied. miRNAs and siRNAs are chemically indistinguishable and can produce silencing in a similar manner. They differ in their biogenesis: siRNAs commonly originate from invading or aberrant nucleic acids (transposons, viruses, and transgenes), whereas miRNAs originate from endogenous genes. Another important distinction is that siRNAs act in *cis*, silencing the same molecule from which they are derived, while miRNAs act in *trans*, silencing mRNAs from other genes [9–11].

Recently, various types of ssRNAs have been described. Among these, we find the *trans*-acting siRNAs (ta-siRNAs) (21–22 nt), a type of ssRNA that combines both siRNA and miRNA pathways since they originate from a nuclear *TAS* gene that is transcribed to an mRNA, which is then cleaved by a miRNA. The cleaved product is then processed into siRNAs directed against another mRNA, thus acting in *trans* [12, 13]. There also are natural antisense transcript-derived siRNAs (nat-siRNAs) (21–24 nt) that are quitar porque tambien hay trans-acting nats siRNAs derived from naturally occurring overlapping regions of sense and antisense transcripts [14]. The heterochromatic siRNAs (hcRNAs) or repeat-associated siRNAs (ra-siRNAs) (~24 nt) are derived from transposons, repeat elements, and heterochromatin regions. They function in the RNA-dependent DNA methylation pathway by mediating histone

modification and/or DNA methylation at the target sites [15, 16]. The long siRNAs (lsiRNAs) (30–40 nt) depend on DCL1 and AGO7 for their biogenesis and function by decapping or by 5′-3′ degradation of target mRNAs [17]. The long miRNAs (lmiRNAs) (24 nt) are involved in asymmetric DNA methylation [18]. Special cases found only in animals are the relatively long scan RNAs (scnRNAs) (~29 nt), which are involved in genome editing in *Tetrahymena thermophila* [19]. The piwi-RNAs (piRNAs) (24–31 nt) are coded in large clusters and are processed in a manner independent of Dicer; they associate specifically with the PIWI subfamily of AGO proteins and are restricted to metazoans [20, 21].

There has undoubtedly been a revolution in molecular biology caused by these ssRNAs; this revolution is driven not only by the implicit importance of these molecules in eukaryote molecular biology but also by their potential applications in various areas. They include prospective developments for gene therapy, cancer, stem-cell research, and antiviral treatments for humans and animals [22] as well as important improvements in various plant traits [23].

25.2
The Silence within: Plant miRNA Pathway

miRNAs were first discovered in *Caenorhabditis elegans* in the early 1990s, in which genetic screenings in a mutant with developmental abnormalities revealed a short noncoding RNA (*lin-4*) complementary to a coding gene (*lin-14*) to be responsible for the phenotype [24]. The molecular mechanism became clearer after it was determined that the phenotype was due to a gene silencing process guided by dsRNAs [3, 25, 26]. It took some time until the full picture of the miRNAs was revealed, and it was not until 2002 that miRNAs were discovered for the first time in plants [27, 28]. We now know that these miRNAs act in similar silencing pathways and are present in many eukaryotes.

In plants, miRNAs originate from nuclear genes (named *MIRNA* genes) and are transcribed by RNA polymerase II into primary miRNAs (pri-miRNAs), with sizes varying from 100 nt to a few kilobases. A DCL protein processes the pri-miRNA into a precursor miRNA (pre-miRNA: 70 to 400 nt). This pre-miRNA forms a characteristic hairpin-like structure. A subsequent processing step by DCL slices the pre-miRNA to form a miRNA:miRNA* duplex (21–22 nt). The duplex is then methylated and exported from the nucleus to the cytoplasm where it will join an AGO protein to form the silencing complex (RISC). Only the mature miRNA strand, which is usually the one with less stable 5′ end pairing, is retained in the complex, while the passenger (miRNA*) strand is degraded. This complex will guide the silencing of complementary mRNAs (targets) [10, 29, 30].

One important difference between animal and plant miRNAs is the higher degree of complementarity in the miRNA:target pair in plants to produce effective silencing. Other differences include the targeted region in the mRNA (any mRNA region for plants and 3′ UTR for animals,) and the outcome of miRNA silencing (mostly mRNA cleavage in plants and translational repression in animals) [31, 32].

Since their first discovery in *Arabidopsis*, the repertoire of known miRNAs has grown to include more than 120 miRNA families from more than 120 plant species [33]. Most of the described miRNAs are known to target transcription factors and play a role in different developmental processes such as leaf polarity and shape, vascular tissue and meristem development, transition from juvenile to mature growth phase, flowering time and flower organ identity, stomatal development, and so on [34–37]. There is also mounting evidence of their importance in biotic and abiotic stress responses in plants [38, 39].

25.3
The Next-Generation Microscope: New Tools for miRNA Studies

To date, too few miRNAs have been studied and even less discovered using traditional "forward" genetic approaches [40, 41]. Most miRNAs are coded by multiple loci in the genome and show in consequence functional redundancy. For this reason and their small size, the identification of miRNAs by loss-of-function mutant screens was often too difficult [29]. Reverse genetics is, therefore, the tool of choice for miRNA studies. To identify new miRNAs, two approaches were traditionally used, often simultaneously, computational prediction of miRNAs and/or cloning and sequencing of small RNAs. Computational approaches relied on various characteristics of known miRNAs such as their conservation among species (both primary and secondary structure), their position in intergenic regions or introns, and the high-energy folding for the miRNA precursors. These approaches were useful only in plants with sequenced genomes or with large sets of ESTs (expressed sequence tags) or GSS (Genome Survey Sequences) [42, 43].

Direct cloning of small RNA libraries does not need fully sequenced genomes, and was the method used to discover many plant miRNA families. Briefly, this method involves (i) RNA isolation and recovery of the ssRNA fraction in an acrylamide gel, (ii) ligation of adapters, (iii) reverse transcription, and (iv) cloning and sequencing by traditional methods. This was often time consuming and expensive, and some miRNAs with low expression were difficult to obtain [29, 43].

To identify stress-responsive miRNAs, it is crucial to determine differential expression of miRNAs in different conditions. Northern blot hybridization and microarray analyses were often used for this purpose, with the disadvantage of not giving an accurate quantification. Quantitative PCR (qPCR)-based strategies were then developed for quantifying miRNA and miRNA precursors and have proved to be effective [43]. Although these previous methods are being used and constantly improved upon, miRNA investigation seems to be moving in a new direction propelled by next-generation sequencing technologies.

The sequence-by-synthesis (SBS) technology or Solexa/Illumina sequencing [44] seems to be the most suitable strategy for miRNA identification and expression studies. This approach uses reversible nucleotide terminators to sequence short DNA fragments (signatures). The processing prior to sequencing involves basically the same steps as traditional sequencing except for cloning (reverse transcription

and adapter ligation). Although the sequence length of SBS is short (around 100 bases at present) compared to other technologies such as 454 or pyrosequencing (400 bases), it is long enough to capture the full-length sequence of small RNA molecules. More importantly, with SBS millions of signatures in parallel are obtained. This enhanced capacity is enough to capture almost all the small RNA molecules present in a given sample [45]. Also, Solexa/Illumina sequencing allows a more accurate quantification of miRNAs, based on the number of reads [46]. This has allowed extensive studies on miRNA expression under different conditions in plants [47–49].

After miRNA identification and expression quantification, the next logical step is the miRNA target prediction and validation. There is software available for target prediction, constructed on base-to-base complementarities, pairing energy, or both [50, 51]. Target prediction is considerably easier in plants than in animals given their higher degree of complementarity in the miRNA:target pair, although there are still some obstacles to overcome for an accurate target prediction such as target accessibility and prediction of translational repression [52, 53].

To validate miRNA targets, quantification using Northern blot was commonly used. It was usually accompanied by transformation approaches such as miRNA overexpression. A cheaper and more powerful method is based on 5′ RACE. This method detects *in vivo* products of miRNA cleavage by reverse transcription and PCR of the 5′ end of a cleaved miRNA target. The sequencing of the PCR product reveals the precise position of target cleavage [54].

Target validation, like miRNA discovery, has been revolutionized by next-generation sequencing technologies. Recently, a pair of methods has been developed to allow deep and simultaneous sequencing of all mRNAs cleaved by miRNAs at a given stage: the degradome sequencing methods. The strategy involves capturing either uncapped polyadenilated mRNAs or capped nonpolyadenilated mRNAs, which are miRNA-cleaved products that are then sequenced using next-generation technologies. These methods also have the additional advantage of being useful to identify new targets that were not predicted by bioinformatics [55–57].

Some of the disadvantages of next-generation sequencing for both miRNA discovery and target validation include their cost, the large data sets generated, and the work on bioinformatics needed to process the data. The last is especially problematic because there is not yet clear consensus on the computational methods used for the analysis of these data. However, as these technologies get cheaper and bioinformatics software becomes more sophisticated, miRNA research will be more accessible to different groups worldwide.

25.4
Small Weapons for the Arms Race: Plant miRNAs and Biotic Stress

Plants are commonly attacked by pathogenic bacteria, fungi, viruses, insect pests, and nematodes. Understanding and controlling these attacks is of special agronomical

interest given the enormous economical losses and the human welfare risks associated with plant diseases. Many advances have been gained in the understanding of plant–pathogen interaction with the aim of developing biotic stress-resistant plants. miRNAs have not been excluded from molecular plant pathology and the importance of this pathway in both plant defense and pathogen attack seems to be greater than was once thought for plants.

A general mechanism of miRNA-mediated "antipathogen" defense is represented in Figure 25.1. This mechanism involves mainly an increased expression of miRNAs targeting negative regulators (or repressors) of plant defense, as well as the repression of miRNAs targeting positive regulators of plant defense, thus activating or enhancing defense responses. In the case of viruses, direct targeting of viral genomes by plant miRNAs may also be involved. Pathogen counterdefense is exerted mainly by suppressing the silencing pathway. We will next examine this general model in detail.

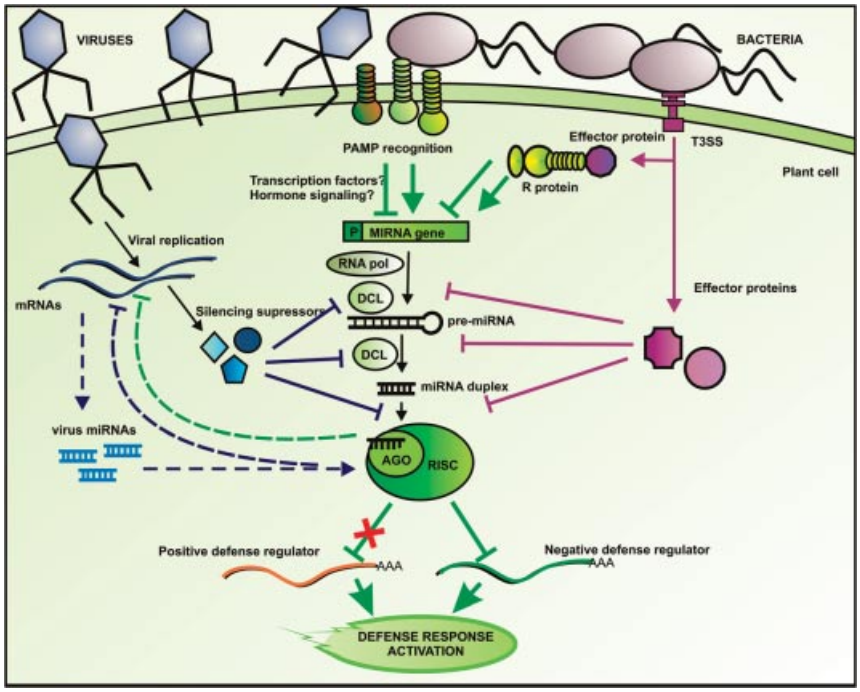

Figure 25.1 General mechanism of miRNA-mediated plant–pathogen interactions. Discontinuous lines indicate hypothetical pathways. T3SS: type-3 secretion system; PAMP: pathogen-associated molecular pattern; R protein: resistance protein; DCL: Dicer-like; AGO: Argonaute; RISC: RNA-induced silencing complex; RNA pol: RNA polymerase.

25.4.1
Suppress and Conquer: Viruses versus Plant miRNAs

The main plant defense against viruses is mediated by the siRNA pathway, through the generation of virus-derived siRNAs (vsRNAs). In this mechanism, dsRNAs are produced during viral replication and are then processed into primary and secondary siRNAs that silence mRNAs from the virus and stop its replication [39]. The siRNA pathway can be considered an "adaptive" response in the sense that virtually any replicating virus could be recognized and silenced by the plant. It is also effective because the signal is amplified and transferred from cell to cell preventing the spread of the virus to noninfected cells [58, 59].

Since their discovery, miRNAs have been postulated as important molecules in plant antiviral response. A few evidences support this hypothesis: the presence of viral suppressors affecting the miRNA pathway [60], the presence of conserved 20–24 nt sequences between plant and virus genomes [61], the differential susceptibility to virus in miRNA defective plants [62, 63], and the increasing amount of evidence of antiviral activity of miRNAs in animals [64].

Because virus nucleic acids interact directly with the host, miRNAs could be a suitable tool to affect the outcome of the virus–host interaction. Plant miRNAs could target viral genomes to directly impair their replication. This has so far been demonstrated in various cases in animal-infecting viruses [64–66]. The possibility of this process naturally occurring in plants has long been discussed, bearing in mind the possible disadvantages that the miRNA pathway has with respect to the siRNA pathway. Mainly, the miRNA pathway is not an adaptive response since the evolution of viral genomes would be fast enough to surpass the evolution of miRNAs, rendering the former ineffective in the short term [67, 68].

Employing a bioinformatics approach, we showed that several endogenous plant miRNAs have potential antiviral activity through complementarity with plant-infecting viral genomes, including miRNA families known to be differentially regulated under viral infection [65]. This is also strengthened by experiments using artificial miRNAs (amiRNAs) showing that the miRNA pathway can be effective in antiviral defense and that target complementarity is enough to impair viral replication (see Section 25.7.2) [66–68]. Our results may indicate a supporting antiviral function of the miRNA pathway to the siRNA defense mechanism or they may reflect an ancestral antiviral role for miRNAs [65].

Viruses could also encode miRNAs directed against the plant genomes (or even their own genomes) that will use the host miRNA machinery to be processed and execute their silencing effect. This mechanism has been described only in animal-infecting viruses [69, 70]. So far, the closest mechanism found in plants is encoding of sRNAs by the cauliflower mosaic virus (CaMV) that share complementarity with *Arabidopsis* genome regions [71].

There could also be indirect mechanisms mediated by miRNAs that could affect plant–virus interactions. For example, the expression of plant miRNAs targeting plant transcripts can be altered in response to virus recognition to affect the viral replication and spread. Indeed various plant miRNAs are now known to be

upregulated or downregulated after viral infection [72–77]. However, the effect of this differential regulation in the outcome of the interaction is not well established in most cases. There are some exceptions where a clearer role for miRNA regulation has been established: miR1885 is induced in response to Turnip mosaic virus infection in *Brassica rapa* and is known to target a TIR-NBS-LRR class disease-resistance gene [76]. In the case of miR164, it has been proved that its induction upon viral infection is due to hormone-dependent specific transcriptional activation [74]. Notably, next-generation sequencing or microarray methods have not being used yet for miRNA profile expression studies under viral infection, so the regulation of many miRNA-mediated processes upon viral infection is still unknown.

Nevertheless, viruses count on a powerful tool to interfere with the plant silencing machinery: the viral suppressors of gene silencing. These suppressors are proteins coded by the virus that affect siRNA and miRNA biogenesis in different ways. Some interfere with the processing of dsRNAs into ssRNAs [78], while others can interfere with the loading of sRNAs into RISC through ssRNA sequestration, can directly interfere with AGO proteins [79, 80], or may interfere with other processes including ssRNA methylation and spread of ssRNAs between cells [81]. The abundance of silencing suppressors among viruses reflects the strong selective pressure that plant sRNA-mediated silencing imposes on viral replication.

25.4.2
Being Effective: Bacteria versus Plant miRNAs

Plant resistance proteins have being considered the main molecules involved in plant defense against pathogens. An arms race model of protein evolution has been proposed for this system. In this model, a first layer of plant defense is achieved through the recognition of common features of microbes called PAMPs (pathogen-associated molecular patterns) or MAMPs (microbe-associated molecular pattern) by PAMP receptors called PRRs (pattern recognition receptors) [82]. This recognition triggers a series of events including callose deposition, ROS (reactive oxygen species) production, ion fluxes and reprogramming gene expression. This mode of action is usually known as PAMP-triggered immunity (PTI) [82]. To overcome PTI, bacteria have developed proteins called effectors that are injected into the plant cell through the type III secretion system (a syringe-like complex capable of secreting proteins) [82]. These effectors affect the PTI, thus resulting in a successful infection. In response, plants have developed resistance (R) proteins that specifically recognize bacterial effectors and trigger a specific defense response. This mechanism is usually known as effector-triggered immunity (ETI) [82].

Plant–bacteria interactions, unlike the virus case, do not involve nucleic acid exchange as a general mode of action (with known exceptions as with the genus *Agrobacterium*). Therefore, the antibacterial function of miRNAs may be exerted fundamentally through the regulation of host gene expression. Such mechanism was first revealed in the interaction between *Arabidopsis* and *Pseudomonas syringae* pv. tomato strain DC3000 (PtoDC3000), where miR393 was found to be induced in response to the flagellin-derived peptide flg22, the most-studied PAMP. This miRNA

targets the F-box family of auxin receptors TIR1 [83]. TIR1 silencing impairs auxin signaling, consequently restricting bacterial growth. These results did not only demonstrate the role miRNAs play in antibacterial defense but also implied a previously unknown importance of auxin in pathogen defense [83]. It was later discovered that PtoDC3000 can use effectors to suppress the miRNA pathway to promote disease. Effector proteins, AvrPto and HOPT-1, were found to interfere with miRNA accumulation through DCL1 and AGO activity, respectively [84]. Taken together, these results suggest an important role plant miRNAs play in response to bacteria.

Some other miRNAs have been identified to be differentially expressed under bacterial infection. Notably, miR167 and miR160 are both induced in response to PtoDC3000 and target auxin responsive factors [39, 48]. However, it has also been found in *Arabidopsis* that miR160 and miR393 expression is reduced in response to infection by *Agrobacterium tumefasciens*, with a consequent increase in the auxin level [85]. This suggests that some miRNAs could act in a pathogen-specific manner upon bacterial infection.

miRNAs 162, 168, and 825 have been shown to be downregulated in response to PtoDC3000 [48]. miR162 and miR168 regulate elements of the miRNA pathway (DCL1 and AGO1). The repression of these miRNAs would produce an overall increase in miRNA silencing activity, thus revealing a bacteria-responsive regulatory loop in the miRNA pathway and a crucial role for DCL1 and AGO in antibacterial defense [86, 87]. Recently, it has been confirmed that AGO1 plays a crucial role in PTI because AGO-impaired plants are more susceptible to bacterial infection and show decreased callose deposition and gene expression in response to PAMPs [49]. miR825 targets Cu/Zn-superoxide dismutases (SOD) and may play a role in ETI since its expression was detected to be downregulated specifically upon recognition of avrRpm1 and avrRpt2, two Pseudomonas effectors [88].

The repertory of PAMP-responsive miRNAs has been recently expanded in the *Arabidopsis*-PtoDC3000 system through the next-generation sequencing analysis, which allowed the identification of 16 upregulated miRNAs, among them not only the already known miR167 and miR160 but also miR158, miR169, miR391, and miR396 [49]. Eleven downregulated miRNAs (including miR156, miR398, and miR773) were also reported [49]. However, the mechanism by which bacteria-responsive miRNAs undergo transcriptional regulation has not been extensively studied. The promoter region of miR393 seems to be PAMP responsive, but the signaling between PAMP recognition and miRNA induction is unknown [89].

Studies on bacteria-responsive miRNAs outside *Arabidopsis* have not been published. However, our preliminary study, employing next-generation sequencing, allowed us to identify 14 upregulated and 10 downregulated conserved miRNA families during infection by *Xanthomonas axonopodis* pv. manihotis in *Manihot esculenta* (cassava), an important food crop in Third World countries. These include some known bacteria-responsive miRNAs such as miR160, miR167, and also new ones such as miR394, miR477 (both upregulated), and miR535 (downregulated). We have also identified bacteria-responsive miRNAs that are not shared with *Arabidopsis* such as miR2911 (upregulated, and probably restricted to the close relatives of cassava and *Populus*) (Pérez-Quintero *et al.*, unpublished results).

Other types of ssRNAs have been identified to mediate antibacterial responses, including a nat-siRNA induced upon R protein recognition of effector avrRpt2 in *Arabidopsis*; this nat-siRNA targets a negative regulator of ETI [90]. A lsiRNA is also responsive to PtoDC3000 infection and silences another negative regulator of ETI [17]. Both these ssRNAs make the plants resistant to bacterial infection.

In addition, miRNAs also play a role in regulating the interaction with beneficial bacteria. For example, in *Medicago truncatula* miR169 regulates the expression of transcription factor MtHAP2-1, involved in nodule development in response to *Rhizobium* infection. The expression of miR169 restricts the action of MtHAP2-1 to the nodule meristematic zone, thus promoting nodule differentiation [91]. Recently, various studies have addressed the role of miRNAs in symbiotic interactions with nitrogen-fixing bacteria, specifically in *M. truncatula* and soybean (*Glycine max*). Different miRNAs appear to be involved in various stages of bacteria colonization and root nodule formation. These include some of the miRNAs involved in the regulation of the auxin-silencing pathway such as miR160 and miR393 [92]. Other families known to be involved in symbiotic interactions are miR168 and miR159, which are differentially expressed during nitrogen-fixing bacteria recognition [92], and miR172, highly expressed in mature nodules [93]. Some species-specific miRNAs such as miR222, miR283, and miR235 in soybean may also play a role in symbiotic interaction [93]. Notably, most miRNAs known to be involved in interaction with beneficial bacteria are conserved among a wide group of plants including plants that do not form nodules.

25.4.3
To be Determined: Other Plant Pathogens and miRNAs

Too little is known about the role of miRNAs in plant interaction with other pathogenic organisms such as oomycetes, fungi, nematodes, and insects. With the notable exception of miRNAs role in the interaction of *Pinus taeda* with the rust fungus *Cronartium quercuum* f. sp. *fusiforme*, where 10 families are known to be downregulated in galls induced by the pathogen, including various species-specific miRNAs that target resistance protein, [94]. Undoubtedly, this is an exciting field to be explored and hopefully the new technologies will serve to enrich our knowledge of miRNAs role in interaction with various pathogens.

25.5
A Versatile Response to a Changing Environment: miRNAs and Abiotic Stress

As sessile organisms, plants cannot move to escape from extreme and changing conditions of the environment. Thus, plants have evolved different strategies to respond to these changes: morphological adaptations, physiological responses, and, at the molecular level, a fine-tuned reprogramming of gene expression. Regulating transcription initiation has been classically considered the main mechanism to

control gene expression. In consequence, several transcription factors involved in response to abiotic stresses have been discovered and characterized. With the discovery of miRNAs, a new layer of complexity in regulation of gene expression has been added. Several miRNAs have been recently identified to be responsive to different abiotic stresses; some of these are represented in Figure 25.2. This section describes the role the miRNA pathway plays in response to abiotic stress.

25.5.1
Elementary: Soil Elements' Uptake and miRNAs

Macro- and micronutrients in soils are essential to plants; however, the availability of these nutrients is not homogeneous in all soil types. Plants have developed different strategies to respond to the fluctuating nutrient concentrations in the environment including miRNA regulation [95]. One of the most studied miRNAs associated with abiotic stress is miR399, which is involved in the response to phosphorus (P) stress conditions. First identified in *Arabidopsis* and rice [96], miR399 is induced under low P conditions and targets a gene encoding for an ubiquitin-conjugating enzyme

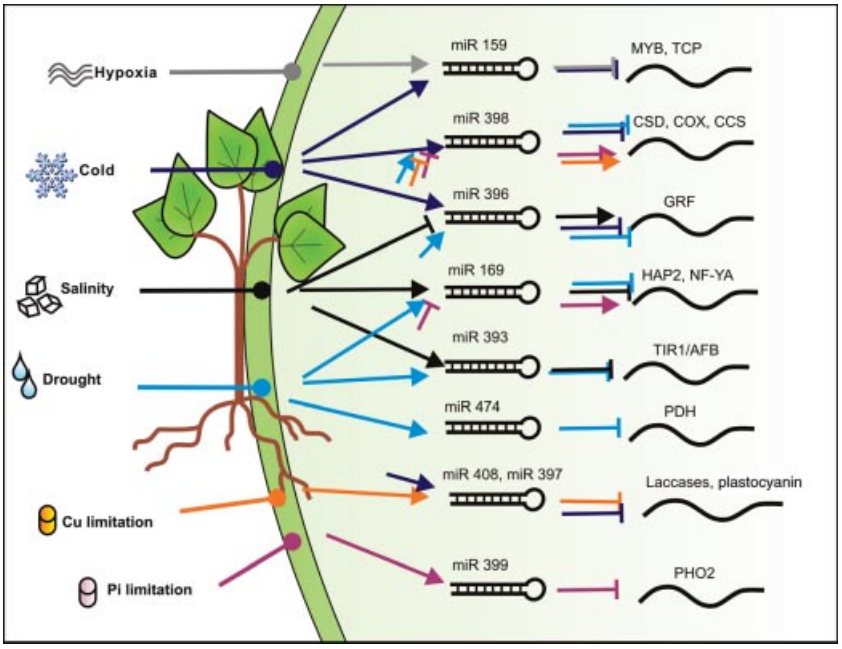

Figure 25.2 Some miRNA families involved in abiotic stress responses and their targets. Arrows indicate induction and blocked lines indicate inhibition. Some arrows have been shortened and some relations have been obviated for a better understanding of the figure. MYB and TCP: transcription factor families; CDS: Cu/Zn-superoxide dismutases; COX: cytochrome-*c* oxidase; CCS1: chaperone; GRF: growth regulation factor; HAP2 = NF-YA: nuclear transcription factor Y alpha; TIR1: transport inhibitor response 1; ARB: auxin F-box (AFB); PDH: proline dehydrogenase; PHO2: phosphate 2, ubiquitin-conjugating enzyme.

E2 [96], named *PHO2*, which is subsequently downregulated as miR399 is induced [97–100]. When expressed, the miRNA (miR399) and its target (*PHO2*) colocalize in the vascular cylinder of the root [98]. *Arabidopsis* transgenic plants that overexpress miR399 do not show accumulation of *PHO2* even under high P concentration, accumulate more P in shoots than wild plants, and show classical P toxicity symptoms (chlorosis and necrosis) [99]. The fact that toxicity observed in transgenic plants overexpressing miR399 was caused by the enhanced Pi uptake and the retention of P in old leaves suggests a transmission of a shoot-derived signal to roots that should move through the phloem [98, 100]. Recently, it was demonstrated that this signal is, in fact, the miR399 itself, which moves from shoots to roots conserving their function in these distal cells [101, 102]. miR399 seems to specifically function in response to P deficiency since it is not regulated in response to other nutrients (nitrogen, potassium, sulfate, or carbohydrates) [97, 99]. In addition, *PHO2* is protected from miRNA-mediated degradation to reduce the content of P in the shoots; this is achieved through the expression of the noncoding endogenous gene *IPS1* (induced by phosphate starvation 1), whose sequence is complementary to miR399, but it is not cleaved by it and is therefore employed to sequester the miRNA and allow *PHO2* accumulation [103]. This mechanism is known as target mimicry and has great potential for genetic transformation (see Section 25.7.1).

The use of large-scale genomics approaches allowed the identification of additional induced (miR156, miR778, miR827, and miR2111) and repressed (miR169, miR395, and miR398) miRNAs in *Arabidopsis* under phosphate deficiency [102, 104]. In soybean, using miRNA-based microarrays made it possible to identify 57 P-responsive miRNAs from 27 families. Various *cis*-elements related to phosphorus response were also found such as PHT1 element (high-affinity phosphate transporter 1) and PHR1 element (regulator of P-deficiency response) [105].

Regarding other nutrients, to study miRNA responses to nitrogen (N), the gene expression profile from specific root cell types was measured in response to an N influx. On the basis of the gene expression data, it was demonstrated that miR167 was repressed in response to nitrogen and concomitantly the expression of its target *ARF8* (an auxin response factor, ARF) was induced. Transgenic plants overexpressing miR167 showed loss of nitrogen control over lateral root emergence [106]. Other N-responsive miRNAs include miR169 and miR398 [102].

In the case of iron, some miRNAs are known to be induced under iron deprivation conditions in *Arabidopsis* including miR159a, miR169b, miR169c, miR172c, miR172d, miR173, miR394a, and miR394b [107]. An *IDE* (iron deficiency-responsive element) was found in the promoter region of some of these miRNAs [107].

On the other hand, the soil may contain not only nutrients but also potentially harmful contaminants such as heavy metals. Plants growing under conditions simulating heavy metal stress (excess or limitation) have displayed differential expression of some miRNA families. Three miRNA families are induced under low concentrations of copper (Cu) in *Arabidopsis*: miR397, miR408, and miR857. These miRNAs target laccases and plastocyanin, two secreted copper-containing proteins [108]. In the case of the miR397:laccases pair, expression of target proteins increases as copper concentration increases and is negatively correlated with miRNA

expression. However, proteins with similar function, but not regulated by the known miRNAs, display similar behavior (perhaps, regulated by unknown miRNAs) [108].

In *M. truncatula*, 38 stress-responsive miRNAs were identified in plants exposed to high concentrations of cadmium (Cd), including the induced miR171, miR319, miR393, and miR529 and the repressed miR166 and miR398; of this set, miR393 and miR171 (both induced) were experimentally validated [109]. Curiously, these families were repressed in *Brassica napus* under similar Cd conditions [110]. In rice, using next-generation sequencing of small RNAs from plants exposed to toxic concentrations of Cd, it was possible to identify several miRNAs with tissue-specific differential expression, including miRNAs induced mainly in roots (miR601, miR602, and miR603) and miRNAs downregulated in leaves and roots (miR602 and miR606 in leaves and miR604 in roots) [111]. Among these, miR604 targets a gene coding for a lipid transfer protein (LTP) previously associated with response to external stimuli [111].

25.5.2
The Silent Treatment: Cold and miRNAs

In response to low temperature, plants switch on a series of responses to overcome this condition, given the potential risks cold represents to the overall physiology of the plant. Initially, mir393 and miR319 were found to be induced and miR298 to be downregulated by cold in *Arabidopsis*; notably these miRNAs were also responsive to salinity, dehydration, and ABA [96]. Recently, through microarray analyses miR396, miR397, miR172, miR169, miR408, miR168, miR171, miR393, miR319, miR165, and miR400 were added to the list of differentially expressed miRNAs under cold conditions in *Arabidopsis* [112]. This miRNA data was subsequently employed to develop a computational algorithm to predict and annotate additional miRNAs that were further validated experimentally [113], managing to include miR156/157, miR164, miR394, and miR398, as well as cold-responsive miRNAs [113].

Brachypodium distachyon shows cold tolerance and constitutes an excellent model to understand the role of miRNAs in low-temperature response. Recently, several miRNAs were identified to be expressed in *B. distachyon* plants grown under cold conditions, including 27 conserved families and, more interestingly, 129 nonconserved [114]. Three known miRNAs (miR169, miR172, and miR397) were induced by cold stress, and novel miRNAs miR911, miR912, miR913, miR917, and miR918 showed clear changes in their expression under cold treatment [114]. In *P. thricocarpa*, another set of 19 cold stress-responsive miRNAs was identified from microarray data, 15 induced and 4 repressed [115].

In general terms, the targets predicted by these cold stress-responsive miRNAs include proteins with a broad spectrum of cellular functions, indicating a complex regulation network in responses to low-temperature conditions. Promoter analysis for some of these miRNAs has allowed the identification of several low-temperature-responsive elements (LTRs) [112] as well as other stress-responsive motifs such as the ABA response elements (ABRE), MYB binding sites, and heat stress-responsive elements (HSE) [113].

25.5.3
Out of Breath: Hypoxia and miRNAs

Hypoxia or low availability of oxygen is a known cause of stress in plants. One of the most typical conditions favoring the hypoxia is water logging that causes a drastic reduction in productivity in important crops. So far, a couple of studies have addressed differential expression of miRNAs under hypoxia. Using miRNA microarrays, 39 hypoxia-responsive miRNAs were discovered in maize, targeting not only mainly transcription factors as usual but also proteins involved in carbohydrate and lipid metabolism [116]. Similarly in *Arabidopsis*, 25 hypoxia-responsive miRNA families were identified using next-generation sequencing. Importantly, similar changes in miRNA expression to those caused by hypoxia were observed when a chemical treatment directed to block the normal mitochondrial respiration was applied, indicating a pivotal and active role of the mitochondria in the signal transmission during the response to oxygen deprivation [117]. The search for *cis*-elements regulating the expression of the above-mentioned miRNAs allowed the identification of motifs such as ARE (anaerobic response element), LTR, and several hormone-responsive elements (ABA, gibberellin, and ethylene) governing miRNA expression [116].

25.5.4
In Deep Water: Water Balance Stresses (Drought and Salinity) and miRNAs

The accelerated desertification of cultivable land and the climate change have brought several problems associated with water availability. Drought has the greatest effect on agriculture, causing significant losses to several economically important crops [118]. The use of different approaches has allowed the identification of several drought-induced miRNAs in *Arabidopsis* such as miR393, miR397, and miR402 [96] as well as miR167, miR168, miR171, and miR396 [112]. Conserved miRNAs, miR171 and miR393, were also induced in rice plants by drought [119], but not in *M. truncatula* [120]. These miRNAs target transcription factors and as mentioned in Section 25.4, miR393 targets TIR, an F-box protein that is a positive regulator of auxin signaling. The inhibition of TIR1, caused by increased expression of miR393, suggests an arrest of plant growth under drought stress [96, 112]. In *M. truncatula*, drought-induced miRNAs include miR398 and miR408 [120]. Together, these results reinforce the idea of overlapping function of some miRNAs in response to different conditions. In maize, miR474 was identified to be upregulated in response to drought [47], causing repression of target proline dehydrogenase gene (*PDH*) and thus favoring the accumulation of proline [47]. Proline has a protective function during drought preventing membrane damage and protein denaturation [47]. Among the *cis*-elements regulating drought-responsive miRNAs, there are MYB sites involved in drought induction (MBS) [112], as well as DREs (dehydration-responsive element)/CRT (C-repeat) in the upstream region of rice miR169g that binds the ERF/AP2 family transcription factors under drought stress [119].

Salinity has become a serious problem for plants predominantly due to intensive agricultural practices that along with climate change produce long and hotter

summers and cause decrease in rainfall. All these factors prevent the elimination of excessive salts present in soils [121]. In *Arabidopsis*, initial work showed miR393 to be strongly induced by salinity, while miR397b and miR402 were moderately induced [96]; miR156, miR159, and miR394 were shown to be specifically induced in response to salinity, while other 11 miRNAs were also induced by cold and by other abiotic stresses [112]. Thus, recent works have implicated miR156 and miR159 in other types of stresses as well (Table 25.1). In maize, the comparison of miRNA expression between two maize lines, one salt tolerant and other salt sensitive, allowed the detection of 18 miRNAs induced only in the salt-tolerant line indicating a varietal-dependent response to salt stress [122].

Some important loci-specific differences in miRNA families and their targets have been found in salinity responses. For example, from the 17 members of the miR169 family in rice, only miR169g and miR169n were induced in response to salt stress [119, 123]. Of the several transcription factors of the NF-YA family predicted as targets of miR169, only NF-YA8 was downregulated [123].

In rice, miR396 is repressed under salinity and alkaline stress [124]. In addition, *Arabidopsis* and rice transgenic plants overexpressing miR396 show a decrease in their tolerance to both stresses [124]. Also, seed germination was retarded in transgenic *Arabidopsis* plants expressing constitutively miR417, a salt-repressed miRNA, under conditions of high salinity, indicating a role of this miRNA as a negative regulator of seed germination under salinity [125], whereas plants over-expressing miR402 showed an accelerated growth under this stress condition [126].

25.6
The Strange Case of miR398: Crosstalk between miRNA-Mediated Responses to Biotic and Abiotic Stresses

One of the best-characterized miRNAs related to stress responses is miR398 that targets Cu/Zn-SOD enzymes (*CSD1* and *CSD2*), cytochrome-*c* oxidases (COX), and the chaperone CCS1 [29, 127, 128]. miR398 has been found to be repressed under some abiotic stress conditions known to induce ROS (reactive oxygen species) production in *Arabidopsis*, such as high light levels and heavy metals (Cu^{2+} and Fe^{3+}). The mRNA expression of its targets *CSD1* and *CSD2* mRNA was coordinately increased [128]. These enzymes are involved in the ROS detoxification, by converting superoxide radicals (O_2^-) to hydrogen peroxide. The expression of miR398 was also reduced after ozone fumigation, high salinity, or inoculation with avirulent strains of the bacteria PtoDC3000 [88]. Curiously, in these cases only the mRNA levels for *CSD1*, but not for *CSD2*, were inversely correlated with the expression of miR398 [88] indicating a possible specific role of these SOD enzymes in particular kinds of stresses. In addition, it was shown that transgenic *Arabidopsis* plants overexpressing a miR398-resistant version of *CSD2* present a higher accumulation of *CSD2* transcripts and in consequence are more tolerant to different oxidative agents [128]. In *Populus trichocarpa* plants treated with ABA or subjected to salt stress, miR398 is induced at early stages (first 3–4 h), but after 48 h the induction declines and is finally

Table 25.1 Commonly studied differentially expressed miRNA families under different types of stress.

accumulated again over a prolonged stress (72 h). In *Arabidopsis* plants grown under the same conditions, miR398 shows an opposite response, indicating a species-specific behavior of some miRNAs in stress responses [129]. miR398 also plays an important role in response to copper stress conditions. Under low copper concentrations, it was demonstrated that the stability of *COX5b* mRNA was regulated by the action of miR398 [128, 130]. It has also been shown to be repressed in *Arabidopsis* plants growing in low nitrogen or phosphorus [102, 104], and in *M. truncatula* in response to Cd [109]. Furthermore, miR398 was induced in response to cold and sucrose in *Arabidopsis* [113, 131] and to drought in *M. truncatula* [120]. Importantly, it has been shown that miR398 can produce silencing of targets with imperfect complementarity (thus having targets that often escape traditional target prediction) and produce silencing through translational repression instead of mRNA cleavage [127, 131].

The differential expression under various conditions of miR398 and other extensively studied miRNA families is summarized in Table 25.1. As is clear from these results, many miRNAs may be playing more than one role in different types of stress.

The case of miR398 is revealing in the sense that although a clear biological role has been established for this family with an evident effect on the outcome of stress responses as in the case of ROS detoxification and copper regulation [128, 130], some aspects of its regulation are still unclear, as well as the role it may play in other types of stresses.

As we have seen in this chapter, miRNA regulation may vary in a tissue-specific [91, 105, 111], stress-specific, and species-specific manner (Table 25.1). In addition, nontraditional miRNA-mediated silencing such as translational repression through imperfect miRNA:target pairing (parameters for this type of pairing are still unknown) can occur [53, 127, 131]. And more importantly, there are multiple layers of complexity in miRNA regulation that are often difficult to assess; this complexity arises from multiple *cis*-elements that control miRNA transcription (e.g., one miRNA may be regulated by various transcription factors), as well as the multiplicity of targets for one miRNA, and multiple loci expressing related miRNA (families) and each loci perhaps under different transcriptional control. Recently, through bioinformatics, the complexity of miRNA regulatory networks was analyzed (although expression levels and *cis*-regulatory elements were not yet considered), showing a high degree of connectivity for some miRNAs [132].

Although differential expression has been the usual method for identifying biologically relevant miRNAs, all the above-mentioned factors may be affecting the outcome that these differentially expressed miRNAs may bring upon physiological processes, making it hard to differentiate truly significant stress-responsive miRNAs from those resulting from interconnectivity or pleiotropic effects. This must be taken into account when assigning a biological role to miRNAs, especially when genetic transformation strategies for stress resistance are intended.

25.7
Viva la Revolución: Using miRNA-Mediated Strategies to Develop Stress-Resistant Crops

25.7.1
Imitation of Silence: Artificial miRNAs in Plants' Genetic Transformation

As we mentioned before, one of the big drivers behind miRNA studies is the prospects that these molecules offer in genetic transformation to improve agronomic traits in plants. One way to use miRNAs in genetic transformation is through amiRNAs, which basically consist of transgenes made of endogenous miRNAs modified to silence any desired target.

amiRNAs are designed from an endogenous miRNA precursor that is used as a structural support in which the miRNA:miRNA* region is replaced with a specific miRNA complementary to the desired target sequence. The processing *in planta* of this new precursor will be the same as the endogenous one, as long as the secondary structure of the precursor is kept intact [133–135]. When designing an amiRNA, the sequence must be optimized in specificity and effectiveness; this means to select a

sequence with no potential off-targets in the desired genome and with high affinity for the target. Bioinformatics tools are available for these analyses [136]. The designed miRNA and the passenger strand are then inserted to replace the miRNA:miRNA* duplex in the endogenous miRNA precursors. The sequence can be inserted in plasmids containing the precursor through directed mutagenesis, overlapping PCR, or enzymatic digestion [136, 137]. The amiRNA transformation vector must have a termination sequence and a promoter. Inducible and constitutive promoters have shown good results in amiRNA-mediated transformation [133, 136, 138, 139]. A schematic representation of this method can be seen in Figure 25.3.

Prior to amiRNAs, various methods for plant transformation and functional gene studies based on small silencing RNAs were developed. These had some advantages over traditional methods (i.e., transposon tagging, insertional mutagenesis, and TILLING) like being able to simultaneously silence related genes and silencing genes in an inducible or tissue-specific manner [133]. These methods were based on the production of dsRNAs from a given source that produced siRNAs to silence the desired gene, for example, antisense RNA, hp-RNA, and virus-induced gene silencing (VIGS) [140, 141]. Although these tools are still widely used, they have some disadvantages regarding specificity and stability. The inserts used in these strategies are often long (>200 bp) and will not only generate a large number of siRNAs complementary to various regions of the mRNA but also possibly generate siRNAs

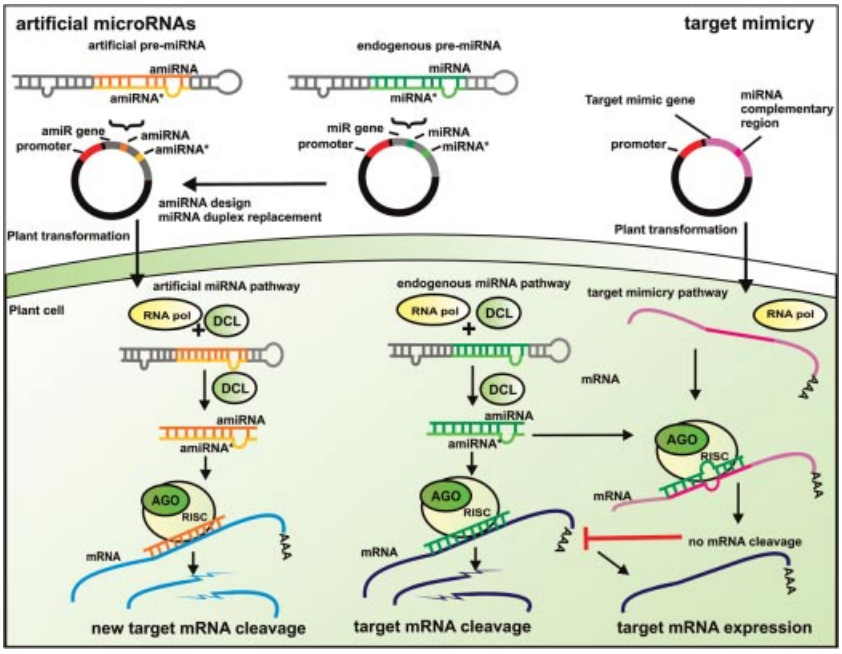

Figure 25.3 miRNA-related plant genetic transformation strategies: artificial miRNAs (amiRNAs) and target mimicry. DCL: Dicer-like; AGO: Argonaute; RISC: RNA-induced silencing complex; RNA pol: RNA polymerase.

partially complementary to undesired regions of the genome (off-targets) that are usually hard to predict. It is estimated that 50–70% of the genes in a genome could produce off -targets if used in RNA silencing strategies [137, 139, 142]. Moreover, these transgenes can be autosilenced resulting in a loss of the desired phenotype (a silenced gene) after several generations [137, 138, 143].

Successful amiRNA-mediated gene-silencing experiments have been conducted in dicotyledonous plants (*A. thaliana*, *M. truncatula*, tomato, tobacco, and soybean) [135, 144, 145], monocotyledonous plants (rice and wheat) [146, 147], mosses (*Physcomithrella patens*) [142], and even algae *(Chlamydomonas reinhardtii*) [137, 138]. They have shown to offer some advantages over other ssRNA-mediated strategies; these include (i) specificity as high as with endogenous miRNAs, (ii) absence of off targets, and (iii) absence of secondary siRNA formation or nonautonomous effects [135, 139, 144, 146, 148, 149]. They have been shown to be stable through various generations [137, 138, 146]. Also, it is possible both to generate constructs expressing multiple and unrelated amiRNAs due to their small size [66, 150] and to design amiRNAs targeting specific alleles or splice forms of a given gene [136]. It has also been proposed that amiRNAs pose fewer biosafety or environmental problems when applied to agriculture than other strategies [23, 68].

There are, however, some difficulties in working with amiRNAs. The success rate of amiRNA, inferred from various published studies, may vary from 75 to 90 % [66, 67, 139, 144, 148, 151]. The reasons why some genes cannot be silenced through amiRNAs are not yet clear. A possible explanation may be the difficult accessibility of the target mRNA to the RISC, which could be overcome in amiRNA design by thermodynamically modeling mRNA accessibility [152]. Also, amiRNA activity may be impaired by a negative regulation mechanism where the artificially produced silencing is compensated by an increase in the transcription rates of the targeted mRNA, though this has not been proved yet [136].

Along with amiRNAs, other novel miRNA-related strategies have been developed to improve plant genetic transformation. Artificial ta-siRNAs have been designed in a similar way to that of amiRNAs by replacing the siRNA region in the TASc1 ta-siRNA gene (which requires miR173-mediated cleavage to produce siRNAs) with sequences complementary to new desired targets, producing effective silencing [153]. There is also a technique to improve amiRNA's effectiveness by designing them from long primary miRNAs instead of pre-miRNAs [154].

Likewise, another promising strategy is target mimicry, where a noncleavable mRNA is inserted into the plant to interact in a non-silencing manner with a miRNA, thus inhibiting its activity (Figure 25.3). This strategy would allow modulation of the expression level of endogenous miRNAs to achieve a greater expression of genes normally regulated by miRNAs. Although this strategy has not being extensively exploited yet, recently a valuable large-scale collection of knockdowns for *Arabidopsis* was made comprising most known miRNA families in this plant [23, 103, 155].

So far, amiRNAs and related strategies have been used in a few model and crop plant species, particularly *Arabidopsis*, where there are even ongoing efforts to have amiRNA libraries covering all annotated genes [133]. In a short time, the techniques have spread to a larger number of plant species and are rapidly becoming reliable

tools for functional gene analysis [23, 145, 156]. amiRNAs are still a technique used mostly for research purposes, and they have not been yet extensively employed in crops to improve agronomical traits such as stress resistance. The potential for the technique is great, and probably we are not so far from having commercially available crop varieties transformed with amiRNAs.

25.7.2 Biotic Stress Resistance

From early in their development, it was foreseen that one of the greatest potentials for amiRNAs would be to produce plants with enhanced stress resistance, especially for antiviral defense. Unlike other types of stresses, viral infection has been already addressed through miRNA-mediated technologies. It has been demonstrated using amiRNAs that the miRNA pathway in plants can function in antiviral defense. Transgenic *Arabidopsis* and tobacco plants have been transformed to develop resistance against TMV (turnip mosaic virus), TuMV (turnip yellow mosaic virus), and CMV (cucumber mosaic virus) by inserting amiRNAS complementary into viral genome regions [66–68, 150]. These efforts have revealed resistance at cellular level, inheritable, more efficient than siRNA-mediated strategies, and successful in blocking viral replication and movement [66, 67]. Furthermore, it has been possible to create transgenic plants with dimeric amiRNAs directed against different viruses resulting in plants with a wide spectrum of viral resistance [66, 150].

There are, however, some difficulties to overcome when considering a widespread use of amiRNAs in antiviral defense. The presence in many viruses of silencing suppressors that interfere with the miRNA machinery poses an obstacle that could be solved by designing amiRNAs directed against silencing suppressors [66, 67]. The most important objection comes from the fact that viral genomes evolve a lot faster than plant miRNAs and can evade miRNA targeting by mutating the targeted region [150, 157]. A solution has been proposed that mainly consists of a "polymeric strategy" where transgenic plants have amiRNAs directed against several viral regions, preferentially conserved [66, 68, 150]. The effectiveness of such strategy has not being completely tested yet.

The use of amiRNAs to develop resistance against other pathogens can be slightly more difficult than with viruses since there is no direct interaction with the pathogen's nucleic acids. Thus, efforts for amiRNA-mediated antipathogen resistance should aim at modifying the plant defense responses through miRNA regulation, which could also work as an indirect way for antiviral defense.

Our present knowledge of miRNA roles in antipathogen defense points to two principal modes of regulating plant defense (Figure 25.1): the induction of miRNAs targeting negative regulators of plant defense and the repression of miRNAs targeting positive regulators of plant defense. These two strategies could be artificially reproduced in plants in various ways: (i) by overexpressing pathogen-induced miRNAs, (ii) using amiRNAs directed against negative regulators of plant defense, and (iii) through target mimicry using mRNAs binding to miRNAs cleaving positive regulators of plant defense.

Overexpression of pathogen-induced miRNAs, as in the case of PtoDC3000-responsive miR393 in *Arabidopsis*, has proven to increase resistance to bacterial infection; however, some developmental defects have been observed [83] that are undesirable when trying to take this strategy to crops. Additional attempts to improve antipathogen resistance by miRNA overexpression are scarce.

In the case of amiRNAs and target mimicry, with these strategies, it could be possible to accentuate existing miRNA-mediated responses in plants, for example, by introducing new amiRNAs in plants to target auxin response factors coupled to pathogen-inducible promoters (in the same way as miR393 and miR160 act) or using pathogen-inducible target mimicry to further repress the activity of miRNAs such as miR825. The techniques could also be used to develop novel resistance mechanisms by insertion of amiRNAs targeting negative regulators of plant defense, which are not normally under miRNA regulation. However, given the mentioned difficulties in assessing miRNA roles in stress (see Section 25.6), these approaches must be coupled to a complete understanding of miRNA-regulated networks.

25.7.3
Abiotic Stress Resistance

By understanding the complex regulatory circuits involved in miRNA-mediated gene expression, it is possible to think of ways to manipulate these circuits to produce plants with an increased tolerance to a particular kind of abiotic stress. There are some examples where the manipulation of miRNA regulation has produced desired effects in plants. In one case, overexpression of a mimic *CSD* gene, resistant to miR398 degradation, produced plants more tolerant to higher levels of light and heavy metals [128]. The potential to manipulate miRNAs to obtain desired traits is great, although it should be considered carefully.

One possibility to modify miRNA-mediated responses to abiotic stress, which has already been explored, is to produce transgenic plants overexpressing miRNAs to increase the degradation of their target genes; varying results have been obtained with this approach. For example, overexpression of miR402 (a salinity- and drought-induced miRNA family) produced an accelerated seedling growth under salinity stress condition [126], which would be a desired trait for crops to grow in difficult soils. However, the overexpression of particular miRNAs could produce undesired effects. For example, transgenic plants with constitutive expression of miR399 (normally induced under P starvation) displayed an increased accumulation of P without great adverse effects [99], whereas in other cases, plants overexpressing miR399 showed toxicity symptoms produced by the uncontrolled P uptake and by a pronounced P translocation from roots to shoots [100].

Caution must also be exerted when trying to translate results from research in model species into crops due to the mostly unknown species-specific effects on miRNA responses despite the high conservation of some miRNA families. For example, in one case, the overexpression of conserved miR396 in rice produced a

reduced tolerance to salinity and alkali conditions [124], while the overexpression of this miRNA in *Arabidopsis* increased the tolerance to drought and other abiotic stresses [158].

Engineering new miRNA pathways using amiRNAs and target mimicry may also be possible as our knowledge of abiotic stress responses increases.

25.8 Conclusions and Perspectives

The use of miRNAs as a tool for plant genetic engineering is exciting and likely to be highly rewarding, and there are surely many ongoing efforts to exploit the miRNA pathway for crop improvement. However, there are still large gaps in our knowledge of miRNA-mediated regulation as is evident from the increasing inventory of differentially expressed miRNA under stress conditions for which a clear physiological outcome in stress responses has not been established.

The complexity of the regulatory networks mediated by miRNAs in plants is perhaps still not fully perceived. There is undoubtedly a need to establish comprehensible links between the transcriptome, the microme (microRNome or microtranscriptome), the degradome, and the proteome (including regulatory *cis*-elements) in order to conceive the modification or creation of miRNA pathways without adverse physiological consequences. Efforts should thus be addressed to model gene regulatory networks incorporating large sets of biological data; this is now more feasible than once expected due to the significant improvements in sequencing technologies, bioinformatics, and systems biology.

The expansion of miRNA research to plants different from the traditional models may also be essential to future miRNA genetic transformation given the species-specific differences in conserved miRNA regulation and the unexplored potential of phylogenetically restricted miRNA families. This is particularly true for stress responses where such variability is displayed among relatively narrow phylogenetic ranges (e.g., the wide range of environmental adaptations among the *Poaceae*). The results shown by miRNA research on relatively new models for specific processes (such as soybean and *M. truncatula* for root symbiosis studies and *B. dystachion* for cold responses) confirm the importance of this type of studies, and it is our expectation that this field will grow to include less explored plants such as mangroves for salinity and drowning tolerance and cassava for drought tolerance.

Acknowledgments

We would like to thank Paul Chavarriaga, Katie Murphy, and Rafik Neme for their revision of and useful corrections to this manuscript. We also thank Dirección de Investigaciones sede Bogota (Universidad Nacional), Colciencias, Ministerio de Agricultura de Colombia, for financial support.

Transcription Factors: Improving Abiotic Stress Tolerance in Plants

Tetsuya Ishida, Yuriko Osakabe, and Shuichi Yanagisawa

Plant growth and productivity are greatly affected by environmental abiotic stresses, including drought, high salinity, high or low temperature, nutrient starvation, and excess metals in soils. After perceiving these stress signals, plants modulate the expression levels of various genes to adapt to and overcome environmental changes. Transcription factors thus play central roles in the regulatory networks that mediate the adaptation of plants to various environmental stresses. Although our knowledge of the transcription factors associated with abiotic stress response in crops is still limited, a number of such transcription factors have been recently identified, mainly in the model plant, *Arabidopsis thaliana*. In addition, several examples of transcription factors being successfully utilized to improve abiotic stress tolerance have now been reported, suggesting that this is a promising strategy to enhance stress tolerance in crops. In this chapter, we provide an overview of the present knowledge of plant transcription factors associated with various abiotic stress responses and their potential application to the enhancement of abiotic stress tolerance in plants.

26.1
Introduction

Plants must adequately adapt to fluctuations in the environment in which they grow as they cannot move from place to place. During the adaptation to stress conditions, plants modulate the expression of numerous genes. For instance, it has been shown by transcriptome analysis that drought stress induces expression of 277 genes, and represses another 79 genes, in *Arabidopsis* [1]. The expression levels of individual genes can be modulated through transcriptional control, alternative splicing events, and changes in RNA stability. Furthermore, the abundance of functional and active proteins can be regulated in response to stress signals by translational control, posttranslational modifications, and degradation mechanisms. Although abiotic

Improving Crop Resistance to Abiotic Stress, First Edition.

stress responses in plants likely include various mechanisms to induce specific proteins, transcriptional control appears to be an important component of these processes.

Transcriptional control is typically exerted through the action of transcription factors that are specifically involved in particular signal responses. To more fully understand the molecular mechanisms underlying stress-responsive gene expression and thereby uncover potential strategies to improve stress tolerance in plants, the identification of the key transcription factors involved is absolutely necessary. Only a limited number of such analyses using crops have been conducted to date, but transcription factors associated with abiotic stresses, namely, drought, high salinity, cold and heat, nutrient starvation, and excess metals in the soil, have been identified in recent studies both in the model dicot *Arabidopsis* and in rice, a monocot plant and one of the most important crops in the world. Furthermore, several successes in improving stress tolerance have also been reported using these identified transcription factors. In this chapter, we provide an overview of these successful applications and also of the present knowledge of transcription factors involved in stress responses in plants.

26.2
Transcription Factors Involved in the Drought Stress Response

As water limitation severely impacts agricultural productivity, the enhanced tolerance to drought is one of the most important and sought after traits in the molecular breeding of crops. Drought stress exerts its effects on various cellular and molecular events in plants, particularly upon the expression of a variety of genes that are involved in not only stress tolerance but also in the enhancement of stress response pathways. Indeed, transcriptome analyses have now indicated that more than 300 transcripts are modulated by drought stress [1]. Owing to the diverse effects of drought stress, plant responses to water stress are thought to be regulated by an orchestrated but complex series of signaling networks, the details of which remain to be elucidated [2, 3]. Furthermore, as drought and salinity stresses have been found to cause similar changes in the transcriptome in *Arabidopsis* [4], the signaling pathways associated with these stresses may influence and activate each other or operate through a shared mechanism. In addition, a plant hormone, abscisic acid (ABA), has been shown to play a critical role in drought stress. ABA is dramatically produced under drought and salinity stress conditions and influences the expression of various genes that respond to them. Drought and salinity stress signaling and ABA signaling therefore are integrated into a complex regulatory network that forms part of the stress response mechanism in plants.

The cellular processes that operate in response to drought stress are initiated by the perception of these conditions by specific sensors. Recent studies have revealed the role of AtHK1/AHK1 in the perception of drought stress. AtHK1/AHK1 is a histidine kinase in the two-component signaling system, which also mediates

osmotic stress signaling in prokaryotes [5, 6]. Tran *et al*. have shown that AHK1 functions as an osmosensor and that its overexpression improves tolerance to drought stress in *Arabidopsis* [6]. RPK1, a receptor-like kinase that is localized to plasma membrane and controls several ABA responses in *Arabidopsis*, was also found to be involved in the early steps of osmotic stress signaling in plant cells [7, 8]. As the components that function directly downstream of AtHK1/AHK1 and RPK1 have yet to be identified, the molecular mechanisms underlying drought stress signaling in plants remain mostly unknown. However, in the past decade, the knowledge of the transcriptional control that functions during drought stress signaling has increased markedly through the identification of several transcription factors that play critical roles in the drought stress response in plants (Table 26.1).

26.2.1
DREB2 Transcription Factors

Similar to other types of transcriptional regulation, stress-responsive transcription is mediated by particular *cis*-acting elements and *trans*-acting transcription factors that recognize these *cis*-elements [3]. Indeed, the drought-responsive *cis*-element (DRE, 5′-TACCGACAT-3′) has been identified in the promoter regions of drought and salinity stress-inducible genes. Furthermore, a part of the DRE (5′-CCGAC-3′) has also been reported to function as the *cis*-element that regulates transcription from various cold-responsive gene promoters, and has been designated as the C-repeat (CRT) and the low-temperature-responsive element (LTRE) [9–12]. This suggests a close relationship between the regulatory mechanisms for drought and cold stress-responsive gene expression. Transcription factors that specifically recognize the DRE/CRT sequence have now been identified using yeast one-hybrid screening and are referred to as DREB1/CBF (DRE binding protein 1/CRT binding factor) and DREB2 [11, 13]. DREB1/CBF and DREB2 form the DREB/CBF family, a subfamily of the plant-specific AP2 (APETALA2)/ERF transcription factor family [14].

Although the function of DREB1/CBF was specifically characterized in the cold stress response in *Arabidopsis*, as discussed further later, expression of the *DREB2* genes, *DREB2A* and *DREB2B*, is induced by both dehydration and salinity stress but not by cold stress [13–15]. Hence, DREB2 appears to be involved in both the drought and the salinity stress response. This induction of *DREB2* genes precedes the induction of other stress-responsive genes that play roles in stress tolerance, such as *LEA* (late-embryogenesis abundant protein) genes, in agreement with the primary role of DREB2 in the drought stress response. However, the overexpression of *DREB2A* under the control of the cauliflower mosaic virus 35S RNA (35S) promoter does not affect the stress tolerance of transgenic *Arabidopsis* plants. This unexpected contradiction was resolved by further characterization of the DREB2A protein, which revealed that posttranslational modification is necessary for its full activation [13]. Indeed, Sakuma *et al*. showed that the negative regulatory domain exists in the central region of DREB2A and that deletion of this negative regulatory

Table 26.1 Transcription factors involved in drought, salinity, cold, and heat stress tolerance.

Class	Type	Gene	*cis*-elements	Induction	Stress	References

"—" indicates that the binding sequence and the inducer have not been identified yet. Bracket indicates that gene disruption improved stress tolerance.

domain results in the production of a constitutively active form of this protein [16]. Hence, transgenic *Arabidopsis* plants overexpressing the constitutively active form of DREB2A showed a stronger tolerance to drought stress, accompanied by an upregulation of various stress-responsive genes [16]. The protein that interacts with the negative regulatory domain of DREB2A has recently been identified, as DRIP1 (DREB2A interacting protein 1), and is a C_3HC_4 RING domain-containing protein. Furthermore, negative regulatory mechanisms for DREB2A activity was suggested to involve 26S proteasome pathway-dependent proteolysis mediated by DRIP1 and its homologue DRIP2 [17].

Interestingly, the upregulated genes in the transgenic *Arabidopsis* overexpressing DREB2A include not only drought and salinity stress-responsive genes under these conditions but also genes encoding heat shock proteins (HSPs) [18]. As expected, transgenic *Arabidopsis* plants overexpressing such genes also show an increased tolerance to heat stress, whereas the corresponding knockout plants are impaired in this respect [18]. This observation also implies the presence of a complex regulatory network involving a crosstalk among various stress signaling pathways.

26.2.2
Transcription Factors that Interact with the ABA-Responsive Element in Drought Stress-Responsive Promoters

Drought and salinity stress conditions are partly mediated by ABA that induces expression of various genes through the ABA-responsive *cis*-element, the ABRE. Both DRE/CRT and ABRE have been found in many stress-responsive gene promoters, suggesting that ABRE also plays a role in stress-responsive transcription [3]. AREB/ABFs (ABRE binding proteins/ABRE binding factors) have been identified in *Arabidopsis*, and they are bZIP-type transcription factors [19, 20]. Consistent with their roles, the AREB/ABF transcripts accumulate in response to the exogenous application of ABA and to drought and salinity stress treatments [20]. Furthermore, the overexpression of ABF3 and ABF4/AREB2 in *Arabidopsis* increases the expression of ABA-responsive genes such as the LEA genes and results in the enhancement of ABA sensitivity, glucose sensitivity, and drought stress tolerance [21]. The overexpression of ABF2/AREB1 in *Arabidopsis* also enhances ABA and glucose sensitivity and improves drought tolerance. In contrast, the *abf2*/*areb1* mutants exhibited reduced sensitivity of glucose, which was not observed in the *abf3* and *abf4*/*areb2* mutants [22]. Similar effects caused by overexpression of ABF/AREB proteins but different phenotypes by disruption of *ABF*/*AREB* genes may be suggestive of redundant but different roles. Similar to DREB2A, the modification of the ABF2/AREB1 protein was found to be required for the full activation of ABF2/AREB1 [23, 24]. The overexpression of the active form of ABF2/AREB1 in *Arabidopsis*, therefore, increased ABA-responsive gene expression and drought tolerance more strongly [23, 24].

The transactivation activity of ABF2/AREB1 has been shown to depend on ABA and thus is lower in the ABA-insensitive mutant *abi1* [20]. Since the ABI1 protein is a phosphatase 2C (PP2C) [25, 26], ABA-dependent phosphorylation/dephosphorylation is thought to be involved in the activation of AREB/ABF proteins. Indeed,

Furihata *et al*. have shown that ABA treatment stimulates the activity of a 42-kDa protein kinase in *Arabidopsis* and induces the phosphorylation of Ser/Thr residues at R-X-X-S/T sites in AREB1 [24]. Furthermore, it has been revealed that the activity of the 42-kDa kinase toward ABF1, ABF2/AREB1, and ABI5 is impaired in the *snrk2.2snrk2.3* double mutant that harbors mutations in two genes encoding type-2 SNF1-related protein kinases (SnRK2.2/SRK2D and SnRK2.3/SRK2I) [27]. The *snrk2.2snrk2.3snrk2.6* triple mutant shows severe phenotypes in terms of the ABA sensitivity, the phosphorylation of ABF/AREBs, and the ABA-dependent gene expression [28–31]. The SnRKs have, therefore, been shown to be involved in the activation of AREB/ABFs. It was recently revealed that ABA promotes interactions between ABA receptors, PYR/PYL/RCARs, and PP2Cs, ABI1 and ABI2, which are negative regulators of ABA signaling [32, 33], and thereby inhibits PP2C activity to control ABA signaling [34, 35]. Therefore, ABA likely regulates ABF/AREB activity through the PYR/PYL/RCAR–PP2C–SnRK cascade and then contributes to the drought and salinity stress response pathways, although the exact mechanism is unknown.

26.2.3
Additional Transcription Factors Involved in the Drought Stress Response

Transcription factors of the MYB, NAC, and other families have also been suggested to play roles in the drought response in plants [3]. One of these is a novel C_2H_2-type transcription factor, DST (DROUGHT AND SALT TOLERANCE), which controls the expression of genes involved in H_2O_2 homeostasis and mediates H_2O_2-induced stomatal closure and abiotic stress tolerance in rice [36]. Both H_2O_2 and hydroxyl radicals are typical reactive oxygen species (ROS). ROS production is induced by both abiotic and biotic stress, including high light, osmotic stress, and pathogen attack, and ROS detoxification is one of the most important steps in stress tolerance. Further characterization of DST might, therefore, clarify the interaction between ROS and ABA signaling pathways in the drought and salinity stress responses.

Another transcription factor associated with drought and salt stresses is an *Arabidopsis* factor that is structurally related to the human NF-X1 protein (nuclear transcription factor X-box binding 1) and contributes to salt and defense responses [37, 38]. Li *et al*. have shown that NFYA5, a drought stress-inducible nuclear transcription factor Y, plays a role in controlling stomatal aperture and drought tolerance [39]. Several transcription factors have also been found to regulate stomatal apertures under conditions of drought stress. Overexpression of an NAC transcription factor in rice, SNAC1 (stress-responsive NAC 1), which is expressed in guard cells, leads to an increased ABA sensitivity and stomatal closure and results in improved drought and salt tolerance [40]. Two MYB transcription factors, AtMYB60 and AtMYB61, which are also expressed mainly in guard cells, have been functionally characterized as important modulators of stomatal aperture and drought tolerance in *Arabidopsis*. AtMYB60 is a negative regulator of stomatal closure under drought stress conditions and the *atmyb60* null mutation results in the constitutive reduction of stomatal opening, whereas AtMYB61 is a positive regulator of this process and its loss

of function results in more-open stomata [41, 42]. *OCP3*, encoding a transcription factor of the homeodomain family, also plays a role in controlling the ABA-induced stomatal aperture and drought resistance [43]. These factors are likely to be associated with complex mechanisms underlying drought stress signaling in stomata.

26.3 Transcription Factors that Mediate the Response to Cold Stress

As the expression of DREB1/CBF proteins (DREB1A-C/CBF1-3) is induced by cold stress [13, 15], these factors appear to be specifically engaged in the transcriptional regulation of cold stress-responsive genes. Consistent with their induction, the overexpression of *DREB1B/CBF1* under the control of the 35S promoter increases tolerance to cold stress in *Arabidopsis* [44]. Interestingly, however, the overexpression of *DREB1/CBF* enhances the tolerance to not only cold stress but also drought and salinity stress conditions [13, 45, 46], suggesting either that a crosstalk exists among stress signaling pathways or that a mechanism shared by different stress signaling pathways is activated. Although the improved tolerance to cold stress indicates that the utilization of *DREB1/CBF* is an effective approach to improve cold stress tolerance, transgenic *Arabidopsis* lines overexpressing *DREB1/CBF* also show severe growth defects [45]. Hence, Kasuga *et al*. were able to overexpress *DREB1/CBF* under stress conditions using only a stress-inducible promoter [45]. As the newly generated transgenic *Arabidopsis* did not manifest any negative effect in terms of plant growth [45], the strategy with *DREB1/CBF* appears to be now a practical approach that can be applied to crop improvement. In fact, the overexpression of *DREB1/CBF* genes also increased tolerance to freezing, chilling, and drought stress in various plant species, including *Brassica napus*, tobacco, tomato, rice, wheat, and maize [47–54]. The overexpression of *DREB1/CBF* in *Arabidopsis* triggers the upregulation of not only various stress-responsive genes including LEA protein and cold-inducible KIN protein genes but also a C_2H_2 zinc finger transcription factor gene. This gene, termed *STZ*, is one of the direct target genes of DREB1/CBF [55, 56]. Because the overexpression of STZ, which functions as a transcriptional repressor, also enhances the tolerance to drought stress [56], the transcriptional cascade including DREB/CBF and STZ appears to play a key role in the cold stress response in *Arabidopsis*.

The presence of a complex regulatory mechanism underlying the expression of DREB1/CBF in response to stress signals has been revealed. The *ICE1* (*inducer of CBF expression 1*), *HOS1* (*high expression of osmotically responsive gene 1*), and *MYB15* genes were found to encode factors involved in this regulatory mechanism (Figure 26.1). ICE1, a basic helix–loop–helix (bHLH) transcription factor, is a major positive regulator of *CBF3* through the binding of multiple *cis*-regulatory elements in the promoter and promotion of transcription [57, 58]. On the other hand, HOS1 is a RING-type ubiquitin E3 ligase that negatively regulates *DREB1/CBF* gene expression [59]. Miura *et al*. showed that the low-temperature-induced sumoylation of ICE1 is mediated by the SIZ1 protein, a SUMO E3 ligase, and that this process is a key regulatory component of cold stress-responsive gene expression [60]. This process is

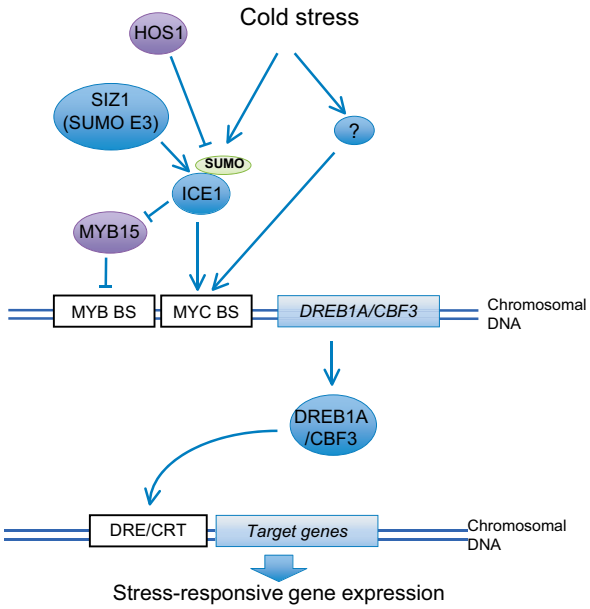

Figure 26.1 The transcriptional network that operates during the cold stress response. The DREB1A/CBF3 transcription factor that binds the DRE/CRT *cis*-acting elements and regulates transcription is expressed under the control of multiple components, including MYB15, ICE1, SIZ1, and HOS1, in response to cold stress.

inhibited by HOS1, which mediates the ubiquitination and degradation of ICE1 [58, 61]. MYB15 that interacts with ICE1 is another regulator that binds and negatively regulates transcription from the *CBF* promoters [62]. Thus, cold stress influences *DREB1/CBF* gene expression via protein sumoylation and ubiquitination and fine-tunes the expression of various stress-responsive genes during the stress tolerance response in plants (Figure 26.1) [63].

On the other hand, CAMTA3, a member of the CAMTA (calmodulin binding transcription activator) family of transcription factors, has been shown to be a positive regulator of the *DREB1C/CBF2* gene [64]. The *camta3* mutant plants show a reduced induction of *CBF2* under cold stress conditions, and the *camta1 camta3* double mutant shows a reduced freezing tolerance. This suggests a connection between calcium signaling and cold-regulated gene expression.

26.4
Transcription Factors Mediating the Response to Heat Stress

Heat stress tolerance (thermotolerance) is also under the control of coordinated signaling pathways [65]. Heat stress or heat shock induces the synthesis and accumulation of heat shock proteins in both plants and animals. The HSPs comprise

five protein families, namely, the HSP100, HSP90, HSP70, and HSP60 families and the small HSPs (sHSPs) [66]. HSPs primarily function as molecular chaperones to prevent the aggregation of denatured proteins caused by heat shock and to promote the appropriate refolding of denatured proteins [67].

The heat-inducible expression of *HSP* genes is regulated by heat shock transcription factors (HSFs) that are conserved in eukaryotes. HSFs bind to heat shock-responsive elements (HSEs), which are conserved *cis*-elements in the *HSP* gene promoters [68]. Among 21 HSFs in *Arabidopsis*, AtHsfA1a and AtHsfA1b have already been shown to play important roles in the expression of *HSP* genes in the early phase of the heat shock response [69, 70]. Furthermore, Guo *et al.* have determined the AtHsfA1a binding sites *in vivo* and shown that they are located in the promoter regions of a set of classical heat shock protein genes and a transmembrane CLPTM1 family protein gene [71]. A heat stress-induced HSF, AtHsfA2, has also been shown to activate *HSP* expression and then enhance acquired thermotolerance in *Arabidopsis* [72].

The heat stress response is mediated through the modulation of HSF activity by HSPs. Under nonstress conditions, constitutively expressed HSFs are inactivated by the binding of HSPs and maintained in the cytosol. However, when plants perceive heat stress, the HSP–HSF complexes dissociate and the HSFs localize to the nucleus to regulate gene expression [73–76]. Furthermore, the activity of HSFs is also known to be regulated by additional mechanisms. For instance, the activity of HSFs is modulated through phosphorylation/dephosphorylation events in response to heat stress [74, 77]. On the other hand, the heat stress response has also been found to be decreased by the heat shock factor binding protein 1 (HSBP1) that binds HSFs and then inhibits HSF activity [74]. Interaction with HSBP1 thus represents another regulatory mechanism for HSF activity.

Interestingly, the drought stress-responsive transcription factor, DREB2A, also influences heat tolerance [16, 17]. The overexpression of *DREB2A* in *Arabidopsis* increases heat tolerance by inducing the expression of the *AtHsfA3* gene [78, 79]. NF-X1 that was initially identified as a transcription factor associated with the salinity stress response [37, 38] has also been reported to contribute to heat tolerance [80]. These findings consistently indicate a connection between heat stress and other stress signaling pathways in the complex regulatory network that mediates stress responses in plants.

26.5
Transcription Factors Involved in Nutrient Deficiency

Plant nutrients in the soil, particularly nitrogen and phosphorus, are major factors that affect plant growth. Plants have, therefore, developed mechanisms to effectively absorb and utilize plant nutrients. In the past decade, several transcription factors involved in nutrient deficiency have been identified. Furthermore, genetic modifications based on these factors suggest that they may be potent tools for improving plant growth under nutrient-deficient conditions (Table 26.2).

26.5.1 Transcription Factors Involved in the Nitrogen Response

Nitrogen is a macronutrient that is required in abundance for plants. Plants actively attempt to obtain inorganic nitrogen in the soil due to the constitutive constraints on nitrogen availability in natural ecosystems. Although plants can use both nitrate and ammonia in the soil as a nitrogen source, nitrate is the major source for land plants. The possible roles of nitrate, nitrite, and glutamine as nitrogen signals that regulate cellular processes in plant cells have been proposed in the past [83–87], and nitrate has been well characterized as the main nitrogen signal. Therefore, both nitrate-inducible responses and nitrogen-deficient responses are likely to be closely related to nutrient-deficient stress responses. Transcription factors involved in nitrate-inducible and nitrogen-deficient responses are given equal weight in this section.

Transcriptome analysis of nitrogen-deficient response in rice roots has revealed that the modulation of a number of genes, including putative transcription factor genes, is induced by nitrogen-deficient conditions [88]. However, no additional information on these genes has yet been reported. On the other hand, the nitrate-inducible response in plants has been analyzed in more detail. Transcriptome analysis has revealed that the expression of numerous genes is modulated in response to the nitrate supply even in the *Arabidopsis* mutant that has little nitrate reductase (NR) activity [84, 89, 90]. Thus, nitrate has been suggested to function as a signal molecule and to directly modulate gene expression because it is reduced to ammonium by reductive reactions catalyzed by two enzymes, NR and nitrite reductase (NIR), and then assimilated into glutamine. Furthermore, a *cis*-element that is sufficient to drive nitrate induction was recently identified in promoter analysis of the *Arabidopsis* gene for NIR [91]. This element did not respond to glutamine, although the expression of *NIR* was found to be repressed by glutamine, in an experiment that defined the multiple *cis*-elements involved in the nitrogen response [91].

Transcription factors that bind directly to the identified nitrate-responsive *cis*-element have not been elucidated as yet. However, several genes encoding transcription factors are known to respond to nitrogen starvation or nitrate supply. *Arabidopsis ANR1*, which encodes an MADS transcription factor, is expressed preferentially in roots [92]. Although lateral roots proliferate in response to a localized nitrate supply, this proliferation does not occur when expression of *ANR1* is suppressed or *ANR1* is disrupted [92, 93]. *ANR1* was also found to be induced by nitrate starvation and repressed by the subsequent nitrate resupply, suggesting a possible feedback regulation of the lateral root growth rates via the nitrogen status of the plant [93]. There are also seven other MADS-box genes, which are slightly upregulated by nitrate starvation [93].

An *Arabidopsis* gene for NSR1, which is structurally close to the PHR1 (PHOSPHORUS STARVATION RESPONSE 1) transcription factor involved in the phosphate (Pi) starvation response [94], is also induced by nitrate starvation, although it has not yet been characterized in any detail [95]. The *Arabidopsis NLP7* gene that encodes a RWP-RK transcription factor also appears to be involved in the nitrogen response, although its expression is not regulated by the nitrogen source or by the presence of nitrate [96]. When the *NLP7* gene was disrupted in *Arabidopsis*, the plants exhibited the features of nitrogen-starved plants, such as an increase in the ratio of root/shoot, a longer primary root, and a higher lateral root density. Induction of the nitrate transporter genes (*NRT2.1* and *NRT2.2*) and the NR genes (*NIA1* and *NIA2*) by nitrate was found to be impaired in the *nlp7* mutant. Thus, NLP7 is a putative regulatory protein for nitrogen assimilation, although there is no direct evidence that NLP7 directly regulates the expression of nitrate-inducible genes.

The nitrate-inducible *LBD37/38/39* genes of *Arabidopsis* are members of the *LBD* (*LATERAL ORGAN BOUNDARY DOMAIN*) family of transcription factors [97]. Because these genes are induced by not only nitrate but also other

nitrogen sources, ammonium and glutamine, these genes are nitrogen responsive rather than nitrate responsive. Overexpression of *LBD37*, *LBD38*, or *LBD39* suppresses the expression of *PAP1* and *PAP2* that encode MYB transcription factors regulating expression of genes involved in anthocyanin synthesis [98]. The overexpression of *LBD37*, *LBD38*, or *LBD39* also repressed the expressions of nitrate transporter genes and NR genes [97], suggesting that LBD37/38/39 proteins play negative roles in the nitrogen response.

An *Arabidopsis* gene, *GNC* (*GATA, NITRATE-INDUCIBLE, CARBON-METABOLISM INVOLVED*), was also shown to be a nitrate-inducible gene [99]. This gene encodes a GATA transcription factor and is expressed in leaves and buds in response to nitrate, but not in roots. In the *gnc* mutant, the chlorophyll level is reduced and the expression of genes involved in carbon metabolism is repressed. The *gnc* mutant was also found to be more sensitive to exogenous glucose, whereas transgenic *Arabidopsis* overexpressing *GNC* is less so. Carbon and nitrogen metabolism are closely linked [100] because nitrogen assimilation requires not only inorganic nitrogen but also the carbon skeleton 2-oxoglutarate (2-OG) that is produced from photoassimilated carbohydrates. On the basis of the phenotype of the *gnc* mutant and the *GNC* overexpressors, GNC is proposed to function in the regulation of carbon and nitrogen metabolism in response to nitrate.

Although recent studies have identified several transcription factors involved in the nitrate response and/or nitrate status in plant cells, the enhancement of nitrogen assimilation, one of the most important agricultural traits sought after by breeders, has not been achieved yet using these factors. However, such enhancement was achieved using Dof1, a member of plant-specific Dof transcription factor family (Figure 26.2) [101]. The transgenic *Arabidopsis* lines expressing the Dof1 transcription factor, a putative regulator of 2-OG production, were found to show enhanced nitrogen assimilation and a larger pool of organic nitrogen and thus show better growth under the low-nitrogen conditions (Figure 26.2) [102]. This suggested the importance of the coordinated modulation of carbon and nitrogen metabolism in improving the adaptive ability of plants to nitrogen-deficient environments.

26.5.2
Phosphate Starvation-Responsive Transcription Factors

26.5.2.1 PHR1 Involved in Phosphate Starvation Response

Phosphorus is a major structural component of nucleic acids and membrane lipids and takes part in the regulation of many biochemical and physiological processes. Plants acquire phosphorus as inorganic phosphate (Pi). Several transcription factors involved in the Pi starvation response have been recently identified in vascular plants. Among these, PHR1 from *Arabidopsis thaliana* was the first to be isolated and is thus the most well characterized of these transcription factors [94]. The gene encoding PHR1 was identified by a genetic screen of a transgenic *Arabidopsis* line harboring the *AtIPS1::GUS* reporter construct that was specifically responsive to Pi starvation. In the *phr1* mutant, the root/shoot ratio was impaired and anthocyanin did not

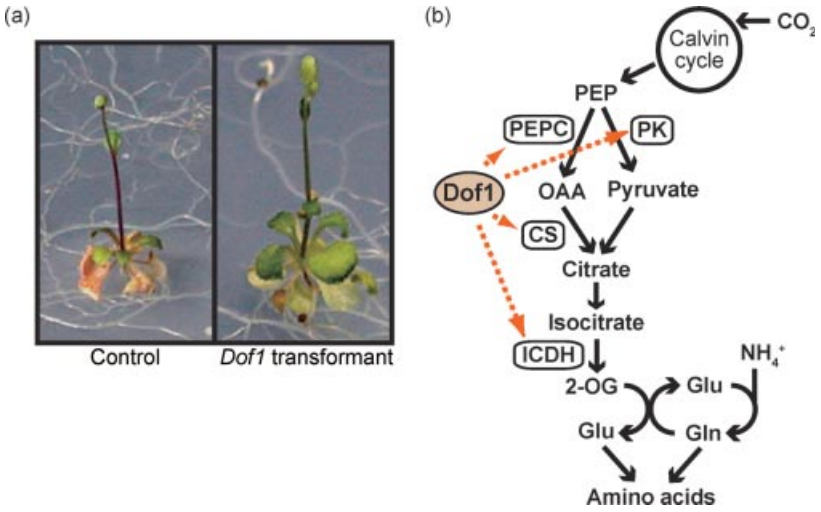

Figure 26.2 Improvement of plant growth by Dof1 under the low-nitrogen conditions. (a) The glutamine content is lower in control *Arabidopsis* plants than the transgenic *Arabidopsis* plants expressing the Dof1 transcription factor, and control *Arabidopsis* plants withered their leaves earlier when they were grown under the low-nitrogen conditions. (b) The metabolic pathway for nitrogen assimilation in plants. PEP: phosphoenolpyruvate; OAA: oxaloacetate; PEPC: phosphoenolpyruvate carboxylase; PK: pyruvate kinase; CS: citrate synthase; ICDH: isocitrate dehydrogenase. PEPC, PK, CS, and ICDH genes are putative target genes of the Dof1 transcription factor.

accumulate under Pi starvation conditions. Furthermore, the cellular Pi content was lower in the *phr1* mutant than in the wild-type *Arabidopsis* under Pi-sufficient conditions. In accordance with the *phr1* mutant phenotype, the expression of several Pi-responsive genes including genes encoding Pi transporters, acid phosphatases, and enzymes involved in anthocyanin biosynthesis was found to be impaired in the *phr1* mutant [94, 103, 104]. Conversely, when *PHR1* was overexpressed in *Arabidopsis*, the Pi content in the shoots increased, accompanied by the elevated expression of several Pi starvation-responsive genes [104].

PHR1 is a member of the MYB-CC gene family, which is a subtype of the MYB superfamily and includes 15 members in *Arabidopsis* [105]. Among these, PHL1 (PHR1-LIKE1) is phylogenetically most closely related to PHR1. It has been shown that PHR1 and PHL1 are functionally redundant in *Arabidopsis* [105] and form heterodimers to bind an imperfect palindromic DNA sequence called P1BS (5′-GNATATNC-3′), which are enriched in the promoter regions of many Pi starvation-responsive genes [94, 105–107]. Although *PHR1* expression is not affected by the Pi status, another *PHR1* homologue, *PHR2*, was found to be induced by Pi deprivation [94, 95]. Thus, PHR2 could also be involved in the Pi starvation response, although it has not yet been characterized in sufficient detail. Although rice has two *PHR1* homologues, *OsPHR1* and *2*, only the *OsPHR2* overexpressor accumulates

excess Pi in its shoots with upregulated levels of Pi starvation-responsive gene transcripts, similar to *PHR1* overexpressing *Arabidopsis* [104, 108].

In addition to the analyses of the physiological roles of PHR1 and related factors, the molecular regulation of PHR1 expression has also been studied. Because the expression levels of *PHR1* and the nuclear localization of the PHR1 protein are unchanged by the Pi status, posttranslational modifications can be considered to be the regulatory mechanism for PHR1 activity [94]. Indeed, the PHR1 protein was revealed to be sumoylated by SIZ1, a small ubiquitin-like modifier (SUMO) E3 ligase [109]. The functional relationship between PHR1 activity and sumoylation was further shown by the modified expression of target genes of PHR1 in the *siz1* mutant. These target genes, *AtIPS1* and *AtRNS1*, were induced more slowly in the *siz1* mutant than the wild type by Pi starvation, in agreement with the putative positive regulation of PHR1 by SIZ1. The *siz1* mutant also exhibited more severe Pi starvation phenotypes under such conditions, such as retarded primary roots, extensive lateral roots, and root hair development, an increase in the root/shoot growth ratio, and anthocyanin accumulation, although the intracellular Pi content in the *siz1* mutant was similar to that of wild- type *Arabidopsis* [109].

A microRNA, miR399, was found to be another of the PHR1 targets [103]. In plants, miRNAs recognize specific mRNA sequences based on sequence complementarity and function to cleave their target mRNAs. As the target of miR399 is the mRNA of *PHO2* encoding a ubiquitin-conjugating E2 enzyme, *Arabidopsis* lines overexpressing miR399 exhibit a phenotype similar to that of the *pho2* mutant [103, 110]. Interestingly, other small noncoding RNAs from *AtIPS1* and *At4* contain a sequence motif that is partially complementary to miR399 and inhibit the cleavage of *PHO2* mRNA by miR399 [111, 112]. As the expression of *AtIPS1/At4* is also induced by Pi starvation, differential induction modes of miR399 and *AtIPS1/At4* and/or the translocation of miRNA399 has been suggested to regulate the *PHO2* mRNA level in response to changes in the availability of Pi [113].

26.5.2.2 **Additional Transcription Factors Induced by Phosphate Starvation**

In addition to PHR1 and its homologues, several other transcription factors have been shown to be involved in the Pi starvation response. Some of them were identified through microarray analysis of Pi starvation-responsive genes [106, 114]. *MYB62* of *Arabidopsis* encodes an R2R3-type MYB transcription factor and its expression in leaves is induced by Pi starvation [115]. When *MYB62* is overexpressed, the root system architecture is altered. Furthermore, the root/shoot ratio increases under conditions of Pi sufficiency, anthocyanin accumulates, and the acid phosphatase activity is elevated. The expression of several Pi starvation-induced genes has also been shown to be suppressed in *MYB62* overexpressing lines. Thus, MYB62 is suggested to function as a repressor of the Pi starvation response [115].

Arabidopsis ZAT6, encoding a C_2H_2 zinc finger transcription factor, was also found to be induced by Pi starvation [116]. Overexpression of *ZAT6* in *Arabidopsis* leads to an

increased accumulation of anthocyanin and acid phosphatase secretion, a reduction both in the Pi uptake and in the total Pi content, and retardation of primary roots in young seedlings. However, when plants overexpressing *ZAT6* become older, they form longer lateral roots, which leads to an increased root/shoot ratio and total Pi content. Moreover, the expression of several Pi starvation-inducible genes is suppressed in the *ZAT6* overexpressing lines, indicating that *ZAT6* is also a repressor of the Pi starvation response.

WRKY75 is another Pi starvation-inducible gene [117]. The suppression of *WRKY75* by RNAi results in an increased anthocyanin accumulation, reduced Pi uptake, and reduced acid phosphatase activity. In addition, the lateral root length and number and the root hair number are increased in these knockdown plants, leading to an increased Pi content. Furthermore, the expression of Pi starvation-inducible genes is also suppressed in the *WRKY75* RNAi lines. Hence, *WRKY75* has been suggested to be a positive regulator of Pi starvation response. The involvement of another WRKY gene, *WRKY6*, in the Pi starvation response was also indicated by the phenotype of *Arabidopsis* lines overexpressing this gene under low Pi conditions. Similar to the *pho1* mutant, these transgenic lines were found to be defective in loading Pi into the xylem [118, 119]. It was shown that WRKY6 can bind to two W-boxes of the *PHO1* promoter to repress the *PHO1* gene. In addition, WRKY42, the closest homologue of WRKY6, also represses *PHO1* expression. Furthermore, degradation of the WRKY6 protein by the 26S proteasome under low Pi conditions was found to cause the repression of *PHO1* [118], indicating a molecular mechanism for Pi starvation that is mediated by a transcription factor.

Another Pi starvation-inducible gene in *Arabidopsis*, *BHLH32*, encodes a bHLH transcription factor [120]. In the *bhlh32* mutant grown under Pi-sufficient conditions, the Pi starvation-inducible expression of PPCK (phosphoenolpyruvate carboxylase kinase) genes, anthocyanin accumulation, and root hair formations were promoted. Also, the Pi content in the mutant was higher than that of the wild-type *Arabidopsis*. Thus, BHLH32 is likely to be a negative regulator of the Pi starvation response.

The *OsPTF1* (*Rice Pi starvation-induced transcription factor 1*) gene encoding a bHLH transcription factor was identified using a subtractive hybridization method with a cDNA library that was constructed using mRNA from rice roots subjected to Pi starvation [121]. The expression of *OsPTF1* was found to be upregulated by Pi starvation in roots but remained constitutively active in shoots. Transgenic rice plants overexpressing *OsPTF1* showed increase in the tiller number, shoot and root biomass, and the Pi content under low Pi conditions compared to wild-type rice plants.

Although the involvement of several Pi starvation-inducible transcription factor genes in the Pi starvation response has been conclusively shown by phenotypic analyses of the corresponding mutants and/or transgenic plants, the molecular functions of these factors and their target genes remain to be clarified.

26.5.3
Transcription Factors Associated with the Sulfur Starvation Response

Sulfur is an essential macronutrient required for plant growth. Plants uptake sulfate in the soil and use it for synthesis of cysteine and methionine, which are further utilized for the biosynthesis of other sulfur-containing organic compounds. Because of the important roles a number of sulfur-containing compounds play in plants, sulfur starvation induces the expression of sulfate transporters and activates the uptake of sulfate in roots. It is known that SULTR1;1 and SULTR1;2 are the high-affinity sulfate transporters in *Arabidopsis*, the transcripts of which are upregulated by sulfur starvation and downregulated by the sulfur-containing metabolites, cysteine and glutathione [122]. Analysis of the *SULTR1;1* gene promoter revealed the presence of a sulfur-responsive *cis*-element (SURE), which directs both the induction of this gene by sulfur starvation and its repression by cysteine and glutathione [123]. Furthermore, a 7-bp sequence within the SURE was found to be the core sequence that functions in the response to sulfur starvation. This core sequence is present in many sulfur starvation-responsive gene promoters [123], although not in the *SULTR1;2* promoter. No SURE binding protein has yet been identified.

Although transcription factors directly regulate the expression of sulfur starvation-responsive genes, a mutation in a gene encoding the SLIM1 (SULFUR LIMITATION 1) transcription factor has been found to affect the sulfur starvation-responsive gene. *SLIM1* was identified through the analysis of an *Arabidopsis* mutant in which the expression of GFP originating from the *SULTR1;2* promoter::GFP construct was abolished under sulfate starvation conditions [124]. SLIM1 is a member of the EIN3/EIL family that includes the ethylene-responsive transcription factors, EIN3 and EIL1, in *Arabidopsis* [125], but appears to be functionally distinguishable from other members of the EIL family, as they cannot rescue the phenotype of the *slim1* mutants [124]. In the *slim* mutant, the sulfate uptake activity was reduced and the growth of primary roots was inhibited under the sulfur-limiting conditions. Transcriptome analysis of the *slim1* mutant revealed that *SLIM1* functions to upregulate the genes for several isoforms of sulfate transporters, including SULTR1;1 and SULTR1;2 that function to uptake sulfate and SULTR4;2 that functions to release sulfate from the vacuoles in root tissues [122, 126] in response to sulfur starvation. In addition, a serine acetyltransferase gene, *SERAT3;1*, involved in cysteine synthesis, and a thioglucosidase gene involved in the degradation of glucosinolates for catabolic sulfur recycling were found to be upregulated under sulfate starvation conditions in the SLIM1-dependent manner [127]. The expression of genes encoding enzymes involved in the biosynthesis of glucosinolate, a major sulfur-containing secondary metabolite [128], was also affected by the *slim1* mutation. Hence, SLIM1 is proposed to be a global regulator of sulfate metabolic pathways [124]. Since the level of *SLIM1* mRNA is not modulated by changes in the sulfur conditions, posttranscriptional modifications in response to sulfur starvation may be critical for controlling SLIM activity [124]. Despite the close relationship between the SLIM activity and the sulfur starvation response, it is still unknown whether SLIM directly regulates genes that function in the regulatory network underlying the sulfur starvation response.

26.5.4
Iron Response-Related Transcription Factors

Iron is an essential micronutrient for plants and is required for cellular processes including photosynthesis and nitrogen fixation in legumes. Under aerobic or alkaline conditions, iron is present in an oxidized low-soluble Fe(III) form in the soil, which is not readily available for plants. Plants thus need to develop a mechanism for the effective acquisition of iron in the soil. Higher plants, with the exception of grasses, release protons around the roots to lower the pH, induce the expression of Fe(III) chelate reductase to reduce iron to the more-soluble Fe(II) form, and induce an Fe(II) transporter system for the uptake of Fe(II) into the root epidermis. This plant response to iron deficiency is called the strategy I response [129]. On the other hand, grasses have evolved a distinct strategy for iron uptake that is known as strategy II. They produce molecules of the mugineic acid family called phytosiderophores (PSs). PSs are secreted around the roots to form the soluble Fe(III)–PS complex, which is then taken up into the root cells through the Fe(III)–PS complex transporters [129].

The tomato FER was the first identified transcription factor associated with the strategy 1 response [130]. FER is a bHLH transcription factor expressed in roots under iron-deficient conditions [130]. Its abundance appears to be posttranscriptionally modulated, as it is detectable only when the iron levels are low. This is despite the fact that *FER* is constitutively and strongly expressed under the control of the 35S promoter [131]. In the *fer* mutant tomato, there is a decrease in Fe(III) chelate reductase activity and expression of the Fe(II) transporter gene [130]. Similarly, *Arabidopsis* FIT1/FRU (Fe-DEFICIENCY-INDUCED TRANSCRIPTION FACTOR1/FER-LIKE REGULATOR OF IRON UPTAKE), an orthologue of tomato FER [130, 131], was shown to be involved in the expression of the Fe(III) chelate reductase (FRO2) gene and promote the accumulation of Fe(II) transporter (IRT1) in the roots under iron-deficient conditions [132, 133]. The overexpression of FIT1 did not affect the expression of *FRO2* and *IRT1*. However, when FIT1 was coexpressed strongly with AtbHLH38 or AtbHLH39, which physically interact with FIT1, both *FRO2* and *IRT1* were constitutively expressed regardless of the iron conditions [134]. Furthermore, Fe(III) chelate reductase activity was higher in the transgenic *Arabidopsis* lines, coexpressing FIT1 and AtbHLH38 or AtbHLH39, than in the wild-type and transgenic lines overexpressing *FIT1*, *AtbHLH38*, or *AtbHLH39* alone. Moreover, the coexpressors accumulate IRT1 protein regardless of the iron conditions, resulting in the accumulation of more iron in their shoots [134]. As the *AtbHLH38* and *AtbHLH39* genes are upregulated under conditions of iron deficiency [134, 135], the cooperative action of FIT1, and AtbHLH38 and AtbHLH39, has been shown to play a critical role in the response to this stress.

The transcription factor involved in the strategy II response has also been identified through the profiling of iron deficiency-induced genes [136, 137]. This was a rice bHLH transcription factor, OsIRO2. Under iron-deficient conditions, rice plants overexpressing *OsIRO2* exhibited improved growth, whereas the knockdown lines generated by RNAi showed a reduced biomass and accumulated less iron [137]. The expression of many genes involved in PS biosynthesis and a Fe(III)-PS transporter

gene, *OsYSL15*, was enhanced in the *OsIRO2* overexpressors and repressed in the RNAi lines [137, 138]. Recently, it has been shown that *OsIRO2* expression is regulated by another transcription factor, IDEF1 [139]. IDEF1 is a member of the ABI3/VP1 family of transcription factors and binds to the iron deficiency-responsive *cis*-element, IDE1, which is present in the promoter of the barley *IDS2* gene involved in PS biosynthesis [139, 140]. Transgenic rice expressing *IDEF1* under the control of an iron deficiency-inducible promoter exhibited improved tolerance to iron deficiency [139], accompanied by a stronger expression of genes involved in PS biosynthesis, including *OsYSL15*, a Fe(II) transporter gene *OsIRT1*, and a metal-nicotianamine transporter gene *OsYSL2* [139, 141, 142].

Another iron deficiency-responsive *cis*-element, IDE2, was found in the promoter of the barley *IDS2* gene [140], and it has been shown that a rice NAC transcription factor, IDEF2, binds to this *cis*-element [143]. When IDEF2 function was repressed using the RNAi technique and chimera repressor gene-silencing technology (CRES-T), the resulting rice plants accumulated more iron in both their shoots and their roots under iron-sufficient conditions. On the other hand, under conditions of iron deficiency, the iron concentration appears to be lower in the shoots of the RNAi and CRES-T rice lines, whereas the iron concentrations in the roots were higher in transgenic lines. This phenomenon was explained by the hypothesis that the severe suppression of *OsYSL2* in the *IDEF2 RNAi* rice and the CRES-T rice lines under iron deficiency might prevent OsYSL2 from translocating iron from the roots to the shoots [142, 143]. Transcripts of *IDEF1* and *IDEF2* are constitutively expressed regardless of the iron conditions, and IDEF proteins may therefore be modified and regulated posttranscriptionally [139, 143].

26.5.5
Zinc Deficiency-Responsive Transcription Factors

Zinc is an essential micronutrient and an essential cofactor for many transcription factors, protein interaction domains, and enzymes both in plants and in animals [144]. Members of the ZIP family of metal transporters play a major role in zinc uptake in plants [145]. In *Arabidopsis*, a *ZIP* transporter gene, *ZIP4*, is strongly induced in response to zinc deficiency [146]. Using *ZIP4* promoter fragments as baits in a yeast one-hybrid assay, two homologous transcription factors, bZIP19 and bZIP23, were identified recently [147]. These factors act redundantly, and the expression levels of both genes are higher under zinc-deficient conditions. Furthermore, the *bzip19 bzip23* double mutant exhibited a zinc deficiency-hypersensitive phenotype under zinc-deficient conditions. Both the bZIP19 and the bZIP23 proteins were found to bind a 10-bp imperfect palindromic sequence, termed the ZDRE. Subsequently, ZDRE motifs were identified in the promoters of *ZIP* transporter genes that are responsive to zinc deficiency. Consistent with the roles bZIP19 and bZIP23 play in zinc deficiency-responsive transcriptional control, zinc deficiency-responsive *ZIP* transporter genes were not found to be induced in the *bzip19 bzip23* double mutant by a zinc deficiency. Orthologues of bZIP19 and bZIP23, their target genes, and the ZDRE motif are conserved in different plant species, indicating that

mechanisms underlying the zinc-deficiency response are conserved in the plant kingdom [147].

26.6 Transcription Factors Involved in Responses to Excess Metals in the Soil

Some metals in the soil are known to induce stress responses. Transcription factors involved in the tolerance to excess aluminum (Al) and cadmium (Cd) in the soil have been identified, suggesting that they could be used in future strategies to develop metal-resistant crops.

26.6.1 Transcription Factors Mediating Al Tolerance

Ionic Al that is produced in acidic soils inhibits root elongation, even at low concentrations. The consequent inhibition of water and nutrient uptake results in a reduction in crop production [148]. One of the best-known mechanisms to tolerate Al is to excrete organic acid anions, which chelate this metal [148]. In the case of *Arabidopsis*, malate is excreted and the expression of a malate transporter gene, *AtALMT1*, is induced in response to Al [149]. *STOP1* (*SENSITIVE TO PROTON RHIZOTOXICITY 1*) encoding a C_2H_2-type zinc finger protein was found to be a regulator of this Al response [150]. An *Arabidopsis* mutant, *stop1*, was originally isolated by its hypersensitivity to proton rhizotoxicity and was found to exhibit shorter roots under Al stress and low pH conditions. On the other hand, another C_2H_2-type zinc finger protein, ART1 (Al resistance transcription factor 1), regulates Al tolerance in rice [151]. Similar to the case of the *stop1* mutant of *Arabidopsis*, the root length of the *art1* mutant was shorter than that of the wild-type rice under Al stress. In response to Al, ART1 induces the expression of Al tolerance genes including *STAR1* and *STAR2*, which encode ATP binding and transmembrane domains of a novel ABC transporter, respectively [151, 152]. The ABC transporter transports UDP glucose, which may be used to modify the cell wall [152]. Neither the *STOP1* transcript levels nor the *ART1* transcript levels were affected by Al treatment, suggesting that the expression of *STOP1* and *ART1* may be posttranscriptionally regulated by the Al conditions. As microarray data have shown that genes downstream of STOP1 are different from those of ART1, except in a few cases, STOP1 and ART1 were suggested to produce Al tolerance via different mechanisms in distinct plant species [151, 153].

26.6.2 The HsfA4a Transcription Factor that Confers Cd Tolerance

Cd is one of the most dangerous heavy metals in the environment. Recently, class A4 heat shock transcription factors (HsfA4a) were found to confer Cd tolerance in rice and wheat (*Triticum aestivum*) [154]. Wheat and rice HsfA4a proteins were identified as factors that conferred Cd tolerance to a Cd-hypersensitive yeast strain. Over-

expression of wheat *HsfA4a* was also found to enhance Cd tolerance in transgenic rice plants, whereas the knockdown of *HsfA4a* in rice increased the sensitivity to Cd, suggesting that *HsfA4a* plays an important role in Cd tolerance in rice. In both rice and wheat, Cd treatment induces the expression of *HsfA4a*, which in turn induces the expression of a gene encoding a metallothionein that is a well-known chelator of Cd. Although further analysis including the identification of additional target genes of HsfA4a might be necessary, phenotypic analysis of transgenic rice plants overexpressing *HsfA4a* has already suggested that the HsfA4a transcription factor will be useful in the future development of Cd-resistant plants to enable the phytoremediation of Cd-contaminated fields.

26.7 Conclusions and Prospects

As described in this chapter, a number of transcription factors involved in abiotic stress responses have been identified over the past decade. Although most were found in *Arabidopsis*, the knowledge obtained using this and other model plants has allowed us to identify functional homologues in commercially important crops and to develop strategies for enhancement of stress tolerance in these plants. Transcription factors associated with stress responses may possess the potential to induce the systematic activation and/or repression of stress-responsive genes in perfect synchrony. Thus, when expression of multiple components in a single cascade or pathway or activation of multiple different cascades or pathways is needed to improve tolerance to a particular stress signal, the utilization of transcription factors could be an ideal strategy. In fact, the expression of Dof1 led to the enhancement of nitrogen assimilation and better growth under nitrogen-deficient conditions, which had not been adequately achieved through the genetic modification of genes for enzymes involved in nitrate reduction and assimilation (Figure 26.2). This is a good example of how the use of transcription factors can improve stress tolerance via the synchronous modification of multiple genes.

The phenotypes of transgenic plants overexpressing some transcription factors have already indicated that it is possible not only to improve tolerance to abiotic stress and increase plant productivity but also to develop metal hyperaccumulator plants for the phytoremediation of contaminated soil or water. Many transcription factors are likely expressed in plant cells. Indeed, more than 1000 genes encoding putative transcription factors have been identified in the *Arabidopsis* genome [155]. However, the functions of most of the plant transcription factors have not yet been determined. Thus, identifying the unknown functions of plant transcription factors may make it possible in the future to generate crops with superior characteristics.

Recent advances in our understanding of the physiological and molecular features of transcription factors associated with abiotic stress suggest that posttranslational control is a key regulatory mechanism in many cases. This agrees with the general hypothesis that the gene expression associated with the primary response is mediated by preexisting transcription factors. Hence, the genetic modification of mechanisms

underlying such posttranscriptional control may be a strategy to improve the stress tolerance of crops. This might be particularly true when the simple overexpression of a transcription factor does not produce the expected phenotype or results in a strong phenotype with negative effects. In fact, when DREB1/CBF was constitutively and strongly expressed under the control of the 35S promoter, growth defects were induced as the stress response in general involves growth arrest. Further analysis of the regulatory mechanisms underlying transcription factor activity control in plants is thus warranted and would expand the opportunities to develop crops with an improved tolerance to environmental stresses in a more sophisticated manner.

Polyamines in Developing Stress-Resistant Crops

Francisco Marco, Rubén Alcázar, Teresa Altabella, Pedro Carrasco, Sarvajeet Singh Gill, Narendra Tuteja, and Antonio F. Tiburcio

Polyamines (PAs) are small protonated compounds with key roles in plant development and physiological processes. PAs may also function as stress messengers in plant responses to different stress signals. Recent studies using exogenous application of polyamines and more contemporary genetic manipulation of polyamine levels in crops and model species point to their involvement in stress protection. The different mechanisms by which polyamines exert their functions are presently being unraveled and involve different modes of action that are summarized in this chapter. Polyamines are integrated with other stress-related hormone pathways, such as abscisic acid (ABA), reactive oxygen species (ROS) signaling, nitric oxide, and regulation of ion channels that are now being elucidated. Also, polyamines are implicated in the transcriptional regulation to abiotic and biotic stresses as revealed in recent global transcriptome analyses. The genetic manipulation of polyamine levels has been proven to be an efficient tool for enhancing stress tolerance in many plant species. A number of examples and their potential application to crops for a sustainable agriculture are discussed in this chapter, along with the most recent advances in our understanding of the regulation and mode of action of polyamines.

27.1
Introduction

27.1.1
PA Biosynthesis and Catabolism in Plants

Plants live in an ever-changing and often unpredictable environment that represents the major limiting factors for agricultural crop productivity. Plants, unlike animals, cannot move and therefore encounter a variety of environmental stresses throughout their life cycle. It is predicted that the environmental stresses will become more intense and frequent with climate change, especially global warming. Among abiotic stresses, cold, heat, salinity, and drought adversely affect plant growth and productivity and restrict the crops to reach their full genetic potential [1].

World population is also increasing at an alarming rate and expected to reach around 10 billion by 2050, which will witness serious food shortages. Therefore, reducing crop loss is a major challenge to meet the increasing food demand [2]. Plants employ various strategies to cope with the ever-changing environmental fluctuations [3].

Polyamines (PAs) are a group of polycationic amine-containing compounds whose most predominant forms are the diamine putrescine (Put), triamine spermidine (Spd), and tetramine spermine (Spm) that play a pivotal role in the regulation of developmental and physiological processes in plants [4]. Put, Spd, and Spm molecules differ in the number of aminopropyl moieties added to the carbon skeleton of Put, and thus they differ in their number of positively charged amine groups at the physiological pH of the cell. Metabolic studies indicate that the intracellular levels of PAs in plants are mostly regulated by anabolic and catabolic processes (Figure 27.1), as well as by their conjugation to hydroxycinnamic acids and other macromolecules such as proteins and DNA.

The PA biosynthetic pathway starts with the synthesis of the diamine Put. In mammals and fungi, Put biosynthesis is exclusively derived from ornitine (Orn) decarboxylation in a reaction catalyzed by ornithine decarboxylase (ODC). Plants and bacteria can also synthesize Put via an alternative pathway involving arginine (Arg) decarboxylation by arginine decarboxylase (ADC), as well as two additional successive

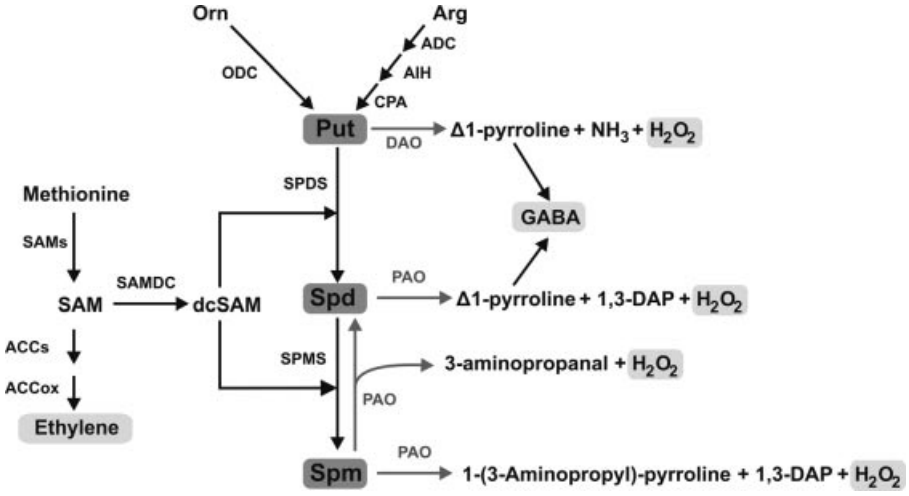

Figure 27.1 Polyamine biosynthesis and catabolism in plants. Biosynthetic pathways are indicated in black and degradation routes in grey. steps involving agmatine iminohydrolase (AIH) and *N*-carbamoylputrescine amidohydrolase (CPA) activities. Put serves as a precursor of Spd and Spm by consecutive additions of aminopropyl groups catalyzed, respectively, by Spd synthase (SPDS) and Spm synthase (SPMS). Both enzymes use decarboxylated *S*-adenosylmethionine (dcSAM) as donor of aminopropyl moieties, which is formed by decarboxylation of SAM in a reaction catalyzed by SAM decarboxylase (SAMDC) (Figure 27.1).

PAs are degraded by oxidative deamination in reactions catalyzed by amine oxidases, in particular diamine oxidases (DAOs) and PA oxidases (PAOs). DAOs display high affinity for diamines, similar to Put, producing Δ^1-pyrroline, H_2O_2, and ammonia (Figure 27.1). Δ^1-pyrroline is catabolized into γ-aminobutyric acid (GABA) (Figure 27.1), which is ultimately converted into succinic acid, a component of the Krebs cycle. PAOs oxidize secondary amine groups from Spd and Spm, leading to the formation of 4-aminobutanal or (3-aminopropyl)-4-aminobutanal, along with 1,3-diaminopropane (DAP) and H_2O_2 (Figure 27.1). Spm could also be backconverted to Spd by PAOs with concomitant production of 3-aminopropanal and H_2O_2. Therefore, the PA metabolic pathway is also interconnected with other metabolic routes involved in the formation of various signaling molecules and metabolites that are relevant to plant stress responses such as ethylene, GABA, or H_2O_2 (Figure 27.1) [5].

Many evidences point to the requirement of Put and Spd for plant life and development. Depletion of Put and Spd levels by genetic or chemical means is lethal in yeast, protists, and plants [6–9]. Indeed, all living organisms analyzed so far contain endogenous pools of Put and Spd. Conversely, Spm-deficient organisms seem viable but show different degrees of dysfunction, thus suggesting an important involvement of Spm in growth and developmental processes [10–13].

In plants, PAs have been implicated in a wide array of fundamental processes such as cell cycle, transcriptome regulation, hormone signaling, plant growth and development, and response to biotic and abiotic stresses [14–21].

27.2 PAs and Stress

The first observation on the effects of stress in PA levels in plants was reported by Richards and Coleman [22], who showed an increase in the endogenous levels of Put in oat plants grown under potassium starvation. Since then, a large number of studies have shown an increase in PA levels in response to different biotic and abiotic stresses [14, 16, 23]. Stress-triggered PA accumulation correlates with enhanced tolerance to different stresses, such as salinity [24–27], chilling [27, 28], osmotic and acidic stresses [29], radiation-induced oxidative stress [30], and so on [23].

Also, early studies based on the application of exogenous PAs or PA biosynthesis inhibitors have also been useful to identify correlation between PA stress accumulation and plant tolerance [16]. Nevertheless, it has to be noted that exogenous application of PAs may have certain limitations, such as differences in the uptake rates between replicates, the possible deleterious effects of PAs when applied to

membranes at high doses, and an insufficient specificity of the inhibitor applied in some instances, determined frequently by differences in the localization of the inhibitor and the target enzyme [31].

Since the identification of the oat *ADC* by Bell and Malmberg [32], many genes coding for enzymes involved in PA metabolism have been cloned from several plant species and their expression under stress conditions analyzed [14, 33]. Reports from those experiments show that some of the PA biosynthetic genes raise their expression levels in response to stress, although with different kinetics. Some PA biosynthetic genes are rapidly induced shortly after stress treatment and undergo a continuous rise or a minor change with a prolonged period of stress. Conversely, others are induced only when the stress is exerted for a certain period. These observations indicate a differential regulation of PA biosynthetic genes during stress, consistent with different pathways involved in the regulation of PA biosynthesis under stress [34]. When trying to combine transcriptional profiles from independent experimental designs, the different kinetics may depend on several factors, such as plant species, duration, and intensity of stress or stress sensitivity of the experimental materials [24, 25, 35, 36]. Hence, rather than analyzing single genes in the PA pathway, a broader approach that aims to analyze the whole PA biosynthetic transcriptome is more informative for the study of gene kinetics. Unfortunately, there are very few examples where these approaches have been undertaken [34, 37–40].

27.3 Transgenic Modifications of PA Biosynthetic Route and Improvement of Stress Tolerance

The identification and cloning of the genes coding for PA biosynthetic enzymes has also allowed the generation of transgenic plants with altered endogenous PA levels, in order to overcome the problems arising from the use of exogenous PAs or the lack of specificity of certain PA biosynthetic inhibitors. Table 27.1 summarizes a number of examples of overexpression of *ODC*, *ADC*, *SAMDC*, and *SPDS* in rice, tobacco, pear, sweet potato, and *Arabidopsis* during over the years, with different results concerning the modification of one or more specific PAs, but all showing in common an enhanced tolerance against a broad spectrum of stress conditions (Table 27.1). Enhanced tolerance always correlated with elevated levels of Put and/or Spd and Spm. Transgenic rice plants carrying oat *ADC* under control of an abscisic acid (ABA)-inducible promoter showed higher ADC activity, higher Put level, and increased biomass under salt stress than wild-type plants [41]. Similarly, constitutive overexpresssion of *Datura stramonium ADC* gene in rice produced transgenic plants that accumulated higher levels of Spd and Spm than the wild type when exposed to drought stress. These lines also showed an improvement in drought tolerance, with a lower degree of chlorophyll loss and leaf curling than the wild type [29]. More recently, constitutive homologous overexpression of *ADC* genes in *Arabidopsis* also leads to transgenic plants with elevated Put levels and resistant to freezing conditions [42] and

Table 27.1 Abiotic stress tolerance in plants with overproduction of PAs obtained by transgenic modification.

Gene	Source	Transgenic plant	Overexpression	Overproduction	Tolerance	Reference

drought stress [43]. Salt tolerance has also been obtained in tobacco plants overexpressing mouse *ODC*, which showed higher Put levels, a better germination frequencies, and a less degree of wilting in salt than wild-type plants [44].

SAMDC cDNAs have been also used to generate transgenic plants with elevated PA levels (Table 27.1). Constitutive overexpression of *Tritordeum SAMDC* gene in rice resulted in a three- to fourfold increase in Spd and Spm levels in the transformed plants [26]. Stress tolerance of those plants was demonstrated by their normal growth and development under NaCl stress. The tobacco plants obtained by Waie and Rajam [45] are another example of heterologous constitutive *SAMDC* overexpression where a human *SAMDC* gene was driven by a constitutive *CaMV35S* promoter. The transgenic tobacco lines obtained showed higher Spd and Put levels, as well as tolerance to salt and drought stresses [45]. More recently, transgenic tobacco plants overexpressing carnation *SAMDC* also showed a broad-spectrum tolerance to abiotic stresses [46]. Transgenic tomato plants with high levels of Spm and Spd and tolerant to heat stress have been obtained by constitutive overexpression of yeast *SAMDC* gene [47]. Also, homologous overexpression of *SAMDC1* gene in *Arabidopsis* leads to elevated Spm levels and enhanced tolerance to salt stress [67].

Transgenic plants overexpressing *SPDS* share common features of elevated Spd levels as well as broad-spectrum stress tolerance (Table 27.1). Thus, overexpression of *SPDS* from *Cucurbita ficifolia* in *Arabidopsis* enhanced tolerance to chilling, freezing, drought, salinity, osmosis, and paraquat [48]. Transformation of the same gene into sweet potato (*Ipomoea batatas*) produced transgenic plants with more tolerance to salt and drought than the wild type [49]. Higher Spd titers are also found in transgenic pear plants overexpressing apple *MDSPDS1* gene, being also more tolerant than wild-type plants when exposed to $AlCl_3$ long-term stress [50].

On the other hand, Wi and Park [51] employed an alternative way to raise PA levels by favoring the flux of SAM to PAs using antisense silencing of ethylene biosynthesis genes *ACC synthase* and *ACC oxidase* in tobacco. Transgenic plants obtained raised Put and Spd levels and increased their tolerance to oxidative, high salinity, and acid stresses [51]. Previously, high PA levels were also found in a tobacco DFMO-resistant line, which was also resistant to acidic stress conditions [52].

In summary, all these examples show the correlation between accumulation of Put and Spd and Spm with stress tolerance, often with a broad spectrum of stresses. This correlation is also reinforced by the results obtained from loss-of-function mutations in PA biosynthetic genes. For example, EMS mutants of *Arabidopsis thaliana spe1-1* and *spe2-1* (which map to *ADC2*) showing reduced ADC activity are deficient in PA accumulation after acclimation to high NaCl concentrations and exhibit more sensitivity to salt stress [53]. Another study shows that a Ds insertion mutant (*adc2-1*), with Put levels diminished up to 75% of wild-type plants, is more sensitive to salt stress, whereas its salt-induced injury is partly reverted by the addition of exogenous Put [54]. Other *ADC1* (*adc1-2*, *adc1-3*) and *ADC2* (*adc2-3*, *adc2-4*) mutant alleles are more sensitive to freezing, and this phenotype is partially rescued by adding exogenous Put [37]. On the other hand, *acl5/spms Arabidopsis* double mutants that do not produce Spm and thermospermine are hypersensitive to salt and drought stresses, and the phenotype is mitigated by application of exogenous Spm [55].

27.4
Possible Mechanisms of PA Action in Stress Responses

Taken together, results presented in the above sections indicate that elevated PA levels represent a stress-induced protective response with a protective role. However, the precise mechanism of action by which PAs could protect plants from challenging environmental conditions remains unclear, although some progress has been made [4, 56].

Classically, the most common explanation for protective roles of PAs have been related to their chemical structure: the polycationic nature of PAs at physiological pH enables them to modulate ion balance of the cell and interact with anionic molecules, such as DNA, RNA, proteins, and membrane lipids [57, 58]. PA binding to proteins or nucleic acids could not only protect them from degradation but also provide a molecule with the most stable conformation under stress conditions. A large number of evidences suggested that exogenous application of PAs (di-, tri-, and tetraamines) were shown to stabilize plant cell membranes, protecting them from damage under stress conditions [33, 59], and endogenous PAs are also suggested to participate in sustaining membrane integrity [60].

Also, an antioxidative role has been proposed for PAs due to a combination of their possible role as radical-scavenging molecules by means of their dual anion and cation binding properties [61] and their capability to inhibit both lipid peroxidation [62] and metal-catalyzed oxidative reactions [63]. Spm, Spd, and Put all reduce level of superoxide radicals generated by senescing plant cells [64]. Alternatively, PA catabolism produces H_2O_2, a signaling molecule that can enter the stress signal transduction chain promoting an activation of an antioxidative defense response. Owing to the fact that this peroxide production could also be a source of oxidant species, the role of PAs acting as antioxidants is still a matter of debate [23].

On the other hand, more recent data show that modification of endogenous PA levels alters the expression of an important number of genes, most of them stress related. Some of these stress-related genes could promote the synthesis of more protective compounds and render stress tolerance. This is seen, for example, in tobacco *SAMDC* overexpressing plants that have higher levels of expression of several antioxidant enzymes, such as ascorbate peroxidase, superoxide dismutase, and glutathione *S*-transferase [46]. Microarray analysis of *Arabidopsis* plants overexpressing *SPDS* shows that those transgenic plants have higher expression levels of some stress-related transcription factors, such as DREB, WRKY, B-box zinc finger proteins, NAM proteins, and MYB, along with stress-regulated genes, such as low-temperature-induced protein 78 (LTI78 or rd29A) [48]. More recently, analysis of transcriptome profiles of *Arabidopsis* plants overexpressing homologous *ADC2*, *SAMDC1*, or *SPMS* shows a preferential induction of stress-related genes [65–67]. When the expression profiles of those Put and Spm overproducer plants are compared, a set of 71 genes always appear to be upregulated and enriched in stress-related genes, including Ca^{2+} signaling-related proteins, as well as several putative transcription factors [66].

The existence of plant PA modulon expression system, in a situation similar to the systems proposed previously in *Escherichia coli* [68] and yeast [69], could be one of the possible explanations for some of the transcriptional changes observed in PA accumulating plants, although the identification of members of this plant PA modulon is still an issue unresolved. In the future, an additional effort in the isolation of the transcription factors controlling expression of genes when PA metabolism is modified is needed to clarify the possible existence of a "PA plant modulon."

Also, most of the transcriptional changes observed could be a consequence of crosstalk of PAs and other signaling routes [70]. There are some evidences of crosstalk between PAs and ABA. Upregulation of PA biosynthetic genes *ADC2*, *SPDS1*, and *SPMS* and accumulation of Put under drought stress in *Arabidopsis* are mainly ABA-dependent responses [34]. Evidence of crosstalk with Spm and ABA is also shown in *SAMDC1* overexpressing *Arabidopsis* plants, with elevated levels of ABA due to the induction of *NCED3*, a key enzyme involved in ABA biosynthesis [67].

A possible link between PAs, Ca^{2+} homeostasis, and stress responses has also been pointed out [56]. Spm control of Ca^{2+} allocation through regulating Ca^{2+} permeable channels, including CAXs, has been described as a possible way of action for the protective role of Spm against high salt and drought stress [13, 71]. Moreover, changes in free Ca^{2+} in the cytoplasm of guard cells are involved in stomatal movement that may explain drought tolerance induced by Spm. What is more, Ca^{2+} signaling genes are one of the gene categories mainly upregulated in Put and Spm overproducer plants [66]. Also, a "Spm signaling pathway" has been proposed to explain the role of enhanced PA accumulation observed during pathogen response in *Arabidopsis* [72, 73]. This signaling pathway could function via the merged signal of Spm-activated Ca^{2+} influx and H_2O_2 produced by Spm degradation for PA oxidases. Both processes are able to trigger mitochondrial dysfunction and activation of the cell death programme [73].

Put, Spd, and Spm also regulate stomatal responses by reducing their aperture and inducing closure [74, 75]. It has been proposed that PAs could regulate stomatal closure in a mechanism involving peroxide production by polyamine oxidation, as well as interactions with nitric oxide (NO) signaling [76]. Thus, PAs could act synergically with reactive oxygen species (ROS) and NO in promoting ABA responses in guard cells [56]. PAs could also regulate stomatal closure responses by their capacity to block fast-activating vacuolar cation channels by their charge properties, as well as affecting protein kinase and phosphatase activities that regulate ion channel functions [56].

In summary, PA action in plant stress responses seems to imply several layers of action. Figure 27.2 illustrates the possible mechanisms underlying enhanced stress tolerance shown by plants with enhanced PA production obtained by transgenic modification. In conclusion, manipulation of polyamine metabolism seems to be a good strategy to obtain tolerant plants, both by the protecting role that PA can exert by their structure and by their capacity to act as a key regulatory molecule in stress responses. Combination of both factors could lead to improved stress tolerance in plants (Figure 27.2).

All these studies demonstrated that a transgenic approach involving PA biosynthetic genes may be a good strategy to improve crop tolerance against harsh environments so as to meet the requirements of a challenging global environment.

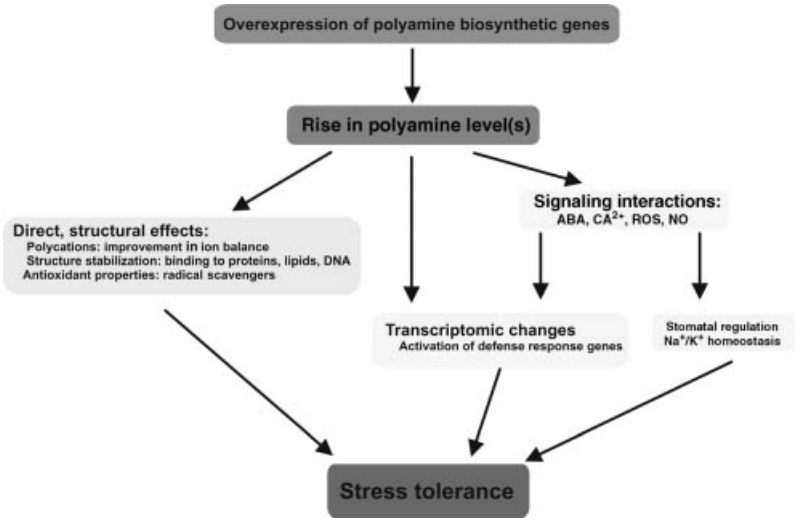

Figure 27.2 Possible mechanisms underlying enhanced stress tolerance via transgenic alteration of polyamine biosynthetic genes. Overexpression of PA biosynthetic genes leads to changes in PA levels in plants (accumulation of individual or total PAs) that could act, on the one hand, as antioxidants to scavenge excessive free radicals or as membrane stabilizers through binding to structures with negatively charged groups, such as DNA, proteins, and lipids, and on the other hand, being able to activate plant defense response mechanisms directly (by unknown mechanisms) and by interactions with other signaling pathways, such as ABA, Ca^{2+}, or NO. Combination of these factors could lead to plant stress tolerance. Adapted from Ref. [33].

Interestingly, broad-spectrum tolerance (salinity, drought, low and high temperature, and parquet toxicity) is observed for some of the transgenic plants overexpressing *ADC*, *SPDS*, or *SAMDC* (Table 27.1). Such multiple abiotic stress tolerance is of practical importance since plants often suffer from several concurrent forms of environmental stress during their life cycle.

Wheat: Functional Genomics of Abiotic Stress Tolerance

Paramjit Khurana, Harsh Chauhan, and Neetika Khurana

Abiotic stresses such as extreme temperatures and water availability, high salt, and deficiencies or toxicity of minerals severely affect productivity of cereal crops worldwide. These stresses become even more disastrous in present environment of climate change. Wheat is one of the most important cereal crops providing approximately 20% percent of calories in human food. Wheat is grown in adverse environments, especially high temperature and low water availability, thereby limiting yield potential. There is ample variation available in abiotic stress tolerance in germplasm of wheat and its wild relatives. However, it has been relatively less exploited due to poor understanding of wheat genome and its molecular basis of stress response. Functional genomics is now widely seen as providing tools for dissecting abiotic stress response in various crop plants. Functional genomics involve many related approaches such as global gene expression profiling, identification of responsive genes/alleles, followed by mutant analysis or transgenic approaches to assign the function of specific gene or its product protein. Since wheat genome is not sequenced, genome-wide collection of ESTs and full-length cDNAs is important for structural and functional analysis of wheat genes responsive to abiotic stresses. This chapter deals with the present knowledge of wheat functional genomics and prospects of molecular breeding for abiotic atress tolerance.

28.1
Introduction

Wheat is an important crop globally and ranks second in production as a cereal crop. Being a staple food, demand for wheat in developing countries is expected to grow at around 2.2% annually similar to the existing rate of production growth; thus, it has been postulated that by 2020 one billion tonnes of wheat would be required to feed the population [1]. Of the various factors influencing wheat crop productivity, abiotic stresses play an important role. Climate change acceleration leading to global warming and higher CO_2 has a major impact on wheat productivity and world wheat production is predicted to decline by as much as 8% from the 2008/09 record volume (FAO, 2009). Thus, to develop improved wheat varieties, molecular genetic

Improving Crop Resistance to Abiotic Stress, First Edition.
Edited by Narendra Tuteja, Sarvajeet Singh Gill, Antonio F. Tiburcio, and Renu Tuteja

tools and functional genomics need to be utilized and integrated into the existing breeding practices. Though wheat genome has been refractory due to its large genome size (16 000 Mb), amplification of transposable elements (TEs), coupled with duplication of chromosome segments, and polyploidization, a number of approaches have been developed for wheat genomic research. Development of transgenic wheat, massive EST collections, and cDNA arrays along with comparative genomics approaches have opened new opportunities for wheat improvement. To identify agronomically important genes, the function of genes must be known. Thus, of late, functional genomics is fast emerging as a major tool for wheat improvement.

28.2
Functional Genomics Approaches

28.2.1
Proteomics

For functional analysis of proteins, their structural analysis is necessary. Morita *et al.* [2] developed a novel way of screening protein folding and function by using wheat germ cell-free system. This was the first experimental evidence of the applicability of the wheat germ cell-free protein synthesis system to high-throughput structural analysis of functional proteins. In the same year, Majoul *et al.* [3] analyzed the effect of high-temperature stress on wheat endosperm proteome by employing two-dimensional electrophoresis coupled with analysis by matrix-assisted laser desorption/ionization mass spectrometry and tandem mass spectrometry and characterized heat-induced proteins. The same group in 2004 [4] analyzed the nonprolamin fraction that contains albumins and globulins and functionally identified 42 proteins, some involved in carbohydrate metabolism and others associated with abiotic stresses and heat shock proteins. Using a similar approach, Bahrman *et al.* [5] identified wheat leaf protein expression profile and found that most of them are involved in carbohydrate metabolism. For further enhancing wheat leaf proteome research, Donnelly *et al.* [6] used a combination of protein and expressed sequence tag database and partially characterized the wheat leaf proteome. They found that a majority of proteins were involved in energy production and primary or secondary metabolism. Mamone *et al.* [7] undertook a more detailed characterization of wheat gliadin proteins providing insight into the complex nature of gliadin production. Techniques involving subproteome fractionation combined with two-dimensional electrophoresis and protein identification led to an effective separation of the highly abundant gliadins and glutenins from much less abundant albumins and globulins [8]. An interactome of proteins associated with abiotic stress was developed by using a yeast-two-hybrid GAL4 system and specific protein interactive assays [9]. This revealed a networking of regulatory factors such as phospholipase C and GTP binding protein, VRN1/2, that play vital roles during vernalization, flower initiation, and abscisic acid signaling along with various abiotic stress-related proteins. Gobaa *et al.* [10] using 1BL.1RS translocation lines provided valuable insight into the

endosperm protoeome. They found that in the translocated genotypes the loss of a dimeric α-amylase inhibitor may explain the dough stickiness associated with such genotypes. Upregulation of a certain γ-gliadin with nine cysteine residues indicated the regulation involved in the synthesis of prolamines in the wheat endosperm.

Merlino *et al.* [11] analyzed soluble proteins by two-dimensional electrophoresis and MALDITOF in 112 recombinant inbred lines ("opata 85" × "synthetic W7984") and identified heat shock proteins, β-amylases, UDP-glucose pyrophosphorylases, peroxidases, and thioredoxins. Winning *et al.* [12] examined the implications of different drought treatments on the protein fractions in grains of winter wheat using proton nuclear magnetic resonance spectrosocopy followed by chemometric analysis. The results indicated that protein metabolism is highly influenced by multiple drought events. In a recent study on flooding stress and cell wall proteome of wheat roots, Kong *et al.* [13] employed a gel-based proteomic and LC-MS/MS-based proteomic techniques and found that most upregulated proteins belonged to the category of defense and disease responses. However, downregulation of three proteins such as methionine synthase, β-1,3-glucanases, and β-glucosidase suggested that wheat seedlings respond to flooding stress by restricting cell growth. Thus, the various proteomics studies identified several key proteins leading to a newer discipline called "metabolomics."

28.2.2
Metabolomics

Metabolomics includes a large number of metabolomic reactions that represents the dynamic changes from one condition to the other. Balmer *et al.* [14] analyzed the amyloplast proteome from developing wheat endosperm, and identified 289 proteins involved in carbohydrate metabolism, plastid division, energetics, nitrogen and sulphur metabolism, nucleic acid-related reactions, synthesis of amino acids, isoprenoids, fatty acids, transport, signaling, stress, and related processes. This study thus presents a broad metabolic capability of amyloplasts. On the basis of this proteomic data, Dupont [15] organized the putative amyloplast proteins into proposed metabolic and biosynthetic pathways. An "amyloplast metabolic map" was thus created emphasizing the role played by amyloplasts in endosperm metabolism.

28.2.3
RNA Interference-Based Gene Silencing

RNAi silencing has emerged as a potential tool for functional genomics for hexaploid wheat. It is particularly advantageous for polyploid species such as wheat since it allows the silencing of all homologous gene copies [16]. Yan *et al.* [17] developed the first stable wheat transgenics using RNAi transformation. They reported the reduction of VRN2 RNA by RNA interference resulting in reduced flowering time. In another study by Travella *et al.* [18], RNAi constructs expressing *phytoene desaturase* (PDS) and *ethylene insensitive 2* (EIN2) were introduced by particle bombardment-mediated transformation in wheat and the endogenous target mRNA levels of three homologous genes were seen to decrease due to RNAi silencing. This study also

demonstrated that homozygous transgenic plants have a stronger reduction in target mRNA and thus have severe phenotypic changes compared to heterozygous plants, thus also emphasizing a dosage effect of RNAi in hexaploid wheat. Uauy *et al.* [19] cloned a wild wheat allele encoding an NAC transcription factor (NAM-B1) and showed that reduction in RNA levels of the *TaNAM* genes by RNA interference delayed senescence and decreased protein content, zinc, and iron in wheat grains. Yue *et al.* [20] report the silencing of high molecular weight (HMW) glutenin subunit IDX5 that caused reduction in gluten content and dough quality. Thus, RNAi has been identified as an effective tool to manipulate gene expression for studying functional genomics in polyploids such as wheat.

28.2.4
TILLING

Targeting-induced local lesions in genomes (TILLING) has been reported as an efficient tool for functional genomics in plants [21]. Slade *et al.* [22] demonstrated the use of TILLING, a reverse genetic, nontransgenic approach for the identification of 246 alleles of *waxy* locus encoding granule-bound starch synthase I (GBSSI), in both hexaploid and tetraploid wheat. They also demonstrated that the triple homozygous mutant contains mutations in two *waxy* loci created through TILLING, and a preexisting deletion of the third homologue displayed a near-waxy phenotype. Slade and Knauf [23] reviewed the advantages of TILLING over RNAi transformation, especially for identification of genetic variations in complex genomes required for functional genomic studies. However, till date LI-COR gene analyzers, which use fluorescently labeled primers, were used for TILLING techniques, which is an expensive setup. But recently, a nondenaturing polyacryamide gel setup that uses ethidium bromide was used by Uauy *et al.* [24]. They developed mutant populations of pasta and common wheat and each was characterized by TILLING multiple genes revealing high mutation density in both populations. Thus, TILLING approach provides evidence of the presence of many novel alleles for functional genomic studies.

28.2.5
Transcriptomics

For wheat functional genomics, any alterations in the transcriptome during developmental processes or abiotic stresses would be very useful in assessing gene functions. Wilson *et al.* [25] randomly picked EST clones from 35 cDNA libraries of different stages of wheat grains and plant development and functionally annotated them. High-density microarrays based on these libraries were also produced. In 2005 [26], they presented the use of 9155 wheat unigene cDNA microarrays and reported changes in the wheat embryo transcriptome during maturation and germination. As expected, accumulation of many mRNAs encoding proteins involved in amino acid biosynthesis and metabolism, cell division and cell development, signal transduction, lipid metabolism, energy production, protein turnover,

respiration, initiation of transcription and translation, and ribosomal composition were observed. Also described were changes in abscisic acid signaling and mRNAs encoding *viviparous1* (VP1), suggesting a detailed analysis of transcriptomics to enable manipulation and development of new wheat varieties with superior traits.

Lopato [27] enabled the importance and role of proteins involved in posttranscriptional processes such as splicing in the developing wheat grain. The wheat homologue of *AtRSZ33* splicing factor, designated *TaRSZ38*, was shown to be expressed in the embryo and in mitotically active tissues of the endosperm by *in situ* hybridization and immunodetection. By employing *TaRSZ38* as the bait in a two-hybrid screen, they identified additional proteins that showed high homology to known splicing factors, thus annotating *TaRSZ38* protein to be involved in spliceosome formation. Laudencia-Chingcuanco *et al.* [28] studied global gene expression patterns by using 8 K wheat cDNA microarrays in developing caryopses and functionally annotated genes with respect to their expression in the respective developmental stages. Similarly, Wan *et al.* [29] investigated the transcriptome of wheat developing caryopses by Affymetrix GeneChip® wheat oligonucleotide arrays, which has probes for 55 052 transcripts. Gene expression of 14 550 transcripts was found to be differentially regulated at different development stages.

SAGE (serial analysis of gene expression) for the transcriptome analysis of developing caryopsis in wheat was employed by McIntosh *et al.* [30]. Poole *et al.* [31] generated 71 930 long SAGE tags from 6 libraries of 2 wheat genotypes grown under hot and dry conditions. By using single-copy puroindoline a and b genes, this SAGE analysis revealed the presence of antisense transcripts that may have a role in gene regulation. The regulation by antisense transcripts was further confirmed by Coram *et al.* [32] by developing a novel protocol to assay sense and antisense-strand transcription on the 55 K Affymetrix GeneChip wheat genome array, which is a 3′ *in vitro* transcription (3′IVT) expression array. Of the 110 sense–antisense transcript pairs, most were annotated as genes involved in energy production, suggesting that photosynthesis is likely to be regulated by antisense transcripts. Schreiber *et al.* [33] compared gene expression profiles in barley and wheat by Affymetrix gene chips and reported their transcriptomes to be highly correlated and of use in analyzing functional genomics of these cereals.

28.2.6
Transgenics

There has been an unprecedent increase in our knowledge of functional genomics in wheat by utilizing various newer approaches already discussed. However, the traditional transgenic approach allows the introduction of gene of interest with selective modifications. Enhancing nutritional quality, resisting biotic and abiotic stresses, and herbicide and pesticide resistance would enable to predict the function of introduced genes [34]. There are various reports utilizing wheat as a system for raising transgenics for the characterization of a desired gene. Generating gene knockouts by the introduction of T-DNAs or transposons into wheat has been found to be very useful for analyzing the gene functions [35].

28.3
Wheat Genomic Resources

28.3.1
ESTs

Functional genomics exploits various genomic tools, one of them being EST sequence databases, which has accelerated the pace of gene discovery. There are several publicly available EST databases for wheat where one can download all the available EST data from hexaploid wheat and other Triticeae species. One such site for downloading wheat EST data is http://wheat.pw.usda.gov/NSF/curator/wheat_est.html, where processed 5′ EST data, 5′ EST raw data, quality scores, 3′ EST data, and trace files are available for download. EST contig assembly is performed using a program Phrap (www.phrap.org/). It is necessary to assess the level of library redundancy. Sequencing of individual cDNA libraries was then carried out. The results provide unique ESTs to a specific library. According to the GenBank dbEST database (http://www.ncbi.nih.gov/dbEST/dbEST_summary.html), there are now over 1 067 304 *Triticum aestivum* ESTs available to the public by the ITEC (International Triticeae EST Cooperative) effort and other sequencing projects (dbEST release 012910). Several studies available made use of these EST databases for comparative mapping revealing structural and functional relatedness [35–37]. Several groups worked on construction of cDNA libraries generating ESTs and their utilization for selection of distinct sequence motif unigenes, mapping with wheat aneuploid and deletion stocks, required for wheat genomics and functional genomics studies [38, 39]. Several studies in 2006 focused on the digital expression analysis of these high-quality ESTs obtained from various stages of wheat growth and development and biotic and abiotic stress-related issues such as temperature, drought, photoperiod, moisture, and ABA [40–42]. A large number of stress-responsive genes were identified and their putative functions were analyzed according to gene ontology. Comparison between different wheat genomes (B and D) was also reported on the basis of unique ESTs associated with various abiotic stresses such as heat, cold, drought, salinity, and aluminum by Ramalingam *et al.* [43].

28.3.2
Full-Length cDNA Resource

Construction of full-length cDNAs provides the putative annotation based on homology search against several protein databases. One database that provides full-length coding sequences for wheat along with their annotation is TriFLDB: Triticeae full-length CDS Data Base (http://trifldb.psc.riken.jp/index.pI). The current version provides 8530 putative full-length wheat cDNA sequence and their annotations. Similarly, another wheat genetic resource database (KOMUGI) provides several tissue-specific, biotic and abiotic stress-related cDNA sequences (www.shigen.nig.ac.jp/wheat/komugi/ests/tissue). cDNA resource/library has also been constructed from young spikelets of hexaploid wheat and 24056 ESTs were obtained from both ends of cDNA clones [44]. Till date, it has been found useful in mainly

biotic stresses. There are studies describing the construction of full-length cDNA library from wheat stripe rust fungus [45]. Kawaura *et al.* [46] generated a high-quality, full-length cDNA resource for common wheat and 6162 clones were sequenced. About 10% of the clones were uniquely present in wheat while rest showed high homology to those of rice. They analyzed their expression patterns in 28 different tissues and abiotic stress treatments, the differential expression suggests that molecular selection occurred during the diversification of wheat and rice and is considered a valuable asset for functional genomics in wheat.

28.3.3
Wheat Mutants

As a wheat genetics resource, reverse genetics approach includes the creation of mutants by targeting specific gene to assess its function. A collection of several knockout mutants in wheat has been generated to assess the function of genes involved in biotic stress. Several mutants were isolated in wheat that showed increased resistance toward fungal causal agent of yellow rust, brown rust, blotch fungus such as *Mycosphaerella graminicola* and *Pyrenophora tritici-repentis* [47–51]. For understanding fungal gene expression related to pathogenicity, Goswami *et al.* [52] constructed 3 cDNA libraries and the probable functions of 49 genes inferred. One mutant showed reduced sporulation and delayed spread of *Fusarium* on wheat. Several studies also focused on the identification and molecular characterization of *waxy* mutants in wheat [53–55]. Three WAXY proteins (granule-bound starch synthase I) have been characterized for the development of new waxy wheat lines.

Many vernalization-related mutants such as VRN1 and VRN2, the *mvp* mutants (maintained vegetative phase) of einkorn wheat (*T. monococcum*) that has *null* alleles of VRN1, have also been very useful in analyzing genes that control photoperiod and flowering-time genes [56–59]. The analysis indicated a genetic network of flowering-time genes in wheat leaves and the need for a more detailed molecular characterization of the *mvp* mutants. However, attention is now focused on creation of mutants with respect to abiotic stress. Thermotolerant mutants [60] and salt stress mutants [61] have already been characterized to study the genetic basis of stress tolerance in wheat.

28.3.4
Introgression Lines

Introgression lines derived from multiple inbred strains serve as a powerful resource for studying multiple quantitative trait loci by introducing specific traits. For the generation of biotic/abiotic stress-resistant wheat, development of alien addition/substitution lines, and thus introgression lines, become essential. However, the pairing homologous 1 (Ph1) locus restricts chromosome pairing and recombination during meiosis. Thus, to uncover the mechanism of the Ph1 locus, various Ph1 and Ph2 mutants and introgression lines have been developed [62–64]. Several young isogenic lines and their genetic analyses have also contributed to the detailed characterization of regulatory regions of VRN1 vernalization genes [65, 66]. For

understanding the mechanism of resistance for biotic stress tolerance, near-isogenic lines for wheat rust resistance gene Lr34/Yr18 were examined [67]. For abiotic stress, several RIL (recombinant inbred line) and NIL (near-isogenic line) populations were analyzed for the effect of heat stress on CMS (cellular membrane thermostability) and GluD-1 [68, 69]. To understand the role of each chromosome during cold tolerance, 20 isogenic lines of wheat were analyzed [70]. However, further studies are essential for understanding the mechanism of resistance for biotic and abiotic stress tolerance.

28.4 Wheat Functional Genomics for Various Stresses

28.4.1 Drought Stress

Among several abiotic stresses, water stress is the most widespread in wheat. Several studies therefore focus on the accumulation of LEA (late embryogenesis abundant) proteins, osmolytes (proline, glycine, etc.), as adaptive mechanisms for protection against drought stress. Pellegrineschi *et al.* [71] expressed the *AtDREB* gene (dehydration responsive element binding) under the control of a stress-induced promoter *rd29* in wheat. The transgenics raised showed some tolerance to drought stress by a 10 day delay in wilting. Selote *et al.* [72] demonstrated limited ROS (reactive oxygen species) accumulation in the leaves and roots of drought-acclimated wheat (*T. aestivum* cv.306) that caused minimal membrane damage. In another related study, Xu *et al.* [73] examined the transcript accumulation of wheat PP2Ac-1 (catalytic subunit of protein phosphatase 2A) during water stress. Transgenic tobacco plants overexpressing *TaPP2Ac-1* gene were found to be resistant to water deficit. A "feedback mechanism" was proposed to be operating under drought stress conditions in mitochondria involving ROS production by Pastore *et al.* [74]. The function of wheat calreticulin (*TaCRT)* toward drought stress was demonstrated by *TaCRT*-overexressing tobacco (*Nicotiana benthamiana*) plants that showed enhanced drought resistance by higher WUE (water use efficiency), WRA (water retention ability), RWC (relative water content), and lower MDR (membrane damaging ratio) under water deficit conditions [75]. Transcriptome profile of wheat "opata" roots under drought stress revealed 394 transcripts differentially regulated with a fold change of at least 1.5 between stressed and control roots [76]. The genes of importance were putative glucanases and class III peroxidases. Kam *et al.* [77] identified 47 Q-type zinc finger protein genes from *T. aestivum* and analyzed their expression profile in different organs during leaf development and aging, drought stress, and ABA and sucrose treatment. They concluded that 30 genes were predominantly expressed in roots and 37 *TaZFP* genes responded to drought stress. Recently, Ergen *et al.* [78] compared global expression profiles of drought-tolerant and -sensitive wild emmer wheat genotypes at two different time points in two different tissues (root and leaf) using the Affymetrix GeneChip wheat genome array. The data revealed several unique genes and signal related pathways such as IP3, ethylene, ABA-dependent signaling,

and a faster induction of ABA-dependent transcription factors in the tolerant genotype, suggesting some unique transcriptome pathways in wild emmer wheat that correlated with their ability to withstand drought conditions.

28.4.2 Salinity Stress

Wheat is exposed to salt stress as it is mainly grown under irrigated and rain-fed conditions [79]. Na^+ exclusion, Na^+ compartmentalization, and K^+ uptake are some of the adaptive mechanisms reported in wheat. Colmer *et al.* [80] discussed different sources of Na^+ exclusion among various genomes that make up tetraploid wheat (*T. durum*), hexaploid bread wheat (*T. aestivum*), and wild relatives such as *Aegilops* spp. and *Thinopyrum* spp. In the same year, Kawaura *et al.* [81] constructed a 22 K wheat oligo-DNA microarray with 148 676 ESTs of common wheat. They analyzed 1811 genes whose expression changed more than twofold in response to salt stress. Such global gene profiling studies help to understand the mechanism of salt tolerance in wheat.

Using a comparative genomics approach, Huang *et al.* [82] utilized rice genome sequence and wheat EST data to identify and characterize a candidate gene for *Nax1* responsible for low Na^+ concentration in leaf blades. They reported two putative sodium transporter genes (*TmHKT7A1–2*) related to *OsHKT7*, out of which *TmHKT7A2* was expressed in roots and leaf sheaths of salt-tolerant durum wheat line 149, which correlated well with the physiological role of *Nax1* in reducing Na^+ concentration.

Another adaptive measure other than Na^+ exclusion studied in wheat is its ability to retain K^+. Cuin *et al.* [83] used the noninvasive ion flux measuring technique to measure K^+ flux from roots in two bread and two durum wheat genotypes, contrasting in their salt tolerance. Kawaura *et al.* [84] designed oligo-DNA microarrays from approximately 32 000 unique wheat genes. They observed 5996 genes differentially expressed when treated with salt for different intervals by more than twofold. These genes were assigned functions using gene ontology (GO) and categorized as transcription factors, transcriptional regulators, DNA binding functions, and some as early-responsive genes and late-responsive genes as transferase and transporters. For creating novel germplasm for improving salt tolerance in bread wheat, Mullan *et al.* [85] chose *Lophopyrum elongatum* (tall wheat grass). They induced recombination of chromosome 3E from tall wheat grass with chromosome 3A and 3D from bread wheat and using molecular marker analysis and genomic *in situ* hybridizations provided a novel germplasm that could be deployed to enhance Na^+ exclusion in bread wheat, thus providing novel functional genes that also give an insight into the mechanism of salt tolerance in wheat.

28.4.3 Low-Temperature Stress

Low-temperature stress/cold stress to wheat plants produces many morphological, biochemical, and physiological changes. Thus, expression profile of differentially

expressed genes under cold stress is desirable and advantageous. For the same purpose, Gulick *et al.* [86] performed microarray analysis with cDNA inserts from 1184 wheat ESTs that represented 947 genes. Transcriptome comparison of winter and spring wheat revealed more than 300 genes expressed under cold stress of which 65 were differentially regulated between the cultivars. To study the function of wheat alternative oxidase (*AOX*) genes under low temperature, Sugie *et al.* [87] produced transgenic plants by introducing wheat *aox1a* under the control of CaMV 35 S promoter in *Arabidopsis thaliana*. The results revealed that levels of reactive oxygen species decreased in transgenic plants under low-temperature stress and recovery of total respiration activity under low temperature occurred rapidly in the transgenic plants, suggesting that *AOX* alleviates oxidative stress when the cytochrome pathway of respiration is inhibited under abiotic conditions.

Monroy *et al.* [88] compared the gene expression in winter wheat cultivar CDC Clair and spring wheat cultivar Quantum, under cold stress by a 5740 feature cDNA amplicon microarray that was enriched for signaling and regulatory genes. About 450 genes were found to be regulated by cold and among them about 130 were for signaling or regulatory gene candidates that included various transcription factors, protein kinases, ubiquitin ligases, and GTP, RNA, and calcium binding proteins. Kobayashi *et al.* [89] isolated *Wlip19*; wheat lip19 homologue that encoded a *bZIP-type* transcription factor, which expressed under low temperature in seedlings and was found in higher amount in the freezing-tolerant cultivar. Transgenic tobacco plants expressing *Wlip19* showed enhanced tolerance to freezing and other abiotic stress as well. Under the control of promoter sequences of four wheat *Cor/Lea* genes, *Wdhn13*, *Wrab17*, *Wrab18*, and *Wrab19*, expression of a GUS reporter gene was enhanced by *Wlip19* expression in wheat callus and tobacco plants. Thus, it was concluded that WLIP19 acts as a transcription regulator of *Cor/Lea* genes under abiotic stress tolerance.

28.4.4
High-Temperature Stress

The effect of global warming on various crop plants can be estimated by the yield loss, which is maximum in the case of wheat [90]. However, not many studies have been reported detailing the expression analysis or assessing the function of genes that can contribute to functional genomics in case of wheat under heat stress. Nonetheless, Gallie *et al.* [91] analyzed the translation elongation factors from wheat during heat shock treatment. They examined the protein levels and isoelectric state of elongation factor (EF) 1α and 2 in the regulation of translation. EF2 expression level from wheat seeds decreased slightly under heat stress; however, no changes were observed in the number or levels of isoforms observed. Campbell *et al.* [92] cloned two heat stress-inducible members of HSP101/ClpB family (*TaHSP101 B* and *TaHSP101 C*) that were found to be inducible by heat stress treatments, dehydration, and ABA, thus suggesting role of *HSP101* in osmotic stress responses. Gulli *et al.* [93] isolated and characterized four cDNAs encoding HSP101 in durum wheat. The expression analysis revealed their differential regulation under heat stress. Thus, this data would be useful in analyzing the functions of *HSP101* family members.

Genome-wide gene expression profiling using GeneChip wheat genome array of two wheat genotypes, Chinese Spring (CS), susceptible to heat stress, and "TAM107," tolerant to heat stress, was undertaken by Qin *et al.* [94] and found 6560 probe sets responsive to heat treatment. These genes belong to heat shock proteins (HSPs), transcription factors, phytohormone biosynthesis/signaling, calcium and sugar signal pathways, RNA metabolism, ribosomal proteins, primary and secondary metabolism, and biotic and abiotic stresses. Ristic *et al.* [95] observed *rubisco activase* (*RCA*) expression in four genotypes of wheat and a positive correlation was found among the wheat 45–46 kDa *RCA* of different genotypes under heat stress, suggesting an important role played by endogenous levels of *RCA* as well.

Detailed transcriptome analysis has been carried out through suppression subtractive hybridization of heat-stressed and nonstressed tissues of wheat at three different development stages, that is, young seedlings, prepollinated flowers, and developing grains [96]. In all, 5500 ESTs were generated, out of which 3516 high-quality ESTs were submitted to GenBank. Their differential expression was confirmed by cDNA macroarray and by Northern/RT-PCR analysis. Some of the transcripts that showed high induction by high-temperature stress are stress-related proteins. Real-time PCR of selected genes gave further insight into their putative roles that, however, needs functional validation through transgenic technology.

28.4.5
Signaling Network

Plants respond to various abiotic stresses through their interconnection, which contributes to protection of the plant against unfavorable environmental conditions. There are various mechanisms by which plants respond to abiotic stresses such as drought, salt, and cold stress. However, Ca^{2+} signaling is a universal early-responsive mechanism that involves calcium sensors, such as calmodulin, calmodulin-like proteins, calcineurin B-like proteins, and calcium-dependent protein kinases [97]. Wang *et al.* [98] functionally analyzed a novel Ca^{2+}-permeable channel gene *TaTPC1* from wheat. This putative membrane protein showed enhanced expression under high salinity, PEG, low temperature, and ABA. *TaTPC1*-overexpressing transgenic plants exhibit more stomatal closing under Ca^{2+} than the control plants, suggesting a role for the calcium channels in response to various abiotic stresses in wheat. Charron *et al.* [99] identified and characterized plant lipocalins and lipocalin-like proteins. They analyzed the expression of wheat lipocalins under various abiotic stress responses such as PEG-induced dehydration, salt, high-temperature, and freezing stress that correlated with the capacity of the plant to develop freezing tolerance. Data mining also revealed that lipocalins are present in desiccation-tolerant red algae *Porphyra yezoensis* and the cryotolerant yeast *Debaryomyces hansenii*, suggesting the putative function as protection of the photosynthetic system against temperature stress.

Egawa *et al.* [100] isolated a DREB2 homologue *Wdreb2*, a candidate gene for a transcription factor of the *Cor/Lea* genes; its detailed expression analysis indicated its activation in drought, cold, salt, and exogenous ABA treatment. They also showed

three transcript forms of *Wdreb2* (α, β, and γ) through alternative splicing and their differential expression. Faik *et al.* [101] reported the characterization of 34 wheat fasciclin-like arabinogalactan-proteins (FLAs) by expression and bioinformatics analysis. The wheat EST databases and RNA gel blots indicated that most of the *TaFLA* genes are expressed in reproductive organs and roots and two of them are upregulated by cold treatment in roots. This study laid the foundation for analysis of the function of each *TaFLA* protein in plant development during abiotic stress responses. Stephenson *et al.* [102] identified 37 *NY-F* genes in wheat in the global DNA databases. NF-Y is a trimeric complex that binds to the CCAAT-box, highly conserved promoter element in eukaryotes. Quantitative RT-PCR revealed that some of them were predominantly expressed in the endosperm and three were activated under drought conditions, indicating a plant-specific biological role for this transcription factor family.

Xu *et al.* [103], for the first time, isolated a *TaERF1* (*T. aestivum* ethylene responsive factor 1) with a conserved DNA binding domain, a conserved N-terminal motif (MCGGAIL), and a putative phosphorylation site (TPDITS) in the C-terminal region, substrate for *TaMAPK1* protein kinase. Transactivation assays of *TaERF1* in tobacco leaves revealed the activation of GUS reporter gene driven by GCC-box indicating that *TaERF1* binds to the GCC-box and transactivates reporter gene expression. Expression analysis of *TaERF1* revealed its induction in drought, salinity, low-temperature stress, and exogenous ABA, ethylene, and salicylic acid indicating its involvement in multiple stress and signal transduction pathways. Expectedly, overexpression of the *TaERF1* gene improved tolerance to abiotic stresses in transgenic plants. A study by Brini *et al.* [104] has shown that transgenic *A. thaliana* plants overexpressing one of the two wheat vacuolar Na^+/H^+ antiporter *TNHX1* or H^+ pyrophosphatase *TVP1* showed resistance to high salt concentration and water deficit conditions. There is increased osmotic adjustment in transgenic plants due to accumulation of more Na^+ and K^+ in their leaf tissue than the control plants. Similarly, Kobayashi *et al.* [105] generated tobacco transgenic plants expressing *Wdreb2* (wheat DREB2 homologue) with clearly improved freezing and osmotic stress tolerance in tobacco plants. The GUS expression was enhanced by cold, drought, and ABA treatment under the control of *Cor/Lea* promoter sequences in transgenic plants, indicating WDREB2 could be a transcription factor that positively regulates wheat *Cor/Lea genes* under various abiotic stresses. Jung *et al.* [106] examined four wheat *O*-methyl transferases (OMT) genes, involved in primary and secondary metabolism. Their tissue-specific expression and differential regulation in response to various abiotic stresses and hormones such as PEG, Cold, NaCl, UV-B, wounding, and methyl jasmonate, salicylic acid, ethylene, and ABA was studied that signifies functional diversity of wheat *OMT*s in response to differential expression.

Three homologues of the DBF (dehydration-resposive element binding factors) gene family in wheat were isolated by Xu *et al.* [107] and designated as *TaAIDFs a,b,c* (*T. aestivum* abiotic stress-induced DBFs). *TaAIDFa* transcript was upregulated under drought, salinity, cold stress, and exogenous ABA. Also, overexpression of *TaAIDFa* in transgenic *Arabidopsis* showed enhanced tolerance toward drought and osmotic stresses. Shaw *et al.* [108] identified 31 *Dof* (DNA binding with one finger) genes in

bread wheat and studied their expression analysis. While most of the *TaDof* genes expressed in vegetative organs, they were also downregulated by drought and activated by light and dark cycle. The data indicate the number of genes involved in photosynthetic process or sucrose transport, suggesting its potential role in the photosynthetic process. Kovacs *et al*. [109] compared the effects of cold, osmotic stress, and ABA on polyamine accumulation in wheat variety CS and in two-derived chromosome 5A substitution lines (*T. spelta* 5A) and CS (Cheyenne 5A) with lower and higher levels of freezing tolerance, respectively. The differential regulation provides an insight into the involvement of polyamines in abiotic stress adaptation to plants and the possible regulatory role of chromosome 5A. Mao *et al*. [110] generated transgenic *Arabidopsis* plants overexpressing wheat *TaSnRK2.4* (sucrose nonfermenting 1-related protein kinase 2) under the control of CaMV35S promoter resulting in enhanced tolerance to drought, salt, and freezing stresses. Morphological and physiological assays revealed decreased rate of water loss, enhanced higher relative water content, strengthened cell membrane stability, improved photosynthesis and increased osmotic potential, indicating *TaSnRK2.4* acts as a multifunctional regulatory factor in *Arabidopsis*.

A comprehensive study of CDPK was provided by Li *et al*. [111]. They isolated 14 full-length cDNA sequences of CDPKs and analyzed their expression profile under various biotic and abiotic stresses such as cold, H_2O_2, salt, drought, powdery mildew, abscisic acid, gibberellic acid, suggesting their role in multiple signal transduction pathways. Using knowledge of this crosstalk between biotic and abiotic stress signaling pathways involving CDPKs, Li *et al*. [112] developed a model depicting possible roles of wheat CDPK genes under various biotic and abiotic stress conditions. Thus, utilizing this knowledge of CDPK genes and other Ca^{2+} sensors provides a strong foundation for further functional characterization of genes involved in Ca^{2+} signaling-mediated stress tolerance in wheat plants.

28.5
Wheat Functional Genomics for Plant Growth and Development

Berna *et al*. [113] studied the expression of germin-like proteins, which constitute a ubiquitous family of plant proteins. They observed the expression of *gf-2.8* gene in abiotic stresses such as heavy metal ions Cd^{2+}, Cu^{2+}, and Co^{2+}, polyamines, and biotic stress such as wounding and TMV infection, thus suggesting its role in several aspects of plant growth and development. Yao *et al*. [114] identified 18 *expansin* genes from wheat that were expressed in leaf, root, and the developing seed. Four *β-expansin* genes were expressed in the internode tissue in F1 hybrids, suggesting important roles of *expansin* gene family in growth and development. Kulshreshtha *et al*. [115] isolated and functionally characterized a *PHY*gene (*TaPHYC*) from wheat that shared structural similarity with rice *PHYC* containing four exons and three introns. Reverse transcriptase-PCR (RT-PCR) analysis showed it to be a constitutively expressed gene in all organs under light/dark conditions, but showed maximum upregulation in 3 day-old dark-grown seedlings.

Zhao *et al*. [116] isolated 42 putative wheat MADS-box genes and their expression analysis revealed differential expression patterns in various organs and development stages such as primary root tips, whole spikelets (lodicules, palea, stamens, and pistil), leaf, and stem indicating their universal role in wheat growth and development. Paolacci *et al*. [117] functionally characterized 45 MIKC-type MADS-box genes by RT-PCR and northern hybridization revealing the putative functions of the genes by comparing expression patterns with functionally characterized *Arabidopsis* MADS-box genes. Recently, Kovalchuk *et al*. [118] isolated and characterized *TaPR60* gene from bread wheat, which encodes a small cysteine-rich protein with a hydrophobic signal peptide that might direct the TaPR60 protein to a secretory pathway. To understand the function of this gene, yeast two-hybrid screen of a cDNA library prepared from developing wheat grain was performed, where TaPR60 was used as a bait and the interacting proteins were found to be involved in the proteolytic processing and secretion of *TaPR60*.

28.6 Comparative Genomics

Global comparative sequence analysis at the level of both DNA and protein sequence is performed with the aim of deriving structural, functional, and evolutionary relationships across several species [119]. *Arabidopsis* and rice are considered two model species suitable for comparative genomics. *Arabidopsis* is used as a model for all flowering plants, while rice is used as a model for genomes of cereals like wheat. Through comparative analysis, Mullan *et al*. [120] studied genes that control Na^+ accumulation, such as *HKT1* and *SOS1* in *Arabidopsis*; wheat orthologues were identified, characterized, and confirmed through similar intron–exon structure in *Arabidopsis* and rice. On the basis of additional exons identified in the predicted *NHX1* and *SOS1* genes of rice and wheat compared to *Arabidopsis*, they suggested evolutionary relationships among them. Boutrot *et al*. [121] performed comparative analysis of rice nonspecific lipid transfer protein (nsLTPs) and wheat ESTs and thus identified 156 putative wheat *LTPs*, where the majority (91) were from "Chinese Spring" cultivar. Thus, plant *nsLTPs* were categorized on the basis of sequence similarity and/or phylogenetic clustering.

Recently, *Brachypodium distachyon* (L.) is emerging as a model system for cereals because of its small genome, short life cycle, self-fertility, diploid accessions, and simple growth requirements [122]. It is phylogenetically very similar to wheat and barley, and thus various genomic resource studies involving the construction of cDNA libraries, BAC libraries, EST sequences, linkage map, and the complete genome sequence are under development [123]. This group has also developed a transformation method with efficiency as high as 41%, which will play an important role in comparative genomics. Microcolinearity was found to be more conserved for the Q gene region between wheat and rice than between wheat and *Brachypodium*, but phylogenetic analysis indicates *Brachypodium* is more closely related to wheat than rice [124]. Its syntenic relationship with rice and wheat is being analyzed by

structural characterization of its genome and construction of a BAC-based physical map [125, 126].

28.7 Conclusions

With utilization of wheat genomic resources along with functional genomics approaches, though slow yet a steady progress in wheat functional genomics is evident. Since complete wheat genome sequencing is not possible in near future, *Brachypodium* genome would serve as a platform for identification and functional analysis of genes of importance in wheat. In the meantime, availability of more ESTs/full-length cDNAs approach would be used for allele mining and molecular breeding. With the availability of cereal genomes such as rice, maize, sorghum, and so on, the field of comparative genomics appears promising and complex genomes such as wheat may also benefit with the progress in the area of plant genomics. It is expected that the coming century will witness landmark discoveries and pathfinding leads in our understanding of plant biology in general and help plant improvement in unprecedented ways.

Wheat: Mechanisms and Genetic Means for Improving Heat Tolerance

Kuldeep Singh, Vishal Chugh, Gurpreet K. Sahi, and Parveen Chhuneja

Heat stress is one of the major abiotic stresses that reduce crop productivity. Global warming effects are expected to increase the probability and intensity of heat waves, thus exacerbating the existing conditions. In wheat, reduction in yield in hot climates is primarily due to reductions in duration of growth and development. In addition, heat stress results in early leaf senescence and adverse physiological and biochemical changes. There is a strong need to develop crop plants, especially wheat for improved tolerance toward heat stress. This can be achieved by a thorough understanding of (i) various plant responses to high-temperature stress, (ii) by understanding mechanisms of heat stress tolerance, and (iii) by developing possible strategies for enhancing heat tolerance. Adverse affects of heat stress include decline in photosynthesis, increase in photorespiration, reduced water availability, loss of integrity and function of cell membrane, production of reactive oxygen species (ROS), and so on. In order to cope up with stress, plants employ a number of defense mechanisms, which includes overexpression of various enzymatic and nonenzymatic antioxidants to scavenge ROS, maintenance of membrane stability, production of various compatible solutes and metabolites, and induction of various signaling cascades. Understanding all these mechanisms can help us improve heat tolerance in plants using conventional and molecular breeding protocols and transgenic approaches. Heat tolerance in crop plants is reported to have been achieved by genetic engineering of expression of heat shock proteins, increasing the level of osmolytes and various cell detoxification enzymes, and altering membrane fluidity. Considerable variability in thermotolerance has been observed in wheat, especially in wild species including *Aegilops speltoides*. These tolerant species need to be exploited through integration of conventional and molecular breeding approaches. Armed with such wide information and techniques, it will be possible to rationally utilize these for the production of heat-tolerant genotypes with improved productivity.

Improving Crop Resistance to Abiotic Stress, First Edition.

29.1 Introduction

As the world population grows exponentially, there is a need to both increase agricultural productivity and expand productive areas into warmer climates of the world. Both of these goals require significant breeding efforts to improve high temperature tolerance of cereal yield and quality. Cereal breeding to date had utilized only a limited number of progenitor and nonprogenitor germplasm resources and emphasized a high-yield potential under favorable environmental conditions narrowing down genetic diversity of stress resistance traits, including heat stress tolerance. Heat stress is a major challenge to wheat productivity in India [1]. Screening of germplasm against environmental stresses, based on physiological parameters and biochemical markers, constitutes a powerful tool to help resolve this problem. Wheat is the most widespread cereal in terms of area planted. Bread and durum wheat (*Triticum aestivum* and *T. durum*) occupy an estimated area of 200 million ha globally. Though India is the second largest producer of wheat in the world, the average productivity is 2770 kg ha^{-1} against 3885 kg ha^{-1} in China and 8043 kg ha^{-1} in the United Kingdom, the Netherlands, and other NW European countries. In India, the lower productivity is due to shorter crop duration and period of grain filling and higher temperatures during crop growth, particularly during grain filling [2].

Continual heat stress affects approximately 7 million ha of wheat in developing countries, while terminal heat stress is a problem in 40% of temperate environments, which cover 36 million ha. Continual heat stress is defined by a mean daily temperature of over 17.5 °C in the coolest month of the season [3], and over 50 countries (importing more than 20 million tons of wheat per year) experience this type of stress throughout the wheat cycle. The food security of India depends to a large extent on wheat crop. Stagnation of wheat yield, declining production in the past few years, after touching the peak of 76.37 million ton in the crop season of 1999–2000, and recent imports have shaken the confidence of the nation, raising apprehensions about the country's ability to produce adequate food to meet the demand of the growing, economically ascendant population. Wheat yield in Punjab declined from 4.7 to 4.2 ton ha^{-1} between 2000 and 2005 [4]. The negative impact of a temperature increase of 0.4 °C observed between 1980 and 2000 on global wheat production has been demonstrated [5]. Average global temperatures are predicted to rise by 2 °C over next 50 years making many wheat growing regions even less suitable, based on predicted temperature ranges.

Wheat (*T. aestivum* L.), like other C_3 species, is not physiologically adapted to perform well under high temperatures. It has been reported that a 1 °C rise in temperature during grain filling shortens this period by 5% and proportionally reduces harvest index and grain yield [6]. Photosynthesis, as measured by carbon exchange rate, was found to be optimum at 25 °C [7]. Yet, temperatures of 35–40 °C are common in many wheat-producing areas of the world [8]. Biomass production can be substantially suppressed by the effects of heat stress on decreasing photosynthesis, impairing respiration, inactivating enzymes, and disrupting

membranes [9]. The adverse effects of heat stress on plant productivity are very pronounced in winter wheat in the southern plains during seedling establishment (late summer) and grain-filling stages (late spring) where high temperatures are common during these critical developmental stages.

29.2 Environmental and Physiological Nature of Heat Stress

Heat stress is often defined as the rise in temperature beyond a threshold level for a period of time sufficient to cause irreversible damage to plant growth and development. In general, a transient elevation in temperature, usually 10–15 °C above ambient, is considered heat stress. Transient or constant high temperature provoked damage at the morphological, anatomical, physiological, and biochemical levels in plants and may drastically reduce economic yield. High-temperature stress may lead to altered geographical distribution and growing season of agricultural crops by allowing the threshold temperature for the start of the season and crop maturity to reach earlier [10]. At moderately high temperature, injuries or death may occur only after long-term exposure while at very high temperatures, severe cellular injury and even cell death may occur within minutes, which could be attributed to a catastrophic collapse of cellular organization [11]. Direct injuries due to heat stress include protein denaturation and aggregation, and increased fluidity of membrane lipids, whereas indirect or slower heat injuries include inactivation of enzymes in chloroplast and mitochondria, inhibition of protein synthesis, protein degradation, and loss of membrane integrity [12]. Heat stress also affects the organization of microtubule asters in mitotic cells and elongation of phragmoplast microtubules [13]. These injuries eventually lead to starvation, inhibition of growth, reduced ion flux, and production of toxic compounds and reactive oxygen species (ROS) [11].

The extent to which heat stress occurs in specific climatic zones is a complex issue. Plants can be damaged in different ways by either high day or high night temperatures and by either high air or high soil temperatures. In addition, crop species and cultivars differ in their sensitivity to high temperatures. Studies comparing responses of contrasting species to heat indicated that photosystem II of cool season species such as wheat is more sensitive to heat than that of rice and pearl millet, which are adapted to much higher temperatures [14].

In general, heat tolerance can be defined as the ability to maintain integrity of cellular and subcellular structures and metabolic pathways (cellular heat tolerance) that allow continued plant growth and reproduction during and after exposure to heat stress conditions (whole-plant heat tolerance). Immediate exposure to heat stress mediates a cascade of signal transduction that changes the expression of genes and accumulation of transcripts, thereby leading to the synthesis of various stress-related proteins, as a stress tolerance strategy [15]. Expression of various heat shock proteins (HSPs) is known to be a very important adaptive strategy in acquiring heat stress tolerance. These proteins of molecular mass in the range of 10–200 kDa have chaperone-like activities and are involved in the signal transduction during heat

stress [16]. The tolerance conferred by HSPs results in improved physiological phenomena such as photosynthesis, assimilate partitioning, water and nutrient use efficiency, and membrane stability [17]. However, not all the plant species or genotypes within species have similar capabilities to cope with the heat stress. Tremendous variations exist within and between species providing opportunities to improve crop heat stress tolerance through various advanced techniques of molecular breeding and genetic engineering for developing crops with improved heat tolerance and to combat this universal environmental adversary.

29.3 Heat Stress Threshold

A threshold temperature refers to a value of daily mean temperature at which a detectable reduction in growth begins. Upper and lower developmental threshold temperatures have been determined for many plant species through controlled laboratory and field experiments. A lower developmental threshold or a base temperature is one below which plant growth and development stop. Similarly, an upper developmental threshold is the temperature above which growth and development cease. Knowledge of lower threshold temperatures is important both for physiological research and for crop production.

Upper threshold temperatures for some major crop species are presented in Table 29.1. The magnitude of heat stress rapidly increases as temperature increases above a threshold level and complex acclimation effects can occur that depend on temperature and other environmental factors. High-temperature sensitivity is particularly important in tropical and subtropical climates, as heat stress may become a major limiting factor for field crop production. This is because under high temperature conditions, plants tend to divert resources to cope with the heat stress and thus limited photosynthates would be available for reproductive development, which can

Table 29.1 High temperature threshold levels for some crop plants [18].

Crop plant	Threshold temperature (°C)	Growth stage
Wheat	26	Postanthesis
Tomato	30	Emergence
Brassica	29	Flowering
Cool season pulses	25	Flowering
Corn	38	Grain filling
Rice	34	Grain filling
Cotton	45	Reproductive
Pearl millet	35	Seedling
Ground nut	34	Pollen production
Cowpea	41	Flowering

accelerate senescence, diminish seed set and seed weight, and reduce yield [19]. Another effect of heat stress in many plant species is induced sterility when heat is imposed immediately before or during anthesis.

29.4
High-Temperature Impact and Plant Responses to Heat Stress

High temperatures are known to have deleterious effects on photosynthesis, respiration, and reproduction. At molecular level, these effects are brought about by altered gene expression and manifested at the biochemical and metabolic level, membrane stability, and production of heat shock proteins. The latter are postulated to protect organisms from the damaging effects of heat and other forms of stress [20]. Activities of the various enzymes involved in cellular processes are affected by increased temperature. The concept of thermal kinetic window (TKW) of an enzyme is defined as the temperature range in which the Michaelis–Menten constant (K_m) of the enzyme remains within 200% of the optimum. Whole-plant response to temperature stress reflects the thermal dependence of K_m of different enzymes. A 5 °C increase results in selective expression of HSPs, with continued synthesis of normal cellular proteins. With further increase in temperature, synthesis of HSPs predominates, while the others are inhibited. At still higher temperatures, even the synthesis of HSP is inhibited. An earlier study conducted in maize (*Zea mays* L.) kernels demonstrated that heat stress decreases protein accumulation and alters composition of the kernels [21]. Figure 29.1 represents various changes taking place under the influence of heat stress.
