This spectrum of dysfunction is common to all hypophosphatemia from any cause, whether nutritional or otherwise. Examples unrelated to dietary phosphorus intake include severe vitamin D deficiency rickets, in which the hypophosphatemia is due not so much to insufficient absorption of dietary phosphorus as to high levels of production of PTH (which lowers the TmP, and hence the plasma  $[P_i]$ ). The same is true for renal tubular acidosis, familial hypophosphatemia, Fanconi's syndrome, or any condition in which tubular  $P_i$  reabsorption is reduced (directly or indirectly) and hence renal clearance of  $P_i$  is high. Examples include X-linked hypophosphatemia, autosomal dominant hypophosphatemic rickets, tumoral osteomalacia, and, in some cases, fibrous dysplasia. In the first, the defect is due to an inactivating mutation in an endopeptidase (PHEX), leading to increased synthesis of FGF-23 (and hence renal phosphate wasting). The second is due to an activating mutation of the FGF-23 gene,

rendering FGF-23 resistant to proteolytic change. Tumoral osteomalacia comes about because of inappropriate secretion of FGF-23 (and other phosphatonins) by the neoplastic tissue (Strom and Jüppner, 2008).

As noted above, hypophosphatemia almost never occurs spontaneously for dietary reasons alone. However, with respiratory alkalosis or after major catabolic episodes, or recovery from alcoholic bouts, from diabetic ketoacidosis, or from similar situations, refeeding with calorie-rich sources without paying attention to phosphorus needs will usually produce serious and possibly fatal hypophosphatemia (Knochel, 1977, 1985; Bushe, 1986; Dale *et al.*, 1986). The so-called "refeeding syndrome" or "refeeding hypophosphatemia" is a well recognized problem following gut shut-down for any cause (Stein *et al.*, 1966; Travis *et al.*, 1972; Ritz, 1982; Knochel, 1985; Young *et al.*, 1985; Marik *et al.*, 1996). It is generally considered to be due to cellular uptake of phosphate as glucose moves into cells replenishing exhausted energy stores, and can occur following as little as 48 hours without oral feeding, particularly in previously malnourished individuals. Finally, aluminum-containing antacids, by binding diet phosphorus in the gut, can also produce hypophosphatemia in their own right, as well as aggravating phosphate deficiency related to these other problems (Lotz *et al.*, 1968).

Similarly, in infants, severe hypophosphatemia is likely to occur only in situations of parenteral nutrition, in which intakes of phosphate are inadequate, or with inappropriate administration of fluid and electrolyte therapy which causes excessive renal phosphorus loss, or with rapid refeeding after prolonged dietary restriction (Koo and Tsang, 1977; Weinsier and Krumdieck, 1981). In the case of severely malnourished infants, especially with accompanying severe diarrhea, hypophosphatemia has been reported with an associated hypokalemia and hypotonia (Freiman *et al.*, 1982).

### Excess

In assessing the potential for harmful effects of increasing phosphorus intakes, it may be helpful to recall that phosphorus intakes by humans fall at the low end of the continuum of standard pet and laboratory animal chows (see Table 29.2). The published tolerable upper intake level (TUIL or, more commonly today, simply UL) for adult humans is 129 mmol (4000 mg)/day (Institute of Medicine, 1997). Few individuals ever even approach that level.

The adverse effects of hyperphosphatemia (and high Ca  $\times$  P product values) include metastatic calcification,

particularly of the kidney and the coronary arteries, and, in some species, increased porosity of the skeleton. The kidney effects have been studied mainly in rats and mice (McFarlane, 1941; Craig, 1959; Hamuro *et al.*, 1970), have required very high phosphate loads in addition to the animals' already high basal phosphate intakes, and in several reports have required partial reduction of renal tissue mass for their expression. The bony lesions have been described in rabbits (Jowsey and Balasubramaniam, 1972) and bulls (Krook *et al.*, 1975). As with kidney toxicity, the bony lesions required extremely large phosphate intakes – in rabbits about 40-fold human intakes (per kilogram), and in the bulls feeding of a ration designed to support milk production in cows. None of these situations has any evident relevance to human nutrition or to human dietary intake of phosphate.

In humans the most common cause of significant hyperphosphatemia is not high intake, but renal failure. With advanced kidney failure especially, even sharply reduced phosphorus diets may still be excessive (in the sense that they still lead to hyperphosphatemia). Moreover, serum  $[P_i]$  is positively associated with coronary artery calcification and with cardiovascular disease risk in patients with ESRD. Management of serum  $[P_i]$  is a major problem in patients with ESRD. Concern has been expressed that even individuals with normal renal function may exhibit the same sort of adverse association between serum  $[P_i]$  values at the high end of the normal range and subsequent cardiac disease (Foley *et al.*, 2008, 2009). The associations found to date are weak; nevertheless, it remains true that the upper end of the normal range for ECF  $[P_i]$  is defined empirically, and it is not clear whether a value of, for example, 1.4 mmol/L is more or less salubrious than a value of 1.1 mmol/L.

While ECF in adults is less than half saturated with respect to  $\text{CaHPO}_4$ , elevation of plasma  $[P_i]$ , if extreme, can bring the ECF to the point of saturation. Under such conditions susceptible tissue matrices will begin to accumulate calcium phosphate crystals, particularly if local pH rises above 7.4. This almost never occurs in individuals with normal renal function, mainly because urine phosphate excretion rises in direct proportion to dietary intake. As Figure 29.1 shows, the upper limit of the nominal normal adult range for serum  $[P_i]$  occurs at absorbed intakes above 70 mmol/day. At 62.5% absorption, that means *ingested* intakes of 114 mmol/day. The distributional data of NHANES (Table 29.1) indicate that, out of the total population, only a very few adolescent and young adult men consume close to this level (Moshfegh *et al.*,

2009). Hyperphosphatemia can also be a problem in such conditions as vitamin D intoxication.

There has also been concern expressed about apparently rising phosphorus intake in recent years, for example because of a presumed population-level increase in phosphorus intake through such sources as cola beverages and food phosphate additives (Calvo and Heath, 1988). A high-phosphorus diet inevitably produces a slightly higher level of plasma  $[P_i]$ , especially during the absorptive phase after eating. It has been speculated that any elevation of serum  $[P_i]$ , even within the usual normal range, could have adverse effects on the skeleton (Calvo and Heath, 1988; Calvo *et al.*, 1988, 1990). In the animal studies cited above, increased bony porosity develops (Jowsey and Balasubramaniam, 1972; Krook *et al.*, 1975). It is known that phosphate loads in humans lead acutely to very slight drops in ECF  $[\text{Ca}^{2+}]$  and to elevated PTH levels (Calvo and Heath, 1988). However, these changes revert to normal by 5 days while still on the high-phosphorus intake (Silverberg *et al.*, 1986). The acute, mild hypocalcemic effect is often attributed to the formation of calcium phosphate complexes in plasma, with a resultant reduction in  $[\text{Ca}^{2+}]$ . This in turn would lead to enhanced PTH release. However, as noted above, it is doubtful that this is the correct explanation. Rather, it is more likely that the initial fall in  $[\text{Ca}^{2+}]$  following elevation of plasma  $P_i$  is produced by direct inhibition of PTH-mediated osteoclastic release of calcium from bone, cited earlier (Raisz and Niemann, 1969). (Thus, rather than harmful, this inhibition of bone resorption could actually be considered potentially beneficial to bone, since it amounts to a relative resistance to the bone-resorbing effects of PTH.)

Diets high in phosphorus and low in calcium produce a sustained rise in PTH (Calvo *et al.*, 1988, 1990) which has been presumed to be harmful for bone; but diets low in calcium without extra phosphorus produce the same change (Silverberg *et al.*, 1986) and for that reason it is unlikely that the high phosphorus component of the altered intake is the culprit in the first instance. More to the point, chronic administration of ~65 mmol phosphorus per day in men for at least 8 weeks produced no effect on calcium balance or calcium absorption relative to a diet containing only 26 mmol phosphorus (Spencer *et al.*, 1965, 1978). Calcium intake (low, normal, or high) had no influence on this lack of effect, further underscoring the lack of physiological relevance of the dietary Ca:P ratio in adults. Further, calcium kinetic studies performed in adult women in whom phosphorus intake was doubled (from 37 mmol to 74.5 mmol – an intake well above the

95th percentile in NHANES) showed no effect whatsoever on bone turnover processes after 4 months of treatment (Spencer *et al.*, 1965). Thus it seems unlikely that phosphorus intakes, within the range currently experienced by the US population, adversely affect bone health.

## Future Directions

The fundamental importance of phosphorus for life is well established, and, while more could be learned, no health policy decisions hinge on unresolved issues of basic phosphorus cell chemistry. On the other hand, four important areas of the understanding of phosphorus metabolism need elucidation:

- Better understanding of the role of the phosphatonins (and especially FGF-23), to include quantitative details of the endocrine feedback loop regulating serum [P<sub>i</sub>].
- Elucidation of the consequences (if any) of variations in serum [P<sub>i</sub>]; specifically, is there an optimal value within the nominal “normal” range, and, if so, does this optimum vary with age?
- Development of more effective means of controlling hyperphosphatemia in patients with end-stage renal disease.
- Determination of whether high FGF-23 levels, produced by hyperphosphatemia, exert adverse off-loop effects on various body systems.

## MAGNESIUM

STELLA LUCIA VOLPE, PhD, RD, LDN, FACSM

*Drexel University College of Nursing and Health Professions, Philadelphia, Pennsylvania, USA*

### Summary

Magnesium is a required mineral and cofactor for over 300 metabolic reactions in the body. The body consists of about 25 g of magnesium, with about 50–60% in the bone and the remainder in soft tissue. Magnesium ( $Mg^{2+}$ ) is a divalent metal ion. It is the fourth most abundant cation in the body after calcium, potassium, and sodium. Food sources high in magnesium include green, leafy vegetables, unpolished grains, and nuts. Magnesium deficiency may lead to cardiovascular disease, hypertension, the metabolic syndrome, and type 2 diabetes mellitus.

### Introduction

Magnesium (Mg) is a required mineral and a cofactor for over 300 enzymatic reactions in the body (Bohl and Volpe, 2002; Elin, 2010). These reactions include: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) synthesis, protein synthesis, cell growth and reproduction, adenylate cyclase synthesis, cellular energy production and storage, preservation of cellular electrolyte composition, and stabilization of mitochondrial membranes (Rude and Oldham, 1990; Newhouse and Finstad, 2000; Bohl and Volpe, 2002; Chubonov *et al.*, 2005; Elin, 2010). Magnesium plays a primary role in controlling nerve transmission, cardiac excitability, neuromuscular conduction, muscular contraction, vasomotor tone, and blood pressure (Rude and Oldham, 1990; Elin, 1994; Newhouse and Finstad, 2000; Bohl and Volpe, 2002; Chubonov *et al.*, 2005).

Magnesium deficiency has also been linked to the metabolic syndrome, insulin resistance, and diabetes mellitus in humans and animal models, and thus Mg plays a role in glucose metabolism (Rodriguez-Moran and Guerrero-Romero, 2003; Song *et al.*, 2004, 2005; Huerta *et al.*, 2005; Soltani *et al.*, 2005; Everett and King, 2006; He *et al.*, 2006; Mayer-Davis *et al.*, 2006).

### Magnesium Concentration in the Body

The body consists of about 25 g of magnesium, with about 50–60% in the bone, and the remainder in soft tissue (Bohl and Volpe, 2002; Elin, 2010). Less than 1% of total body magnesium is in the blood (Elin, 2010). Note that most of the clinical laboratory data are derived from the assessment of serum magnesium concentrations (Elin,

**TABLE 30.1** Distribution of magnesium in the body

Location	Concentration
Bone	0.5% of bone ash
Muscle	9 mmol/kg wet weight
Soft tissue	9 mmol/kg wet weight
Adipose tissue	0.8 mmol/kg wet weight
Serum magnesium (free)	~0.56 mmol/L
Saliva, gastric, bile	0.3–0.7 mmol/L
Sweat	0.3 mmol/L

Adapted from Elin (1994).

2010), though this has changed in the last several years as other methods of magnesium assessment have evolved such as evaluating plasma ionized magnesium, red blood cell magnesium, and, though more cumbersome, urinary magnesium via the magnesium loading test.

Approximately one-third of skeletal magnesium is exchangeable, acting as a pool for maintaining normal extracellular magnesium levels (Elin, 1994) (Table 30.1). Normal serum magnesium concentrations range from 1.8 to 2.3 mg/dL (Institute of Medicine, 1997), and this concentration is tightly regulated. Wary *et al.* (1999) reported that 30 healthy male volunteers showed no significant change in plasma magnesium levels after 1 month of supplementation with 12 mmol/day of magnesium lactate. Conversely, Day *et al.* (2010) reported significantly increased serum magnesium levels in post menopausal women after they consumed magnesium-supplemented water for 84 days (120 mg/L of magnesium as magnesium bicarbonate in spring water, compared with a control). Though serum magnesium concentrations are often used to evaluate magnesium status in clinical and research settings, recall that it may not be the best indicator of magnesium status.

## Chemistry and Functions

Magnesium ( $Mg^{2+}$ ) is a divalent metal ion. It is the fourth most abundant cation in the body after calcium, potassium, and sodium (Rude, 1998). Magnesium is the most prevalent intracellular divalent cation and the second most abundant intracellular cation after potassium (Elin, 1987; Rude, 1998). It is usually bound to ligands, and forms comparatively stable complexes (Frausto da Silva and Williams, 1991; Elin, 1994). Ionized magnesium represents the physiologically active form of the mineral;

however, protein-bound and chelated magnesium act as buffers for the ionized pool (Elin, 1994).

There are a minimum of three different body pools of magnesium in the human body: one with a quick turnover (from about 1.6 to 28 hours), largely comprised of extracellular magnesium; a second with a turnover rate of half the first pool, primarily consisting of intracellular magnesium (about 11 days); and a third pool containing skeletal magnesium with a slow turnover rate (>11 days) (Wester, 1987; Feillet-Coudray *et al.*, 2000, 2002).

Approximately 30% of serum magnesium is bound to protein, while the majority of the residual portion is ionized and filtered through the kidney. Intracellular magnesium is bound principally to protein and energy-rich phosphates (Frausto da Silva and Williams, 1991; Bohl and Volpe, 2002). The principal role of magnesium in the body is to complex highly charged anions, such as polyphosphates and nucleic acids, to support enzyme–substrate interactions, or stabilize the conformation of polymers (Wester, 1987; Bohl and Volpe, 2002).

Magnesium is required for a number of metabolic reactions including: aerobic and anaerobic metabolism; glycolysis, both directly as an enzyme activator, and indirectly as part of the magnesium–adenosine triphosphate (ATP) complex; and in oxidative phosphorylation (Elin, 1987, 2010). Magnesium is also required for the adequate supply of purines and pyrimidines for RNA and DNA synthesis. Magnesium may directly augment adenylate cyclase activity, as well as sodium-potassium-ATPase activity (Maguire, 1984), which is required for the active transport of potassium (Dorup and Clausen, 1993). Magnesium also plays a significant role in protein kinase activity.

Hekmat-Nejad *et al.* (2010) recently studied the steady-state kinetics of kinase activity and magnesium requirements of the interleukin-1 receptor-associated kinase-4. Interleukin-1 receptor-associated kinase-4 (IRAK-4) is a serine/threonine-specific protein kinase that plays a crucial role in intracellular signaling cascades that are mediated by interleukin-1 (IL-1) receptors. Hekmat-Nejad *et al.* (2010) reported that more than one  $Mg^{2+}$  ion interacts with the phosphoryl transfer activity of IRAK-4, and that the enzyme has its greatest activity in the presence of 5–10 mM of free  $Mg^{2+}$ . Furthermore, though one divalent metal is required for catalysis as part of a chelate complex with ATP, their kinetic evidence demonstrated that unbound  $Mg^{2+}$  further enhanced the catalytic activity of IRAK-4.

FIG. 30.1 Magnesium absorption.

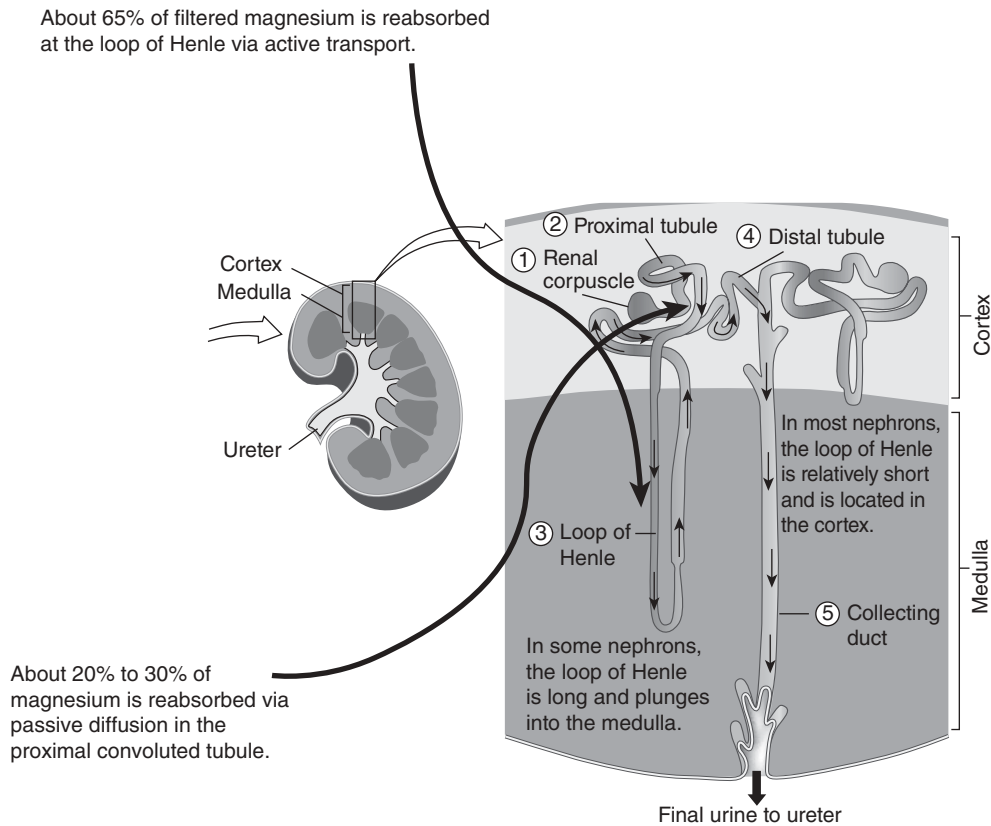

Magnesium has been called “nature’s physiological calcium channel blocker” (Iseri and French, 1984; White and Hartzell, 1989; Schmid-Elsaesser *et al.*, 2006), because, during magnesium depletion, intracellular calcium increases. It has been well documented that calcium plays an important role in skeletal and smooth muscle contraction; therefore, magnesium depletion can lead to muscle cramps, hypertension, and coronary and cerebral vasospasms (Institute of Medicine, 1997). Schmid-Elsaesser *et al.* (2006) reported that magnesium prevented delayed ischemic neurological deficits in patients with aneurysmal subarachnoid hemorrhage equally as effectively as nimodipine (a calcium-channel blocker). Studies combining their use may be worth researching, because of the differences in their properties; however, magnesium has very few side-effects, and may be a promising treatment itself.

In addition, magnesium therapy may show promise as an important adjuvant therapy for acute myocardial infarction (Sadeh, 1989; Horner, 1992; Herzog *et al.*, 1995). Because magnesium is an inorganic calcium channel blocker (Iseri and French, 1984; White and Hartzell, 1989), its ability to decrease infarct size may be a result of magnesium’s calcium channel blocking action at the level of the plasma membrane or an intracellular site (Sadeh, 1989).

## Absorption and Homeostasis

Like most minerals, the amount of magnesium absorbed is inversely related to the amount consumed. Though magnesium is absorbed throughout the intestinal tract, the greatest amount of magnesium is absorbed in the distal jejunum and ileum (Rude, 1998), with about 40–60% net absorption rate from food (Figure 30.1). Magnesium is absorbed via active transport and passive diffusion; active transport accounts for a greater fractional absorption of magnesium at low dietary intakes, while passive diffusion occurs at higher dietary intakes, resulting in lower fractional absorption (Fine *et al.*, 1991; Kayne and Lee, 1993). Calbindin- $D_{9k}$  may play a role in magnesium absorption (Institute of Medicine, 1997); however, its role has not been clearly defined.

The kidney is the primary organ regulating magnesium homeostasis (Quamme and Dirks, 1986). About 65% of filtered magnesium is reabsorbed at the loop of Henle via active transport (Quamme and Dirks, 1986) (Figure 30.2). Approximately 20–30% of magnesium is reabsorbed via passive diffusion in the proximal convoluted tubule of the kidney, which is associated with calcium, sodium and water transport (Schwartz *et al.*, 1984; Rude, 1998) (Figure 30.2). Though excessive magnesium is almost entirely excreted through the kidneys, this is not the case during

**FIG. 30.2** The kidney – the primary organ in regulating magnesium homeostasis.

magnesium deficiency. During magnesium deficiency, the kidney prevent magnesium loss by excreting less than 12 to 24 mg/day of magnesium (Rude, 1998). Renal magnesium excretion is augmented by diets high in sodium, calcium, and protein, as well as caffeine and alcohol consumption (Mahalko *et al.*, 1983; Martinez *et al.*, 1985; Massey and Whiting, 1993). Although the method(s) of magnesium transport in the intestine and kidney have not been elucidated, at present, there have not been any specific hormones or other compounds that have been designated to play a major role (Rude, 1998).

### Factors Affecting Absorption

A dietary intake averaging about 300 to 350 mg/day of magnesium will typically result in a fractional absorption rate between 30% and 50% (Schwartz *et al.*, 1984). A number of factors can decrease magnesium absorption, including fiber, phytates and oxalates from fruits, vegetables, and grains; excessive alcohol intake; and medications such as diuretics. Phosphorus, calcium, and protein have also been shown to decrease magnesium absorption. It

appears that the phytate in high-fiber foods results in the binding of magnesium to the phosphate groups on the phytates, leading to decreased magnesium absorption (Franz, 1989; Wisker *et al.*, 1991; Brink and Beynen, 1992; Greger, 1999).

Several researchers have reported no effects of either high-calcium diets (up to 2000 mg/day) on magnesium absorption, or high-magnesium intakes (up to 826 mg/day) on calcium absorption (Schwartz *et al.*, 1984; Abbott *et al.*, 1994). Nevertheless, because many calcium channels are reliant on magnesium, intracellular calcium levels increase with magnesium deficiency (Dacey, 2001). Moreover, persons who have low serum-magnesium concentrations and are also calcium deficient do not react to calcium supplementation until the magnesium deficiency has been corrected (Al-Ghamdi *et al.*, 1994; Dhupa and Proulx, 1998). Parathyroid hormone (PTH) is most likely the principal reason for this occurrence, because magnesium deficiency impairs PTH release and its uptake by bone (Estep *et al.*, 1969; Freitag and Martin, 1979; Al-Ghamdi *et al.*, 1994; Dhupa and Proulx, 1998).

Protein has also been linked with impaired magnesium status; magnesium absorption is lower when dietary protein is less than 30 g/day (Hunt and Schofield, 1969). Higher protein intakes of more than 94 g/day may result in increased renal magnesium excretion due to the increased acid load; however, magnesium retention remained the same on higher-protein diets (Mahalko *et al.*, 1983; Wong *et al.*, 1986). Others have reported that, when compared with lower protein intakes (43 g/day), magnesium absorption and maintenance were improved with higher protein intakes (93 g/day) (Schwartz *et al.*, 1973).

Though there is no definitive research on how boron may affect magnesium absorption, there does seem to be an interaction between boron and magnesium (Volpe *et al.*, 1993; Meacham *et al.*, 1994, 1995). It appears that, when boron concentrations are low, magnesium may be the mineral called upon to take on boron's roles in the

body (Volpe *et al.*, 1993). Furthermore, it appears that boron supplementation may increase serum magnesium concentrations over time (Meacham *et al.*, 1994, 1995).

### Magnesium Transport

Magnesium transport in and out of cells requires carrier-mediated transport systems (Gunther, 1993; Romani *et al.*, 1993). Magnesium efflux from the cell is linked to sodium transport, while magnesium influx is associated with sodium and bicarbonate transport; however, it uses a different method than that of magnesium efflux (Gunther, 1993; Romani *et al.*, 1993; Institute of Medicine, 1997).

### Magnesium Requirements

The United States dietary reference intakes (DRIs) for magnesium are listed in Table 30.2. These represent the

**TABLE 30.2** Dietary reference intakes for magnesium

Age and sex	AI (mg/day)	RDA (mg/day)	UL <sup>a</sup> (mg/day)
<i>Infants (boys and girls)</i>			
0–6 months	30	NA	Unable to establish for magnesium supplementation
7–12 months	75	NA	
<i>Children (boys and girls)</i>			
1–3 years	NA	80	65
4–8 years	NA	130	110
9–13 years	NA	240	350
<i>Males</i>			
14–18 years	NA	410	350
19–30 years	NA	400	350
31–>70 years	NA	420	350
<i>Females</i>			
14–18 years	NA	360	350
19–30 years	NA	310	350
31–>70 years	NA	320	350
<i>Pregnancy</i>			
14–18 years	NA	400	350
19–30 years	NA	350	350
31–50 years	NA	360	350
<i>Lactation</i>			
14–18 years	NA	360	350
19–30 years	NA	310	350
31–50 years	NA	320	350

AI, adequate intake; EAR, estimated average requirement; RDA, recommended dietary allowance; UL, tolerable upper intake levels; NA, not applicable.

most recent DRIs for magnesium, which were last established in 1997. Though the requirements for the United States are slightly higher than some countries (e.g. England has a Recommended Daily Allowance of 300 mg/day, with an upper limit of 350 mg/day), in general, magnesium requirements are within 300 to 450 mg/day throughout the world.

The indicators used to establish the estimated average requirements (EAR) for magnesium were based upon magnesium balance studies, since there were not sufficient data to determine an advantage for maximal magnesium retention (Institute of Medicine, 1997). Because magnesium intake from foods has not been shown to result in adverse effects, the tolerable upper intake level (UL) of magnesium

was established by assessing pharmacological doses of magnesium (e.g. magnesium salts) that resulted in adverse outcomes (Institute of Medicine, 1997). (Refer to later section entitled “Effects of magnesium excess” for examples of adverse outcomes with high levels of magnesium intake.)

## Food Sources of Magnesium

Magnesium is a ubiquitous mineral, found in a number of foods. Food sources high in magnesium include green, leafy vegetables, unpolished grains, and nuts. Intermediate sources of magnesium include meats, starches, and milk. Refined foods are poor sources of magnesium. Table 30.3

**TABLE 30.3** Food sources of magnesium

Food	Content (mg)
Halibut, cooked, 3 ounces	90
Almonds, dry roasted, 1 ounce	80
Cashews, dry roasted, 1 ounce	75
Soybeans, mature, cooked, ½ cup	75
Spinach, frozen, cooked, ½ cup	75
Nuts, mixed, dry roasted, 1 ounce	65
Cereal, shredded wheat, 2 rectangular biscuits	55
Oatmeal, instant, fortified, prepared with water, 1 cup	55
Potato, baked with skin, 1 medium	50
Peanuts, dry roasted, 1 ounce	50
Peanut butter, smooth, 2 tablespoons	50
Wheat bran, crude, 2 tablespoons	45
Black-eyed peas, cooked, ½ cup	45
Yogurt, plain, skim milk, 8 fluid ounces	45
Bran flakes, ½ cup	40
Vegetarian baked beans, ½ cup	40
Rice, brown, long-grained, cooked, ½ cup	40
Lentils, mature seeds, cooked, ½ cup	35
Avocado, California, ½ cup pureed	35
Kidney beans, canned, ½ cup	35
Pinto beans, cooked, ½ cup	35
Wheat germ, crude, 2 tablespoons	35
Chocolate milk, 1 cup	33
Banana, raw, 1 medium	30
Milk chocolate candy bar, 1.5 ounce bar	28
Milk, reduced fat (2%) or fat free, 1 cup	27
Bread, whole wheat, commercially prepared, 1 slice	25
Raisins, seedless, ½ cup packed	25
Whole milk, 1 cup	24
Chocolate pudding, 4-ounce ready-to-eat portion	24

More foods can be found at the following website (USDA website): [http://www.nal.usda.gov/fnic/cgi-bin/nut\\_search.pl](http://www.nal.usda.gov/fnic/cgi-bin/nut_search.pl).

lists several sources of magnesium (US Department of Agriculture, 2003; National Institutes of Health, Office of Dietary Supplements, 2005).

## Magnesium Deficiency

Though approximately 60% of adults in the United States do not consume the dietary reference intake for magnesium, the long-term effects of this low intake have not been adequately reported (Nielsen, 2010). In addition to lower dietary intakes of magnesium, magnesium deficiency may now be more common because of the increased incidence of the metabolic syndrome and type 2 diabetes mellitus, which increase magnesium excretion (or, perhaps, some of these chronic diseases may be a result of poor magnesium intake). “Marginal-to-moderate magnesium deficiency through exacerbating chronic inflammatory stress may be contributing significantly to the occurrence of chronic diseases such as atherosclerosis, hypertension, osteoporosis, diabetes mellitus, and cancer” (Nielsen, 2010).

In addition, many weight-loss diets do not provide the proper amount of micronutrients. Gardner *et al.* (2010) compared the micronutrient intake between overweight or obese women who had been randomly assigned to four popular diets that differed in their macronutrient distribution. They found that micronutrient intake decreased to inadequacy in a large proportion of the individuals in all the diets. Magnesium was one of the micronutrients found to be inadequate in intake. They suggested that there could be a “micronutrient advantage” to low-energy diets, which could positively affect health and weight loss.

Magnesium deficiency may be caused by excessive alcohol intake, certain medications (e.g. diuretics), malabsorption (typically resulting from short bowel syndrome, celiac disease [gluten-sensitive enteropathy], and Crohn’s disease), and/or inadequate intake of magnesium (Institute of Medicine, 1997). Loss of appetite, nausea, vomiting, fatigue, and weakness are early signs of magnesium deficiency. As magnesium deficiency worsens, such symptoms as numbness, tingling, muscle contractions and cramps, seizures, personality changes, and coronary spasms (angina pectoris) can emerge (Institute of Medicine, 1997; Rude, 1998).

Magnesium deficiency has been shown to lead to hypocalcemia, neuromuscular excitability, osteoporosis, diabetes mellitus, and cardiac complications, such as hypertension, dysrhythmias, angina pectoris, acute myocardial infar-

tion, and dyslipidemias (Gums, 2004; Shecter, 2010). Magnesium supplementation will reverse most of these conditions. Normen *et al.* (2005) assessed whether magnesium (and calcium and sulfate) would be absorbed from mineral water in subjects who had an ileostomy. The main purpose of conducting this randomized, controlled, crossover study was to assess if the mineral water would provide an alternative for individuals at risk for developing a deficiency due to low intakes. When compared with the control period, participants absorbed 30% more magnesium with the mineral water, with consumption during meals showing greater absorption (Normen *et al.*, 2005). Therefore, supplementation with magnesium in the form of mineral water appears to be a viable method of increasing intake and absorption.

## Effects of Deficiency

Severe hypomagnesaemia (<12.3 mg/dL) has been associated with increased mortality rates (41%) in patients admitted to a postoperative intensive care unit (ICU) compared with patients in ICU with normal serum magnesium concentrations (13%) (Chernow *et al.*, 1989). The authors concluded that low serum magnesium levels, though not a sensitive or precise predictor of patient survival, was frequent among postoperative ICU patients, and that patients with severe hypomagnesemia had more cases of hypokalemia (which can lead to dysrhythmias) and greater mortality rates than patients with comparable illnesses who had normal serum magnesium concentrations (Chernow *et al.*, 1989).

## Cardiovascular Disease

Magnesium may play a role in the management of acute myocardial infarction and atherosclerosis (Elin, 1994; Shecter, 2010). Because cardiovascular disease typically does not manifest itself until later in life, it is important that there is an improved understanding of ionized magnesium metabolism, which will lead to a better comprehension of the chronic changes in magnesium status that may be dormant (Elin, 1994). Rosenlund *et al.* (2005) did not find a protective effect against myocardial infarction in individuals who consumed drinking water that had higher levels of magnesium. Similarly, and more recently, Day *et al.* (2010) did not find positive effects of magnesium-supplemented spring water on cardiovascular risk markers in postmenopausal women, 50 to 70 years of age with a body mass index (BMI) of 20 to 35 kg/m<sup>2</sup>.

Conversely, Hashimoto *et al.* (2010) measured 728 participants from the general Japanese population, with a mean age of 67 years (68.4% were women), to determine the risk of serum magnesium levels and cardiovascular disease risk. They reported that low serum magnesium concentrations were related to risk of carotid artery alteration.

Mathers and Beckstrand (2009) reviewed randomized controlled trials and prospective studies for the safety of magnesium supplementation in individuals with coronary heart disease or risk of coronary heart disease. They did not find any adverse events from magnesium supplementation in any of the published research. They reported, based on published work, a modest association between a lower risk of coronary heart disease in men and increased magnesium intake, and thus suggest diets higher in magnesium as a possible method for lowering the risk of cardiovascular disease. Furthermore, Shecter (2010) states as follows:

there are theoretical potential benefits of magnesium supplementation as a cardioprotective agent in CAD [coronary artery disease] patients, as well as promising results from previous work in animal and humans. These studies are cost effective, easy to handle and are relatively free of adverse effects, which gives magnesium a role in treating CAD patients, especially high-risk groups such as CAD patients with heart failure, the elderly and hospitalized patients with hypomagnesemia. Furthermore, magnesium therapy is indicated in life-threatening ventricular arrhythmias such as Torsades de Pointes and intractable ventricular tachycardia.

As noted by Bobkowski *et al.* (2005), “Idiopathic mitral valve prolapse (IMVP) refers to the systolic displacement of one or both mitral leaflets into the left atrium, with or without mitral regurgitation.” IMVP is most commonly seen among young women and may be caused by latent tetany due to magnesium deficiency (as a result of either insufficient intake or excessive urinary loss). Galland *et al.* (1986) reported that latent tetany due to magnesium deficiency is seen in 85% of IMVP cases. Because normal plasma magnesium levels are not indicative of magnesium deficiency, Bobkowski *et al.* (2005) recommend that laboratory evaluation should include assessment of plasma, and erythrocyte and urinary magnesium concentrations, as well as blood and urinary markers of calcium. Furthermore, correction of the symptoms by the oral magnesium load test (5 mg of magnesium/kg/day) is indicative of the cause being magnesium deficiency. Finally, the authors state that

it is necessary to combine magnesium-sparing diuretics or physiological doses of vitamin D with oral magnesium supplementation to sustain the positive results (Bobkowski *et al.*, 2005).

### **Blood Pressure**

One of the recommendations from the Canadian Hypertension Education Program is to “follow a reduced fat, low cholesterol diet with an adequate intake of potassium, magnesium and calcium” (Khan *et al.*, 2005). It appears that diets high in calcium, magnesium, and potassium help to manage hypertension, though the results of epidemiological studies have provided stronger evidence for this (Ascherio *et al.*, 1992; Ma *et al.*, 1995) than magnesium supplementation trials (Sacks *et al.*, 1995; Yamamoto *et al.*, 1995). Nevertheless, as is often the case with nutritional studies, more than one nutrient may play a role. Appel *et al.* (1997) reported a significant reduction in blood pressure in non-hypertensive adults who increased their dietary intake of magnesium by approximately 247 mg/day through increased consumption of fruits and vegetables. These individuals also increased their potassium intake and calcium intake through non-fat dairy consumption (Appel *et al.*, 1997); both minerals positively influence blood pressure. More recently, the Dietary Approaches to Stop Hypertension (DASH) trial (essentially, a diet high in fruits, vegetables, and low-fat dairy, with reductions in fat and cholesterol intake), has led to significant reductions in hypertension (Chen *et al.*, 2010). Though magnesium cannot be singled out as the primary effect of the decrease in hypertension with the DASH diet, the increased intake of magnesium (and potassium) plays a role in decreasing hypertension. Furthermore, the DASH diet has been shown to decrease the risk of coronary heart disease (a decrease that has been reported over a 10-year period) (Chen *et al.*, 2010).

Research has shown that magnesium supplementation alone will decrease hypertension. In a 24-week, double-blind, placebo-controlled study by Baker *et al.* (2009), 50 patients with implantable cardioverter defibrillators, who also had hypertension, received either 504 mg of elemental magnesium per day (in the form of six tablets of magnesium L-lactate) or a placebo. They reported that 86% of the total sample had an intracellular magnesium deficiency at baseline. Systolic blood pressure was significantly lowered in patients who were supplemented with magnesium at 12 weeks and at 24 weeks. Additionally, intracellular magnesium levels were found to be a better indicator

of magnesium status compared with serum magnesium concentrations.

### **Diabetes Mellitus and the Metabolic Syndrome**

There is growing evidence that magnesium deficiency is related to diabetes mellitus and to the metabolic syndrome. Investigations have also shown the effectiveness of magnesium supplementation in reversing diabetes mellitus and the metabolic syndrome in individuals who are magnesium deficient (Guerrero-Romero and Rodríguez-Morán, 2006; Volpe, 2008; Guerrero *et al.*, 2009; Davì *et al.*, 2010).

Magnesium's effect on insulin sensitivity may be a result of insulin's regulation of the shift of magnesium from the extracellular to the intracellular space (Paolisso and Barbagallo, 1997). A sub-optimal magnesium concentration within the body, such as in a person with diabetes mellitus, may lead to malfunctioning tyrosine kinase activity at the insulin receptor level, leading to insulin resistance (Paolisso and Barbagallo, 1997).

Kirii *et al.* (2010) reported an inverse relationship between dietary intake of magnesium and age- and BMI-adjusted diabetes incidence in men and women 40 to 65 years of age. Evangelopoulos *et al.* (2008) reported a strong inverse association between serum magnesium concentrations and the metabolic syndrome. They also reported that, as serum magnesium levels decreased, the number of metabolic syndrome components increased. Furthermore, there was a relationship between serum magnesium concentrations and C-reactive protein levels, indicating the relationship between magnesium and inflammation, which could lead to the metabolic syndrome.

Afridi *et al.* (2008) evaluated the levels of potassium, calcium, magnesium, and sodium in blood, urine, and hair in individuals with hypertension and diabetes mellitus compared with those without hypertension who had diabetes mellitus. They found that individuals with diabetes mellitus who had hypertension and/or were normotensive had lower levels of potassium, calcium, and magnesium, but had higher levels of sodium compared with controls.

Guerrero-Romero *et al.* (2004) set out to establish whether oral magnesium supplementation would improve insulin sensitivity in individuals who had both insulin resistance (homeostasis model assessment of insulin resistance index [HOMA-IR] index >3.0) and hypomagnesemia, defined as serum magnesium concentrations <0.74 mmol/L (Guerrero-Romero and Rodríguez-Morán,

2002; Rodríguez-Morán and Guerrero-Romero, 2003). Participants were randomly assigned to receive either 2.5 g/day of magnesium chloride (12.5 mmol or 300 mg of magnesium) or a placebo. Individuals who were supplemented with magnesium significantly increased their serum magnesium concentrations compared with the control subjects. Individuals who were supplemented with magnesium also significantly reduced HOMA-IR index, with no change seen in the control subjects.

Prevention of type 2 diabetes mellitus is extremely important, but so is its treatment. Rodríguez-Morán and Guerrero-Romero (2003) evaluated whether oral magnesium supplementation (300 mg of magnesium) improved insulin sensitivity as well as metabolic control in individuals with both type 2 diabetes mellitus and decreased serum magnesium concentrations (<0.74 mmol/L). They studied 63 individuals who qualified for this 16-week, randomized, double-blind, placebo-controlled trial. At 16 weeks, those who received the magnesium supplementation had a significantly greater serum magnesium concentration than control subjects. Those who were supplemented also significantly improved insulin sensitivity and metabolic control, based on a lower HOMA-IR index, lower fasting blood glucose levels, and lower glycosylated hemoglobin concentrations compared with control subjects. These two prospective trials demonstrate that magnesium supplementation can be an effective agent in improving insulin sensitivity.

Diabetes mellitus can lead to long-term complications, such as angiopathy (cardiovascular disease), neuropathy (nerve damage), nephropathy (kidney disease), and retinopathy (retinal problems with the eye).

Because of the high rate of cardiovascular disease that occurs with diabetes mellitus, Soltani *et al.* (2005) examined whether oral magnesium administration would prevent vascular complications in rats with diabetes. The rats were separated into six groups: two groups received tap water for 8 weeks (control), two groups (made diabetic by injection of STZ) were treated with magnesium sulfate (10 g/L) added to the drinking water, and two groups (made diabetic by injection of STZ) received tap water only. Mean arterial blood pressure and mean perfusion pressure of the mesenteric vascular bed were significantly lower in the magnesium-treated rats than in the non-treated rats. The authors concluded that magnesium sulfate supplementation was effective in preventing vascular complications associated with diabetes mellitus (Soltani *et al.*, 2005).

### Body Mass Index

Though there is no direct association between magnesium and body mass index [BMI: weight (kg)/height (m<sup>2</sup>)], there may be a relationship between the two. Wang *et al.* (2005) assessed calcium, copper, iron, magnesium, potassium, sodium, and zinc concentrations in the hair samples of women 20 to 50 years of age ( $n = 392$ ). The women were separated into four groups based upon their BMI: BMI <18 kg/m<sup>2</sup>, BMI = 18 to 25 kg/m<sup>2</sup>, BMI = 26 to 35 kg/m<sup>2</sup>, and BMI >35 kg/m<sup>2</sup>. The group with a BMI <18 kg/m<sup>2</sup> had the highest ratios for calcium:magnesium, iron:copper, and zinc:copper, but the lowest ratio for potassium:sodium (Wang *et al.*, 2005). In contrast, the group with a BMI >35 kg/m<sup>2</sup> had the highest ratio for potassium:sodium, but the lowest for iron:copper and zinc:copper (Wang *et al.*, 2005). There were significant differences between groups in hair magnesium concentrations. More research is required to evaluate if there is a direct link between obesity and magnesium deficiency. However, magnesium deficiency is related to the inflammatory response (e.g. increased C-reactive protein), and obesity is characterized by low-grade inflammation, thus there may be a stronger relationship between obesity and magnesium deficiency than is currently known (Nielsen, 2010; Rayssiguier *et al.*, 2010).

### Osteoporosis

Osteoporosis is widespread chronic disease that results in 2 million fractures per year in the United States, costing more than \$17 billion in health care (Rude *et al.*, 2009). Women are more affected than men by osteoporosis, and have an average magnesium intake in their diets of only about 68% of the recommended intake (Rude *et al.*, 2009). Magnesium deficiency has been shown to be a risk factor for osteoporosis (Saito *et al.*, 2004; Stendig-Lindberg *et al.*, 2004). Stendig-Lindberg *et al.* (2004) reported a significant increase in radial bone mineral density in women after 750 mg/day of magnesium supplementation for 6 months, followed by 250 mg/day of magnesium for 18 months.

In more recent studies, Ohgitani *et al.* (2005) found a negative correlation between fingernail magnesium concentration and lumbar bone mineral density. Additionally, Day *et al.* (2010) did not find that magnesium-supplemented spring water improved biomarkers of bone in postmenopausal women.

None the less, there is a need for prospective clinical trials to elucidate the effects of magnesium intake (via

supplementation and/or increased dietary intake) on the prevention of osteoporosis in humans (Rude *et al.*, 2009). Mechanisms that may explain how magnesium deficiency may result in osteoporosis include impaired production of PTH and 1,25-dihydroxyvitamin D<sub>3</sub>; and a compound P-stimulated release of inflammatory cytokines (Rude *et al.*, 2009).

### Calcium Stones

One of the effects of magnesium deficiency is hypocalcemia, which can then lead to calcium urolithiasis (calcium stones).

Magnesium has been shown to reduce calcium oxalate crystallization in human urine (Massey, 2005).

Johansson *et al.* (1980) reported that, in 56 individuals given magnesium hydroxide, 45 were free of recurrences of new calcium stones, and those who did have recurrences only had 0.03 stones per year during a 2-year follow-up period, compared with 0.8 stones per year prior to the magnesium treatment. Of the 34 individuals who had no prophylactic magnesium therapy, 15 had experienced calcium stones after 2 years.

Conversely, in a retrospective study of 7000 patients suffering from calcium oxalate stones, Schwartz *et al.* (2001) reported that calcium stone formation was slightly, but not significantly, increased in patients with hypomagnesuria. They stated that:

The beneficial effects of urinary magnesium on stone formation may be less than previously reported. The role of oral magnesium supplementation and the subsequent increase in urinary magnesium in calcium urinary stone formation remains unknown . . . If magnesium has a protective effect, it may work through pathways that enhance citrate excretion.

Massey (2005) reported that clinical-trial evidence does not support the use of magnesium oxide or magnesium hydroxide as an exclusive therapy for calcium oxalate stones; however, when magnesium is added to potassium citrate therapy, there are better outcomes.

### Magnesium Supplementation

Magnesium supplementation may be required in specific conditions that may decrease magnesium absorption, or result in excessive loss (Ladefoged *et al.*, 1996; Kelepouris and Agus, 1998; Vormann, 2003). As previously discussed, some medications may result in magnesium deficiency,

such as some diuretics, antibiotics, and anti-cancer medications (Ramsey *et al.*, 1994; Lajer and Daugaard, 1999). Some examples of these medications are the diuretics Lasix, Bumex, Edecrin, and hydrochlorothiazide; antibiotics, e.g. gentamicin, amphotericin, and cyclosporin; and anti-cancer medication (cisplatin).

Hypomagnesemia occurs in approximately 30–60% of individuals with alcoholism (Abbott *et al.*, 1994; Elisaf *et al.*, 1998). Low serum magnesium concentrations occur in about 90% of individuals who are going through withdrawal from alcohol (Abbott *et al.*, 1994; Elisaf *et al.*, 1998).

Those with Crohn's disease, gluten-sensitive enteropathy (celiac disease) or regional enteritis, or who have had intestinal surgery, or have other chronic malabsorptive problems may lose magnesium through diarrhea and fat malabsorption (Rude and Olerich, 1996). These individuals may be candidates for magnesium supplementation.

It has been shown that individuals who have poorly managed diabetes mellitus may require supplementation. This is due to the fact that they have increased urinary magnesium excretion coupled with hyperglycemia (Volpe, 2008).

As previously stated, magnesium interacts with calcium and potassium. Therefore, persons with persistently low blood calcium and potassium concentrations may actually have a fundamental problem with magnesium deficiency. Supplements with magnesium may help to alleviate the calcium and potassium deficiencies.

There is emerging evidence that individuals with mild to moderate asthma may benefit from oral magnesium supplementation (Kazaks *et al.*, 2010). In a 6.5-month randomized, placebo-controlled trial (340 mg of magnesium per day versus a placebo), individuals who were supplemented with magnesium had improved objective measures of bronchial reactivity and improved subjective measures of asthma management and quality of life.

Another group of individuals who may require magnesium supplementation comprises older adults. The National Health and Nutrition Examination Surveys (NHANES, both 1999 to 2000 and 1998 to 1994) have shown that older individuals have lower dietary magnesium intakes than do younger individuals (Bialostosky *et al.*, 2002; Ford and Mokdad, 2003). Furthermore, older individuals have a greater rate of renal magnesium excretion and a lower rate of intestinal magnesium absorption, exacerbating the problem of a low intake (Institute of

Medicine, 1997). Many older adults are on multiple medications, possibly leading to a drug–magnesium interaction, further aggravating the decreased intake and absorption and increased renal excretion (Institute of Medicine, 1997).

## Effects of Magnesium Excess

Magnesium intake from food substances has not been shown to be harmful; however, magnesium intake from excess supplement intakes has been shown to be harmful (Institute of Medicine, 1997). A UL for magnesium has been established by the Institute of Medicine (1997) (Table 30.2).

The main initial effect of excess magnesium intake is diarrhea; magnesium is known for its cathartic effect (Rude and Singer, 1980; Fine *et al.*, 1991). Nausea and abdominal cramping may also occur (Ricci *et al.*, 1991).

High serum magnesium concentrations can result in renal failure, which is typically accompanied by high intakes of non-food sources of magnesium (Randall *et al.*, 1964; Mordes and Wacker, 1978). For example, high doses of magnesium-containing laxatives and antacids have been shown to cause toxicity (Xing and Soffer, 2001).

Signs of excess magnesium can be similar to magnesium deficiency and include changes in mental status, nausea, diarrhea, appetite loss, muscle weakness, difficulty breathing, extremely low blood pressure, and irregular heartbeat (Ho *et al.*, 1995; Nordt *et al.*, 1996; Whang, 1997; Jaing *et al.*, 2002).

## Methods for Assessing Magnesium Status in Individuals

Serum magnesium is perhaps the most common and straightforward method of assessing magnesium status. An atomic absorption spectrophotometer is used to evaluate magnesium concentration. A serum magnesium concentration of <1.8 mg/dL is indicative of magnesium depletion (Elin, 1987). However, Elin (2010) states:

The traditional method to establish a reference interval for the SMC [serum magnesium concentration] is flawed by the large number of “normal” individuals who have a subtle chronic negative magnesium balance due to a significant decrease in magnesium intake over the past century. Evidence-based medicine should be used to establish the appropriate lower limit of the reference interval for health and I recommend 0.85 mmol/L based on current literature.

The decrease in magnesium in the diet has led to chronic latent magnesium deficiency in a large number of people since their SMC is still within the reference interval due to primarily the bone magnesium supplementing the SMC. These individuals need adjustment of their diet or magnesium supplementation to achieve a normal magnesium status for health.

Nevertheless, plasma ionized magnesium may be a better method of assessing magnesium status (Institute of Medicine, 1997). Other techniques to assess magnesium status include: clinical evaluation, blood mononuclear cells, magnesium excretion, intracellular magnesium assessment, red blood cell magnesium concentration determined by nuclear magnetic resonance, magnesium balance studies, magnesium tolerance test, and epidemiological studies and meta-analysis (Institute of Medicine, 1997). The magnesium tolerance test has been used for a number of years, and is considered the “gold standard” for assessing magnesium status in adults but not in infants and children (Institute of Medicine, 1997). In the magnesium tolerance test, the renal excretion of magnesium is assessed and is based on magnesium that has been supplied through a parenteral route (Institute of Medicine, 1997). Although the magnesium tolerance test may be a good indicator of hypomagnesemia, it does not appear to be sensitive enough to sense changes in magnesium status in healthy individuals who have been given magnesium supplementation (Institute of Medicine, 1997).

Approximately 99% of the body’s magnesium is intracellular; thus, assessment of intracellular ionized magnesium is physiologically appropriate (Malon *et al.*, 2004). These authors examined ionized magnesium in erythrocytes to establish reliable methodology in the evaluation of functional magnesium status. Malon *et al.* also assessed ionized magnesium and total serum magnesium (by atomic absorption spectrometry). The measurements were conducted in critically ill postoperative patients. The authors reported hypomagnesemia in 15.9% of the patients using total serum magnesium, compared with 22.2% using ionized magnesium, and 36.5% using ionized magnesium in erythrocytes. Malon *et al.* concluded that ionized magnesium in erythrocytes may be the best method to detect hypo- or hypermagnesemia.

## Future Directions

Given magnesium’s role in many reactions in the body, there are a number of research areas that could be pursued,

especially those that may help to prevent disease. It is clear that magnesium may improve insulin resistance, but what is the mechanism behind its action? Many scientists connect the mechanism to magnesium’s role with tyrosine kinase and in the inflammatory response. Basic scientific research needs to be conducted to ascertain the mechanisms involved. In addition, longitudinal studies in humans are required to evaluate the levels of magnesium necessary to prevent chronic disease. These need to be followed by magnesium supplementation studies to evaluate the effectiveness of supplementation on the prevention of disease, and the effects it may have on exercise performance.

### Summary

Although some limitations exist in interpreting earlier studies, most experts today commonly recommend decreasing the intake of sodium chloride (salt) while increasing that of potassium because these maneuvers could save lives and reduce health costs. Sodium is an essential mineral vital in the balance of bodily fluids, i.e. the amount of bodily sodium is directly correlated with fluid volume. Most people in the Western world ingest more sodium chloride than generally recommended, which can result in volume expansion, edema, and elevated blood pressure. In general, the INTERMAP study corroborated the findings of INTERSALT and most other epidemiological studies in finding higher sodium intakes associated with higher blood pressure leading to many cardiovascular perturbations. In contrast, too small a circulating volume emanating from low sodium ingestion can cause symptoms and signs ranging from tiredness and low blood pressure to outright disorientation and shock. In contrast to sodium, ingestion of adequate amounts of potassium is associated with lower blood pressures and better cardiovascular performance. Circulating potassium enters all tissues and has profound effects on the function of some organs, primarily depolarization and contraction of the heart. Too much potassium ingestion in the face of renal perturbations can lead to potassium overload and serious cardiovascular complications.

### Introduction

#### *Life and the Ancient Seas*

Many scientists assume that the existence of ancient seas on Earth were essential for development of life (Follman and Brownson, 2009). Life is estimated to have begun 2 billion years ago in the Pre-Cambrian seas, which provided mobility, dissolved substances such as sodium, potassium, and chloride, and stable physico-chemical conditions (Conway, 1942, 1947; Smith, 1943; Elkinton and

Danowsky, 1955; Battarbee and Meneely, 1978). The presence of seas on Earth is unique in the solar system (Encrenaz, 2008). No other planet possesses surface liquid water to the extent to which it occurs on Earth: >70% of its surface. The minute amount of water present elsewhere in the solar system exists as ice (Encrenaz, 2008).

Although life probably started in the sea billions of years ago, terrestrial forms are believed to have emerged only 360 million years ago (Battarbee and Meneely, 1978). Strengthening the contention that life began in seas is

knowledge that terrestrial life forms had to retain their own internal sea in the form of extracellular and intracellular body fluids containing electrolytes in order to live on land (Smith, 1953; Elkinton and Danowski, 1955). Man probably came upon the scene 2 million years ago (Pitts, 1974).

The proportions of sodium, chloride, and potassium in ancient seas have been closely linked with life. Table 31.1 compares estimated concentrations of many constituents in seawater during various geological periods with that of human plasma and muscle water (Conway, 1947; Smith, 1953; Elkinton and Danowski, 1955). It is interesting to speculate on whether life could have evolved from ancient seas had they possessed the current distributions of electrolytes, which have changed significantly with time. Over many centuries, the concentrations of sodium and chloride have steadily increased, whereas that of potassium has decreased.

An interesting hypothesis concerning the evolution of life is based upon knowledge that potassium content in the Pre-Cambrian seas was much higher with respect to sodium than now. Many relate this observation to the high potassium concentrations within cells. Later, with emergence of life from seas having higher sodium content, this became the basis for the high levels of sodium in extracellular fluid (Macallum, 1926). Regardless of whether these suppositions are real, cells in the body could survive, grow, and function only by retaining a friendly environment via tight regulation of an internal sea.

### **Maintaining the Sea Within**

Kidneys played a major role in the emergence of terrestrial life. Homer Smith (1943, 1953) and later Robert Pitts (1974) discussed the crucial role of kidneys in regulating ions and fluid in the body that allowed vertebrates to leave the sea. The renal regulation of sodium, chloride, and potassium in body spaces is especially crucial because the presence of these cations and anions dictates the size of the body fluid compartments via effects on osmolality, and they play a significant role in acid–base balance. A major difference between plasma and the past and current seas is the presence of proteins in the former. Proteins occupy ~6% of the blood plasma volume. Healthy kidneys protect the circulating concentrations of proteins by preventing renal losses.

In addition to renal regulation, oral intake of these micronutrients is also of paramount importance (Dahl, 1958). Dietary intake has changed over the years, and these changes play a prominent role in the overall health of numerous modern countries. Nutritional intake can strongly influence development of many prevalent current health perturbations (Suter *et al.*, 2002; Hooper *et al.*, 2003). With the emergence of the modern Western diet, cardiovascular and metabolic disorders have become relatively more common (Suter *et al.*, 2002; Hooper *et al.*, 2003). Cardiovascular diseases (CVD) account for approximately 50% of mortality beyond age 65 (Kotchen and Kotchen, 2003). Cordain *et al.* (2005) noted seven crucial areas in modern diets that may relate to the prevalence of

modern diseases. Prominent among the listings is the sodium–potassium ratio.

### **Problems with the Modern Western Diet**

Diets from earlier times and those from primitive areas of the world today compared with the modern Western diet contain(ed) higher proportions of potassium relative to sodium (Frassetto *et al.*, 2001). This reversal of potassium and sodium concentrations in the food supply may play a significant role in the development of many chronic diseases (Frassetto *et al.*, 2001; Cordain *et al.*, 2005; Brown *et al.*, 2009). Too much sodium consumption has the proclivity to raise blood pressure and create cardiovascular perturbations (Brown *et al.*, 2009). Differently put, Americans consume too little potassium, roughly one-half the recommended adequate intake. In contrast to sodium, potassium tends to benefit the cardiovascular system (Frassetto *et al.*, 2001). Frassetto *et al.* (2009) compared effects of changing from the modern diet to a Paleolithic one containing more potassium and fiber (Cordain, 2002). The Paleolithic diet includes lean meat, fruits, vegetables, and nuts, and excludes cereal grains, dairy, and legumes. Even short-term consumption (10 days) of a Paleolithic diet relative to the modern diet improved blood pressure and glucose tolerance, decreased insulin secretion, increased insulin sensitivity, and improved lipid profiles (Frassetto *et al.*, 2009).

### **General Lifestyle Recommendations Today**

Although some limitations exist in interpreting earlier studies (Lackland and Egan, 2007), lowering sodium intake and raising potassium intake is commonly recommended by most experts (Appel, 2009b). Modest reduction of salt intake could save lives and reduce health costs (Asaria *et al.*, 2007; Bibbins-Domingo, 2010). To strengthen the reasoning behind consuming less sodium and more potassium, these two cations will be discussed in detail separately.

## **Sodium**

### **Generalizations about Sodium and Salt**

To gain better understanding of sodium balance, it is necessary to differentiate between sodium and salt (sodium chloride). Sodium is an essential mineral (micronutrient) vital in the balance of body fluids. Dietary sodium is usually measured in grams, and sometimes in milliequivalents or millimoles. The most common source of dietary

sodium is table salt, sodium chloride. Because table salt is only 40% sodium, the remaining 60% being chloride, it is necessary to discern whether any reference to mass is discussing grams of sodium or salt. In the US, one teaspoonful of table salt contains 5.75 g of salt, equivalent to 2.3 g of sodium. A realistic average daily intake of salt by the general public in the United States today is roughly  $6.0 \text{ g} \pm 1.0$  (SEM) – close to a US teaspoonful – providing about  $2.4 \text{ g} \pm 0.4$  (SEM) of sodium.

Most people living in the Western world ingest more sodium than generally recommended and thus face consequences of an overload. For adolescents and adults of all ages (14 years and older), the Institute of Medicine (IOM) set the tolerable upper intake level (UL) at 2300 mg per day. The UL is the highest daily nutrient intake level that is likely to pose no risk of adverse health effects, for example, for sodium, increased blood pressure for almost all individuals in the general population. The IOM recognized that the association between sodium intake and blood pressure was continuous and without a threshold (i.e. a level below which the association no longer exists). The UL was based on several trials, including data from the Dietary Approaches to Stop Hypertension (DASH) sodium trial. The IOM noted that, in the DASH-sodium trial, blood pressure was lowered when target sodium intake was reduced to 2300 mg per day, and lowered even further when sodium was targeted to the level of 1200 mg/day (IOM, 2005). The United Kingdom recommended nutritional intake (RNI) advocates an upper limit of 1.6 g (<http://wikipedia.org/wiki/Salt>). The National Research Council of the National Academy of Sciences suggests a daily range of 1.1 to 3.3 g for adult intake. The American Heart Association recommends that intake of 2.3 g per day not be exceeded. It is wise to individualize recommendations to certain groups of individuals. People with hypertension as suggested above, African-Americans, and older adults tend to have a greater blood-pressure response to sodium challenge and should be advised appropriately. Many believe that an average daily intake should not exceed 1.5 g of sodium in individuals with hypertension.

In contrast to sodium overload, sodium deficiency is less common for it is hard to exclude salt from the modern diet, and normal kidneys are primed to prevent excessive losses in the urine. Table 31.2 lists the sodium content of some common foods. Harmful losses may nevertheless occur due to excess sweating during heavy exertion and/or may be associated with high external temperatures and

**TABLE 31.2** Approximate values for sodium content in some common foods<sup>a</sup>

Foodstuff	Sodium	
	(mmol)	(mg)
Apple, raw, with skin (1 apple, 138 g)	0.04	1
Flounder/sole species, cooked, dry heat (3 oz, 85 g)	3.9	89
Banana, raw (1 cup, 150 g)	0.09	2
Beer, regular (12 oz, 355 g)	0.6	14
Bread, commercially prepared, white (1 slice, 25 g)	7.4	170
Cocoa, unsweetened powder (1 tbsp, 5.4 g)	0.04	1
Cocoa mix, powder (3 heaping tsp, 28.35 g)	6.2	143
Corn flakes (1 cup, 28 g)	8.8	202
Egg, scrambled (1 large, 61 g)	7.4	171
Lemon meringue pie, prepared (1 piece, 113 g)	7.2	165
Pancake, fast-food butter/syrup (2 pancakes, 232 g)	48	1104
Pizza, fast-food pepperoni (1 slice, 106 g)	29.1	670
Red wine (3.5 oz, 103 g)	0.17	4
Spaghetti, cooked, enriched, no salt (1 cup, 140 g)	0.04	1
Tuna, canned in oil, drained solids (3 oz, 85 g)	13.1	301

<sup>a</sup>Based on USDA National Nutrient Database for Standard Reference, Release 22, 2009.

require replacement (Sawka *et al.*, 2007). Too severe restriction of dietary sodium can also lead to harmful body depletion (Dahl *et al.*, 1955). Physicians treating renal patients with hypertension and congestive heart failure by reducing the body content of sodium via reduced intake and/or diuresis are not infrequently surprised by an elevation of blood urea (BUN), indicating too much removal. This may be a sign of too little blood flow to the kidneys and suggests that other organs are being poorly perfused as well. Subjective signs of sodium deficiency include thirst, nausea, weakness, fatigue, disorientation, and cramps.

### Composition of Sodium and Chloride in the Body

The total body sodium of a normal adult averages ~60 mmol/kg body weight (Pitts, 1959). For the typical 70-kg person this is approximately 4200 mmol – almost 100 g of sodium as depicted in Figure 31.1, top. Bone contains roughly 1680 mmol, that is, about 40% of the total body sodium. Approximately 2520 mmol of the remaining sodium resides in the extracellular and intracellular fluid. In addition to that in bone, roughly 50% of total sodium is extracellular and 10% is intracellular.

Sodium stores can be classified as exchangeable and non-exchangeable (Pitts, 1959). Via measurements using radioactive isotopes, exchangeable sodium has been estimated at 42 mmol/kg body weight (Figure 31.1, bottom).

Sodium compartments in an average 70-kg man

Exchangeable sodium compartments in an average 70-kg man

**FIG. 31.1** Sodium compartments. ECF, Extracellular fluid; ICF, intracellular fluid.

Exchangeable sodium consists of all extracellular sodium, all intracellular sodium, and less than half the bone sodium. Essentially all non-exchangeable sodium is in bone, where it is buried within the bone structure. Exchangeable sodium is important because, when sodium is lost from the blood plasma into the urine or feces, it can be replaced rapidly from other compartments via diffusion. In turn,

sodium retained in edema is also spread out among these various compartments.

Total body chloride averages 33 mmol/kg body weight – that is, a 70-kg person has 2310 mmol chloride (Pitts, 1959). The majority of the chloride, ~70%, is distributed in the extracellular fluid. Much of the remaining chloride is localized in the collagen of connective tissue and is largely exchangeable.

### **Sodium Homeostasis**

Over 40 years ago Dahl (1958) remarked, “Widespread use of salt has received little attention from nutritionists.” This certainly is not the case today. It is now generally recognized that a substance in such common use as salt might be noxious when consumed in amounts determined by dietary customs and tastes. It is further recognized that potential adverse effects from salt consumption are also influenced by genetic factors and the simultaneous intake of other nutrients, such as potassium, magnesium, and calcium (Nurminen *et al.*, 1998).

As indicated above, the amount of sodium consumed (intake) must equal the amount of sodium lost (output) to maintain balance. Calculating intake is fairly simple. Sodium essentially is absorbed completely in the small intestine. Therefore, if 4 g sodium is ingested, 4 g is delivered to the body. Salt intake can be influenced by salt appetite, and the brain renin–angiotensin system is important in this respect. We know this because intracerebral injection of angiotensin II stimulates salt appetite whereas blocking formation of angiotensin II via central administration of captopril diminishes salt appetite (Fitzsimmons, 1980). Thirst also plays a significant role in the regulation of volume and body space size. Changes in osmolality related to sodium and chloride homeostasis influence the thirst mechanism and the release of vasopressin, which affects the handling of water in the renal collecting duct (Robertson, 1987).

In contrast to calculating input, calculating output can be difficult because a number of routes must be considered in the estimate. Normal losses of sodium occur through the skin, feces, and urine. In the absence of considerable physical effort or heat stress, only small amounts are lost via the skin, mainly by sweating with lesser losses through skin sloughing. In subjects who were ambulatory but not actively working or sweating, daily consumption of 100–150 mg sodium led to average daily losses of <25 mg sodium. The investigators attributed this small loss to desquamation of epithelial cells, sebaceous secretions,

unnoticed sweat, and possibly some insensible perspiration (Dahl *et al.*, 1955). Changing production of salt-retaining hormones such as aldosterone can regulate losses of sodium in sweat. Conn (1949) demonstrated that healthy individuals sweating as much as 5–9 L/day could decrease sodium concentrations in sweat to as little as 0.1 g/L after acclimatization. Under normal conditions, skin losses are small but substantial amounts of sodium can be removed through excess sweating.

Loss of sodium via feces is small even when sodium intake is high (Baldwin *et al.*, 1960). On a daily sodium intake ranging widely from 0.05 to 4.1 g/day, only 10–125 mg appeared in stools (Dole *et al.*, 1950). Cases of severe diarrhea may result in substantial losses. Potential losses via hair, nails, saliva, semen, and menstruation are too negligible in the overall picture to be considered.

It is safe to state that more than 90% of sodium output is via the kidneys. When sodium intake is acutely reduced to an extremely low value, urinary sodium excretion falls exponentially over 4–5 days; increased sodium intake above a certain level results in the excretion of an increased amount after a few days (Strauss *et al.*, 1958). The intake of sodium is accurately estimated by the amount present in urine in the absence of gross sweating. Pragmatically, the small amounts in the sweat and feces can be ignored in the overall calculations of balance, because the amount of sodium in the modern Western diet is relatively large.

The overall control of body sodium homeostasis via the interplay of various factors on the kidneys is incompletely understood. Both intrarenal and extrarenal factors are involved. Associated with sodium homeostasis, extrarenal mechanisms working interdependently are plasma renin activity (Laragh *et al.*, 1972); plasma angiotensin II (Brown *et al.*, 1972); aldosterone production (Brown *et al.*, 1972); atrial natriuretic peptide (Sagnella, 1987); catecholamines such as adrenaline, noradrenaline, and dopamine (Romoff *et al.*, 1979); hormones such as vasoactive intestinal peptide (Duggan and Macdonald, 1987); and possible Na<sup>+</sup>,K<sup>+</sup>-ATPase inhibitors (deWardener and MacGregor, 1983; Blaustein, 1985).

To re-emphasize, the major control for sodium output is via renal excretion. In Figure 31.2 we depict an example of what generally happens when sodium intake suddenly increases. In our example, the usual daily dose of 4 g sodium is balanced by 4 g excreted (day 0). The body is in so-called homeostasis, since output matches input. On day 1, intake is doubled to 8 g, and the increased intake

**FIG. 31.2** Results of increasing dietary sodium intake. Daily sodium intake doubled from 4g to 8g on day 1. Sodium excretion initially does not equal the higher intake but over 3–4 days once more equals intake, never to exceed it. See body of text for more detailed explanation.

is continued over the ensuing period of time. On day 1, excretion rises more than the previous day when intake was less but falls short of actual intake that day. On days 2 and 3, sodium excretion continues to rise with the higher sodium challenge and eventually matches the daily intake. We are in balance with the increased intake as mentioned previously but at what cost? The crucial point here is that excretion does not exceed intake to overcome the earlier retention. Accordingly, it is apparent from the depiction that sodium consumed earlier is retained such that total body sodium has risen a percentage point or two. This in turn leads to a similar rise in the extracellular fluid volume. On the doubled sodium intake, we have once again reached a homeostatic point where output matches input but with a higher total body sodium and balance. Most physicians believe that this can be harmful over the long run and must be removed by lessening intake or increasing sodium excretion, perhaps via the use of diuretics. The lesson to be learned here is that cutting down intake of sodium should lead to lower total body

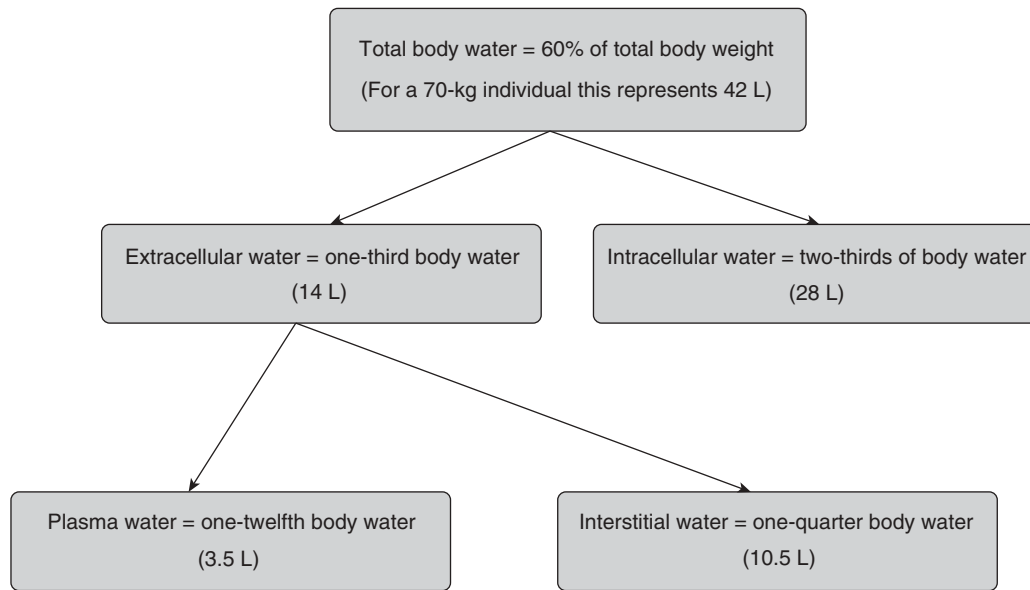

sodium, less fluid volume, and in general a healthier status – especially in terms of blood pressure and the cardiovascular system.

### **Maintenance of Body Fluid Compartments**

The total body water content of an individual varies roughly between 45% and 70% of body weight, a range of 50–60% being most representative of normal adults (Pitts, 1959, 1974). Infants have proportionately more water, whereas the elderly have less. Females have proportionately less water than do males. As illustrated in Figure 31.3, body water is divided into extracellular and intracellular compartments: one-third extracellular and two-thirds intracellular. The extracellular compartment is further divided into plasma and interstitial fluid. The latter is roughly three times larger than the former, that is, one-twelfth and one-quarter of the total body water.

Sodium and chloride, being the most important electrolytes of the extracellular compartment, determine the extracellular volume to a great extent. Circulating proteins also influence the relationship between the plasma and interstitial fluid volumes. The endothelium of the capillaries allows rapid distribution of diffusible ions and water but restricts the passage of protein between the plasma and interstitial fluid. Interstitial fluid, therefore, is an ultrafiltrate of plasma. Because of the virtual absence of protein with its negative charge on one side of the capillary wall (1% vs. 6%), diffusible ions distribute themselves according to the Gibbs–Donnan rule, i.e. more anions such as chloride and bicarbonate will be on the relatively protein-free side of the membrane (interstitial space) (Pitts, 1974). Nevertheless, the sum of the cations and anions must be equal on each side of the membrane. The presence of the non-penetrable protein also causes a slight increase in oncotic pressure on the plasma side that is balanced by the hydrostatic pressure developed by the heart. Sodium is maintained in the extracellular compartment and potassium in the intracellular compartment mainly through the actions of the  $\text{Na}^+, \text{K}^+$ -ATPase exchange pump. Accordingly, sodium is the major cation in the extracellular fluid and the major osmotic particle outside the borders of the cell, whereas potassium is concentrated within the cells.

In the above discussion, sodium and chloride have been considered together. Total amounts of both sodium and chloride determine the size of the extracellular space. Restriction of dietary chloride without restriction of sodium prevents expansion whereas it is well recognized

**FIG. 31.3** Body fluid compartments. Total body water is broken down into extracellular and intracellular compartments. The extracellular water is broken down further into plasma and interstitial water.

that administration of sodium coupled to other anions such as bicarbonate has a negligible effect on expansion of the extracellular body space (Kotchen, 2005). The average concentration of sodium, estimated via specific electrodes or flame photometry, is 135–145 mmol/L, and of chloride, estimated by titration and specific electrodes, is 98–108 mmol/L. Because of various forces maintaining high sodium concentration in the extracellular fluid, infusions of normal saline result predominantly in expansion of the extracellular space. Infusions of dextrose solutions result in the fluid distribution between intracellular and extracellular water compartments.

### **Clinical Conditions Associated with Sodium Perturbations**

Edema, the accumulation of excess fluid in the body, can lead to symptoms such as swelling of a part or all of the body (Michelis and Rakowski, 1988). Accumulation of fluid in the lungs leads to difficulty in breathing. Causes of generalized edema are listed in Box 31.1: the major causes relate to cardiac, renal, or hepatic perturbations. Sodium chloride retention may indicate a physiological response of the kidneys to what is perceived as inadequate arterial blood volume or may reflect an abnormal renal response to internal damage or hormonal imbalances. In

### **BOX 31.1 Causes of generalized edema**

- Cardiac

  - Nonsteroidal anti-inflammatory drugs
  - Chlorpropamide
  - Tolbutamide
  - Hormones
- Protein malnutrition
- Idiopathic edema

addition to treating the major cause of the edema, the excess fluid is often treated by limiting the intake of salt and/or removing excess sodium by using diuretics (Ellison, 1994). Too small a circulating volume can cause symptoms

and signs ranging from tiredness and low blood pressure to outright disorientation and shock. Judicious replacement of salt and water often overcomes this status. Protein malnutrition may cause edema in a number of poor countries and can be overcome by including more protein in the diet.

The subject of hyponatremia (low serum sodium) and hypernatremia (high serum sodium) (Michaelis and Davis, 1988) is beyond the scope of this chapter. Suffice it to say that hyponatremia can be associated with an excess of total body sodium as well as with an excess of water, because the overall water volume is important in the disturbance. Thus, a patient with hyponatremia may not be depleted of body sodium but instead may have an excess of intravascular water (e.g. if an increase in water volume exceeds an increase in sodium, hyponatremia will develop despite the increase in total body sodium) (DeVita and Michaelis, 1993). Similarly, hypernatremia can occur in the face of low or normal body sodium if dehydration (i.e. water depletion) is present. In hospitalized patients the prevalence of hyponatremia (defined as sodium concentration  $<135$  mmol/L) is commonly as high as 15–22%, but more severe dilutions of  $<130$  mmol/L are seen in only 1–4% of patients (Verbalis, 1998). Symptoms may vary depending on the acuteness of the hyponatremia; slow decreases in sodium (nausea, lassitude, muscle cramps) are usually less severe than rapid decreases (confusion, coma, convulsions).

## **Sodium and Hypertension**

### **Historical Perspective**

Many observations and clinical studies over the past century implicate salt (sodium and chloride) intake in hypertension (Haddy and Pamnani, 1995). Around 1900, French workers proposed that hypertension arose from failure of kidneys to adapt to excess dietary salt (Ambard and Bedaujard, 1904). In support, Allen (1925) showed that severe restriction of dietary salt in many hypertensive patients reduced blood pressure, which he believed was due to an unknown renal defect in sodium excretion. The beneficial effects of the famous Kempner rice diet, an early low-sodium diet prescribed by many physicians, were attributed to low sodium content (Kempner, 1948). Hypertension in the elderly and blacks is generally characterized by low plasma renin activity, suggesting volume expansion and less sodium excretion when challenged with this cation (Haddy and Pamnani, 1995). Furthermore, the elevated blood pressure of blacks responds especially well

to treatment with diuretics (Fries, 1979). However, studies limited to industrialized societies have not always found a conclusive relationship between blood pressure and sodium excretion (Pickering, 1980; INTERSALT Cooperative Group, 1988).

What is known about the genetic component of sodium-induced hypertension? Laboratory studies provide evidence that Allen (1925) could be correct – that a genetic component works through kidneys. Dahl *et al.* (1962) developed two rat substrains, one exquisitely sensitive to salt and one very resistant, and showed that the expression of the genetic defect in salt-sensitive rats was in the kidneys. The salt-resistant rats were nephrectomized and then received kidneys from the salt-sensitive rats; hypertension developed when these rats ate high-salt diets (4–8% by weight). In contrast, nephrectomized salt-sensitive rats receiving kidneys from salt-resistant rats did not develop hypertension while eating high-salt diets. Experiments using isolated kidneys from the salt-sensitive rats confirmed an intrinsic renal defect that allows less sodium excretion compared with the salt-resistant rats at comparable inflow pressures (Tobian *et al.*, 1979). Tobian *et al.* (1979) also reported that thiazide diuretics overcame hypertension in the salt-sensitive rats.

### **Salt Sensitivity**

As mentioned previously, not all studies have found a close relationship between salt and hypertension (Pickering, 1980). A plausible explanation for the difficulty in associating sodium consumption with blood pressure may be that the connection pertains only to those individuals that are “salt sensitive.” Some individuals can eat large amounts of sodium without affecting blood pressure markedly, because they excrete excess sodium adequately. However, more than half of those with hypertension have a marked increase in blood pressure in response to a sodium challenge (Sullivan, 1991). These individuals tend to retain the sodium, because they excrete the sodium load more slowly. Normotensive relatives of hypertensive subjects, especially older individuals, show a blunted natriuretic effect. Supporting the contention that sodium retention is important in the pathogenesis of hypertension is that those individuals on a modern, Western diet have an extracellular fluid volume 15% greater than those on a more primitive diet who exhibit less hypertension (Haddy and Overbeck, 1976).

Many believe that blood pressure rises to compensate for sodium and water retention, because elevated blood

pressure allows the kidney to excrete more sodium and water to maintain balance (Guyton *et al.*, 1972). In general, more blacks than whites have difficulty handling a sodium challenge, and hypertension is more prevalent in the black population, suggesting genetic predisposition. Inappropriate renal sodium handling can occur via many initiating causes: e.g. inheritance of inborn renal transport defects, presence of circulating factors influencing renal reabsorption, or decreasing renal mass. Other factors associated with salt sensitivity include female gender, aging, obesity, insulin resistance, and a positive history of hypertension (Suter *et al.*, 2002).

Perhaps the greatest ability of salt intake to elevate blood pressure occurs in those individuals said to have “resistant hypertension” (Appel, 2009a; Pimenta *et al.*, 2009). Resistant hypertension is defined as being present in patients with uncontrolled blood pressure despite therapeutic use of three or more medications generally accepted as being beneficial for pressure reduction (Pimenta *et al.*, 2009). Blood pressure of two different groups of patients with resistant hypertension were examined: one on low sodium (1.2 g per day), the other on high (5.7 g per day). Comparing blood pressures, the lower-level group showed a reduced average systolic blood pressure of 22.7 mm Hg and a diastolic of 9.1 mm Hg compared with the high-level group.

### **INTERSALT and INTERMAP**

Two large epidemiological studies examined the role of salt in hypertension. These have been labeled INTERSALT and INTERMAP (INTERSALT Cooperative Research Group, 1988; Dennis *et al.*, 2003). In the INTERSALT study, sodium excretion data from 52 centers throughout the world were examined (INTERSALT Cooperative Research Group, 1988). The ranges of intake, adjusted for body mass index and alcohol intake, were roughly from 50 to 250 mmol (1.2 to 5.8 g) sodium over 24 hours. The INTERSALT Cooperative Research Group reported that the prevalence of hypertension was 1.7% in non-obese subjects consuming a low-sodium diet compared with 11.9% for non-obese subjects consuming a high-sodium diet. Interestingly, the four centers with the lowest sodium excretion also had the lowest average systolic and diastolic blood pressures. Although the INTERSALT study shows a positive correlation between blood pressure and sodium ingestion from the 52 participating centers, removal of data from the four centers reporting the lowest sodium intake lessens the significance of the correlation. One

assumption based on these and other data is that a sodium intake of <100 mmol/day (2.3 g/day) would lead to a healthful reduction in blood pressure even in individuals without hypertension.

The INTERSALT study was carried out between 1985 and 1987. Approximately 10 years later (1996–1999), the INTERMAP study was performed (Dennis *et al.*, 2003; Robertson *et al.*, 2005). INTERMAP followed measurements of dietary sodium intake and urinary sodium excretion in men and women aged 40–59 years, from 17 population samplings. Multiple samples from the number of population groups indicated were obtained: Japan (4), China (3), the United Kingdom (2), and the United States (8). Food recalls and timed urine specimens were used to estimate salt intake. In general, the INTERMAP study corroborated the findings of INTERSALT and most other epidemiologic studies in finding higher sodium intakes associated with higher blood pressures (Dennis *et al.*, 2003; Robertson *et al.*, 2005). In corroboration, the well-recognized studies with the Dietary Approach to Stop Hypertension (DASH) diet revealed that the lowest blood pressures were found with the lowest sodium intake: 500 mg/day (Sacks *et al.*, 2001).

## **Dietary Salt**

### **Importance of Chloride**

Early on, the chloride moiety was assumed to be responsible for the blood pressure disorders – possibly because the measurement of chloride was much more accurate than that of sodium and afforded better evaluation (Kaunitz, 1978). Later, the development of the flame photometer led to more emphasis on the sodium moiety as the major perturbation in the significant elevation of blood pressure by salt. However, the two ions seem to work together to control extracellular volume and blood pressure. It is worth repeating that the sodium coupled to chloride – not so much to other anions such as bicarbonate – affects fluid distribution in the extracellular compartment (Kotchen, 2005). Therefore, although most references here are to “sodium,” it is important to remember that sodium and chloride are coupled most of the time in the actions, both good and bad.

### **Intake and Requirements**

Primal herbivorous humans probably consumed  $\leq 10$  mmol/day (0.2–0.3 g/day) of sodium (Dahl, 1958; Meneely and

Dahl, 1961). On a successful hunting day, carnivorous humans might even have ingested as much as 60 mmol (1.4 g) sodium. Over the ensuing years, however, humans developed a significant salt appetite that brought about an estimated increase in sodium intake of 87–260 mmol/day (2.0–6.0 g/day). No doubt this increase has occurred because most individuals experience enhanced flavor and improved texture of foods with added salt. Also, salt serves as a preservative and thickener. The bottom line is that many who depend on food for a livelihood believe that salt makes cheap, unpalatable foods taste better at a low cost. Unfortunately, the ubiquitous nature of salt in foods has allowed the general public to become accustomed to high levels.

Sodium intake varies greatly among countries according to reports in the late 1980s (Simpson, 1988). At that time, daily intake was  $\geq 300$  mmol (6.9 g) by some Japanese men; 235 mmol (5.4 g) in Finland; 150–170 mmol (3.5–3.9 g) in the United States, Thailand, and New Zealand; 62 mmol (1.4 g) in a Polynesian island; and  $< 30$  mmol (0.69 g) in the Amazon Jungle, New Guinea Highlands, and the Kalahari Desert (Engstrom *et al.*, 1997). The values for the United States are slightly higher than the average daily intake reported 10 years later by the United States Department of Agriculture (USDA, 1997). Between 1994 and 1996, the typical US diet had an average sodium content of 3.27 g/day that significantly exceeded the average potassium content of 2.62 g/day according to the Agriculture Department (USDA, 1997). Recent guidelines from the Institute of Medicine urge the FDA to set government standards for amount of salt added by manufacturers, restaurants, and food-service companies, because analysts estimate that population-wide reductions in sodium intake could prevent more than 100 000 deaths annually (Henney *et al.*, 2010).

Japan in the late 1950s had the dubious distinction of having the highest death rate from strokes of any nation (He and MacGregor, 2009). In 1960, the Japanese government initiated a program to reduce salt intake from 13.5 to 12.1 g/day over 10 years. Paralleling this decrement were falls in blood pressure and an 80% reduction in stroke mortality despite increases in fat intake, cigarette smoking, alcohol consumption, and obesity. Since the 1970s, the Finnish Ministry of Social Affairs and Health has worked closely with food companies to decrease salt content of products and has educated physicians to lower sodium intake (Tuomilheto *et al.*, 1984). Sodium intake decreased at least 40% during this period (Havas *et al.*, 2007) and prevention of cardiovascular diseases was noted

(Puska *et al.*, 1998). The British government's Food Standards Agency has a goal of reducing sodium consumption by 33% over 5 years. Why is this necessary? Lifetime probability of hypertension approaches 90%. Worldwide more than 26% of adults have hypertension. Virtually all reports on clinical trials examining the lessening of sodium in the diet found reduction in blood pressure, and lowered incidence of strokes and, to a lesser extent, coronary events (Strazzullo *et al.*, 2009).

Brown *et al.* (2009) recently updated the information concerning salt intake throughout the world. In the 21st century, sodium intake around the world remains well in excess of physiological needs, i.e. intake may be five to 20 times above need. In part, the multiple sources of sodium contribute to the prevalence of sodium ingested worldwide. In North America and Europe, 75% of sodium intake is via manufactured foods, with cereals and baked goods being the largest contributors. In the Far East, salt added at home and in soy sauce proved to be the largest contributors.

### **Tackling the Problem**

Concerning disturbances in the balance of sodium, the major problem usually lies with input, not output. Concerning output, healthy kidneys are amazing in their ability to compensate adequately under most circumstances for either too little or too much sodium intake. This is important to the average individual with normal renal function who from day to day pays little attention to sodium balance even though his intake varies markedly. An example of a usual balance of sodium chloride might be the following: 10.5 g/day in foods and a dietary output of 10.5 g/day (in urine [10.0 g/day], sweat [0.25 g/day], and feces [0.25 g/day]). In the case of too little intake, the healthy kidney conserves sodium at the expense of hydrogen and potassium (Pitts, 1974). The renal conservation of sodium is so efficient that, if necessary, a daily intake of only a few millimoles is required to balance the small non-urinary losses of sodium (Pitts, 1974).

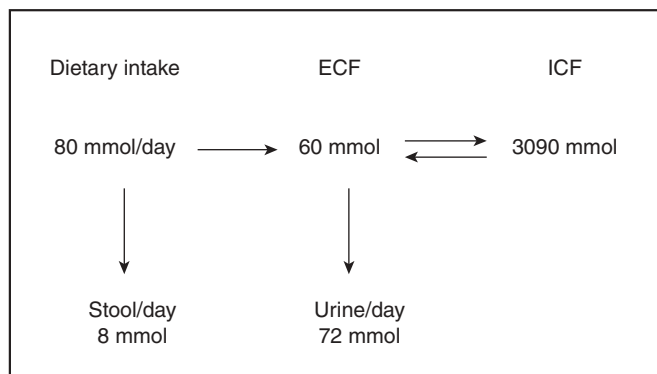

Although the problem usually lies on the intake side, recent changes have started to take place because the public is becoming alarmingly aware of the consequences of "too much salt." The major effort to decrease sodium intake between 1980 and 1990 was via salt shakers (0.06 vs. 0.02 mmol [1.4 vs. 0.5 g]). Unfortunately, sodium intake emanating directly from foods, by far the major source, was not affected (Havas *et al.*, 2007). Thus, overall sodium intake has not decreased enough to satisfy most health experts (He and MacGregor, 2007; Cook, 2008).

A decrease in sodium can often be accomplished successfully without affecting consumer enjoyment of food products if it is done in a stepwise process that systematically and gradually lowers sodium levels across the food supply (Henney *et al.*, 2010). In addition to hypertension, heavy consumption of salt-laden foods such as breads, grains, and cereal products increases the risk of strokes, osteoporosis, obesity, stomach cancer, and kidney stones, left ventricular hypertrophy, congestive heart failure, and severity of asthma (Mickleborough and Fogarty, 2006; Frassetto *et al.*, 2008; He *et al.*, 2008; Forrester *et al.*, 2010).

## Potassium

### General Background

Potassium is the major intracellular cation and plays a significant role in several physiological processes (Brown, 1986; Perez *et al.*, 1988; Latta *et al.*, 1993). Circulating potassium enters all tissues and has profound effects on the function of some organs, particularly depolarization and contraction of the heart. A number of organ systems are involved in maintaining potassium balance. Under usual circumstances, roughly 90% of ingested potassium is absorbed via the gastrointestinal tract for use in the body, leaving the remaining 10% to be excreted in stools (Figure 31.4). Potassium is readily absorbed in the small intestine in proportion to the presented load. Circulating concentrations are relatively stable, because cells immediately take up most potassium entering the body. Cellular uptake is facilitated by insulin, catecholamines, and aldosterone. Since the kidney is the principal excretory organ and decreased renal function from any cause may result in excess potassium retention, it usually takes from several

**FIG. 31.4** Potassium distribution balance in a normal 70-kg man. ECF, Extracellular fluid; ICF, intracellular fluid.

days to as much as 3 weeks for the kidney to adapt to excess potassium intake. When kidneys cannot respond appropriately, the gastrointestinal tract can reestablish balance, at least in part, by eliminating increased amounts of potassium (i.e. 30–40% of daily intake) (Brown, 1986).

### Facts about Potassium

The total body potassium of a normal adult male averages 45 mmol/kg body weight (Pitts, 1959), i.e. the body of a 70-kg person has 3150 mmol (120 g) potassium. Only 60 mmol or ~2% of potassium is distributed in the extracellular fluid. Virtually all the body's potassium is labile and exchangeable. A typical balance of potassium for an average 70-kg man is depicted in Figure 31.4. The circulating potassium concentrations are low, ~3.5–5.0 mmol/L, and the plasma concentration of potassium is often a poor indicator of tissue potassium stores. Intracellular potassium is maintained at 140–150 mmol/L (Hayslett and Binder, 1982). Potassium status not only depends on the intake and output of potassium but on its distribution as well (Perez *et al.*, 1988). Distribution depends on the energy-consuming processes at the cell membranes in which sodium extrusion is coupled to entry of potassium. Although the kidneys can adapt to high and low potassium intakes over a period of 2–3 weeks, the minimum rate of excretion is 5 mmol/day. Taken together with obligatory extra renal losses, this implies that potassium balance cannot be achieved on intakes <10–20 mmol/day (<0.4–0.8 g/day) (Perez *et al.*, 1988).

### Functions of Potassium within the Body

A major function of potassium is membrane polarization. Membrane polarization depends on the concentrations of internal and external potassium (on either side of the membrane). The major clinical features of disordered potassium homeostasis relate to perturbations in membrane function, especially in the neuromuscular and cardiac conduction systems. Accordingly, both deficient and excessive circulating potassium concentrations can lead to disorders in cardiac, muscle, and neurological functions.

### Sources

Because potassium is the principal cation of the intracellular fluid, the major source of dietary potassium is the cellular materials consumed in foodstuffs (Table 31.3). It is a major constituent of meats, vegetables, and fruits (Institute of Medicine, 2004). Consequently, a potassium-free diet is virtually impossible to devise. Since most foods

**TABLE 31.3** Approximate values for potassium content in some common foods<sup>a</sup>

Foodstuff	Potassium	
	(mmol)	(mg)
Apple, raw, with skin (1 apple, 138 g)	3.8	148
Asparagus, boiled no salt (4 spears, 60 g)	2.6	103
Avocado, raw California (1 oz, 28.35 g)	3.7	144
Banana, raw (1 banana, 118 g)	10.8	422
Beef patty, 75% lean/25% fat, broiled (3 oz, 85 g)	6.3	246
Beer, regular (12 oz, 355 g)	2.5	96
Butter, salted (1 tbsp, 14.2 g)	0.08	3
Celery, raw (1 stalk, 40 g)	2.7	104
Chicken, breast meat only, roasted (half breast, 86 g)	5.6	220
Egg, scrambled (1 large, 61 g)	2.1	84
Frankfurter, beef (1 frankfurter, 45 g)	1.8	70
Milk, whole, 3.25% milk fat (1 cup, 244 g)	8.9	349
Sweet potato, baked in skin (1 potato, 146 g)	17.7	694
Sweet potato, boiled without skin (1 potato, 156 g)	9.2	359
Tomato juice, canned, salt added (1 cup, 243 g)	14.2	556

<sup>a</sup>Based on USDA National Nutrient Database for Standard Reference, Release 21, 2008.

contain some potassium, mineral imbalances do not, as a rule, occur through dietary inadequacies but rather through excessive fluid losses from sweating, diarrhea, or the use of diuretics.

The potassium content of the average American diet ranges between 50 and 100 mmol/day (2.0–4.0 g/day). Foods containing high concentrations of potassium include avocado, apricots, cantaloupes, lima beans, oranges, and all meats, poultry, and fish. Milk and yogurt, as well as nuts, are recognized as being excellent sources of potassium (Institute of Medicine, 2004). Apple juice, asparagus, beets, carrots, peas, and lettuce are considered to have moderate levels. Those often listed as low in potassium are blueberries, cabbage, beans, mushrooms, pineapples, and plums. The famous DASH (Dietary Approach to Stop Hypertension) diet to ameliorate elevated blood pressure is higher in potassium than the typical American diet (McGill *et al.*, 2008).

Only a small portion of oral potassium absorbed remains in the extracellular compartment. Normal rates of dietary intake cause only negligible changes in plasma levels. At high intakes of 200–300 mmol/day (8–12 g/day), patients unaccustomed to large loads may develop a significant elevation in circulating potassium despite normal renal function (Perez *et al.*, 1988). Potassium loads augment secretions of insulin, catecholamines, and aldosterone which help maintain balance.

### Dietary Recommendations

Our ancestors consumed a diet relatively high in potassium in contrast to that consumed in modern societies. This recent lowering of intake is associated with the increasing consumption of processed foods low in potassium and a reduced intake of fruits and vegetables. The average potassium intake in the modern world has been estimated to be around 70 mmol/day or 2.8 g/day (Anderson *et al.*, 2010) – far from the current recommendation of 120 mmol/day (4.7 g/day). Most individuals who eat a reasonably healthy diet that includes fresh fruits and vegetables consume sufficient potassium.

The following dietary intakes of potassium according to age have been recommended by the Food and Nutrition Center of the Institute of Medicine (Institute of Medicine, 2004).

#### Infants

0–6 months: 0.4 g/day

7–12 months: 0.7 g/day

#### Children and adolescents

1–3 years: 3.0 g/day

4–8 years: 3.8 g/day

9–13 years: 4.5 g/day

14–18 years: 4.7 g/day

#### Adults

19-up: 4.7 g/day

### **Potassium and Blood Pressure**

In contrast to deleterious effects of high sodium intake that frequently increase blood pressure, ingestion of more potassium may influence blood pressure favorably by lowering any elevations (Cappuccio and MacGregor, 1991; Bari and Wingo, 1997). Many studies have shown that potassium has a good blood-pressure-lowering effect, especially in salt-sensitive individuals (He and MacGregor, 2008). The beneficial effects of potassium (even magnesium and calcium) work, at least in part, through an effect on sodium balance: a greater sodium excretion despite no change in intake (Perez *et al.*, 1988; Latta *et al.*, 1993).

A high intake of potassium has been reported to protect against increased blood pressure and other cardiovascular risks (Cappuccio and MacGregor, 1991; Newsom *et al.*, 2003; He and MacGregor, 2008). Analysis of results from the INTERSALT study shows a lowering of systolic blood pressure at higher potassium excretory rates, presumably reflecting higher intakes (INTER-SALT Cooperative Research Group, 1988). Various clinical trials suggest a lowering of blood pressure in persons taking potassium supplements (Siani *et al.*, 1991). One meta-analysis reviewed 19 clinical trials involving a total of 586 participants (Cappuccio and MacGregor, 1991). Results showed that oral potassium supplements significantly lowered systolic blood pressure (−5.9 mm Hg) and diastolic blood pressure (−3.4 mm Hg). In mildly hypertensive individuals, a low-potassium diet can augment the already elevated systolic and diastolic pressures and also causes sodium retention (Krishna and Kapoor, 1991). In normal people, dietary potassium depletion can also cause sodium retention and augmented blood pressure (Krishna *et al.*, 1987). Low intake of potassium rather than excess sodium consumption may be more important in the prominence of severe hypertension among blacks (Langford and Watson, 1990; Weinberger, 1993). In addition to benefiting hypertensive individuals, potassium supplementation of diabetics could appreciably check the negative effects of diabetic vascular disease by enhancing vascular perfusion and improving carbohydrate metabolism (Whang and Sims, 2000). Over and above the natriuretic effects of potassium, increased urinary kallikrein (Valdes *et al.*, 1991) and stimulation of the Na<sup>+</sup>, K<sup>+</sup>-ATPase in vascular smooth muscle cells and adrenergic nerve terminals (Haddy, 1983, 1988) may be important in lowering blood pressure.

The DASH diet seems particularly effective in lowering blood pressure. Results from two DASH studies have been published (Appel *et al.*, 1997; Sacks *et al.*, 2001; Bray

*et al.*, 2004). The basic diet resulted in a marked reduction of blood pressure. Although many nutrients are responsible for the overall effect, potassium is probably most important in producing the beneficial effects. In the second DASH-sodium trial, salt intake was monitored at three different levels, with the greatest effects on blood pressure being seen with the lowest sodium intake. A 12-month follow-up study was instituted to determine the effects of the DASH diet with sodium reduction after discontinuation of the feeding intervention (Ard *et al.*, 2004). Compared with control participants, DASH diet participants ate more fruit and vegetables and maintained reduced blood pressure even though their sodium intake increased. Organic forms of potassium may be more influential than inorganic forms in lowering blood pressure (Sebastian *et al.*, 2006)

A recent report indicated that a higher sodium-to-potassium excretion ratio is associated with the increased risk of cardiovascular diseases (Cook *et al.*, 2009). This association is stronger for the ratio than for sodium and potassium alone. Therefore, diets that lower the overall intake of sodium while increasing the intake of potassium are recommended for the best cardiovascular health.

### **Severe Disturbances in Potassium Balance**

Total body potassium can be decreased and lead to decreased serum concentration of potassium, i.e. hypokalemia (Hayslett and Binder, 1982; Brown, 1986). However, hypokalemia can also result from shifts of potassium out of the blood and into the cells even though total body potassium is normal. Common causes of hypokalemia include increased renal excretion (poor renal tubular function, diuretic drugs), adrenal disorders (hyperaldosteronism), increased gastrointestinal losses (vomiting, diarrhea), increased uptake by cells (insulin, beta-adrenergic agonists), and decreased intake (chronic alcoholism, anorexia nervosa). Mild hypokalemia may be asymptomatic or present with muscle weakness, constipation, fatigue, and malaise. Patients with underlying cardiac diseases are prone to arrhythmias. Moderate hypokalemia may result in more severe constipation, an inability to concentrate urine accompanied by polyuria, and a tendency for the development of encephalopathy in patients with concomitant renal disease. Severe hypokalemia can result in muscular paralysis and even in poor respiration because of immobilization of the diaphragm and decreased blood pressure.

Diuretic usage is the most common cause of hypokalemia in the United States (Gennari, 1998). Elderly women using long-acting thiazides or loop diuretics are at increased risk. A low-sodium/high-potassium diet, lower doses of diuretic agents, and substitution of different antihypertensive drugs may ameliorate the problem. Patients with normal renal function who receive diuretics and digitalis-type compounds may need potassium supplementation or an agent that reduces potassium loss via the kidneys, e.g. aldactone, triamterene, or amiloride. Laxative abuse often leads to hypokalemia and can be overcome by ceasing to use the causative agent.

When high circulating concentrations of potassium are present (hyperkalemia), it is important to differentiate between pseudohyperkalemia and/or laboratory error and the actual increases in total body potassium. Pseudohyperkalemia is not a real increase in circulating potassium but rather a response to a condition that should be recognized. Pseudohyperkalemia may arise from hemolysis of red blood cells with potassium release into the serum or potassium release into serum from massive leukocytosis or thrombocytosis. In the case of true hyperkalemia, the most important clinical manifestation is cardiac arrest caused by perturbations in electrical (membrane) conduction. Various characteristic changes in the electrocardiogram assessment aid in the diagnosis. Neuromuscular symptoms of too much potassium include tingling, paresthesia, weakness, and flaccid paralysis. In addition to spurious hyperkalemia caused by hemolysis or too many blood cells in the specimen, other common causes of true hyperkalemia are decreased renal excretion; adrenal disorders; and the use of medications such as spironolactone, triamterene, amiloride, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, and heparin.

### **Treatment for Severe Potassium Perturbations**

Oral replacement in deficiency states is generally preferable to intravenous administration, and the amount given depends on the body deficit. A rough rule is that a 1 mmol/L decrease in circulating levels is equivalent to 200–300 mmol of body potassium stores. Oral or intravenous potassium at a dose of 40–120 mmol/day generally improves all symptoms of hypokalemia. Any intravenous fluid should contain  $\leq 40$  mmol/L and administration should be  $< 10$  mmol/hour. If more rapid administration is necessary, it should be performed with electrocardiogram monitoring.

Hyperkalemia is, of course, treated by eliminating excess intake and reversing the other causes mentioned above.

When the problem is severe and immediate action must be taken, several therapeutic choices exist. First, one can antagonize the membrane effects by giving calcium gluconate or hypertonic saline. Second, cellular uptake of potassium can be stimulated by giving sodium bicarbonate, glucose, or insulin. Finally, potassium can be removed from the body by using certain diuretics (thiazides), cation-exchange resins (Kayexalate), and dialysis (peritoneal or hemodialysis).

Chronic hyperkalemia is treated by eliminating excess potassium from the extracellular space and reversing the primary cause of the disturbance and any cofactors that would increase potassium retention. Many drugs and conditions accentuate potassium retention. Drugs causing hyperkalemia include  $\beta$ -adrenergic blocking agents, digitalis, arginine succinylcholine, potassium penicillin, potassium salts, angiotensin-converting enzyme inhibitors, and potassium-retaining diuretics (aldactone, triamterene, amiloride). Acidosis, insulinemia, low levels of catecholamines, and hypoaldosteronism may contribute to high levels of circulating potassium.

Hypokalemia is often associated with metabolic alkalosis. Therefore, replacement of potassium in the form of potassium chloride may ameliorate the alkalosis more effectively. Hypomagnesemia is somehow related to hypokalemia. The latter may prove resistant to replacement until the magnesium deficiency is corrected. Drugs causing hypokalemia include diuretics, antibiotics (carbenicillin, penicillin, polymyxin B, gentamicin), drugs causing magnesium wasting, and drugs causing metabolic alkalosis.

### **Contraindications**

Potassium supplementation must be considered carefully in the face of evident renal failure because kidneys are the major regulator of potassium homeostasis. Because some potassium salts can be irritating to the gut lining, patients with severe gastrointestinal stress such as previous history of ulcers and bleeding should be considered carefully for oral potassium replacement.

### **Future Directions**

It is important to note that when life emerged from the safe confines of the relatively stable seas, it became necessary to retain at all times a similar internal sea-like environment (extracellular and intracellular body fluid) within acceptable limits. Falling short or exceeding the acceptable range would lead to disaster. This meant that the daily intake of salts and electrolytes had to equal losses and vice

versa, that is, the intake and output of sodium, potassium, and chloride over a finite period of time had to equal each other. It is obvious that any phenomenon necessary for life, such as maintaining the *correct* balance of electrolytes and fluids, has to be controlled by more than one mechanism: checks and balances regulating intake and output. Therefore, when symptoms occur because the acceptable limits for a healthy existence have not been maintained, more than one mechanism is involved. Of further note, adaptations to change often occur gradually. Accordingly, attempts to treat perturbations are more successful when they can be instituted gradually, either by correcting the major pathological processes involved or by carefully replacing deficits or correcting excesses of fluids and electrolytes. Diet-wise, the average individual would benefit from increasing his/her potassium intake while limiting the intake of sodium chloride (salt). A rational therapeutic approach to ameliorate or overcome perturbations in fluid and electrolyte balance mandates a solid knowledge of pertinent physiology and pathophysiology.

## HUMAN WATER AND ELECTROLYTE BALANCE

ROBERT W. KENEFICK, PhD, SAMUEL N. CHEUVRONT, PhD,  
SCOTT J. MONTAIN, PhD, ROBERT CARTER, III, PhD, AND  
MICHAEL N. SAWKA, PhD

*US Army Research Institute of Environmental Medicine, Natick, Massachusetts, USA*

### Summary

Among the greatest challenges to body water homeostasis is the imposition of prolonged exercise and environmental stress. Sweating results in water and electrolyte losses. Because sweat output often exceeds water intake, there is an acute water deficit that results in a hypertonic hypovolemia and intracellular and extracellular fluid contraction. Although water and electrolyte needs increase as a result of exercise, physiological and behavioral adaptations allow humans to regulate daily body water and electrolyte balance so long as food and fluid are readily available. Although there is presently no consensus for choosing one hydration assessment approach over another, deviations in daily fluid balance can be determined with the use of two or more markers, which should provide added diagnostic confidence when serial measures are made. Hypohydration increases heat storage by reducing sweating rate and skin blood-flow responses for a given core temperature. In addition, hypohydration increases the risk for heat exhaustion and is a risk factor for heat stroke. Aerobic exercise tasks can be adversely affected if hypohydration exceeds 2% of normal body mass, with the potential effect greater in warm environments and lesser in cool environments. Hyperhydration provides no thermoregulatory or exercise performance advantages over euhydration in the heat. Excessive consumption of hypotonic fluid over many hours can lead to hyponatremia. Marked electrolyte losses can accelerate the dilution and exacerbate the problem. Hyponatremia can be avoided by proper attention to diet and fluid needs.

### Introduction

Humans typically maintain stable day-to-day body water and electrolyte balance so long as food and fluid are readily available (Institute of Medicine, 2005). The ability to

detect and correct for water and electrolyte flux is essential considering the potential day-to-day imposition of physical activity and environmental stressors and the negative consequences of gross fluid and electrolyte imbalances on health and performance.

Water (total body water) plays many unique and vital roles within the body. Water is the principal chemical constituent of the human body and serves as the solvent for biochemical reactions supporting cellular homeostasis (Institute of Medicine, 2005). Water is also essential to sustain cardiovascular volume, and serves as the medium for transport within the body by supplying nutrients and removing waste. Water has unique properties, such as high specific heat, which allow it to absorb metabolic heat within the body, thus playing a vital role in thermoregulation. In addition, cell hydration is an important signal to regulate cell metabolism and gene expression (Haussinger and Gerok, 1994).

For an average young adult male, total body water is relatively constant and represents 50–70% of body weight (Sawka, 1988). The distribution of total body water is divided into intracellular fluid (ICF) and extracellular fluid (ECF) compartments. The ICF and ECF contain ~67% and ~33% of total body water, respectively. The ECF is further divided into the interstitial and plasma spaces (Sawka, 1988). Figure 32.1 depicts these fluid compartments and common mechanisms for compartmental fluid exchange.

The hydration of lean body mass is fairly constant (~73% water) across the lifespan and independent of sex and ethnicity. As a result, variability in total body water is primarily due to differences in body composition (Institute of Medicine, 2005). For example, using the equation, total body water =  $0.73 \times \text{lean body mass} + 0.1 \times \text{fat mass}$  (Institute of Medicine, 2005), two individuals of 90 kg and body compositions of 15% and 30% fat will have total

body water values of 57.2 L and 48.7 L, respectively. Thus, similar absolute total body water losses would result in a greater percentage of total body water losses for individuals with more body fat.

Water balance represents the net difference between water intake and loss. However, when losses exceed intakes, total body water is decreased. Within the course of a day, it is not uncommon to see wide deviations in hydration status. The most common type of dehydration (hypertonic hypovolemia) is caused by a net loss of hypotonic body fluids such as sweat, e.g. during heavy physical labor or exercise. For example, individuals may dehydrate during physical activity or exposure to hot weather because of fluid non-availability or a mismatch between thirst and body water losses (Costill, 1977; Sawka, 1992). In these instances, the person begins the task with normal total body water and dehydrates over a prolonged period. A different type of dehydration (isotonic dehydration) occurs as a result of illness (diarrhea, vomiting), exposure to extreme environments (cold, high altitude), injury (hemorrhage, burns), or use of certain medications (diuretics).

Fluid replacement is encouraged during physical activity to avoid excessive dehydration, as water losses that exceed approximately 2% of initial body mass have been repeatedly shown to compromise endurance performance capability (Sawka *et al.*, 2007). However, indiscriminate drinking of water and other electrolyte-poor beverages without consideration of need can have negative consequences. Hyponatremia is a clinical example of the consequences of overdrinking and can be produced by drinking in excess of volume necessary to restore total body water, and by drinking in excess of what is necessary to preserve electrolyte balance (Vrijens and Rehrer, 1999; Montain *et al.*, 2001).

This chapter reviews the physiology, needs, and assessment of human water and electrolyte balance. The extent to which water and electrolyte imbalances affect temperature regulation and exercise performance are also considered. Throughout the chapter, euhydration refers to normal body water content, hypohydration refers to a body water deficit, and hyperhydration to increased body water content. Dehydration refers to the dynamic loss of body water.

**FIG. 32.1** Schematic of the approximate volume of water and mechanisms for exchange between plasma, interstitial fluid (ISF), and intracellular fluid (ICF) compartments. Example assumes total body water (TBW) of ~45 L for a 70-kg individual. Adapted from Sawka (1988).

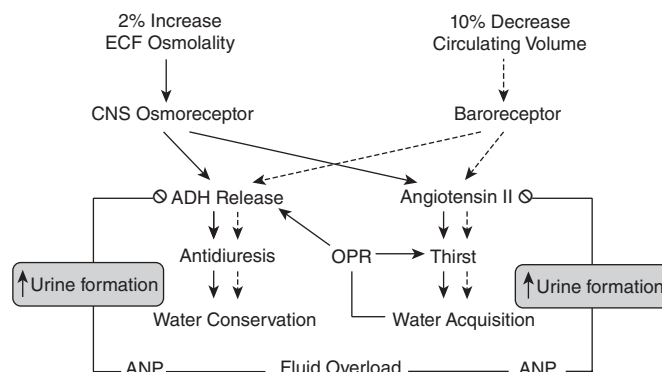

## Physiology of Water and Electrolyte Balance

Net body water balance (loss = gain) is generally regulated well as a result of thirst and hunger drives coupled with

free access to food and beverage (Institute of Medicine, 2005). This is accomplished by neuroendocrine and renal responses (Andreoli *et al.*, 2000) to body water volume and tonicity changes, as well as non-regulatory social-behavioral factors (Rolls and Rolls, 1982). These homeostatic responses collectively ensure that small degrees of hyper- and hypohydration are readily compensated for in the short term. Using water balance studies, Adolph (Adolph and Dill, 1938; Adolph, 1943) found that daily body water varied narrowly between 0.22% and 0.48% in temperate and warm environments, respectively. However, exercise and environmental insult often pose a greater acute challenge to fluid balance homeostasis.

When body water deficits occur from sweat losses, a hypertonic hypovolemia generally results. Plasma volume decreases and plasma osmotic pressure increases in proportion to the decrease in total body water. Plasma volume decreases because it provides the fluid for sweat, and osmolality increases because sweat is ordinarily hypotonic relative to plasma (Costill, 1977). Resting plasma osmolality increases in a linear manner from about 288 mosmol/kg when euhydrated to more than 300 mosmol/kg when hypohydrated (Institute of Medicine, 2005). The increase in osmotic pressure is primarily due to increased plasma sodium and chloride with no consistent effect on potassium concentrations (Edelman *et al.*, 1958; Senay, 1968; Kubica *et al.*, 1983). Figure 32.2 shows the impact of hyperosmotic hypovolemia on fluid regulation, i.e. conservation of water at the site of the kidney and acquisition of water via the stimulation of thirst.

Incomplete fluid replacement decreases total body water and, as a consequence of free fluid exchange, affects each fluid space (Figure 32.1) (Costill *et al.*, 1976; Nose *et al.*, 1983; Durkot *et al.*, 1986; Singh *et al.*, 1993). For example, Costill *et al.* (1976) determined the distribution of body water loss among the fluid spaces as well as among different body organs during hypohydration. They dehydrated humans via exercise and heat exposure to a range of body mass losses from 2.2% to 5.8% of body mass and determined the fluid deficit apportioned between plasma and the intracellular and extracellular spaces. At a 2.2% body mass loss, 10% of total body water losses were from the plasma and 30% and 60% were from the intracellular and extracellular spaces, respectively. At 5.8% body mass loss, 11% of total body water losses were from the plasma, and 50% and 39% were from the intracellular and extracellular spaces, respectively. This demonstrates that hypohydration results in osmotic water redistribution from the intracellular to extracellular fluid space to maintain blood volume,

**FIG. 32.2** Schematic diagram of fluid regulation in situations of fluid deficit and surfeit. Solid lines indicate the osmotically stimulated pathways (primary) and dashed lines indicate volume-stimulated pathways (secondary). ⊖ indicates negative feedback pathways; ANP, atrial natriuretic peptide; ADH, antidiuretic hormone; CNS, central nervous system; ECF, extracellular fluid; OPR, oropharyngeal reflex. Adapted from Reeves *et al.* (1998).

but it also underscores that body water losses are shared among all fluid compartments.

Different methods of dehydration are known or suspected to affect the partitioning of body water losses differently than those just described. For example, diuretics increase urine formation and generally result in the loss of both solutes and water. Diuretic-induced hypohydration generally results in an isotonic hypovolemia, with a much greater ratio of plasma loss to body water loss than either exercise or heat-induced hypohydration (Kubica *et al.*, 1983). As a result, relatively less intracellular fluid is lost after diuretic administration, since there is not an extracellular solute excess to stimulate redistribution of body water. Factors such as heat acclimatization status, posture, climate, and mode and intensity of exercise can also produce significant variability in the distribution of fluids throughout body fluid compartments.

## Consequences of Fluid Imbalance

During prolonged physical exercise, profuse sweating coupled with the challenges of drinking enough often leads to dehydration by 2–6% of typical body mass (Sawka *et al.*, 2005). Although this is more common in hot environments, similar deficits are observed in cold climates when working in heavy clothing (O'Brien *et al.*, 1996). The mismatch between intakes and losses is due to

physiological and behavioral factors. There are other situations where individuals purposefully dehydrate to gain a performance advantage. For example, boxers, power lifters, and wrestlers will dehydrate to compete in lower weight classes, presumably to improve their strength-to-mass ratio.

Water deficits increase the core temperature and heart-rate response to exercise and increase perception of effort to perform any given physical task (Sawka, 1992). In warm weather, the core temperature is typically increased an additional 0.1–0.2°C for every percent body weight lost due to water losses, whereas heart rate increases an additional 3–5 bpm (Sawka, 1992; Institute of Medicine, 2005). The magnitude of the penalty is of sufficient magnitude that it effectively negates the core temperature and cardiovascular advantages conferred by high aerobic fitness and heat acclimation (Sawka, 1992). In cooler weather, hypohydration induces a more modest impact on core temperature and heart rate (Cheuvront *et al.*, 2005a).

The thermal and cardiovascular burden accompanying dehydration are regulated adjustments to compensate for the reduced ability to deliver heat from core to skin without compromising blood pressure. Consistent with this hypothesis are observed increases in the threshold core temperature for skin vasodilatation and commencement of sweating, and reduced sensitivity of each to changes in core temperature (Kenney and Johnson, 1992; Montain *et al.*, 1995). Both the singular and combined effects of plasma hyperosmolality and hypovolemia have been implicated for mediating these thermoregulatory adjustments (Sawka, 1992). As mentioned earlier, the thermal and cardiovascular adjustment is tempered in cooler environments (Sawka *et al.*, 1983; Kenefick *et al.*, 2004; Cheuvront *et al.*, 2005a).

A physiological consequence of hypohydration is deterioration in the ability to perform endurance-type physical activities. For example, McGregor *et al.* (1999) reported that semi-professional soccer players who were hypohydrated by >2% of body mass were less able to sprint during the later stages of a variable-intensity running protocol meant to simulate match play. They also took longer to complete an embedded soccer dribbling task. Hypohydration appears to have little or no effect on muscular strength (Greiwe *et al.*, 1998; Evetovich *et al.*, 2002) or anaerobic performance (Jacobs, 1980; Cheuvront *et al.*, 2005a) but sometimes has been reported to reduce dynamic small-muscle endurance (Montain *et al.*, 1998; Bigard *et al.*, 2001) and tolerance to repeated bouts of high-

intensity work (Judelson *et al.*, 2007). Hypohydration in excess of 2% body mass is, however, associated with deterioration in the ability to execute sport-specific skills (Dougherty *et al.*, 2006; Baker *et al.*, 2007). For example, Baker *et al.* (2007) reported that basketball players attempted fewer shots and were less able to make shots linked with movement (e.g. lay-up) when hypohydration had exceeded 3%, and shooting was further impaired when 4% hypohydrated. While the mechanism remains unresolved, it may be linked to changes in vestibular function and/or vestibular sensitivity as a consequence of water deficit (Lepers *et al.*, 1997; Gauchard *et al.*, 2002).

The threshold for performance decrements appears to be at or about >2% of body mass, at least in temperate–warm–hot environments (Cheuvront *et al.*, 2003). As the level of dehydration increases, aerobic exercise performance is degraded proportionally (Institute of Medicine, 2005). It has previously been demonstrated that high levels of aerobic fitness and acclimatization status provide some thermoregulatory advantage. However, dehydration seems to cancel out this protective effect during exercise heat stress (Buskirk *et al.*, 1958; Sawka *et al.*, 1983; Merry *et al.*, 2010). A review of studies (Cheuvront *et al.*, 2003) that observed the specific effects of hypohydration (–2% body mass) on aerobic exercise performance found that, in environments of >30°C, aerobic exercise performance was decreased by anywhere from 7% to 60%. It also appears that the magnitude of the effect increases as exercise extends beyond 90 minutes. Overall what can be taken from this review is that the impact of hypohydration on prolonged work effort is magnified by hot environments and probably worsens as the level of hypohydration increases.

The performance penalty accompanying hypohydration may be dampened in cool weather. Cheuvront and Sawka (2005) observed an 8% reduction in total work during a 30-minute cycling time trial when hypohydrated by 3% of body mass in a 20°C environment. However, in a 2°C environment, no effect of hypohydration was observed. More recently, Kenefick *et al.* (2010) observed decrements in aerobic performance (15-minute cycling time trial) of –3%, –5%, –12%, and –23% in 10°C, 20°C, 30°C, and 40°C respectively, when volunteers were hypohydrated by 4% of body mass. Therefore, the temperature cusp at which dehydration altered aerobic exercise performance to an extent considered meaningful appears to be at 20°C.

The physiological factors that contribute to the hypohydration-mediated aerobic exercise performance

**FIG. 32.3** The impact of dehydration on physiological function and ability to perform work/exercise relative to percent losses in body mass. Adapted from Greenleaf (1992).

decrements include increased body core temperature, increased cardiovascular strain, increased glycogen utilization, and perhaps altered central nervous system function (Montain *et al.*, 1998; Febbraio, 2000; Nybo and Nielsen, 2001; Cheuvront *et al.*, 2010b). Though each factor is unique, evidence suggests that they interact to contribute in concert, rather than in isolation, to degrade aerobic exercise performance (Cheuvront *et al.*, 2003). The relative contribution of each factor may differ depending on the specific activity, environmental conditions, heat acclimatization status, and athletic prowess, but elevated hyperthermia probably acts to accentuate the performance decrement. One explanation for the impact of hypohydration on exercise performance is a reduction in circulating blood and plasma volume. Cardiac filling is reduced and larger fractional utilization of oxygen is required at any given workload (Cheuvront *et al.*, 2010b). Ultimately, these responses have a negative impact on exercise/work performance, especially in warm/hot environments.

Hypohydration and hyperthermia have also been shown to degrade cognitive/mental performance when concentration, skilled tasks, and tactical issues are involved (Institute of Medicine, 2005). The evidence is stronger for a negative effect of hyperthermia than for mild hypohydration on degrading cognitive/mental performance (Cian *et al.*, 2000), but the two are closely linked when physically active in warm/hot weather. The impact of hypohydration

on physiological function, ability to perform work/exercise and survivability are depicted in Figure 32.3.

## Illnesses and Disease

In clinical medicine, disturbances of body fluid and electrolyte balance are associated with significant medical costs, morbidity, and mortality across the lifespan (Warren *et al.*, 1994; Black *et al.*, 2003). Fluid and electrolyte imbalances represent a common problematic complication of acute medical treatment scenarios (e.g. cardiovascular, renal, burns) and are also functionally linked to a number of acute and chronic diseases (Manz, 2007). The World Health Organization (1995) considers hypohydration of  $\leq 5\%$  of body mass to be mild on a life-threatening scale. When substantial solute (electrolyte) is lost in situations of long duration work and heat stress (profuse sweating), or during cold or high-altitude exposure, and in numerous illnesses and disorders (e.g. gastroenteritis, hyperemesis, diuretic treatment, dialysis), an isotonic or hypotonic hypovolemia is the result (World Health Organization, 1995; Mange *et al.*, 1997; Cheuvront *et al.*, 2005b; Sawka *et al.*, 2007). However, proper diagnosis of hypovolemia of isotonic or hypotonic origins, especially in austere environments, remains elusive because an accurate and reliable method for assessment has not yet been developed (McGee *et al.*, 1999).

It has been suggested that chronic plasma hypertonicity as a result of hypohydration may promote obesity and related metabolic dysregulation, and may play a role in chronic disease (Haussinger *et al.*, 1993; Keller *et al.*, 2003; Stookey *et al.*, 2004). Presently, support is limited, but there is increasing evidence that chronic mild hypohydration may account for various morbidities including urolithiasis (kidney stones), urinary tract infections, bladder and colon cancer, constipation, hypertension, venous thromboembolism, coronary artery disease, mitral valve prolapse, stroke, gallstones, glaucoma, and dental diseases (Manz, 2007). While further epidemiological studies will be needed to determine possible links between chronic hypohydration and these morbidities, the dangers of over-drinking (hyponatremia), are well known.

### Hyponatremia

Hyperhydration is not easy to sustain since overdrinking of water or carbohydrate-electrolyte solution produces a fluid overload that is rapidly excreted by the kidneys (Figure 32.2) (Freund *et al.*, 1995). However, excessive intake of hypotonic fluid, especially over an extended time, can dilute plasma sodium to dangerously low levels (<135 mEq/L). Dilution of plasma sodium will induce movement of water from the extracellular fluid into cells. If it occurs rapidly and is of sufficient magnitude, this fluid shift can congest the lungs, swell the brain, and alter central nervous system function. The clinical signs and symptoms associated with hyponatremia include confusion, disorientation, mental obtundation, headache, nausea, vomiting, aphasia, incoordination, and muscle weakness with the severity of symptomatology related to the magnitude of decline in serum sodium and the rapidity with which it develops (Knochel, 1996). Complications of severe and rapidly evolving hyponatremia include seizures, coma, pulmonary edema, and cardiorespiratory arrest. Symptomatic hyponatremia arises during clinical care, but has developed in otherwise healthy individuals participating in marathon and ultramarathon competition (Davis *et al.*, 2001; Speedy *et al.*, 2001; Hew *et al.*, 2003), military training (Garigan and Ristedt, 1999; O'Brien *et al.*, 2001), and recreational activities (Backer *et al.*, 1993).

The hyponatremia associated with prolonged exercise most often occurs when individuals consume low-sodium drinks or sodium-free water in excess of sweat losses, either during or shortly after completing exercise (Garigan and Ristedt, 1999; Montain *et al.*, 2001; Speedy *et al.*, 2001). Unreplaced sodium losses contribute to the rate and mag-

nitude of sodium dilution. In those individuals who produce a relatively salty sweat, there are situations where drinking sodium-free water at rates near to or slightly less than sweating rate can theoretically produce biochemical hyponatremia when coupled with the progressive loss of electrolytes (Montain *et al.*, 2001). As such, the mechanism that leads to exercise-associated hyponatremia is overdrinking in its absolute (volume-related) and relative forms (relative to sodium loss).

Exercise-associated hyponatremia can be prevented by not drinking in excess of sweating rate, and by consuming salt-containing fluids or foods when participating in exercise events that produce multiple hours of continuous or near-continuous sweating.

### Hydration Assessment

Human hydration assessment is a key component for prevention and proper treatment of fluid and electrolyte imbalances (Mange *et al.*, 1997; Oppliger and Bartok, 2002; Chevront *et al.*, 2005). The efficacy of any assessment marker depends critically upon the nature of body fluid losses. In many clinical and most sports medicine situations, hypertonic hypovolemia occurs when there is net loss of hypotonic body fluids (Mange *et al.*, 1997; Chevront *et al.*, 2005; Sawka *et al.*, 2007). The rise in extracellular tonicity is a hallmark clinical feature that provides diagnostic distinction from isotonic or hypotonic hypovolemia (Feig and McCurdy, 1977; Mange *et al.*, 1997). Hypotonic fluid losses modulate renal function and urine composition in accordance with the body water deficit (Robertson and Mahr, 1971), thus providing the fundamental framework for using blood (osmolality, sodium, fluid regulatory hormones) and urine (osmolality, specific gravity, color) as principal body-fluid hydration assessment measures.

Although plasma osmolality is the criterion hydration assessment measure for large-scale fluid needs assessment surveys (Institute of Medicine, 2005), the optimal choice of method for assessing hydration is limited by the circumstances and intent of the measurement. Popular hydration assessment techniques vary greatly in their applicability to laboratory or field use because of methodological limitations which include the necessary circumstances for accurate measurement, ease of application, and sensitivity for detecting small but meaningful changes in hydration status (Table 32.1). Large population heterogeneity explains, in part, why there are presently few hydration

**TABLE 32.1** Laboratory hydration assessment techniques summary

Technique	Advantages	Disadvantages
<i>Complex markers</i>		
Total body water (dilution)	Accurate, reliable	Analytically complex, expensive, requires baseline and serial measures
Plasma osmolality	Accurate, reliable (clinical standard)	Analytically complex, expensive, invasive
<i>Simple markers</i>		
Fluid input/output	Accurate, reliable (clinical standard)	Requires urinary catheter and serial measures
Urine concentration	Easy, rapid, screening tool	Easily confounded, timing critical, frequency and color subjective
Body mass	Easy, rapid, screening tool	Requires baseline; confounded by changes in body composition
<i>Other markers</i>		
Blood:		
Plasma volume	No advantages over osmolality (except hyponatremia detection for plasma sodium)	Analytically complex, expensive, invasive, multiple confounders
Plasma sodium		
Fluid balance hormones		
Bioimpedance	Easy, rapid	Requires baseline, multiple confounders
Saliva	Easy, rapid	Highly variable, multiple confounders
Physical signs	Easy, rapid	Too generalized, subjective
Tilt test (orthostatic challenge)	Rapid	Highly variable, insensitive, requires tilt table or ability to stand
Thirst	Positive symptomatology	Subjective and variable, develops late and is quenched early

Adapted from Institute of Medicine (2004) and Cheuvront *et al.* (2005).

**TABLE 32.2** Biomarkers of hydration status

Measure	Euhydration	Population reference interval	Dehydration
Total body water (L)	<1%	N/A	≥3%(?)
Plasma osmolality (mmol/kg)	<290	285–295	≥297
Urine specific gravity (units)	<1.02	1.005–1.035	≥1.025
Urine osmolality (mmol/kg)	<700	300–900	≥831
Urine color (units)	<4	N/A	≥5.5
Body weight <sup>a</sup> (kg)	<1%	N/A	≥2%

<sup>a</sup>Potentially confounded by changes in body composition during very prolonged assessment periods. Compiled from Kratz *et al.* (2004), Cheuvront *et al.* (2005, 2010a), and Sawka *et al.* (2007).

status markers that display potential for high nosological sensitivity from a practical, single measure (Cheuvront *et al.*, 2010a). Change measures can provide good diagnostic accuracy, but their usefulness also depends on the homogeneity of measures taken on the same person if day-to-day monitoring is desired (Cheuvront *et al.*, 2010a). More acute change measures (over hours) require a valid baseline and control over confounding variables. Table 32.2 provides definable thresholds which can be used as a

guide to detect a negative body fluid balance stemming from hypertonic hypovolemia. Hydration should be considered adequate when any two assessment outcomes are consistent with euhydration (Table 32.2) (Cheuvront and Sawka, 2005; Sawka *et al.*, 2007). Values that occur between euhydration and hypohydration represent typical human variation (Kratz *et al.*, 2004) in homeostatic set-points relating to biology as well as to social (diet) and environmental (exercise, climate) influences.

### Water and Electrolyte Needs

Human water and electrolyte needs should not be based on a “minimal” intake, as this might eventually lead to a deficit and possible adverse performance and health consequences. The Food and Nutrition Board of the Institute of Medicine instead base the dietary recommended intake (DRI) for water needs on an adequate intake (AI). The AI is based on experimentally derived intake levels that are expected to meet nutritional adequacy for essentially all members of a healthy population. The AI level for water is 2.7 to 3.7 L/day for sedentary women and men over age 19, respectively (Institute of Medicine, 2005). These values represent total water intake from all fluids (80%) and foods (20%). The AI for sodium is 1.5 g/day, or 3.8 g/day sodium chloride (Institute of Medicine, 2005). It should be recognized, however, that endurance athletes and occupational laborers performing extended hours of work, particularly in warm climates, may greatly exceed the AI for water and sodium (Institute of Medicine, 2005).

Table 32.3 (Rehrer and Burke, 1996) illustrates the wide variability in hourly sweat losses observed both within and between sports and occupations. Depending upon the duration of activity and heat stress exposure, the impact of these elevated hourly sweat rates on daily water requirements will vary. Figure 32.4 depicts generalized modeling approximations for daily water and sodium requirements based upon calculated sweating rates as a function of daily energy expenditure (activity level) and air temperature (Institute of Medicine, 2005). Applying this prediction model, it is clear that daily water requirements can increase two- to six-fold from baseline by simple manipulation of either variable. For example, daily water requirements for any given energy expenditure in temperate climates (20°C) can triple in very hot weather (40°C). In addition to air temperature, other environmental factors also modify sweat losses to include relative humidity, air motion, solar

**TABLE 32.3** Sweating rates for different sports

Sport	Mean (L/h)	Range (L/h)
Water polo	0.55	0.30–0.80
Cycling	0.80	0.29–1.25
Running	1.10	0.54–1.83
Basketball	1.11	0.70–1.60
Soccer	1.17	0.70–2.10

Data compiled from Rehrer and Burke (1996).

load, and choice of clothing for protection against environmental elements (Latzka and Montain, 1999). Therefore, water losses, and hence water needs, will vary considerably among moderately active people based on changing extraneous influences.

Sweat contains electrolytes, primarily sodium chloride and to a lesser extent potassium, calcium, and magnesium (Costill *et al.*, 1975; Costill, 1977; Verde *et al.*, 1982). Sweat sodium concentration averages ~35 mEq/L (range 10–70 mEq/L) and varies depending upon diet, sweating rate, hydration level, and heat acclimation state (Allan and Wilson, 1971; Costill *et al.*, 1975). Sweat potassium concentration averages 5 mEq/L (range 3–15 mEq/L), calcium averages 1 mEq/L (range 0.3–2 mEq/L), magnesium averages 0.8 mEq/L (range 0.2–1.5 mEq/L), and chloride averages 30 mEq/L (range 5–60 mEq/L) (Costill, 1977). Neither gender, maturation nor aging seems to have marked effects on sweat electrolyte concentrations (Morimoto *et al.*, 1967; Meyer *et al.*, 1992). Sweat glands reabsorb sodium by active transport, but the ability to reabsorb sweat sodium does not increase proportionally with the sweating rate. As a result, the concentration of sweat sodium increases at high sweating rates (Allan and

**FIG. 32.4** Daily water needs and required daily sodium intake estimated from sweat-loss predictions as a result of changes in physical activity and air temperature. Daily energy expenditures of A = 3600 kcal/day, B = 2900 kcal/day, C = 2400 kcal/day, and D = 1900 kcal/day corresponds to very active, active, low activity, and sedentary. Adapted from Institute of Medicine (2005).

Wilson, 1971; Costill *et al.*, 1975; Buono *et al.*, 2008). Heat acclimation improves the ability to reabsorb sodium, thus heat-acclimated persons have lower sweat sodium concentrations (>50% reduction) for any given sweating rate (Allan and Wilson, 1971).

Generalized modeling approximations for daily sodium needs based upon calculated sweating rates as a function of daily energy expenditure (activity level) and air temperature (Institute of Medicine, 2005) are presented in Figure 32.4. This analysis assumes that persons are heat acclimated and have a sweat sodium concentration of 25 mEq/L (about 0.6 g/L). The average American diet contains ~4 g/day sodium (Institute of Medicine, 2005) but varies greatly depending upon ethnic preferences for food. Increases or decreases in sodium stores are usually corrected by adjustments in a person's salt appetite. In addition, when physical activity increases, the additional caloric intake associated with increased activity usually covers the additional sodium required (Institute of Medicine, 2005). Therefore, sodium supplementation is generally not necessary, as normal dietary sodium intake appears adequate to compensate for sweat sodium losses (Sawka *et al.*, 2007). There are two exceptions: first, prolonged heavy sweating can produce substantial salt losses, and secondly, for those unacclimated to the weather, during the first few days of warm/hot weather as they will be secreting saltier than usual sweat. Salting food to taste is usually an adequate solution in these circumstances. Another strategy is to rehydrate with fluids containing ~20 mEq/L of sodium. Most commercial sports beverages approximate this concentration (Sawka *et al.*, 2007).

## Fluid Replacement

The 2007 American College of Sports Medicine Position Statement on Exercise and Fluid Replacement (Sawka *et al.*, 2007) summarizes current knowledge regarding fluid and electrolyte needs and the impact of their imbalances on performance and health. This statement stresses the fact that individuals have varying sweat rates, and individual fluid needs can be very different despite performing a similar task in nearly identical environmental conditions. The ACSM Position Statement also provides recommendations in relation to hydration prior to, during, and following exercise/activity. Briefly, the objective is to begin physical activity euhydrated and with normal plasma electrolyte levels. If sufficient beverages are consumed with

meals and a protracted recovery period (8 to 12 hours) has elapsed since the last exercise session, then the person should already be close to being euhydrated (Institute of Medicine, 2005). During exercise the objective is to drink enough fluid to prevent excessive dehydration (>2% body mass loss) to accrue and compromise performance. The amount and rate of fluid replacement depends upon an individual's sweating rate, the exercise duration, and opportunities to drink. It is recommended that individuals should monitor body mass changes during training/activity to estimate their sweat lost during a particular exercise task with respect to the weather conditions.

Carbohydrate consumption can be beneficial to sustain exercise intensity during high-intensity exercise events of ~1 hour or longer, as well as less intense exercise/activity sustained for longer periods (Coyle and Montain, 1992). Carbohydrate-based sports beverages are used to meet carbohydrate needs, while attempting to replace sweat water and electrolyte losses. Carbohydrate solutions of 5–10% consumed at a rate of 1 L per hour would approximate a consumption rate of 1 g per minute, which has been demonstrated to maintain blood glucose levels and exercise performance (Coyle and Montain, 1992). The greatest rates of carbohydrate delivery have been achieved with a mixture of simple sugars (e.g. glucose, sucrose, fructose, maltodextrin).

The Institute of Medicine also provides general guidance for composition of "sports beverages" for persons performing prolonged physical activity in hot weather (Institute of Medicine, 1994). The need for these different components will depend on the specific exercise task (e.g. intensity and duration) and weather conditions, and can be met using non-fluid sources such as gels, energy bars, and other foods. Following activity, consumption of normal meals and snacks with a sufficient volume of plain water will restore euhydration, provided the food contains sufficient sodium to replace sweat losses (Institute of Medicine, 2005). If hypohydration is substantial (>2% body mass loss) with a relatively short recovery period (<4–6 hours), then an aggressive rehydration program may be merited (Maughan *et al.*, 1996).

In most cases of gastrointestinal tract disturbances that result in diarrhea and/or vomiting (~1 day), typical intake of food and fluid over the course of a few days will correct fluid and electrolyte losses. However, when these maladies are left untreated, prolonged bouts (>1 day) may require a unique fluid replacement strategy. Severe hypohydration

of this type can require intravenous rehydration and hospitalization. However, when possible, oral rehydration with an oral electrolyte solution is the treatment of choice and is recommended by the World Health Organization (1995). While sport drinks contain carbohydrate and electrolytes, they are specifically designed for situations of hypertonic hypovolemia. The fluid and electrolyte losses resulting from diarrhea and/or vomiting (isotonic dehydration) can be more rapidly corrected with oral rehydration solutions containing 50–90 mEq per liter of sodium and ~20 mEq per liter of potassium, and ingested with complex carbohydrates (World Health Organization, 1995).

## Future Directions

The ability to assess hydration state is vitally important in clinical, occupational, and sport settings. Further work is required to develop simple, accurate, non-invasive technologies or methods that can assess hydration state without the need for baseline or repeated measures.

A wide range in the percent decrement of aerobic exercise performance due to dehydration has been reported in the literature. Further work is needed to more precisely define the specific impacts of dehydration on aerobic exercise performance.

In the scientific literature a number of chronic health conditions have been suggested to be associated with hydration, including kidney stones, gallstones, bladder, colon and other cancers, arrhythmias, and blood clots among other conditions. Further work is required to determine if any link between hydration state and these and other conditions exists.

The etiology of skeletal muscle cramps has been debated in the scientific literature. Dehydration and sodium deficits have been proposed as a causal mechanism. Further work is required to determine the relationship between dehydration/sodium deficits and skeletal muscle cramps.

## Acknowledgments

The authors would like to thank Kurt Sollanek for technical assistance in preparing this chapter. The views, opinions, and/or findings contained in this chapter are those of the authors and should not be construed as an official Department of the Army position, or decision, unless so designated by other official documentation. Approved for public release; distribution unlimited.

## IRON

PETER J. AGGETT, MSc, FRCP, FRCPCH

*Lancaster University, Lancaster, UK*

### Summary

Iron is essential for energy metabolism, mixed-function oxidase systems, neurodevelopment and function, connective-tissue synthesis, hormone synthesis, and antioxidant activity. Over 80% of systemic iron is involved in acquiring and delivering oxygen (hemoglobin), or storing it (myoglobin) to support systemic metabolism. Since iron has such diverse and fundamental roles, the effects of iron deficiency can be protean, subtle, and difficult to distinguish from other nutrient deficiencies; however, anemia and compromised physical performance, psychomotor development, and immune function are important consequences. The systemic trafficking and use of iron exploit its interchange between ferrous and ferric states, and protect tissues from the oxidative damage that ionic iron can cause. The protection involves minimizing the entry of iron into the body by down-regulating absorption of iron, and by a tight recycling of systemic iron. Iron needed to replace losses is gained by derepressing the absorption of iron. Any immune activation overrides iron-responsive homeostasis, and creates a functional iron deficiency called the anemia of chronic disease. This adaptation makes it difficult to assess iron deficiency and the efficiency of iron absorption from foods. Similar issues arise from the natural adaptations of iron turnover that occur in children and pregnant women. The causes of iron deficiency and the population groups at risk are the same as for other nutrients. Iron deficiency is likely to be accompanied by other deficiencies, and many studies inappropriately attribute anemia and its accompanying defects to iron deficiency alone. A major cause of such deficiencies is blood loss secondary to intestinal infestations. WHO reports have emphasized these points in relation to therapeutic and preventive strategies to reduce the prevalence of iron deficiency. If they were to be eradicated, there would be less need for concern about the quantity and availability of iron intakes.

### Introduction

Sources for unreferenced material in this chapter can be found in the suggestions for further reading. Iron (atomic weight 55.85, atomic number 26) comprises 6.2% of the

Earth's crust and is the fourth most common element, after oxygen, silicon, and aluminium. Iron binds strongly to oxygen, and its most abundant ores, magnetite and hematite, are both oxides (Earnshaw and Greenwood, 2010). Iron also complexes with sulfur and nitrogen, forming

iron–sulfur clusters (ISCs) comprising four-coordinated iron with four or fewer sulfur atoms, and heme, which is a six-coordinated iron within a porphyrin ring. These molecules may have contributed to the origin of life and to the subsequent genesis of atmospheric oxygen (Theil and Goss, 2010). Iron enters the food chain through its mobilization from geochemical sources by bacterial siderophores (Doherty, 2007).

Iron's oxidation states range from  $-2$  to  $+6$ : ferrous ( $\text{Fe}^{2+}$ ) and ferric ( $\text{Fe}^{3+}$ ) are the most biologically relevant. Ferrous iron is easily oxidized by oxygen to ferric iron. However, the process, involving the Haber–Weiss–Fenton reactions:

also produces oxidative radicals, which damage proteins, nucleic acids, lipids, and carbohydrates, and generate more reactive species including sulfur and nitrogen radicals. Organisms have evolved chains of carriers by which iron is distributed to its functional sites, with minimal risk of oxidative damage and simultaneously overcoming problems arising from the poor solubility of iron, particularly ferric iron, at physiological pH. The effectiveness of this system is evident in that the intracellular concentration of iron at  $10^{-4}$  M is far higher than the aqueous solubility of ferric iron ( $10^{-18}$  M) (Theil and Goss, 2009), and intracellular free iron is restricted to  $10^{-24}$  M (Doherty, 2007).

## Functions of Iron

The biological functions of iron are achieved via four categories of metalloproteins: (1) the globin–heme, non-enzymatic ferroproteins (e.g. hemoglobin, myoglobin, and neuroglobin); (2) heme enzymes which are involved with electron transfer (e.g. cytochromes a, b, and c, cytochrome c oxidase) and oxidase activities (e.g. cytochrome P450 (mixed-function) oxidases, myeloperoxidase, peroxidases, catalase, and sulphite oxidase); (3) iron–sulfur clusters involved in electron transfer in energy production (succinate, isocitrate and NAPH dehydrogenases, and aconitase) and oxidoreductase activities (e.g. xanthine oxidase); and (4) activities that depend on iron as a cofactor (e.g. phenylalanine, tyrosine, and tryptophan hydroxylases, and proline and lysine hydroxylases).

Globin–hemes are transporters of oxygen, carbon dioxide, carbon monoxide, and nitric oxide (e.g. hemo-

globin and neuroglobin), stores of oxygen (e.g. myoglobin and neuroglobin), and scavengers of free radicals (Brunore and Vallone, 2006). Heme is made in mitochondria where  $\text{Fe}^{2+}$  iron is inserted into protoporphyrin IX whose synthesis is completed in mitochondria. Most heme is incorporated into hemoglobin, but there are carriers which export heme to avoid its excess accumulation in mitochondria, or to support cytosolic production of heme enzymes. The reactivities of individual heme proteins are determined by interactions between the two components, e.g. in heme enzymes, iron switches between  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  whereas this does not happen with globin–heme proteins.

Hemoglobin is a tetramer comprising two pairs of  $\alpha$ - and  $\beta$ -globin–heme units, each of which bind a molecule of oxygen; thus a molecule of hemoglobin transports four oxygen molecules which is 1.34 mL of oxygen per gram of hemoglobin, and as a result blood carries 50–70 times more oxygen than would plasma alone. Erythrocytic hemoglobin binds and releases oxygen, forming oxyhemoglobin and deoxyhemoglobin, respectively; the process depends on a histidine molecule in the globin which coordinates with the heme iron and controls its spin state. The iron is in a low spin state at the pulmonary alveolar–capillary interface, where, relative to the peripheral tissues, the  $p\text{O}_2$  is high, the  $p\text{CO}_2$  is low, and the pH is less acidic. This and a conformational change in the globin enable the unit to accommodate and bind oxygen without the ferrous iron becoming oxidized. In peripheral tissues, the higher  $p\text{CO}_2$ , lower  $p\text{O}_2$ , and more acidic milieu protonate the histidine, which switches the iron to a high spin state, reducing its affinity for oxygen, which is released. This phenomenon, including its enhancement by cooperativity between the hemoglobin subunits, is known as the Bohr effect. The release of oxygen is also facilitated by phosphate anions, higher temperature, and 2,3-diphosphoglycerate, a glycolytic product, which displaces oxygen from heme. Deoxyhemoglobin is able to transport carbon dioxide to the lungs, but because  $\text{CO}_2$  is highly soluble in plasma this mechanism accounts for only 15–20% of carbon dioxide excretion. The fetus has a form of hemoglobin which has a higher affinity for oxygen than adult hemoglobin. This enables the fetus to acquire oxygen from maternal hemoglobin at the placenta and subsequently to release it in the low  $p\text{O}_2$  in utero.

Myoglobin is a monomeric, mainly muscle, store of oxygen. It functions analogously to hemoglobin but the heme–globin complex is adapted to function in the ambient  $p\text{O}_2$ , pH, and  $p\text{CO}_2$  of muscle.

Cytochrome P450 oxidase is not a single entity. There are over 11 000 activities involving a diverse range of metabolic pathways and substrates. These include phase I metabolism of xenobiotics, and the metabolism of endogenous substrates including organic acids, fatty acids, prostaglandins, steroids, and sterols including cholesterol, and vitamins A, D, and K.

The citric acid cycle and respiratory chain involves six different heme proteins and six iron–sulfur centers, as well as copper-based electron transfer from cytochrome c to

cytochrome c oxidase at the ultimate transfer of electrons to molecular oxygen.

## Iron: Systemic Distribution and Turnover

Adult women and men contain 3.5–4 g iron, which represents about  $4.3 \times 10^{22}$  atoms of iron to underpin its functions. The iron (see Figure 33.1) is distributed as hemoglobin: 3000–3500 mg; myoglobin: 400–500 mg;

**FIG. 33.1** Diagrammatic representation of iron turnover in the body: there is a cycle centered principally on the use and reuse of endogenous iron to sustain hemoglobin concentrations in the erythrocytes, alongside a smaller pool in other tissues which turns over as the tissues are renewed. The major depots of iron are in the liver and reticulo-endothelial system as ferritin and hemosiderin, muscle and other organs, and the red-cell hemoglobin. Iron is lost from the gut in shed enterocytes and minor blood loss, and from integumental loss which amounts to about 1–2 mg/day. This loss, and other needs to replace menstrual loss or to support the synthesis of new tissue, are replenished by intestinal uptake and transfer. Blood from the spleen mixes with that from the intestine in the portal circulation and enters the liver where the hepatocytes are able to sense the transferrin iron load and adjust the production of hepcidin secretion to control the absorption of iron. Cp, Ceruloplasmin; Dcytb, duodenal cytochrome B reductase; DMT1, divalent metal transporter 1; FPN, ferroportin; FTN, ferritin; HO1, haemoxygenase 1; Hp, hephaestin; ISC, iron–sulfur cluster; TFR, transferrin receptor;  $\nabla$ , apotransferrin;  $\nabla$ , transferrin.

heme and non-heme enzymes: 100 mg; ferritin and hemosiderin: 1000 mg; transferrin: 3 mg; and an intracellular or transit pool: 7 mg. The body cannot excrete iron; systemic iron is efficiently conserved and recycled, and basal losses, losses from menstruation, and the needs for the synthesis of new tissue are balanced by adjustments in gastrointestinal absorption. Thus only a small proportion of dietary iron needs to be absorbed.

Ferritin is an iron depot found in the cytosol and mitochondria of all cells. It is a hollow sphere of 24 apoferritin subunits with six channels through which iron can enter and leave the molecule. There are two types of subunits, heavy (H) and light (L), and the ratio of these influences the mobility of the iron and varies between organs. H chains predominate in the heart and brain, and L chains in the liver and spleen. H chains have ferroxidase activity which facilitates storage of iron as a ferric hydroxyphosphate. Each ferritin molecule can reversibly bind up to 4500 atoms of iron but usually only 20–50% of this capacity is occupied. Mitochondrial ferritin has a 75% homology to H ferritin and a smaller homology to L ferritin. Ferritin may be an iron reserve, but it also rapidly sequesters iron in response to inflammation, ionic iron, and the risk of oxidative damage. Hepatocytic ferritin is a depot to top up the systemic cycle and is the primary repository of excess iron. The other large ferritin pool, in the reticulo-endothelial system (RES), is part of the endogenous recycling pool of iron supporting the erythron. Ferritin is degraded by proteasomal lysis and the iron is recycled. However, with chronic iron excess or inflammation, accumulated ferritin is incompletely degraded, producing hemosiderin which contains iron that is not mobilizable but which may still cause oxidative damage.

Transferrin (TFN) is the main carrier of iron in the circulation and extracellular space, distributing iron to cell-surface transferrin receptors (TFRs) on erythroblasts and other tissues. It is synthesized principally in the liver as a sialylated glycoprotein, apotransferrin, which binds one or two ferric molecules. Its degree of sialylation affects its function; in pregnancy it is highly sialylated, favoring uptake of iron by the placenta, whereas, if there is less sialylation – as happens with infections or eclampsia – it binds TFRs less effectively.

The recycling of endogenous iron involves about 35 mg of iron daily and is at least 90% efficient; hence the body only needs to absorb enough iron to replace basal losses (~14 µg/kg body weight per day), which approximates to 1–2 mg/day.

The systemic turnover of iron recycles iron in tissues; the major focus is the salvage and recycling of the heme iron in the erythron. About  $10^{11}$  senescent red cells are phagocytosed daily, mostly by macrophages in the spleen. The heme is degraded by macrophage hemoxygenase to iron, biliverdin, and carbon monoxide. One gram of hemoglobin contains 3.47 mg of iron, and the released iron is then either deposited in the macrophages' ferritin or exported as ferric iron by a membrane carrier, ferroportin (FPN), to apotransferrin for transit elsewhere. Heme is potentially toxic because, without the globin molecule to control it, heme iron is an active oxidant. However, there is a protein, hemopexin, which scavenges any free heme in the plasma and delivers it to hepatocytes for degradation.

There are two types of TFR. TFR1 is in all tissues, but is most dense on erythroblasts, lymphoid cells, and the neuroepithelium, and TFR2 is mainly located on the hepatocytic basolateral membrane and is a sensor for iron homeostasis.

The transferrin–TFR1 complexes are endocytosed. Any local cellular need for iron up-regulates both TFR1 and the cytoskeletal support for endocytosis. The endosome is acidified, and at pH 5.5 the ferric iron is released and reduced and the resultant ferrous iron is transported with a proton into the cytoplasm by a divalent metal transporter 1 (DMT1) located on the endosomal membrane. There is also a separate, DMT1-independent means (using transient receptor potential cation channel, mucolipin subfamily [TRPML.1] protein) of translocating iron across the endosomal membrane. The residual endosomal complex returns to the cell surface. It is not clear how iron is trafficked in the cytosol: it is part of a poorly characterized, labile iron pool. However, a chaperone, poly(rC)-binding protein 1 (PCBP1), has been identified which delivers ferrous iron to ferritin. Iron is also passed to sites for the synthesis of ISCs and enzymes, or is conveyed to mitochondria where it binds to a mitochondrial carrier, mitoferrin, and is distributed to mitochondrial ferritin, used to synthesize ISCs, or transferred to ferrochelatase which places ferrous iron into protoporphyrin IX to make heme (Richardson *et al.*, 2010).

## Iron Absorption: Gastrointestinal Mucosal Uptake and Transfer

Separate mechanisms exist for the mucosal uptake of non-heme iron, heme iron (mainly from meat), and ferritins. Lactoferrin and other ferritins are not significant dietary

sources of iron. Gastrointestinal acidity and proteolysis may release non-heme iron from its matrix, but more extensive digestion might be needed to release heme and ferritin. It is possible therefore that the routes for the uptake of the three forms of iron are differently distributed along the intestine. Ferric and ferrous irons are most soluble in acid conditions, and non-heme iron is predominantly absorbed as ferrous iron in the proximal duodenum, i.e. before hepato-pancreatic secretions increase the luminal pH. None the less non-heme iron can be absorbed in the distal intestine.

Mucosal uptake of ferrous iron involves the aggregation of iron by the surface mucus and glycocalyx of the epithelial brush border. Any ferric iron is converted by a brush-border ferrireductase, duodenal cytochrome B reductase (DcytB), to ferrous iron which is then co-transported, with protons, across the brush-border membrane by an enterocytic DMT1. There may be another pathway for the uptake of ferric iron from mucin but this has not been fully characterized (Conrad and Umbreit, 2002).

Ferritin in an intact or partly degraded form is taken up by carrier-mediated endocytosis in the small intestine (Lönnerdal, 2009). Heme is only soluble at neutral or alkaline pHs such as those of the jejunum and ileum, but as yet a definitive carrier for its uptake has not been characterized. A candidate heme carrier protein, which is distributed throughout the small intestine, has been isolated, but it is probably a folate transporter, unless it has both functions. The relative importance of the uptake mechanisms is currently unclear, but it is noteworthy that DMT1-deficient mice absorb iron well.

Iron taken up in heme is released by an enterocytic hemoxygenase and joins a common transit pool of ferrous iron with non-heme iron, and, probably, that from ferritin. The ferrous iron is transported by an uncharacterized mechanism to the basolateral membrane where it is exported by FPN and oxidized either by plasma ceruloplasmin or by a related copper-dependent oxidase, hephaestin, which is co-located with ferroportin. The resultant ferric iron then binds to apoferritin and is distributed via the portal and systemic circulations. Eighty percent of transferrin iron is delivered for hemoglobin synthesis, and the half-life of the iron in plasma is about 75 minutes.

## Iron Homeostasis: the Regulation of Iron Acquisition and Distribution

Iron homeostasis is controlled at cellular and systemic levels, and is sensitive to the need for iron, hypoxia, and

inflammation. The response to inflammation can override adaptation to an inadequate iron supply.

### Homeostasis of Cellular Iron

Cellular iron homeostasis is mediated by two iron-responsive proteins (IRP1 and IRP2) which bind to iron-responsive elements (IREs) on untranslated regions (UTRs) of mRNAs for proteins involved in iron kinetics. When iron supply is limited, IRP1 binds the 5'UTR and represses the translation of the mRNAs for the two apoferritin chains, ferroportin, hypoxia-inducible factor 2 $\alpha$  and  $\alpha$ -levulinic acid synthetase which is the initial and rate-limiting enzyme in heme synthesis. This stops ferritin sequestration of iron, and FPN export of iron, and reduces its use by inhibiting synthesis of erythropoietin and heme; simultaneously, IRP binding to the 3'UTR of the mRNAs for TFR1, DMT1, and an organizing molecule for the actin cytoskeleton necessary for endocytosis, prevents nucleolysis and sustains production of the cellular apparatus for the uptake of iron (Richardson *et al.*, 2010; Ye and Rouault, 2010).

If cells have an adequate supply of iron, the IRPs dissociate from the IREs and their synthesis is reduced. IRP1 exists in two forms. In one, when iron supply is adequate, IRP1 binds a cytosolic ISC forming a complex that has aconitase activity. When there is a cellular lack of iron, the aconitase disassembles and IRP1 binds to its IRE. IRP1 may also be controlled by the same mechanism as IRP2. This involves F-box/LRR-repeat protein 5 (FBXL5), a highly conserved protein analogous to an oxygen-binding non-heme protein, hemerythrin, found in invertebrates and bacteria. In iron-replete cells FBXL5 enables the proteasomal lysis of IRPs, but in the absence of iron FBXL5 is unstable and unable to stimulate proteolysis of IRP2 and IRP1, which are then available to bind to the IREs (Richardson *et al.*, 2010; Ye and Rouault, 2010). This iron-responsive intracellular homeostasis of iron is disrupted by inflammation; reactive oxygen and nitrogen radicals, nitric oxide and phosphorylation inhibit the formation of cytosolic aconitase from IRP1, irrespective of any need for iron.

### Homeostasis of Absorption and Systemic Turnover of Iron

The gastrointestinal absorption of iron is regulated in response to systemic needs for iron, and as part of the response of iron turnover to inflammation and some stressors. The intestinal mucosal uptake and transfer of all three

forms of dietary iron are inversely related to systemic serum ferritin concentrations, particularly at values below a threshold of 60  $\mu\text{g/L}$ . The elements of this control are achieved through transcriptional control of the carriers involved in iron acquisition and distribution during cell production. The expression of DMT1 and FPN would be set when macrophages are produced in the RES, or when enterocytes are produced by enteroblasts in the epithelial crypts. Further control is provided by a hormone, hepcidin, and by cellular mechanisms.

Hepcidin is synthesized by hepatocytes and, to a lesser extent, by monocytes, macrophages, and adipocytes, as an 84 amino acid prepropeptide, which is subsequently modified to a prohormone and then to the active hormone of 25 amino acids (Nemeth and Ganz, 2009). Hepcidin is down-regulated by increased iron needs and by hypoxia, and is up-regulated by inflammation. It blocks the export of iron from enterocytes and macrophages by inducing the degradation of FPN. It also reduces DMT1 activities. The iron retained in the cells is sequestered in ferritin and, in the case of enterocytes, the iron is subsequently lost into the gut lumen when the cells are shed. The hepatic sensory regulation of hepcidin expression involves an interaction of HFE (a membrane-bound protein which has long been known to be linked with hereditary hemochromatosis), TFR1, and TFR2: usually HFE is associated with TFR1, but it can be displaced by transferrin. If this happens, HFE binds instead to TFR2, and the HFE–TFR2 complex activates a membrane complex of a bone morphogenic protein (BMP6) and haemojuvelin (HJV), which co-stimulate phosphorylation and activation of a transcription factor for the expression of hepcidin. This stimulus is inhibited by proteolysis of HJV by a membrane-bound protease, matriptase, but it is not known how this is regulated. In hypoxic conditions, including iron deficiency and anemia, hypoxia-inducible factor (HIF) depresses hepcidin expression and stimulates erythropoiesis, thereby ensuring an iron supply for red cell production. In inflammatory states interleukins 1 and 6 stimulate hepcidin production.

The generic cellular control of iron homeostasis operates also in the enterocyte, and high levels of iron in the mature enterocyte induce ferritin by local control mechanisms. This sequesters iron and blocks its transfer to the portal circulation, thereby reducing the risk of systemic iron overload. Additionally, enterocytes have an isoform of FPN which is not down-regulated if the cells are iron deficient; this enables intestinal transfer of iron in iron deficiency.

## Inborn Disorders of Iron Kinetics and Use

The hemochromatoses include at least five inherited overload syndromes arising from unregulated absorption of iron caused by defects in HFE, HJV, hepcidin, TFR2, and FPN (Pietrangelo 2004; OMIM, 2012). Dysregulation of iron turnover also results from loss of ceruloplasmin, matriptase, transferrin and defective sialylation of transferrin and from defects in proteins involved with the assembly of iron–sulfur clusters and intracellular trafficking of iron. The latter causes functional and structural defects of the heart, central nervous system (Friedrich's ataxia), muscle (myopathies), red cell formation (sideroblastic anemias), and mitochondrial function (Ye and Rouault, 2010; OMIM, 2012).

## Influence of Inflammation on Iron Kinetics

Activation of the immune system by chronic and acute infections, malignancy, inflammatory conditions in the bowel, joints, and kidneys, and even low-grade inflammatory states such as obesity, induce an adaptive state called the anemia of chronic disease (ACD) (Weiss and Goodnough, 2005). ACD is manifest as a mild anemia (hemoglobin 80–95 g/L) that is unresponsive to iron, with normal red-cell indices and reduced erythropoiesis; a normal or elevated serum ferritin accompanied by subnormal serum values of iron; a normal or reduced serum value of transferrin, which has a low saturation with iron; normal values for TFR1; and a ratio of serum transferrin receptors/log ferritin concentrations  $<1$  (Weiss and Goodnough, 2005). These changes are mediated by inflammatory cytokines (interferon- $\gamma$ , tumor necrosis factor- $\alpha$ , and interleukins) that up-regulate hepcidin, and by the cellular responses to reactive species. Collectively these increase the uptake and sequestration of iron by cells, especially macrophages, and block its export by FPN. The inflammatory mediators stimulate phagocytosis of senescent red cells and reduce erythropoietin production and effectiveness by direct actions on the kidneys and erythroblasts. Increased output of hepcidin reduces the absorption of iron and augments the signals for the retention of iron by macrophages. The adaptation may have evolved as a protection against damage caused by “free iron” liberated by tissue damage, and to deny pathogens access to iron (Doherty, 2007). ACD can become sustained and lead to a significant paradoxical functional iron deficiency syndrome

despite there being appreciable amounts of iron in tissue depots (Weiss and Goodnough, 2005).

## Iron and the Infant

Neonates have 150–250 mg of iron and hemoglobin levels of 160–180 g/L. They adapt to the higher  $pO_2$  ex utero, by reducing synthesis of fetal haemoglobin, the levels of which fall to 90–110 g/L at 3–4 months. At 4–6 months of age, hemoglobin production resumes with the synthesis of adult hemoglobin. The degraded hemoglobin releases 50–60 mg of iron which is deposited in reticuloendothelial ferritin. In early infancy serum ferritin concentrations are as much as 400  $\mu\text{g/L}$ ; these fall to about 30  $\mu\text{g/L}$  as the endogenous iron depot is used for new tissue synthesis. Therefore there is a risk of iron deficiency at 6–9 months; however, the iron reserve can be increased by 30–50 mg of iron if, at birth, the cord is not clamped until it has stopped pulsing, thereby letting these late pulsations transfer the 32% of the neonate's blood volume which is in the fetal circulation of the placenta back to the baby (McDonald and Middleton, 2008). Thus until 6 months of age, healthy babies have little if any need for iron from external sources (Ziegler *et al.*, 2009). Compared with that available from its systemic depots, relatively little iron is received by babies from breast milk, the iron content (0.2–0.4 mg/L) of which is not altered by either maternal iron deficiency or supplementation. Intestinal absorption is down-regulated until 6 months of age when infants become more reliant on exogenous iron.

## Iron and Women in Their Reproductive Years

The demands of menstruation, pregnancy, lactation, and, in adolescence, growth on iron homeostasis and iron requirements are uncertain. There are concerns that women may be at risk of inadequate iron supply because contemporary lifestyle and diets favor reduced energy expenditure and the consumption of diets with a lower iron density than those on which humans evolved (Hallberg and Hulthen, 2002).

Menstrual blood loss of adolescent girls is marginally less than that of older women, and in nutritional risk assessments of iron nutriture it is assumed that adolescent menstrual losses match those in adult women. There is little intra-individual variation in blood loss but considerable interindividual variation. Estimates of menstrual loss

in different countries are consistent in showing that 95% of women lose 118 mL or less per cycle with median and mean losses of 30 mL and 44 mL respectively: these equate to iron losses of 0.49 mg and 0.7 mg/day (Hallberg and Hulthen, 2002). Intrauterine devices increase menstrual blood loss two- to fourfold, whereas oral contraceptive users have smaller median menstrual blood and iron losses (e.g. 18 mL/cycle and 0.26 mg/day) with mean losses of 26 mL/cycle and 0.43 mg/day. There is an inverse correlation between menstrual blood loss and serum ferritin concentrations; on average an increase in menstrual iron loss of 1 mg/day is associated with a reduction in serum ferritin of 7  $\mu\text{g/L}$ .

## Measuring Iron Status

Adequate iron status (i.e. sufficiency) implies having normal erythropoiesis and iron functions that are not limited by iron supply, as well as having a reserve. There is no single unequivocal marker of iron deficiency or excess, except, perhaps, for serum ferritin at extreme deficiency or excess. Assessment of deficiency and excess relies on the use and interpretation of markers of (1) functional iron, i.e. hemoglobin concentrations (Table 33.1), and indices of reduced red-cell mean cell volume (MCV; 80–94 fL) and mean cell hemoglobin (MCH; 27–32 pg); (2) the adequacy of iron supply to tissues, serum iron (10–30  $\mu\text{mol/L}$ ), transferrin saturation (16–50%), red-cell zinc protoporphyrin (>80  $\mu\text{mol/mol Hb}$ ), and serum transferrin receptors; and (3) tissue depots, indicated by serum ferritin concentrations (males 15–300  $\mu\text{g/L}$ , and females 15–200  $\mu\text{g/L}$ ). Each of these markers is subject to con-

**TABLE 33.1** Hemoglobin thresholds used to define anemia at sea level

Group	Hemoglobin (g/L)
Children	
0.5–4.99 years	110
5–11.99 years	115
12–14.99 years	120
Non-pregnant women >15 years	120
Pregnant women	110
Men (>15 years)	130

Values for those of African heritage are 4–10 g/L lower than those of Caucasian origin. A further amendment used by the WHO classifies anemia as mild, moderate, or severe, according to whether the values are above 80%, 80–60%, or below 60% of the appropriate population threshold.

founding, particularly from coexistent infections and nutritional deficiencies (Gibson, 2005). An approach was developed for NHANES II using combinations of markers such as serum ferritin, transferrin saturation, and erythrocyte protoporphyrin, or MCV, transferrin saturation, and erythrocyte protoporphyrin: individuals with two or more abnormal values in either trio could be considered iron deficient. Other approaches use hemoglobin, serum ferritin values, and serum transferrin receptors coupled with C-reactive protein and alpha-1-acid glycoprotein as indicators of acute and chronic inflammatory disease (World Health Organization/Centers for Disease Control and Prevention, 2004). The sTfR/log ferritin ratio may be a marker of iron depots; positive ratios indicate that stores are present whereas negative values do not. The ratio may be less influenced by inflammation, and an algorithm based on serum thresholds and sTfR/log ferritin ratios to differentiate iron-deficiency anemia and anemia of chronic disease, or a combination of the two, has been proposed (Weiss and Goodnough, 2005). Diagnosing iron deficiency on the basis of the response to an iron supplement is unreliable if ACD or additional nutrient deficiencies are present.

Each  $\mu\text{g/L}$  of serum ferritin in the circulation is equivalent to 7–10 mg of stored iron. Serum ferritin originates from the RES macrophages and not from hepatocytes; the value therefore underestimates total systemic ferritin iron, and since hepatocytes are the first tissue to accumulate any surplus iron, serum ferritin is a poor marker of early iron overload.

## Dietary Sources of Iron

The proportions of non-heme iron, heme, and ferritin in the diet reflect the relative intakes of animal and plant material, and usually non-heme sources predominate. Generally meats and plants are similar sources of iron: the richest include cereals, pulses, vegetables, nuts, shellfish, fish, and meat. Cereal sources may contribute about 40% of iron intake, and about half of that may come from iron fortification of breakfast cereals. Additionally non-heme iron is acquired as fortification or restoration of iron lost during processing, and from contamination. The latter arises from extrusion processes and from cast-iron cooking utensils, particularly if citrate or similarly acidic ingredients are used.

Iron is present in many forms in plants, including complexes which may either enhance or reduce its availability

for mucosal uptake. The iron content of plant cultivars varies appreciably. An example is that of non-aromatic rice which contains about 11 mg/kg compared with 18 mg/kg in aromatic rice. The proportion of total iron coming from heme in meat is also variable. The heme content of foods is measured indirectly as the difference between an initial assay of inorganic iron content and a subsequent measurement of the total iron content of the sample. The proportion of total iron derived from heme in meat ranges in beef from 64% to 78% and between 52% and 83% in other red meats. Cooking reduces the water and fat content of meat, thereby increasing the iron content on a weight-for-weight basis.

The above points illustrate sources of uncertainty in food composition data on iron. Additionally composition reference data do not provide information from which the effect of the food matrix on the availability of iron could be assessed.

## Bioavailability of Iron

The efficiency with which dietary iron is utilized in the body is influenced by (1) the physico-chemical form of iron; (2) dietary factors affecting the amount of luminal iron that is available for intestinal uptake, both of which are dietary factors (Hallberg and Hulthen, 2002; Hurrell and Egli, 2010); and (3) the homeostatic settings of the mucosa to take up and transfer iron to the body, both of which adapt to the body's need for iron, and to inflammation (i.e. ACD).

Non-heme iron compounds that are soluble in acid are most available in the proximal gut lumen. Inhibitors of non-heme iron's availability include phytates found in whole-grain cereals, legumes, nuts, and seeds, and other phosphates (e.g. caseins) whose effects may be exacerbated by calcium and magnesium. Polyphenols found in tea, particularly black tea, and coffee are more powerful inhibitors than those from herb teas, cocoa or red wine; perhaps because they have higher levels of galloyl esters and tannates. Adding milk to black tea or coffee does not improve the availability of iron.

Practices such as soaking, germination, or fermentation before cooking may enable intrinsic phytase to break down phytate. Cooking itself may improve the solubilization of iron by physically degrading phytate; this would be particularly appropriate for oats which have little phytase activity. It is difficult to predict the effect of processing on the bioavailability of iron; for instance, milling grain

removes its husk which is rich in phytate, but also removes much of the iron content. Thus, although the processing may have improved availability, there may not be enough iron left for that to be of any benefit.

Bioavailability of non-heme iron is enhanced by organic acids such as ascorbic acid, malic acid, tartaric acid, lactic acid, and citric acid, which occur naturally in fruit and vegetables and in fermented products. Heat processing may destroy some of these. Meat improves the uptake of non-heme iron, but it is not clear how this is achieved.

Bioavailability enables dietary sources of iron to be ranked; however, quantitative values of availability cannot be extrapolated to a food or diet universally, partly because of uncertainties about the dietary characteristics, and importantly also because of systemic adaptation. The use of dietary characteristics to derive equations and models to predict the bioavailability of iron are of limited value (Beard *et al.*, 2007).

The principal determinants of bioavailability of iron are usually the systemic need for the element and the homeostatic setting for the absorption of iron. The effects of inhibitors and enhancers on bioavailability are often overestimated because they have used single-meal studies, and have made no allowance for adaptation, which might take 3–7 days, or the iron status of the study subjects.

Fortunately, in the case of iron, it is possible to use isotopes differentially to correct for the subjects' iron status and gut adaptation. The dietary components of bioavailability are of particular importance when intestinal adaptation is not sufficient to acquire enough iron to meet systemic needs for the metal. This is important in planning management strategies for endemic iron deficiency, and in the assessment of intake reference values.

## Iron Intake Reference Values

Table 33.2 gives two sets of reference dietary intake values for iron (European Commission Scientific Committee for Food, 1993; Institute of Medicine, 2001). The advisory groups involved explain the bases for their values, and describe the limitations of the data which they had available. The values support public health measures and are cautious, and although they support assessments of dietary intakes, they are not diagnostic of iron deficiency or excess. The discrepancies between the two sets of recommendations arise in the areas of most uncertainty, which are the needs of children and of menstruating, pregnant, and lactating women, and the impact of homeostatic adaptation on the bioavailability of iron. The uncertainties in the reference values, composition tables, and status determina-

tion are reflected in the lack of congruence between population surveillance data on iron intakes, the apparent prevalence of iron deficiency, and dietary reference values (Scientific Advisory Committee on Nutrition, 2011).

## Iron Deficiency

Inadequate intakes of iron relative to needs may occur during periods of rapid growth, particularly in infancy, early childhood, and adolescence. Inappropriate diversification of diet, the use of cows' milk or of low-nutrient-density foods, or inappropriate vegetarian diets are common causes in late infancy and early childhood. Maldigestion and malabsorption as causes of reduced iron absorption arise from reduced gastroduodenal acidity, enteropathies (e.g. celiac disease), and intestinal mucosal damage. These conditions are also associated with malabsorption and systemic loss of protein and other nutrients, including iron. Similarly blood loss from the gastrointestinal, genito-urinary, and respiratory tracts entails the loss of other endogenous nutrients as well as iron. Globally the major causes of iron deficiency and anemia are probably the enteropathies and blood losses caused by gastrointestinal parasites such as *Helicobacter pylori*, *Necator americanus*, *Ancylostoma duodenale*, *Trichuris trichiura*, and schistosomes (which may also cause urinary blood loss) (Steketee, 2003). ACD would accompany these conditions, as it does with infectious causes of hemolytic anemias such as malaria (Doherty, 2007).

### Features of Iron Deficiency

Iron deficiency, with or without anemia, is associated with numerous defects. Studies in animal models show inefficient energy metabolism, with altered glucose and lactate metabolism; and reduced muscle myoglobin content and impaired muscle strength and endurance. Reduced cytochrome oxidase activity has been found in muscle and the intestinal mucosa. Impaired collagen synthesis and associated osteoporosis have been noted, and the latter may also in part be secondary to interrupted hydroxylation of vitamin D. Vitamin A metabolism is also disturbed. Other defects include altered prostaglandin metabolism; impaired dopaminergic and serotonin neurotransmission, particularly in dopaminergic areas such as the substantia nigra, globus pallidus, cerebellar nuclei, and hippocampus; defective neuromyelination and synapse and dendrite development; and altered brain membrane fatty acid profiles with, for example, less docosahexaenoic acid (Georgieff, 2008).

Functional psychomotor defects include increased anxiety, impaired memory and spatial navigation, and delayed responses to auditory and visual stimuli. These phenomena provide plausible mechanistic bases for inferring that iron deficiency, both with and without anemia, has similar effects in humans, and show that tissues with a rapid turnover, a specialized function or high energy dependency, such as immunocytes, enterocytes, brain and muscle, are likely to have overt defects.

### Iron Deficiency in Humans

Since the causes and effects of iron deficiency usually involve intakes and losses of other nutrients, and disruption of the utilization of other nutrients and substrates, it is often difficult to ascribe specific features to iron deficiency or even to expect that pure isolated iron deficiency exists, although it may do so in developed communities with inappropriate diets in young people. However, iron deficiency appears as a component of a broader and variable syndrome of nutritional deficiency. Thus classic features ascribed to iron deficiency such as koilonychia, soft nails, glossitis, cheilitis, mood changes, muscle weakness, and impaired immunity may be secondary to several other deficiencies. This is relevant to both clinical and public-health nutrition.

The hematological criteria for assessing iron adequacy are described above, but any coincidental ACD needs to be considered (Weiss and Goodnough, 2005).

Anemia reduces circulatory transport and supply of oxygen to muscle, impairing endurance capacity and energetic efficiency which are further compromised by reduced myoglobin content. In humans, reductions by phlebotomy of customary hemoglobin values to 100–110 g/L reduced aerobic capacity by 16–18%. In adults, iron-responsive fatigability and defects in endurance capacity of muscle during aerobic exercise training have been seen in groups without anemia but with subnormal serum ferritin concentrations (Brownlie *et al.*, 2004). Although data are inconclusive, there is a risk that iron deficiency, or even mild anemia, or both, reduce voluntary activity and work productivity.

Iron deficiency reduces the proportion of circulating T lymphocytes and impairs T-cell lymphocyte proliferative responses. Impairments also affect neutrophil activity, phagocytosis, and microbicidal activity with a weakened neutrophil respiratory burst, free radical production and myeloperoxidase activity, and secretion of interleukin-2. However, B-cell functions are little affected.

### **Iron Deficiency and Cognitive, Motor, and Behavioral Development**

Iron is transported across the blood–brain barrier (BBB) by mechanisms analogous to those in other tissues (Moos *et al.*, 2007). The BBB is an effective boundary and it protects the CNS from systemic iron overload as in the hemochromatoses. Ferric iron is delivered by transferrin to neurones and oligodendrocytes. The CNS accumulates iron until early adulthood. Undoubtedly iron deficiency in animal models compromises neurological and psychomotor development with critical periods, particularly in infancy and early childhood, when the defects are irredeemable. Furthermore, models suggest that in young animals iron is preferentially distributed to erythroid tissues rather than the brain and other organs, implying that deficiencies of iron might occur in the brain unaccompanied by anemia. Iron-deficient and anemic infants and children have delayed attention, poor recognition memory, and reduced reward-seeking behaviors, and are more withdrawn and have poor social interactions. However, research in this area is confounded by concomitant nutrient deficiencies, socioeconomic factors, infections, and, not least, difficulties in standardizing outcomes, and characterizing the causes and degree of iron deficiency; many studies only consider the degree of anemia and assume that it is caused by iron deficiency (McCann and Ames, 2007).

It is difficult to identify thresholds of iron-deficiency anemia, or ages at which defects may occur, because most studies have not been designed to address these public health risk assessment issues. Existing studies imply that iron-responsive defects occur at hemoglobin values below 80, 95, and 110 g/L, and that early-life deficiencies may persist. However, children from poor environments may be more vulnerable to the long-term cognitive deficits than those from more affluent backgrounds. There is some evidence that adolescent girls who were anemic as toddlers have altered memory and that maternal iron deficiency impairs their responsiveness to their children. Additionally, iron therapy normalizes cognitive function in young, iron-deficient, anemic women.

There are other conditions that have a variable and unpredictable response to iron therapy. These include sleep disturbances, disturbed thermal regulation, breath-holding attacks in early childhood (Zehetner *et al.*, 2010), and restless-leg syndrome in adults (Connor *et al.*, 2009). Any primary role of altered iron supply in the pathogenesis of these is unclear.

### **Iron in Pregnancy and Lactation**

Red cell mass increases until 32–34 weeks' gestation in response to a two- to fourfold increase in erythropoietin production; the usual inverse relationship between erythropoietin and red cell mass is lost but it reappears later in pregnancy if the hemoglobin falls below 90 g/L. Transferrin production also increases with a more dense sialylation which favors its binding to placental receptors. However, the hematocrit, hemoglobin, and serum iron, ferritin, and transferrin fall because at the same time the plasma volume expands by about 1.3 L. This increase is independent of the preceding non-pregnant plasma volume, which is about 2.7 L. The increase is larger for multiple pregnancies and multigravida. Thus the declining values reflect the physiological hemodilution of pregnancy, and are not necessarily indicative of iron deficiency or anemia. The plasma volume expansion stops at the end of the second trimester, and decreases near term.

The efficiency of iron absorption increases during pregnancy and is sustained during lactation; iron bioavailability has been shown to increase from 7% at 12 weeks' gestation to 66% at 30 weeks. This of course contradicts ideas that women who become pregnant need to increase their iron intakes, and is consistent with observations that women do not increase their intakes during pregnancy.

The risk of adverse outcomes such as low birth weight and premature delivery is increased at hemoglobin values below 90 g/L or above 130 g/L. This range reflects the healthy range of hemoglobin in pregnancy: lower values may indicate a degree of anemia whereas values above the range indicate failure of normal adaptation, possibly secondary to other causes of failed pregnancy. The limits are not well defined; the lower limits from various studies vary between 86 and 105 g/L, at least in part because the values were not taken at the same stage of pregnancy. The most predictive values are those determined in early pregnancy; later values, particularly those from the last trimester, correlate poorly with outcomes. Interpreting such data in populations beset by infections and nutritional deficiencies is further complicated by the possible effects of ACD and because infections, especially parasitism, are independent causes of impaired placental perfusion and function, intra-uterine growth retardation, and early onset of labour (Steketee, 2003). Iron supplements may improve women's hematological parameters in pregnancy, but have little impact in reducing adverse outcomes in women with normal levels of hemoglobin. Some studies suggest beneficial effects of iron supplementation on reducing the

incidence of low birth weight if it is initiated early in pregnancy. There are few data to enable a confident risk assessment of the influence of birth spacing on iron requirements in pregnancy. There is no general agreement on the need for increased reference intakes of iron during pregnancy and lactation. Extra iron is needed, but whereas some advisory bodies (European Commission Scientific Committee for Food, 1993; Scientific Advisory Committee on Nutrition, 2010) think that this can be acquired from the customary diet by physiological adaptation, others do not rely on this and advise higher reference values (Institute of Medicine, 2001). None the less, many agencies no longer advise regular iron supplements during pregnancy, recommending them only for women with hemoglobin values less than 110 g/L in the first trimester and 105 g/L at 28 weeks' gestation.

### **Treatment and Prevention of Iron Deficiency**

For both populations and individuals it is important to treat the cause of the iron deficiency and any coexisting nutritional deficiencies; more often than not, as in nutritional rehabilitation from pan-malnutrition, it is best to do this before giving any iron. This applies particularly to clinical management. Iron salts used to treat iron deficiency include orally taken ferrous sulphate (60 mg of iron/300 mg of the salt), ferrous fumarate (65 mg of iron/200 mg of the salt), and ferrous gluconate (35 mg of iron/300 mg of the salt), although other preparations are available for oral and parenteral use. The response to iron should be monitored, and if this is not possible or practical, then dosage should be cautious.

At a population level, iron fortification of foods can be undertaken and has been thoroughly considered (World Health Organization/Food and Agricultural Organization of the United Nations, 2006). Strategies for the selection of fortificants have to consider the oxidative effects of inorganic iron salts on the organoleptic properties, and shelf-life of the products. Preferred fortificants are ferrous sulphate or ferrous fumarate, either as simple salts or encapsulated within shells of vegetable oils or stearates; electrolytic iron; and sodium iron EDTA. Recent innovations include microencapsulated ferrous fumarate "sprinkles" that can be sprinkled over food, and a micronutrient powder containing a phytase (Troesch *et al.*, 2009). The latter is used to fortify complementary feeds and to optimize the availability of the intrinsic iron, thereby minimizing the risks of high exposure to iron (see next section). Strategies involving multi-micronutrient supplements are

increasingly being applied to address coincident deficiencies and to assuage uncertainty about the identity of the limiting nutrients other than iron (Allen *et al.*, 2009).

### **Iron Overload**

The risk of iron overload from dietary sources is negligible with normal intestinal function (European Food Safety Authority, 2004) and there are insufficient data to inform a risk assessment to set upper safe limits for iron consumption. In the UK, for adults without medical supervision, a guidance level of 17 mg iron/day for supplemental iron was set based on gastrointestinal effects, and in North America a tolerable upper intake level of iron intake from all sources of 45 mg/day was advised based on interactions with other transition elements (Institute of Medicine, 2001). Acute intakes of iron solutions without food induce gastritis, nausea, abdominal pain, vomiting, and faintness. Large intakes of 20 mg elemental iron per kilogram body weight, or more, cause corrosive hemorrhagic necrosis of the intestine with loose stools and blood loss, hypovolemic shock, damage and failure of systemic organs, and death.

Chronic iron overload with hemochromatoses has an increased incidence of systemic cancer, cardiovascular disease, neurological disease, arthropathies, and diabetes mellitus, but there is no evidence in the general population, including heterozygotes for hemochromatoses, that these or colorectal cancer are associated with dietary intakes of iron. However, there is a probable positive correlation of the incidence of colorectal cancer with exposure to meat and processed meat products (World Health Organization/Food and Agricultural Organization of the United Nations, 2006).

African iron overload, previously called Bantu siderosis, is an ecogenetic disorder arising from a combination of a genetic defect and increased exposure to iron from food and beer that have been prepared or stored in iron utensils. The abnormal iron overload is distributed in the Kupffer (RES) cells of the liver in contrast to the hemochromatoses in which the excess iron is in the hepatocytes.

There are unresolved concerns about the significance of interactions between iron, zinc, and copper along their kinetic pathways; for example, they all may use DMT1, and all bind to transferrin. Iron can inhibit the utilization of zinc and copper with adverse effects on growth (Sachdev *et al.*, 2006), immune function, and ceruloplasmin concentrations. However, the circumstances in which these

phenomena occur and their significance are fully characterized, and it is not clear which components of bioavailability are involved.

The acute-phase re compartmentation of iron might be a host defense mechanism to restrict the availability of iron to pathogens. Bacterial pathogens need iron, and to acquire it they create local tissue redox and acid conditions that cause release of iron from its binding sites, and they release siderophores that can strip iron from iron-proteins and from heme. If iron is freely available, for example from iron overload or haemolysis as in malaria, bacteremias, commonly with enteric organisms, may arise. Thus the effect of iron supplements on malaria may depend on more subtle interactions than a direct one between the metal and the plasmodium. The same point probably applies to interactions between iron supply and its homeostasis with HIV and tuberculosis, for which at the population level there are few data on whether they are exacerbated by iron supplementation (Doherty, 2007). The avidity of enteric bacteria for iron may explain why iron supplements and fortification have been considered to increase the incidence of diarrheal disease but not that of non-diarrheal or respiratory disease. The WHO has advised that, in areas of high risk of malarial transmission, “folic acid supplementation should be targeted at children who are anemic and at risk of iron deficiency and that they should also receive concurrent protection from malaria and other infectious diseases” (World Health Organization/UNICEF, 2006).

### Public Health and Preventive Measures to Combat Iron Deficiency

The data on the effects of iron deficiency are not as good as those on the association of defects with anemia, which suggest that, irrespective of their pathogenesis, hemoglobin values of less than 110 g/L have adverse effects. Thus it is understandable that public health measures should address anemia and its several causes, rather than iron deficiency per se. The latter would anyway be addressed by measures to reduce blood loss and improve nutritional intake as a general measure.

The elements of preventing iron deficiency are similar in both developed and developing countries, although appropriate cultural and locale-specific emphases need to be applied. The key components at all ages involve minimizing iron loss from intestinal and other parasites, ensuring access to adequate diets, and being aware that

multi-nutrient supplements are probably needed to ensure adequate nutrition in general and effective use of dietary and supplemental iron. In children, delayed clamping of the cord at birth and sustaining breastfeeding are additionally important (Lutter, 2008). It needs governmental interventions to support the infrastructural interventions to achieve these measures, which would have a broader benefit because they would break the infection–malnutrition cycle. National, regional, and local governments need to appreciate the socioeconomic benefits of reducing the prevalence of iron deficiency (Hunt, 2002). The political will to act on this could be generated by an increased engagement and empowerment of the citizenry who themselves could undertake some of the basic public-health and sanitary measures which would control some of the causes of iron deficiency.

### Future Directions

Uncertainties persist about how much iron we need, how to determine iron status, and how to ensure adequate iron status in individuals and populations. The assessment and management of iron deficiency and anemia will probably continue to be conflated and conservative. The challenge lies in how to use new knowledge in cell biology to address these core issues. Part of this strategy will entail refining our current approaches by using improved understanding of iron trafficking and use to appraise critically our current practice and investigative approaches. It is particularly important to appreciate the difference between iron deficiency and anemia, and to be able to consider, in the context of risk assessment and management, whether the differentiation matters or not. Assessment of requirements and of status will benefit from applying improved awareness of how iron homeostasis interacts with that of other nutrients, and possibly more importantly with other systemic phenomena such as any degree of inflammation. This should also influence the use of iron supplementation and fortification programs, bearing in mind concerns about trace-element interactions causing other deficiencies, impaired growth, and activation of infections, in which regard the role of enteric pathogens is probably important. It is unlikely that new markers of iron status will emerge, but it may be possible using cell biology to better validate existing markers or to evolve algorithms to assess the adequacy of dietary intakes, systemic iron supply and function. Overall it is important that iron should be considered in a broad nutritional and health context.

## ZINC

ROBERTA R. HOLT, BSc, JANET Y. URIU-ADAMS, PhD, AND CARL L. KEEN, PhD

*University of California, Davis, California, USA*

### Summary

The trace element zinc is essential to a diverse array of structural, catalytic, and regulatory functions in mammals. With no known storage form of this element, zinc deficiency is rapidly induced in animal models, and, in humans, zinc deficiency contributes to reduced growth and immune function. While severe zinc deficiency is not common in the developed world, marginal zinc deficiency could contribute to a number of disease states. Current research is focused on understanding the cellular regulation of zinc including intracellular transporters that shuttle zinc within organelles, and between cells and the extracellular space, and the role of zinc in human health.

### Introduction

The importance of zinc has long been recognized; zinc ores being used in the making of brass as early as 1000 AD. Zinc was recognized as a distinct element in 1509, and evidence of its essentiality was demonstrated in plants in 1869 and in experimental animals in 1933 (Todd *et al.*, 1933). Approximately 10% of proteins encoded in the mammalian genome require zinc for their proper structure and function (Andreini *et al.*, 2006). Most physiological processes are dependent on zinc, and the metabolism and regulatory roles of zinc are areas of considerable research. Given its wide prevalence in foodstuffs, naturally occurring zinc deficiency was long considered to be unlikely; however, in 1961, zinc deficiency was reported to be a problem in parts of the Middle East. In 2002, the World Health Organization estimated that nearly half of the

world's population had suboptimal zinc status, and that, globally, zinc deficiency is a major risk factor for disease mortality and morbidity (WHO, 2002). Conversely, zinc toxicity can also represent a public health risk.

### Chemistry

Zinc has an atomic number of 30 and an atomic weight of 65.37. Zinc is a period 4, group 12 d-block element with a complete d subshell and an oxidation state of 2. Zinc is a strong Lewis acid and has an affinity for thiol and hydroxyl groups and for ligands containing electron-rich nitrogen as a donor (Vallee and Auld, 1990). In biological systems, zinc is virtually always in the divalent state, and as such does not exhibit direct redox chemistry; however, when coupled as a zinc–thiol complex, as seen

with cysteine ligands, zinc is key to redox signaling (Foster and Samman, 2010). Zinc has a coordination geometry of 4, which, as will later be described, is important structurally for gene regulation (Maret and Li, 2009).

Zinc can be measured using a variety of methodologies. Zinc radioisotopes are routinely measured using gamma-ray spectrometry, liquid scintillation spectrometry, and autoradiography. Stable isotopes of zinc are typically measured using thermal ionization mass spectrometry, fast atom bombardment mass spectrometry, and inductively coupled mass spectrometry. Zinc occurs as five stable isotopes with the following natural abundances:  $^{64}\text{Zn}$ , 48.89%;  $^{66}\text{Zn}$ , 27.91%;  $^{67}\text{Zn}$ , 4.11%;  $^{68}\text{Zn}$ , 18.57%; and  $^{70}\text{Zn}$ , 0.62%.

Atomic absorption spectrophotometry (AAS) is the most common method used to measure total zinc concentrations. Samples analyzed for zinc by AAS typically need to either undergo dry ashing (approximately 500°C) or wet ashing, with the latter often accomplished with the use of nitric or other acids. Fluorescent probes (e.g. Zinquin [(2-methyl-8-p-toluenesulphonamido-6-quinolyloxy) acetic acid] and protein biosensors that can measure free zinc concentrations within cells are increasingly being used to further our understanding of zinc metabolism and its regulatory roles (Tomat and Lippard, 2010).

## Metabolism

The homeostatic regulation of zinc metabolism is still being elucidated; however, it is generally understood as the balance between absorption of dietary or endogenous zinc and the excretion of endogenous zinc. With regard to dietary zinc, the net delivery of zinc to the organism is a function of the total amount of zinc in the diet and its bioavailability. As with most minerals, zinc absorption typically exceeds the amount actually utilized; therefore, to maintain zinc homeostasis the excess zinc needs to be excreted. The exact mechanism of this regulation is the focus of a number of ongoing research programs.

### Tissue Zinc

Zinc is present in all organs, tissues, fluids, and secretions of the body, with total body zinc content in the adult ranging from 1.5 g in women to 2.5 g in men. Zinc is primarily an intracellular ion, with well over 95% of the total body zinc found within cells (Jackson, 1989). The largest percentage of zinc can be found in the skeletal

muscle (57%), followed by bone (29%), with remaining tissues and blood contributing approximately 14% (Jackson, 1989). In most species, plasma zinc represents approximately 0.1% of total body zinc, with typical concentrations being on the order of 1  $\mu\text{g}/\text{mL}$ . Approximately 75% of plasma zinc is associated with albumin, with the remainder bound to  $\alpha_2$ -macroglobulin (15–30%) and amino acids (~1%; primarily cysteine and histidine) (Tapiero and Tew, 2003). The zinc concentration in erythrocytes is an order of magnitude higher than that of plasma (~1 ng/10<sup>6</sup> cells). The majority of erythrocyte zinc (~85%) is associated with carbonic anhydrase, and approximately 5% is associated with superoxide dismutase (SOD). As plasma zinc is commonly analyzed as a biomarker for zinc status (see below), it should be noted that the use of hemolyzed blood samples can yield artificially high plasma zinc concentrations. Circulating mononuclear and polynuclear cells can contain appreciable amounts of zinc (~5 ng/10<sup>6</sup> cells), and they are sometimes used to assess zinc status (Milne *et al.*, 1985; Gibson *et al.*, 2008).

## Absorption

### Pre-Absorption Factors

The bioavailability of zinc is largely a function of the presence or absence of substances in the food matrices that influence the absorption of zinc. These include food components that form insoluble zinc complexes that inhibit zinc absorption, or elements that compete with zinc at absorption sites thereby inhibiting zinc uptake. For example, phytate (myoinositol hexaphosphate), which is found in plant foods such as seeds, roots, and tubers, can significantly inhibit zinc absorption in many species, including humans, by forming insoluble complexes. The consumption of high-phytate diets has been linked to the induction of zinc deficiency in humans, particularly in situations where the overall diet is marginal in zinc content (Hambidge *et al.*, 2010). A ratio of phytate to zinc above 10 increases the risk of poor zinc utilization. Removal of phytate from a food such as soy protein can significantly increase zinc availability from the product. Fermentation of bread can reduce its phytic acid content and significantly improve zinc absorption. The selection of low phytate variants of certain crops, such as maize, barley, and rice, may also represent an approach to improving the zinc bioavailability from these foods (Lonnerdal *et al.*, 2011). Extrusion cooking, which is used for breakfast cereals, can inhibit the degradation of phytic acid in the gut and cause

less efficient absorption of zinc (Sandstrom and Lonnerdal, 1989).

In contrast to inhibitory factors, some dietary factors can enhance zinc availability. For example, meats, liver, eggs, and seafood are considered to be good sources of zinc because of the relative absence of chemical constituents that inhibit zinc absorption and because of the presence of certain amino acids that improve zinc solubility. Several amino acids can form zinc complexes with high stability constants, which may facilitate zinc uptake (Krebs, 2000; Lonnerdal, 2000).

Within the intestinal lumen, pH does not seem to influence zinc uptake; rather, after a meal, digestive enzymes release zinc from food matrices. Zinc available for absorption is a combination of that provided by diet as well as from endogenous sources of zinc, such as biliary and pancreatic secretions (Krebs, 2000; Lonnerdal, 2000). The free zinc is able to form coordination complexes with amino acids, phosphates, and other organic acids, which can further influence zinc bioavailability. For example, zinc preferentially binds to the amino acid ligands histidine and cysteine forming a stable complex that enhances absorption (Scholmerich *et al.*, 1987). Evidence indicates that a zinc–histidine complex is absorbed 30–40% more efficiently than zinc–sulfate complexes (Scholmerich *et al.*, 1987).

### Intestinal Absorption

In monogastric animals, zinc is mainly absorbed from the duodenum, jejunum, and ileum, with very little being absorbed from the stomach. Zinc absorption has been estimated at 20–40% (Tapiero and Tew, 2003), with maximal absorption occurring in either the distal duodenum or proximal jejunum (Lee *et al.*, 1989; Krebs, 2000). These areas of the small intestine are characterized by increased expression of specific zinc transporters, such as Zrt/Irt-like protein (Zip)<sup>4</sup> and Zinc Transporter (ZnT)<sup>1</sup>, which are involved in apical and basolateral enterocyte zinc flux, respectively (Yu *et al.*, 2007; Cousins, 2010; Wang and Zhou, 2010).

Zinc transport across the brush border occurs by both a saturable carrier and a non-saturable transport mechanism that appears to be energy-independent. At low to normal luminal concentrations of zinc (0.1–1.8 mM), the active transport carrier mechanism predominates (Hoadley *et al.*, 1987; Lee *et al.*, 1989). With high zinc intakes (luminal concentration >1.8 mM), the non-saturable mechanism for zinc absorption becomes prominent and

may involve paracellular passive zinc diffusion. The precise mechanisms underlying the regulation of zinc absorption have remained elusive despite intensive investigation. A number of zinc transporters have now been described and are classified into two families, the ZnT (SLC30) family, and the Zip (SLC39) family (Lichten and Cousins, 2009; Wang and Zhou, 2010). Ten ZnTs and 14 Zips have been identified, with dietary zinc currently known to influence about eight of these (Lichten and Cousins, 2009). Zip<sup>4</sup>, found on the enterocyte apical membrane, is known to be regulated by zinc intake, and is a major contributor to the saturable kinetics of zinc absorption (Wang and Zhou, 2010). Individuals with the genetic disorder acrodermatitis enteropathica (AE), who have a mutation in the Zip<sup>4</sup> gene, can develop signs of severe zinc deficiency if supplementary dietary zinc is not provided (Lichten and Cousins, 2009).

The ileum is the major site for ZnT-1. It is localized to the basolateral membrane and appears to regulate the export of zinc across the enterocyte into the mesenteric capillary where it is carried by the portal blood to the liver (Wang and Zhou, 2010). ZnT-2 is found in acidic vesicles that accumulate zinc in the duodenum and jejunum. ZnT-4 is found in all parts of the small intestine. ZnT-2 and ZnT-4 are involved in the flux of zinc in the endosomes, possibly regulating intracellular trafficking of zinc (Cousins *et al.*, 2006; Sekler *et al.*, 2007; Wang and Zhou, 2010). All of these transporters are found primarily in villus cells, and much less frequently in crypt cells. A superfamily of human zinc transport proteins has been identified (zinc importer proteins, ZIP1 and ZIP2) that are involved in cellular zinc uptake. These proteins are localized in the plasma membrane and have structural characteristics typical of other transport proteins (e.g. permeable membrane domains, a transport channel, and high-affinity binding domains). Within the cell, the disposition of zinc is diverse. Zinc trapped within the enterocyte is eventually lost in the feces in the normal course of mucosal cell turnover. In all cell types, intracellular zinc may be used for zinc-dependent processes, become bound firmly to metallothionein (MT) and held within the cell, or pass through the cell. Low-molecular-weight cellular proteins, such as MT, can bind zinc, as well as other divalent metals such as copper and cadmium. Zinc induces MT in mucosal cells, but only at relatively high dietary intakes.

The bioavailability of zinc is determined from the amount of zinc that is available from the food matrix and

the total amount of zinc in the food (Hambidge *et al.*, 2010; King, 2010). As discussed above, a number of food components, such as phytate, can interfere with zinc absorption; therefore, stable isotope studies are often employed in order to determine the fraction or percent of zinc absorbed from the diet (i.e. fractional zinc absorbed), which is subsequently multiplied by the total dietary zinc to determine the bioavailable quantity of zinc (i.e. total zinc absorbed) (King, 2010). Short-term, controlled, dietary human intervention trials have determined that total zinc absorbed is associated with zinc intake and not status (Chung *et al.*, 2008; King, 2010), with an inverse association between intake and fractional zinc absorption which is representative of the known saturation kinetics of zinc absorption (Hambidge *et al.*, 2010). Therefore, a diet that is low in zinc will have an increased fractional zinc absorption, but reduced total zinc absorbed, compared with a diet that is zinc adequate (Chung *et al.*, 2008).

It is also well recognized that select divalent metal ions, such as iron, can compete with zinc for mucosal cell binding sites and transporters such as divalent metal transporter 1 (DMT1), although the significance of this interaction with respect to overall zinc balance can be questioned. Zinc and copper can also compete for cell transporters; however, while secondary copper deficiencies can clearly arise as a consequence of excessive zinc intakes (see below), high levels of dietary copper have not been reported to be a significant issue with respect to zinc absorption. Presumably this is due to the fact that dietary copper intakes are normally much lower than those of zinc. In animals, high-calcium diets can impair zinc absorption (Sandstrom and Lonnerdal, 1989) whereas, in humans, zinc balance is not affected by the addition of calcium salts unless the diet is also high in phytate (Lonnerdal, 2000). Early studies suggested that folic acid supplementation could also interfere with zinc homeostasis; however, subsequent studies with either short- or long-term folic acid supplementation demonstrated no effect on zinc absorption or homeostasis (Campbell, 1996).

### Excretion

Approximately 2.6–4.6 mg of zinc is secreted into the duodenum following a meal, mainly from pancreatic secretions. Additional sources of endogenous zinc include bile and gastroduodenum secretions, zinc from transepithelial flux from mucosal cells, and mucosal cells that are sloughed into the gut (Hambidge *et al.*, 1986). An intact enteropancreatic zinc circulation is important for maintenance

of body zinc as much of the zinc secreted into the gut is reabsorbed. The amount of zinc secreted into the gut is affected by zinc intake. In humans, extremely low zinc intakes are associated with low endogenous fecal zinc losses (<1 mg/day) while extremely high zinc intakes can result in losses of over 5 mg/day (Baer and King, 1984; Jackson *et al.*, 1984). Fecal excretion is the major route of unabsorbed dietary zinc and endogenous zinc excretion (Hambidge *et al.*, 2010). An increase in the fecal excretion of endogenous zinc provides the “fine control” needed to balance the net retention of zinc with metabolic needs. Endogenous fecal zinc losses can be increased several-fold to maintain zinc homeostasis with high intake of zinc (Coppen and Davies, 1987). Data from zinc tracer studies show that 90–98% is lost in the feces while only 2–10% is recovered in the urine (Hambidge *et al.*, 1986). Typical urinary excretion rates are about 400–600 µg zinc/day arising largely from the low molecular weight zinc pool (Hambidge *et al.*, 1986). Except in extreme zinc deficiency or supplementation conditions, dietary zinc does not have a major impact on urinary zinc excretion. Typically, 95% of zinc that is filtered by the glomerulus will be reabsorbed (Victory *et al.*, 1981). Several factors can affect urinary zinc excretion including the rate of urine production (or the urine volume) and creatinine excretion. Urinary zinc losses are also significantly elevated when catabolism is increased such as in severe burn cases, trauma/surgery, starvation, or under treatment with chelating agents such as ethylenediaminetetraacetic acid (EDTA) (Hambidge *et al.*, 1986). Loss of zinc up to 1 mg/day also occurs via surface loss (desquamation of skin, hair outgrowth, and sweat), which can be affected by marked changes in dietary zinc intake (Milne *et al.*, 1984). Semen secretions can contribute up to 1 mg and menstrual secretions can account for 0.1–5 mg of endogenous zinc losses (Hess *et al.*, 1977).

Zinc excretion can be increased when supplements of tin are given (50 mg) (Johnson *et al.*, 1982); however, this is not thought to be a common problem as dietary tin intake is typically low (<1 mg/day). High levels of dietary cadmium do not appear to impact zinc absorption, but can alter zinc distribution in the body via competition for MT binding sites (Goyer, 1997).

### Homeostasis

To date, specific zinc “stores” that are homeostatically controlled have not been identified. In all species studied, signs of zinc deficiency occur quickly after the individual

consumes a zinc-deficient diet, indicating that zinc stores are not readily available. Total body zinc is maintained by the regulation of intestinal absorption, intracellular and tissue distribution, and the excretion of endogenous zinc pools (King *et al.*, 2000). This is possibly achieved by changes in the expression of zinc transporters (Tapiero and Tew, 2003; Cragg *et al.*, 2005; Wang and Zhou, 2010; Fukada *et al.*, 2011). For example, in the enterocyte, apically located Zip4 is down-regulated with high zinc intake and up-regulated when zinc intake is reduced (Wang and Zhou, 2010). Similarly, as intracellular zinc rises, transporters such as ZnT-1 are up-regulated, thereby increasing zinc efflux into intracellular vesicles (Wang and Zhou, 2010).

As noted above, long-term storage pools of zinc have not been identified. However, it can be argued that MT-bound zinc may be a short-term zinc pool. In favor of this idea is the observation that MT is inducible by dietary zinc via the metal response element (MRE) and metal-binding transcription factor (MTF-1) (see below). Furthermore, it is known that acute and chronic changes in tissue MT concentrations can result in marked alterations in plasma zinc concentrations as well as the intracellular distribution of zinc. Interestingly, MT-null mice have been reported to have relatively normal lifespans, and they do not show marked alterations in zinc metabolism (Wastney and House, 2008). An exception to the above is when zinc metabolism is studied in MT-null mice exposed to certain acute challenges, such as high concentrations of inflammatory cytokines like interleukin 1, interleukin 6, and tumor necrosis factor- $\alpha$ . The typical hypozincemia that is observed in cytokine-challenged animals is not evident in the MT-null mice. Whether this represents a benefit or a risk to the animal has yet to be defined.

Albumin has a low association constant for zinc, thus albumin zinc represents a highly exchangeable pool of zinc for tissue uptake. The kidneys are able to filter amino acid-bound zinc. Because the pool of zinc in tissues is large relative to plasma, small variations in the zinc content of tissues can markedly affect plasma zinc. For example, a stress-induced increase in zinc retention in the liver can result in a 40% reduction in plasma zinc. In contrast, even minor muscle catabolism can release enough zinc to increase plasma levels. This issue should be considered when blood samples are taken from individuals following a prolonged fast. In contrast, plasma zinc levels fall following a meal (Küilerich *et al.*, 1980; McMillan and Rowe, 1982). Together, these data show that the use of

plasma zinc concentrations to assess zinc status can be complicated.

Considerable information about zinc pools and their turnover has been obtained from kinetic modeling studies using zinc stable isotopes. Elimination of absorbed zinc from the body is best described by a two-component model (Hambidge *et al.*, 1986). The initial rapid phase, thought to primarily represent the initial uptake and release of zinc from the liver, has a half-life in humans of approximately 12.5 days. The slower turnover phase reflects differing rates of zinc turnover in various extrahepatic tissues and has a half-life of approximately 300 days (Hambidge *et al.*, 1986). The uptake and turnover of zinc can be relatively slow, as observed in the central nervous system and bones, or relatively fast as observed in the pancreas, liver, kidney, and spleen. Uptake and exchange of zinc in red blood cells and muscle are slower than in the viscera. In rats, dietary zinc restriction enhances zinc retention in soft tissues and organs by reducing zinc turnover (Coppen and Davies, 1987). These homeostatic adjustments protect tissue zinc concentration from marked decline. In humans, daily loading with 100 mg of zinc can increase the turnover of the slower zinc pool (Aamodt *et al.*, 1982).

A number of factors can influence zinc homeostatic regulation. The age of the individual can influence absorptive capacity. Suboptimal zinc status has been reported to be common in the elderly; whether or not zinc absorption is reduced in the elderly is a subject of debate (Fairweather-Tait *et al.*, 2008). Increased fractional zinc absorption has been reported to occur in women during pregnancy and lactation (Donangelo *et al.*, 2005). In addition, changes in zinc transport may regulate absorption and deposition into milk (Kelleher and Lonnerdal, 2009).

## Physiological (Biochemical) Function

Data mining of potential metal–protein binding domains has identified over 3000 putative zinc proteins in humans. Zinc has a role in a multitude of catalytic, structural, and regulatory functions (Andreini *et al.*, 2006; Cousins *et al.*, 2006; Tuerk and Fazel, 2009). Given its multitude of functions, it is not surprising that a deficit of this element can pose serious, and diverse, physiological challenges. A brief outline of some of the biochemical and physiological functions of zinc is presented below.

Zinc has been confirmed as an important component of over 50 enzymes representing all six International Union

of Biochemistry (IUB) classes (Vallee, 1983; Hambidge *et al.*, 1986). With respect to these metalloenzymes, zinc can function in a catalytic, co-catalytic or structural fashion (Clegg *et al.*, 2005; Stefanidou *et al.*, 2006). The catalytic site of enzymes such as carbonic anhydrase, alcohol dehydrogenase, and carboxypeptidase form and break bonds via Lewis acid–base chemistry through the coordination of zinc to three amino acid side chains of histidine, glutamate, aspartate or cysteine and water (McCall *et al.*, 2000; Clegg *et al.*, 2005; Stefanidou *et al.*, 2006). Two or more zinc ions plus other metals, such as magnesium, serve in a co-catalytic role within alkaline phosphatase and phospholipase C (McCall *et al.*, 2000).

In addition, zinc serves to stabilize the tertiary structure of a number of proteins, including those involved in DNA replication and reverse transcription, through the coordination of side chains from amino acids such as cysteine (Stefanidou *et al.*, 2006). Moreover, transcription factors known as “Zn-finger” regions contain repeated cysteine and histidine domains that bind zinc in a tetrahedral configuration. These Zn-finger domains mediate the interaction of proteins to other proteins, DNA, RNA, and lipids (Matthews and Sunde, 2002; Klug, 2010). Transcription factors can contain several Zn-fingers, each with a set of triplet amino acid sequences involved in DNA base recognition, allowing for specificity to a DNA sequence (Hartwig, 2001). Members of the nuclear receptor family including glucocorticoid, retinoic acid and vitamin D<sub>3</sub> receptors utilize Zn-fingers to recognize their DNA binding domain. Zn-finger binding domains also exist in enzymes involved in DNA repair, cell cycle control, and apoptosis (Hartwig, 2001). Given the widespread occurrence of Zn-finger binding domains, it would be reasonable to speculate that this function of zinc would be highly protected; however, there are reports that severe zinc deficiency can influence Zn-finger-dependent transcription factors (Duffy *et al.*, 2004).

While the zinc ion itself is not redox active, zinc-coordinated to the sulfur of cysteine within catalytic sites or structural proteins allows for the potential of redox regulation (Maret, 2006). Similarly, zinc can help to ensure biomembrane structure and function, due in part to its ability to: (1) interact with and stabilize thiol groups of antioxidant enzymes and membrane channel proteins; (2) displace redox active transition metals, such as iron; and (3) reduce production of transition metal-induced reactive oxygen species (ROS) through the induction of MT (Willson, 1989; O’Dell, 2000; Laity and Andrews, 2007).

Indeed, one of the primary regulatory roles of zinc is through the activation of MTF-1, a six-Zn-finger-containing transcription factor, which after complexing zinc, binds to the MT promoter as well as to the promoters for ZnT-1 and  $\gamma$ -glutamylcysteine synthase (Beyersmann and Haase, 2001; Maret, 2006; Laity and Andrews, 2007).

## Zinc Deficiency

Deficits of zinc can affect a multitude of systems, including the central nervous, reproductive, integumentary, skeletal, gastrointestinal, and immune systems (Tuerk and Fazel, 2009). Zinc deficiency can be both inherited and acquired. As stated above, AE is a rare, inherited, autosomal recessive disease (Aggett, 1989). In AE, the intestinal uptake and transfer of zinc across the apical membrane is impaired due to a defect in the Zip4 gene (Lichten and Cousins, 2009). An increased risk of an acquired zinc deficiency has also been reported for patients receiving total parenteral nutrition (TPN) solutions that are low in zinc, or who are treated with divalent metal chelating agents and drugs (e.g. the use of penicillamine therapy for Wilson’s disease). In addition, zinc deficiency can be the result of malabsorption syndromes, chronic alcoholism, and, as discussed above, the consumption of diets high in phytate (Tuerk and Fazel, 2009).

The expression of zinc deficiency in an individual depends on the severity of the deficiency and other factors, but classic signs of severe zinc deficiency include growth retardation, diarrhea, skin and eye lesions, neuropsychiatric changes, and alopecia (Aggett, 1989). Dwarfism, hypogonadism, and delayed sexual maturation were initially observed in Middle Eastern adolescents consuming diets high in phytate (Prasad *et al.*, 1961). Skin lesions found on the extremities and near body orifices that are often erythematous and pustular in nature, and increased loss of hair, which may become hypopigmented with a reddish hue, are common to severe forms of zinc deficiency (Hambidge *et al.*, 1986; Aggett, 1989). Zinc is particularly concentrated in the retina and other eye structures, and severe zinc deficiency has been reported to alter vision (Grahn *et al.*, 2001). A synergistic relationship between zinc and vitamin A status has been postulated that could be detrimentally altered with a zinc deficiency (Christian and West, 1998).

The major pathophysiological abnormalities contributing to secondary zinc deficiency are zinc malabsorption and excessive urinary zinc losses. Therefore, any disease or

condition that increases transit time for absorption or alters the integrity of the gastrointestinal mucosa, such as is the case with enteric infections and inflammation, can affect zinc absorption. Patients who become zinc deficient often have conditions that predispose them to the problem, such as diarrhea, inflammatory bowel disease, and other malabsorptive conditions such as Crohn's disease, sprue, and short bowel syndrome. Recently, there has been increasing concern that zinc deficiency might be a common complication of gastric bypass surgery (Salle *et al.*, 2010). Specifically, surgical procedures that promote malabsorption, such as Roux-en-Y gastric bypass (RYGB) and duodenal switch, have been reported to produce a zinc deficiency in 40% and 91% of patients, respectively, 12 months post-surgery (Salle *et al.*, 2010). Significantly, it has been estimated that over 350 000 gastric bypass surgeries were performed globally in 2008, with 40% of these using RYGB (Padwal *et al.*, 2011); therefore, it could be predicted that up to 56 000 of these individuals could have been zinc deficient as late as a year post-surgery. Alarming, if one considers the increasing prevalence of severe obesity in many countries and the associated use of bypass surgery, the potential is there for literally millions of new cases of marginal zinc deficiency over the next decade.

Diarrhea is a complication of AE, in those receiving TPN, and in those with intestinal infection. Zinc supplementation has been shown to be an effective treatment for acute diarrhea, especially in children (Berni Canani *et al.*, 2010; Yakoob *et al.*, 2011). Enteric pathogens promote diarrhea by enhancing secretion of chloride ion, with subsequent loss of water, through a number of species-specific pathways. In *in vitro* model systems, zinc supplementation has been shown to inhibit three out of four key signaling pathways involved in chloride ion secretion including inhibition of cyclic AMP, the inducible isoform of nitric oxide synthase (iNOS), and transactivator factor peptide (Tat)-induced  $\text{Ca}^{2+}$ -dependent chloride ion secretion (Berni Canani *et al.*, 2010).

A number of potential mechanisms underlying zinc deficiency-induced pathology have been advanced based on cell culture and animal model systems. In animals, zinc deficiency during early development is highly teratogenic. Typical malformations associated with severe zinc deficiency in experimental animals include brain and eye defects, spina bifida, cleft lip and palate, and numerous malformations of the heart, lung, skeleton, and urogenital system (Keen and Hurley, 1989). In addition to the gross

structural defects evident at birth, biochemical alterations from developmental zinc deficiency can persist into adulthood. Illustrative of this, Beach and co-workers (Beach *et al.*, 1982) reported that offspring of mouse dams who were fed moderately low-zinc diets ( $5 \mu\text{g}$  zinc/g diet) during pregnancy had immunological abnormalities that persisted over several generations, despite dams and offspring receiving adequate zinc diets after birth. Similarly, recent reports show that developmental zinc deficiency in rats can result in persistent alterations in nitric oxide pools that can be associated with elevated blood pressure (Tomat *et al.*, 2010, 2011). As outlined below, the mechanisms leading to zinc-deficiency-associated abnormal development are multifactorial in nature. Biochemical lesions proposed to contribute to the teratogenicity of zinc deficiency include altered DNA and protein synthesis, alterations in cell proliferation and survival, impairment in tubulin polymerization with resultant reductions in cell motility and division, chromosomal defects, altered cell signaling, and excessive peroxidation of cell membrane lipids (Keen and Hurley, 1989; Uriu-Adams and Keen, 2010). In addition to its impact on the fetus, zinc deficiency during late gestation can result in parturition difficulties with delayed deliveries and excessive bleeding (Apgar, 1985; Keen and Hurley, 1989).

When dietary zinc intake is insufficient, the first response is to conserve tissue zinc by reducing endogenous losses. Tissue zinc loss is not uniform: plasma, liver, bone, and testicle zinc concentrations decrease, with apparent conservation of tissue zinc concentrations in hair, skin, heart and skeletal muscle (King *et al.*, 2000). If the dietary deficiency is mild, zinc homeostasis may be re-established and no further functional or biochemical changes occur. However, with a markedly deficient diet, the organism cannot reestablish homeostasis through adjustments in endogenous losses and growth. As a consequence, an increase in tissue catabolism occurs, and a generalized tissue dysfunction develops quickly. Zinc deficiency can be induced rapidly in some species. For example, within 24 hours of consuming a zinc-deficient diet, plasma zinc concentrations in the rat can be decreased by as much as 50% (Hurley *et al.*, 1982). That this reduction in plasma zinc can be functionally significant is illustrated by the observation that the feeding of a zinc-deficient diet to pregnant rats for only a few days during the first trimester is sufficient to cause embryonic abnormalities (Uriu-Adams and Keen, 2010). Although all species may not respond to a zinc-deficient diet as rapidly as the rat, the lack of any

appreciable zinc stores under homeostatic control is a consistent finding for all mammalian species to date.

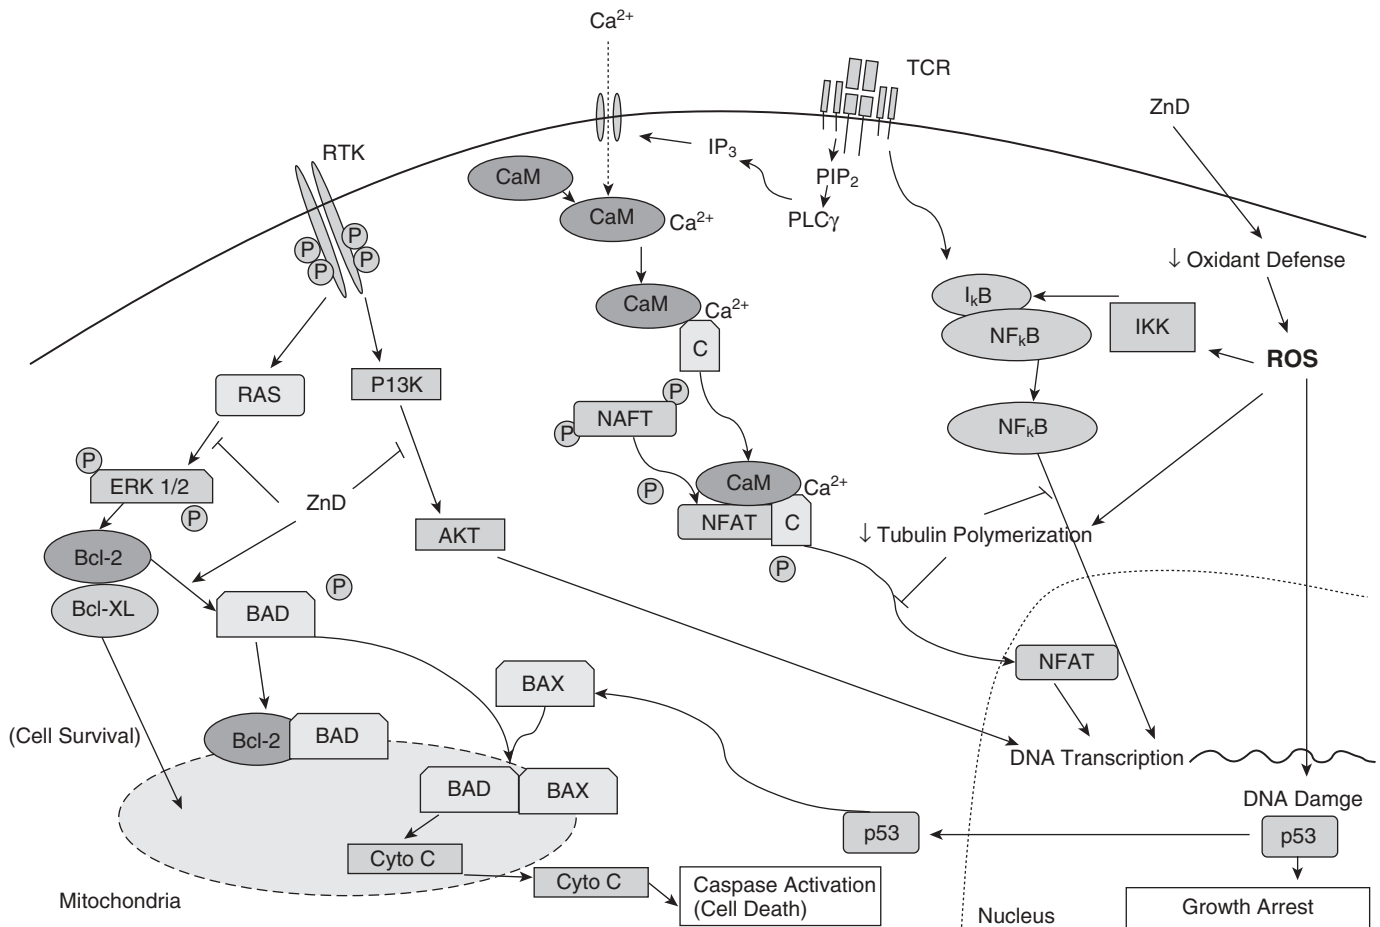

Early effects of zinc deficiency for many species include anorexia and cyclic feeding. In rats, it has been suggested that dietary zinc stimulates food intake via the activation of vagal afferents, which subsequently stimulates the release of the hypothalamic orexigenic peptides orexin and neuropeptide Y (Ohinata *et al.*, 2009). Regardless of the biochemical explanation for the anorexia, the cyclic food intake pattern of zinc-deficient animals may represent an adaptation of the animal to increase muscle catabolism and release zinc into the plasma pool for zinc-dependent processes used by hepatic and extrahepatic tissues including the embryo and fetus. For example, in pregnant animals fed a zinc-deficient diet, increased fetal apoptosis is observed during periods of increased maternal food intake (relatively low plasma zinc), versus those time periods where food intake is low (relatively high plasma zinc) (Uriu-Adams and Keen, 2010). Impaired growth is also associated with zinc deficiency, which, like cyclic food intake, has been suggested to represent an accommodation of the animal to the zinc deficit by increasing zinc availability for zinc-dependent metabolic processes. An alternative explanation for the slower rate of growth is that it is secondary to the anorexia and the concomitant reduction in food intake. However, animals fed diets adequate in zinc, in amounts equivalent to those consumed by zinc-deficient animals, gain considerably more weight than the zinc-deficient animals. Thus, the lower weight gain observed with zinc deficiency cannot be ascribed solely to reduced food intake (O'Dell and Reeves, 1989).

As stated above, zinc is essential for a number of biological processes including enzyme function and protein structure. In addition, zinc deficiency alters DNA and protein expression. Zinc deficiency has been shown to affect DNA integrity in humans (Song *et al.*, 2009) as well as experimental animals (Song *et al.*, 2010). Alterations in cell proliferation and survival pathways are also induced with zinc deficiency. These include a number of downstream events regulated by growth factors through receptor tyrosine kinase signaling, such as insulin-like growth factor (IGF), which functions to inhibit apoptosis and promote cell differentiation to increase growth. For example, in zinc-deficient cell culture systems, a reduced phosphorylation of Ras-dependent extracellular-signal-regulated kinase (ERK 1/2), as well as the serine/threonine protein kinase, AKT, results in a dephosphorylation of the Bcl-2-associated death promoter protein (BAD); leaving BAD to form het-

erodimers with anti-apoptotic factors Bcl-2 and Bcl-XL, and with pro-apoptotic Bcl-2-associated X protein (BAX). The BAD/BAX heterodimer can then proceed to permeabilize mitochondrial membranes, resulting in cytochrome C release and subsequent caspase activation, leading to apoptosis (Clegg *et al.*, 2005; Uriu-Adams and Keen, 2010) (Figure 34.1). The increase in oxidative stress that is observed during zinc deficiency can induce cell cycle arrest and apoptosis through oxidation of proteins, lipids and DNA. The tumor suppressor protein p53 is involved in the detection and repair of DNA or in triggering apoptosis. The DNA binding region of p53 contains zinc. In zinc-deficient cells p53 expression is increased, but its DNA binding ability can be reduced. Zinc prevents the oxidation of redox-sensitive thiol groups in cysteine, and can reduce ROS production by displacing redox active transition metals. Zinc deficiency activates NADPH oxidase and the inducible isoform of nitric oxide synthase (NOS), which can increase both ROS and reactive nitrogen species (RNS). Finally, zinc plays a role in cytoskeletal function, which is involved in the translocation to the nucleus of transcription factors such as nuclear factor kappa B (NFκB) and nuclear factor of activated T-cells (NFAT) (Mackenzie *et al.*, 2002; Aimo *et al.*, 2010; Uriu-Adams and Keen, 2010) (Figure 34.1).

A potential consequence of zinc-deficiency-induced changes in cell signaling is marked alterations in several components of the immune system (Table 34.1). In animals and humans, zinc deficiency can result in thymic atrophy and reduced cell-mediated and humoral immune responses (Fraker and King, 2004). Zinc deficiency induces apoptosis in susceptible cells during key stages of lymphopoiesis. For example, Pro- and Pre-B cells maturing within the bone marrow have reduced levels of anti-apoptotic Bcl-2 compared with mature B cells. A reduction of Pre-B cell numbers is observed with zinc deficiency; whereas zinc deficiency has little effect on the mature B cell (Fraker and King, 2004). Similar effects are observed with double-positive T-cells, which could account for the reduction of thymic size observed with zinc deficiency. Mature T-helper and cytotoxic cells are not affected by a reduction in zinc (Fraker and King, 2004), but an increase in the number of myeloid cells (i.e. neutrophils and monocytes) is observed with zinc deficiency (Tuerk and Fazel, 2009).

In addition to effects on cellular number, zinc influences immune cell activity. Natural killer (NK) cell activity is zinc dependent. Zinc is required for the interaction of the

**FIG. 34.1** Zinc deficiency and cellular signaling. Depending on the cell type, zinc deficiency influences a number of signaling pathways involved in cell proliferation, cell survival, and death. For example, a number of growth hormones activate receptor tyrosine kinases (RTK); zinc deficiency reduces extracellular signal-regulated kinase (ERK 1/2) phosphorylation by RAS and promotes dimerization of pro-apoptotic Bcl-2-associated death promoter (BAD), with anti-apoptotic Bcl-2, thereby reducing functional mitochondrial Bcl-2. Zinc-deficiency-induced increases in reactive oxygen species (ROS) affect nuclear factor of activated T-cells (NFAT); nuclear factor kappa beta (NFκB); and AKT gene expression through a reduction of tubulin polymerization and translocation of these transcription factors to the nucleus. In addition, zinc-deficiency-induced increases in ROS result in DNA damage and activation of p53 signaling, leading to growth arrest. Further signaling by p53 can facilitate Bcl-2-associated X protein (BAX) translocation to the mitochondria and dimerization with BAD, increasing mitochondrial permeability, cytochrome C (Cyto C) release, and subsequent activation of caspases that initiate apoptosis (cell death). TCR, T-cell receptor; CaM, calmodulin; C, calcineurin; IκB, inhibitor of κB; IKK, IκB kinase; PIP<sub>2</sub>, phosphatidylinositol 3,4-bisphosphate; PLCγ, phospholipase C-γ; PI3K, phosphatidylinositol 3-OH kinase; IP<sub>3</sub>, inositol triphosphate.

killer cell immunoglobulin-like receptors (KIRs) of the NK cell with major histocompatibility complex (MHC)-I molecules. Therefore, zinc deficiency increases non-specific lytic activity of the NK cell, as well as reducing NK activity (Rink and Gabriel, 2001). In addition to reduced T-cell numbers, a reduction in Th1 cytokines (interferon-(IFN)-

γ and interleukin (IL)-2) is observed whereas Th2 cytokines are unaffected (IL-4, IL-6, IL-10) (Ibs and Rink, 2003). Recently, it has been proposed that ionic zinc in lozenges reduces the severity of cold symptoms by enhancing IFN-γ production and inhibiting intracellular adhesion molecule-1 (ICAM-1), resulting in overall antiviral

**TABLE 34.1** Zinc deficiency and immune function

Immune effect	Reference
Decreased epithelial barrier functions (i.e. gastrointestinal, skin, respiratory)	Fraker and King (2004)
Increased susceptibility of infection	Keen and Gershwin (1990)
Suppression of oral tolerance	Finamore <i>et al.</i> (2003)
Suppression of delayed-type hypersensitivity reactions	Keen and Gershwin (1990)
Increased Pre- and Pro-B cell apoptosis	Fraker and King (2004)
Increased thymic atrophy	Fraker and King (2004)
Reduced thymulin	Rink and Gabriel (2001)
Increased double-positive T-cell apoptosis	Fraker and King (2004)
Altered T-cell receptor (TCR) signaling	Haase and Rink (2009)
Decreased T helper (Th1) cytokines	Ibs and Rink (2003)
Increased myeloid cell (i.e. neutrophils and monocyte) numbers	Tuerk and Fazel (2009)
Increased non-specific natural killer (NK) cell lytic activity	Rink and Gabriel (2001)

response (Eby, 2010; Singh and Das, 2011). Several aspects of T-cell receptor (TCR) signaling are influenced by zinc. Activation of the TCR complex involves the recruitment and dimerization of lymphocyte protein tyrosine kinases (Lck) by zinc-dependent mechanisms (Haase and Rink, 2009). Further downstream, zinc affects the activation of signaling pathways and transcription factors, such as NFAT, NF $\kappa$ B, and MAPK kinases, that regulate cytokine gene expression (Haase and Rink, 2009; Honscheid *et al.*, 2011; Yu *et al.*, 2011). With its diverse influence over immune signaling, the trafficking of intracellular zinc via the expression of specific zinc transporters and MT is an active area of research (Cousins *et al.*, 2006; Eide, 2006; Nishida *et al.*, 2009; Overbeck *et al.*, 2008; Yu *et al.*, 2011). MT expression is induced by the pro-inflammatory cytokines IL-1, IL-6, and TNF- $\alpha$ , and hormones such as the glucocorticoids, epinephrine, and glucagon (Schroeder and Cousins, 1990; Mocchegiani *et al.*, 2009; Takeda and Tamano, 2010). It has been postulated that the pro-inflammatory cytokines can increase glucocorticoid release, resulting in an induction of MT synthesis via the glucocorticoid response element on the MT promoter (Schroeder and Cousins, 1990). In addition, IL-6 has been demonstrated to increase hepatocyte Zip14 expression, therefore increasing intracellular zinc which can induce MT synthesis via MTF-1 (Liuzzi *et al.*, 2005). The end result is a redistribution of zinc to the liver during stress and an inflammation-induced acute phase response, resulting in hypozincemia (Schroeder and Cousins, 1990; Liuzzi *et al.*, 2005). Therefore, perturbation of intracellular MT expression may have profound implications for a number of inflammatory conditions and chronic disease states.

Mild-to-marginal states of zinc deficiency may go undetected as individuals at risk may not display the specific clinical features of zinc depletion. Although the occurrence of severe zinc deficiency in humans is well documented, whether a physiologically significant mild zinc deficiency exists in humans is controversial. Currently, research in this area is hampered by the lack of reliable, sensitive biomarkers for zinc status (Gibson *et al.*, 2008). Demonstration of mild zinc deficiency in humans is not as straightforward as in experimental animals. If one is to use impaired growth velocity as the primary clinical feature of mild zinc deficiency, several studies have provided convincing evidence that zinc supplementation reverses this trend (Hambidge, 2000). Moreover, meta-analyses of well controlled trials examining the effects of zinc supplementation in children show improved growth (Hambidge, 2000; Brown *et al.*, 2002).

A marginal zinc deficiency may occur in those with an increased utilization of zinc, such as during periods of increased growth or in pregnancy, particularly if their dietary zinc intake is also low. Women with AE first provided evidence that a severe zinc deficiency results in poor pregnancy outcomes (King, 2000; Uriu-Adams and Keen, 2010). Subsequently, Jameson was the first to associate a low maternal serum zinc status in the first trimester of pregnancy with congenital malformations, fetal dysmaturity, prematurity, and maternal complications in otherwise healthy women (Jameson, 1976). That report stimulated further research examining the relationship between zinc status and pregnancy outcome. Detailed reviews of this topic are available (Apgar, 1985; Swanson and King, 1987; Keen and Hurley, 1989; King, 2000; Uriu-Adams and

Keen, 2010). Several groups have reported that mothers of infants with congenital anomalies, or who suffer from pregnancy complications, have lower plasma zinc concentrations than other mothers; however, this is an inconsistent finding (King, 2000; Uriu-Adams and Keen, 2010).

Numerous clinical situations can result in reduced absorption, increased loss, or increased need for zinc. Cadmium from sources such as cigarette smoke competes with zinc for transport mechanisms, such as Zip8 and MT (He *et al.*, 2009); thus, zinc deficiency could increase the risk for cadmium toxicity, and potentially lead to an individual's susceptibility to the development of chronic diseases including cardiovascular disease (Messner *et al.*, 2009; Afridi *et al.*, 2011) and cancer (Kazi *et al.*, 2010). Patients with alcoholic liver disease are often characterized by hyperzincuria, hypozincemia, and low liver zinc concentrations compared with controls or with patients without cirrhosis (Kang and Zhou, 2005). Because the teratogenic expression of zinc deficiency is similar to that of fetal alcohol spectrum disorders (FASD), alcohol-induced zinc deficiency has been proposed as a mechanism underlying the development of FASD (Keen *et al.*, 2010). It has been estimated that half of the elderly do not meet the recommended dietary allowance (RDA) for zinc (Hodkinson *et al.*, 2007), potentially placing them at risk for osteoporosis and impaired cognitive and immune function (Meunier *et al.*, 2005; Yamaguchi, 2010). Finally, epidemiology studies have shown an association between reduced zinc status in those with diabetes (Islam and Loots, 2007; Jansen *et al.*, 2009). Alterations in zinc

metabolism have been shown to occur in both diabetic humans and experimental animals. Adult rats with genetically or chemically induced diabetes are characterized by zinc accumulation in the liver and kidney and by hyperzincuria (Failla and Kiser, 1983; Uriu-Hare *et al.*, 1989). Both type I and type 2 diabetic patients can exhibit hyperzincuria, which increases with the severity of the diabetes (Walter *et al.*, 1991). It has been postulated that the hyperzincuria can result in a conditioned zinc deficiency in some individuals, and hypozincemia is a relatively common finding in diabetics (Walter *et al.*, 1991). However, randomized controlled zinc supplementation trials for the prevention of type 2 diabetes have failed to show a benefit (Beletate *et al.*, 2007).

### Requirements, Recommended Dietary Allowance, Upper Limits, and Evaluation of Zinc Status

Age, sex, pregnancy, and lactation are all factors that were used by the US Institute of Medicine for the dietary zinc recommendations in 2001. The suggested values were based on a combination of factors including balance and isotopic zinc tracer studies, and a mix of zinc supplementation studies (Table 34.2) (Institute of Medicine, 2001). The factors and underlying principles that were used to estimate the RDA, estimated average requirement (EAR), average intake (AI) and tolerable upper intake levels (UL) for zinc are described in detail in the committee's

**TABLE 34.2** Dietary reference intakes

Life stage	Age	AI (mg/day)		EAR (mg/day)		RDA (mg/day)		UL (mg/day)	
		Male	Female	Male	Female	Male	Female	Male	Female
Infants	0–6 months	2.0	2.0					4.0	4.0
	7–12 months			2.5	2.5	3.0	3.0	5.0	5.0
Children	1–3 years			2.5	2.5	3.0	3.0	7.0	7.0
	4–8 years			4.0	4.0	5.0	5.0	12.0	12.0
	9–13 years			7.0	7.0	8.0	8.0	23.0	23.0
	14–18 years			8.5	7.3	11.0	9.0	34.0	34.0
Adults	>19 years			9.4	6.8	11.0	8.0	40.0	40.0
Pregnancy	14–18 years				10.0		12.0		34.0
	19–50 years				9.5		11.0		40.0
Lactation	14–18 years				10.9		13.0		34.0
	19–50 years				10.4		12.0		40.0

AI, adequate intake; EAR, estimated average requirement; RDA, recommended dietary allowance; UL, tolerable upper intake level.

Data from Institute of Medicine (2001).

report. A key question facing the field today is to what extent zinc intake levels below the suggested RDA represent a true health risk.

At present, a major impediment to the identification of the extent and severity of suboptimal zinc status in select populations is the lack of sensitive, specific, and agreed-upon biomarkers for zinc status (King, 2011). As noted above, while an assessment of zinc status is often based on an analysis of plasma zinc concentrations, this approach can be fraught with difficulties as plasma zinc values can be affected by numerous factors including acute meal-related changes, circadian variations, fasting, and cytokine-induced changes in tissue zinc stores (Hurley *et al.*, 1982; King, 2011). It is generally agreed that plasma zinc concentrations can be a poor indicator of whole-body zinc status for the above reasons. It can also be argued that, with respect to humans, plasma zinc concentrations do not significantly decrease until dietary zinc levels are so low that homeostasis cannot be reestablished. Thus, while plasma zinc measurements may have potential value in the identification of individuals with severe deficiencies, they may be of limited value with respect to the identification of cases of marginal deficiency. In all cases, it should be stressed that, when plasma zinc measurements are used as predictors of zinc status, it is important to control for other metabolic factors that can influence the concentrations of this element (e.g. stress, fasting, diurnal considerations, hormonal state, etc.) (Institute of Medicine, 2001). As a complement to plasma zinc concentrations, the measurement of zinc in leukocytes, erythrocytes, saliva, and hair have all been advanced as possible approaches to the assessment of zinc status (Gibson *et al.*, 2008; Cummings and Kovacic, 2009); however, similar to plasma zinc, none of the above measurements are thought to be sensitive with respect to the identification of marginal zinc deficiency (Institute of Medicine, 2001).

A different approach to the assessment of zinc status has been the measurement of the activity of zinc-dependent enzymes such as angiotensin converting enzyme (ACE) or extracellular SOD. However, similar to plasma zinc concentrations, measurements of the above enzyme activities have not been shown to be sensitive to conditions of marginal zinc status. Zinc-regulated genes have also been proposed to be useful as indices of zinc status. In this regard the assessment of MT concentrations, as well as MT mRNA concentrations, in circulating cells (erythrocytes, reticulocytes, and monocytes) have shown promise;

however, the widespread use of this approach has been limited by difficulties in developing assays that can be easily employed (Cao and Cousins, 2000; Liuzzi and Cousins, 2004). The concentrations of certain hormones and growth factors, such as growth hormone and IGF, have also been proposed to be sensitive to zinc status; however, these markers show little specificity.

Given the above, a suite of markers, as opposed to single markers, may more accurately reflect zinc status (Lowe *et al.*, 2009). As an example of this, it is known that zinc deficiency can result in hypogeusia (taste impairment). A report by Takeda *et al.* (2004) found that, in patients with zinc-deficiency-related hypogeusia, serum zinc concentrations were within the normal range; however, the ratio of ACE activity (apo-ACE/holo-ACE) was a more sensitive indicator of zinc status than serum zinc. The discovery of the ZnT (SLC30/CDF) and ZIP (Zrt/IRT-like proteins) families of zinc transporters involved in the regulation, export, and import of zinc in a variety of tissues prompts the question of whether the protein or mRNA of a suite of these proteins can be used as biomarkers for zinc status. Using quantitative real-time polymerase chain reaction (RT-PCR), it has been shown that modest dietary zinc supplementation in humans (15 mg zinc/day for 10 days) increased MT and ZnT1 mRNA, and decreased Zip3 mRNA in dried spots of whole blood, indicating that these targets were responsive to zinc supplementation (Aydemir *et al.*, 2006).

## Food and Other Sources of Zinc

Foods can differ widely in their zinc content. For example, zinc concentrations range from 0.03 mg/100 g egg white, to 1 mg/100 g chicken meat, to 75 mg/100 g oysters. Shellfish, beef, and other red meats are good zinc sources, as are nuts and legumes (USDA, 2010). Whole-grain cereals are relatively rich in zinc, and are the primary plant source of zinc (USDA, 2010). Zinc is mostly contained in the bran and germ portions, thus, nearly 80% of the total zinc in these foodstuffs can be lost in the wheat milling process (Hambidge *et al.*, 1986). There is no standard enrichment policy for zinc but some breakfast cereal manufacturers fortify the zinc content of their product in amounts ranging from 25% to 100% of the United States RDA, depending on the end consumer. Apart from fortification, other strategies include enhancing agricultural practices so that the ratio of zinc to phytate is increased. For example, plant zinc concentrations may be enhanced

if grown in zinc-rich soil or treated with zinc-rich fertilizers (Cakmak, 2008).

The availability of zinc in the United States food supply has been estimated at 16.2 mg per capita per day (USDA 2005). As noted above, total dietary zinc intakes will be influenced greatly by an individual's food choices. Animal products, especially meat, provide about 70% of the zinc consumed by the average individual in the United States. Frequently, zinc intakes are correlated with protein intake, but the exact relationship is influenced by protein source. For example, diets consisting primarily of eggs, milk, poultry, and fish have a lower zinc to protein ratio than those composed of shellfish, beef, and other red meats. Similar variations occur in vegetarian diets in that diets with a high zinc to protein ratio contain liberal quantities of legumes, whole grains, nuts, and cheese, whereas diets that are based on fruits and vegetables have relatively low zinc to protein ratios. Mean intakes from adult self-selected mixed diets in the United States have been reported to range from 9.5 to 15.4 mg zinc/day (Institute of Medicine, 2001). During the first 6 months of life, zinc intake varies with the mode of feeding. Zinc intake in breast-fed infants tends to decline over the first year of life from 2.3 mg/day at 1 month of age to 0.94 mg/day at 6 months (Institute of Medicine, 2001); formula-fed infants consume approximately 5.5 mg/day between 2 and 11 months of age (Briefel *et al.*, 2000). The zinc content of commercial infant formulas depends on the fortification policy of the manufacturer, but still contributes substantially to daily zinc intake (Arsenault and Brown, 2003). Children 1 to 8 years old consume 6.9 to 9 mg/day and girls and boys (9–13 years old) report daily intakes of about 9.6 to 11.8 mg; the daily intake of adolescents (14 to 18 years) is reported as approximately 9.3 mg for girls and 15.1 mg for boys. The range of intake for elderly populations is 8.6 to 13.8 mg/day (Briefel *et al.*, 2000; Institute of Medicine, 2001). Due to supplement use by pregnant and lactating women, zinc intakes are often higher in these groups, 9.2 mg and 10.4 mg, respectively, than the reported 8.5 mg/day for adult women (Briefel *et al.*, 2000; Institute of Medicine, 2001).

The bioavailability of zinc can be significantly affected by other diet constituents, thus it is important to note that simple calculations of dietary zinc intakes can be misleading with respect to the prediction of the zinc status of an individual. Such calculations are of value, however, with respect to the identification of potential at-risk populations. As an example, in a diet survey of pregnant Hispanic

women living in an agricultural region of California, it was estimated that approximately 45% of the women surveyed had dietary zinc intakes that were below the EAR for this population group (9.5 mg zinc/day) (Harley *et al.*, 2005). Based on this finding, one interpretation is that marginal zinc deficiency is a significant health problem in many countries, including the United States, and that studies aimed at the assessment of zinc status in such population groups would clearly be warranted. However, as part of their survey, the above investigators also collected information regarding supplement use. When the zinc provided by the supplements was added to the estimated zinc intake from food, the percentage of women who had combined zinc intakes from food and supplements below the EAR fell to 4.5% (Harley *et al.*, 2005). The above illustrates the importance of considering the zinc intake from supplements, as well as the potential use of fortified functional food products.

## Excess and Toxicity

Although rare, cases of acute zinc toxicity in humans resulting from exposure to excessive amounts of zinc have been reported. Exposure to zinc can occur through three routes: through the skin, by inhalation, and by ingestion. Dermal exposure to zinc is not thought to represent a significant toxicological risk. Metal fume fever is considered to be the most common form of zinc toxicosis through inhalation. This disease occurs as a consequence of the inhalation of zinc-containing smoke, which typically contains zinc oxide. Signs can develop within 8 hours and include hyperpnoea, profuse sweating, and general weakness. Signs of acute zinc toxicity have been reported to disappear within 1–4 days after the individual is removed from the zinc-contaminated environment (Plum *et al.*, 2010).

With respect to zinc toxicity due to excessive ingestion of zinc in the diet, or the ingestion of non-food zinc-containing products, isolated outbreaks of zinc toxicity have occurred as a result of the consumption of foods and beverages contaminated with zinc released from galvanized containers. Typical signs of acute zinc toxicosis include abdominal pain, diarrhea, nausea, and vomiting (Fosmire, 1990; Plum *et al.*, 2010). Doses of zinc in excess of 200 mg/day are typically emetic. A fatal outcome was reported in a woman who was inadvertently given 1.5 g of zinc intravenously over a 3-day period. It can be noted that, in companion animals, zinc toxicity can result from the

consumption of zinc-galvanized nuts and bolts or die-cast toys, and of coins, specifically, US and Canadian pennies minted after 1987 and between 1997 and 2001, respectively (Cummings and Kovacic, 2009).

The long-term consumption of zinc supplements in excess of 150 mg/day has been reported to result in low serum HDL levels, gastric erosion, and depressed immune function (Fosmire, 1990; Plum *et al.*, 2010). The major reported consequence of the long-term excessive ingestion of zinc supplements is the induction of secondary copper deficiency, which is thought to be due to the competitive interaction between these elements with regard to intestinal absorption (Plum *et al.*, 2010). Relatively low levels of dietary zinc can interfere with copper absorption. An intake of 18.5 mg/day for 2 weeks was reported to increase copper excretion in the feces (Festa *et al.*, 1985). Ten weeks of zinc supplementation at 50 mg/day was reported to result in reductions in erythrocyte copper–zinc SOD activity (Yadrick *et al.*, 1989). Sickle cell patients given zinc supplements of 150 mg/day were reported to be characterized by hypocupremia (Prasad *et al.*, 1978). Based on the ability of zinc to reduce the gastrointestinal uptake of copper, in 1997, zinc acetate was approved by the US Food and Drug Administration for the treatment of Wilson's disease, an inborn error of copper metabolism that causes excessive tissue accumulation of copper (Anderson *et al.*, 1998). It is important to note that over-aggressive use of zinc supplements in the treatment of Wilson's disease can result in a copper deficiency (Horvath *et al.*, 2010).

Recently, additional potential sources of excessive zinc in the environment have been identified. Several investigators have suggested that the excessive use of denture creams that contain zinc may represent a toxicological risk as they may contribute to the development of a copper deficiency (Nations *et al.*, 2008; Tezvergil-Mutluay *et al.*, 2010; Barton *et al.*, 2011). Given the significant number of individuals who use denture cream, the above hypothesis merits investigation. Similar concerns potentially exist for the use of zinc lozenges for colds. While current recommendations are for a brief period of use (Singh and Das, 2011) at a total recommended daily dose (i.e. 80 mg/day for 3–7 days), a number of side-effects have been reported in studies, including nausea (Das and Singh, 2011; Singh and Das, 2011). As with the excessive use of denture creams, there is the potential for a reduction in copper status if zinc lozenges are consumed in large amounts for

a prolonged period of time, such as might occur if an individual takes them prophylactically during the cold season, or if an individual consumes lozenges in amounts that exceed what is recommended. Another potential source of excessive zinc in the environment that has been identified is zinc oxide nanoparticles, which are used in a number of industries. Preliminary data suggest that these particles are occurring at increasing concentrations in several foodstuffs and water sources and have been shown to be cytotoxic in some in vitro models (Croteau *et al.*, 2011; Som *et al.*, 2011). Given their widespread use, the potential human health risks of zinc nanoparticles are an area that also demands research.

Observations that high amounts of zinc in the diet can result in reductions in copper uptake, and potentially copper deficiency, were critical in the setting of the current UL values for zinc in the United States and Canada. Based on the report by Yadrick *et al.* (1989) that young women who had daily dietary zinc intakes over a period of 10 weeks of the order of 60 mg (50 mg provided through the consumption of zinc supplements and approximately 10 mg provided by the foods typically consumed by the individuals) were characterized by reductions in erythrocyte SOD activity, a lowest observed adverse effect level (LOAEL) of 60 mg/day for dietary zinc was determined. After using an uncertainty factor of 1.5, a UL of 40 mg/day was identified for adult men and women.

While the logic that drove the current UL for zinc is certainly reasonable, it is critical to note that the UL value was in essence derived from a study in which the majority of “dietary” zinc was obtained from a dietary supplement. There is a need for additional studies that can provide more information on LOAELs for zinc when different types of zinc supplements are used, or when naturally occurring high zinc foods, as well as zinc-fortified foods, are included in the diet. Underscoring the need for such studies is the observation that the use of dietary supplements is widespread in many developed countries (Bailey *et al.*, 2011). Zinc-containing supplements in particular are being widely used for multiple purposes ranging from the desire to improve athletic performance or cognitive skills, to the perceived need to reduce the onset and progression of a vast array of chronic diseases as well as the common cold. When coupled with the observation that suboptimal zinc status may represent a significant public health concern in select populations, there is a clear need for more work aimed at the evaluation of what constitutes

a “safe and appropriate” intake of zinc. Of critical importance in such studies will be the need also to better define the extent to which an individual’s dietary copper intake, and copper status, influence their response to “high” zinc diets.

## Future Directions

Our knowledge of the metabolism of zinc and its physiological roles has been significantly advanced over the past decade. However, there are still major gaps in our understanding of zinc metabolism on several fronts. The homeostatic mechanisms that help regulate tissue and cellular zinc concentrations are still not well characterized. Similarly, there is minimal information regarding how subtle changes in intracellular and extracellular zinc pools contribute to metabolic regulation. In contrast to early literature that suggested that zinc deficiency, as well as zinc toxicity, were relatively rare events, recent literature suggests that zinc deficiency may be common in certain populations, and there is emerging evidence that zinc toxicity may also increasingly be a public health concern. The above has resulted in a stimulation of research that is focused on better defining the short- and long-term consequences of not just severe zinc deficiency and toxicity, but also the effects associated with marginal deficits or excesses of this essential nutrient. Critical to the above work will be the identification of suites of biomarkers that, when combined, can give an accurate indication of zinc status.

## COPPER

JOSEPH R. PROHASKA, PhD

*University of Minnesota Medical School Duluth, Duluth, Minnesota, USA*

### Summary

Research during the past five years has provided new and exciting insights about copper homeostasis at the cellular level. Ongoing investigations employing the tools of molecular genetics and confocal microscopy are certain to identify additional genes and proteins required for the transport of copper across membranes and its utilization within various cellular compartments. Elucidation of the direct and indirect roles of copper in the development and degeneration of the nervous system, the integrity of the cardiovascular and skeletal systems, and the activities of the immune system will certainly be facilitated by judicious use of molecular techniques such as gene knockout, overexpression, functional genomics, and proteomics. Stable isotope technology has provided an understanding of whole-body copper metabolism in healthy adults. Continued application of this methodology and increased use of mathematical modeling are expected to provide new information about copper metabolism and requirements for selected populations, and especially those likely to be at higher risk of developing copper deficiency. These include premature and term infants, pregnant malnourished adolescents, the institutionalized elderly, and individuals with chronic diseases such as cystic fibrosis, Crohn's disease and other malabsorption syndromes. Studies in animals suggest the possibility that marginal copper deficiency, though difficult to diagnose, may compromise our ability to adapt metabolically to various physiological, pathophysiological, and emotional stresses. Development of a panel of sensitive biochemical and functional indices for the accurate assessment of copper status represents an important challenge for investigators interested in the biology and nutrition of copper.

### Introduction

Copper was thought essential for humans as early as the middle of the nineteenth century but was proven to be required through careful experimental work in plants and rodents in the 1920s. Organisms use protein-bound ox-

dized cupric ion ( $\text{Cu}^{2+}$ ) or reduced cuprous ion ( $\text{Cu}^+$ ) for a number of single-electron transfer reactions involving oxygen. Sophisticated mechanisms for the regulated acquisition, tissue distribution, utilization, and excretion exist so as to prevent deleterious reactions from copper excess. Major advances in our understanding of copper homeos-

tasis have evolved through the use of molecular genetics which may impact human health and disease and impact the Dietary Recommended Intakes.

## Biological Functions of Copper

Humans contain about 1 mg copper/kg body weight. Copper has no known structural role, nor is there a major copper storage reservoir; rather, copper serves as an essential catalytic cofactor for many mammalian cuproenzymes (Table 35.1). The metal centers in these proteins bind oxygen and produce water, superoxide, or hydrogen peroxide in addition to various organic products. These cuproenzymes are involved in fundamental processes in energy production, iron utilization, maturation of the extracellular matrix, activation of neuropeptides, and neurotransmitter synthesis. The physical properties of these enzymes have been reviewed elsewhere (Linder and Hazegh-Azam, 1996).

Mammalian copper-dependent amine oxidases (EC 1.4.3.6) include a group of enzymes found in plasma and tissues as dimers. They deaminate monoamines and diamines, releasing aldehydes, ammonia, and hydrogen peroxide. They are inhibited by semicarbazide and contain the cofactor 2,4,5-trihydroxyphenylalanine quinone (TPQ) whose synthesis is also copper-dependent (Brazeau *et al.*, 2004). They may function in metabolism of certain amines or may be involved in intracellular signaling by generation of hydrogen peroxide. An example is vascular adhesion protein-1 (VAP-1), a copper amine oxidase that

is involved in leukocyte trafficking (Salmi and Jalkanen, 2001). Absence of the protein, also called amine oxidase, copper-containing-3 (AOC3), decreased both leukocyte and lymphocyte homing and attenuated inflammatory responses (Stolen *et al.*, 2005).

Ceruloplasmin (Cp) is blue multicopper oxidase, also known as ferroxidase, which oxidizes ferrous iron thought to be important in loading transferrin, the ferric iron transport protein. Cp is an abundant 132-kD plasma glycoprotein made and secreted mainly by liver. Brain and other organs such as spleen, kidney, and heart express a splice variant GPI-anchored form of Cp (Mostad and Prohaska, 2011). Individuals with aceruloplasminemia clearly demonstrate an essential function of Cp as they are characterized by low serum iron, high iron deposits in liver, brain and pancreas, and the development of insulin-dependent diabetes (Hellman and Gitlin, 2002). However, copper metabolism is normal in aceruloplasminemic patients. Studies with Cp-null mice confirmed the impairment in iron mobilization and normal copper metabolism (Meyer *et al.*, 2001). Thus, former hypotheses suggesting that the main function of Cp was to transport copper are likely false.

Cytochrome c oxidase (CCO), also known as mitochondrial complex IV, contains 13 protein subunits, two heme groups, zinc, magnesium, and three copper ions. CCO catalyzes the reduction of molecular oxygen to water and generates a proton gradient that is necessary for ATP synthesis. The assembly of CCO is dependent on additional accessory proteins, some of which are involved in copper delivery and insertion into subunits I and II. Adequate dietary copper is necessary to support the activity and stability of CCO. Mutations resulting in total loss of CCO are likely lethal. Mutations in the assembly proteins affect CCO and result in pathophysiology (Hamza and Gitlin, 2002).

Dopamine- $\beta$ -monooxygenase (DBM) requires copper in each of its four subunits and ascorbate as a cosubstrate to convert dopamine to norepinephrine. DBM is expressed in adrenal medulla, sympathetic neurons of the peripheral nervous system, and noradrenergic and adrenergic neurons in brain. Deletion of the DBM gene is lethal for mouse embryos, suggesting a critical role of norepinephrine during development (Thomas *et al.*, 1995).

Mammals have three separate genes that produce proteins that catalyze dismutation of superoxide, the univalent reduction product of molecular oxygen. Two of these proteins, Cu,Zn-superoxide dismutase (SOD1) and

**TABLE 35.1** Mammalian copper-dependent enzymes

Enzyme	Function
Amine oxidases	Oxidative deamination
Ceruloplasmin	Fe <sup>2+</sup> oxidation
Cytochrome c oxidase	Oxygen electron transfer
Dopamine- $\beta$ -monooxygenase	Norepinephrine synthesis
Extracellular superoxide dismutase	Superoxide disproportionation
Hephaestin	Fe <sup>2+</sup> oxidation
Lysyl oxidase	Elastin cross-linking
Peptidylglycine $\alpha$ -amidating monooxygenase	Peptide C-terminal $\alpha$ -amidation
Superoxide dismutase 1	Superoxide disproportionation
Tyrosinase	DOPA quinone synthesis
Zyklopen	Fe <sup>2+</sup> oxidation

extracellular superoxide dismutase (EC-SOD) require copper. The other protein is located in the mitochondrial matrix, manganese superoxide dismutase (SOD2). Both SOD1 and EC-SOD also contain zinc as a cofactor. SOD1 is a homodimer of subunit size 16kD. EC-SOD is a tetramer of subunit size 135kD that functions as an antioxidant in the extracellular matrix and is the predominant dismutase in extracellular fluids such as lymph, synovial fluid, and plasma (Fattman *et al.*, 2003). Studies with EC-SOD knockout mice support a role for this protein and extracellular superoxide in modulating vascular tone by interacting with nitric oxide (Jung *et al.*, 2003).

Hephaestin is multicopper oxidase that is 50% identical to Cp. It was discovered as the defective gene product in sex-linked anemia in mice. The mutation resulted in iron retention in the intestine, suggesting an iron efflux function similar to Cp (Kuo *et al.*, 2004). Recently another Cp homolog, *zyklopen*, was described that may function in placental iron efflux (Chen *et al.*, 2010).

Lysyl oxidase (LO) (EC 1.4.3.13), a copper-dependent amine oxidase, contains a unique cofactor, lysyl tyrosyl quinone (LTQ), required for the oxidative deamination of specific lysine residues in the extracellular matrix (Kagan and Li, 2003). This reaction initiates the formation of cross-links that stabilize elastin and collagen. Discovery of at least four additional genes expressing proteins related to LO (LOXL1-4), with conserved catalytic domain, copper and cofactor binding sites, that are highly expressed in specific tissues, is opening a new chapter for investigation and function of these cuproenzymes (Molnar *et al.*, 2003).

Peptidylglycine  $\alpha$ -amidating monooxygenase (PAM), like DBM, requires both copper and ascorbate as cofactors. PAM is required for post-translational modification of many peptides to their bioactive forms. Copper and ascorbate are required for monooxygenase activity to convert C-terminal glycine residues to hydroxyglycyl residues that are subsequently hydrolyzed by a lyase domain to produce  $\alpha$ -amidated peptides and glyoxylate (Eipper *et al.*, 1992). PAM is especially enriched in the nervous and endocrine system with very high levels in the pituitary and cardiac atria. The importance of PAM has recently been documented by demonstrating embryonic lethality in mice following gene ablation (Czyzyk *et al.*, 2003). Importantly, PAM heterozygote mice have impaired thermoregulation and enhanced sensitivity to seizures (Bousquet-Moore *et al.*, 2010). More than half of all neuropeptides require PAM for activation and underscore this important role of copper in biology. Examples of these

neuropeptides include: adrenomedullin, calcitonin, cholecystokinin, gastrin, neuropeptide Y, oxytocin, substance P, thyrotropic hormone-releasing hormone (TRH), vasoactive intestinal peptide (VIP), and vasopressin (Bousquet-Moore *et al.*, 2010).

Tyrosinase, monophenol oxidase, performs a highly specialized function in melanin biosynthesis in melanocytes. Mutational loss of catalytic function leads to albinism. Copper restriction confirms an important role of tyrosinase in pigmentation as achromotrichia is observed in domestic and laboratory animals consuming diets low in copper.

In response to changes in nutritional copper intake, there are a number of enzymes whose activity either increases or decreases; however, these changes do not necessarily mean these are cuproenzymes (Prohaska, 1988). There are other proteins that may have catalytic properties dependent on copper but are less well established, including clotting factors V and VIII, S-adenosylhomocysteine hydrolase, prion protein, and others (Prohaska, 1988).

There are a number of copper-binding proteins in mammals that function as transport proteins and copper chaperones to maintain copper homeostasis (Bertinato and L'Abbé, 2004; Prohaska and Gybina, 2004). Additional roles for these copper binding proteins continue to be elucidated (Table 35.2). CCS and COMMD1 both impact

**TABLE 35.2** Mammalian copper-binding proteins

Protein	Putative copper function
Albumin	Plasma transport
Amyloid precursor protein	Transport
Atox1	Chaperone, transcription factor
ATP7A	Efflux, metallation
ATP7B	Efflux, Cp metallation
CCS	SOD1 chaperone, HIF-1 $\alpha$ activity
Clotting factors V, VIII	Unknown
COMMD1	Biliary excretion, SOD1 assembly
Cox11	CCO chaperone
Cox17	CCO chaperone
Ctr1	Transport
Ctr2	Transport
$\alpha$ 2-Macroglobulin	Plasma transport
Metallothionein	Storage
Prion protein	Unknown
Sco1	CCO chaperone
Sco2	CCO chaperone
XIAP	Ubiquitination of COMMD1 and CCS

**FIG. 35.1** Cellular copper transport and excretion – intestine to liver.  $\text{Cu}^+$  is transferred across the enterocyte plasma membrane by Ctr1. Copper binds to chaperones (Atox1, Cox17, and CCS) that deliver copper to targeted cuproenzymes (CCO and SOD1) or copper-translocating ATPases (ATP7A and ATP7B). ATPases move copper into the trans Golgi network for incorporation into apo-cuproenzymes (e.g. intestine Heph and liver aCp) or to cytoplasmic vesicles near plasma membranes to mediate copper efflux. Copper pools are also associated with mitochondria (MT). Specialized copper binding proteins function in liver (COMMD1 and XIAP) to regulate ATP7B and copper efflux. They also regulate SOD1 and CCS. Mitochondria possess several chaperones needed to deliver copper to CCO.

HIF-1 $\alpha$  function (van de Sluis *et al.*, 2007; Feng *et al.*, 2009). ATOX1 appears to be a transcription factor in cell cycle regulation (Itoh *et al.*, 2008). X-linked inhibitor of apoptosis (XIAP) is a copper binding protein that regulates survival of both CCS and COMMD1 (Brady *et al.*, 2010). COMMD1 regulates dimerization of SOD1 (Vonk *et al.*, 2010).

## Copper Homeostasis

### Whole-Body Metabolism

Tracer studies have contributed markedly to our present understanding of mammalian copper metabolism. Ingested food and digestive secretory fluids (salivary, pancreatic, and biliary) all contribute to the copper pool present in the intestinal lumen. Copper likely enters small intestinal epithelial cells by a facilitated process that involves a specific cuprous ion carrier, Ctr1, located on the brush-border surface (Figure 35.1) The tissue acquisition of newly absorbed copper occurs in two phases. The first involves vectorial transport of copper across the basolateral membrane of the enterocyte into portal circulation where it is transported to liver in association with albumin and  $\alpha$ 2-macroglobulin. Newly arrived copper is secreted into plasma bound to Cp; however, the lack of disturbances in copper metabolism in aceruloplasminemia patients and mice clearly demonstrates that plasma Cp does not mediate cellular acquisition of copper. Plasma has a small non-Cp component, likely amino acid complexes; however, the mechanisms by which protein-bound or amino-acid-

bound copper is transported from plasma into cells remain unknown.

Copper concentration varies with tissue (Linder and Hazegh-Azam, 1996). Generally, copper is not stored in tissues, suggesting that differences in concentrations of the

metal may reflect relative quantities of cuproenzymes. Transport of copper from the liver into the bile represents the primary route for excretion of endogenous copper. This pathway is immature in fetal and neonatal liver, thereby accounting for the storage of hepatic copper at these early stages of development. Likewise, cholestasis can result in accumulation of hepatic copper after the neonatal period. Copper of biliary origin and non-absorbed oral copper are eliminated from the body in feces. Daily losses of copper in urine are minimal in healthy individuals.

Stable isotope studies with healthy human subjects under controlled conditions have shown that both absorption and retention of copper readily respond to wide fluctuations in dietary copper intake. Under normal copper intake conditions it has been estimated that true copper absorption is about 10% since there is a 30% loss of newly absorbed copper via the endogenous secretion pathway involving active biliary excretion (Harvey *et al.*, 2005). Absorption of ingested copper appears to increase when dietary intakes are low (Turnlund *et al.*, 1998). Likewise, copper retention in many organs, particularly in brain and heart, is markedly increased in response to restricted copper intake in the rat (Levenson and Janghorbani, 1994). However, the ability of these adaptive mechanisms to maintain normal copper status in humans is exceeded when chronic dietary copper intake is less than 0.7 mg/day below that present in typical western diets, which average about 1.2 mg/day in the USA (Milne and Nielsen, 1996; Turnlund *et al.*, 1997).

### **Cellular Homeostasis**

Cells adapt to obtain adequate but not excessive amounts of copper using a complex set of transporters and metallochaperones (Figure 35.1, Table 35.2). Luminal copper must be reduced to cuprous ion for uptake by Ctr1. This reduction process has not been elucidated but may be provided by Dcytb or Steap2, two putative reductases reviewed elsewhere (Collins *et al.*, 2010). Ctr1 is a transmembrane protein essential for copper distribution to the organism as deletion is lethal to embryos and surviving heterozygous knockout mice *Ctr1* +/- have reduced copper content and function in selected organs (Kuo *et al.*, 2001; Lee *et al.*, 2001). If a redundant copper transport system does exist, as suggested from in vitro cell culture studies with immortalized cell lines and studies in Caco-2 cells, it must be weak since it cannot replace Ctr1 function in the whole animal.

Imported cytoplasmic copper binds to a group of ubiquitous copper chaperone proteins and perhaps other copper binding species such as metallothioneins I and II (MT). Metallothioneins are cysteine-rich proteins with high affinity for heavy metal ions. They provide cells with a secondary system of detoxification when the copper efflux process is either not operational (e.g. during early stages of development and when efflux is defective) or when activity of the efflux pump becomes inadequate during acute exposure to high amounts of copper. Chaperones directly deliver copper to target proteins in cytoplasm and in membranes of organelles for incorporation of copper to apo-cuproproteins (Prohaska and Gybina, 2004).

The copper chaperone for superoxide dismutase, CCS, transfers copper to cytoplasmic and intermitochondrial membrane space SOD1. Deletion of CCS results in low SOD1 activity, a phenotype similar to SOD1 knockout mice (Wong *et al.*, 2000). Cox17 is necessary to deliver copper to the mitochondria for CCO assembly. Deletion of Cox17 results in embryonic lethality in a temporal pattern similar to Ctr1 knockout mice (Takahashi *et al.*, 2002). Within the mitochondria additional chaperones (Cox11, Sco1 and Sco2) are necessary to deliver copper to CCO subunits I and II (Hamza and Gitlin, 2002). Atox1 delivers copper to P-type ATPases that mediate energy-dependent transport of the metal to the lumen of the trans-Golgi network for incorporation of the metal into secretory copper-dependent proteins such as Cp, DBM, LO, PAM, and tyrosinase. Deletion of Atox1 results in perinatal mortality with symptoms consistent with copper deficiency (Hamza *et al.*, 2001).

Two distinct copper-translocating, P-type ATPases have been identified (Lutsenko, 2010). Hepatocytes, mammary tissue, and certain neurons express the copper translocating ATPase, ATP7B, whereas other cells have a highly homologous ATPase, ATP7A. It is now recognized that ATP7A and ATP7B cycle between the trans-Golgi network and cytoplasmic vesicles. ATP7A is the protein missing or mutated in humans with Menkes' disease that results in copper deficiency. ATP7B is the protein mutated in Wilson's disease and leads to hepatic copper overload toxicity. When intracellular copper is low or normal, copper ATPases are localized predominantly in the trans-Golgi network to facilitate the delivery of the metal to secretory apo-cuproproteins. As cellular copper increases, the ATPases are redistributed into cytoplasmic vesicles

(Lutsenko and Petris, 2003). Fusion of copper-loaded cytoplasmic vesicles with the canicular membrane of the hepatocyte is required for biliary copper excretion (Figure 35.1). This process requires another protein, COMDD1, that interacts with ATP7B and is missing in canine copper toxicosis, a disorder of liver copper overload (Tao *et al.*, 2003). Fusion of copper-loaded vesicles with the basolateral surface of enterocyte and placental trophoblast are likely to facilitate copper efflux to plasma and transfer of placental copper to the fetal compartment, respectively. The high efficiency of the copper efflux pathway is supported by minimal binding of copper to cytoplasmic MT after weaning.

Some have suggested that MT might be a copper storage pool or provide a buffer for copper during times when the metal is limiting (Suzuki *et al.*, 2002). Perhaps copper is stored in a vesicular compartment and transported by Ctr2, a protein homologous to Ctr1 that provides this function in budding yeast and that has been shown to impact copper uptake (van den Berghe *et al.*, 2007).

There are many copper binding proteins whose functions remain unknown (Prohaska, 1988). Recent candidates include prion protein PrP<sup>C</sup> and amyloid precursor protein APP. Some suggest a function of PrP<sup>C</sup> is to transport copper into brain and serve as another superoxide dismutase or chaperone for SOD1 (Brown, 2001). However, others found no changes in brain copper or SOD1 activity in PrP<sup>C</sup> knockout mice or transgenic mice overexpressing this protein 10-fold (Waggoner *et al.*, 2000). Stronger evidence exists for amyloid precursor protein APP. APP-null mice have increased brain copper levels (White *et al.*, 1999). In contrast, mice overexpressing APP have reduced brain copper levels (Maynard *et al.*, 2002). These observations suggest a role for APP in regulation of brain copper content. Since APP is expressed in all major tissues, it may function elsewhere in modulating copper homeostasis. Some studies indicate that APP mRNA expression may be regulated by copper (Bellingham *et al.*, 2004).

## Factors Affecting Copper Status

When thresholds of copper exposure exceed adaptive responses, development of copper deficiency or toxicity can occur. In addition to copper intake, other dietary components and physiological factors can affect the bioavailability and tissue exposure to copper.

## Copper Intake

The copper content of the typical diet in the United States provides the majority of adults with a slight excess of intake over the current RDA, 0.9 mg (Pennington and Schoen, 1996). However, certain gender and age groups appear to consume less than the RDA levels (Hunt and Meacham, 2001). Absorption efficiency can range between 50% and 25% when diets contain 1–7 mg of copper, respectively. The richest food sources of copper include shellfish, nuts, seeds, organ meats, wheat-bran cereals, whole-grain products, and chocolate foods. Vegetarian diets generally contain a generous supply of copper, though the efficiency of copper absorption seems lower (Hunt *et al.*, 1998). Multi-mineral and vitamin supplements represent another potential source of copper intake, although copper is often present in adult, pediatric, and prenatal formulations as cupric oxide which is very poorly absorbed (Baker, 1999). Drinking water can be an additional source of copper. Although fresh drinking water generally contains very low levels of copper, regional variability and leaching from copper pipes leads to exposure differences.

## Copper Bioavailability

Adverse effects of certain proteins, zinc, iron, molybdenum, ascorbic acid, certain amino acids, and certain saccharides on copper absorption and utilization have been reported (Lonnerdal, 1998). It is clear that administration of high doses of zinc will induce copper-deficient signs in both infants and adults. Recently, this has become an issue in subjects exposed to high zinc via denture cream (Hedera *et al.*, 2009). Perhaps low intake of dietary zinc can impact copper status of humans (Milne *et al.*, 2001). Dietary fiber appears to have minimal impact on copper absorption by adults in contrast to effects on zinc and iron availability. Infants may be more sensitive to bioavailability perturbations since digestive processes and the regulation of copper absorption and excretion are not fully mature.

## Physiological Conditions

Gender, age, and pregnancy may impact copper absorption and retention (Johnson *et al.*, 1992). Hepatic levels of copper bound to MT are elevated markedly during the final trimester of fetal development, presumably as a copper storage pool to provide the rapidly growing newborn with a supply of copper. However, adequate copper during lactation is necessary to prevent its

deficiency. Plasma levels of copper increase transiently during episodes of inflammation and infection since Cp synthesis and secretion are stimulated by proinflammatory cytokines. Similarly, plasma copper and Cp are elevated in response to increased plasma estrogen (Linder and Hazegh-Azam, 1996). The significance, if any, of changes in plasma copper on whole body metabolism, utilization, and requirement is unknown. Studies in rats following copper injection show that lactation markedly enhances the avidity of the mammary gland for copper (Donley *et al.*, 2002). These studies collectively illustrate that copper requirements and metabolism are impacted by physiological state.

### Genetic Factors

Human copper requirements will be influenced by genetic factors that determine the expression of copper homeostatic genes. In elegant studies in fungi, many of the genetic and transcriptional details of copper homeostasis have been worked out (Rutherford and Bird, 2004). Thus far, no copper-responsive mammalian transcription factors have been discovered with the possible exception of ATOX1 (Itoh *et al.*, 2008). Steady-state mRNA levels of Ctr1, ATP7A, and ATP7B are not altered by dietary copper deficiency in mammals (Prohaska and Gybina, 2004). Rather, transport and efflux are regulated by copper-dependent post-translational trafficking (van den Berghe and Klomp, 2010). Genetic aberrations in copper metabolism in humans are evident due to mutations of ATP7A (Menkes' disease) or ATP7B (Wilson's disease), two genes coding for copper efflux transporters.

### Copper Requirement

Dietary reference intakes (DRIs) for copper were established in 2001 (Trumbo *et al.*, 2001). Recommended dietary allowance (RDA) for adult males and females was set at 0.9 mg. This is approximately a 1.8 mg/kg copper diet based on a 2000 kcal and 500 g dry weight estimate. Prior to 2001, the recommended Estimated Safe and Adequate Daily Dietary Intake of copper for adults was 1.5–3.0 mg/day. The RDA for pregnancy is 1 mg and for lactation 1.3 mg. Work with mice suggests the possibility that the human RDA for pregnancy/lactation may be set too low (Prohaska and Brokate, 2002). The same dietary level of copper that was lethal to pups during mid-lactation produced no discernible changes in copper status to non-lactating adult females. The tolerable upper intake level

(UL) for copper is 10 mg. Using a categorical regression model with many published data sets, a value of 2.6 mg was estimated to provide the best intake to avoid deficiency and minimize toxicity (Chambers *et al.*, 2010). This level of intake is approximately two times higher than the reported level of copper intake in North America.

### Copper Deficiency

Common characteristics of severe copper deficiency in mammals include hypochromic anemia (refractory to iron supplementation), neutropenia, thrombocytopenia, hypopigmentation, plus anatomical and functional abnormalities in the skeletal, cardiovascular, and immune systems (Uauy *et al.*, 1998). Copper deprivation during the fetal and neonatal periods also causes neurological abnormalities. Although many of these diverse effects seem associated with decreased activities of known cuproenzymes (Table 35.1), unequivocal evidence that the decline in catalytic activity actually alters the metabolic flux and generation of products in specific pathways remains somewhat elusive.

Inadequate tissue levels of copper result from insufficient absorption of exogenous copper and excessive losses of endogenous copper. The pleiotropic effects of defective cellular copper transport in individuals with Menkes' disease are consistent with tissue copper deficiency observed in experimental animals. Acquired copper deficiency is relatively rare in humans, although reports of copper deficiency in infants, children, and adults continue to appear in the clinical literature. Groups that are susceptible to developing copper deficiency include the following: individuals at any age receiving total parenteral nutrition without supplemental copper for extended periods; preterm infants fed milk-based formula without adequate copper; infants recovering from malnutrition or chronic diarrhea, patients undergoing chronic peritoneal dialysis; severe burn patients; ambulatory renal dialysis patients; and individuals consuming excessive doses of zinc, antacids, or copper chelators.

Copper deficiency can also develop in humans with malabsorption syndromes. Examples of conditions that can compromise copper status include: celiac disease, cystic fibrosis, and sprue. Recently, the intervention of surgical resection of the short bowel to manage obesity has surfaced as a major factor in adult onset copper deficiency that is only partially corrected by supplementation (Griffith *et al.*, 2009). An RDA intake of copper may be too low

under these conditions. Impact of copper deficiency, regardless of its etiology, can have a major impact on several biological systems.

### **Cardiovascular System**

Anatomical, electrical, mechanical, and biochemical abnormalities are evident in hearts of young animals fed diets severely restricted in copper. Severely copper-deficient young rats often die of ventricular rupture. Many of the defects are generally assumed to result from decreased activities of various cardiac cuproenzymes, including CCO, DBM, LO, PAM, or SOD1 as reviewed elsewhere (Medeiros and Wildman, 1997). Notable observations are that cardiac hypertrophy in copper-deficient rats is not dependent on anemia; marginally copper-deficient diets also induce cardiac abnormalities; and adult rats fed a copper-deficient diet develop cardiovascular defects, but not hypertrophy. Exciting new data in mice with cardiac deletion of *Ctr1* suggest that development of hypertrophy is intrinsic to the heart and requires no systemic disturbance (Kim *et al.*, 2010).

Development of cardiovascular abnormalities in animals fed low copper diets provides the conceptual basis for speculation that copper deficiency contributes to the incidence of ischemic heart disease in humans. Although cardiac arrhythmias were experienced by several subjects ingesting low-copper diets in metabolic trials, healthy adults in other studies, in which low-copper diets were fed for extended periods, had normal cardiac function. Individuals with Menkes' disease exhibit pathology in major vessels but not the heart (Danks, 1988).

Copper status can also impact the circulatory system. Proper cross-linking in large vessels, as well as vasoactivity in arterioles, capillaries, and venules, are copper dependent (Saari and Schuschke, 1999). Dietary copper deficiency increases histamine-mediated protein leakage in venules by increasing numbers of localized mast-cells, inhibits platelet interactions that lead to thrombogenesis, and decreases nitric oxide-induced relaxation of arteriolar smooth muscle cells. Copper status also has an impact on the acute inflammatory response including vasodilation, protein extravasation from microvascular leakage, and neutrophil adhesion and diapedesis. These lines of investigation are expected to uncover specific roles for copper in the regulation of peripheral blood flow and hemostasis.

Altered blood lipid profiles, blood pressure, and anemia can all impact the cardiovascular system and are known to be impacted by copper status. Hypertriglyceridemia and

hypercholesterolemia are frequently observed in severe copper deficiency, and involve alteration in thiol status (Kim *et al.*, 1992). Copper deficiency also increases plasma HDL protein levels in rats. This change appears to be due to enhanced transcription of apolipoprotein A-I gene in liver (Wu *et al.*, 1997). Gel shift assay suggested that binding of hepatocyte nuclear factor 4 and other undefined nuclear proteins to oligonucleotides containing one of the regulatory sites in the promoter of apoA-I gene is enhanced by copper deficiency.

### **Hemopoietic System**

It is likely that copper plays a fundamental role in myeloid progenitor cell differentiation, as a prominent feature of copper deficiency is alteration in erythrocyte (lower), neutrophil (lower), and platelet (higher) levels. The anemia of copper deficiency is a consequence of fewer red blood cells and also of a lower hemoglobin content per cell. Some believe the primary determinant of anemia is a failure to absorb and retain dietary iron following dietary copper deficiency (Reeves *et al.*, 2005). Others believe it is related to a failure to mobilize iron from tissue stores such as liver because Cp (ferroxidase) is copper dependent. However, Cp-null mice and aceruloplasminemia in humans do not result in pronounced anemia. The role of copper in iron biology is quite complex (Collins *et al.*, 2010). It would appear that the anemia associated with copper deficiency is the result of failure to utilize iron properly rather than of a failure to deliver iron to bone marrow (Prohaska, 2011).

### **Immune System**

Clinical and experimental reports indicate that inherited and acquired copper deficiencies often are associated with increased risk of infection (Prohaska and Failla, 1993). Severe copper deficiency generally changes the phenotypic profiles of immune cells in blood, bone marrow, and lymphoid tissues, and suppresses a number of activities of lymphocytes and phagocytic cells. In vitro DNA synthesis and IL-2 secretion by mitogen-treated splenic T-lymphocytes and respiratory burst activity of neutrophils were markedly impaired in cells from animals fed diet marginal in low copper (Hopkins and Failla, 1995). Recently a role for copper in macrophage function has emerged (White *et al.*, 2009).

Neutropenia is a hallmark of copper deficiency in humans. Several recent studies have suggested that moderate and even marginal copper deficiency also affect some

activities of T-lymphocytes and phagocytic cells adversely. In vitro responsiveness of T-lymphocytes to mitogenic activation was decreased after adult males were fed a diet with 0.38 mg copper per day for 6 weeks. This alteration was associated with a reduction in plasma copper and activities of several cuproenzymes, but not hematologic indices (Kelley *et al.*, 1995). Similarly, IL-2 synthesis by a human T-cell line and bactericidal activity and secretion of proinflammatory cytokines TNF- $\alpha$ , IL-1, and IL-6 by a human monocytic cell line were decreased after inducing moderate copper deficiency with a copper chelator (Hopkins and Failla, 1999). These changes were eliminated by supplementation of medium with copper, but not iron or zinc, and were not associated with alterations in cellular iron status or general metabolic activities.

The decreased synthesis of IL-2 in low-copper T-cells results from decreased transcription of the IL-2 gene in activated cells. Although these results support a direct role for copper in the ability of defense cells to respond to stimuli, unique roles that copper plays in the maturation, activation, and effector activities of immune cells remain unknown. Likewise, the link between suppressed activities of immune cells in copper-deficient humans and increased susceptibility to infection remains weak, partly because of the inability to accurately assess marginal and moderate deficiencies of this micronutrient.

### **Nervous System**

The essentiality of adequate copper intake and utilization for the normal development of the brain is well recognized (Lutsenko *et al.*, 2010). Domestic animals grazing on pastures low in copper produced offspring that exhibited ataxia and severe neuronal pathology (Smith, 1983). Neuronal pathology is a salient feature of infants who die of Menkes' disease. Copper accumulates in brain during late gestation and lactation. Thus, restricted intake of copper by pregnant and lactating individuals has severe consequences for offspring. In fact, rats that experienced copper deficiency during the perinatal period exhibited permanent behavioral abnormalities, even after ingesting a copper-adequate diet for 6 months (Prohaska and Hoffman, 1996; Penland and Prohaska, 2004). Even marginal copper deficiency can impact the brain. Brain copper was significantly lower in rats fed a diet containing moderate copper (2.8 mg/kg) than in those fed adequate copper (6.7 mg/kg); whereas growth and copper concentration in liver, lung, and bone were similar for the two dietary groups (Hopkins and Failla, 1995). Similarly maturation of hippocampus and dentate gyrus was impaired in rats

subjected to moderate copper deficiency during gestation and lactation (Hunt and Idso, 1995). These studies underscore the importance of adequate copper during perinatal development.

The neurochemical functions of copper are thought to be associated with the cuproenzymes that are present in most tissues (Table 35.1) and several unique cuproproteins. Copper deficiency alters the enzyme activity and protein level of rodent brain CCO, DBM, SOD1, and PAM (Prohaska *et al.*, 2005). Perhaps altered enzyme activity and levels are responsible for the altered neuropathology and behavior. Transfer of copper from plasma to neurons and delivery to cuproenzymes require Ctr1, Atox1, ATP7A, and perhaps ATP7B. Ctr1 +/– mice and Atox1 –/– mice have lower brain copper levels and decreased CCO activity (Hamza *et al.*, 2001; Lee *et al.*, 2001). Brindled mice that contain a non-functional ATP7A protein have altered PAM activity as evidenced by peptide amidation defects (Stevenson *et al.*, 2003). A glycosylphosphatidylinositol-anchored form of Cp that is synthesized from an alternatively spliced RNA variant has been identified in brain (Patel *et al.*, 2002). Ablation of the Cp gene in mice is associated with iron overload in brain. In contrast, dietary copper deficiency, and lower Cp activity, are associated with lower brain iron (Prohaska and Gybina, 2005). Judicious use of gene knockout techniques are expected to reveal unique neurochemical roles of copper and to elucidate mechanisms of neuronal pathology that accompany imbalances in copper homeostasis.

Although it is generally believed that copper is most critical during brain development, other neurological functions depend on adequate copper throughout life. Recently, several cases of adult myelopathy have been characterized and associated with low serum copper and Cp, implying a relationship to a copper-deficient state (Kumar *et al.*, 2004).

### **Skeletal and Integumentary System**

There is a well established association between decreased LO activity, connective tissue disorders, generalized osteoporosis, and bone defects that occur in dietary and inherited copper deficiency in humans and other species (Danks, 1988). LO and perhaps LOXL proteins are involved in cross-linking of collagen.

Bone abnormalities are common in copper-deficient infants and resemble features observed following vitamin C deficiency (Uauy *et al.*, 1998). Changes include osteoporosis, bone fractures, spur formation, and subperiosteal new bone formation. Relationships between copper and

bone health exist in adults as well. Long-term studies suggest that copper supplementation may decrease bone loss. Reduction of copper intake from 1.6 to 0.7 mg/day for 8 weeks increased the rate of bone resorption as assessed by urinary excretion of pyridinium cross-links in healthy adult males; this change was reversed after restoration of dietary copper to 1.6 mg/day (Baker *et al.*, 1999). However, supplementation of healthy males and females aged 22–46 years with 3 and 6 mg copper/day for 6 weeks did not affect biochemical markers of bone formation or resorption. The possibility that long-term supplementation of aging males and females with copper may retard net losses of bone merits further investigation.

### Copper Toxicity

It is not surprising that the incidence of copper toxicity is quite low in the general population considering the homeostatic regulation of copper absorption and excretion. Copper, like inorganic iron, can participate in Fenton chemistry and generate reactive oxygen species (Prohaska, 1997). Symptoms associated with the ingestion of fluids and foods contaminated with large quantities of copper usually include metallic taste and gastrointestinal distress. Copper was used historically to induce vomiting. The recent North American UL for copper is 10 mg. Results from a multicenter (Chile, Northern Ireland, USA) study indicate the No Adverse Effect Level (NOAEL) in drinking water was about 5 mg copper per liter. Taste of copper in water was detected at about half this level (Araya *et al.*, 2003). WHO guidelines indicate a provisional safety of 2 mg copper per liter. The safety of copper in drinking water is controversial (Brewer *et al.*, 2010).

Inclusion of copper in micronutrient and complete nutritional supplements does not seem to pose any adverse effects. Supplementation of adults with 10 mg copper daily as cupric gluconate for 12 weeks did not cause gastrointestinal difficulties or liver damage in a double-blind study (Pratt *et al.*, 1985). Immaturity of biliary excretion and increased efficiency of copper absorption suggest potential risk of copper toxicity in infants. Accumulation of toxic levels of copper in livers of children diagnosed with Indian childhood cirrhosis, certain infants in the Austrian Tyrol, and those with idiopathic copper toxicosis is often associated with use of copper-contaminated water to prepare infant formula and other foods that were stored or prepared in brass vessels (Araya *et al.*, 2003). Public health programs aimed at changing practices associated with infant feeding and genetic dilution have largely eliminated

the incidence of these diseases. Obviously, individuals with Wilson's disease and other inherited or acquired disorders that impair elimination of excess copper via the biliary route should avoid ingestion of copper-fortified products and copper-contaminated water.

### Assessment of Copper Status

Identification of copper-status biomarkers that are sensitive, non-invasive, and reliable indicators continues to be problematic (Harvey *et al.*, 2009). Experimental studies with young animals show that moderate to severe reductions of the copper content of standard formulations of nutritionally adequate, semi-purified diets usually induces a relatively rapid decline in plasma copper and Cp activity. The impact of dietary treatment on the concentration of the metal and cuproenzyme activities in cells and tissues is dependent on numerous factors, including severity of the reduction in dietary copper, species, strain, organ, and gender. The traditional approach in human studies has been to examine the level of copper and activities of cuproenzymes in plasma and blood cells. Reductions of plasma copper and Cp are often observed in individuals with diagnosed copper deficiency. However, estrogen status and conditions such as pregnancy, infection, inflammation, and some cancers increase plasma Cp and copper levels, thereby compromising their utility as reliable indicators for screening copper status. Even under well-controlled conditions, dietary copper must be reduced to 0.6 mg copper/day or less for periods of at least 6 weeks for healthy adults before markers decline. Other potential markers that have been monitored in various human studies include copper content in platelets and mononuclear cells, and activities of SOD1 in erythrocytes and CCO in platelets and mononuclear cells. Influences of factors other than copper, required sample volume, wide variations within individuals, and technical difficulties represent difficulties for using these markers as reliable indicators for assessing copper status.

Other cuproenzymes deserve further evaluation as possible indicators of copper status. Serum and tissue activity of PAM in rats are correlated with dietary copper intake (Prohaska *et al.*, 2005). A study using plasma from several subjects with a mild variant of Menkes' disease and an individual with acquired copper deficiency suggested that the assay may be a useful marker of copper status in humans (Prohaska *et al.*, 1997). Studies in an adult subject with acquired copper deficiency and response to copper supplementation suggest activity of plasma diamine

oxidase as a biomarker (DiSilvestro *et al.*, 1997; Kehoe *et al.*, 2000). The utility of this enzyme as a marker of copper status may be limited, since a number of pathological conditions of the intestine or kidney, and pregnancy, affect plasma activity (Failla, 1999). Another potential assessment tool has recently been proposed. In rodents following copper deficiency the immunoreactive content of SOD1 is lower and that of its specific chaperone, CCS, is markedly higher (Bertinato *et al.*, 2003; Prohaska *et al.*, 2003). Thus the ratio of CCS to SOD1 protein is markedly higher in copper-deficient tissues including erythrocytes (West and Prohaska, 2004). CCS mRNA in peripheral blood mononuclear cells seems responsive to copper supplementation (Suazo *et al.*, 2008).

Although functional and behavioral activities in animals and in vitro cellular assays have been shown to be quite responsive to marginal and moderate reductions in copper, their potential utility for evaluating copper status in humans remains unknown currently.

## Future Directions

Continued use of novel genetic and dietary investigations will reveal exciting clarification of the mechanisms responsible for copper homeostasis. It is very clear that the cellular copper binding proteins do more than chaperone for metallation. Elucidation of robust biomarkers will help establish copper needs for special groups and for special clinical circumstances. Reevaluation of the current copper DRI levels will require solid experimental and clinical data on subjects of various ages and physiological states.

## Acknowledgment

Several in-press manuscripts were shared by my colleagues in the copper-research field.

## IODINE AND IODINE DEFICIENCY DISORDERS

MICHAEL B. ZIMMERMANN, MD

*Swiss Federal Institute of Technology, Zürich, Switzerland*

### Summary

Iodine is an essential component of hormones produced by the thyroid gland. Thyroid hormones, and therefore iodine, are essential for mammalian life. Optimal dietary iodine intakes for healthy adults are 150–250 µg/day. In regions where iodine in soils and drinking water is low, humans and animals may become iodine deficient. Iodine deficiency has multiple adverse effects in humans due to inadequate thyroid hormone production that are termed the iodine deficiency disorders. Assessment methods for iodine deficiency include urinary iodine concentration, goiter, newborn thyroid-stimulating hormone, and blood thyroglobulin. Globally, it is estimated that 2 billion individuals have an insufficient iodine intake, many in developing countries. However, iodine deficiency also affects industrialized countries: ~50% of continental Europe remains mildly iodine deficient, and iodine intakes in other industrialized countries, including the United States, the United Kingdom and Australia, have fallen sharply in recent years. Iodine deficiency during pregnancy and infancy may impair growth and neurodevelopment of the offspring and increase infant mortality. Deficiency during childhood reduces somatic growth and cognitive and motor function. In most countries, the best strategy to control iodine deficiency in populations is carefully monitored iodization of salt, one of the most cost-effective ways to contribute to economic and social development.

### Introduction

In 1811, Courtois discovered iodine as a violet vapour arising from seaweed ash while manufacturing gunpowder for Napoleon's army. Gay-Lussac identified it as a new element, and named it iodine (atomic weight 126.9g/atom), from the Greek word meaning "violet"

(Zimmermann, 2008b). The Swiss physician Coindet, in 1813, hypothesized that the traditional treatment of goiter with seaweed was effective because of its iodine content, and successfully treated goitrous patients with iodine. In 1851, the French chemist Chatin published the hypothesis that iodine deficiency was the cause of goiter, and, in 1896, Baumann and Roos discovered iodine in the thyroid

(Zimmermann, 2008b). In the first two decades of the twentieth century, pioneering studies by Swiss and American physicians demonstrated the efficacy of iodine prophylaxis in the prevention of goiter and cretinism. Today, control of the iodine deficiency disorders is an integral part of most national nutrition strategies.

I am satisfied. I have seen the principal features of Swiss scenery – Mount Blanc and the goiter – and now for home.  
Mark Twain, 1880

## Ecology and Dietary Sources

Iodine (as iodide) is widely but unevenly distributed in the Earth's environment. In many regions, leaching from glaciation, flooding, and erosion have depleted surface soils of iodide, and most iodide is found in the oceans. The concentration of iodide in seawater is  $\sim 50 \mu\text{g/L}$ . Iodide ions in seawater are oxidized to elemental iodine, which volatilizes into the atmosphere and is returned to the soil by rain, completing the cycle (Küpper *et al.*, 2011). However, iodine cycling in many regions is slow and incomplete, leaving soils and drinking-water iodine depleted. Crops grown in these soils will be low in iodine, and humans and animals consuming food grown in these soils become iodine deficient. In plant foods grown in deficient soils, iodine concentration may be as low as  $10 \mu\text{g/kg}$  dry weight, compared with  $\sim 1 \text{ mg/kg}$  dry weight in plants from iodine-sufficient soils.

Iodine-deficient soils are common in mountainous areas (e.g. the Alps, Andes, Atlas, and Himalaya ranges) and areas of frequent flooding, especially in South and Southeast Asia (for example, the Ganges River plain of north-eastern India). Many inland areas, including central Asia and Africa, the Midwestern Region of North America, and central and eastern Europe, are iodine deficient. Iodine deficiency in populations residing in these areas will persist until iodine enters the food chain through addition of iodine to foods (e.g. by iodization of salt) or through dietary diversification via introduction of foods produced outside the iodine-deficient area.

The native iodine content of most foods and beverages is low. In general, commonly consumed foods provide  $3\text{--}80 \mu\text{g}$  per serving (Pearce *et al.*, 2004; Haldimann *et al.*, 2005). Foods of marine origin have higher iodine content because marine plants and animals concentrate iodine from seawater. Iodine in organic form occurs at high levels in certain seaweeds. Inhabitants of the coastal regions of Japan, whose diets contain large amounts of seaweed,

have remarkably high iodine intakes amounting to  $50\text{--}80 \text{ mg/day}$ . In the United States the median intake of iodine from food in the mid-1990s was estimated to be  $240\text{--}300 \mu\text{g/day}$  for men and  $190\text{--}210 \mu\text{g/day}$  for women (Institute of Medicine, 2001). Major dietary sources of iodine in the United States are bread and milk (Pearce *et al.*, 2004). In Switzerland, based on direct food analysis, mean intake of dietary iodine is  $\sim 140 \mu\text{g/day}$ , mainly from bread and dairy products (Haldimann *et al.*, 2005). In many countries, use of iodized salt in households for cooking and at the table provides additional iodine. Boiling, baking, and canning of foods containing iodized salt cause only small losses ( $\leq 10\%$ ) of iodine content (Chavasit *et al.*, 2002).

Iodine content in foods is also influenced by iodine-containing compounds used in irrigation, fertilizers, and livestock feed. Iodophors used for cleaning milking machines and transport containers can increase the native iodine content of dairy products. Traditionally, iodate was used in bread making as a dough conditioner, but it is being replaced by non-iodine-containing conditioners. Erythrosine is a red coloring agent high in iodine that is widely used in foods, cosmetics, and pharmaceuticals. Dietary supplements often contain iodine. Based on data from the Third National Health and Nutrition Examination Survey (NHANES III), 12% of men and 15% of non-pregnant women took a dietary supplement that contained iodine, and the median intake of iodine from supplements was  $\sim 140 \mu\text{g/day}$  for adults (Institute of Medicine, 2001). Other sources of iodine include water purification tablets, radiographic contrast media, medicines (e.g. amiodarone, an antiarrhythmic drug, contains  $75 \text{ mg/tablet}$ ), and skin disinfectants (e.g. povidone-iodine contains  $\sim 10 \text{ mg/mL}$ ).

## Absorption, Metabolism, and Excretion

Iodine is ingested in several chemical forms. Iodide is rapidly and nearly completely absorbed in the stomach and duodenum. The sodium/iodide symporter (NIS), a transmembrane protein on the apical surface of enterocytes, mediates active iodine absorption (Nicola *et al.*, 2009). Iodate, widely used in salt iodization, is reduced in the gut and absorbed as iodide. In healthy adults, the absorption of iodide is  $>90\%$  (Institute of Medicine, 2001). Organically bound iodine is typically digested and the released iodide absorbed, but some forms may be absorbed intact. For example,  $\approx 75\%$  of an oral dose of thyroxine, the thyroid hormone, is absorbed intact.

Iodine deficiency is the main cause of endemic goiter (see later in this chapter), but other dietary substances that interfere with thyroid metabolism can aggravate the effect and they are termed goitrogens (Gaitan, 1990). A well-known example is linamarin, a thioglycoside found in cassava, which is a staple food in many developing countries. If cassava is not adequately soaked or cooked to remove the linamarin, it is hydrolyzed in the gut to release cyanide, which is metabolized to thiocyanate. Thiocyanate blocks thyroidal uptake of iodine. Other goitrogenic substances are found in millet, sweet potato, beans, and cruciferous vegetables (e.g. cabbage). Unclean drinking water may contain humic substances that block thyroidal iodination. Industrial pollutants, including resorcinol, perchlorate, and phthalic acid, may also be goitrogenic. Most of these substances do not have a major clinical effect unless there is coexisting iodine deficiency.

Deficiencies of selenium, iron, and vitamin A exacerbate the effects of iodine deficiency. Glutathione peroxidase and the deiodinases are selenium-dependent enzymes. In selenium deficiency, accumulated peroxides may damage the thyroid, and deiodinase deficiency impairs thyroid hormone synthesis (Zimmermann and Kohrle, 2002). These effects have been implicated in the etiology of myxedematous cretinism (see next section). Iron deficiency reduces heme-dependent thyroperoxidase activity in the thyroid and impairs production of thyroid hormone. In goitrous children, iron deficiency anemia blunts the efficacy of iodine prophylaxis while iron supplementation improves the efficacy of iodized oil and iodized salt (Zimmermann, 2006). Vitamin A deficiency in iodine-deficient children increases TSH stimulation and risk for goiter, probably through decreased vitamin A-mediated suppression of the pituitary TSH $\beta$  gene (Zimmermann *et al.*, 2007).

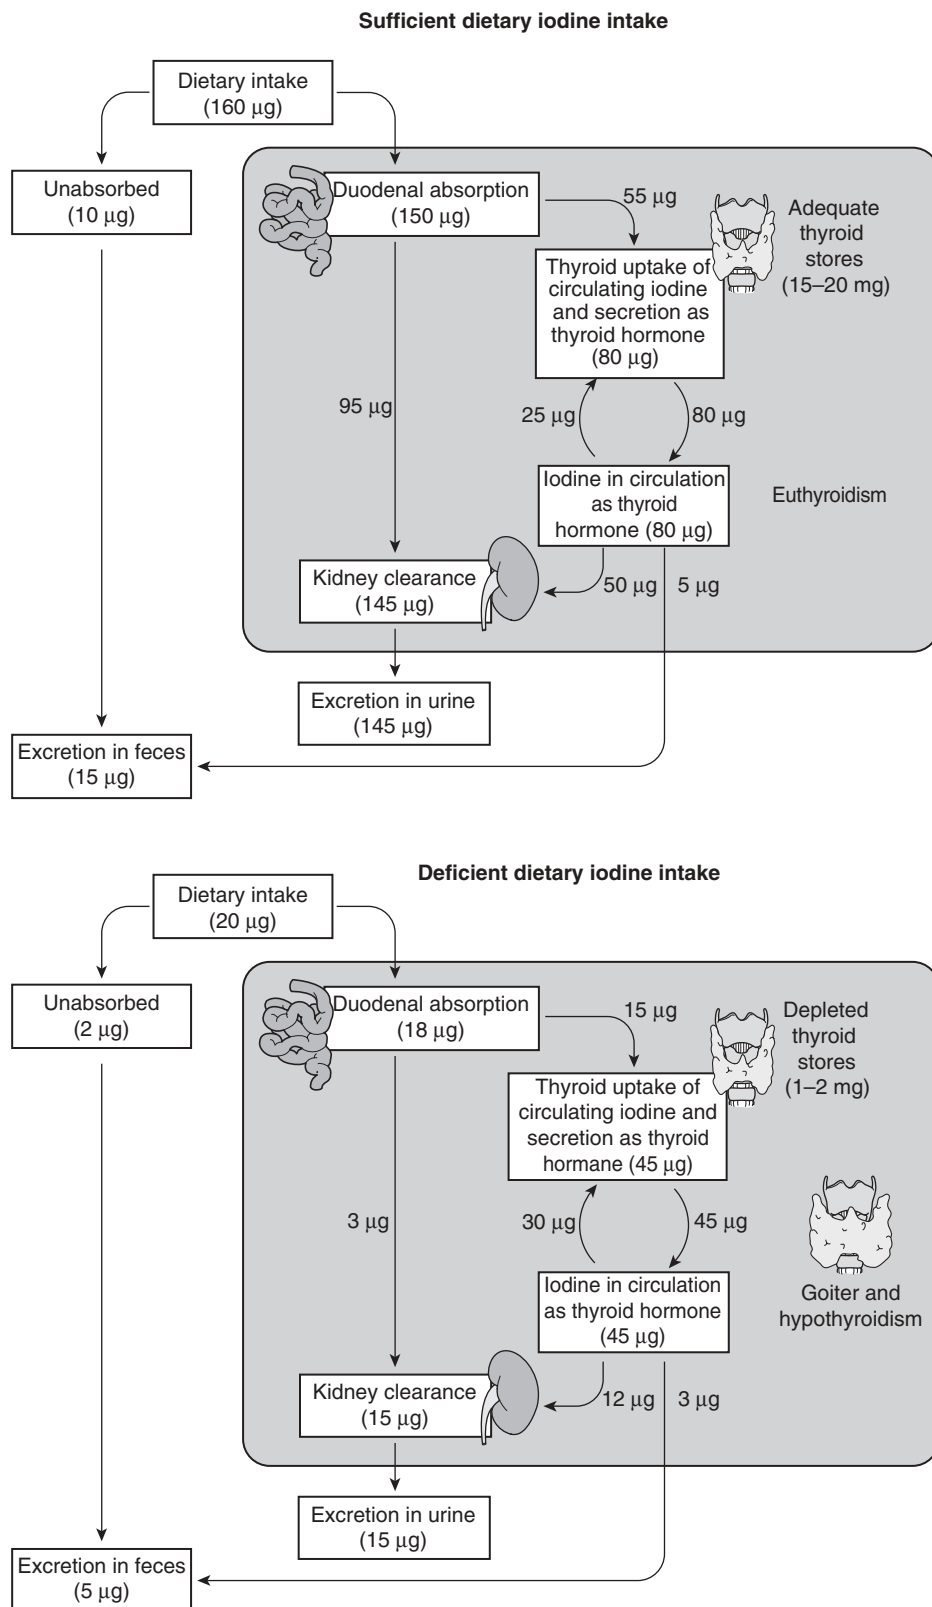

The distribution space of absorbed iodine in the body is nearly equal to the extracellular fluid volume. Iodine is cleared from the circulation mainly by the thyroid and kidney (Figure 36.1), and whereas renal iodine clearance is fairly constant, thyroid clearance varies with iodine intake. In conditions of adequate iodine supply,  $\leq 10\%$  of absorbed iodine is taken up by the thyroid. In chronic iodine deficiency, this fraction can exceed 80%. During lactation, the mammary gland concentrates iodine and secretes it into breast milk to provide for the newborn. Iodine in the blood is turned over rapidly; under normal circumstances, plasma iodine has a half-life of  $\sim 10$  hours,

but this is shortened if the thyroid is overactive as in iodine deficiency or hyperthyroidism.

The body of a healthy adult contains up to 20 mg of iodine, of which 70–80% is in the thyroid. In chronic iodine deficiency, the iodine content of the thyroid may fall to  $<1$  mg. In iodine-sufficient areas, the adult thyroid traps 60–80  $\mu\text{g}$  of iodine per day to balance losses and maintain thyroid hormone synthesis. An NIS in the basolateral membrane transfers iodide into the thyroid at a concentration gradient 20 to 50 times that of plasma (Eskandari *et al.*, 1997). The NIS concentrates iodine by an active transport process that couples the energy released by the inward translocation of sodium down its electrochemical gradient to the simultaneous inward translocation of iodine against its electrochemical gradient.

Thyroglobulin (Tg), a large glycoprotein (molecular weight 660 000), is the carrier of iodine in the thyroid. At the apical surface of the thyrocyte, the enzymes thyroperoxidase (TPO) and hydrogen peroxide oxidize iodide and attach it to tyrosyl residues on Tg, to produce monoiodotyrosine (MIT) and diiodotyrosine (DIT), the precursors of thyroid hormone (Figure 36.2). TPO then catalyzes the coupling of the phenyl groups of the iodotyrosines through a di-ether bridge to form the thyroid hormones. Linkage of two DIT molecules produces tetraiodothyronine or thyroxine (T<sub>4</sub>), and linkage of an MIT and a DIT produces triiodothyronine (T<sub>3</sub>). Thus, T<sub>3</sub> is structurally identical to T<sub>4</sub> but has one less iodine (at the 5' position on the outer ring) (Figure 36.3). Iodine comprises 65% and 59% of the weights of T<sub>4</sub> and T<sub>3</sub>, respectively. In the thyroid, mature Tg, containing 0.1 to 1.0% of its weight as iodine, is stored extracellularly in the luminal colloid of the thyroid follicle. After endocytosis, endosomal and lysosomal proteases digest Tg and release T<sub>4</sub> and T<sub>3</sub> into the circulation. MIT and DIT are not normally released into the blood. Iodine is removed from their tyrosines by a selenium-dependent deiodinase and is then recycled for use within the thyroid, conserving iodine (Kohrle and Gartner, 2009).

In the circulation, thyroid hormone is bound non-covalently to carrier proteins, mainly thyroxine-binding globulin, but also to transthyretin and albumin. In target tissues – liver, kidney, heart, muscle, pituitary, and the developing brain – T<sub>4</sub> is deiodinated to T<sub>3</sub>. T<sub>3</sub> is the main physiologically active form of thyroid hormone and binds to nuclear receptors. The thyroid hormone receptors have been cloned and regulatory DNA elements identified in thyroid hormone responsive genes (Yen,

**FIG. 36.1** Over 90% of dietary iodine is absorbed in the duodenum. Iodine (as iodide) is cleared from the circulation mainly by the thyroid and kidney. Thyroid clearance varies with iodine intake. Above: in iodine-sufficient individuals with adequate thyroid iodine stores, about 35% of circulating iodide is taken up by the thyroid to balance losses and maintain thyroid hormone synthesis. Below: in chronic iodine deficiency, the fraction of circulating iodide cleared by the thyroid increases to about 65% but the iodine content of the thyroid is depleted and hypothyroidism develops.

**FIG. 36.2** Iodine pathway in the thyroid cell. Iodide (I<sup>-</sup>) is transported into the thyrocyte by the sodium iodide symporter (NIS) at the basal membrane and migrates to the apical membrane. The I<sup>-</sup> is oxidized by the enzymes thyroperoxidase (TPO) and hydrogen peroxidase (H<sub>2</sub>O<sub>2</sub>), and attached to tyrosyl residues in thyroglobulin (Tg) to produce the hormone precursors iodotyrosine (MIT) and diiodotyrosine (DIT). The residues then couple to form thyroxine (T4) and triiodothyronine (T3) within the Tg molecule in the follicular lumen. Tg enters the cell by endocytosis and is digested. T4 and T3 are released into the circulation, and non-hormonal iodine on MIT and DIT is recycled within the thyrocyte.

2001). Hormone–receptor interactions stimulate several pathways, including the adenosine triphosphate (ATP) and inositol phosphate–Ca<sup>2+</sup> cascades, which in turn stimulate or inhibit protein synthesis.

Both T4 and T3 are degraded through a complex series of pathways, and their turnover is relatively slow: the half-lives of T4 and T3 are ~5 days and 1.5–3 days (Oppenheimer *et al.*, 1975). The released iodine enters the plasma iodine pool and can be taken up again by the thyroid or excreted by the kidney. More than 90% of ingested iodine is ultimately excreted in the urine, with only a small amount appearing in the feces.

The principal regulator of thyroid hormone metabolism is thyroid-stimulating hormone (TSH), a protein hormone (molecular weight ~28 000) secreted by the pituitary. TSH secretion is controlled through negative feedback by the level of circulating thyroid hormone, modulated by TSH-releasing hormone from the hypothalamus. In the thyroid,

TSH increases iodine uptake through stimulation of NIS expression. TSH exerts its action at the transcription level of the NIS gene through a thyroid-specific enhancer that contains binding sites for the transcription factor Pax8 and a cAMP response element-like sequence (Taki *et al.*, 2002). TSH also stimulates breakdown of Tg and release of thyroid hormone into the blood. Because the primary stimulus to TSH secretion is circulating thyroid hormone, an elevated serum TSH concentration generally indicates primary hypothyroidism, while a low concentration indicates primary hyperthyroidism.

## Physiologic Function and Deficiency Disorders

Thyroid hormone regulates a variety of physiologic processes, including reproductive function, growth, and development. During pregnancy, thyroid hormone crosses the

**FIG. 36.3** Iodine is an essential component of the thyroid hormones, thyroxine (T<sub>4</sub>) and triiodothyronine (T<sub>3</sub>).

placenta to the fetus early in the first trimester, before the fetal thyroid is functioning. In the developing brain, it influences cell growth and migration (Morreale de Escobar *et al.*, 2004). It also promotes growth and maturation of peripheral tissues and the skeleton. Thyroid hormone increases energy metabolism in most tissues, and raises the basal metabolic rate.

Iodine deficiency has multiple adverse effects on growth and development in animals and humans. These are collectively termed the iodine deficiency disorders (IDD) (Table 36.1), and are one of the most important and common human diseases (World Health Organization, 2007). They result from inadequate thyroid hormone production due to lack of sufficient iodine.

Thyroid enlargement (goiter) is the classic sign of iodine deficiency (Figure 36.4A). It is a physiologic adaptation to chronic iodine deficiency. As iodine intake falls, secretion of TSH increases in an effort to maximize uptake of available iodine, and TSH stimulates thyroid hypertrophy and hyperplasia. Initially, goiters are characterized by diffuse, homogeneous enlargement, but over time thyroid follicles

**TABLE 36.1** Iodine deficiency disorders by age group

Age group	Health consequences of iodine deficiency
All ages	Goiter Increased susceptibility of the thyroid gland to nuclear radiation
Fetus	Abortion Stillbirth Congenital anomalies Perinatal mortality
Neonate	Infant mortality Endemic cretinism
Child and adolescent	Impaired mental function Delayed physical development
Adults	Impaired mental function Reduced work productivity Toxic nodular goiter; iodine-induced hyperthyroidism Hypothyroidism in moderate-to-severe iodine deficiency

Adapted from World Health Organization (2007).

may fuse and become encapsulated, a condition termed nodular goiter. Large goiters may be cosmetically unattractive, can obstruct the trachea and esophagus, and may damage the recurrent laryngeal nerves and cause hoarseness.

Although goiter is the most visible effect of iodine deficiency, the most serious adverse effect is damage to the developing brain. Severe iodine deficiency during pregnancy is associated with a greater incidence of stillbirths, abortions, and congenital abnormalities. Iodine prophylaxis with iodized oil in pregnant women in areas of severe iodine deficiency reduces fetal and perinatal mortality (Zimmermann, 2009). The fetal brain is particularly vulnerable to iodine deficiency. Normal levels of thyroid hormones are required for neuronal migration and myelination of the central nervous system (Auso *et al.*, 2004). The most severe form of neurological damage from fetal hypothyroidism is termed cretinism. It is characterized by gross mental retardation along with varying degrees of short stature, deaf mutism, and spasticity (Zimmermann *et al.*, 2008) (Figure 36.4B). Up to 10% of populations with severe iodine deficiency may be cretinous. Iodine prophylaxis has completely eliminated the appearance of new cases of cretinism in previously severely iodine-deficient Alpine regions in Switzerland, Austria, and Italy.

© MB Zimmermann

**FIG. 36.4.** (A) Large nodular goiter in a 14-year-old boy in northern Morocco, with tracheal and esophageal compression and hoarseness, likely due to damage to the recurrent laryngeal nerves. (B) This 9-year-old girl from western China demonstrates the three characteristic features of neurological cretinism: severe mental deficiency together with squint, deaf mutism, and motor spasticity of the arms and legs. Reproduced with permission from Michael B. Zimmermann.

Although new cases of cretinism are now rare, iodine deficiency still affects approximately one-third of the global population (see later) and can impair cognitive development. A meta-analysis concluded that moderate-to-severe iodine deficiency (severity of iodine deficiency was defined by the cut-off values for median urinary iodine concentrations shown in Table 36.4) reduces mean IQ scores by 13.5 points (Bleichrodt *et al.*, 1996). Iodine deficiency is one of the most common causes of preventable mental impairment worldwide. Even in areas of mild to moderate iodine deficiency, cognitive impairment in school-age children is at least partly reversible by administration of iodine (Zimmermann *et al.*, 2006a; Gordon *et al.*, 2009).

Only a few countries – Switzerland, the Scandinavian countries, Australia, the United States, and Canada – were completely iodine sufficient before 1990. Since then, widespread introduction of iodized salt has produced dramatic reductions in iodine deficiency. The World Health Organization recently estimated the worldwide prevalence of iodine deficiency. Defined as a UI <100 µg/L, just over 2 billion individuals have inadequate iodine nutrition, of whom 266 million are school-age children (Table 36.2). The prevalence of iodine deficiency in school-age children is 31.5% (de Benoist *et al.*, 2008). In Australia, the United

**TABLE 36.2** Prevalence of iodine deficiency in general population (all age groups) and in school-age children (6–12 years), by WHO region, in 2007

WHO region <sup>a</sup>	Population <sup>b</sup> (millions) with urinary iodine <100 µg/L (%)	
	General population	School-age children
Africa	312.9 [41.5%]	57.7 [40.8%]

<sup>b</sup>Based on population estimates for 2006 (see also United Nations, 2011). Data from de Benoist *et al.* (2008).

Kingdom, and the United States, three countries previously iodine sufficient, iodine intakes are falling. Australia and the United Kingdom are now mildly iodine deficient, and in the United States the median UI in women is 130 µg/L, still adequate but less than half the median value of 321 µg/L found in the 1970s (Perrine *et al.*, 2010).

Dairy products are an important iodine source in US diets, and women who do not consume dairy products may be at risk for iodine deficiency (Perrine *et al.*, 2010). These changes emphasize the importance of regular monitoring of iodine status in countries throughout the world.

## Requirements and Status Assessment

The US Food and Nutrition Board of the National Academy of Sciences has set an adequate intake (AI) for iodine in infancy and a recommended dietary allowance (RDA) for children, adults and pregnant and lactating women (Institute of Medicine, 2001) (Table 36.3). The WHO has established recommended nutrient intakes for iodine (World Health Organization, 2007) (Table 36.3). Iodine requirements for different age and population groups have been established based on studies of radioiodine uptake by the thyroid, balance studies, and factorial estimates (Institute of Medicine, 2001).

Several methods are available for assessment of iodine status. The most commonly used are measurement of thyroid size and concentration of urinary iodine (UI) (World Health Organization, 2007). Additional indicators include newborn thyrotropin (TSH), and blood concentrations of thyroglobulin, thyroxine (T4) or triiodothyronine (T3). As discussed below, UI is a sensitive indicator of recent iodine intake (days), and serum Tg shows an intermediate response (weeks to months), whereas changes in the goiter rate reflect long-term iodine nutrition (months to years).

Two methods are available for measuring goiter: neck inspection and palpation, and thyroid ultrasonography. Goiter surveys are usually done in school-age children. By

palpation, a thyroid is considered goitrous when each lateral lobe has a volume greater than the terminal phalanx of the thumbs of the subject being examined. In the classification system of WHO, grade 0 is defined as a thyroid that is not palpable or visible, grade 1 is a goiter that is palpable but not visible when the neck is in the normal position (i.e. the thyroid is not visibly enlarged), and grade 2 goiter is a thyroid that is clearly visible when the neck is in a normal position.

In areas of mild to moderate iodine deficiency, where goiters are small, measurement of thyroid size by ultrasonography is a more objective and precise method and is preferable to palpation. Portable ultrasound equipment can be used in the field, and goiter classified according to international reference criteria for iodine-sufficient children by age, gender, and body surface area (Zimmermann *et al.*, 2004a). The total goiter rate is used to define severity using the following criteria: <5%, iodine sufficiency; 5.0–19.9%, mild deficiency; 20.0–29.9%, moderate deficiency; and >30%, severe deficiency (World Health Organization, 2007).

In areas of endemic goiter, although thyroid size predictably decreases in response to increases in iodine intake, thyroid size may not return to normal for months or years after correction of iodine deficiency (Zimmermann *et al.*, 2003a). During this transition period, the goiter rate is difficult to interpret because it reflects both a population's history of iodine nutrition and its present status. Despite this lag period, a sustained salt iodization program will decrease the goiter rate to <5% in school-age children, and this indicates disappearance of iodine deficiency as a significant public health problem (World Health Organization, 2007).

**TABLE 36.3** Recommendations for iodine intake ( $\mu\text{g}/\text{day}$ ) by age or population group

Age or population group	US Institute of Medicine <sup>a</sup>		Age or population group	World Health Organization <sup>b</sup>
	EAR	AI or RDA		
Infants 0–12 months	–	110–130	Children 0–5 years	90
Children 1–8 years	65	90	Children 6–12 years	120
Children 9–13 years	73	120		
Adults $\geq 14$ years	95	150	Adults >12 years	150
Pregnancy	160	220	Pregnancy	250
Lactation	200	290	Lactation	250

AI, adequate intake; EAR, estimated average requirement; RDA, recommended daily allowance; RNI, recommended nutrient intake.

<sup>a</sup>Data from Institute of Medicine (2001).

<sup>b</sup>Data from World Health Organization (2007).

Because >90% of ingested iodine is excreted in the urine, UI is an excellent indicator of recent iodine intake. Most methods of measuring UI are based on the Sandell-Kolthoff reaction, in which iodide catalyzes the reduction of yellow ceric ammonium sulfate to the colorless cerous form in the presence of arsenious acid (Bier *et al.*, 1998). UI can be expressed as a concentration ( $\mu\text{g/L}$ ), in relation to creatinine excretion ( $\mu\text{g iodine/g creatinine}$ ), or as 24-hour excretion ( $\mu\text{g/day}$ ). To estimate iodine intakes in individuals, 24-hour collections may be preferable. For populations, because it is impractical to collect 24-hour samples in field studies, UI can be measured in spot urine specimens from a representative sample of the target group, and expressed as the median, in  $\mu\text{g/L}$  (World Health Organization, 2007) (Table 36.4). Variations in hydration among individuals generally even out in a large number of samples, so that the median UI in spot samples correlates well with that from 24-hour samples. Creatinine may be

unreliable for estimating daily iodine excretion from spot samples, especially in malnourished subjects where creatinine concentration is low. Spot UI measurements in population studies are often misinterpreted. Although the median UI is a population indicator, it is a common mistake to assume that all subjects with a spot UI <100  $\mu\text{g/L}$  are iodine deficient, but, even in iodine-sufficient regions where intrathyroidal iodine stores are adequate, individual spot UI concentrations are highly variable from day to day.

Daily iodine intake for population estimates can be extrapolated from UI, using estimates of mean 24-hour urine volume and assuming an average iodine bioavailability of 92%. This can be done using the following formula (Institute of Medicine, 2001):

$$\text{Urinary iodine } (\mu\text{g/L}) \times 0.0235 \times \text{body weight (kg)} \\ = \text{daily iodine intake}$$

**TABLE 36.4** Epidemiological criteria from the World Health Organization for assessment of iodine nutrition in a population based on median or range of urinary iodine concentrations

Population group	Iodine intake	Iodine nutrition
<i>School-age children</i>		
<20 $\mu\text{g/L}$	Insufficient	Severe iodine deficiency
20–49 $\mu\text{g/L}$	Insufficient	Moderate iodine deficiency
50–99 $\mu\text{g/L}$	Insufficient	Mild iodine deficiency
100–199 $\mu\text{g/L}$	Adequate	Optimum
200–299 $\mu\text{g/L}$	More than adequate	Risk of iodine-induced hyperthyroidism in susceptible groups
>300 $\mu\text{g/L}$	Excessive	Risk of adverse health consequences (iodine-induced hyperthyroidism, autoimmune thyroid disease)
<i>Pregnant women</i>		
<150 $\mu\text{g/L}$	Insufficient	
150–249 $\mu\text{g/L}$	Adequate	
250–499 $\mu\text{g/L}$	More than adequate	
$\geq 500 \mu\text{g/L}^a$	Excessive	
<i>Lactating women<sup>b</sup></i>		
<100 $\mu\text{g/L}$	Insufficient	
$\geq 100 \mu\text{g/L}$	Adequate	
<i>Children less than 2 years of age</i>		
<100 $\mu\text{g/L}$	Insufficient	
$\geq 100 \mu\text{g/L}$	Adequate	

<sup>a</sup>The term “excessive” means in excess of the amount needed to prevent and control iodine deficiency. There may be an increased risk of adverse effects at this level of intake.

<sup>b</sup>In lactating women, the numbers for median urinary iodine are lower than the iodine requirements, because of the iodine excreted in breast milk. Data from World Health Organization (2007).

Using this formula, a UI of 100 µg/L in an average adult corresponds roughly to a daily intake of 150 µg.

Because serum TSH is determined mainly by the level of circulating thyroid hormone, which in turn reflects iodine intake, TSH can be used as an indicator of iodine nutrition. However, in older children and adults, although serum TSH may be slightly increased by iodine deficiency, values often remain within the normal range. TSH is therefore a relatively insensitive indicator of iodine nutrition in adults. In contrast, TSH is a sensitive indicator of iodine status in the newborn period. Compared with the adult, the newborn thyroid contains less iodine but has higher rates of iodine turnover. Particularly when iodine supply is low, maintaining high iodine turnover requires increased TSH stimulation. Serum TSH concentrations are therefore increased in iodine-deficient infants for the first few weeks of life, a condition termed transient newborn hypothyroidism. In areas of iodine deficiency, an increase in transient newborn hypothyroidism, indicated by >3 % of newborn TSH values above the threshold of 5 mU/L whole blood, suggests iodine deficiency in the population (Zimmermann *et al.*, 2005a). TSH is used in many countries for routine newborn screening to detect congenital hypothyroidism. If already in place, such screening offers a sensitive indicator of iodine nutrition. Newborn TSH is an important measure because it reflects iodine status during a period when the developing brain is particularly sensitive to iodine deficiency.

Thyroglobulin (Tg) is synthesized only in the thyroid, and is the most abundant intrathyroidal protein. In iodine sufficiency, small amounts of Tg are secreted into the circulation, and serum Tg is normally <10 µg/L. In areas of endemic goiter, serum Tg increases due to greater thyroid cell mass and TSH stimulation, and is a sensitive indicator of iodine status (Zimmermann *et al.*, 2003b; Vejbjerg *et al.*, 2009). Tg can also be assayed on dried blood spots taken by a finger prick, simplifying collection and transport (Zimmermann *et al.*, 2006b), and Tg in school-age children is now recommended to assess iodine status in populations (World Health Organization, 2007). In contrast, thyroid hormone concentrations are poor indicators of iodine status. In iodine-deficient populations, serum T<sub>3</sub> increases or remains unchanged, and serum T<sub>4</sub> usually decreases. However, these changes are often within the normal range, and the overlap with iodine-sufficient populations is large enough to make thyroid hormone levels an insensitive measure of iodine nutrition.

## Prophylaxis and Treatment

There are two methods commonly used to correct iodine deficiency in a population: iodized oil and iodized salt. In nearly all regions affected by iodine deficiency, the most effective way to control iodine deficiency is through salt iodization (World Health Organization, 2007). All salt for human consumption, including salt used in the food industry, should be continuously iodized. In Switzerland, previously affected by endemic goiter and cretinism, a monitored national program, in place for over half a century, has effectively eliminated iodine deficiency (Zimmermann *et al.*, 2005a). Iodine can be added to salt in the form of potassium iodide (KI) or potassium iodate (KIO<sub>3</sub>). Because KIO<sub>3</sub> has higher stability in the presence of salt impurities, humidity, and porous packaging (Diosady and Mannar, 2000), it is the recommended form. Iodine is usually added at a level of 20–40 mg iodine/kg salt, depending on local salt intake (World Health Organization, 2007). But in industrialized countries, because 80–90% of salt consumption is from purchased processed foods (Sanchez-Castillo *et al.*, 1987; Andersen *et al.*, 2009), if only household salt is iodized it will not supply adequate iodine. Thus, although it is critical that the food industry use iodized salt, in many countries it is not added to processed foods. Food producers are often reluctant to add iodized salt because of the widespread misperception that iodine can precipitate adverse sensory changes in their products. However, this does not occur, as the iodine is added in only minute amounts; fortified salt has only parts-per-million concentrations. The current push to reduce salt consumption to prevent chronic diseases and the policy of salt iodization to eliminate iodine deficiency do not conflict: iodization methods can fortify salt to provide recommended iodine intakes even if per capita salt intakes are reduced to <5 g/day (World Health Organization, 2008).

As a result of a major international effort led by WHO, the United Nations Children's Fund (UNICEF) and the International Council for the Control of Iodine Deficiency Disorders (ICCIDD), more than 120 countries have implemented salt iodization programs and ~70% of people worldwide have access to iodized salt in 2006, compared with <10% in 1990 (United Nations Children's Fund, 2008). However, when coverage is not complete, iodized salt use is often lowest in the poorest socioeconomic classes, typically the population most affected by iodine deficiency. For a national program to succeed, ≥95% of salt for human

consumption should be iodized according to government standards at the production or importation site. Worldwide, sustainability of iodized salt programs has become a major focus. These programs are fragile, and require a long-term commitment from national governments, donors, consumers, and the salt industry. In several countries where iodine deficiency had been eliminated, salt iodization programs fell apart, and iodine deficiency recurred (Dunn, 2000). Children in iodine-deficient areas are vulnerable to even short-term lapses in iodized salt programs (Zimmermann *et al.*, 2004b).

In some regions, iodization of salt may not be practical for control of iodine deficiency, at least in the short term. This may occur in remote areas where communications are poor or where there are numerous very small-scale salt producers. In these areas, other options for correction of iodine deficiency should be considered, such as iodized oil (World Health Organization, 2007). Iodized oil is prepared by esterification of the unsaturated fatty acids in seed or vegetable oils, and addition of iodine to the double bonds. It can be given orally or by intramuscular injection. The intramuscular route has a longer duration of action (up to 2 years), but oral administration is more common because it is simpler. Iodized oil is recommended for populations with moderate to severe iodine deficiencies that do not have access to iodized salt, and may be targeted at women of child-bearing age, pregnant women, and children. The recommended dose is 400 mg iodine per year for women and 200 mg iodine per year for children 7–24 months of age (World Health Organization, 2007). Iodine can also be given as potassium iodide or iodate as drops or tablets, and in drinking or irrigation water (Squatrino *et al.*, 1986). Iodine supplements (~150 µg/day) are recommended for pregnant and lactating women residing in areas of mild to moderate iodine deficiency. In the United States, because it is uncertain if dietary iodine intakes are adequate in pregnancy, expert groups have recently called for iodine supplementation of this group (Becker *et al.*, 2006). In countries where iodized salt programs supply sufficient iodine to older children and pregnant women, weaning infants, particularly those not receiving iodine-containing infant formula milk, may be at risk of iodine deficiency (Andersson *et al.*, 2010).

## Excess and Toxicity

Acute iodine poisoning caused by ingestion of many grams causes gastrointestinal irritation, abdominal pain, nausea,

vomiting, and diarrhea, as well as cardiovascular symptoms, coma, and cyanosis (Pennington, 1990). Most people are remarkably tolerant of high dietary intakes of iodine. The US Food and Nutrition Board of the National Academy of Sciences has set a tolerable upper intake level (UL) for iodine (Institute of Medicine, 2001). The UL is the highest level of daily intake that is likely to pose no risk of adverse health effects in almost all individuals. The UL is 200 µg/day for ages 1–3 years, 300 µg/day for ages 4–8 years, 600 µg/day for ages 9–13 years, 900 µg/day for ages 14–18 years, and 1100 µg/day thereafter. Individuals with autoimmune thyroid disease or chronic iodine deficiency may respond adversely to intakes lower than these (Zimmermann, 2008a).

In iodine-sufficient individuals, the earliest effect of high iodine intakes is typically an increase in serum TSH without a decrease in serum T<sub>4</sub> or T<sub>3</sub>, a condition termed subclinical hypothyroidism. Large excesses of iodine inhibit thyroid hormone production, leading to increased TSH stimulation, thyroid growth, and goiter. A clinical trial in healthy adults found TSH concentrations were increased by total iodine intakes of ≥750 µg/day (Chow *et al.*, 1991). In children, chronic intakes of ≥500 µg/day are associated with increased thyroid volume, an early sign of thyroid dysfunction (Zimmermann *et al.*, 2005b). Iodine-induced goiter and hypothyroidism can occur in newborns due to high maternal intakes, or through exposure to excess iodine at delivery from the use of antiseptics containing beta-iodine (Nishiyama *et al.*, 2004). Prospective studies in China have suggested chronic excess iodine intakes are associated with a small increase in subclinical hypothyroidism and autoimmune thyroiditis, but not overt hypo- or hyperthyroidism (Teng *et al.*, 2006).

A rapid increase in iodine intake of populations with chronic iodine deficiency may precipitate iodine-induced hyperthyroidism (IIH) (Delange *et al.*, 1999). This is more likely to occur if the iodine is given in excess, e.g. if the iodine content of iodized salt is too high, or when iodine-containing medication is given. IIH occurs mainly in older people with nodular goiter. Thyrocytes in nodules often become insensitive to TSH control, and, if iodine supply is suddenly increased, these autonomous nodules may overproduce thyroid hormone (Corvilain *et al.*, 1998). Symptoms of IIH include weight loss, tachycardia, muscle weakness, and skin warmth, without the ophthalmopathy of Graves' disease. IIH is dangerous when superimposed on underlying heart disease, and may be lethal. Introduction of iodine prophylaxis has been associated with increased

hospitalizations for IIH in Europe, the United States, and several African countries. The incidence tends to gradually abate, but may rise again when the level of iodine in salt is increased. Its occurrence should not be an argument against salt iodization, as the underlying cause of most autonomous nodules and IIH is chronic iodine deficiency. To reduce risk for IIH, the iodine level in salt should be monitored and reduced if too high.

## Future Directions

Future research priorities in iodine nutrition should include correlation of community iodine intake with thyroid disease, the potential role of iodine in fibrocystic breast disease and the immune response, and interactions with other nutrients, particularly vitamin A, iron, and selenium. In the field of IDD, efforts should focus on ensuring adequate iodine during pregnancy and infancy. Monitoring indicators for these key target populations need to be developed and tested. More research on the effects of high intakes of iodine from iodized salt and/or other sources could lead to better estimates of the UL for iodine in different ages and populations. Globally, the elimination of iodine deficiency is within reach, but effort is needed to cover the remaining populations at risk and to ensure quality control and sustainability of existing iodized salt programs.

## SELENIUM

EMILY N. TERRY, MS AND ALAN M. DIAMOND, PhD

*University of Illinois at Chicago, Chicago, Illinois, USA*

### Summary

The essential trace element selenium has been a focus of attention due to its impact on human health, with there being consequences to both its deficiency and excess. While there is considerable knowledge of selenium's metabolic pathways, the means whereby it impacts immunity, and susceptibility to viral infection and a host of human diseases, remain under investigation. Many of the biological consequences of selenium status are likely to be mediated by its role as a constituent of selenium-containing proteins, one class of which includes selenium as the amino acid selenocysteine, which is encoded by the UGA codon within selenoprotein mRNAs. Future efforts to better appreciate how selenium impacts health and disease will likely result in a better understanding of selenium's biology and an improved basis from which to make recommendations about the optimal amount that should be included in the diet.

### Introduction

Selenium is a trace element that was discovered in 1817 by Jons Jacob Berzelius following analysis of a red deposit on a lead wall of a sulfuric acid plant in Sweden. Following examination of its properties, and finding a similarity to tellurium, named as a reference to earth, this new element was named selenium after the moon goddess, Selene. In the late 1930s and into the 1940s, selenium was mostly known for its toxicity in farm animals. Acute poisoning in horses, for example, was referred to as "blind staggers" and was characterized by blindness, excessive perspiration, abdominal pain, colic, diarrhea, increased heart and respiration rates, and lethargy. Chronic toxicity in these animals was referred to as "alkali disease" and resulted in symptoms

including alopecia and cracked hooves. In contrast, insufficient intake of selenium in animals can result in a variety of symptoms, such as nutritional muscular dystrophy, which appears as muscle weakness, loss of weight, diarrhea, and decreased fertility (reviewed in Koller and Exon, 1986). As a consequence, it became common practice to supplement feed with selenium to ensure adequate dietary intake. The essentiality of selenium to good health rather than being a toxin was established by Schwarz and Foltz in 1957 following their description of the prevention of liver necrosis in vitamin E-deficient rats given selenium supplementation (Schwarz and Foltz, 1958). A major breakthrough in understanding the biology of selenium occurred when its incorporation into protein was reported by Rotruck *et al.* (1973) and Flohe *et al.* (1973), and it

later became apparent that there was an entire family of proteins in which selenium was present in the form of selenocysteine. In this chapter, we describe the nutritional aspects of selenium biology, ranging from its metabolism to its impact on human health and with an emphasis on the family of proteins that include selenium as a critical component.

## Dietary Selenium, Recommended Daily Allowance, and Assessment

The accumulation of selenium in foods begins with its uptake by plants from the soil, the resulting concentration of which varies dramatically by region throughout the world. Since the amount of selenium in the soil affects its availability in feeds for livestock, standard supplementation strategies for animals in selenium-poor areas has been implemented (Ullrey, 1992; Ellison, 2002). The form of selenium taken up by plants is typically inorganic selenate ( $\text{SeO}_4^{2-}$ ) or selenite ( $\text{SeO}_3^{2-}$ ), which is then ultimately used to produce selenomethionine, the predominant form found in plants, through the sulfur assimilation pathway (reviewed in Terry *et al.* (2000) and Li *et al.* (2008a)). More than 50% of the selenium found in plants is selenomethionine or its methylated forms, although selenocysteine is also significantly present. Uptake of selenium may also be influenced by additional variables such as acidity, oxygen levels, amount of rainfall, and sulfur levels (Zayed and Terry, 1994; Haygarth *et al.*, 1995; Miladinovic *et al.*, 1998; Li *et al.*, 2008a).

The content of selenium in the diet is influenced by where the food is grown; the impact of growth location is less in places where a sizable portion of the diet is obtained from varied locations. Selenium intake in humans is principally from the consumption of meat, fish, and egg, which contain high levels of selenium in relation to other foods, ranging from 180 to 800 ng/g ([http://www.ars.usda.gov/main/site\\_main.htm?modecode=12-35-45-00](http://www.ars.usda.gov/main/site_main.htm?modecode=12-35-45-00)). Most plants do not accumulate high levels of selenium, but a few noted exceptions include members of the *Brassica* genus, which includes broccoli and kale, and garlic and mushrooms (~300 µg/g) (reviewed in Dumont *et al.*, 2006), and brazil nuts, which contain the highest levels of bioavailable selenium (Thomson and Robinson, 1990; Ip and Lisk, 1994; Thomson *et al.*, 2008). How food is processed may also affect selenium dietary availability; for example, heating food during preparation may decrease selenium content by volatilization (Thomson and Robinson, 1990).

As a consequence of the geological distribution of selenium and regional dietary customs, selenium intake levels vary greatly among populations. In areas such as parts of China which are associated with diseases attributed to selenium deficiency, intake has been reported to be as low as 7–11 µg per person per day. In other parts of China which are associated with selenosis, intake ranges from 750 to 4990 µg per person per day. Countries where dietary selenium levels are generally low include Croatia, Germany, Sweden, and New Zealand, and countries with higher selenium intake include Canada, Greece, the United States, and Venezuela (Combs, 2001). A comprehensive compilation of worldwide selenium intake levels as well as blood and plasma selenium contents was published in 2001 (Combs, 2001) and the levels of plasma selenium in populations of the world are displayed in Figure 37.1.

### Tissue Distribution

The amount of total body selenium is typically dependent upon the region one lives in, with the population of the United States exhibiting high total body selenium levels of over 13 mg, whereas others, such as people living in New Zealand, contain approximately 6 mg (Zachara *et al.*, 2001). The major site of selenium storage in the body is skeletal muscle, accounting for approximately 28–46% of the total selenium pool depending on the population analyzed (Oster *et al.*, 1988; Zachara *et al.*, 2001). The kidneys contain the highest amount of selenium on a per-weight basis, with 470 ng/g wet tissue, as compared with skeletal muscle which contains only 51 ng/g wet tissue as determined in a cohort of Polish individuals (Zachara *et al.*, 2001). Liver selenium levels fall midway between those of kidney and muscle. The typical distribution of selenium in human organs generally lies in the order kidney > liver > spleen > pancreas > heart > brain > lung > bone > skeletal muscle.

### Assessment of Selenium Status

In order to appreciate the impact of selenium on human health, there needs to be a reliable means of determining the status of individuals and populations and of relating these data to health outcomes. However, multiple methods are currently employed to assess selenium status, and which is the most appropriate is a complicated issue. One consideration is the source of the biological material from which the measurements are being made. Different tissues and body fluids can be utilized, with the most commonly used being whole blood, plasma, serum, erythrocytes,

**FIG. 37.1** Levels of plasma/serum selenium ( $\mu\text{g/L}$ ) in distinct global populations. Specific regions of countries are indicated, where available. Data represents an average of plasma/serum selenium concentrations as presented in Combs (2001). AUS, Australia; AUT, Austria; BDI, Burundi; BEL, Belgium; BGR, Bulgaria; BIH, Bosnia and Herzegovina; BOL, Bolivia; CHE, Switzerland; CHL, Chile; CHN, China; COL, Colombia; CUB, Cuba; CZE, Czech Republic; DEU, Germany; DNK, Denmark; EGY, Egypt; ENG, England; E. Sib., Eastern Siberia; ESP, Spain; EST, Estonia; FIN, Finland; FRA, France; HI, Hawaii; HRV, Croatia; HUN, Hungary; IND, India; IRL, Ireland; ISR, Israel; ITA, Italy; JAM, Jamaica; JPN, Japan; K/K-B Areas, Keshan/Kaschin-Beck Areas; KOR, Korea; MEX, Mexico; MKD, Macedonia; MNE, Montenegro; NER, Niger; NGA, Nigeria; NLD, Netherlands; NOR, Norway; NZL, New Zealand; POL, Poland; PRT, Portugal; Rur, rural, non-Keshan; RUS, Russia; SAU, Saudi Arabia; SCO, Scotland; SGP, Singapore; SI, South Island; SRB, Serbia; SVK, Slovakia; SWE, Sweden; TAI, Taiwan; Trans-B, Trans-Baikal; TUR, Turkey; Urb, Urban; USA, United States; VEN, Venezuela; ZAF, South Africa; ZAI, Zaire; C, Central; E, eastern; S, southern; W, western.

urine, hair, and nails (reviewed in Gibson, 1989; Salbe and Levander, 1990). Measurements of plasma selenium are most often cited but may not be the most reliable (Burk *et al.*, 2006), while blood and urine provide an indication of short-term selenium intake. Analysis of hair and nails is more typically used as a measure of long-term intake over months and years. Plasma and serum samples may provide the best result for immediate changes in selenium status, whereas whole blood can provide longer-term status (reviewed in Thomson, 2004). Analysis of selenium in

urine generally provides information on recent intake, typically within the most recent days (reviewed in Thomson, 2004).

The use of blood or urine is relatively non-invasive, and samples are easy to process and store, while the analysis of hair or toenails may be even more convenient and typically provides a more reliable assessment of long-term status. However, hair can be contaminated by common grooming and cleansing products which often contain selenium, and the growth rate of hair, which may influence selenium

accumulation, is variable among individuals and can be dependent on their health status (Morris *et al.*, 1983; LeBlanc *et al.*, 1999). Nails have a more consistent growth rate and are less prone to contamination (reviewed in Thomson, 2004). Urine selenium levels were more closely correlated with predicted intake as assessed through food frequency questionnaires and duplicate food samples. Selenium levels are directly quantified by mass spectrometry of blood and urine (Reamer and Veillon, 1983) and by neutron activation analysis of nails or hair (Morris *et al.*, 1983).

Indirect measures of selenium status by quantification of selenium-containing proteins can also be used. One approach is to use the measured activity of the selenoprotein glutathione peroxidase (GPx), either in plasma or erythrocytes, using a coupled spectrophotometric assay. However, this approach may be most applicable in determining selenium deficiency as individuals with what are often considered adequate selenium levels are likely to have maximized GPx activity and therefore this approach may not be appropriate for assessment of higher intakes (Brown *et al.*, 2000). More recently, the quantification of selenoprotein P (SEPP1), the major selenoprotein in plasma, has also been considered for these purposes. SEPP1 levels were shown to be optimized at 75 µg/day of selenium intake as compared with GPx in the serum which was said to have a maximal activity at 35 mg/day (Xia *et al.*, 2005). An evaluation of the different methods used to determine selenium status has been published (Ashton *et al.*, 2009).

### **Selenium RDA**

The recommended daily allowance (RDA) for selenium indicated by the Food and Nutrition Board of the Institute of Medicine is 55 µg/day (0.7 µmol/day) for healthy adults over age 13; a higher intake is suggested during pregnancy (60 µg/day) and lactation (70 µg/day). These values are based on the expected intake of selenium that would maximize the activity of the glutathione peroxidase (GPx-3) selenoprotein, which is found in the highest concentration in the plasma (Institute of Medicine, 2000). This RDA is clearly below that required to reach maximal levels of all of the selenoproteins. For example, a population in a region in China showed maximal activity of GPx-3 when supplemented with 37 µg/day selenomethionine, and twice that amount of selenite (Xia *et al.*, 2005). However, SEPP1 levels did not reach maximal activity at either of these doses, or at the highest doses administered (61 µg/day selenomethionine or 66 µg/day selenite). There

continues to be significant debate as to what an appropriate selenium RDA should be and the basis for making the decision. Clearly, higher intake than the RDA would be required to maximize the levels of all of the selenoproteins, and, using an additional criterion of need, it was suggested that men required 80 µg/day and women 57 µg/day to maintain selenium balance, and these values were dependent on lean body mass and historical selenium intake (Levander, 1984).

### **Diseases of Excess and Deficiency**

The interest in the possible benefits of selenium supplementation follows a long history in which selenium was given more attention because of its associated toxicity. Thousands of animals were killed by selenium overdose and the adverse effects associated with high-level selenium intake which are referred to as selenosis. Selenosis has also been reported in humans, most often in regions of the world where there are very high levels of selenium in the soil and consequently in the plants grown in that soil (Yang *et al.*, 1983). Symptoms of selenosis include hair loss, brittle and discolored nails, dermatitis if exposure was topical, peripheral neuropathy, nausea, diarrhea, fatigue, and irritability (reviewed in Nuttall, 2006). One of the additional signs of selenosis is an odor on the breath resembling garlic. Selenosis can occur due to exposure to selenium from industrial sources, and several cases of individuals overdosing on selenium appear in the literature. A striking example of selenium toxicity occurred in a 2008 outbreak of selenosis affecting 201 individuals in nine different states in the United States (MacFarquhar *et al.*, 2010). These individuals suffered from the classical signs of selenosis, over 70% reporting diarrhea, fatigue, and hair loss. Each was taking a multivitamin supplement that was labeled to contain 200 µg of selenium in the form of sodium selenite per ounce of supplement, the recommended dose. Subsequent analysis of the product revealed that it in fact contained 40 800 µg per ounce, approximately 200 times the level indicated on the label.

The exact causes for the symptoms associated with selenium toxicity are likely to be multifactorial and to include the erroneous substitution of selenium for sulfur in the sulfur-containing amino acids cysteine and methionine, as well as the induction of selenium-associated oxidative stress. Exposure of either cells in culture to high levels of selenium or of animals given excessive selenium supplements led to enhanced mutagenesis, the induction

of chromosomal abnormalities such as micronuclei formation, and the induction of cell-cycle arrest and apoptosis (reviewed in Valdiglesias *et al.*, 2010). Examples of selenosis continue to be reported but they are rare, and perhaps a greater concern is the adverse consequences of selenium supplementation resulting from taking the recommended doses, concerns that emerged following the results of selenium supplementation clinical trials.

The best known disease associated with selenium deficiency is Keshan disease, a serious cardiomyopathy first described in Keshan County in north-east China. The disease is endemic among the poor population of the region, being most prevalent among younger women and children, and results in myocardial necrosis and eventually congestive heart failure. Given the low selenium status of the afflicted population, the Chinese government initiated an oral selenium supplementation program that greatly reduced the disease incidence (Xia *et al.*, 1989). However, the disease cannot be fully prevented by selenium supplementation, which indicates that there are additional likely etiological factors. Evidence has been presented that infection with a Coxsackie B virus (Li *et al.*, 2000) and increased risk found in association with a polymorphism in the glutathione peroxidase 1 (GPx-1) selenium-containing protein (Lei *et al.*, 2009; Xiong *et al.*, 2010) are contributing factors. Kashin-Beck disease is an osteoarthropathy also endemic to China and is associated with joint destruction and possibly dwarfism (Schepman *et al.*, 2011). Selenium deficiency also occurs in Kashin-Beck endemic regions, and a recent meta-analysis of 15 trials with selenium supplementation has supported the benefits of intervening with selenium supplementation in preventing the disease (Zou *et al.*, 2009). As with Keshan disease, increased risk of Kashin-Beck disease is found in association with a polymorphism in GPx-1 (Xiong *et al.*, 2010). Myxedematous cretinism is endemic in a region of both selenium and iodine deficiency in central Africa (Dumont *et al.*, 1994), and the deficiency of these elements in the diet is likely to contribute to the thyroid pathology seen in these cases (Kohrle *et al.*, 2005).

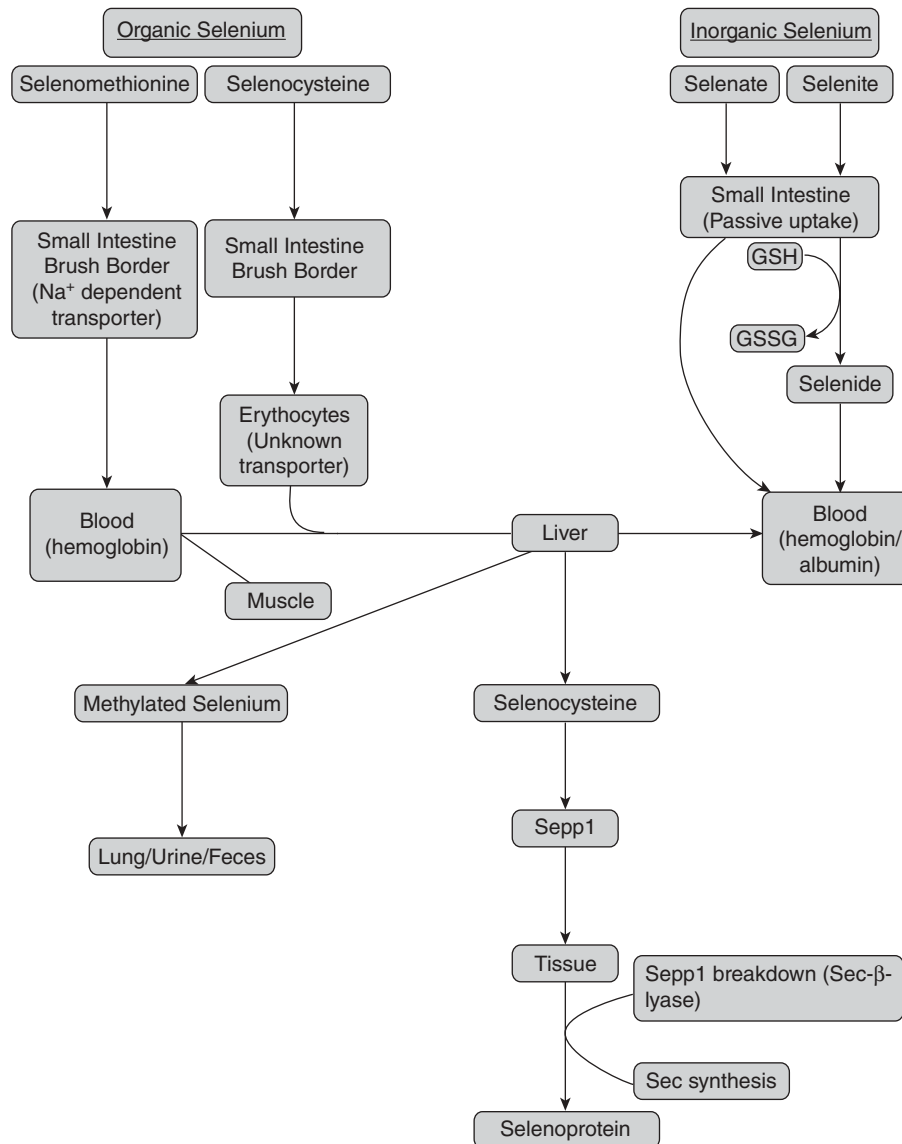

## Metabolism

### ***Ingestion, Absorption, and Transport***

The bioavailability of selenium depends on the form ingested, such as whether the forms are organic or inorganic, as well as other dietary components that might

inhibit uptake such as heavy metals, and varies between species (reviewed in Thomson, 1998). Organic selenium is predominantly found as selenomethionine, although selenocysteine and methylated forms of selenomethionine are also ingested (reviewed in Rayman, 2008). Inorganic forms include selenite and selenate salts. Selenomethionine is the most readily absorbed form of dietary selenium, and is metabolized following active transport from the small intestine by a sodium-dependent transporter (Wolffram *et al.*, 1989). After absorption, selenomethionine is found bound to hemoglobin and then accumulates in liver and muscle (Beilstein and Whanger, 1986; Yeh *et al.*, 1997). Selenocysteine is also taken up in the intestine, but at a less efficient rate than selenomethionine, as shown in a simulated digestion experiment (Shen *et al.*, 1997). Selenocysteine is absorbed by red blood cells by an unknown transporter (Imai *et al.*, 2009). The inorganic selenium is absorbed passively and is stored less efficiently than organic forms (reviewed in Fairweather-Tait *et al.*, 2010). Selenite is more bioavailable than selenate, and can be seen in erythrocytes within minutes of intravenous administration in rats (Suzuki *et al.*, 1998). Selenite is metabolized to selenide following reduction by glutathione, and then can be found bound to albumin or hemoglobin and is transported to the liver for further processing (Haratake *et al.*, 2008). Conversely, selenate is taken up in plasma and transported, unmetabolized, to the liver where it is metabolized or is excreted in urine (Kobayashi *et al.*, 2001). Selenide is then used for conversion to selenocysteine for selenoprotein incorporation (reviewed in Rayman, 2000). The major metabolic steps in selenium processing are presented in Figure 37.2.

The major organ for controlling selenium levels in the body is the liver where it is designated for excretion or for further processing for use in selenoproteins, which include the major transport selenium-containing protein, Sepp1 (Burk and Hill, 2009). Sepp1 is an extracellular protein containing 10 selenocysteines and comprises the major form of selenium in plasma. Sepp1 accounts for approximately 44% of the selenium in plasma, whereas GPx3 accounts for approximately 30%; the remaining 37% is associated with albumin (Janghorbani *et al.*, 1999). The major means of selenium supply to the brain and testes is by uptake of Sepp1 via the apolipoprotein E Receptor-2 (ApoER2) (Olson *et al.*, 2007), and via megalin, another member of the lipoprotein receptor family, in kidney proximal tubule epithelial cells (Olson *et al.*, 2008). Sepp1

**FIG. 37.2** The major steps of selenium metabolism ranging from ingestion to excretion. GSH, Glutathione; GSSG, reduced glutathione; Sec, selenocysteine.

enters the tissue where the protein is catabolized by Sec- $\beta$ -lyase and the products are funneled into selenium metabolism (Esaki *et al.*, 1982).

### Excretion

Selenium for excretion is metabolized in the liver to trimethylselenium by S-adenosylmethionine methylation or to selenosugars, with evidence that selenosugars are the predominant form excreted (Suzuki *et al.*, 2005).

Metabolized selenium is primarily excreted via the kidneys in urine either as selenosugars or as methylated selenide, which, together with absorption, function to regulate homeostasis. In cases of excess selenium intake, selenium is not trimethylated, and is excreted from the lung as dimethyl selenide (Kremer *et al.*, 2005). Rats injected with high doses of selenium (2 mg/kg) demonstrated excretion via the lungs of up to 26% of the initial dose after 24 hours, as compared with 14% excreted via the kidneys as

trimethylselenonium (Vadhanavikit *et al.*, 1987). Intestinal excretion of selenium was thought to be a minor method of excretion with most of it being excreted by this route unabsorbed; however, evidence points to intestinal excretion being a form of homeostatic control (Hawkes *et al.*, 2003). In men given supranutritional levels of selenium, approximately half of the detected selenium excreted was in the feces (Bugel *et al.*, 2008).

## Selenium and Human Health

### **Selenium, Viral Infectivity, and Immunity**

Dietary intake of selenium may have an effect on immune function in humans. Most of the data in support of this comes from studies examining the physiological consequences of selenium deficiency. Reduced intake of selenium has been shown to negatively affect the components of the innate immune system, such as B- and T-lymphocytes and neutrophils that participate in the response to infectious challenge, and these effects are likely to be mediated through the action of selenoproteins (reviewed in Arthur *et al.*, 2003). Animal studies have indicated that selenium status could adversely affect interleukin-2, its high-affinity receptor, interferon  $\gamma$ , and CD40 ligand levels (Hoffmann *et al.*, 2010). Given the possible role of selenium in inflammation, it is noteworthy that selenium levels may have an impact on both the risk and severity of asthma. Conflicting data regarding the impact of selenium levels and asthma in humans as well as animal data indicate a bimodal response where lower or higher levels of selenium are associated with increased asthma (reviewed in Hoffmann and Berry, 2008). The authors suggest that the complexity of the issue may result from the ability of selenium to both stimulate the immune system and enhance the levels of antioxidant selenoproteins that might provide protection to the lung.

In addition to the possible role of selenium in influencing immune function, its levels may have an impact on viral infectivity and the consequential impact on the diseases associated with those infections. This may be most apparent in the case of the pediatric cardiomyopathy associated with selenium deficiency, Keshan's disease (see earlier in this chapter). In spite of the success of the vast selenium supplementation program that dramatically reduced disease incidence, the seasonal pattern of incidence indicated the likely involvement of another etiological determinant, and the detection of the coxsackie virus (a picornavirus), in Keshan tissue prompted further

examination. Animal studies support the role for this virus in this disease as it was shown that mice fed a selenium-deficient diet developed cardiac disease following infection with a relatively benign CVB3 coxsackie virus whereas mice with adequate selenium levels did not develop myocarditis (Beck *et al.*, 1994). It was subsequently shown that the pathology observed in the selenium-deficient mice was associated with the acquisition of six point mutations in the CVB30 genome that accounted for the change in virulence (Beck *et al.*, 1995) and that this effect may have been mediated by the reduced levels of the GPx-1 selenoprotein that occur during selenium deficiency (Beck *et al.*, 1998). Selenium deficiency has also been shown to exacerbate the disease induced by influenza viruses (Beck *et al.*, 2001), including H1N1 (Yu *et al.*, 2010). Although there was an indication that low selenium levels might be a contributor to HIV-associated mortality (Baum *et al.*, 1997), the results of randomized placebo-controlled selenium intervention trials have not yielded a clear answer to the question of the nutrient's benefits in the management of AIDS (Pitney *et al.*, 2009).

### **Selenium and Cancer**

Much of the attention directed towards evaluating the role of selenium in human health has centered on its potential use in reducing cancer incidence. This focus can be traced back over 40 years ago when inverse associations between dietary selenium intake and cancer mortality were first realized (Shamberger and Frost, 1969). Since then, there have been a significant number of epidemiological studies investigating the relationship between selenium intake and cancer incidence, and many but certainly not all have revealed an inverse association for a diverse list of cancer types (reviewed in Whanger, 2004). Perhaps the strongest data in this regard are for cancers of the colon and prostate. For example, a case-control study in Montreal involving 402 incidence cases of colon cancer from a cohort of 1048 incidence cases and 688 population-based controls indicated a statistically significant inverse correlation between toenail selenium levels and the risk of colon cancer for both genders (OR = 0.42 at  $p = 0.009$ ) (Ghadirian *et al.*, 2000). A significant inverse association between selenium levels and the incidence of large adenomatous polyps, after adjusting for confounding variables in patients less than 60 years of age (OR = 0.17,  $p = 0.029$ ), has also been reported (Fernandez-Banares *et al.*, 2002). These conclusions were substantiated by an analysis of pooled data from three independent studies (Jacobs *et al.*, 2004) and a recent

study similarly showing the inverse association between serum selenium levels and the risk of advanced colorectal adenoma (Peters *et al.*, 2006).

Research involving animal models has also indicated that selenium supplementation may be a useful strategy to reduce cancer risk. Hundreds of independent reports have shown that providing rodents with selenium at non-toxic doses can reduce tumor incidence, being protective for most organs and against a wide range of carcinogens (El-Bayoumy, 1991). Selenium supplementation studies in humans are few, and the Nutritional Prevention of Cancer (NPC) trial conducted by Clark *et al.* in 1991 received considerable attention. The study (Clark *et al.*, 1996) was a double-blind trial to examine the efficacy of providing 200 µg a day of selenium as selenized yeast on the recurrence of non-melanoma skin cancer as compared with placebo. The results of this study indicated that selenium supplementation did not protect against skin cancer, but long-term follow-up revealed that there was protection against prostate cancer for those men with lowest baseline selenium status (Duffield-Lillico *et al.*, 2003). Encouraged by the collective data indicating a possible protective effect of selenium on prostate cancer incidence, the Selenium and Vitamin E Cancer Prevention Trial (SELECT), a double-blind placebo-controlled supplementation study began in 2001 involving over 35 000 men from the United States, Canada, and Puerto Rico randomized to selenium, vitamin E, both or placebo (Lippman *et al.*, 2005). Unlike the NPC trial, men were given selenium in the form of selenomethionine. The SELECT trial was terminated ahead of schedule in 2008 for an apparent lack of efficacy of the supplements (Lippman *et al.*, 2009). There have been several commentaries offering explanations of the apparent contradictions between the animal, epidemiological and supplementation results on selenium efficacy in reducing cancer risk (El-Bayoumy, 2009; Hatfield and Gladyshev, 2009; Rayman, 2009; Schrauzer, 2009).

### Mechanism of Cancer Prevention

While the animal and human epidemiological data indicate a likely role for selenium in cancer prevention, the mechanisms involved remain elusive and controversial. It is attractive to assume that many of the beneficial effects of selenium are due to its consequential effects on selenoproteins because many of these are regulated by selenium intake, several have clear antioxidant functions, and there is a significant amount of data indicating that genetic variants of selenoproteins are associated with disease risk and

outcome (Rayman, 2009; Zhuo and Diamond, 2009). In support of this concept, mice genetically engineered to express reduced selenoprotein levels are predisposed to develop premalignant lesions linked to both colon and prostate cancer (Diwadkar-Navsariwala *et al.*, 2006; Irons *et al.*, 2006). In the case of the colon cancer study, it was shown that selenoprotein-dependent and -independent mechanisms of cancer prevention were accounting for the effects (Irons *et al.*, 2006). This is consistent with a large body of evidence indicating that non-protein selenium metabolites can exert an anti-cancer effect by targeting tumor cells, although this typically requires relatively high concentrations of selenium. The use of such non-protein forms of selenium in cancer prevention and control have recently been reviewed (Nadiminty and Gao, 2008).

Whatever the mechanism, it appears as if selenium may be exerting its beneficial function, at least in part, by preventing mutations. The evidence that selenium protects DNA from damage comes from studies beginning in the 1980s that used both yeast and mammalian systems (Rosin, 1981; Diamond *et al.*, 1996). Supplementation of the culture media of Chinese hamster ovary cells with low levels of selenium (30 nM) in the form of sodium selenite significantly reduces the mutation frequency following exposure to X-rays (Diamond *et al.*, 1996). Selenium can also increase the repair of N-nitrosobis(2-oxopropyl) amine-induced single-strand breaks, even when provided 2 days post-carcinogen exposure (Lawson and Birt, 1983; Lawson, 1989), and induce DNA repair synthesis in an isolated rat liver cell system (Russell *et al.*, 1980); also, selenomethionine induced a DNA repair response in human fibroblasts (Seo *et al.*, 2002). Both p53 and BRCA1 may be involved in the mechanism by which selenium reduces DNA damage (Fischer *et al.*, 2006). In this regard, the observation that genomic instability in cells of women who were BRCA1 mutation carriers, as measured by chromosome breakage in cultured lymphocytes from these patients, could be complemented by oral selenium supplementation is particularly interesting (Kowalska *et al.*, 2005). Additionally, in a different cohort of women also carrying the BRCA1 mutation, supplementation was shown to reduce the formation of 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-OH-dG), a DNA adduct caused by increased reactive oxygen species in cells (Dziaman *et al.*, 2009). A subsequent increase in urinary 8-OH-dG levels was noted, which indicates that selenium could be protecting against mutation by actually increasing the role of repair by base excision.

### **Selenium and Diabetes**

The results of the NPC trial were encouraging and generated enthusiasm for the continued development of selenium for use in cancer prevention. A secondary analysis of the NPC trial was conducted to assess whether selenium supplementation would reduce the incidence of type 2 diabetes (Stranges *et al.*, 2007). Surprisingly, there was a higher incidence of type 2 diabetes in the selenium-supplemented group (HR = 1.55, 95% CI 1.03–2.33). In addition, the data indicated a statistically significant dose–response gradient with the greatest risk for type 2 diabetes occurring in the supplemented group within the highest tertile of baseline selenium levels (HR = 2.7, CI 1.30–5.61). As discussed in the paper, the determination of an association between selenium supplementation and diabetes had significant limitations, including the use of self-reported data, diabetes not being the primary endpoint, and the absence of significant data on diabetes-associated risk factors. Furthermore, sampling was from a subset population that was relatively older and from a low-selenium region.

The SELECT selenium supplementation trial was terminated early for apparent lack of efficacy of the test compounds and, of note, a non-significant increase in the risk of diabetes in the group receiving selenium was observed (RR = 1.07, 99% CI 0.94–1.22;  $p = 0.16$ ) (Lippman *et al.*, 2009). The possibility that selenium might increase the risk of diabetes therefore appeared in two independent clinical supplementation trials, conducted in two different populations and with different forms of selenium, raising concerns over the possible risks of selenium supplementation especially among those with higher baseline levels.

Human epidemiological data also indicated a possible risk of diabetes associated with higher selenium intake. An examination of NHANES data on US populations indicated an increased risk of type 2 diabetes among those with the highest selenium levels, as well as associations with adverse serum-lipid profiles and arterial disease (Bleys *et al.*, 2007; Laclaustra *et al.*, 2009). A similar report indicating an association between higher selenium levels, poor lipid profiles, and arterial disease among British citizens was also published (Stranges *et al.*, 2010). Bleys *et al.* (2008) also investigated the relationship between serum selenium levels and all causes of death, also using NHANES data. They reported a non-linear association between serum selenium levels and deaths by all causes, and specifically those due to cancer. Below a baseline serum concentration of 130 ng/mL, increased selenium levels were

associated with a reduced risk of all-cause mortality and cancer-associated deaths; there was no effect of selenium within the range 130–150 ng/mL; and there was evidence for increased risk of death from all causes as well as cancer mortality above 150 ng/mL. Thus, the results of supplementation/epidemiological studies might indicate that there are individuals, such as those with adequate or relatively high levels of selenium, who may be at greater risk of disease were they to supplement their diets with selenium. Such a response to selenium supplementation, where low or high levels of selenium may be detrimental with the optimal levels lying somewhere in between, is supported by research in dogs indicating a U-shaped dose–response curve between the levels of selenium in toenails and DNA damage in prostatic tissue (Waters *et al.*, 2005) and these data have recently been discussed in comparison with what has been observed in humans (Chiang *et al.*, 2009).

### **Selenoproteins**

Selenium-containing proteins generally fall into one of three categories (reviewed in Behne and Kyriakopoulos, 2001; Kryukov *et al.*, 2003). One of these classes includes those proteins containing selenomethionine in which selenium, due to its structural similarity to sulfur, incorporates non-specifically into the sulfur-containing amino acids (Gladyshev and Hatfield, 2001). The most common and best studied class of selenium-containing proteins includes those that contain the amino acid selenocysteine (Sec). Throughout evolution, from bacteria to man, Sec is incorporated co-translationally by its insertion in response to UGA codons that otherwise would serve as translational termination signals. In eukaryotes, the recognition of UGA as Sec requires a regulatory sequence, called a SECIS element, in the 3′-untranslated region of the selenoprotein mRNA (Berry *et al.*, 1991). All in-frame UGA codons contained in a SECIS-including mRNA are recognized as encoding Sec, which is incorporated into the elongating peptide by a unique translational machinery that includes a highly unusual tRNA (Lee *et al.*, 1989), an elongation factor, as well as other proteins required for selenoprotein synthesis (reviewed in Driscoll and Copeland, 2003; Bellinger *et al.*, 2009).

Based on *in silico* analyses, there are 25 human Sec-containing selenoprotein genes and 24 in the mouse (Kryukov *et al.*, 2003). Most of the selenoproteins can be classified by the position of the Sec residue: either those that contain Sec in the carboxy-terminus of the protein

or those that contain Sec in the amino-terminus as part of the CxxC motif (reviewed in Lobanov *et al.*, 2009). Human selenoproteins can be considered to belong to seven functional classes: antioxidant enzymes (GPx-1, GPx-2, GPx-3, GPx-4, GPx-6, SelK, SelR, SelW), redox signaling (TrxR1, TrxR2, TrxR3), thyroid hormone metabolism (DIO1, DIO2, DIO3), selenocysteine biosynthesis (SBP2), selenium transport (SelP), protein folding (Sep15, SelN, SelM, SelS), and others of unknown function (reviewed in Gromer *et al.*, 2005; Papp *et al.*, 2007). The biological roles of many of these proteins, even when their enzymatic functions have been resolved, continue to be investigated and a description of each of them, including their biochemical functions, biological roles, and chromosome locations, can be found in the literature (reviewed in Gromer *et al.*, 2005; Papp *et al.*, 2007; Bellinger

*et al.*, 2009). Table 37.1 provides a list of selenoproteins implicated in human disease by genetic evidence. As a protein class, selenoproteins are critical for normal tissue function as has been extensively investigated using mice in which selenoprotein synthesis is selectively inhibited in individual organ systems. These studies and the resulting pathology have been reviewed (Moustafa *et al.*, 2003).

The third class of selenium-containing proteins includes those proteins in which selenium is bound but not incorporated into an amino acid. One such protein is the selenium binding protein 1 (SBP1) (Bansal *et al.*, 1989). The human selenium-binding protein gene (SBP1, SELENBP1, or hSP56) (Chang *et al.*, 1997) is located on chromosome 1 at q21–22, and is the homolog of the mouse SP56 gene which was originally reported as a 56-kDa mouse protein that stably bound <sup>75</sup>selenium (Bansal *et al.*, 1989). The

**TABLE 37.1** Selenoproteins implicated in disease risk and etiology by genetic evidence<sup>a</sup>

Selenoprotein	Disease	Genetic factor	Reference

<sup>a</sup>These examples do not include situations where specific selenoproteins are implicated in cancer progression due to observed loss of heterozygosity (LOH) in DNA obtained from tumor samples. Examples of LOH at selenoprotein loci can be found in Zhuo and Diamond (2009).

<sup>b</sup>"-" indicates a position 5' of the start codon.

human cDNA contains a 472 amino acid encoding open reading frame (Chang *et al.*, 1997) and protein resides in both the nucleus and the cytoplasm (Chen *et al.*, 2004). It is expressed in a variety of tissue types, including the heart, lung, kidney, and tissues of the digestive tract. The form of selenium in SBP1 is unknown as is the nature of its association: the selenium remains bound to the protein when electrophoresed in SDS acrylamide gels but dissociates at extremes of pH (Bansal *et al.*, 1989). The function of SBP1 is unknown although it may be involved in intra-Golgi transport (Porat *et al.*, 2000), and its reported association with the von Hippel–Lindau protein-interacting deubiquitinating enzyme 1 indicates SBP1 may function in protein degradation (Jeong *et al.*, 2009). SBP1 levels inversely correlate with poor clinical outcome in patients with lung, ovarian, and colon carcinoma (Yang and Sytkowski, 1998; Chen *et al.*, 2004; Huang *et al.*, 2006; Kim *et al.*, 2006; Li *et al.*, 2008b). More recently SBP1 was found to become silenced by methylation in colon cancers, and it can influence sensitivity to oxidative stress, cell migration, and tumorigenesis (Pohl *et al.*, 2009).

### **Selenoproteins and Thyroid Hormone Function**

Among the selenoproteins with more clearly defined functions are the three iodothyronine deiodinases (DIO), types I, II, and III, that activate or deactivate thyroid hormone by the removal of specific iodine atoms (reviewed in Bianco *et al.*, 2002; Bianco and Kim, 2006). Reduced levels of selenium in the diet can result in thyroid dysfunction as a result of consequential reduction in DIO, and this has been extensively reviewed (Schomburg and Kohrle, 2008). In addition, mutations in the gene for SECIS Binding Protein 2 (SBP2), a protein that recognizes the SECIS element to facilitate the appropriate recognition of in-frame UGA codons (Copeland and Driscoll, 1999), were shown in 2005 to be associated with abnormal thyroid tests (Dumitrescu *et al.*, 2005), and this association was subsequently reported again among additional families (Dumitrescu *et al.*, 2010). These effects are likely to be mediated, at least in part, by the consequences of altered DIO regulation.

### **Selenoprotein N**

Selenoprotein N (SelN) was discovered following an in silico scan of nucleotide sequence databases in search of SECIS elements (Lescure *et al.*, 1999). SelN contains one Sec residue and is a glycoprotein found within the endoplasmic reticulum. This protein is localized in skeletal

muscle and implicated as a causative factor in “Rigid Spine Muscular Dystrophy” (RSMD), which now belongs to a family of SelN-related myopathies (Moghadaszadeh *et al.*, 2001; Arbogast and Ferreiro, 2010). Linkage disequilibrium indicated SelN’s involvement in RSMD and other SelN-related myopathies, which are characterized by weak neck and trunk musculature, hypotonia, scoliosis, and elevated creatine kinase levels (Arbogast and Ferreiro, 2010). SelN mRNA is highly expressed in fetal tissue, with a subsequent reduction into adulthood (Moghadaszadeh *et al.*, 2001). There are multiple different mutations involved in SelN-related myopathies, the most common of which mutates the Sec codon (TGA) to TAA, inserting a stop codon and truncating the mRNA (Moghadaszadeh *et al.*, 2001; Tajsharghi *et al.*, 2005). Other forms of SelN-related myopathies exhibit mutations within the SECIS element, but with more mild effects than in those carrying the truncated mRNA.

### **The Glutathione Peroxidases**

The glutathione peroxidases (GPx1-7) represent a conserved group of five selenium-containing enzymes (GPx1-4, GPx6) as well as three others in which cysteine is substituted for selenocysteine. GPx have been studied extensively, using reducing equivalents from glutathione to detoxify peroxides. The least studied of the selenium-containing GPx is GPx6, expressed in the olfactory epithelium (Kryukov *et al.*, 2003). The non-selenium-containing enzymes include GPx5 which is expressed in the epididymis (Vernet *et al.*, 1996) and considered to be involved in protecting that organ from oxidative stress (Chabory *et al.*, 2009) and GPx7 which was detected by in silico analysis (Kryukov *et al.*, 2003) and considered to be involved in antioxidant defenses in breast cancer cells (Utomo *et al.*, 2004). GPx1 is the oldest and best studied of the family, being ubiquitously expressed in most tissues. GPx2 (also known as the gastrointestinal GPx) has a more restricted expression pattern, being highest in the liver and gastrointestinal tract (Chu *et al.*, 1993; Florian *et al.*, 2001). The plasma glutathione peroxidase, GPx3, is produced by the proximal tubule of the kidney and is abundant in the plasma (Tham *et al.*, 1998) where its biological role is still unclear. The phospholipid/cholesterol hydroperoxide detoxifying glutathione peroxidase, GPx4, is highly unusual as not only does it function as a peroxidase (Zhang *et al.*, 1989), but it also undergoes polymerization and fills a major structural role in the midpiece of mature spermatozoa (Ursini *et al.*, 1999).

A strong indication of the impact of any of the selenoproteins on human health is the association of polymorphic variants of the gene that encode for a particular selenoprotein and increased risk for specific disease. For the GPx1 gene, a polymorphism resulting in either a leucine or proline at position 198 of the protein has been shown to be associated with increased risk of cancers of the lung, breast, bladder, prostate, liver, and lymphomas (reviewed in Rayman, 2009, and Zhuo and Diamond, 2009). In addition to data indicating that polymorphisms in selenoprotein genes are associated with increased cancer risk, loss of one of two copies of the genes for GPx1 is also associated with cancers of the lung, breast, colon, and the head and neck (Ratnasinghe *et al.*, 2000; Hu *et al.*, 2005). Clonal expansion of cells that lose one of two copies of a particular gene is often taken as an indication that the gene provides a protective function and that loss either unmasks a recessive mutation or reduces the amount of a protective enzyme.

### **Selenoprotein Genetics and Disease**

Polymorphisms in the genes for other selenoproteins (GPx-4, SePP, Sep15, and TRR) have also been associated with cancer risk or mortality of cancer (reviewed in Rayman, 2009; Zhuo and Diamond, 2009). In the case of Sep15, a protein believed to function in the quality control of protein folding (Korotkov *et al.*, 2001), functional allelic variants of this protein associated with cancer risk have been implicated in cancers of the breast (Hu *et al.*, 2001) and lung (Jablonska *et al.*, 2008), and in malignant mesothelioma (Apostolou *et al.*, 2004). More recently, an association between a Sep15 polymorphism and prostate cancer-associated mortality was reported (Penney *et al.*, 2010). SEPS1 (SelS, selenoprotein S) is an endoplasmic reticulum-associated protein implicated in inflammation, and polymorphisms of this gene have been associated with both coronary heart disease (Alanne *et al.*, 2007) and preeclampsia, a condition of pregnancy-associated hypertension (Moses *et al.*, 2008).

### **Future Directions**

The interest in selenium and its impact on human health began with concerns over its toxicity. The focus has shifted to better understanding how individuals who receive adequate dietary levels benefit through the resultant prevention of disease. This will necessitate a continued effort to define the level of selenium intake that will enhance its

health-promoting effects, requiring improved methods of assessment and evaluation that are based on research findings. This challenge is perhaps best exemplified by the recent lack of efficacy of selenium supplementation in reducing the incidence of prostate cancer in the SELECT prostate cancer trial. This large study proceeded as a result of a substantial body of evidence that selenium could prevent cancer of several types in animal models and that selenium levels in the diet are inversely correlated with prostate cancer risk. However, there remains a large gap in the understanding of how different forms of selenium are eventually used by the body; of the mechanisms by which selenium prevents disease; and of the biological roles for most of the 25 selenocysteine-containing proteins. Similarly, the functions of other proteins that bind selenium remain to be clarified. Such information, partnered with a better appreciation of the impact of individualized genetic diversity among humans on selenium-influenced health outcomes, should be gathered prior to the launch of large supplementation studies. Furthermore, increased knowledge of selenium biology will be critical to understanding the risks and benefits of enhancing dietary selenium intake, perhaps based on a particular person's baseline levels, and thus making revised recommendations as to how much selenium to consume in order to reduce disease incidence.

## MANGANESE, MOLYBDENUM, BORON, CHROMIUM, AND OTHER TRACE ELEMENTS

FORREST H. NIELSEN, PhD

*Grand Forks Human Nutrition Research Center, USDA-ARS-NPA, Grand Forks, North Dakota, USA*

### Summary

This review presents current knowledge about the essentiality, biochemical function, beneficial actions, deficiency signs, absorption, transport, retention, excretion, and nutritional importance of the trace and ultra trace elements manganese, molybdenum, boron, chromium, arsenic, fluoride, nickel, silicon, strontium, and vanadium in human nutrition. Although the nutritional importance of each of the elements covered in this chapter is limited, unclear, or speculative, emerging evidence indicates that some of these elements have beneficial bioactivity in nutritional or reasonable supra-nutritional amounts. They may become recognized in a manner similar to other essential nutrients provided in supra-nutritional amounts, or phytonutrients and omega-3 fatty acids in nutritional amounts, in promoting health and preventing chronic disease in humans. Therefore, future studies are needed to determine the mechanisms behind the beneficial effects, whether some effects reflect an essential function, and the dietary intakes that give optimal response.

### Introduction

If the lack of a mineral element cannot be shown to cause death or interrupt the life cycle, then that element is not generally considered essential unless it has a defined biochemical function. On this basis, two elements, manganese and molybdenum, discussed in this chapter, are well established essential elements because they are known

enzyme cofactors. Genetic defects eliminating some of these cofactor functions result in death in humans. Currently, however, human excessive or high intakes of manganese and molybdenum causing pathological or pharmacological effects receive more attention than low intakes because their nutritional deficiencies have not been clearly identified in the general population. Boron and chromium have not been firmly established as nutrition-

ally essential because they lack clearly defined biochemical functions. However, numerous human studies have shown that boron in nutritional amounts and chromium in supra-nutritional amounts may influence health and disease by directly or indirectly producing beneficial functional outcomes. Thus, boron and chromium will receive significant attention in this review. Numerous other elements have been suggested to be of nutritional importance because of some promising physiological or clinical finding, most often in an animal model or special human situation. Of these elements, arsenic, fluorine, nickel, silicon, strontium, and vanadium have received the most research attention focused on their nutritional and pharmacological properties, and thus will be briefly discussed. Possible nutritional importance of elements other than those above will be only summarized in a table because there is limited recent evidence that provides further support for them having significant beneficial effects in humans. (Note: To achieve the guideline limit for the number of references for this review, other review articles instead of original reports often will be cited.)

## Essential Trace Elements

### **Manganese**

#### **Essentiality Basis and Biochemical Function**

The essentiality of manganese has been known for about 80 years. Manganese deficiency has been induced in many animal species (Freeland-Graves and Llanes, 1994). However, because manganese deficiency has been difficult to induce or identify in humans, it is considered to be of limited nutritional concern. None the less, manganese is an established essential nutrient for humans because it activates numerous enzymes and is a constituent of several metalloenzymes (Leach and Harris, 1997). Enzymes that are activated by manganese include oxidoreductases, lyases, ligases, hydrolases, kinases, decarboxylases, and transferases. Most enzymes activated by manganese in higher animals and humans also are activated by other metals, especially magnesium; exceptions are the manganese-specific activation of glycosyltransferases, glutamine synthetase, farnesyl pyrophosphate synthetase, and phosphoenolpyruvate carboxykinase. Arginase, pyruvate carboxylase, and manganese superoxide dismutase (MnSOD or SOD2) are manganese metalloenzymes found in humans and animals. MnSOD is essential for life; a deletion mutation in mice results in death within 5–21 days of birth (Macmillan-Crow and Cruthirds, 2001). The

neonatal mice exhibit myocardial injury, neurodegeneration, lipid peroxidation, fatty liver, anemia, and severe mitochondrial damage. The essentiality of MnSOD contrasts with cytosolic and extracellular Cu, Zn SOD; gene deletions for these enzymes are not lethal.

#### **Deficiency Signs and Beneficial and Toxicological Actions**

Manganese deficiency causes a variety of effects depending on the animal species (Freeland-Graves and Llanes, 1994). Deficiency causes depressed growth, testicular degeneration, and seizures in rats; slipped tendons or perosis in chicks; osteodystrophy and severe glucose intolerance in guinea pigs; and ataxia in mice and mink. Signs of nutritional manganese deficiency in humans have not been firmly established. Perhaps the most convincing case of manganese deficiency is that of a child on long-term parenteral nutrition who exhibited diffuse bone demineralization and poor growth that were corrected by manganese supplementation (Norose and Arai, 1987). In another study, men fed a purified diet supplying only 0.11 mg/day of manganese for 39 days developed a finely scaling minimally erythematous rash, decreased serum cholesterol, and increased serum alkaline phosphatase activity (Freeland-Graves and Llanes, 1994).

A low manganese status, however, may contribute to disease processes. Low dietary manganese has been associated with osteoporosis, diabetes, epilepsy, atherosclerosis, impaired wound healing, and cataracts (Klimis-Tavantzis, 1994). Recently, decreased plasma manganese and associated increased nitric oxide have been associated with childhood asthma (Kocyigit *et al.*, 2004) and Alzheimer's disease (Vural *et al.*, 2009). In addition, low maternal blood manganese concentration has been associated with increased risk of low birth weight and fetal intrauterine growth retardation (Wood, 2009). Animal findings providing support for some of these associations have been described previously (Nielsen, 2006a). These findings probably reflect the participation of manganese-activated enzymes or metalloenzymes in carbohydrate metabolism, arginine metabolism, antioxidant action, and proteoglycan synthesis. None the less, direct evidence of dietary manganese deficiency inducing a pathological condition in humans is lacking.

Because documented human manganese deficiency is so rare and manganese was considered one of the least toxic of the essential trace elements, manganese in the past was perceived mostly as an irrelevant nutritional concern for

humans. However, manganese is now receiving significant attention as a toxicological concern for individuals whose normal homeostatic mechanisms are undeveloped, bypassed, or ill-functioning. High retention of manganese in tissues, especially in brain, has been reported for individuals receiving parenteral nutrition high in manganese (Dickerson, 2001; Hardy, 2009) and for individuals undergoing hemodialysis (da Silva *et al.*, 2007; Klein *et al.*, 2008), especially when normal excretion via the hepatobiliary system is impaired. In addition, biliary excretion of manganese is poor in neonates (Aschner and Aschner, 2005); thus, high intakes of manganese may result in increased tissue and brain levels in infants. Manganese toxicity has clinical features similar to those of idiopathic Parkinson disease, including disequilibrium, tremor, muscle spasms, tinnitus, and hearing loss (da Silva *et al.*, 2007). Iron deficiency may exacerbate manganese toxicity because it enhances manganese absorption (Finley, 2004) and animal experiments suggest that iron deficiency may increase retention of manganese by the brain (Garcia *et al.*, 2007). Low magnesium status may be another manganese toxicity concern. Pigs fed diets containing only 25% of the dietary recommendation for magnesium died suddenly and showed heart changes when the diet was high in manganese (52 mg/kg) (Miller *et al.*, 2000).

#### Absorption, Transport, Retention, and Excretion

Adult human absorption of manganese from diets apparently ranges from about 1% to 5% (Aschner and Aschner, 2005). Arriving at this range was difficult because endogenous manganese is mostly excreted through biliary, pancreatic, and intestinal secretions (Aschner and Aschner, 2005; Buchman, 2006). If manganese status is adequate, endogenous excretion of absorbed manganese into the gut is so rapid that it is difficult to determine the portion of fecal manganese not absorbed from the diet and the portion endogenously excreted. In addition, manganese absorption decreases as manganese intake increases and increases with low manganese and/or iron status (Finley, 2004; Aschner and Aschner, 2005). Iron status apparently affects manganese absorption because the primary non-heme iron transporter, divalent metal transporter 1 (DMT 1), in the intestine also transports manganese (Hansen *et al.*, 2009). Infants during the neonatal period are apparently much more efficient than adults in absorbing and retaining manganese (about 20% contained in formula) (Aschner and Aschner, 2005).

Absorption of manganese apparently occurs equally well throughout the small intestine. Manganese apparently is absorbed by an active transport system that most likely involves DMT 1 (Buchman, 2006). Diffusion has also been implicated in manganese absorption; it especially may come into play when manganese intakes are high (Nielsen, 2006a).

Both  $Mn^{2+}$  bound to plasma  $\alpha$ -2-macroglobulin and  $Mn^{2+}$  bound to albumin have been suggested to be the form of manganese in blood (Buchman, 2006). Regardless of form, manganese is rapidly removed from the blood by the liver, and more than 90% of absorbed manganese is excreted in the bile (Hardy, 2009). A fraction of absorbed manganese is oxidized to  $Mn^{3+}$ , perhaps by ceruloplasmin, and is transported in plasma bound to transferrin, albumin, and  $\beta$ -globulin transmanganin (Buchman, 2006).

Metabolically active organs with high numbers of mitochondria, where manganese is predominantly found (such as liver, kidney, and pancreas), have relatively high manganese concentrations. Manganese is present in extremely low concentrations in whole blood (7.7–12.1  $\mu$ g/L) and serum (0.38–1.1  $\mu$ g/L) (Hardy, 2009). The range of manganese concentrations in mammalian tissues generally range between 0.3 and 2.9  $\mu$ g/g (Aschner and Aschner, 2005). About 25% of the estimated 10–20 mg of manganese in the body is in bone (Buchman, 2006).

Excretion of manganese occurs mainly via the bile and thus in the feces. Very little manganese is excreted in the urine, and urinary excretion does not correlate with dietary intake (Hansen *et al.*, 2009).

#### Dietary Guidance

The Food and Nutrition Board (Institute of Medicine, 2001) has set adequate intakes (AI) and tolerable upper intake levels (UL) for manganese, which are shown in Table 38.1. Although the manganese AI for adult females is 1.8 mg/day and for adult males is 2.3 mg/day, adults fed a diet containing 0.8 to 1.0 mg/day under carefully controlled experimental conditions did not exhibit any obvious differences from those fed amounts of manganese  $\geq$ AI (Finley, 2004; Nielsen, 2006a). Also, under carefully controlled experimental conditions, normal healthy adults fed amounts of manganese higher than the UL (20 mg/day) were not adversely affected (Finley, 2004). Good food sources of manganese include unrefined grains, nuts, and leafy vegetables.

**TABLE 38.1** Dietary reference intakes (DRIs): recommended dietary allowances (RDAs), adequate intakes (AIs) and tolerable upper levels (ULs) for boron, manganese, molybdenum, and other trace elements

## Molybdenum

### Essentiality Basis and Biochemical Function

Molybdenum is an established essential nutrient based on its need for a cofactor containing a pterin nucleus that is required for the activity of sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase in mammals (Johnson, 1997). Sulfite oxidase apparently is most critical for human health. The lack of this enzyme because of a defect in the gene coding for it or a genetic mutation resulting in molybdenum cofactor deficiency results in death in early childhood; some children survive only a few days (Johnson, 1997; Reiss and Johnson, 2003). The lack of xanthine dehydrogenase or deficiency in aldehyde oxidase does not have such dire consequences.

### Deficiency Signs and Beneficial Actions

There has been no further expansion in the characterization of molybdenum deficiency in animals beyond that described in previous reviews (Mills and Davis, 1987; Nielsen, 2006a). In rats and chicks, molybdenum deficiency aggravated by excessive dietary tungsten results in the depression of molybdenum enzymes, disturbances in uric acid metabolism, and increased susceptibility to sulfite toxicity. Deficiency uncomplicated by high dietary tungsten or copper in goats resulted in depressed food consumption and growth, and impaired reproduction, characterized by infertility and elevated mortality in both mothers and offspring.

Nutritional molybdenum deficiency has not been unequivocally identified in humans other than in one individual with Crohn's disease and a short bowel; he was nourished by total parenteral nutrition for 18 months (Abumrad *et al.*, 1981). After 12 months, this patient developed hypermethioninemia, hypouricemia, hyperoxypurinemia, hypouricosuria, and very low sulfate excretion; these changes were exacerbated by methionine administration. In addition, the patient suffered mental disturbances that progressed to coma. Supplementation with ammonium molybdate improved the clinical condition, reversed the sulfur-handling defect, and normalized uric acid production.

No beneficial effects of molybdenum supplementation in nutritional amounts have been reported. However, some beneficial effects have been reported for supra-nutritional or pharmacological amounts of tetrathiomolybdate and sodium molybdate. Tetrathiomolybdate inhibits metal transfer functions between

copper trafficking proteins (Alvarez *et al.*, 2010). Copper-lowering therapy by tetrathiomolybdate has been found to inhibit cancer growth in five rodent models, and in advanced and metastatic cancer in dogs and humans (Brewer, 2003). In animal studies, tetrathiomolybdate inhibited pulmonary fibrosis induced by bleomycin, hepatitis induced by concanavalin A, cirrhosis induced by carbon tetrachloride (Brewer, 2003), and hyperglycemia induced by streptozotocin (Zeng *et al.*, 2008). Sodium molybdate was found to prevent hyperinsulinemia and hypertension induced by fructose in rats (Güner *et al.*, 2001).

### Absorption, Transport, Retention, and Excretion

Documented cases of molybdenum deficiency and toxicity may be rare because the body is able to adapt to a wide range of intakes. Molybdenum is readily absorbed, with food-bound molybdenum about 16% less bioavailable than soluble complexes (e.g. ammonium molybdate) over a broad range of intakes. Men absorbed 90–94% of daily intakes of molybdenum ranging from 22 to 1490 µg (Novotny and Turnland, 2006, 2007). Animal studies indicate that the absorption of molybdenum can be reduced by diets or foods high in sulfur; the sulfate anion is a competitive inhibitor of molybdenum absorption (Mills and Davis, 1987).

Molybdate is transported loosely attached to erythrocytes in blood (Johnson, 1997). Concentrations of molybdenum in tissues, blood, and milk vary with molybdenum intake. For example, reported plasma concentration for men with an intake of 22 µg/day was 0.51 µg/L; with an intake of 121 µg/day it was 1.17 µg/L; and with an intake of 1490 µg/day it was 6.22 µg/L (Novotny and Turnland, 2007). Highest concentrations of molybdenum are found in liver, kidney, and bone (normally >1 mg/kg dry weight) (Johnson, 1997). The concentration of molybdenum in other tissues is usually between 0.14 and 0.20 mg/kg dry weight. The molybdenum in liver is entirely present in macromolecular association, partly as known molybdoenzymes and the remainder as the molybdenum cofactor.

After absorption, most molybdenum is turned over rapidly and eliminated as molybdate through the kidney (Johnson, 1997; Novotny and Turnland, 2006, 2007). Urinary excretion is increased with increasing molybdenum intake. Thus, excretion rather than regulated absorption is the major homeostatic mechanism for molybdenum.

### Dietary Guidance

The Food and Nutrition Board (Institute of Medicine, 2001) has set a molybdenum AI for infants, recommended dietary allowances (RDA) for adults, and ULs, which are listed in Table 38.1. Many people do not achieve the estimated average requirement (EAR) of 34 µg/day or the RDA of 45 µg/day. According to NHANES III (1988–1994) data, median molybdenum intakes for adult females and males were 22.7 and 23.9 µg/day, respectively (Institute of Medicine, 2001). The lack of documented cases of nutritional molybdenum deficiency suggests that the EAR and RDA may be too high, or that a search for molybdenum-responsive syndromes in humans may be warranted. Good food sources of molybdenum include milk and milk products, pulses, organ meats (liver and kidney), and cereals.

## Beneficial Bioactive Trace Elements

### Boron

#### Essentiality Status and Biochemical Function

Boron has been shown to be essential for the completion of the life cycle (i.e. deficiency causes impaired growth, development, or maturation such that procreation is prevented) for organisms in all phylogenetic kingdoms (Hunt, 2002; Nielsen, 2008). In the animal kingdom, boron deprivation prevented procreation in both the African clawed frog (*Xenopus laevis*) and zebrafish (*Brachydanio rerio*). However, because a biochemical function has not been clearly defined for boron in higher animals, it is only considered a beneficial bioactive element for humans.

The diverse responses reported for low intakes of boron in higher animals have made it difficult to identify a primary mechanism responsible for the bioactivity of boron. The wide range of responses is probably secondary to boron influencing a cell signaling system, or the formation and/or activity of an entity that is involved in many biochemical processes.

At the pH of most biological fluids, boron exists mainly as boric acid, which reacts with biomolecules with hydroxyl groups to form boron esters. This reaction occurs best when the groups are adjacent and *cis* (same side of the molecule), such as ribose (Hunt, 2002; Ricardo *et al.*, 2004), which is a component of adenosine. Boron might influence cellular activity by reacting with signaling molecules containing adenosine or formed from an adenosine-containing precursor. *S*-Adenosylmethionine and diadenosine phosphates (signaling nucleotides) have

higher affinities for boron than any other currently recognized boron ligands present in animal tissues (Hunt, 2002). About 95% *S*-adenosylmethionine is used for methylation of DNA, RNA, proteins, phospholipids, hormones, and neurotransmitters, which yield *S*-adenosylhomocysteine that can be hydrolyzed to homocysteine and used to form cysteine. Boron deprivation increased plasma cysteine and homocysteine, and decreased liver *S*-adenosylmethionine and *S*-adenosylhomocysteine in rats (Nielsen, 2009a). The bacterial quorum-sensing signal molecule, auto-inducer AI-2, is a furanosyl borate ester synthesized from *S*-adenosylmethionine (Chen *et al.*, 2002). Quorum sensing is the cell-to-cell communication between bacteria accomplished through exchange of extracellular signaling molecules (auto-inducers). These findings suggest that boron may influence *S*-adenosylmethionine formation or utilization.

Boron also strongly binds oxidized nicotinamide adenine dinucleotide (NAD<sup>+</sup>). Extracellular NAD<sup>+</sup> binds to the plasma membrane receptor, CD38 (an adenosine diphosphate (ADP)-ribosyl cyclase), which converts NAD<sup>+</sup> to cyclic ADP ribose (ADPR) that is released intracellularly (Eckhert, 2006). ADPR binds to the ryanodine receptor and releases Ca<sup>2+</sup> from the endoplasmic reticulum (Eckhert, 2006). Thus, boron may be bioactive through binding NAD<sup>+</sup> and ADPR and inhibiting the release of Ca<sup>2+</sup>. Ca<sup>2+</sup> is a signal ion for many processes in which boron has been shown to have an effect, including insulin release, bone formation, immune response, and brain function.

Boron also may be bioactive through forming diester borate complexes with phosphoinositides, glycoproteins, and glycolipids, which contain *cis*-hydroxyl groups, in membranes. The finding that boron changes the ability of some hormones to express their actions supports the suggestion of a role affecting membrane receptors or signal transduction. Boron deprivation apparently decreases insulin sensitivity in chicks and rats (Hunt, 2008), increases the requirement for vitamin D to prevent gross bone abnormalities in chicks and rats (Nielsen, 2008), results in the need for exogenous thyroxine for tail resorption, and makes oocytes not responsive to progesterone in frogs (Fort *et al.*, 2002). The finding that the borate transporter NaBC1 conducts Na<sup>+</sup> and OH<sup>-</sup> across cell membranes in the absence of boron (Park *et al.*, 2004) suggests that boron may affect the transduction of regulatory ions across cell membranes.

### **Beneficial Actions and Deficiency Signs**

**Boron and Bone.** Microcomputed tomography ( $\mu$ CT) of the fourth lumbar vertebrae found that boron deprivation (0.1 vs. 3 mg/kg diet) decreased bone volume fraction and trabecular thickness, and increased trabecular separation and structural model index (a lower value or more plate-like structure is preferable) in rats (Nielsen and Stoecker, 2009). Boron deprivation (0.07 vs. 3 mg/kg diet) in rats also has been shown to decrease alveolar bone (primary support structure for teeth) repair in rats (Gorustovich *et al.*, 2009), and growth in mice (Gorustovich *et al.*, 2008). Histological examination revealed that boron deprivation decreased osteoblast surface and increased quiescent bone-forming surface in the alveolus. These findings, in addition to boron deprivation impairing the maturation of the bone growth plate in chicks (Nielsen, 2008), and inducing limb teratogenesis in frogs (Fort *et al.*, 2002), suggest that boron is beneficial to bone growth and maintenance through affecting osteoblast and/or osteoclast presence or activity and not through affecting bone calcium concentrations.

**Boron and Brain.** Findings showing that nutritional intakes of boron have beneficial effects on central nervous function are among the most supportive in demonstrating that boron is a beneficial bioactive element for humans (Nielsen, 2008). Boron deprivation of older men and women altered electroencephalograms (EEG) such that they suggested states of reduced behavioral activation (i.e. drowsiness) and mental alertness. The EEG changes may have been responsible for the finding that boron deprivation impaired cognitive processes of attention, encoding skills and memory, and psychomotor measures of manual dexterity and fatigue. Boron-deprived (0.1 mg vs. 3.1 mg/kg diet) rats were found to be less active based on reduced number, distance, and time of horizontal movements, front entries, margin distance, and vertical breaks and jumps in a spontaneous activity evaluation (Nielsen and Penland, 2006).

**Boron and the Inflammatory or Immune Response.** The suggestion that boron may influence the inflammatory or immune response is supported by a study of mice infected with the nematode *H. bakeri* (Bourgeois *et al.*, 2007). Boron deprivation down-regulated 30 of 31 cytokines or chemokines associated with the inflammatory response 6 days post-primary infection. An opposite pattern was found at 21 days post-challenge; mice consuming boron-low diets had >100% increases in 23 of 31 cytokines

determined. These findings are consistent with lower serum tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interferon- $\gamma$  after lipopolysaccharide injection in pigs fed a boron-low diet than a diet supplemented with nutritional amounts of boron (Spears and Armstrong, 2007). When injected with an antigen (*Mycobacterium butyricum*) to induce arthritis, boron-supplemented (2.0 mg/kg diet) rats had less swelling of the paws and lower circulating concentrations of natural killer cells and CD8a<sup>+</sup>/CD4<sup>-</sup> cells than did boron-deprived (0.1 mg/kg diet) rats (Hunt, 2007).

**Boron and Cancer.** Based on a study of 95 cases and 8720 controls, low dietary boron was associated with increased prostate cancer risk (Cui *et al.*, 2004). Boric acid in concentrations similar to that in blood was found to inhibit the proliferation of some human prostate cancer cell lines in vitro (Barranco and Eckhert, 2004). Cervical smears of 472 women with a high mean boron intake (8.41 mg/day) and 587 with marginal mean boron intake (1.26 mg/day) identified 15 cases of cytopathological indications of cervical cancer in boron-low women and none in the boron-high women (Korkmaz *et al.*, 2007). In a study of 763 women with lung cancer and 838 matched healthy controls, boron intake was inversely associated with the incidence of cancer; odds increased substantially if they were not on hormone replacement therapy (Mahabir *et al.*, 2008). In a study of 124 premenopausal breast-cancer patients, boron was associated with decreased number of estrogen-receptor negative tumors relative to estrogen-receptor positive tumors (Touillaud *et al.*, 2005). Unidentified confounders may have an impact on the association between boron and cancer.

**Boron Deficiency Signs.** As indicated above, boron has been found to be essential for frogs (*Xenopus*) and zebrafish (Nielsen, 2008). Boron-deficient male frogs exhibit atrophied testes, decreased sperm counts, and sperm dysmorphology; female frogs exhibit atrophied ovaries and impaired oocyte maturation. Most embryos from boron-deprived frogs die before 96 hours of development. The early cleavage stage of zebrafish development was found to be most sensitive to boron deficiency; 46% of fertilized boron-deficient embryos did not complete the blastula stage compared with 2% for boron-adequate embryos. Adult F<sub>1</sub> boron-deficient zebrafish exhibited photophobia. The critical experiment demonstrating that boron is essential to complete the life cycle or has a defined biochemical role in mammals is lacking. However, boron deficiency

signs in higher animals and humans may be deduced from beneficial effects (described above) of nutritional amounts of boron.

### Absorption, Transport, Retention, and Excretion

About 85% of ingested boron is absorbed and then efficiently excreted via the urine mainly as boric acid (Nielsen, 2006a, 2008). As a result, urinary boron mirrors boron intake. During transport in the body, boron most likely is weakly attached to organic molecules containing *cis*-hydroxyl groups. A mammalian boron transporter (Park *et al.*, 2004) that has substantial homology to the plant boron transporter AtBor1 discovered in *Arabidopsis thaliana* (Takano *et al.*, 2005) and yeast (*Saccharomyces cerevisiae*) (Kaya *et al.*, 2009) has been identified. NaBC1 is essential for boron homeostasis, growth, and proliferation of mammalian HEK293 cells (Park *et al.*, 2004). A boron transporter may have been responsible for the observation that RAW264.7 and HL60 cells accumulate boron against a concentration gradient (Ralston and Hunt, 2004).

Boron is distributed throughout soft tissues at concentrations mostly between 1.39 and 1.85  $\mu\text{mol/kg}$  fresh tissue (0.015–2.0  $\mu\text{g/g}$ ) (World Health Organization, 1998). Based on studies with postmenopausal women, normal fasting plasma boron concentrations range from 3.14 to 8.79  $\text{mmol/L}$  (34–95  $\text{ng/mL}$ ) (Nielsen, 2006a).

### Dietary Guidance

The Food and Nutrition Board of the National Academy of Sciences (Institute of Medicine, 2001) set ULs, which are shown in Table 38.1, but did not set an RDA for boron. Both animal and human data were used by the World Health Organization (1996) to suggest that an acceptable safe range of population mean intakes of boron for adults could be 1–13  $\text{mg/day}$ . Many people apparently have boron intakes of less than 1  $\text{mg/day}$ . The Continuing Survey of Food Intakes by Individuals (CSFII), 1994–1996, indicated that boron intakes ranged from a low of about 0.35  $\text{mg/day}$  to a high of about 3.0  $\text{mg/day}$  for adults (Institute of Medicine, 2001). Rich food sources of boron are fruits, leafy vegetables, nuts, legumes, and pulses.

## Chromium

### Essentiality Status and Biochemical Function

Approximately 50 years ago, trivalent chromium was reported to be the active component of the “glucose tolerance factor” that alleviated glucose tolerance in rats fed

torula yeast–sucrose diets (Moukarzel, 2009). This finding was accepted as proof for chromium essentiality for higher animals. Essentiality for humans gained acceptance when it was reported between 1977 and 1986 that chromium supplementation alleviated glucose intolerance and/or neuropathy exhibited by three patients on long-term total parenteral nutrition (Moukarzel, 2009). Since then, no reports of chromium supplementation helping patients on long-term parenteral nutrition have appeared. In addition, efforts to induce consistent signs of chromium deficiency in animals have not produced convincing findings. Nutritional, metabolic, physiological, or hormonal stressors generally had to be employed to induce experimental animals to apparently respond to chromium deprivation (Vincent and Stallings, 2007). In most cases, the responses were not remarkable. Thus, after decades of effort that has produced no consistent deprivation signs or conclusive, specific, defined, biochemical functions, the essentiality of chromium has become uncertain and a controversial issue.

$\text{Cr}^{3+}$  is the most stable oxidation state of this element and most likely the form of importance in biological systems. In aqueous solutions,  $\text{Cr}^{3+}$  complexes are relatively inert kinetically such that ligand-displacement reactions have half-times in the range of several hours. Therefore, chromium is unlikely to be involved as a metal catalyst at the active site of enzymes where the rate of exchange needs to be rapid. However, chromium may have a structural role such as in the tertiary structure of a protein or nucleic acid. In addition, chromium may bind ligands in the proper orientation to facilitate enzymatic catalysis; this may be the role of chromodulin (Vincent and Bennett, 2007), which was previously called low-molecular-weight chromium-binding substance. Chromodulin has been described as a naturally occurring mammalian oligopeptide with a mass of about 1.5 kDa that is composed of glycine, cysteine, aspartate, and glutamate and that binds four chromic ions tightly and cooperatively ( $K_a \sim 10^{21} \text{M}^{-4}$ ) (Vincent and Bennett, 2007). Apochromodulin (apparently the predominant form *in vivo*) can accept chromic ions from other biological molecules such as transferrin, which may serve as a transporter of chromium (Vincent and Bennett, 2007).

Two potential functions have been described for chromodulin. Because chromodulin carries chromium into the urine after a large dose is given, it has been suggested that this oligopeptide is nothing more than a vehicle for the detoxification and excretion of chromium (Stearns, 2007).

However, substantial evidence suggests that chromodulin potentiates insulin's effects by amplifying insulin-dependent protein tyrosine kinase activity of the insulin receptor; this stimulation apparently is dependent upon the chromium content of chromodulin (Vincent and Bennett, 2007). It is hypothesized that the binding of insulin to its receptor on an insulin-sensitive cell causes a conformational change resulting in the autophosphorylation of tyrosine residues on the internal side of the receptor. The receptor becomes an active tyrosine kinase that transmits the insulin signal into the cell. In response to insulin, chromium also moves into insulin-sensitive cells, which contain apochromodulin, to form holochromodulin. The holochromodulin then binds to the receptor to assist in maintaining it in an active form, thus amplifying the receptor's kinase activity. When blood insulin decreases, a change in the conformation of the insulin receptor causes a release of holochromodulin from the cell to blood and excretion in the urine.

Chromium up-regulates mRNA levels of insulin receptor GLUT 4 (glucose transporter), glycogen synthase, and uncoupling protein-3 in cultured skeletal muscle cells (Qiao *et al.*, 2009). This up-regulation, however, may be occurring through the amplification of insulin, which also increases mRNA for those metabolic substances. None the less, chromium, or a biologically active form of chromium, might have a role in regulating gene expression of a critical substance in glucose metabolism. This is supported by the finding that RNA synthesis directed by free DNA *in vitro* has been shown to be enhanced by the binding of chromium to the template.

Another possible role suggested for chromium is the activation of GLUT 4 trafficking via a cholesterol-dependent mechanism (Chen *et al.*, 2006). Chromium was found to alter plasma membrane cholesterol and mobilized GLUT 4 to the plasma membrane in cultured cells. It was suggested that chromium may have reduced membrane cholesterol through an effect on AMP-activated protein kinase.

### **Beneficial Actions and Deficiency Signs**

Substantial evidence exists to indicate that chromium has beneficial bioactivity under certain circumstances. Numerous reports from various research groups have described beneficial effects provided by chromium supplementation in subjects with varying degrees of glucose intolerance, ranging from hypoglycemia to insulin-dependent diabetes (Anderson, 1998). A systematic review

of randomized controlled trials found that chromium supplementation slightly but significantly improved glycemia in patients with diabetes (Balk *et al.*, 2007). The review found no significant effects of chromium on lipid or glucose metabolism in people without diabetes. In addition, numerous other studies have found that chromium supplementation did not improve carbohydrate metabolism in individuals with metabolic syndrome, impaired glucose tolerance, or type 2 diabetes (Cefalu and Hu, 2004). Patient selection and chromium dosage may have been responsible for the inconsistent findings. A clinical response to chromium (i.e. decreased glucose and improved insulin sensitivity) apparently is most likely in insulin-resistant individuals with type 2 diabetes and highly elevated fasting plasma glucose and hemoglobin A<sub>1c</sub> concentrations (Cefalu *et al.*, 2010). Supra-nutritional amounts of chromium generally were needed to be therapeutically effective, which could mean that chromium was acting pharmacologically, not nutritionally.

Chromium supplementation has also been hypothesized to decrease body fat (weight loss) and to increase muscle or lean body mass. These hypotheses were based on the assumption that chromium would amplify the action of insulin under all circumstances, and this amplification would result in less glucose being converted into fat and in an up-regulation of protein synthesis for muscle gain. Findings indicating that chromium does not affect glucose metabolism or insulin action in people without insulin resistance and diabetes (Balk *et al.*, 2007; Cefalu *et al.*, 2010) explain why well-conducted randomized controlled trials showed no effect of supplemental chromium on weight and body composition (Lukaski and Scrimgeour, 2009).

Low toenail-chromium concentration has been associated with cardiovascular disease (Rajpathak *et al.*, 2004; Guallar *et al.*, 2005). However, these epidemiological findings are unable to determine whether the low concentrations indicate a cause or effect of cardiovascular disease. Long-term supplementation trials are needed to ascertain whether chromium supplementation would be beneficial to cardiovascular health.

### **Absorption, Transport, Retention, and Excretion**

Estimates of Cr<sup>3+</sup> absorption, based on metabolic balance studies or on urinary excretion during physiological intakes, range from 0.4% to 2.5% (Institute of Medicine, 2001). Most ingested chromium is excreted unabsorbed in the feces. Most absorbed chromium is excreted rapidly in

the urine.  $\text{Cr}^{3+}$  competes for one of the binding sites on transferrin, and most of the chromium in blood (about 2–3 nmol/L) apparently is found bound to transferrin. The highest levels of chromium in human tissues are found in liver, spleen, and bone (Institute of Medicine, 2001).

### Dietary Guidance

In the absence of a functional criterion for assessing chromium status or need, the Food and Nutrition Board (Institute of Medicine, 2001) set AIs for chromium rather than EARs and RDAs. The AIs shown in Table 38.1 are based on the mean chromium content of well-balanced daily diets (13.4  $\mu\text{g}/1000\text{ kcal}$ ) and estimated energy intakes for each group. No UL was set for dietary chromium ( $\text{Cr}^{3+}$ ) because of insufficient data and little evidence for adverse effects. The toxicity of  $\text{Cr}^{3+}$  is minimized by its propensity to form complexes with oxygen-based ligands that are usually electrochemically inactive and have poor ability to cross cell membranes.

Chromium is widely distributed throughout the food supply, but the chromium content is highly variable among different lots of the same food. Chromium content in foods can be subject to significant decreases or increases during processing. Whole grains, pulses, some vegetables (e.g. broccoli and mushrooms), liver, processed meats, ready-to-eat cereals, spices, and beer are generally good sources of chromium.

## Other Nutritionally Bioactive Trace Elements

### Arsenic

#### Beneficial Actions and Possible Basis for Bioactivity

Arsenic is unquestionably a bioactive element in higher animals and humans. However, most studies of this bioactivity have been directed towards demonstrating that amounts sometimes found in food and water are toxic. High amounts of inorganic arsenic in drinking water have been associated with a number of pathological conditions including cardiovascular disease, dermatological changes, developmental abnormalities, neurologic and neurobehavioral disorders, diabetes, hematological disorders, renal damage, respiratory problems, and various types of cancer, including bladder, colon, kidney, liver, lung and skin cancer (Abernathy *et al.*, 2003). Interestingly, the disorders found vary between areas that report high amounts of arsenic in drinking water, which suggests some other factors may be involved in the arsenic toxicity. The numer-

ous reports appearing in the past five years on arsenic toxicity are beyond the scope of this review. Emphasis will be placed on discussing the concept that homeostatic mechanisms exist for arsenic, and thus there may be intakes that have beneficial effects.

Several animal studies suggest that arsenic ingested in low microgram or nanogram quantities is beneficial in higher animals. Reports between the years 1975 and 1995 indicated that arsenic deprivation (e.g. <12 ng/g diet for rats and chicks; <35 ng/g diet for goats) induced physiological changes in higher animals (Anke, 2005; Nielsen, 2006a). In the goat, pig, and rat, the most consistent signs of apparent arsenic deprivation were depressed growth and abnormal reproduction characterized by impaired fertility and increased perinatal mortality. Death with myocardial damage occurred in arsenic-deprived goats.

Limited epidemiological and animal findings also have suggested that arsenic can have beneficial effects at appropriate low exposures. Compared with exposure to drinking water containing about 50  $\mu\text{g}/\text{L}$ , both low exposure (<50  $\mu\text{g}/\text{L}$ ) and high exposure (>100  $\mu\text{g}/\text{L}$ ) resulted in a higher number of cancers (Kayajanian, 2003). A similar response was seen in an animal study that determined the effects of arsenic on dimethylhydrazine-induced aberrant crypts (Uthus and Davis, 2005). Arsenic in pharmacological amounts as arsenic trioxide has been found to be an effective treatment for some forms of cancer, especially promyelocytic leukemia, through apoptotic, not necrotic, mechanisms (Huang *et al.*, 1999; Murgu, 2001).

Arsenic may be bioactive through affecting the methylation of metabolically or genetically important molecules. Low and excessive arsenic had similar effects on global DNA methylation in cultured Caco-2 cells. When the culture contained low (25  $\mu\text{g}/\text{L}$ ) or high (175  $\mu\text{g}/\text{L}$ ) arsenic, global methylation of DNA was significantly decreased from that of cells grown in culture containing 100  $\mu\text{g}/\text{L}$  (Davis *et al.*, 2000).

#### Absorption, Transport, Retention, and Excretion

In humans and most laboratory animals, more than 90% of inorganic arsenate and arsenite in water, and about 60–70% ingested with food, is absorbed by the gastrointestinal tract mainly by simple diffusion (Nielsen, 2006a). Once absorbed, inorganic arsenic is transferred to various tissues, including the liver, where it is methylated with *S*-adenosylmethionine as the methyl donor (Thomas *et al.*, 2007). Before arsenate is methylated, it is reduced to arsenite; this reduction is facilitated by glutathione.

Arsenite methyltransferase methylates arsenite to form monomethylarsonic acid, which is then reduced to monomethylarsonous acid. Monomethylarsonous acid, a relatively toxic form of arsenic, is rapidly methylated by a methyltransferase to form dimethylarsinic acid. In humans, monomethylarsonous acid is found in urine only when excessive inorganic arsenic is consumed. If excessive amounts of inorganic arsenic are being methylated, dimethylarsinic acid can be reduced to dimethylarsinous acid, which also is a relatively toxic form of arsenic. However, with non-toxic or nutritional intakes of arsenic, dimethylarsinic acid is the final step in the metabolism of arsenic in humans and most animals, and thus is the major form of arsenic in urine, which is the major excretory route for arsenic.

Some foods, especially seafood, contain trimethylated forms of arsenic (arsenobetaine and arsenocholine), which are highly absorbed and rapidly excreted in the urine (Nielsen, 2006a). Most arsenocholine is transformed into arsenobetaine before being excreted in the urine. Arsenosugars, which are found in seaweed, are poorly absorbed. They apparently must be metabolized to a methylated form, which may be facilitated by intestinal bacteria, before the arsenic can be absorbed (Nielsen, 2006a).

Because mechanisms exist for ridding the body of arsenic, no tissue significantly accumulates this element if low or physiological amounts are ingested. Tissue analyses indicate that retained arsenic in most animals and humans is widely distributed in low concentrations (<1.0 µg/g fresh weight) under normal conditions (National Research Council, 2005a). The highest amounts of arsenic are usually found in skin, hair, and nails, probably because inorganic arsenic binds to SH groups of proteins that are relatively plentiful in these tissues.

Excretion of ingested arsenic is rapid, principally in the urine (Nielsen, 2006a). The usual proportions of the forms of arsenic in human urine are about 20% inorganic arsenic, 15% monomethylarsonic acid, and 65% dimethylarsinic acid. The proportions are quite different with the consumption of organic arsenic in forms found in seafood; then trimethylated arsenic such as arsenobetaine predominates.

### Dietary Guidance

The Food and Nutrition Board (2001) set no Dietary Reference Intakes for arsenic. The Total Diet Study (1991–1997) indicated that the median intake of arsenic from foods was only about 2.0 and 2.6 µg/day for women and

men 19–70 years of age, respectively (Institute of Medicine, 2001). Another report gave an estimated mean total arsenic intake in the United States from all food, excluding shellfish, of 30 µg/day (Adams *et al.*, 1994). This intake is similar to intakes of arsenic that were found to be beneficial in animals and in epidemiological studies.

### Fluoride

#### Beneficial Actions and Possible Basis for Essentiality

Fluoride (the ionic form of fluorine) cannot be considered an essential nutrient because the critical experiment showing that it is required to complete the life cycle, or defining a biochemical role for fluoride necessary for life, is lacking. However, one research group found that intra-uterine fluoride deprivation over 11 generations in goats resulted in intrauterine and postnatal growth depression, increased kid mortality, and skeletal and joint deformities in older animals (Anke *et al.*, 2005a). These findings need confirmation or evidence of similar signs in another animal model before they will be accepted as evidence that fluoride might be essential.

Although evidence for essentiality is limited, fluoride certainly has beneficial bioactivity in pharmacological or supra-nutritional amounts. In humans, fluoride protects against pathological demineralization of calcified tissues. Fluoride inhibits tooth enamel degradation by two separate mechanisms (Whitford, 2006). Uptake of fluoride to form fluorohydroxyapatite during tooth development reduces the risk of caries because fluorohydroxyapatite is more acid-resistant than normal hydroxyapatite. After tooth development, fluoride protects enamel by inhibiting acid production by plaque bacteria and enhancing the rate of enamel remineralization during an acidogenic challenge. However, an average daily fluoride intake of 0.05 mg/kg body weight while teeth are developing is associated with mild tooth mottling; this is an intake found when water fluoride concentration is optimal (1.0 mg/L) (Whitford, 2006). Moderate mottling may occur at an average daily intake of 0.1 mg/kg body weight (Whitford, 2006). A recent report indicated that dental fluorosis ranged from 41% among adolescents aged 12–15 to 9% among adults aged 40–49 (Beltrán-Aguilar *et al.*, 2010). Sodium fluoride has been shown repeatedly and reproducibly to increase spinal bone mass in a dose-dependent manner (Ringe, 2004). There has not, however, been a convincing demonstration that fluoride consistently reduces vertebral fracture rate in established spinal osteoporosis (Kleerekoper and Mendlovic, 1993; Ringe, 2004).

Moreover, the therapeutic dosages for osteoporosis (10–30 mg/day) (Whitford, 2006) meet or exceed the tolerable upper intake level (UL) of 10 mg/day for adults (Institute of Medicine, 1997). In animals, high or supra-nutritional amounts of fluoride prevented anemia and infertility caused by iron deficiency, improved suboptimal growth induced by an unbalanced diet, and alleviated nephrocalcinosis induced by phosphorus feeding and soft-tissue calcification caused by magnesium deprivation (Cerklewski, 1997; Nielsen, 2006a).

### Absorption, Transport, Retention, and Excretion

Essentially 100% of fluoride ingested in the fasted state as fluoridated water, and 50% to 80% of fluoride ingested in food, are absorbed from the gastrointestinal tract (Nielsen, 1998a). Absorption of fluoride is rapid with about 50% of a moderate soluble dose absorbed in 30 minutes; complete absorption occurs in 90 minutes. The rapidity of absorption indicates that a significant portion (about 40%) is absorbed from the stomach as HF; the rest is absorbed throughout the small intestine.

Fluoride concentrations in plasma and most soft tissues are low, generally between 0.01 and 0.05  $\mu\text{g/g}$  (Whitford, 2006). About 99% of body fluoride is found in the skeleton and teeth, where it exists mainly as hydroxyfluorapatite (Whitford, 2006). Approximately 50% of fluoride absorbed each day is deposited in calcified tissue (bone and developing teeth) and the rest is cleared by the kidney (Whitford, 2006). The rate of uptake by bone is affected by the stage of skeletal development. Urinary excretion of fluoride is directly related to urinary pH. When renal tubular fluid pH is high, less fluoride exists as hydrogen fluoride (HF), the form that is reabsorbed well, so clearance is high; when the pH is acidic, more HF is formed and reabsorbed, which results in lower clearance (Whitford, 2006). Thus, factors that affect urinary pH, such as diet, drugs, metabolic or respiratory disorders, and altitude of residence, can affect how much absorbed fluoride is excreted.

### Dietary Guidance

The Food and Nutrition Board (Institute of Medicine, 1997) set AIs and ULs for fluoride, which are shown in Table 38.1. The major source of orally ingested fluoride is drinking water. Over 50% of the population in the United States uses water with fluoride adjusted to between 0.7 and 1.2 mg/L (37–63 nmol). Fluoride is ubiquitous in foods, but similar products can vary greatly with source. Thus,

estimating fluoride intakes is difficult. Estimated daily intakes range from 1.4 to 3.4 mg/day for adult males residing in a community with fluoridated water, and 0.3 to 1.0 mg/day in areas without fluoridation (Nielsen, 1998a).

### Nickel

#### Beneficial Actions and Possible Basis for Bioactivity

Nickel is generally acknowledged as being essential for plants and some bacteria. Nickel in these lower forms of life has been identified as an essential component of enzymes whose substrates or products are dissolved gases: hydrogen, carbon monoxide, carbon dioxide, methane, oxygen, and ammonia. Details about these enzymes are given in another review (Nielsen, 2006b).

Nickel is not generally accepted as an essential nutrient for higher animals and humans, apparently because of the lack of a clearly defined specific biochemical function in these species. However, nutritional amounts of nickel prevent several physiological and biochemical changes induced by nickel deprivation in higher animals. Changes induced by nickel deprivation described in a previous review (Nielsen, 2006a) included impaired reproduction (decreased conception rate and sperm production and motility), impaired bone health (decreased strength and altered composition), altered carbohydrate and lipid metabolism (increased plasma lipids and decreased serum glucose), decreased iron status or utilization, and altered thyroid hormone metabolism. Other beneficial effects of nutritional amounts of nickel that have been described include improved bone strength in rats (Nielsen, 2006c) and chicks (Wilson *et al.*, 2001), alleviation of renal damage and high blood pressure induced by a high salt diet in rats (Nielsen *et al.*, 2002), and alleviation of vitamin B<sub>12</sub> deficiency and high blood homocysteine concentrations in pigs (Stangl *et al.*, 2000). The nutritional importance of nickel for humans remains largely unstudied. However, in hemodialysis patients, serum nickel was negatively correlated with plasma total homocysteine (Katko *et al.*, 2008).

Nickel is another element whose diverse beneficial effects at nutritional amounts under a variety of conditions (e.g. stressors that affect methionine and arginine metabolism) have made it difficult to identify a primary mechanism responsible for its bioactivity. Nickel bioactivity might involve the function of gaseous molecules such as oxygen (O<sub>2</sub>), nitric oxide (NO), or carbon monoxide (CO). In most tissues, the molecular and cellular response to a low O<sub>2</sub> tension is the activation of the transcription factor hypoxia-inducible factor 1 (HIF-1). Nickel has the

ability to stabilize HIF-1 $\alpha$  protein and to activate hypoxia-inducible expression of genes (Kang *et al.*, 2006). These genes are involved in angiogenesis, glucose transport, glycolysis, erythropoiesis, and catecholamine metabolism. Activation of the HIF-1 $\alpha$  pathway also increases osteogenesis (Wang *et al.*, 2007). NO synthesis inhibition promotes the renal production of CO by heme oxygenase, which is potently induced by nickel. CO inhibits NO synthase activity and activates guanyl cyclase which results in the production of cGMP. The cGMP signal transduction system has crucial roles in vision, taste, smell, blood pressure control, kidney function, and sperm motility, all of which are affected by nickel (Gordon and Zagotta, 1995; Nielsen *et al.*, 2002).

Nickel also may be bioactive through altering methyl metabolism. The lack of vitamin B<sub>12</sub>, which is involved in methyl metabolism, inhibits the response of rats to nickel supplementation when dietary nickel is low (Nielsen, 2006a) and nickel can alleviate vitamin B<sub>12</sub> deficiency in pigs (Stangl *et al.*, 2000). In addition, nickel ameliorated an increase in serum homocysteine in vitamin B<sub>12</sub>-deficient pigs (Stangl *et al.*, 2000) and decreased homocysteine, cysteine, and *S*-adenosylhomocysteine production by human peripheral monocytes (Katko *et al.*, 2008).

### Absorption, Transport, Retention, and Excretion

Knowledge about the metabolism of nickel has essentially remained unchanged since a previous review of the subject (Nielsen, 2006a). Less than 10% of nickel ingested with food is absorbed by animals and humans. When soluble nickel in water is ingested after an overnight fast, as much as 50%, but usually closer to 20% to 25%, of the dose is absorbed. Nickel absorption is heightened by iron deficiency, pregnancy, and lactation. The mechanism through which nickel is transported through the gut has not been clearly defined, but some studies indicate some nickel is absorbed through an iron-transport system.

Nickel is transported in blood principally bound to serum albumin. Small amounts of nickel in serum are associated with the amino acids histidine and aspartic acid, and with  $\alpha_2$ -macroglobulin (nickeloplasm). The transport of nickel into tissues may involve magnesium and/or iron transport mechanisms. Nickel is widely distributed in tissues in concentrations between 0.01 and 0.2 mg/kg wet weight (National Research Council, 2005b).

Fecal nickel excretion (mostly unabsorbed nickel) is 10 to 100 times higher than urinary excretion. Most of the

small fraction of absorbed nickel is rapidly and efficiently excreted as urinary low-molecular-weight complexes in concentrations generally ranging from 0.1 to 1.3  $\mu$ g nickel/L (Nielsen, 2006a).

### Dietary Guidance

The Food and Nutrition Board (Institute of Medicine, 2001) set no RDA or AI for nickel, but did set ULs, which are shown in Table 38.1. Based on animal studies, a beneficial intake of nickel for humans might be near 50  $\mu$ g/day (Nielsen, 1998a). Typical daily dietary intakes for nickel are 70–260  $\mu$ g/day (Nielsen, 2006a).

### Silicon

#### Beneficial Actions and Possible Basis for Bioactivity

Silicon is nutritionally essential for some lower forms of life (Carlisle, 1997; Nielsen, 2006a; Řezanka and Sigler, 2007). Silicon has a structural role in diatoms, radiolarians, and some sponges. Diatoms, which are unicellular microscopic plants, have an absolute requirement for silicon as monomeric silicic acid for normal cell growth. Silicon also may be essential for some higher plants (e.g. rice).

Silicon is not generally accepted as a confirmed essential nutrient for higher animals and humans because of the lack of a defined specific biochemical function. However, nutritional (10–35 mg/kg diet) and supra-nutritional (e.g. 100–500 mg/kg diet as a soluble salt) levels prevent several physiological and biochemical abnormalities observed in animals fed diets low in silicon (<5 mg/kg diet). Among the first changes reported to be alleviated by silicon (most experiments used supra-nutritional amounts) were abnormal bone structure and strength in chicks and rats, abnormal bone cartilage characterized by decreased hexosamine and increased collagen in chicks, and decreased collagen and polyhydroxylase activity in chick skull bones from cultured chick embryos (Carlisle, 1997; Nielsen, 2006a). Subsequent experiments showed that nutritional amounts of silicon alleviated abnormal bone, hexosamine, and collagen metabolism found in animals fed diets low in silicon (Nielsen, 2006a). A subsequent experiment also found that silicon deprivation reduced bone growth plate thickness and increased chondrocyte density in rats (Jugdaohsingh *et al.*, 2008). Supra-nutritional amounts of silicon also alleviate bone loss in ovariectomized rats (Jugdaohsingh, 2007; Kim *et al.*, 2009), and stimulated gene expression of factors involved in osteoblastogenesis and suppressed

expression of factors involved in osteoclastogenesis in mice (Maehira *et al.*, 2009).

Epidemiological, supplementation, and cell-culture studies have suggested that nutritional intakes of silicon are beneficially bioactive in humans. Dietary silicon was positively associated with bone mineral density in men and premenopausal women of the Framingham Offspring cohort of 1251 men and 1596 women (Jugdaohsingh, 2007). In the same cohort, the beneficial effect of a moderate consumption of beer on hip and spine bone-mineral density was associated with the silicon in the beer (Tucker *et al.*, 2009). Silicon intake also was positively associated with bone mineral density at the spine and femur in premenopausal women and postmenopausal women on hormone replacement therapy in the Aberdeen Prospective Osteoporosis Screening Study (Jugdaohsingh, 2007). Limited findings from supplementation trials suggest that silicon supplementation may increase bone mineral density in women with low bone mass (Jugdaohsingh, 2007). Silicon was found to stimulate collagen type 1 synthesis and osteoblastic differentiation in human osteoblast-like cells in vitro (Jugdaohsingh, 2007). The silicon in silica-based bioactive glass and ceramics has been implicated in the in vivo efficiency of bone implants through involvement in gene up-regulation, osteoblast proliferation and differentiation, type 1 collagen synthesis, and apatite formation (Jugdaohsingh, 2007). In other human-oriented studies, supplementation with choline-stabilized orthosilicic acid significantly improved photodamaged skin surface and mechanical properties and decreased hair and nail brittleness in women (Barel *et al.*, 2005), and increased silicon in drinking water has been associated with decreased incidence of Alzheimer's disease and associated disorders (Gillette-Guyonnet *et al.*, 2007).

The mechanism of action for the beneficial bioactivity of silicon has not been identified. Silicon may have some type of structural or binding role in connective tissue where it is strongly bound in significant concentrations. Silicon easily forms stable complexes with polyols that have at least four hydroxyl groups (Kinrade *et al.*, 1999). Tissue concentrations of polyol compounds, such as hexosamines and ascorbate, used to form the glycosaminoglycans, mucopolysaccharides, and collagen involved in connective tissue stabilization or formation, are affected by silicon status (Carlisle, 1997).

Silicon also may be beneficial by altering the absorption or utilization of other mineral elements (Nielsen, 2006a). Experimental and epidemiological findings suggest that

silicon alleviates the toxic actions of aluminum (Gillette-Guyonnet *et al.*, 2007). This has resulted in the hypothesis that an interaction between silicon (as silicic acid) and aluminum compounds (e.g.  $\text{Al}[\text{OH}]^{2+}$ ) forms an aluminosilicate. This interaction prevents aluminum from competing for iron-binding sites (e.g. in prolyl hydroxylase), which results in decreased functions requiring iron. Supranutritional amounts of silicon also facilitate the absorption, retention, or utilization of copper, iron, and magnesium (Nielsen, 2006a).

### Absorption, Transport, Retention, and Excretion

Early balance studies with animals, and studies with silicate compounds used as additives to food and drugs, indicated that almost all ingested silicon was unabsorbed (Nielsen, 2006a). Recent findings indicate that silicon can be relatively well absorbed when consumed in low or milligram quantities in various foods and drinks. One study found an average of 41% of silicon in food was excreted in urine (an indicator of absorption) (Jugdaohsingh, 2007); another study found 64% of silicon absorbed from alcohol-free beer (Sripanyakorn *et al.*, 2009).

Silicon is not protein-bound in plasma, where it is believed to exist mainly as a neutral orthosilicic acid species that readily diffuses into erythrocytes and other tissues (Jugdaohsingh, 2007). Evidence that silicon entering the bloodstream is efficiently transferred to tissues and urine is that the silicon concentration in blood remains relatively constant over a range of dietary intakes. Human serum normally contains between 11 and 31  $\mu\text{g}/\text{dL}$  (Nielsen, 2009b). Connective tissues, including aorta, bone, skin, tendon, trachea, and fingernails, contain much of the silicon that is retained in the body (Carlisle, 1997).

Absorbed silicon is rapidly excreted (Jugdaohsingh, 2007), mainly in the urine, where it probably exists as orthosilicic acid and/or magnesium orthosilicate (Nielsen, 2006a). The upper limits of urinary excretion apparently are set by the rate and extent of silicon absorption and not by the excretory ability of the kidney, because peritoneal injection of silicon can elevate urinary excretion above the upper limit achieved by dietary intake (Nielsen, 2006a, 2009b). This indicates that silicon homeostasis is controlled by both absorption and excretory mechanisms.

### Dietary Guidance

The Food and Nutrition Board (Institute of Medicine, 2001) judged that animal and human data were too limited for the setting of any DRIs for silicon. On the basis of

extrapolations from animal data, weak balance data from humans, and the usual amount of silicon excreted daily by humans, it has been suggested that a daily minimum requirement for silicon might be near 10–25 mg/day (Nielsen, 2006a, 2009b). The dietary intake of silicon is between 15 and 50 mg/day for most Western populations (Nielsen, 2006a; Jugdaohsingh, 2007). Foods rich in silicon include unrefined grains, some vegetables, and seafood (Jugdaohsingh, 2007). The silicon in barley and hops is solubilized during the beer-making process, which makes this beverage a rich source of silicon (Jugdaohsingh, 2007).

### Strontium

#### Beneficial Actions and Possible Basis for Bioactivity

There is no conclusive evidence that strontium is essential for higher animals and humans, but strontium in supra-nutritional or pharmacological amounts unquestionably has beneficial effects on teeth and bones (Nielsen, 1986, 2006a). In 1949, it was reported that rats and guinea pigs fed diets with no added strontium instead of 3 g of strontium sulfate per kilogram exhibited depressed growth, impaired calcification of bones and teeth, and increased dental caries incidence. More recently, it was found that moderate doses of strontium (e.g. 315–525 mg/L drinking water) stimulated bone formation and volume in rats (Marie *et al.*, 2001), and a supplemental 50 mg strontium per kilogram to a corn–soybean-based diet enhanced breaking strength, mineral content, and mineral density of metatarsals and femurs in young pigs (Pagano *et al.*, 2007).

In 1993, it was found that strontium ranelate (a compound containing the organic acid, ranelic acid, and two atoms of strontium) depressed bone resorption and maintained bone formation in ovariectomized rats (Marie *et al.*, 2001). Since then, strontium ranelate has become a promising pharmaceutical for the treatment of postmenopausal osteoporosis (Marie *et al.*, 2001; Boivin, 2010). Strontium ranelate at 2 g/day has been found to prevent fractures in both spine and hip and to increase bone mineral density in the spine and femur (Boivin, 2010). Similar findings have been obtained with animals supplemented with strontium ranelate in amounts that correspond to the therapeutic dose given to humans (Marie *et al.*, 2001; Boivin, 2010).

The mechanism of action for the beneficial bioactivity of strontium has not been firmly established. In vitro

studies suggest that strontium ranelate both increases bone formation by osteoblasts and decreases bone resorption by osteoclasts (Marie *et al.*, 2001). A suggested mechanism for the anti-catabolic effect of strontium is that it acts upon the calcium-sensing receptor such that osteoclast apoptosis is induced through a signaling pathway similar to but different in some ways from the action of calcium (Hurtel-Lemaire *et al.*, 2009). It has also been suggested that the stimulation of osteoblast replication by strontium ranelate occurs because it activates the calcium-sensing receptor and thus extracellular signal-regulated kinase 1/2 phosphorylation (Marie, 2007).

#### Absorption, Transport, Retention, and Excretion

The metabolism of strontium is similar but not identical to that of calcium. However, wherever there is a metabolically controlled passage of ions across a membrane (e.g. gastrointestinal absorption, renal excretion), calcium is transported better than strontium. Intestinal absorption by adults of various mammalian species ranges from 5 to 25% (Nielsen, 1986). Strontium is absorbed by both passive diffusion and active processes (Marie *et al.*, 2001). The active process is vitamin D-dependent, and is depressed by aging and high dietary calcium and phosphorus (Marie, 2007).

Absorbed strontium is transported in blood with a plasma concentration normally in the range 10–27 μg (0.11–0.31 μmol)/L (Marie *et al.*, 2001). Only a limited amount of strontium is retained, most being preferentially deposited by two distinct processes in bones and teeth. These processes are fairly rapid surface absorption by ionic exchange, and a slow incorporation into bone crystals during their formation (Nielsen, 1986; Marie *et al.*, 2001). Most of the strontium absorbed daily is excreted mainly in the urine, but some is excreted in the bile and sweat.

#### Dietary Guidance

It is difficult to provide dietary guidance for strontium, because most studies of its beneficial bioactivity have used non-nutritional amounts of the element. However, because strontium is associated with improved bone and tooth health, increased intakes of foods that are relatively rich sources of strontium, such as whole grains, and unpeeled fruits and vegetables, would be a prudent recommendation. The typical daily dietary intake of strontium is 1.5–3 mg (Nielsen, 1986).

## Vanadium

### Beneficial Actions and Possible Basis for Bioactivity

Vanadium is essential for some lower forms of life (algae, seaweeds, a lichen, and a fungus) where it is a component of various haloperoxidases (Nielsen, 2006b). Vanadium is generally not accepted as an essential nutrient for higher animals and humans, but it does have beneficial actions in supra-nutritional and perhaps nutritional intakes. Beneficial activity at nutritional intakes is indicated by findings from vanadium deprivation studies (Nielsen, 1998b). As described in previous reviews (Nielsen, 1998b; Anke *et al.*, 2005b), vanadium deprivation resulted in swollen joints, skeletal deformations, and decreased lifespan in goats. Also, an increased death rate, sometimes preceded by convulsions, occurred in kids of vanadium-deprived goats. Vanadium deprivation altered thyroid hormone metabolism, impaired reproduction, and altered bone morphology in rats.

Vanadium in pharmacological or supra-nutritional amounts has been repeatedly found to have beneficial bioactivity. Its ability to selectively inhibit protein tyrosine phosphatases probably explains the broad range of effects reported for vanadium. High intakes of vanadium result in elevated tissue vanadium concentrations that affect cellular regulatory or signaling cascades that modulate gene expression, metabolite flow, and the switch between proliferation and differentiation (Hulley and Davison, 2003). Among the beneficial effects of vanadium are insulin-mimetic action and promotion of bone strength, mineralization, and formation. The insulin-like actions of vanadium have been well reviewed (Marzban and McNeill, 2003; Sakurai, 2007). Early studies showing insulin-mimetic actions of vanadium in animals used extremely high amounts of vanadium that were sometimes toxic (Nielsen, 2006a). The vanadium doses in human experiments were about 100-fold lower than those used in many animal studies, but were an order of magnitude greater (i.e. 100 mg vanadyl sulfate or 125 mg sodium metavanadate/day) than possible nutritional need (Nielsen, 2006a). Efforts are continuing in the hope of finding vanadium insulin-mimetic and anti-diabetic compounds that are non-toxic and thus clinically useful (Sakurai, 2007).

### Absorption, Transport, Retention, and Excretion

Because urine vanadium is usually  $<0.8 \mu\text{g/L}$  and the estimated daily intake of vanadium is 12–30  $\mu\text{g}$ , apparently

$<5\%$  of vanadium ingested normally is absorbed with the remainder being excreted in the feces (Nielsen, 1995). Vanadate is absorbed three to five times more effectively than vanadyl. The different absorbability rates for vanadate and vanadyl, the rate at which vanadate is transformed to vanadyl, and the effects of other dietary components (e.g. chromium, protein, ferrous ion, chloride, aluminum hydroxide) on this transformation and binding influence the percentage of ingested vanadium absorbed.

When vanadate appears in the blood, it is quickly converted into the vanadyl cation (Nielsen, 1995). Vanadyl is bound and transported by transferrin and albumin (Nielsen, 1995). Vanadyl also forms complexes with ferritin in plasma and body fluids. Whether vanadyl-transferrin can transfer vanadium into cells through the transferrin receptor, or whether ferritin is a storage vehicle for vanadium has not been determined. Vanadium is rapidly removed from plasma and is generally retained in tissues under normal conditions at concentrations less than 10 ng/g fresh weight (Nielsen, 1995). Bone apparently is a major sink for excessive retained vanadium. Excretion patterns after parenteral administration indicate that urine is the major excretory route for absorbed vanadium (Nielsen, 1995).

### Dietary Guidance

No RDA or AI was set for vanadium by the Food and Nutrition Board (Institute of Medicine, 2001). Based on animal experiments, any requirement for vanadium would be small; a daily dietary intake of 10  $\mu\text{g}$  would probably meet any postulated requirement (Nielsen, 1998b). Typical intakes of vanadium from foods are 6–18  $\mu\text{g}$  for adults (Nielsen, 2006a). A daily beer (contains about 28  $\mu\text{g/L}$ ) can significantly increase the intake (Anke *et al.*, 2005b).

### Other Elements

In a previous review (Nielsen, 2006a), reports indicating that aluminum, bromide, cadmium, germanium, lead, lithium, rubidium, and tin have beneficial effects in higher animals and/or humans were briefly discussed. Since then, essentially no relevant evidence has appeared that further strengthens the suggestion of beneficial bioactivity for any of these elements. Thus, the findings presented in the previous review are briefly summarized in Table 38.2.

**TABLE 38.2** Reported beneficial bioactivity of aluminum, bromine, cadmium, germanium, lead, lithium, rubidium, and tin

Element	Reported deprivation signs	Reported beneficial bioactivity	Typical daily intake and food sources
Aluminum	<i>Goat</i> : ↑spontaneous abortions, ↓growth, ↓lifespan, leg weakness and incoordination <i>Chick</i> : ↓growth	Stimulates osteoblasts to form bone in vitro by activating a putative G-protein-coupled system	2–25 mg; processed cheese, foods containing baking powder, grains, vegetables, herbs, tea
Bromine	<i>Goat</i> : ↑spontaneous abortions, ↓growth, ↓fertility, ↓lifespan ↓hematocrit, ↓hemoglobin <i>Humans</i> : insomnia	Alleviate ↓growth caused by hyperthyroidism in mice and chicks; substitute for chloride requirement of chicks	2–5 mg; grains, nuts, fish
Cadmium	<i>Rat</i> : ↓growth <i>Goat</i> : ↓growth	Stimulates growth of cells in soft agar; mostly a toxicological concern	10–20 μg; shellfish, grains grown in high cadmium soils
Germanium	<i>Rat</i> : alters bone and liver mineral content, ↓tibial DNA, ↓growth <i>Chick</i> : ↓growth	Anti-tumor and immune-enhancing action in animals; ↑bone strength and mineral density in osteoporotic rats	0.4–1.5 mg; wheat bran, vegetables, pulses
Lead	<i>Rat</i> : ↓growth, anemia, altered iron and lipid metabolism <i>Pig</i> : ↓growth, ↑serum cholesterol and phospholipids	Alleviates iron deficiency in young rats and depressed growth in rats fed unbalanced diet; mostly a toxicological concern	5–50 μg; seafood, foods grown on high-lead soils
Lithium	<i>Goat</i> : ↓fertility, ↓birth weight, ↓lifespan <i>Rat</i> : ↓fertility, ↓birth weight, ↓litter size, ↓weaning weight	↑Growth of some cultured cells; insulin-mimetic and immune-modulating actions; ↓status associated with violent crime, learning disability, and heart disease; anti-manic action	0.2–0.6 mg; eggs, meat, fish, milk, potatoes, vegetables (content varies with geographic origin)
Rubidium	<i>Goat</i> : ↓food intake, ↓growth, ↓lifespan, ↑increased spontaneous abortions <i>Rat</i> : altered tissue mineral concentrations	None found	1–5 mg; fruits, vegetables —especially asparagus, fish, poultry, black tea, coffee
Tin	<i>Rat</i> : ↓growth, ↓response to sound, ↓feed efficiency, altered tissue mineral composition, alopecia	Associated with thymus immune function	1–40 mg; canned foods

Data from Nielsen (2000).

## Future Directions

Because the elements reviewed in this chapter may have unrecognized nutritional importance in promoting health and well-being, further studies about their beneficial intakes are warranted. These studies could include work to:

- Determine why low manganese intakes are associated with chronic diseases such as osteoporosis, atherosclerosis, cataracts, and diabetes.
- Reassess the DRIs for manganese including the validity of the AI and establishment of intakes and conditions under which manganese may be harmful to heart and brain health.
- Determine the mechanisms through which boron apparently promotes bone health, brain function, and immune function, and has anti-cancer activity.
- Define standards for intakes of boron that assure maximal beneficial activity.
- Determine whether nutritional intakes of silicon provide beneficial effects on bone and connective tissue health.
- Establish the conditions under which chromium is beneficial to carbohydrate and lipid metabolism.
- Determine whether low intakes of arsenic are without harm, and whether, at appropriate low intakes, arsenic may be beneficial through an effect on methyl metabolism.
- Determine the mechanism behind the bioactivity of nutritional amounts of nickel that affects methyl metabolism, sensory functions, and kidney function.
- Determine whether strontium has beneficial effects on calcium and bone metabolism in nutritional amounts.

## MATERNAL NUTRIENT METABOLISM AND REQUIREMENTS IN PREGNANCY AND LACTATION

LINDSAY H. ALLEN, PhD

*USDA-ARS Western Human Nutrition Research Center, Davis, California, USA*

### Summary

This chapter describes how the additional nutrient requirements of the mother and her fetus during pregnancy are met by a combination of physiological events that affect maternal nutrient utilization and fetal nutrient transfer, and increased dietary intakes. The physiological changes complicate the interpretation of nutritional status measures in pregnancy. It is clear that the body composition of the mother in the periconceptional period affects pregnancy weight gain, so the newly revised weight-gain recommendations continue to be based on maternal body mass index (BMI) at conception. The adverse effects of consuming an inadequate amount of most vitamins and minerals during pregnancy are partially understood, often from research in developing country populations, but little is known about subclinical or long-term effects of deficiencies or their role in specific adverse pregnancy outcomes. Randomized controlled supplementation trials provide most of the information on this issue. After adjustments during the first postpartum weeks, maternal physiology is much less affected by lactation than by pregnancy. Most nutrient requirements are increased to provide for secretion in milk, but women consuming poor diets or who are depleted in specific nutrients may secrete low amounts of those nutrients. Maternal and/or infant supplementation can sometimes improve this situation.

### Introduction

Enabling pregnant women to meet their nutrient needs has long been a public health priority in the United States and most other countries. This priority is based on evidence that undernutrition prior to and during the period

of reproduction can have serious, short- and long-term adverse effects on the mother and child. Programs designed to improve maternal undernutrition are very cost-effective. In wealthier countries there is increasing information about how variability in diet, nutrient metabolism and requirements of individuals affects pregnancy weight gain,

the risk of preterm delivery, birth defects, and other pregnancy outcomes. Well-designed studies on undernourished women in developing countries have revealed the impact that improved maternal nutrition can have on maternal and infant health. However, rates of preterm delivery, low birth weight, birth defects, and other pregnancy complications are still unacceptably high even in wealthier countries, and there is much to be learned about optimal maternal nutrient requirements during pregnancy and lactation.

## Changes in Maternal Physiology during Pregnancy

### Hormonal Changes

In pregnancy larger amounts of nutrients are required for the growth and metabolism of maternal and fetal tissues, and for storage in the fetus. Some of this additional need is met by increased maternal food intake, but regardless of

dietary intake there are enormous metabolic adjustments in nutrient utilization that support the development of the fetus. Some of the most important changes in serum hormone concentrations, and in tissue deposition and metabolism, are summarized in Table 39.1.

Human chorionic gonadotropin (hCG) and human placental lactogen (hPL) concentrations increase a few days after implantation and maintain the corpus luteum. HPL stimulates placental and fetal growth, modulates fetal intrauterine growth factor (IGF) production, and helps to direct nutrients to the fetus by stimulating maternal fat breakdown and antagonizing the action of maternal insulin. It also stimulates mammary-gland development in preparation for lactation.

Estrogen synthesis is increased from early in pregnancy, and its functions include altering carbohydrate and lipid metabolism, increasing the rate of maternal bone turnover, and stimulating conversion of somatotroph cells in the maternal pituitary to prolactin-secreting mammatrophs

**TABLE 39.1** Changes in hormone concentrations, and in tissue and nutrient deposition during pregnancy

Serum hormones, tissues, and metabolic processes	Week of gestation			
	10	20	30	40
<i>Serum placental hormones</i>

required for the initiation and maintenance of lactation. Progesterone relaxes the smooth muscle cells of the gastrointestinal tract and uterus, stimulates maternal respiration, promotes development of mammary-gland lobules, and prevents milk secretion from occurring during pregnancy.

In general pregnancy is a period of increasing resistance of pancreatic  $\beta$  cells to insulin. This occurs in parallel with the higher secretion of hCG, progesterone, cortisol, and prolactin, and serves to permit glucose, very-low-density lipoproteins, and amino acids to flow to the fetus rather than being deposited in maternal tissues.

Although the weight of the fetus increases throughout pregnancy, about 90% of its ponderal growth occurs in the last 20 weeks (Table 39.1). Fetal growth is accompanied by expansion of the placenta, uterus, and mammary glands. The additional tissues cause maternal metabolic rate to be 60% higher during the last half of pregnancy, creating a need for additional dietary energy. The protein, fat, minerals, and vitamins deposited in fetal and maternal tissues come from increased maternal food intake and/or more efficient intestinal absorption or renal reabsorption, depending on the specific nutrient.

### Changes in Blood and Other Fluids

Plasma volume increases by ~50% (1.5L) by late pregnancy but red cell mass increases by only 15–20%. This “hemodilution of pregnancy” means that hemoglobin and hematocrit concentrations fall, especially during the second trimester when there is the largest rise in plasma volume (Table 39.1), and recommended cut-off values that signify anemia vary by trimester. Concentrations of serum albumin and most nutrients are also lower in pregnancy, because of hemodilution and alterations in turnover. In contrast there is a higher level of most globulins, lipids (especially triacylglycerol), and vitamin E. Renal plasma flow increases by 75% and glomerular filtration rate by 50%, accompanied by higher urinary glucose, amino acids, and water-soluble vitamins.

### Weight Gain During Pregnancy

Guidelines for pregnancy weight gain in the United States were revised by the Institute of Medicine (IOM) in 2009 (Institute of Medicine, 2009); revision was needed because women are becoming pregnant when older and heavier, and are more likely to have multiple pregnancies and to gain too much weight in pregnancy. The guidelines con-

**TABLE 39.2** Pregnancy weight gain recommendations

Body mass index category	Recommended weight gain kg (lb)	Rate of weight gain in second and third trimester Mean (range), lb/wk
Low (BMI <18.5)	12.5–18 (28–40)	1 (1–1.3)
Normal (BMI 18.5–24.9)	11.5–16 (25–35)	1 (0.8–1)
Overweight (BMI >25.0–29.9)	7–11.5 (15–25)	0.6 (0.5–0.7)
Obese (BMI $\geq$ 30.0)	$\geq$ 6.0 (11–20)	0.5 (0.4–0.6)

Reproduced with permission from National Academies Press, Washington, DC.

tinue to recognize that pregnancy weight gain is inversely related to the fatness (body mass index, BMI, weight/height<sup>2</sup>) of the woman at conception. The new recommended weight gains (Table 39.2) are associated with the lowest prevalence of cesarean delivery, excess postpartum weight retention, prematurity, low or high birth weight, and childhood obesity in each BMI category. BMI categories were changed to World Health Organization values.

Obese women tend to gain relatively low amounts of weight and yet produce a normal-birth-weight infant. For this reason, and to minimize excessive postpartum weight retention, it is recommended that they gain much less weight but at least 11 lb (5 kg). It is important for women to enter pregnancy with as normal a BMI as possible; overweight and obesity increase the risk for gestational diabetes and preeclampsia. Recommended weight gain does not differ by maternal age, height or ethnicity. While conception less than 2 years after menarche is associated with increased risk of preterm delivery, low birth weight, and infant mortality, recommended weight gains are the same for adolescent and adult women. Recommendations are higher for women bearing twins; for normal BMI women, 37–54 lb (16.8–24.5 kg); overweight, 16–25 lb (7.3–11.3 kg); and obese, 14–22 lb (6.4–10 kg). Because risk of low birth weight is highest for thin women who gain low amounts of weight during pregnancy, this group should be a priority for targeting nutrition counseling and support. Charts should be used to plot weight gain of individual women and compare it with recommended ranges (North Carolina State Department of Health and Human Services, 2010).

## Metabolism and Recommended Intakes of Nutrients

The profound physiological changes that cause hemodilution, changes in the ratio of free to bound forms of nutrients, and alterations in nutrient turnover and homeostasis, affect our ability to assess nutritional status and requirements during pregnancy. For most nutrients the recommended intake is calculated using a factorial approach. This involves adding estimates of the amount of the nutrient deposited in the mother and fetus, and a factor to cover the inefficiency of utilization for tissue growth, to the requirements for non-pregnant women. For a few nutri-

ents, including folate, some experimental data exist so recommendations can be based on the amount needed to maintain tissue levels and nutrient-dependent function. A summary of recommended nutrient intakes for pregnancy is provided in Table 39.3.

### Energy

Energy requirements are increased to cover energy deposited in the mother and fetus (~180 kcal/day, as a total of 3.8 kg fat and 925 g protein over pregnancy) (Institute of Medicine, 2002/2005). In addition, energy expenditure increases by 8 kcal/week owing to the cost of additional

**TABLE 39.3** Recommended intakes of nutrients for non-reproducing, pregnant, and lactating women<sup>a</sup>

<sup>g</sup>Based on 0.8 g/kg.

fetal and maternal metabolism. These increased needs start primarily in the second trimester, when the estimated energy requirement (EER) is the non-pregnant requirement + (8 kcal/week × 20 weeks). In the third trimester (8 kcal/week × 34 weeks) is added to the non-pregnant requirement + 180 kcal/day. The actual amount of energy required varies greatly among women because of differences in the amount of weight and fat gain, and energy expenditure. One study of ten healthy North American women reported that the cumulative energy costs of tissue metabolism and deposition ranged from 60 000 to 170 000 kcal (252–714 MJ) (Bronstein *et al.*, 1996). It is unclear how this variability in energy deposition translates into recommended energy intakes. Higher energy intakes given during pregnancy to underweight, energy-restricted women can improve birth weight and length, and reduce stillbirths and perinatal mortality (Ceasay *et al.*, 1997; Moore, 1998). A higher energy intake causes more maternal fat deposition as well as a higher metabolic rate, across well and poorly nourished populations (Prentice and Goldberg, 2000). In The Gambia, the mid-pregnancy resting metabolic rate of undernourished women actually fell below pre-pregnancy values, but was significantly increased by energy supplementation. It is evident that although there are adaptations in energy expenditure and deposition depending on energy availability, they do not necessarily enable optimal fetal development. It has been hypothesized that an individual who suffered nutritional restriction in utero has a “thrifty genotype” or “thrifty phenotype,” which may help survival in conditions of nutrient restriction, but may also increase the risk of obesity and type 2 diabetes when the food supply is plentiful. However, this hypothesis is the subject of ongoing debate (Prentice *et al.*, 2005; Wells, 2010). Risk of coronary heart disease, hypercholesterolemia, and hypertension is higher for adults who were born small (Godfrey and Barker, 2000). In utero nutrition may also adversely affect later adult immunocompetence. Also in The Gambia, adults who had been born during the hungry season had an 11-fold higher risk of dying prematurely of infectious diseases than those born during the rest of the year (Moore, 1998). It is becoming increasingly evident that undernutrition in utero has serious long-term consequences for poor health (Langley-Evans, 2006).

At present the best strategy may be to monitor weight gain closely and counsel women to either consume more dietary energy or consume less as needed. Because the requirement for most nutrients increases substantially

more than that for energy, however, recommendations of lower intake must be made with caution. Advice to improve dietary quality and to obtain sufficient exercise is usually appropriate. Excessive weight gain in pregnancy tends to cause excessive weight retention postpartum. Exclusive breastfeeding for at least 6 months reduces the risk of long-term retention of this weight.

### **Essential Fatty Acids**

Essential polyunsaturated fatty acids (PUFAs), which must be consumed in the diet, include the parent essential fatty acids, linoleic acid (LA, 18:2n-6) and  $\alpha$ -linolenic acid (ALA, 18:3n-3) found mainly in seed oils, and their longer-chain more unsaturated derivatives called long-chain polyenes (LCPs). Important LCPs derived from linoleic acid include arachidonic acid and dihomo- $\gamma$ -linolenic acid. Those derived from linolenic acid include eicosapentaenoic acid (EPA) and docosahexanoic acid (DHA). The LA-derived LCPs and EPA are precursors of prostanoids, AA is a structural fatty acid in the brain, and DHA and AA can be converted to biologically active hydroxy fatty acids. The fetal supply of PUFAs depends on maternal PUFA status, which declines as pregnancy progresses. Indeed a review concluded that there is evidence that the PUFA status of some pregnant women is inadequate to support optimal neonatal status especially if there are multiple births (Hornstra, 2000). Neonatal DHA status is associated with their head circumference, birth length and weight, and DHA supplementation of preterm infants caused more rapid visual information processing and attention, and affected retinal function. Research is ongoing to resolve the long-term consequences of neonatal EFA status for function. The major sources of AA are egg yolk and lean meat. DHA is found in meat and fatty fish. The adequate intake (AI) recommendation for linoleic acid is increased from 12 to 13 g/day, and for linolenic acid from 1.1 to 1.4 g/day, based on usual population intakes. Higher intakes of *trans* fatty acids are associated with poorer maternal and neonatal PUFA status so it may be beneficial to consume less of these during pregnancy.

### **Protein**

From very early in pregnancy there are adaptations in maternal nitrogen metabolism that increase nitrogen and protein deposition in the mother and fetus. These include lower urea production and excretion, lower plasma  $\alpha$ -amino nitrogen, and a lower rate of branched chain amino acid transamination (Kalhan, 2000). The RDAs provide

for an additional 925 g of protein deposited in the mother and fetus, of which ~8 g/day are needed during the second trimester and ~17 g/day during the third (Institute of Medicine, 2002/2005). Thus the total RDA is 1.1 g/kg/day or +25 g/day additional protein. Most pregnant women in industrialized countries, and probably the majority in developing countries, consume at least the recommended intake of protein.

### **Vitamin A**

Vitamin A deficiency during pregnancy and lactation is not a public health problem in industrialized countries. There is more concern about the dangers of excessive supplementation with retinol or the analog isotretinoin which is used to treat severe cystic acne. Ingestion of large amounts of retinol has been associated with birth defects including abnormalities of the central nervous system, craniofacial and cardiovascular defects, and thymus malformations (Rothman *et al.*, 1995). The first trimester is most critical because the malformations are derived from cranial neural crest cells. There are about 20 case reports of retinol toxicity during pregnancy although their interpretation is confounded by the fact that the retinol was usually consumed as part of a multinutrient supplement (Azaïs-Braesco and Pascal, 2000). Nevertheless, animal studies are clearly consistent with the teratogenic effects of even a single high dose of retinol. The upper safe limit has been set at 3000 µg daily for women of reproductive age and in pregnancy (World Health Organization, 1998). Large intakes of β-carotene do not have a teratogenic effect.

Vitamin A deficiency is highly prevalent in developing countries. Weekly supplementation of pregnant women in Nepal, where vitamin A deficiency is endemic, reduced maternal mortality by about 44% (West *et al.*, 1999) and an equivalent amount of β-carotene had a similar effect. However, a follow-up trial in Bangladesh by the same investigators found no such benefit, possibly due to the better vitamin A status of that population.

### **Vitamin D**

In both pregnant and non-pregnant individuals the serum concentration of 25-hydroxyvitamin D, the main circulating form of the vitamin, is a good indicator of tissue stores of vitamin D. It crosses the placenta and is converted to the active form, 1,25-dihydroxyvitamin D, by the neonate. The placenta synthesizes 1,25-dihydroxyvitamin D; maternal serum levels are more

than doubled by late pregnancy, and calcium absorption is increased several-fold. Maternal and fetal concentrations of free 1,25-dihydroxycholecalciferol are correlated at term. The main predictors of maternal vitamin D status in Northern California, where low serum concentrations are common, are season of delivery (i.e. the amount synthesized in the skin through the action of ultraviolet light), vitamin D intake from fortified milk and supplements, and skin pigmentation (less being synthesized in darker skin) (Dror *et al.*, 2011). When fortified dairy product intake is low, seasonal fluctuations in serum 25-hydroxyvitamin D are more evident, with little synthesized in the skin during winter in more northern latitudes. In France, about 24% of infants born to unsupplemented mothers in the winter or spring had signs of vitamin D deficiency (Zeghoud *et al.*, 1997). In China, the bones of infants born in the spring were less developed than those born after the summer (Specker *et al.*, 1992). Many other possible adverse outcomes of vitamin D deficiency in pregnancy remain to be confirmed (Dror and Allen, 2010). The RDA is 600 IU (15 µg), the same as for non-pregnant women (Institute of Medicine, 2011). While not all countries recommend routine vitamin D supplements in pregnancy, in the UK, for example, there are now recommendations that these should be taken by women at high risk of deficiency.

### **Vitamin B<sub>6</sub>**

Although plasma concentrations of pyridoxal and pyridoxal phosphate decline more than can be accounted for by hemodilution, this is probably caused by hormonal changes rather than by poorer vitamin status (Institute of Medicine, 1999). Pyridoxal is transferred by active diffusion to the placenta which converts it to pyridoxal phosphate (Schenker *et al.*, 1992). In the United States non-pregnant women's intakes of vitamin B<sub>6</sub> average about 1.5 mg per day but there is no evidence of a significant vitamin B<sub>6</sub> deficiency problem. In Japan, a maternal supplement of 2 mg per day of the vitamin improved vitamin B<sub>6</sub> status and growth of the newborn (Chang, 1999).

### **Folate**

There is a marked increase in folate utilization during pregnancy as a result of the acceleration of reactions requiring single-carbon transfer, the rapid rate of cell division in maternal and fetal tissues, and deposition in the fetus. The recommended intakes for pregnancy are based on the

amount that maintained erythrocyte concentrations in clinical trials.

Randomized controlled trials have proven that taking folic acid supplements before conception and through about the first 4 weeks of pregnancy lowers the risk of genetically predisposed women having a baby with a neural tube defect (NTD) (Heseker *et al.*, 2009). Unfortunately most women are unaware that they are pregnant at this stage. NTDs occur in about 5.5/10 000 births in the United States and up to 40/10 000 in other countries, and tend to recur in subsequent pregnancies. A lower intake of folate from diet plus supplements (Werler *et al.*, 1993; Shaw *et al.*, 1995) or higher erythrocyte folate concentrations (Daly *et al.*, 1995) is inversely related to NTD risk. The metabolic defect that causes NTD, and the mechanisms by which folic acid lowers NTD risk, are not fully understood although disruption of the folate-metabolizing enzyme, serine hydroxymethyltransferase 1, has been implicated most recently (Beaudin *et al.*, 2011). Maternal supplements of 400  $\mu\text{g}$  folic acid/day reduced the occurrence of NTDs in Northern China by up to 80% (Berry *et al.*, 1999), and by 70% in N England, 35% in California, and 28% overall in the USA; the percent reduction is higher in populations with a higher initial prevalence of NTDs (Heseker *et al.*, 2009). The policy of fortifying flour with folic acid has increased folate status substantially in the USA and Canada and elsewhere in the world, and also reduced the prevalence of NTDs (USDA, 2010). This policy improves maternal folate status prior to conception, although some concerns about its safety, especially in combination with use of folic acid supplements, still need to be resolved (Crider *et al.*, 2011). For this reason folic acid fortification of flour is not practiced in Europe.

Pregnant women are recommended to consume 200  $\mu\text{g}$ /day of synthetic folic acid in addition to the non-pregnant RDA of 400  $\mu\text{g}$  per day of dietary folate. The 200  $\mu\text{g}$  of folic acid is equivalent to 400  $\mu\text{g}$  of dietary folate, because food folates have only about half the bioavailability of the synthetic form. This amount of folate will maintain normal folate status in pregnancy and prevent elevated plasma homocysteine concentrations (Institute of Medicine, 1999). Orange juice, dark-green leafy vegetables, and legumes average  $\sim 75\text{--}100\ \mu\text{g}$  folate per serving, and many commercial fortified breakfast cereals provide 100  $\mu\text{g}$  folic acid (about 170 dietary folate equivalents, DFE).

Folic acid supplementation, even when started later in pregnancy, may lower the risk of other birth defects since

low serum or red blood cell folate and elevated plasma total homocysteine concentrations (tHcy) are often associated with other pregnancy complications (Scholl *et al.*, 1997). For example, in a large, retrospective, Norwegian study, women in the upper quartile of plasma tHcy compared with the lower had a 32% greater risk of preeclampsia, 38% more risk of preterm delivery, and 101% more risk of a very low-birth-weight infant (Vollset *et al.*, 2000). A meta-analysis showed that of all vitamin and mineral supplements tested, only folic acid lowered the risk of preterm delivery (Gülmezoglu *et al.*, 1997).

### Calcium

Additional calcium is made available to the fetus by the substantial increase in the efficiency of maternal calcium absorption starting early in pregnancy. Calcium is carried across the placenta by active transport involving calcium binding protein and 1,25-dihydroxyvitamin D. Although maternal bone resorption increases during pregnancy, there is no detectable change in bone mineral content between conception and parturition (Ritchie *et al.*, 1998). There is little need for additional dietary calcium during pregnancy, and calcium supplements do not improve maternal bone calcium or infant bone in the first year of life, even when maternal intakes are very low (Jarjou *et al.*, 2006). Recommended intakes are 1000 mg/day, the same as for non-pregnant women (Institute of Medicine, 2011).

Pregnancy-induced hypertension (PIH) affects about 10% of all pregnancies in the United States, and increases risk of maternal morbidity and mortality. PIH includes preeclampsia, eclampsia, and hypertension. Based on epidemiologic and experimental evidence of a link between calcium intake and PIH, several clinical trials tested whether calcium supplements could reduce this condition. A meta-analysis of 14 randomized controlled trials showed that supplements providing 375–2000 mg calcium reduced maternal blood pressure and lowered risk of gestational hypertension and preeclampsia to 30–40% of controls (Bucher *et al.*, 1996). The risk of preeclampsia was more reduced in six populations with low-calcium diets than in four groups with higher calcium intakes (Villar and Belizán, 2000). In contrast, the multicenter Calcium for Preeclampsia Prevention (CPEP) trial on 4589 pregnant women in the United States found no effect of 2000 mg/day on blood pressure, PIH or preeclampsia (Levine *et al.*, 1997), possibly because their usual dietary calcium intake averaged  $\sim 1100$  mg/day.

## Iron

On average an additional 6 mg iron per day needs to be absorbed during pregnancy (Hallberg, 1988). Iron is retained by the fetus (300 mg), deposited in the placenta (60 mg), used for the synthesis of additional maternal red blood cells (450 mg), lost in blood during delivery (200 mg), and retained by the mother's increased red cell mass after parturition (200 mg). Serum iron is carried on transferrin to transferrin receptors on the placenta, holotransferrin is endocytosed, iron is released, and apotransferrin is returned to the maternal circulation (Harris, 1992). Iron absorption increases several-fold during the second and third trimesters, and it has been calculated based on absorption data that good maternal diets can supply sufficient iron for pregnancy (Barrett *et al.*, 1994). However, WHO estimates that ~18% of women in industrialized countries and from 35% to 75% of those in developing countries are anemic (ACC/SCN, 2000). The Centers for Disease Control and Prevention estimated that about 10% of low-income women are anemic in the first trimester, 14% in the second and 33% in the third (Kim *et al.*, 1992). In another study, rates of iron deficiency anemia among low-income and minority women were 1.8%, 8.2%, and 27.4%, in the first, second, and third trimester, respectively (Iannotti *et al.*, 2005). A much higher percentage of women become iron depleted by the end of pregnancy. Because of hemodilution the hemoglobin cut-offs that signify anemia are 110 g/L in trimesters 1 and 3 and 105 g/L in trimester 2. Serum ferritin concentrations fall, often to barely detectable levels, but transferrin concentrations are almost doubled.

In many countries, including the United States, iron supplementation is routinely recommended for all pregnant women; they should take an additional 30 mg/day starting at ~12 weeks, since not enough can be readily obtained in food (Institute of Medicine, 2001). Attaining adequate iron status prior to conception is important because it is more difficult to replenish stores during pregnancy when iron requirements are higher. Supplements are better absorbed if taken between meals and without coffee or tea (Institute of Medicine, 1993). Anemic women with low plasma ferritin (<30 µg/L) should take 60 to 120 mg of supplemental iron per day until hemoglobin values become normal. Taking iron once a week can also improve hemoglobin and iron status although 60 mg daily is more effective than 120 mg weekly because of the difficulty of consuming enough during the relatively short period of gestation (Beaton *et al.*, 1992).

The advantages of routine maternal iron supplementation, regardless of iron status, are somewhat controversial (Ziaei *et al.*, 2007) so supplements are not given routinely in some countries, including many in Europe. However, benefits include improved maternal hemoglobin and less risk of anemia and iron depletion in late pregnancy, even in industrialized countries (Allen, 2000; Beard, 2000). Also iron supplementation during pregnancy increases iron stores of the infant for ~6 months, which is an advantage especially in developing countries where complementary foods are low in available iron (Preziosi *et al.*, 1997). Infants are at greatest risk of iron deficiency anemia if they were low birth weight and their mother was anemic (de Pee *et al.*, 2002). Severe anemia probably increases the risk of maternal mortality but whether this is true for moderate anemia is uncertain (Brabin, 2001). Numerous studies report an association between preterm delivery and maternal anemia but this relationship has not been proven to be causal (Rasmussen, 2001).

## Zinc

The estimated additional zinc required for pregnancy is ~100 mg, equivalent to 5–7% of the mother's body zinc (Swanson and King, 1987). About half of this zinc is deposited in the fetus, and one-quarter in the uterus. The recommendation is to increase zinc intake by an additional 3 mg/day to a total of 15 mg/day (Institute of Medicine, 2001). Average intakes of pregnant women in the United States are ~10 mg/day with vegetarians consuming much less (Apgar, 1992). Zinc deficiency is more prevalent in populations consuming low amounts of animal-source foods and high amounts of phytate, which inhibits its absorption.

Maternal zinc retention is increased primarily through greater intestinal absorption (King, 2000b). Zinc plays critical roles in cell division, hormone metabolism, protein and carbohydrate metabolism and immunocompetence. Zinc deficiency during pregnancy in animals causes birth defects and intrauterine growth retardation. Of 41 studies that described an association between maternal zinc status and birth weight, 17 found a positive association (Goldenberg *et al.*, 1995; King, 2000b), 10 from industrialized countries and seven from developing countries. Sometimes different studies from the same country found different results. Of 12 randomized, controlled intervention trials, two (in the United States and India) found an increase in birth weight, and six found no effect. There was no impact of 15 or 30 mg zinc daily on gestational age

or size at birth in well-designed, controlled studies in Peru and Bangladesh (Caulfield *et al.*, 1999; Osendarp *et al.*, 2000). However, it is prudent to ensure adequate zinc intake for women at higher risk of zinc deficiency; those with low intakes, on high-fiber diets, with high intakes of supplemental calcium, or iron (>30 mg per dose), and with gastrointestinal diseases that lower zinc absorption (King, 2000b).

### **Iodine**

Iodine deficiency during pregnancy causes cretinism and has permanent adverse effects on the growth, development, and cognitive function of the infant. In areas of severe iodine deficiency iodized oil injection prior to mid-pregnancy produced a marked reduction in cretinism and a 30% reduction in neonatal mortality (Thilly *et al.*, 1978). In the United States and many other countries, iodized salt provides sufficient iodine for pregnant women. The World Health Organization has increased the recommended iodine intake for pregnancy from 200 µg/day to 250 µg/day and states that a urinary iodine excretion of 150–249 µg/L indicates an adequate intake (World Health Organization, 2007). In iodine-depleted populations, i.e. where <90% of households use iodized salt and the median urinary iodine concentration in school-age children is <100 µg/L, the World Health Organization recommends that both pregnant women and their infants be given iodine supplements.

## **Other Nutrition-Related Conditions**

### **Pregnancy in the Obese Woman**

There is general agreement that even moderate degrees of overweight increase the risk of pregnancy complications. Overweight women (BMI ≥25) have about two to six (increasing with higher BMI) times the risk of gestational diabetes, pregnancy hypertension and preeclampsia, diabetes, preterm delivery, and cesarean section compared with those with normal weight (Abenhaim *et al.*, 2007). Their infants are more likely to have low Apgar scores, macrosomia, about three times more perinatal mortality, a higher risk of NTDs, and difficulty in initiating breastfeeding (Hilson *et al.*, 1997). Macrosomic infants are more likely to become obese in later years. Many of these problems are probably caused by the relatively higher plasma insulin concentrations in obese women. Preconceptional counseling about the risks of obesity during pregnancy, followed by dietary counseling and exercise for weight

reduction, is clearly the best preventive strategy. Once they become pregnant, obese women need careful monitoring for diabetes and hypertension, and should be advised to gain lower amounts of weight (see Table 39.2) and to increase exercise.

### **Gestational Diabetes and Preeclampsia**

Gestational diabetes is defined as intolerance to carbohydrate that appears during pregnancy, characterized by higher fasting and postprandial plasma glucose, amino acids (especially branched-chain), and lipids (fatty acids and especially triacylglycerol) (Butte, 2000). Associated risks include large infant birth weight (macrosomia), preeclampsia, and cesarean birth. It may be an extreme manifestation of the normal insulin resistance of pregnancy or reflect a predisposition to type 2 diabetes. Postprandial, but not fasting, concentrations of plasma glucose predict large birth weight. To improve insulin sensitivity and reduce the risk of infant macrosomia, the American College of Obstetricians and Gynecologists recommends spreading snacks and meals across the day, a healthy diet, self-monitoring of glucose and urinary ketones, and exercise (American College of Obstetricians and Gynecologists, 2001). Individuals vary in their needs for insulin therapy and specific dietary changes depending on their weight, blood glucose levels and fluctuations, so consultation with a qualified health-care provider is essential (National Institute of Child Health and Human Development, 2004).

Preeclampsia is a leading cause of maternal and perinatal mortality. Symptoms are the new development of hypertension with proteinuria, edema or both, usually during the third trimester, which can end in eclampsia or severe and potentially fatal seizures. The syndrome involves reduced placental perfusion and maternal endothelial dysfunction. Trials with antioxidant supplements did not reduce risk. Both vitamin D and selenium deficiency have been associated with greater risk but further trials are needed for confirmation. Although the causes of preeclampsia are not yet understood, several risk factors are nutrition-related: maternal obesity, diabetes, hypertension, and hyperhomocysteinemia. Salt restriction is not advised.

### **Alcohol and Caffeine Abuse**

Heavy alcohol consumption in pregnancy has teratogenic effects. Fetal alcohol syndrome affects about 1200 infants annually in the United States. Infants with this condition

are typically growth retarded with facial defects, and have abnormalities of the central nervous, cardiac and genitourinary systems. This syndrome affects 10% of women taking 1.5 to 8 alcoholic drinks per week [0.6 oz (15 mL) of absolute alcohol per drink], and 30–40% of those taking >8 drinks a week. The Surgeon General and the March of Dimes advise that no alcohol be consumed during pregnancy. Alcoholic drinks also displace other dietary items and can alter the absorption and metabolism of nutrients. While there is little evidence that multivitamin–mineral supplements counteract the effects of alcohol, it is prudent to advise these supplements for women who continue to abuse alcohol when pregnant.

Caffeine crosses the placenta and affects fetal heart rate and respiration. Large amounts of caffeine are teratogenic in animals. There is limited evidence that moderate coffee intake lowers birth weight in humans. It has not been proven without doubt that caffeine is safe for pregnant women, so the FDA recommends avoiding or limiting coffee in pregnancy. Caffeine consumption should be limited to <300 mg/day, equivalent to two to three cups of coffee, or four cups of tea, or six cola drinks.

## Physiology of Lactation

At parturition, major hormonal changes lead to the onset of lactation. Estrogen and progesterone secretion fall markedly while the elevated prolactin concentrations are maintained. Prolactin causes the breasts to begin milk secretion. During the first 2 to 7 days postpartum, colostrum is secreted, a thick yellow fluid containing large amounts of immune factors, protein, minerals, and carotenoids. Colostrum can provide the newborn infant with large amounts of maternal antibodies, important because the immune system does not develop fully for some months. Between about 7 and 21 days postpartum the milk is transitional, and after 21 days mature milk is secreted. Suckling is required to empty the breast, which stimulates continued synthesis of prolactin and maintenance of milk production; once lactation is established suckling once a day can sustain milk production but synthesis stops within a few days of suckling cessation. Continued suckling inhibits release of luteinizing hormone and gonadotropin releasing hormone so the return of ovulation and menses is delayed, providing very effective birth control.

The volume of breast milk secreted increases rapidly to about 500 mL on day 5, 650 mL at 1 month, and 700 mL

at 3 months (Neville *et al.*, 1991; Brown *et al.*, 1998). Subsequently the volume is relatively stable but falls during weaning. Although the infant grows continuously larger, its rate of growth declines markedly during the period of lactation, causing a fall in nutrient requirements per unit body weight. Thus, breast-milk production is usually adequate to meet energy and protein requirements of the infant until at least 6 months of age. Mothers can easily produce the amount of milk demanded by their infant, and can feed two or more infants adequately. Exclusive breast feeding is recommended until 6 months of life, and no other fluids or foods should be given. Introducing other liquids or foods introduces sources of infection and contamination, can lower the quantity of nutrients consumed (especially if special infant foods are not used), and may cause premature disruption of milk production. The latest international (WHO) standards for infant growth are based on infants predominantly breastfed for the first 4 to 6 months of life.

## Milk Composition

For the purpose of estimating maternal and infant nutrient requirements the IOM estimates that the average volume of milk produced is 780 mL/day during the first 6 months and 600 mL for the second 6 months. Maternal malnutrition must be very severe before milk volume is affected adversely: production is still normal at a BMI of 18.5 kg/m<sup>2</sup>. Milk fat content may be reduced by less severe malnutrition, however (Prentice *et al.*, 1994).

The protein content of human milk is about 8–9 g/L, and contains roughly equal amounts (about 25%) of lactalbumin and casein, and substantial quantities of lactoferrin and IgA. It is not affected by maternal undernutrition. Cow's milk contains about 35 g/L protein, mostly casein. Feeding undiluted cow's milk to young infants is inadvisable because of the large osmotic load from protein and other solutes, and the risk of occult fecal blood loss and subsequent iron deficiency (Ziegler *et al.*, 1999). About 25% of the total nitrogen in milk is non-protein nitrogen, mainly urea. Lactose concentrations tend to increase throughout lactation, providing an osmotic balance as the content of protein and monovalent items falls slightly. Lactose provides energy, galactose for central nervous system development, and enhanced growth of beneficial lactobacilli in the infant intestine. Fat provides about half of the energy in breast milk. The average fat content is about 3.8%, but hind milk contains substantially more fat

than fore milk. The fatty acid content of the mother's diet affects the amount of fatty acids in her milk.

### **Vitamins and Minerals**

The concentration of several vitamins and minerals in human milk is influenced by maternal diet and/or vitamin status. Table 39.4 summarizes the concentrations of these nutrients in normal milk, and the effect of maternal deficiency and supplementation on milk content and the infant. To predict risks caused by infant or maternal micronutrient deficiencies in lactation, and for planning interventions, it is useful to categorize nutrient deficiencies based on their effect on the nutrient in milk (Allen, 1994). Priority nutrients include vitamin A, thiamin, riboflavin, vitamins B<sub>6</sub> and B<sub>12</sub>, iodine, and selenium. These nutrients are of most concern because low maternal intake or stores reduces their content in milk, which affects the infant adversely. However, the concentration in milk can be restored rapidly by maternal supplementation. Also infant stores of these nutrients are more readily depleted, increasing the infant's dependence on an adequate supply from breast milk or complementary foods. Lower-priority nutrients include folate, calcium, iron, copper, and zinc. Maternal intake and stores of these nutrients have little or no effect on breast-milk concentrations or infant status, or on the amount required from complementary foods. Consequently the mother is less likely to become depleted, and maternal supplementation is more likely to benefit herself than her infant. Milk vitamin D may be low if women are very deficient but their infants will respond readily to vitamin D supplements.

The deficiencies described in Table 39.4 occur predominantly in developing countries (Allen and Graham, 2003) but several do occur in the United States. Examples include low milk vitamin B<sub>12</sub> and subsequent infant deficiency as a result of strict maternal vegetarianism (Specker *et al.*, 1990), and low milk vitamin D and abnormal vitamin D status of infants receiving insufficient exposure to sunlight (Specker, 1994). The American Academy of Pediatrics recommends that all infants who are breastfed should receive 400 IU vitamin D per day as a supplement (Wagner *et al.*, 2008). Infants fed formula but drinking <1 L (1 quart) per day should also receive supplemental vitamin D.

Low concentrations of nutrients in breast milk imply that maternal and/or infant supplementation is needed; breastfeeding is always the best way to feed young infants. Vitamin A in breast milk is adequate in industrialized

countries, but high-dose (200 000 to 300 000 IU) vitamin A supplementation during the first 6 weeks postpartum, while there is minimal chance of conception, is recommended by WHO for increasing breast milk retinol and improving infant vitamin A status in developing countries (Stoltzfus *et al.*, 1993). Vitamin B<sub>12</sub> concentrations in milk from Guatemalan women were one-tenth of those in California, and correlated with both maternal and infant serum B<sub>12</sub> with both groups having a high prevalence of deficiency (Allen *et al.*, 2009). Human milk provides sufficient fluoride for the first 6 months of life, but the infant should be given 0.05 mg/kg/day starting at age 6 months. Iodine can be very low in breast milk in populations with endemic iodine deficiency, and infants and young children consume little iodized salt. Even in Switzerland, for example, weaning infants are at risk of iodine deficiency, especially if they are not consuming infant formulas (Andersson *et al.*, 2010).

### **Maternal Nutrient Requirements During Lactation**

The daily nutrient requirements of the lactating woman are higher than requirements during pregnancy. The higher recommended intakes are based primarily on the amounts secreted in milk. The most recent RDAs assume that the mother secretes about 500 kcal/day in milk, including about 5% as protein, more than 50% as fat, and 38% as lactose (Institute of Medicine, 2002/2005). This falls to 400 kcal/day in the second 6 months. In the first 6 months about 170 kcal/day are obtained from maternal weight loss. Thus the energy requirements in lactation are higher than those of the non-pregnant woman by 330 kcal/day in the first 6 months and 400 kcal/day in the second 6 months. Energy restriction to induce weight loss should not be attempted while breast feeding due to the risk of inadequate intakes of other nutrients in the diet. Exclusive breastfeeding and exercise, combined with a high quality diet, should lead to gradual weight loss during the postpartum period. Recommended protein intakes are increased from 0.8 g/kg/day in the non-lactating woman to 1.3 g/kg in lactation, or by 25 g/day.

The recommended intake of most micronutrients is also increased to cover the amounts secreted in milk (Table 39.3). The only nutrient that is needed in lower amounts during lactation is iron, except for women who need to synthesize large amounts of blood to replace major blood losses during delivery. Bone mineral content

**TABLE 39.4** Effects of maternal micronutrient deficiencies and supplements during lactation on breast milk and infant micronutrient status

Nutrient	Normal milk concentration	Effect of maternal deficiency on milk content	Effect of maternal deficiency on infant	Effect of maternal supplementation on milk content	Effect of maternal supplementation on infant
Vitamin A, $\mu\text{g RE/L}$	500	↓ to 170–500	Low serum retinol, depletion	↑	↑Serum retinol and liver stores for 2–3 months after massive dose
Vitamin D, $\mu\text{g/L}$	0.55	↓ to 0.25	↑Risk of rickets depending on UV light exposure	↑	↑Serum 25(OH)D if dose >2000 IU/day
Thiamin, mg/L	0.21	↓ to 0.11	Beri-beri	↑ to normal	↓Infant beri-beri
Riboflavin, mg/L	0.35	↓ to 0.2	High EGRAC <sup>a</sup>	↑	↓EGRAC in mother and infant
Vitamin B <sub>6</sub> , mg/L	0.93	↓ to 0.9	Neurological problems	↑	↓Neurological problems
Folate, $\mu\text{g/L}$	85	No change	Unknown		None, but ↑ maternal status
Vitamin B <sub>12</sub> , $\mu\text{g/L}$	0.97	↓ to <0.5	↑Urine MMA <sup>b</sup> , neurological problems, developmental delays	↑	↓MMA
Ascorbic acid, mg/L	40	↓ to 25	Unknown	↑(small)	?
Calcium, mg/L	280	↓ to 215	↓Bone mineral but relative influence unclear		None
Iron, mg/L	0.3	No change	None	None	None
Zinc, mg/L	1.2	No change	None	None	None
Copper, mg/L	0.25	No change	None	None	None
Iodine, $\mu\text{g/L}$	110	No change/slight ↓	Uncertain; deficiency in pregnancy more important	↑	Unknown
Selenium, $\mu\text{g/L}$	20	↓ to ≤10	↓Plasma and RBC content	↑	Unknown

<sup>a</sup>EGRAC, erythrocyte glutathione reductase activity coefficient.<sup>b</sup>MMA, methylmalonic acid.

Adapted from Allen (1994) and Allen and Graham (2003).

and urinary calcium fall during lactation to meet the additional calcium requirements for milk production (Prentice, 2000). The loss in mineral content is temporary, and it is gradually regained by about 3 months after weaning. Higher intakes of calcium than the recommended 1000 mg/day do not affect these lactation-associated changes in maternal bone turnover, bone mineral content, or the amount of calcium in breast milk (Institute of Medicine, 2011).

## Future Directions

Although the risk for many adverse pregnancy outcomes are clearly higher in women who are undernourished or consume poor diets, much work remains to be done to confirm observed or hypothesized links between the importance of specific nutrients in causing or preventing (when supplemented) outcomes such as low birth weight, preeclampsia, and preterm delivery. In lactation, one important question is the extent to which the concentration of nutrients in breast milk from undernourished women is inadequate to support optimum infant growth and development, and whether and when maternal supplementation can prevent this potential problem.

## INFANT NUTRITION

WILLIAM C. HEIRD, MD

*Baylor College of Medicine, Houston, Texas, USA*

### Summary

The normal infant experiences a three-fold increase in weight and a two-fold increase in length during the first year of life, and also experiences dramatic developmental changes in organ function and body composition. These rapid rates of growth and development are superimposed on relatively high maintenance needs incident to the higher metabolic and nutrient turnover rates of infants vs. adults. Despite these unique nutritional needs, reference nutrient intakes for the 0- to 6- and the 7- to 12-month-old infant have been established. Some of these as well as specific issues relevant to infant nutrition, e.g. breast vs. formula feeding, introduction of complementary foods, use of formula vs. bovine milk, and the need for preformed long-chain polyunsaturated fatty acids (LC-PUFA), are discussed in this chapter. These discussions are preceded by a discussion of the differences among requirement, recommended intake, and reference intake.

### Introduction

The “requirement” of a specific nutrient is the amount of that nutrient that results in some predetermined physiological endpoint. In infants, this endpoint is usually maintenance of satisfactory rates of growth and development and/or prevention of specific signs of deficiency. The requirement of a specific nutrient is usually defined experimentally, often in a relatively small study population. Thus, the mean requirement of a specific nutrient estimated in this way (the estimated average requirement, or EAR) usually meets the needs of roughly half the population. For some, it may be inadequate whereas, for others, it may be excessive.

In contrast, the recommended daily allowance (RDA) of a specific nutrient is the intake of that nutrient deemed by a scientifically knowledgeable group to meet the “requirement” of most healthy members of a population. If the EAR of a specific nutrient is normally distributed within the population, the RDA usually is set at the EAR of the population plus 2 standard deviations (SD). Since the EARs of many nutrients are not normally distributed, other considerations of population variability frequently are necessary. For example, if the EAR appears to be adequate for most of the population, the RDA may be less than the requirement plus 2 SD.

RDAs are useful guides for nutrient intakes of individuals but they are not useful for ascertaining the adequacy

or inadequacy of an individual's intake of a specific nutrient. Moreover, since the EAR of many nutrients is not known with certainty, it is often difficult to establish an RDA.

Because of the difficulties in establishing an EAR and the uncertainty of an RDA based on limited information concerning requirement, the Food and Nutrition Board, Institute of Medicine (USA) has established dietary reference intakes (DRIs). These include RDAs for the few nutrients for which an RDA can be established as well as other "reference intakes" such as adequate intake (AI) and tolerable upper intake level (UL).

AI, used when an RDA cannot be determined, is the observed or approximated daily intake of a specific nutrient by a group of healthy individuals, e.g. the intake of the breast-fed infant which is the basis of the most recent DRIs for infants under 6 months of age.

The UL is the highest intake of a specific nutrient likely to pose no risk. The UL is not a recommended level of intake but, rather, an aid in avoiding adverse effects secondary to excessive intake.

The DRIs established by the Food and Nutrition Board of the Institute of Medicine (Institute of Medicine, 1998, 2000, 2001, 2002, 2004, 2011a,b), for 0- to 6-month-old and 7- to 12-month-old infants are summarized in Table 40.1.

## Dietary Reference Intakes of Specific Nutrients

### Energy

Since an energy intake that is adequate for almost all individuals will result in excessive weight gain by individuals with a low or average requirement, the reference energy intakes reflect the "estimated" energy requirement (EER), i.e. the energy intake predicted to maintain energy balance in a healthy individual of a defined age, gender, weight, height, and level of physical activity. The EERs are based on predictive equations for normal-weight individuals that include daily energy expenditure measured by the doubly labeled water method plus an allowance for energy deposition. Since an RDA will exceed the EER of many individuals and result in excessive weight gain, setting an RDA for energy would only contribute to the growing prevalence of overweight and obesity. Similarly, the UL is not appropriate for energy because any intake above the EER will result in excessive weight gain.

**TABLE 40.1** Reference intakes of nutrients for normal infants

Nutrient <sup>a</sup>	Intake per day	
	0–6 months	7–12 months
Energy [kcal (kJ)] <sup>b</sup>		
Males	570 (2385)	743 (3109)
Females	520 (2176)	676 (2829)
Fat (g)	31	30
Carbohydrate	60	95
Protein (g) +	9.1	13.5
Electrolytes and minerals		
Calcium (mg)	210	270
Phosphorus (mg)	100	275
Magnesium (mg)	30	75
Sodium (mg)	115	368
Chloride (mg)	178	568
Potassium (mg)	390	702
Iron (mg)	0.27	11 <sup>c</sup> (5)
Zinc (mg)	2	3 <sup>c</sup> (5)
Copper (µg)	200	220
Iodine (µg)	110	130
Selenium (µg)	15	20
Manganese (mg)	0.003	0.6
Fluoride (mg)	0.01	0.5
Chromium (µg)	0.2	5.5
Molybdenum (µg)	2	3
Vitamins		
Vitamin A (µg)	400	500
Vitamin D (µg)	5	5
Vitamin E (mg α-TE)	4	6
Vitamin K (µg)	2.0	2.5
Vitamin C (mg)	40	50
Thiamine (mg)	0.2	0.3
Riboflavin (mg)	0.3	0.4
Niacin (mg NE)	2	4
Vitamin B <sub>6</sub> (µg)	0.1	0.3
Folate (µg)	65	80
Vitamin B <sub>12</sub> (µg)	0.4	0.5
Biotin (µg)	5	6
Pantothenic acid (mg)	1.7	1.8
Choline (mg)	125	150

<sup>a</sup>Unless indicated otherwise, values are adequate intake (AI) (e.g. mean intake of normal breast-fed infants 0–6 months of age or mean intake of 7- to 12-month-old infants from human milk plus complementary foods).

<sup>b</sup>Estimated energy requirement.

<sup>c</sup>RDA.

Data from Institute of Medicine (1998, 2000, 2001, 2002, 2004, 2011).

Expressed per unit of body weight, the EER of the normal newborn infant is about twice that of the normal adult. The greater energy requirement reflects primarily the higher metabolic rate of the infant and the special needs for growth and development. The inefficient intestinal absorption of the infant vs. the adult contributes only minimally to the higher energy requirement of infants fed human milk or modern infant formula.

There is no evidence that either carbohydrate or fat is a superior source of energy. Sufficient carbohydrate to prevent ketosis and/or hypoglycemia is necessary (~5.0 g/kg/day) as is enough fat to provide essential fatty acid requirements (0.5–1.0 g/kg/day of linoleic acid [LA] plus a smaller amount of  $\alpha$ -linolenic acid [ALA]). As discussed below, there is concern that infants may require long-chain polyunsaturated omega-3 and, perhaps, omega-6 fatty acids.

In toto, the minimum needs for carbohydrate and fat amount to no more than ~30 kcal (125.5 kJ)/kg/day, or only approximately a third of the infant's total energy need. Whether the remainder should be comprised of fat or equicaloric amounts of fat and carbohydrate is not known. The acceptable macronutrient distribution range (AMDR) for carbohydrate and fat specified by the Food and Nutrition Board, Institute of Medicine (2002), is 20–25% of total energy as fat and 45–65% of total energy as carbohydrate. While appropriate for older children and adults, the "acceptable" range for fat is lower than conventional intake for infants. Human milk and most currently available formulas contain equicaloric amounts of fat and carbohydrate. This distribution, ~45% of total energy as carbohydrate and ~45% as fat, seems appropriate.

The AI for omega-6 fatty acids (linoleic acid) is 4.4 g/day and 4.6 g/day, respectively, for the 0- to 6-month-old and the 7- to 12-month-old infant. The AI for omega-3 fatty acids ( $\alpha$ -linolenic acid) is 0.5 g/day for both age groups. These reference intakes are based on the intake of these fatty acids in the average volume of human milk ingested from 4 to 6 months of age and the average intake from human milk plus complementary foods from 7 to 12 months of age.

### Protein

The protein requirement of the normal infant also is greater per unit of body weight than that of the adult. In addition, it is thought that the infant requires a higher proportion of essential amino acids than the adult. These include the amino acids recognized as essential (or indis-

pensable) for the adult (i.e. leucine, isoleucine, valine, threonine, methionine, phenylalanine, tryptophan, lysine, and histidine) as well as cysteine and tyrosine. The need for cysteine is thought to reflect the fact that the hepatic activity of cystathionase, a key enzyme in conversion of methionine to cysteine, does not reach adult levels until at least 4 months of age (Sturman *et al.*, 1970; Gaull *et al.*, 1972). The reason for the infant's apparent need for tyrosine is not clear. Recent studies show that even preterm infants can convert phenylalanine to tyrosine (Räihä, 1973; Kilani *et al.*, 1995; Denne *et al.*, 1996).

Human milk protein and all proteins currently used in infant formulas contain adequate amounts of all essential amino acids, i.e. the amounts of each in the volume of human milk necessary to provide the AI for protein intake of the 0- to 6-month-old infant and the RDA for protein intake of the 7- to 12-month-old infant, which is set at the amount deposited in body protein by infants of this age corrected for efficiency plus the same maintenance needs as the adult (Institute of Medicine, 2002).

The required intake of a specific protein depends upon how closely its amino acid pattern resembles that of human milk. Further, the overall quality of a specific protein can be improved by supplementing it with the essential amino acid(s) that result(s) in its quality being low, i.e. the limiting amino acid. Native soy protein, for example, has insufficient methionine but, when fortified with methionine, the quality approaches or equals that of bovine milk protein (Fomon *et al.*, 1973).

The protein sources of most infant formulas, i.e. bovine milk protein and modern preparations of soy protein, like human milk protein, are very high quality proteins. Further, if properly processed, these proteins are utilized nearly as well as human milk protein. Thus, the amounts of these proteins needed are not much higher than the amount of human milk protein needed (Räihä, 1985). The recent DRIs for protein are considerably lower than previous RDAs (i.e. ~1.5 vs. 2.2 g/kg/day) throughout the first year of life.

### Electrolytes, Minerals, and Vitamins

The normal infant's needs for electrolytes, minerals, and vitamins are not as well defined as those for energy and protein. Reference intakes, therefore, are usually the mean intake of each by normally growing 0- to 6-month-old, breast-fed infants or the mean intake of each from human milk and complementary food by the 7- to 12-month-old infant (Table 40.1).

Although the normal newborn infant is thought to have sufficient stores of iron to meet requirements for 4 to 6 months, iron deficiency remains the most common nutrient deficiency syndrome in infancy. This reflects the fact that iron stores at birth as well as the absorption of iron are quite variable. Interestingly, although human milk contains less iron than most formulas, iron deficiency is less common in breast-fed infants. To prevent iron deficiency, routine iron supplementation of breast-fed infants and use of iron-fortified formulas for formula-fed infants is recommended (Committee on Nutrition, AAP, 2009a). The use of iron-fortified formulas in recent decades has dramatically reduced the incidence of iron deficiency and resultant neurodevelopmental delay.

If protein intake is adequate, vitamin deficiencies are rare; if not, deficiencies of nicotinic acid and choline, which are synthesized, respectively, from tryptophan and methionine, may develop. In contrast, if bovine milk and bovine milk formulas were not supplemented with vitamin D, hypovitaminosis D would be endemic among formula-fed infants, particularly those with limited exposure to sunlight. Since breast-fed infants may be as susceptible to development of vitamin D deficiency, routine vitamin D supplementation of breast-fed infants is recommended, particularly if exposure to sunlight is limited (Committee on Nutrition, AAP, 2009b; Institute of Medicine, 2011b).

Routine perinatal administration of vitamin K is recommended as prophylaxis against hemorrhagic disease of the newborn. Thereafter, deficiency of this vitamin is uncommon except in infants with conditions associated with fat malabsorption.

### **Water**

The normal infant's absolute requirement for water probably is considerably less than the DRIs, i.e. 700 mL/day for the 0- to 6-month-old and 800 mL/day for the 7- to 12-month-old. These are the amounts provided by the mean human milk intake of the 0- to 6-month-old and the mean intake of the 7- to 12-month-old from human milk plus complementary food. Because of higher obligate renal, pulmonary and dermal water losses as well as a higher overall metabolic rate, the infant is more susceptible to development of dehydration, with vomiting and/or diarrhea, particularly if solute intake is high. Thus, intake of high-solute foods (e.g. bovine milk) before a year of age is discouraged. The typical breast-fed infant or formula-fed infant usually consumes at least 150 mL/kg/day for the first several weeks of life. Although somewhat higher than

the AI, there is no reason to believe that a fluid intake of this amount is excessive.

### **Feeding in the Second 6 Months of Life**

By 6 months of age, the infant's capacity to digest and absorb a variety of dietary components as well as to metabolize, utilize, and excrete the absorbed products of digestion is near the capacity of the adult (Montgomery, 1991). Moreover, the infant is more active and beginning to explore his/her surroundings. With the eruption of teeth, the role of dietary carbohydrate in development of dental caries must be considered (Mandel, 1991). Consideration of the long-term effects of inadequate or excessive intake during infancy also assumes greater importance as does the psychosocial role of foods.

These latter considerations, rather than concerns about adequate amounts of nutrients, are the basis for many feeding practices advocated for the formula-fed infant during the second 6 months of life. While it is clear that all nutrient needs during this period can be met with reasonable amounts of currently available infant formulas, addition of other foods after 6 months of age is recommended. In contrast, the volume of milk produced by many women does not meet all nutrient needs of the breast-fed infant beyond 6 months of age. Thus, for these infants, complementary foods are an important source of nutrients.

By approximately 12 months of age, most infants have graduated successfully to table food and are content with three meals plus two to three snacks daily. Once a few teeth have erupted and tolerance of solid foods has been demonstrated, weaning can be completed.

Weaning or "follow-on" formulas are popular in many countries. These contain somewhat more protein than standard infant formulas. They also may have a lower fat content and a somewhat higher carbohydrate content. The types of fat and carbohydrate present are similar to those of standard infant formulas (vegetable oils and lactose plus corn-syrup solids). There is no convincing evidence that these formulas are superior to standard infant formulas or bovine milk.

Aside from the association of bottle feeding with dental caries (Mandel, 1991), little is known about either the potential hazards or the non-nutritional role of diet during the latter half of the first year of life. Thus, feeding practices during this period vary widely. None the less, recent surveys indicate that infants fed according to current

practices in the United States receive the reference intakes for most nutrients (Devaney *et al.*, 2004).

## Human Milk vs. Artificial Formula

The ready availability and safety of human milk coupled with the possibility that it may enhance intestinal development, resistance to infection and bonding between the mother and infant make human milk the perfect food for the normal infant. Thus, exclusive breastfeeding for the first 6 months of life with continued breastfeeding throughout the first year of life or longer is recommended (World Health Organization, 1995; Work Group on Breastfeeding, AAP, 1997). This recommendation is supported by evidence that breast-fed infants in both affluent and developing societies have fewer infections during early life than formula-fed infants (Kovar *et al.*, 1984; Brown *et al.*, 1989).

Despite this, it cannot automatically be assumed that maternal milk supply will be adequate and/or constant. Thus, it is essential that breast-fed infants, particularly first-born infants, be followed closely over the first few days to weeks of life to ensure that growth and development are proceeding normally. With proper counseling, most problems with breastfeeding can be corrected and/or avoided.

In large part, the historical problems associated with artificial feeding have been solved. The safety and easy digestibility of modern infant formulas approach the safety and digestibility of breast milk. Further, the clear economic advantages and microbiological safety of breastfeeding are of lesser importance for affluent, developed societies with ready access to clean water and refrigeration than for less developed, less affluent societies. Thus, as advocated by Fomon (1993), a reasonable and conservative approach is to allow the mother to make an informed choice of how she wishes to feed her infant and support her in that decision. As stated by Fomon (1993):

... any woman with the least inclination toward breast feeding should be encouraged to do so, and all assistance possible should be provided by nurses, physicians, nutritionists and other health workers. At the same time, there is little justification for attempts to coerce women to breast feed. No woman in an industrialized country should be made to feel guilty because she elects not to breast feed her infant.

Several formulas are available for feeding the infant who is not breast-fed. All contain the DRIs recommended by the Life Sciences Research Organization (LSRO) (Raiten

*et al.*, 1998) and the European Society of Gastroenterology, Hepatology and Nutrition (Koletzko *et al.*, 2005). Some of these are shown in Table 40.2. Most are available in both a “ready-to-use” and a concentrated liquid form. Powdered products also are available and are being used with increasing frequency. These products usually are the only ones available in many parts of the world.

The most commonly used infant formulas contain mixtures of bovine whey proteins and caseins at a total protein concentration of about 1.5 g/dL. Thus, the infant who receives from 150 to 180 ml/kg/day receives a protein intake of between 2.25 and 2.7 g/kg/day, or as much as 50% more than the intake of the breast-fed infant and, hence, the recent DRI for protein.

At one time, unmodified bovine milk protein, which has a whey:casein ratio of 18:82, was the protein source of all bovine milk formulas. Today, however, the majority of bovine milk formulas available in the United States contain mixtures of bovine milk protein and bovine whey proteins or mixtures of bovine whey proteins and caseins. The casein- and whey-predominant bovine milk formulas are equally efficacious for the normal-term infant.

Formulas containing soy protein as the protein source are available. These are intended for feeding infants who are intolerant of bovine milk protein. (Note: this is different from “soy milk.”) Formulas containing partially hydrolyzed bovine milk protein are also available as are formulas containing only amino acids. These are intended for infants who are intolerant of both bovine milk and/or soy protein.

The major carbohydrate of most bovine milk formulas is lactose. Soy protein formulas usually contain either sucrose or a glucose polymer. Thus, these formulas are useful for the infant with either transient or congenital lactase deficiency.

The fat content of both bovine milk and soy protein formulas accounts for about 50% of the non-protein energy, and the blend of vegetable oils present in most formulas results in absorption of at least 90% of the ingested fat. Most formulas provide adequate intakes of the essential fatty acids, linoleic and  $\alpha$ -linolenic acid. Many also contain the longer-chain, more unsaturated derivatives of these fatty acids (long-chain polyunsaturated fatty acids, or LC-PUFA) that are thought by some to contribute to the better neurodevelopmental outcome of breast-fed vs. formula-fed infants (see below).

The electrolyte, mineral, and vitamin contents of most formulas are similar and, when fed in adequate amounts

(150–180 mL/kg/day), provide the DRIs of these nutrients (Table 40.3). Both iron-supplemented (~12 mg/L) and non-supplemented (~1 mg/L) formulas are available; as mentioned above, iron-supplemented formulas are recommended. Many, in fact, favor making non-supplemented formulas unavailable.

The goal of both breastfeeding and formula-feeding is to deliver enough nutrients to support normal growth and development. As a rule of thumb, the normal-term infant's weight should double by 4–5 months of age and triple by 12 months of age. In general, unless an infant has other

problems, normal growth is accompanied by normal development. Demand feeding is considered preferable, particularly during the early weeks of life. However, most infants easily adjust to roughly an every 3- or 4-hour schedule and, after 2 months of age, rarely demand night feedings.

## Complementary Feeding

Although all nutrient needs for the first year of life can be met with reasonable amounts of currently available infant

formulas, addition of other foods after about 6 months of age is recommended. In contrast, the volume of milk produced by many women may not be adequate to meet all nutrient needs beyond 6 months of age. This is particularly true for iron. Thus, for breast-fed infants, complementary foods are an important source of nutrients.

These foods should be introduced in a stepwise fashion to both breast-fed and formula-fed infants, beginning about the time the infant is able to sit without support. In the United States, rice cereal is usually the first such food given. It and other cereals are good sources of iron but rice cereal is less allergenic and unlikely to cause problems unless there is a family history of food and other allergies. Vegetables and fruits are usually introduced next, followed shortly by meats and, finally, eggs. Increasingly, meats are recommended as among the first foods. These are a good source of iron and zinc.

The order in which complementary foods are introduced is not crucial unless there is a family history of food and/or other allergies. However, it is recommended that only one new food be introduced at a time and that additional new foods should be spaced by at least 3 days to allow detection of adverse reactions to each newly introduced food.

Either home-prepared or manufactured complementary foods are available. The latter are convenient and also likely to contain less salt. Many such products also have supplemental nutrients (e.g. iron) and are available in different consistencies to match the infant's ability to tolerate larger size particles as he or she matures.

Prepared dinners and soups containing a meat and one or more vegetables are quite popular. However, the protein content of these products is not as high as that of strained meat. Puddings and desserts also are popular but, aside from their milk and egg content, are poor sources of nutrients other than energy; thus, intakes of these should be limited. Moreover, intake of egg-containing products should be delayed, especially if there is a family history of food and/or other allergies, until after the infant has demonstrated tolerance to eggs (either a mashed hard boiled egg yolk or a commercial egg yolk preparation).

## Infant Formula vs. Bovine Milk

Although current recommendations are to limit the intake of bovine milk and to avoid low-fat or skimmed milk prior to a year of age (Committee on Nutrition, AAP, 1992), recent surveys show that some 6- to 12-month-old infants, albeit fewer than two decades ago (Martinez *et al.*, 1985;

Ryan *et al.*, 1987), are fed bovine milk rather than infant formula (Fox *et al.*, 2004). More important, many of these infants are fed low-fat or skimmed milk – often, interestingly, on the advice of their physician.

The consequences of this practice, if any, are not known. However, infants fed bovine milk ingest three to four times the DRI of protein and considerably more sodium than the DRI of this electrolyte but less iron and linoleic acid than the DRIs of these nutrients. Ingestion of bovine milk also increases intestinal blood loss and, hence, contributes to development of iron-deficiency anemia (Ziegler *et al.*, 1990).

The protein and sodium intakes of infants fed skimmed rather than whole bovine milk are even higher, the iron intake is equally low, and the intake of linoleic acid is very low. Ironically, while the most common reason for substituting low-fat or skimmed milk for whole milk or formula is to reduce fat and energy intakes, the total energy intake of infants fed skimmed milk is not lower than that of infants fed whole milk or formula (Martinez *et al.*, 1985). This suggests that the infants compensate for the lower energy density of low-fat milk by taking more of it and/or increasing intake of other foods.

Whether the protein and sodium intakes of infants fed whole or skimmed bovine milk warrant concern is not certain. The low iron intake, clearly, is undesirable and may be accompanied by neurodevelopmental delay but medicinal iron supplementation should prevent development of iron deficiency. The low intake of linoleic acid may be more problematical. While signs and/or symptoms of essential fatty acid deficiency appear to be uncommon in infants fed whole or skimmed milk, an exhaustive search for such symptoms has not been made. Moreover, since essential fatty acid deficiency develops in both younger and older infants fed a low content of linoleic acid (Pettei *et al.*, 1991), it is likely that such a search would reveal a reasonably high incidence of biochemical deficiency. On the other hand, infants who were breast-fed or fed formulas with high linoleic acid content early in life may have sufficient body stores to limit the consequences of a low intake later. Since essential fatty acid deficiency in animals is associated with long-term deleterious effects on development (Crawford *et al.*, 1981), it is not wise to assume that biochemical essential fatty acid deficiency without clinically detectable symptoms is without consequences.

Resolving the issues concerning the use of bovine milk is important for economic as well as health reasons. Since the cost of bovine milk is less than half that of infant formula, replacing formula with homogenized bovine milk

obviously would have important economic advantages for many families. In addition, if the Federal Food Assistance programs could provide homogenized bovine milk rather than formula to infants over 6 months of age, the current funds allocated to these programs would permit expansion of benefits to many more needy infants. Clearly, this cannot be considered without further data concerning the consequences of feeding bovine milk.

The practice of substituting skimmed or low-fat milk for whole milk or formula raises a number of more complex questions. For example, the suggestion that infants fed skimmed milk increase their intake of milk and/or other foods to maintain energy intake raises the important question of whether the amount of food intake during infancy may, in some way, imprint intake patterns throughout life. If so, this attempt to improve longevity, or at least cardiovascular health, paradoxically is likely to be more detrimental than a less prudent diet during infancy.

### Long-Chain Polyunsaturated Fatty Acids

Long-chain polyunsaturated fatty acids, by definition, are more than 18 carbons in length and have more than two double bonds. There are several such fatty acids but those that are most relevant to infant nutrition are arachidonic acid (ARA; 20:4n-6) and docosahexaenoic acid (DHA; 22:6n-3). These fatty acids are the most prevalent n-6 and n-3 fatty acids, respectively, in the central nervous system and the latter comprises up to 40% of the fatty acid content of retinal photoreceptor membranes (Martinez, 1992).

Both ARA and DHA can be synthesized, respectively, from the essential fatty acids, linoleic acid (LA; 18:2n-6) and  $\alpha$ -linolenic acid (ALA; 18:3n-3). These fatty acids undergo a series of desaturation and elongation reactions. Thus, the two families compete with each other for the desaturases and elongases involved. These enzymes prefer the n-3 fatty acids but the ratio of the two fatty acids in the diet can be an important determinant of the amount of each LC-PUFA synthesized.

Both term and preterm infants can convert LA and ALA, respectively, to ARA and DHA (Demmelmair *et al.*, 1995; Carnielli *et al.*, 1996; Salem *et al.*, 1996; Sauerwald *et al.*, 1996; Uauy *et al.*, 2000). However, the content of ARA and DHA in plasma and erythrocyte lipids of infants fed unsupplemented formulas is lower than in plasma and erythrocyte lipids of breast-fed infants (Putnam *et al.*, 1982). In addition, autopsy studies show

that the low erythrocyte lipid content of DHA, but not ARA, is accompanied by a lower concentration in brain (Makrides *et al.*, 1994). These differences probably reflect the presence of both fatty acids in human milk but not unsupplemented formula, suggesting that the synthetic pathway does not synthesize enough DHA. The better cognitive development of breast-fed vs. formula-fed infants also has been attributed to the presence of ARA and DHA in human milk (Rogan and Gladen, 1993; Pollock, 1994). In addition, since studies in both rodents and primates have shown that deficiency of n-3 fatty acids compromises visual function (Benolken *et al.*, 1973; Neuringer *et al.*, 1986), a number of studies have addressed differences in visual function of breast-fed vs. formula-fed infants.

Human milk contains a number of factors other than LC-PUFA that are important for development. Thus, the specific role of LC-PUFA in visual and cognitive development cannot be determined by studies of breast-fed vs. formula-fed infants. Moreover, there are major psychosocial and socioeconomic differences between mothers who choose to breast feed rather than formula feed their infants. Thus, many studies have addressed differences in visual function and/or neurodevelopmental status of infants fed LC-PUFA-supplemented vs. unsupplemented formulas. Some of these have shown distinct advantages of LC-PUFA supplementation but others have not. These are discussed more fully by Heird and Lapillonne (2005). The magnitude of the advantage of LC-PUFA supplementation of formulas for visual function in term infants equates to no more than one line on the Snellen chart and this advantage is not apparent at all ages.

Data concerning the effects of LC-PUFA on neurodevelopmental outcome are equally unclear. Some studies have shown up to a  $\sim 0.5$  standard deviation advantage in the Bailey MDI at 18 months of age in infants fed DHA-supplemented vs. unsupplemented formula for the first 4 months of life (Birch *et al.*, 2000). Others, however, have shown no advantages of DHA supplementation (Makrides *et al.*, 2000; Auestad *et al.*, 2001). None, however, has shown disadvantages.

Because of uncertainty concerning the functional effects of LC-PUFA, criticisms of methods used in studies to assess visual function and neurodevelopmental status, and concern about the safety of many of the sources available for supplementation of formulas, a panel of experts chosen by the LSRO to make recommendations for the nutrient content of term infant formulas failed to recommend addi-

tion of LC-PUFA to formulas manufactured and marketed in the United States (Raiten *et al.*, 1998). On the other hand, panels appointed by other agencies evaluating the same data recommend that formulas for term and, particularly, preterm infants be supplemented with LC-PUFA (British Nutrition Foundation, 1992; Food and Agriculture Organization, 1994) and such formulas have been available for more than a decade. Whether they are efficacious remains to be determined.

## Future Directions

Although most infants in modern industrialized countries, whether breast-fed or formula-fed, grow and develop normally, a number of important issues relative to infant nutrition remain unresolved. Some of these are discussed briefly in the preceding sections. Others have been mentioned but not discussed, and still others have not been mentioned. Since it clearly is impossible to discuss all the relevant issues, only those that the author feels should receive the highest priority are discussed.

One such issue is the impact of size at birth and later on subsequent cardiovascular health. Epidemiological studies show a strong relationship between low birth weight as well as low weight at 1 year of age and the incidence of obesity, hypertension, diabetes, and/or cardiovascular disease in adolescence and adulthood (Barker, 1992; Eriksson *et al.*, 1993). Subsequent studies suggested that the risk of adult disease may be greater in those who are small at birth or a year of age but grow rapidly thereafter (Hales and Ozanne, 2003). Studies showing that preterm infants fed formulas that promote more rapid growth for only 4 weeks prior to hospital discharge have higher neurodevelopmental scores at 18 months (Lucas *et al.*, 1990) and 7 years (Lucas *et al.*, 1998) than those fed a less nutrient-dense formula during initial hospitalization. However, the former group has a higher incidence of risk factors for cardiovascular health at 14 to 16 years of age (Singhal *et al.*, 2004). Unraveling these issues obviously will yield important insights concerning optimal nutrition and, hence, growth during early life.

A related issue concerns the effect of intake during early life and intake thereafter. For example, do infants who are overfed tend to eat excessively once they begin feeding themselves? If so, could this contribute to the current epidemic of obesity in children as well as adults?

A final issue of particular relevance is the low prevalence of exclusive breastfeeding for the first 4 to 6 months of life

and the even lower prevalence of breastfeeding for a year or longer, as currently recommended (World Health Organization, 1995; Work Group on Breastfeeding, AAP, 1997). While more than 75% of mothers in the United States begin breastfeeding, fewer than half are still doing so 3 months later. One reason for this may be that many modern mothers work outside the home, many of economic necessity, and today's maternity-leave policies in the United States and other countries make it necessary for many to return to work before the infant is 4 months old. The lack of facilities for collecting breast milk at work and the scarcity of on-site child-care facilities are additional factors making it difficult for women to continue breast feeding after returning to work.

While the need to return to work and the difficulty of continuing to breastfeed after doing so is a logical explanation for the low prevalence of breastfeeding, definitive proof for this explanation is lacking. This is unfortunate since business executives and government officials are unlikely to be enthusiastic about supporting expensive changes in maternity leave and child-care policies that may not increase the prevalence of breastfeeding. These officials also are likely to want data substantiating the advantages of exclusive breastfeeding for the first 6 months of life and continued breastfeeding for the next 6 months, or longer. Such advantages are easy to substantiate in developing countries, where alternatives to breastfeeding are prohibitively expensive or hazardous; however, they are much more difficult to substantiate in more affluent societies. None the less, until this is done, it is unlikely that the expensive social changes that might increase the duration of breastfeeding will be instituted, or that the prevalence of breastfeeding as currently recommended will increase.

## Acknowledgments

## ADOLESCENCE

ASIM MAQBOOL, MD, KELLY A. DOUGHERTY, PhD,  
ELIZABETH P. PARKS, MD, MSCE, AND VIRGINIA A. STALLINGS, MD

*University of Pennsylvania, Perelman School of Medicine, Philadelphia, Pennsylvania, USA*

### Summary

Adolescence represents an important period of growth and development, for which there are specific nutritional needs and considerations. Accrual of bone mass is critical during this stage. Gender-based divergence of specific micronutrient needs emerge during this period. Macronutrient intake, energy requirements and expenditure also change at this age, and hydration status for physically active adolescents is emerging as a very important consideration for health status. Eating behaviors and disorders also frequently emerge at this age. Adolescents are prone to develop eating disorders, and may be at risk for malnutrition from anorexia, bulimia, obesity, and dyslipidemias, which may carry lifelong consequences for health and disease. Preconceptional nutritional status is key to all females of childbearing age, and unique to the adolescent pregnancy are the nutritional and growth needs of both mother and fetus, which may pose specific nutritional concerns and risks.

### Introduction

Adolescence is an important period during which major biological, social, physiological, and cognitive changes take place. Adolescents have special nutritional needs as a result of rapid growth (lean body mass, fat mass, bone mineralization) and maturational changes associated with the onset of puberty. Dietary surveys show that most adolescents do not meet age and gender nutrient recommendations and have inadequate dietary intake of calcium, iron, thiamin, riboflavin, and vitamins A and C (Skiba *et al.*, 1997). Despite their poor dietary intakes, the only clinical nutrient deficiency commonly seen among adolescents is iron-deficiency anemia. Iron deficiency is the most common

nutritional deficiency worldwide, and per the 1999–2000 United States National Health and Nutrition Examination Survey (NHANES) has a prevalence of 5% for males 12–15 years of age, and of 12% for females 12–15 years of age (Centers for Disease Control and Prevention [CDC], 2002). Women of childbearing age may be at the highest risk for iron-deficiency anemia. The global prevalence of anemia is estimated to be 30% in non-pregnant women, rising to 47% during pregnancy (de Benoist, 2008). Iron deficiency during pregnancy bears fetal consequences (low birth weight, preterm delivery) and affects cognitive and physical development of infants, children, and adolescents, and also has an effect on work capacity (Haas and Brownlie, 2001; Rasmussen, 2001). This data

underlies the importance of the nutritional status of adolescent females of childbearing age in particular, as preconceptional nutritional status is critical to their health and that of their babies.

An increasing number of adolescents have problems with excess food intake and obesity. In the United States, obesity prevalence in youths aged 12–19 has increased dramatically from 5% to 18% when comparing NHANES data from 1976–1980 with data in 2007–2008 (Ogden and Carroll, 2010). Obesity is a global concern. The prevalence is increasing worldwide, often in parallel with the nutrition transition from traditional to the modern western diet, with obesity now coexisting in communities where malnutrition from calorie and nutrient deficits had been prevalent (Caballero and Popkin, 2002).

In this chapter we will discuss growth changes, nutritional needs, nutritional assessment, and nutrition-related issues applicable to adolescence. Most of the material presented reflects data emanating from the United States and Canadian populations. The Dietary Reference Intakes published by the Food and Nutrition Board of the Institute of Medicine form the basis for many of the recommendations provided therein, with some global references also provided from the World Health Organization.

## Growth during Adolescence

The age at onset and rate of progression through puberty varies considerably among children (Tanner, 1962). Driven by hormonal changes, resulting alterations in body size, body composition (muscle, fat, bone), and sexual maturation are the basis for increased dietary requirements for energy, protein, and most micronutrients. Boys and girls of similar age differ in some nutritional requirements due to the male adolescent growth spurt occurring approximately 2 years later. Chronic disease and undernutrition can delay the onset of puberty (Zemel and Jenkins, 1989; Ramakrishan *et al.*, 1999; Zeitler *et al.*, 1999). In addition, growth is not a continuous process, but rather a series of small growth spurts varying in amplitude and frequency (Lampl *et al.*, 1993). All of these factors influence an adolescent's nutritional requirements, which will vary within and among individuals over the age range. Adequate nutritional intake is necessary to support a normal pattern of growth and maturation.

The onset of puberty varies by ethnicity. In a national sample of US boys and girls (National Health and Nutrition Examination Survey – NHANES III 1988–1994) evaluated at 8 to 19 years of age (Sun *et al.*, 2002), the median

ages of onset of pubic hair development were 11.2, 12.0, and 12.3 years for Non-Hispanic Black, Non-Hispanic White, and Mexican-American boys, respectively, and 9.4, 10.6, and 10.4 years for Non-Hispanic Black, Non-Hispanic White, and Mexican-American girls, respectively.

A comparison of NHANES III 1988–1994 with NHANES 1999–2002 indicates a decline in the age at menarche from 12.53 to 12.34 years (Anderson and Must, 2005). Higher relative weight was associated with increased likelihood of menarche, suggesting the US obesity epidemic may play a role in the trend for younger menarche. Menarche usually occurs just after the adolescent linear growth spurt. At peak adolescent linear growth velocity, the rate of increase in height is about 10.3 cm/year for boys (range 7.2–13.4) and 9.0 cm/year for girls (range 7.0–11.0) (Tanner, 1962). From the onset of the adolescent growth spurt to the attainment of adult stature, both boys and girls gain about 17% of their final height (Abbassi *et al.*, 1998).

During and following the adolescent growth spurt there is a rapid accrual of bone mass. Peak bone mass is achieved by the end of adolescence or early adulthood (Matkovic, 1992; Theintz *et al.*, 1992). Higher peak bone mass is associated with both greater dietary calcium intake and lower rates of hip fracture later in life (Matkovic, 1992). Thus, adequate calcium intake to ensure optimal accrual of bone mass during childhood and adolescence may have important lifelong health implications (Weaver *et al.*, 1999). To accommodate rapid gains, calcium requirements are higher for adolescents than for children or adults. The recommended dietary allowance (RDA) for calcium and intake data from two NHANES surveys is shown in Table 41.1. The RDA is defined as the average daily dietary nutrient intake level sufficient to meet the nutrient requirement of nearly all healthy individuals (97–98%) in a particular life stage and gender group (Institute of Medicine, 2006).

## Nutritional Needs of Adolescents

Nutritional needs of adolescents are higher than those of children because of rapid growth, sexual maturation, changes in body composition, skeletal mineralization, and changes in physical activity. Physical activity is not necessarily increased, but total energy needs are increased because of larger body size and, in particular, fat-free mass. Unlike children, adolescent males and females differ in their nutritional needs, and some of these sex-based dif-

**TABLE 41.1** Calcium intake (mg/day) for males and females from the National Health and Nutrition Examination 1988–1991 and 1999–2000 surveys

Population group	Males		Females	
	6–11 years	12–15 years	6–11 years	12–15 years
1988–1992 <sup>a</sup>				
Non-Hispanic white	994	822	822	744
Non-Hispanic black	761	688	688	613
Mexican-American	986	890	890	790
1999–2000 <sup>b</sup>				
All race/ethnic groups	843	956	812	661

Recommended dietary allowance of calcium for 4- to 8-year-old children is 1000 mg/day, and 1300 mg/day for children 9–18 years of age (Institute of Medicine, 2010a).

<sup>a</sup>Data from Alaimo *et al.* (1994).

<sup>b</sup>Data from Ervin *et al.* (2004a).

ferences continue into adulthood. Substantial differences in body composition occur, with relatively increased body fat for females and increased lean body mass for males. Nutrient needs are increased for protein, energy, calcium, iron, and zinc. Importantly, preconceptional nutritional considerations are key for females of child-bearing age. Recommended dietary intakes for adolescents (Institute of Medicine, 1998) often represent interpolations based on known requirements for children and adults rather than evidence from adolescent subjects. Nutrient requirements are usually greater for males than for females and for pregnant and lactating females than for non-pregnant females. Review of the Dietary Reference Intakes by age and gender reflect and illustrate the divergent needs for specific nutrients by age and gender.

Often, adolescents' dietary habits differ from those of children and adults. Adolescents tend to skip meals, eat more meals outside their home, and eat snacks (especially soda, candy, and diet and fast foods): up to 20% of adolescents skip breakfast (Videon and Manning, 2003). Some develop strongly held food beliefs, adopt food fads, or become vegetarians. These diet patterns may reflect an expression of independence, a busy lifestyle, alterations of body image perception, or an expression of self-identity, or they may be secondary to peer and social pressures.

Typically, intake of calcium, iron, and vitamins A and C are insufficient in the diets of US adolescents, with boys having somewhat better intake than girls. Adolescents often have high intakes of soda, coffee, tea, and alcohol, and low intakes of milk and juice (Dwyer, 1996). In a large survey of 12 500 children aged 11–18 years, Cavadini and colleagues showed that total energy intake, as well as the proportion of total fat and saturated fat, unexpectedly decreased from 1965 to 1996 (Cavadini *et al.*, 2000). Total milk consumption decreased, accompanied by an increase

in intake of soft drinks and non-citrus juices. Among US high-school students surveyed between 1999 and 2003, only about 17% reported drinking more than three glasses of milk daily (Centers for Disease Control and Prevention, 2005). Fruit and vegetable intake was lower than the recommended five servings per day, and folate, iron, and calcium intakes were lower than stipulated in the recommendations (Institute of Medicine, 1997, 1998, 2001; Cavadini *et al.*, 2000). In adolescent females and low-income youth in general, vitamins B<sub>6</sub>, A, E, iron, calcium, and zinc intakes were low (Story and Alton, 1996). In the typical American adolescent's diet, french fried white potatoes make up 25% of all vegetables consumed; intake of simple sugars exceeds the intake of complex carbohydrates; and more than a third of the dietary fat is saturated fat (Krebs-Smith *et al.*, 1996; Munoz *et al.*, 1997). Additionally, foods with high added simple-sugar content (which in general have fewer nutrients than foods with naturally occurring sugars, have limited nutritional value beyond providing calories, and are commonly referred to as "junk food") and high-fat fast food account for >33% of the daily caloric intake (USDA, 2005).

About 23% of high-school students surveyed between 1999 and 2003 in the National Youth Risk Behavior Survey (Eaton *et al.*, 2010) ate the recommended  $\geq 5$  servings of fruits and vegetables per day. In an earlier survey, fruit and vegetable intake was found to be higher in whites than in adolescents from other ethnic groups (Dwyer, 1996).

Recommendations for adolescent nutrient intake from various sources stress the need for the following: increased intake of calcium-rich and iron-containing foods in adolescent girls; limitation of foods high in simple sugars; decrease in the intake of complex carbohydrate foods that could be retained in the mouth and contribute to dental

**TABLE 41.2** Equations for estimating energy requirement (EER) for adolescents and physical activity level (PAL)

Adolescent group and activity level	Equation
<i>EER by gender</i>	EER (kcal/day) = Total energy expenditure + Energy deposition
<b>Males</b>	
9–18 years	$EER = 88.5 - (61.9 \times \text{age [years]}) + PAL \times [(26.7 \times \text{weight [kg]}) + (903 \times \text{height [m]}) + 25]$
<b>Females</b>	
9–18 years	$EER = 135.3 - (30.8 \times \text{age [years]}) + PAL \times [(10.0 \times \text{weight [kg]}) + (934 \times \text{height [m]}) + 25]$
<i>Pregnancy EER by trimester</i>	EER (kcal /day) = Non-pregnant EER + Pregnancy energy deposition
1st trimester	EER = Non-pregnant EER; needs are not increased
2nd trimester	EER = Non-pregnant EER + 340
3rd trimester	EER = Non-pregnant EER + 452
<i>Lactation EER</i>	EER (kcal/day) = Non-pregnant EER + milk energy output – weight loss
0–6 months postpartum	EER = non-pregnant EER + 500 – 170
7–12 months postpartum	EER = non-pregnant EER + 400 – 0
<i>Physical activity level (PAL)</i>	
Sedentary	PAL >1.0 <1.4
Low active	PAL >1.4 <1.6
Active	PAL >1.6 <1.9
Very active	PAL >1.9 <2.5

Adapted from Institute of Medicine (2006).

caries; use of fluoridated water, dentifrices, topical treatments, and rinses to prevent dental caries; limitation of fat intake to <30% of energy intake, with saturated fat intake <10% and cholesterol <300 mg/day; limitation of salt intake to <6 g/day and daily protein intake more than twice the RDA. The American Academy of Pediatrics recommends that 20–30% of total energy intake should be from dietary fat for this period of rapid adolescent growth (American Academy of Pediatrics, 2004).

### Energy

The exact energy requirement of the individual is difficult to determine (Gong and Heald, 1999). The Dietary Reference Intakes (DRI) issued by the Food and Nutrition Board of the Institute of Medicine provide a method for estimating the requirement for energy as a set of Estimated Energy Requirements (EER, kcal/day) prediction equations (Table 41.2) (Institute of Medicine, 2002). Specifically, the EER for adolescents estimates dietary energy needs by age, gender, weight, and height, and for growth and development changes (as energy deposition for

the accretion of new tissue) and a range of physical activity levels (PAL). The four PAL categories are: sedentary, low active, active, and very active (Table 41.2). Determining the appropriate PAL for individuals remains a challenge. In general, peak energy requirements occur in girls at about 15 to 16 years of age and in boys at about 18 years of age. Active adolescent females require about 2300 kcal/day, whereas males require 2600–3300 kcal/day. Energy needs increase during the second and third trimester of pregnancy and during the first and second 6 months of lactation (Institute of Medicine, 2002). EER are available to estimate energy needs for obese adolescent females and males (Institute of Medicine, 2002).

The NHANES III Survey showed that energy intakes were higher for males than for females, and intakes peaked in late adolescence (Bialostosky *et al.*, 2002). Despite a trend toward decreasing dietary fat intake, fat intake is still higher than recommended (Dwyer, 1996). The dietary reference intakes provide guidance regarding macronutrient distribution, with total fat intake to provide 25–35%, carbohydrates 45–65%, and protein 10–30% of caloric

**TABLE 41.3** Dietary reference intakes (DRI) for total protein for adolescents by life stage and gender

Life-stage group	DRI values (g/kg/day)			
	Estimated average requirement <sup>a</sup>		Recommended dietary allowance <sup>b</sup>	
	Males	Females	Males	Females
9–13 years	0.76	0.76	0.95	0.95
14–18 years	0.73	0.71	0.85	0.85
Pregnancy	–	0.88	–	1.1
Lactation	–	1.05	–	1.3

<sup>a</sup>The average daily nutrient intake level estimated to meet the requirements of half of the healthy individuals in a group.

<sup>b</sup>The average daily intake level to meet the nutrient requirements of 97–98% of healthy individuals in a group.

Adapted from Institute of Medicine (2006).

intake. With respect to type of dietary fat intake, reducing intake of dietary cholesterol, *trans* fats, and saturated fats as much as possible while maintaining 5–10% of linoleic acid and 0.6–1.2% of  $\alpha$ -linoleic acid is recommended. Added sugars, such as those provided in carbonated soda beverages, have little nutritive value (Institute of Medicine, 2006).

### Protein

Protein recommendations are shown in Table 41.3. Most adolescents easily achieve these levels in the United States (Bialostosky *et al.*, 2002). Peak protein requirement coincides with peak energy needs, and corresponds to peak growth rates as opposed to chronological age: protein should account for 12–14% of energy intake. Adolescents at risk for low protein intake are those with eating disorders, malabsorption, chronic disease with anorexia, and socioeconomic limitations resulting in food insecurity. In the event of substantially inadequate energy intake, protein is used for energy, resulting in both protein and energy malnutrition.

### Micronutrients

#### Minerals

Many adolescents have inadequate micronutrient intakes, including calcium, iron, zinc, and magnesium. Calcium and phosphorus are essential for bone health. The former is required for bone mass accretion. Peak bone mass is usually attained by the age of 25, and calcium intake during adolescence is key for lifelong bone health. Though

dietary phosphorus intake is usually adequate, calcium intake is often inadequate in adolescents. National surveys show that calcium intake is less than recommended, and has generally declined over the last 20-plus years. For example, among girls aged 15–18 years, the average calcium intake dropped from 680 mg/day in 1980 to 600 mg/day in 1990 (Albertson *et al.*, 1997). Among girls aged 12–19 years in the NHANES 1999–2000 dietary survey (Ervin *et al.*, 2004a), median calcium intake was 611 mg/day, which is about 51% of the currently recommended 1300 mg/day (Institute of Medicine, 1997). The 2003–2006 NHANES survey suggested that approximately 22% of males 9–13 years of age and 40% of males between 14 and 18 years of age exceeded the adequate intake (AI; the adequate intake of the dietary reference intakes is a recommended intake value based on observed or experimentally determined approximations or estimates of nutrient intake by a group [or groups] of healthy people that are assumed to be adequate, and is used when an RDA cannot be determined) (Institute of Medicine, 2010a). In contrast, only 13% of females between 9 and 13 years of age and 9.5% of females 14–18 years of age had a calcium intake in excess of the AI. Ethnic differences are also noteworthy: calcium intake is lower in Non-Hispanic Black compared with Non-Hispanic White and Mexican-American children and adolescents (Alaimo *et al.*, 1994). Net calcium absorption is highest in infancy and adolescence (Matkovic, 1991). However, it is unlikely that increased efficiency with inadequate intake is sufficient to optimize peak bone mass. Calcium is more efficiently absorbed in combination with lactose in foods, and dairy products provide about 55% of the calcium intake in the US diet. Calcium from other dietary sources is important, however, especially in communities where dairy products are not culturally preferred and for adolescents who have lactose intolerance. Calcium supplementation can increase bone mineral density in children (Johnston *et al.*, 1992), a finding that underscores the importance of adequate calcium intake from all sources.

Despite the iron fortification of many cereal grains, iron deficiency remains common. Iron needs are higher during adolescence because of increases in blood volume and muscle mass for both males and females. In females, needs are further increased by menstrual losses. Groups of adolescent females who are at increased risk for iron deficiency are older, pregnant or athletes. Median iron intake for 12- to 19-year-old girls in the NHANES 1999–2000 survey was 11.7 mg/day, about 78% of the 15 mg/day recommended

for girls aged 14–18 years (Institute of Medicine, 2001; Ervin *et al.*, 2004a). Iron deficiency during pregnancy results in an increased risk of preterm birth and low-birth-weight infants. Young pubertal boys are also at risk for iron-deficiency anemia and then iron needs decrease with slower growth after puberty. Iron deficiency is more common among low-income youth and is seen more often in adolescent females than in adolescent males (Dwyer, 1996). The prevalence of iron deficiency has increased for males 12–15 years of age from 1% (NHANES 1988–1994) to 5% (NHANES 1999–2000) but has remained stable for females at 9% in the United States across the same surveys (Centers for Disease Control and Prevention, 2002). Globally, approximately a quarter of the world's population has iron-deficiency anemia. The highest risk group for iron-deficiency anemia is non-pregnant women of child-bearing age – approximately 470 million of them, and the greatest prevalence by numbers occurs in Africa and Southeast Asia (de Benoist *et al.*, 2008).

Increased zinc is needed for growth and puberty, and zinc intake is often low in adolescents. Zinc deficiency is associated with growth retardation and hypogonadism, and zinc supplementation treats these clinical manifestations.

### Sodium Chloride

Sodium chloride (table salt) intake is excessive in the United States. NHANES III indicated more than 95% of men and 75% of women consumed more than the upper limit for salt. The sodium recommended for adolescents is 1500 mg/day, and the upper limit is 2300 mg/day; excess sodium intake is associated with risk for hypertension and cardiovascular disease. One teaspoon of table salt contains 2300 mg of sodium. Sodium is high in processed food (such as in hot dogs, processed lunch meats, canned soups, and some condiments), which provides an estimated 80% of intake. Reduction of sodium chloride intake is an important public health initiative (USDA, 2005). Conversely, potassium intake is most likely suboptimal (but not in the range to be associated with clinical findings such as cardiac arrhythmias, muscle weakness, and glucose intolerance). An increase in potassium supports lower blood pressure and reduces the negative health effect of sodium. The current recommended potassium intake for adolescents and adults is 4700 mg/day. While potassium chloride may be a useful and available substitute for sodium chloride, the current US recommendations are that potassium intake should come from food sources, not supplements (USDA, 2005; Institute of Medicine, 2006).

### Vitamins

Adolescents' diets are low in vitamins A, B<sub>6</sub>, E, D, C and folic acid. Because girls have lower food intakes than boys, dietary deficiencies are more common in girls (Institute of Medicine, 1998, 2001; Ervin *et al.*, 2004b). Folic acid is a key preconception micronutrient for females of child-bearing age. Folic acid deficiency is associated with increased risk for neural tube defects in the fetus, and ensuring adequate folic acid status before pregnancy by increasing dietary and supplement-based folic acid intake reduces this risk (Centers for Disease Control and Prevention, 1992). Therefore a key concept for all females of childbearing age is to establish optimal nutritional status prior to becoming pregnant.

Vitamin D is essential for bone health as well as many other functions. Vitamin D status is suboptimal among children and adolescents. Lower 25-hydroxyvitamin D levels are more common during the winter season, in individuals with a higher body mass index, and by race, with black race/ethnicity at higher risk than other groups (Rovner and O'Brien, 2008). Vitamin D is obtained via photoconversion of provitamin D at the dermal level by UVB exposure, and by food and supplement intake. Although daily sunlight exposure to the hands and face is sufficient to achieve adequate vitamin D levels in healthy adolescents (Holick, 1997), seasonal fluctuations in sunlight exposure, skin pigment, and health status may affect vitamin D status (Docio *et al.*, 1998). Inadequate intake may be greater in adolescent females than in males (Moore *et al.*, 2004). Adequate vitamin D levels are necessary to facilitate calcium absorption in the gut and for bone health. Newer data suggest that vitamin D influences health status in a myriad of ways, and, as such, the paradigm of optimal vitamin D status and blood concentration is now based on optimal health outcomes. Serum vitamin D status is now considered as a predictor of risk for chronic diseases, including susceptibility to infections, inflammation autoimmune disorders, cardiovascular and neurological disease, and some cancers. There are two important points to note here: first, the nature of the association, i.e. causality between vitamin D status and some of these diseases has not been established; secondly, optimal serum levels with respect to improved health outcomes are in the process of being established.

### Fiber

Adolescents ingest much less than recommended amounts of fiber (Williams *et al.*, 1995; Bialostosky *et al.*, 2002). Average fiber intake is about 12 g/day in comparison to

the 25 g/day recommended by the American Heart Association for blood cholesterol reduction and the 35–45 g/day recommended for reduction of colon cancer risk (Nicklas *et al.*, 1995). The DRI (Institute of Medicine, 2002) recommendations are for males aged 9–13 years to consume 31 g/day, and aged 14–18 years to consume 38 g/day. Female recommended intake is 26 g/day for ages 9–18 years.

## Nutritional Assessment

During the adolescent years, nutritional status assessment is complicated by the influence of puberty on weight, height, and body composition. In addition to standard growth charts (Kuczmarski *et al.*, 2000), height and height-velocity growth charts (Tanner and Davies, 1985), which include a classification for early and late onset of maturation, are useful to assess height growth relative to maturity status. For early- or late-maturing children whose growth deviates from the standard growth curve, these charts are important for the interpretation of growth velocity and patterns. Assessment of sexual maturity is classified according to the stages described by Tanner (1962) for both pubic hair and genital development in boys and for breast development in girls. A self-assessment pictorial questionnaire can be used to establish puberty stage (Morris and Udry, 1980). For assessment of weight-for-height status, the body mass index (BMI; expressed in kg/m<sup>2</sup>) is commonly used. With the use of BMI charts, a sex- and age-specific BMI percentile or *z* scores can be plotted in the same manner as for weight and height. BMI ≤5th percentile is considered underweight, ≥5th percentile to 84.9th percentile is considered normal weight range, ≥85th percentile is considered overweight, and ≥95th percentile is considered to be obese. Caution should be taken to interpret overweight children using only BMI for age and gender as some children may have relatively high weights primarily because of high lean mass rather than high body fat levels, especially in adolescent boys (Krebs *et al.*, 2007)

## Special Nutrition-related Issues

### Obesity

Obesity (defined as a BMI ≥95th percentile) (Kuczmarski *et al.*, 2002) is caused by an energy imbalance in which individuals expend less energy than they consume. A chronic, small energy surplus can have a large effect on weight gain over time and makes the prevention and treatment of obesity challenging.

**TABLE 41.4** Prevalence of obesity (≥95th percentile BMI) in adolescents (ages 12–19 years)

Time frame	Ethnic group		
	Non-Hispanic white	Non-Hispanic black	Mexican
<i>Boys</i>			
1976–1980	3.8	6.1	7.7
1988–1994	11.6	10.7	14.1
1999–2002	14.6	18.7	24.7
2007–2008	16.7	19.8	25.5
<i>Girls</i>			
1976–1980	4.6	10.7	8.8
1988–1994	8.9	16.3	13.4
1999–2002	12.7	23.6	19.6
2007–2008	14.5	29.2	17.5

Data from Hedley *et al.* (2004) and Ogden and Carroll (2010).

As previously stated, the prevalence of obesity in adolescence is increasing internationally (Caballero and Popkin, 2002). According to NHANES data the prevalence of obesity in children and adolescents in the United States has tripled between the 1960s and 2000 but has stabilized in 2003–2006 in children aged 2–19 years (Ogden *et al.*, 2008). (See Table 41.4.) Even with this stabilization, according to the NHANES 2007–2008 surveys, 34.3% of adolescents between the ages of 12–19 years are overweight (BMI ≥85th percentile), and 18.1% are obese (BMI ≥95th percentile) (Ogden and Carroll, 2010). The prevalence of US adolescents in the severe obesity category continues to rise. In 2007 there were 12.5% of adolescents classified as severely obese (BMI ≥97th percentile) as opposed to 4.8% in 2004 (Ogden *et al.*, 2008; Skelton *et al.*, 2009; Ogden and Carroll, 2010). Similarly, childhood obesity prevalence rates although still elevated appear to have stabilized after 2000 in France, and in 2004 in Germany, Poland, Switzerland, and England (Blucher *et al.*, 2009; Salanave *et al.*, 2009; Aeberli *et al.*, 2010; Stamatakis *et al.*, 2010).

The risk of becoming obese as a child and remaining obese as an adult is influenced by family history and by the child's age of onset. There is an 80% chance of an obese adolescent becoming an obese adult (Whitaker *et al.*, 1997). The risk associated with parental obesity is evidenced by the fact that 80% of children with two overweight parents were overweight, 40% of children with one overweight parent are overweight, and only 10% of children with no overweight parents become overweight. Additionally, it has been noted that children with obese

grandparents are about 18 times more likely to be obese than those with non-obese grandparents (Davis *et al.*, 2008). The risk of becoming an obese adult increases seven-fold for adolescents compared with preschool-aged children (Whitaker *et al.*, 1997). This age of obesity onset relationship reinforces the need to prevent and treat obesity in adolescence.

Adolescent physiologic and social challenges lend themselves to increased risk/exacerbation of obesity. The transition from the pubertal stages Tanner stage 1 to Tanner stage 3 is associated with increased fat deposition which is more pronounced in adolescent females who experience early menarche (<11.9 years of age) (Remsberg *et al.*, 2005). Additionally, increased independent food choices and decreased physical activity provide opportunities and challenges for adolescent weight management. Physical activity, dietary factors, sedentary activity, and other environmental influences are variables in adolescent obesity. Obese adolescents are less likely to participate in sports (Levin *et al.*, 2003). With regard to diet, for every additional serving of a sugar-sweetened beverage there is a six-fold increase in the odds of being obese (Ludwig *et al.*, 2001). Similarly, pre-adolescents and young adolescents were 5.5 times as likely to be overweight if they watched television >5 hours/day (Renna *et al.*, 2008). Other common environmental influences include supermarket availability, fast food restaurants and convenience store use, neighborhood safety, presence of a television in the bedroom, eating meals as a family, and family socioeconomic status (Kumanyika, 2008).

### Health Consequences of Obesity

Medical conditions that require immediate intervention (e.g. sleep apnea, type 2 diabetes, hypertension, non-alcoholic fatty liver disease) are increasingly common in obese adolescents (Box 41.1). Whereas at one point diabetes in children was almost entirely type 1, type 2 diabetes now accounts for 44% of all cases of diabetes in children (Nadeau and Dabelea, 2008) as opposed to 95% of diabetes in adults (Campbell, 2009). Eight-four percent of children diagnosed with type 2 diabetes are overweight or obese. The high prevalence of obesity in children with type 2 diabetes emphasizes the importance of glucose screening for diabetes in overweight and obese children (American Diabetes Association, 2000; Barlow, 2007).

Obesity is often associated with psychosocial complications for children and adolescents, including low self-esteem, poor body image, depression, and learning

### BOX 41.1 Medical conditions associated with obesity in adolescents

Hypertension  
Lipid disorders (especially hypertriglyceridemia and low HDL)  
Insulin resistance and type 2 diabetes  
Acanthosis nigricans  
Metabolic syndrome  
Orthopedic problems  
    Slipped capital femoral epiphysis  
    Blount's disease  
Cholelithiasis  
Non-alcoholic steatohepatitis  
Obstructive sleep apnea  
Polycystic ovary syndrome and menstrual irregularities  
Pseudotumor cerebri  
Psychosocial dysfunction

problems. Obese individuals are frequently the targets of social discrimination and stigmatization (Wang *et al.*, 2009). Obese adolescents suffer more frequently from low self-esteem than do overweight pre-adolescents, perhaps because of the greater influence of peers on self-esteem for adolescents (Wang *et al.*, 2009).

### Evaluation and Treatment

The assessment of an obese adolescent should include a routine history and physical examination, which includes a review for signs of obesity-related syndromes or conditions. Screening for associated conditions (e.g. hyperlipidemia, insulin resistance) or contributing processes (e.g. hypothyroidism) should be considered. Additionally, significant family dysfunction or adolescent psychological problems should also be evaluated (Barlow, 2007).

**Behavioral Treatment.** Lifestyle behavioral management should involve the family and others who are key to the adolescent's support. Target behaviors that have been demonstrated to be effective in obesity prevention and treatment include the limiting of sweetened beverages, energy-dense foods, portion sizes, and eating out in restaurants; restricting screen time (TV, computer, and video-games) to  $\leq 2$  hours daily; eating breakfast daily; eating as a family; and encouraging 1 hour of physical activity of a

**TABLE 41.5** Screening guidelines for hypercholesterolemia in adolescents

Indication for screening	Screening test
Total cholesterol >240 mg/dL (6.2 mmol/L) in parents	Non-fasting total cholesterol
Family history of premature heart disease; or total cholesterol >200 mg/dL (5.2 mmol/L)	Two fasting lipid profiles (total cholesterol, triglycerides, HDL, calculated LDL); average the results
Total cholesterol >170–199 mg/dL (4.4–5.2 mmol/L) in patient	Repeat total cholesterol; if average >170 mg/dL (4.4 mmol/L), proceed with lipid profile screening

To convert mg/dl to mmol/L, multiply by 0.02586. 1 lb = 454 g.  
Adapted from American Academy of Pediatrics (1992).

level equal to or greater than moderate on a daily basis (Barlow, 2007).

**Surgical Treatment.** Adolescents with a BMI  $\geq 50$  without co-morbidities or  $\geq 40$  with one or more co-morbidities who are Tanner stage 4 or 5 and have failed lifestyle behavioral management may be eligible for bariatric surgery. Compliance with postsurgical nutritional supplementation and weight management can be particularly challenging with adolescent patients. Bariatric surgery patients are susceptible to developing protein malnutrition, and thiamine, iron, vitamin B<sub>12</sub>, and fat-soluble-vitamin deficiencies (Woo, 2009).

### Hyperlipidemia

Adult cardiovascular disease has its roots in childhood and adolescence. The Bogalusa Heart Study and the Pathobiological Determinants of Atherosclerosis in Youth Research Group found correlations between early atherosclerotic changes seen at autopsy and both total and LDL cholesterol levels (Strong, 1986). These and other studies suggest that adolescents at risk of developing premature atherosclerosis should be identified to effect risk reduction for premature heart disease. Adolescents with cholesterol levels >75th percentile are considered hypercholesterolemic and potentially at risk for adult heart disease (Daniels and Greer, 2008; American Society for Bariatric Surgery, 2010).

Blood cholesterol levels track over time. Thus, adolescents with high cholesterol levels tend to have high levels as young adults. However, tracking is not perfect as cholesterol levels vary between genders and fluctuate with sexual maturation, growth, percentage body fat, and age (Daniels and Greer, 2008; American Society for Bariatric Surgery, 2010). These differences are reflected in the NHANES age- and gender-specific lipoprotein distri-

butions (Jolliffe and Janssen, 2008). Adolescents may have elevated cholesterol levels for a variety of reasons. Primary genetic defects, familial hyperlipidemia, and secondary medical causes of hyperlipoproteinemia should be considered. Inappropriate dietary habits, by themselves or by interaction with any of the above factors, can contribute to moderately raised cholesterol levels. Although a few children have a well defined familial hyperlipidemia, most individuals with hyperlipidemia do not have specific syndromes.

### Screening for Hypercholesterolemia

Adolescents with unavailable or positive family histories for dyslipidemia, or premature cardiovascular disease ( $\leq 55$  years of age for men and  $\leq 65$  years of age for women in a first-degree relative) or those with other risk factors for coronary heart disease such as hypertension (blood pressure  $\geq 95$ th percentile), diabetes mellitus, BMI  $\geq 85$ th percentile, cigarette smoking, or oral contraceptive use should be screened for hypercholesterolemia using a fasting lipid profile (Table 41.5) (Daniels and Greer, 2008).

### Treatment of Hyperlipidemia

Dietary modification is the hallmark for hypercholesterolemia treatment. Dietary goals are similar to those of adults (see Chapter 48, which looks at atherosclerotic disease). Diet modification in adolescents should include supervision by a registered pediatric dietitian in order to ensure a balanced diet that promotes normal growth and development. Besides dietary modification, other cardiovascular disease risk factors such as sedentary lifestyle, obesity, diabetes, hypertension, and smoking should be evaluated and minimized (Daniels and Greer, 2008).

Some adolescents require drug therapy. Children over the age of 8 with “pure” hyperlipidemia (specifically, increased LDL only) (based on the same guidelines as

adults) can be treated with cholestyramine and statins [3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors]. Although considered safe, cholestyramine has considerable gastrointestinal-related side-effects, and dosage commonly makes long-term compliance unsuccessful (Daniels and Greer, 2008).

### **Unhealthy Eating Practices and Eating Disorders**

Concomitant with puberty are a heightened awareness and preoccupation with body image and size. In the western world, the epitome of beauty is for girls to be tall and thin and for boys to be tall and muscular, and many adolescents are dissatisfied with their body image (American Academy of Pediatrics, 2003). Data from the 2008–2009 National Youth Risk Behavior Survey (Eaton *et al.*, 2010) showed that 28% of high-school students described themselves as overweight, with 44% actively trying to lose weight, the prevalence being higher in females (53%) compared with males (31%). By race, the prevalence was higher among white (61%), black (47%), and Hispanic (62%) female students compared with white (28%), black (26%), and Hispanic (42%) male students, respectively. Most students employed healthy measures to achieve weight loss such as eating less food overall or less calories or fat in their meals (28–52%) or exercising more frequently (62%). Yet a surprising proportion reported using increasingly less healthy methods to achieve weight loss such as not eating for more than 24 hours at least once within the 30 days prior to the survey (11%) or vomiting and using laxatives at least once within the past month (4–5%) (Eaton *et al.*, 2010). Complications associated with dieting and decreased energy intake include weight loss, delayed sexual maturation, menstrual irregularities, constipation, weakness, irritability, sleep problems, poor concentration, and impulses to binge eat (American Academy of Pediatrics, 2003).

The number of adolescents with eating disorders (anorexia nervosa and bulimia) has increased steadily since 1950 (Lukas, *et al.*, 1991; Hsu, 1996). Psychosocial issues such as environmental problems, low self-esteem, abnormal family dynamics, and depression are often associated with eating disorders (Rome *et al.*, 2003). Anorexia nervosa is characterized by a persistent, progressive, and severe restriction of food intake, often combined with excessive physical activity. Bulimia is characterized by binge eating that is followed by purging, induced vomiting, diuretic use, exercise, or fasting. While patients with eating disorders usually belong to the middle- or upper-income group,

eating disorders also occur in other economic groups (Kreipe and Dukarm, 1999). Biological factors include a familial increased incidence of eating disorders and neurotransmitter imbalance of serotonin and other neurotransmitters. Groups at risk for developing eating disorders include gymnasts, runners, ballet dancers, and some other athletes. Societal factors include stereotypical and unrealistic body images, women's role in society, and media pressure. The nutritional changes seen with eating disorders are those of malnutrition and starvation. Though most patients with binge-eating disorders are thin, some may be obese. Amenorrhea is usually seen in anorexia nervosa. In the malnourished patient, bradycardia, orthostatic hypotension, hypothermia, wasting, thin pale-colored hair, dry skin, alopecia, acrocyanosis, and poor capillary refill may be evident. Parotid gland enlargement, erosion of dental enamel, and abrasions over the metacarpophalangeal joints (Russell's sign) may be related to induced vomiting. Laboratory evaluation reveals electrolyte abnormalities (hypokalemic alkalosis), anemia, and mildly elevated liver enzymes (consistent with fatty infiltration of the liver seen with malnutrition).

### **Pregnancy**

Sexual activity among American adolescents has increased over the past decades. Predictive factors for sexual activity in early adolescent years include early puberty, poverty, history of sexual abuse, cultural and family patterns of early sexual experience, poor school performance, lack of school goals, and lack of attentive and nurturing parents (Felice *et al.*, 1999). Approximately 1 million teenagers become pregnant every year in the United States (Felice *et al.*, 1999) and the United States has the highest adolescent birth rate of all developed countries. Poverty is a significant factor in adolescent pregnancy (Felice *et al.*, 1999). Accompanying these adolescent pregnancies are challenges and concerns that differ from those that relate to the grown adult. These concerns are associated in the adolescent with increased risk for medical complications including intrauterine growth retardation, neonatal and maternal morbidity and mortality. Micronutrient-associated deficiencies may have consequences such as iron deficiency and anemia, which may have profound implications for the fetus. Intrauterine growth retardation and neonatal demise are greater risks for adolescents less than 14 years of age, and in the African-American population. Prenatal care has improved infant and maternal health and reduced morbidity and mortality.

Nutritional considerations must be borne in mind at the preconception stage, and since many of these pregnancies are unplanned, the considerations are those that are critical for all females at or near childbearing age, for example folic acid intake, and risk reduction for neural tube defects (American Academy of Pediatrics, 1999). Because many adolescent females who get pregnant are psychosocially at risk, efforts to optimize the nutritional support of pregnant teens may have long-term positive health effects on their children (Kleinman, 2009).

Prepregnancy weight is one of the major predictors of birth weight of the child. Both being underweight and overweight increases risk of poor reproductive health outcomes. Underweight females are at risk for preterm delivery, and intrauterine growth retardation is increased, with maternal height a predictor of the fetus's length. Overweight pregnant females are at increased risk for gestational diabetes, pregnancy-induced hypertension, and cesarean-section deliveries. Body mass index (BMI) classification may predict these risks and identify higher-risk individuals for interventions, ideally in the preconception stage but also for the purpose of providing prenatal guidelines. The Institute of Medicine has published new guidelines for total weight gain and rates of weight gain during pregnancy (specifically for the second and third trimesters of pregnancy) based on prepregnancy BMI (Institute of Medicine, 2010b). This information, in addition to weight gain by pediatric BMI classification schema, is summarized in Table 41.6. Weight gain in the first and second trimesters is related to improved birth weight (Hediger *et al.*, 1997). Nutrition and weight gain during the second and third trimester are of particular importance, as maternal deprivation during these critical periods of neonatal development may confer increased risk for chronic condi-

tions including diabetes and cardiovascular disease (Barker, 1995).

Pregnancy energy requirements are based on increased basal metabolic rate as well as energy deposition for accretion of maternal and fetal tissues. Energy requirements increase most in the third trimester. Evidence indicates that adolescent mothers continue to grow in stature and fat-free and bone mass during pregnancy. This growth may occur at the expense of the fetus and result in decreased birth weight despite maternal weight gain, or in suboptimal maternal nutritional status and growth. For this subset of pregnancies, requirements may vary by nutrient; for example, maternal calcium intake may influence bone loss in expectant adolescent females and their growth, as well as bone growth and development in their offspring. Additionally, reduced maternal ferritin, cord blood ferritin, and folate blood levels have been noted in the adolescents who grew during pregnancy (Scholl and Hediger, 1993; Scholl *et al.*, 1997). The fact that pregnant adolescents still grow implies that their nutrient needs are even greater than those for non-adolescent pregnant women. To accommodate the potential growth of the pregnant adolescent, recommendations for gestational weight gain are based on adult prepregnancy BMI, which, when applied to adolescents, results in them being categorized in a lighter weight group. The rationale here is that young teens require more weight gain than their adult counterparts to have infants born at the same size (Scholl, 2008; Institute of Medicine 2010b). Please refer to Chapter 39 of this book for further energy requirements and for macro- and micronutrient needs.

Other micronutrients may pose adverse risks to the fetus if ingested in excess. For example, although vitamin A is important for pregnancy, excessive exposure during the

**TABLE 41.6** New recommendations for total and rate of weight gain during pregnancy, by prepregnancy BMI

Prepregnancy BMI	BMI (kg/m <sup>2</sup> )	Pediatric BMI classification (percentiles)	Total weight gain (lb)	Rates of weight gain (lb/week) during the 2nd and 3rd trimester
Underweight	<18.5	<25th	28–40	1.0 (1–1.3)
Normal weight	18.5–24.9	25th–85th	25–35	1.0 (0.8–1)
Overweight	25.0–29.9	85th–95th	15–25	0.6 (0.5–0.7)
Obese	≥30.0	>95th	11–20	0.5 (0.4–0.6)

Adapted from Institute of Medicine (2010b).

first trimester poses teratogenic risks. Topical acne treatments, which contain synthetic retinol compounds, for example, pose specific increased risks. Exposure to alcohol and tobacco also causes adverse effects on the fetus, and adolescents may be particularly at risk for use of alcohol and tobacco. Glycemic control in adolescents with diabetes may reduce the risk of pregnancy complications and fetal loss as well as birth defects.

In summary, preconceptional as well as prenatal nutritional considerations in the growing adolescent have profound implications for maternal and child health. An underlying understanding of the weight and body-mass issues in adolescent growth and pregnancy, and establishing energy and macronutrient requirements and micronutrients at risk for deficiency or excess at key gestational stages are important determinants of health outcomes for mother and child. Nutritional education and counseling are an important part of pregnant adolescents' prenatal care. Pregnant teens should gain weight at the upper end of the recommended range for their prepregnancy weight (Institute of Medicine, 2010b). Weight gain in the first and second trimesters is related to improved birth weight (Hediger *et al.*, 1997). Pregnant and lactating teens also need additional calories (Institute of Medicine, 2002) and protein (Table 41.3), calcium, iron, vitamins B<sub>6</sub>, C, A, D, and folate. A prenatal supplement that contains vitamins A and D, zinc, calcium, folate, and iron is recommended.

### Vegetarianism

Adolescents may become vegetarians for many reasons including peer pressure, religious expression, humanitarian feelings, weight control, and self-expression, and these decisions for the most part should be respected. According to the American Dietetic Association, vegetarian diets that are appropriately planned and monitored are healthful and nutritionally adequate, and may provide health benefits in disease prevention and treatment (Craig and Mangels, 2009). It is important to know which type of vegetarianism the adolescent is practicing in order to assess the different nutritional risks (Table 41.7). The most common deficiencies include: vitamins B<sub>12</sub> and D, protein, calcium, iron, zinc, iodine, riboflavin, and essential fatty acids. The high fiber and low fat content of vegetarian foods are beneficial, and can result in decreased energy intake. Dietary protein may be used for energy, thus negatively affecting protein status. Because a purely vegetarian diet is deficient in vitamin B<sub>12</sub>, a supplement is needed. High intakes of grains can decrease intestinal absorption of iron,

**TABLE 41.7** Categories of vegetarianism and the associated nutritional risks

Category	Food allowances	Nutritional deficiency risk
Semi-vegetarian	Fish, chicken, milk, eggs	No additional nutritional risks
Lacto-ovo-vegetarian	Milk and eggs	Iron deficiency
Lacto-vegetarian	Milk products only	Iron deficiency
Vegan	No milk, eggs, fish, or meat of any kind	Vitamin B <sub>12</sub> , Vitamin D, zinc, calcium, essential fatty acids, and protein

Adapted from Craig and Mangels (2009).

calcium, and zinc. The vegetarian adolescent should learn about the core dietary principles, and plan a diet that is sufficient in energy, protein, and micronutrients. A daily multivitamin supplement may be beneficial.

Adolescent vegetarian diets are low in energy, with cereals being a major energy source. A study examining whether vegetarian adolescents meet the Healthy People 2010 objectives (Perry *et al.*, 2002) found that they were less likely to consume fast food, sugar-sweetened beverages, and cholesterol. Vegetarian adolescents consumed more folate and iron, and were more likely to consume less than 30% of calories from fat and to consume  $\geq 5$  servings of vegetables and fruit per day (Perry *et al.*, 2002). Vegetarians were more likely to engage in disordered eating behaviors such as binge eating, taking diet pills, intentional vomiting, and the use of laxatives and diuretics than non-vegetarians (Robinson-O'Brien *et al.*, 2009). Thus it is important to explore the reason for choosing a vegetarian diet as for some adolescents the practice of vegetarianism may mask an underlying eating disorder. With appropriate knowledge and guidance, a vegetarian diet for growing adolescents can be designed to meet their nutritional needs and to fit into the complex set of changes in their social, economic, and biological environments.

### Physical Activity and Sports Medicine

For adolescents, current physical activity recommendations include 60 minutes or more per day of moderate to vigorous physical activity (Physical Activity Guidelines

Steering Committee, 2008). Unfortunately, hypokinesia is prevalent among American adolescents, with most not meeting the prescribed intensity or duration of physical activity. From 2008 to 2009 only 18% of students in grades 9 to 12 engaged in physical activity that increased their heart rate and made them breathe hard for at least 60 minutes per day for all 7 days (Eaton *et al.*, 2010). The benefits of regular physical activity, including improved cardiorespiratory fitness, muscle strength, bone and mental health, and reductions in adiposity and disease risk factors are well documented (Physical Activity Guidelines Steering Committee, 2008). Thus, increasing physical activity levels among adolescents is vital for overall health and well-being.

Adequate energy intake for the adolescent is important to ensure proper growth, development, and maturation. Due to the greater energy expenditure from physical activity, the adolescent athlete will have additional nutritional needs. The onset of the adolescent growth spurt and concomitant increased energy requirements is variable. Thus, the estimated energy requirement is based upon equations that consider the adolescent's age, height, weight, and physical activity level classified as sedentary, moderately active, active or very active (Institute of Medicine, 2002, and see Table 41.2). Carbohydrate, fat, and protein in adequate amounts are important to support overall growth and development. Specific to physical activity, the glycolytic capacity of an adolescent may not be fully developed (Eriksson *et al.*, 1973; Eriksson and Saltin, 1974). Therefore fat may play as important a role as carbohydrate in supporting performance and endurance. Competitive athletes' diets commonly are deficient in calcium and iron. Iron needs are higher because of the decreased absorption during strenuous activity and increased losses in sweat and stool. Iron deficiency can lead to anemia with decreased endurance (Petrie *et al.*, 2004).

Adolescent athletes become progressively dehydrated when voluntary fluid intake is insufficient to match sweat losses. Dehydration is common in adolescents during team sports, with children routinely losing 1–3% body weight (Broad *et al.*, 1996; Casa *et al.*, 2005; Decher *et al.*, 2005). Compared with euhydration during exercise, dehydration as low as 2% of initial body weight in adolescents results in an elevated heart rate (Allen *et al.*, 1977) and body core temperature (Bar-Or *et al.*, 1980), suggesting that even low levels of dehydration result in greater physiological stress during exercise in this age group. Few studies have examined the impact of dehydration or pos-

sible performance-enhancing effects of various nutritional products (drinks, bars, gels) on sport-specific performance in adolescent athletes. Dougherty *et al.* (2006) showed that in skilled 12- to 15-year-old boys, basketball performance was impaired by 2% dehydration. Additionally, euhydration with a 6% carbohydrate electrolyte solution significantly improves shooting skill performance and on-court sprinting over euhydration with water alone. It is interesting to note that in this study, as in others (Walker *et al.*, 2004), although encouraged to stay well hydrated, adolescents often arrived for sports competitions already dehydrated by 1 to 2%. Previous studies suggest that, compared with water, flavoring a beverage attenuates the dehydration incurred during exercise in the heat whereas adding flavor plus 6% carbohydrates and 18 mmol/L NaCl prevents dehydration altogether (Wilk and Bar-Or, 1996; Wilk *et al.*, 1998). Thus, it appears that, to enhance drinking behavior in adolescents, beverages should be flavored and contain electrolytes and simple carbohydrates when used as true rehydration fluids in dehydrated young athletes.

## Future Directions

Many food and food-related products, advertising, and popular culture will continue to focus on adolescents as consumers. They have significant freedom in food choices and meal settings, and often are responsible for arranging their meals within a complex family, school, and social environment. With new guidelines for federally supported school meals and the snacks available in school settings, more healthful food and beverage choices and portion sizes will be a part of the adolescent experience. The adolescent obesity epidemic must call attention to the changes needed in nutrition and health awareness at the individual adolescent, family, clinical, and community level. The future direction for nutrition and adolescent health will be to support healthful food and activity choices to maintain a healthy weight. Emphasis will also be placed on ensuring that adolescent females enter young adulthood in optimal nutritional status to support the health and development of the children they may have in their third and fourth decades of life.

## Acknowledgments

Maria R. Mascarenhas, Babette Zemel and Andrew M. Tershakovec contributed to the Adolescence chapter in the

eighth edition of this chapter. Joan I. Schall contributed to the updates for the chapter in the ninth edition.

## NUTRITION AND AGING

MARION SECHER, MD, PATRICK RITZ, MD, PhD, AND BRUNO VELLAS, MD, PhD

*Gérontopôle de Toulouse, Toulouse, France*

### Summary

In the first part of this chapter, we present the effects of aging on nutritional status. We discuss the specificity of the evaluation of nutritional status in the older population, and then present four pathologies illustrating abnormal nutritional status: malnutrition, obesity, sarcopenia, and hydration disorders.

The second part of the chapter considers the effects of nutritional deficiencies on the older population. These are illustrated by three situations: frailty, osteoporosis, and cognitive decline and Alzheimer's disease.

### Introduction

The average age and the proportion of the population which is older increase every year: around the world the number of people aged 60 years and over was estimated at 600 million in 2000, a figure that is expected to rise to 1.2 billion by 2025 and 2 billion by 2050 (WHO, 2009).

Many of the physiological changes associated with aging can be slowed down to some extent by eating a healthy diet and taking physical exercise, and many of the chronic diseases prevalent in older adults are either preventable or modifiable with healthy lifestyle habits. Thus, older adults can experience successful aging that allows them to achieve physical, social and mental well-being over the life course and to participate in society.

Much research has been conducted in recent years to determine how to keep older adults fully functional, physically, mentally, and socially. This chapter examines some

of the areas of aging research currently being conducted, and addresses promising areas of research for the future.

### Effects of Aging on Nutritional Status

#### ***Evaluation of Nutritional Status in the Older Population***

Many geriatric assessment instruments have been developed to diagnose and treat high-risk situations in elderly patients. The major components of a geriatric assessment are:

- measurements of the functional status using Activities of Daily Living (ADL) (Katz, 1983) and Instrumental Activities of Daily Living (IADL) (Lawton and Brody, 1969);
- cognitive status using Mini-Mental State Examination (MMSE) (Folstein *et al.*, 1975);

- psychological health using Geriatric Depression Scale (GDS) (Yesavage *et al.*, 1982);
- physical status using Tinetti Balance and Gait Evaluation (Tinetti, 1986);
- a nutritional evaluation.

Nutritional status in the elderly can be best evaluated with a combination of several approaches using anthropometric, dietary, and biological parameters. Nutritional screening and assessment tools such as the Mini Nutritional Assessment (MNA<sup>®</sup>), which is an example of this combination of measurement systems, can also be used. This nutritional evaluation has to be repeated at times appropriate to the rhythm determined by the clinical setting (geriatric hospital, nursing home, community-dwelling) (Bauer *et al.*, 2010).

The single most important clinical aspect leading to diagnosis of malnutrition is weight change and especially unintentional weight loss. Weight loss is expressed as a percentage of a patient's usual weight or previous value. An able patient should be weighed in underwear or with light clothing, standing on a calibrated scale. Obtaining body weight may be challenging, particularly in frail patients or those with a disability. A calibrated chair or lifting scale should be used for patients who are unable to stand. When assessing body weight, some conditions such as the presence of edema or ascites have to be taken into account because they may lead to an overestimation of weight.

The calculation of Body Mass Index (BMI) (weight (kg)/height (m<sup>2</sup>)) requires measurement of patient's height. In dependent patients or those with kyphosis, stature can be estimated from knee height using Chumlea's formulae (Chumlea *et al.*, 1985). The patient must be able to fold the knee and the ankle to an angle of 90°. The knee-height caliper is used to measure length of the leg from the bottom of the foot to the top of the patella. Then, knee height is inserted into a mathematical formula and converted to stature. To estimate a patient's height, the measure of distance between the sternal notch to the finger roots can also be used (called demispan). Height is then calculated from a standard formula. Alternatively, instead of BMI, a Demiquet index can be computed directly from the demispan (Lehmann *et al.*, 1991). Nevertheless, BMI does not reflect the body composition (fat and muscle mass), and like weight it can be unreliable in the presence of confounding factors such as edema or ascites.

Skinfold measurement can be used as a reflection of fat mass (Frisancho and Flegel, 1982), but it is not an easy tool to use in clinical practice and it cannot be used to assess changes in body-fat mass because of age-related fat redistribution (Hughes *et al.*, 2004). Nevertheless, it could be used in serial measures of an individual over a defined, relatively short-term period. The use of parameters that reflect muscle mass, such as mid-calf or mid-arm circumference, is more appropriate in the elderly because of the relevance of muscle mass in relation to functionality (Portero-McLellan *et al.*, 2010).

A number of screening tools have been developed for identifying older adults at risk of poor nutrition (Bauer *et al.*, 2010). The Simplified Nutrition Assessment Questionnaire (SNAQ), a four-item screening test, has a sensitivity of 88.2% and a specificity of 83.5% for the identification of older persons at risk of a 10% weight loss (Wilson *et al.*, 2005). More recently developed, the Mini Nutritional Assessment (MNA<sup>®</sup>) represents the most widely accepted and validated nutritional assessment tool for older people, regardless of setting, with clearly defined thresholds (Guigoz, 2006). The MNA<sup>®</sup> aims to evaluate the risk of malnutrition without the need for specialized personnel and so permits early nutritional intervention when needed. The MNA<sup>®</sup> instrument is composed of simple measurements and questions to be completed in less than 15 minutes. It consists of 18 self-reported questions derived from four parameters of assessment, anthropometric, general, dietary, and self assessment, administered in two steps (see Figure 42.1). The MNA-SF<sup>®</sup> (Short Form) is a screening tool composed of the first six items that allows the detection of a decline in ingestion over the past 3 months (loss of appetite, decline in food intake, digestive problems, chewing or swallowing difficulties); weight loss during the past 3 months; current mobility impairment; an acute illness or major stress over the past 3 months; a neuropsychological problem (dementia or depression); and a decrease in BMI. The maximum score for this part of the MNA<sup>®</sup> is 14. A score of 12 points or more indicates that the patient has an acceptable nutritional status and that it is not necessary to complete the full MNA<sup>®</sup>. At this stage, it is important to give nutritional advice, to follow the patient's weight regularly (usually every month) and to complete the MNA-SF<sup>®</sup> at regular intervals (every 3 or 6 months) (Secher *et al.*, 2007). A score of 11 points or below is an indication to proceed with the complete version of the MNA<sup>®</sup> (see Figure 42.2). The full MNA<sup>®</sup> evaluates living arrangements, number of

medications, presence of pressure ulcers, number of full meals eaten daily, amount and frequency of specific foods and fluids, and mode of feeding. The patient reports nutritional and health status, and the practitioner must determine mid-arm and mid-calf circumferences. The maximum score of the second part of the MNA<sup>®</sup> is 16. The scores of the two parts must be added to obtain the malnutrition indicator score, which has a maximum of 30. A score of 23.5 or higher classifies an individual as well-nourished. No specific follow-up is needed except to measure the person's weight regularly at routine visits, complete the MNA<sup>®</sup> at regular intervals, and provide general nutritional counselling based upon reminders about the basic rules of balanced food (e.g. recommended daily intake frequencies of fruits and vegetables, starchy foods, dairy products, meats, fish, seafood, and eggs, and reminders about not exceeding recommended intakes of fat and sweetened products); about taking regular daily physical exercise; and about ensuring good hydration. A score between 17 and 23.5 indicates risk of malnutrition. A specific nutritional

intervention program should be implemented, based on the impairments found after assessment by the MNA<sup>®</sup> (items leading to loss of points). The use of concentrated formulas increasing total intake of calories, proteins or micronutrients is a common strategy for improving nutritional status. Nutritional counselling, as just discussed, should always be provided. A score of less than 17 indicates protein-calorie malnutrition. At this stage it is important to quantify the severity of the malnutrition by complete nutritional assessment (biological and anthropometric parameters and food intakes). Nutritional intervention should be started, with specific and reasonable goals set in advance. It is necessary to support the oral route for as long as possible by improving total intake of calories and prescribing oral supplementation.

Assessment of dietary intakes can identify elderly people at risk of malnutrition by quantifying energy and nutrient intake. There is no easy method to assess dietary intakes in clinical practice. The quality of the data depends on the patient, the time of collection, and the tool used. Food

composition tables are required to convert information gathered regarding food intake to consumption of energy and nutrients. One of the most accurate tools is keeping a food diary in which dietary intakes are collected prospectively over several days. Nevertheless, this method is cumbersome to implement. Another method is the 24-hour recall. It is a faster and easier method which retrospectively lists all dietary intakes over the past 24 hours, but it requires a good memory on the part of the patient which is sometimes difficult with the elderly.

Finally, various serum proteins are considered as markers of nutritional status such as albumin and transthyretin (prealbumin). They are not specific for malnutrition because their concentration may be influenced by a wide variety of acute and chronic inflammatory conditions (Baron *et al.*, 2010). Transthyretin is preferred to albumin because of its shorter half-life which means that its concentration more closely reflects recent dietary intakes (Shenkin, 2006).

### **Malnutrition**

Malnutrition is a dynamic phenomenon that starts when nutritional intakes are insufficient to match requirements. Most commonly, malnutrition is used to refer to inadequate intakes of energy and protein, but the same reasoning can be applied to other nutrients (e.g. specific lipids such as long-chain polyunsaturated fatty acids, vitamins, and micronutrients).

Several studies have shown that aging is associated with an increasing prevalence of malnutrition (Bauer and Volkert, 2007). Nevertheless, the prevalence of malnutrition in the elderly varies depending on the parameters used for the diagnosis and on the setting considered: 5–10% of community-dwelling elderly people suffer from malnutrition, a level that increases to 30–60% in nursing-home residents and hospitalized older people (Vellas *et al.*, 2001).

There is no universally accepted clinical definition of malnutrition. However, recent French recommendations (Haute Autorité de Santé, 2007) suggest that malnutrition can be diagnosed when weight loss is 5% or greater within 6 months or when BMI is less than 21 kg/m<sup>2</sup>, or when MNA score is less than 17 or when albumin concentration is less than 35 g/L (without inflammation). Malnutrition is considered severe when weight loss is 10% or greater within 1 month or 15%, or greater within 6 months, or when albumin concentration is less than 30 g/L. It is important to distinguish severe forms of malnutrition

because they are associated with a considerable increase in morbidity and mortality and therefore require rapid nutritional management.

The American Society for Parenteral and Enteral Nutrition summarizes the selected nutrition screening and assessment instrument parameters (Mueller *et al.*, 2011).

Many studies have demonstrated that malnutrition is associated with increased mortality (Milne *et al.*, 2009), especially in neurodegenerative disease (Vellas *et al.*, 2005) and chronic diseases (Norman *et al.*, 2008). Even in populations who appear healthy, a weight loss of 4% or more multiplies the risk of death by 2.7 (Wallace *et al.*, 1995). Malnutrition is also associated with increased morbidity, for example significant impaired immunity (Chandra, 2002); an increased risk of infections (Paillaud *et al.*, 2005); impaired healing after surgical procedures and an increased risk of pressure sores (Dambach *et al.*, 2005); and an increased risk of cognitive decline (see later in this chapter). The economic consequences of malnutrition in elderly people are also considerable, especially in hospital, mainly due to increased length of stay and associated disease and treatment (Elia, 2005). In the elderly, and even more so in catabolic situations, weight loss affects lean mass (mainly muscle) and water reserves more than fat mass (Schneider *et al.*, 2002). This is of particular concern because these are also affected by natural aging (see “Sarcopenia” and “Hydration Disorders” later in this chapter).

Aging is associated with a physiological anorexia (Hays and Roberts, 2006) that is an independent predictor of poor outcomes (Cornali *et al.*, 2005). Food intake gradually diminishes with age: between the ages of 20 and 80 years, the decrease in food intake is approximately 1200 kcal/day for men and 800 kcal/day for women (Bales and Ritchie, 2002). This decrease in appetite is influenced by multiple physiological changes. Much of the intake decrease in early old age is an appropriate response to decreased energy needs due to reduced physical activity and loss of lean body mass (Blanc *et al.*, 2004). Furthermore, following a period of underfeeding, elderly people do not recover their usual intake as efficiently as young people do, and do not regain the total amount of weight lost (Irvine *et al.*, 2004). Other physiological changes associated with aging promote anorexia: changes in taste and smell lead to a decreased desire to eat; early satiety develops with age, related to gastrointestinal changes (delayed gastric emptying and altered gastric distension) and gastric hormone

changes; and increased cytokine activity (Ahmed and Haboubi, 2010).

Multiple non-physiological causes can explain the inadequate nutrient intakes. These include social issues such as financial difficulty in buying food, and isolation. Several studies have demonstrated that the presence of others increased food intake in older adults (Locher *et al.*, 2005). Other causes include medical factors such as malignancy, and psychiatric factors such as depression (Wilson *et al.*, 1998); dental conditions, which may impair the ability to eat (Ritchie *et al.*, 2000); various handicaps such as paralysis from stroke or severe arthritis, which may limit the ability to prepare food and lead to a need for feeding assistance from others; and polymedication and medication side-effects which may affect appetite regulation.

### Obesity

The prevalence of obesity decreases in extreme old age, but remains a common problem in the elderly. Aging is accompanied by an increase in fat mass and a decrease in lean mass (Kyle *et al.*, 2001). There are several explanations of increased fat mass: reduced physical activity and energy expenditure, reduced growth hormone secretion, diminished sex hormones, and decreased resting metabolic rate due to reduction of lean mass. Moreover, fat-mass distribution changes with aging: there is an increased central distribution of fat (intra-hepatic and intra-abdominal), which is associated with insulin resistance and non-insulin-dependent diabetes mellitus (Ahmed and Haboubi, 2010). Overweight and obese older adults are also affected by the problem of decrease in muscle mass with aging (sarcopenic obesity), which is a major determinant of physical function (see the next section).

For the population as a whole, overweight and obesity are associated with increase in all-cause mortality, as well as morbidity related to diseases for which overweight and obesity are risk factors (such as hypertension, dyslipidemia, diabetes, coronary heart disease, stroke, osteoarthritis, sleep apnea, some cancers). Several studies suggest that the relationship of overweight and obesity to mortality declines over time (Flegal *et al.*, 2007; Kulminski *et al.*, 2008). However, a few studies suggest that overweight in old age is associated with increased mortality (Sui *et al.*, 2007; Wannamethee *et al.*, 2007).

Although the mortality risk of obesity may lessen with age, there are still potential metabolic and functional benefits to weight loss in the obese elderly. Weight loss can improve physical function and quality of life for many

older people (Villareal *et al.*, 2011). Nevertheless, negative outcomes are associated with weight loss in overweight older people, such as loss of muscle mass and decrease in bone mineral density (Villareal *et al.*, 2006a,b). Methods of achieving and maintaining weight loss in older adults are the same as in younger adults (Han *et al.*, 2011). Weight loss should be encouraged using moderate caloric restriction with appropriate calcium and vitamin D supplementation and a regular exercise program (see “Sarcopenia” and “Osteoporosis” in this chapter).

### Sarcopenia

Sarcopenia has been defined as the loss of muscle mass and strength that occurs with advancing age (Morley *et al.*, 2001).

Sarcopenia is a complex, multifactorial process facilitated by a combination of voluntary and involuntary factors. These include: the aging process over the life course, less than optimal diet in older age, sedentary lifestyle, chronic diseases, and some drug treatments (Rolland *et al.*, 2008).

Aging leads to intrinsic muscle impairment related to a combination of the reduction in both absolute and relative amounts of type II fibers (glycolytic and mostly used during intense and acute exercise), fatty infiltration and muscular sclerosis within the sarcopenic muscle, a decrease in muscle protein synthesis (myofibrillar and mitochondrial proteins), and impaired postprandial fate of amino acids (Doherty, 2003).

Aging is associated with a gradual chronic increase in the production of proinflammatory cytokines, particularly interleukins (IL-1 and IL-6), leading to a hypercatabolic state (Roubenoff *et al.*, 1998). However, there is little evidence to support the hypothesis that cytokines predict sarcopenia in prospective studies (Schaap *et al.*, 2006).

An age-related decrease in the synthesis of testosterone and oestrogen appears to accelerate the sarcopenia process by causing a decrease in muscle anabolic potential. Testosterone treatment increases muscle mass in young subjects and is accompanied by an increase in strength. This effect is potentiated by exercise. In elderly persons free of disease, things are less clear. It seems that hormonal treatment only mildly increases plasma testosterone concentration and muscle mass, and has a weak effect on muscle strength (Emmelot-Vonk *et al.*, 2008). Moreover, sex-steroid treatment in the elderly is limited by the risk of prostate cancer and cardiovascular events.

Insulin, which also has an anabolic effect on muscle protein metabolism, seems to play a role in the onset of sarcopenia. With aging, increased fat mass promotes insulin resistance. This is characterized by a decline in the anabolic effect of insulin, potentially predisposing to sarcopenia (Roubenoff, 2003).

Sarcopenia is a risk factor for adverse outcomes such as mobility disorders; falls and fractures; impaired ability to perform ADL; disabilities; loss of independence; poor quality of life and increased risk of death (Delmonico *et al.*, 2007; Rolland *et al.*, 2008). A study by Janssen *et al.* (2004) showed that the estimate of the direct health cost attributable to sarcopenia in the United States was \$18.5 billion in 2000, which represented about 1.5% of total health-care expenditures for that year. A 10% reduction in sarcopenia prevalence would result in savings of \$1.1 billion (dollars adjusted to 2000 rate) per year in US health-care costs (Janssen *et al.*, 2004).

Prevalence of sarcopenia varies greatly depending on the definition used for the diagnosis: in 60- to 70-year-old people, prevalence ranges from 5% to 13%, whereas it ranges from 11% to 50% in people older than 80 years (Morley, 2008). A report of the European Working Group on Sarcopenia in Older People (EWGSOP) has recently been published (Cruz-Jentoft *et al.*, 2010) and recommends using the combination of both low muscle mass and low muscle function (strength or performance) for the diagnosis of sarcopenia. Tomography and magnetic resonance imaging are considered to be gold standards for estimating muscle mass in research. Nevertheless, high cost and limited access limit the use of these methods for routine clinical practice. Dual energy X-ray absorptiometry (DEXA) is an attractive alternative method for both research and clinical use to distinguish fat, bone mineral, and lean tissues. There are few well-validated techniques to measure muscle strength, including the widely used handgrip strength. To assess physical performance, several tests are available including the Short Physical Performance Battery (SPPB), usual gait speed, 6-minute walk test, and stair climb power test. The report of the EWGSOP proposed an algorithm in order to identify subjects with sarcopenia based on gait speed measurement, considered to be the easiest and most reliable way to screen sarcopenia in clinical practice. A cut-off point of more than 0.8 m/s identifies patients at risk for sarcopenia (Abellan van Kan *et al.*, 2009).

Sarcopenia could benefit from intervention trials especially if based on physical activity and nutrition. Inadequate

protein intake contributes to the development of sarcopenia. Because elderly people often present multiple pathologies that represent a risk of protein-energy malnutrition, some studies suggest that the recommended protein intakes of 1 g/kg/day are inadequate (Wolfe *et al.*, 2008). In a 3-year prospective follow-up study, authors showed that subjects in the highest quintile of protein intake ( $1.2 \text{ g/kg/day} \pm 0.4$ ) lost 40% less lean mass than subjects in the lowest quintile ( $0.8 \text{ g/kg/day} \pm 0.3$ ) (Houston *et al.*, 2008). For patients identified as malnourished or at risk of malnutrition, some studies have shown that increased protein intake seems to slow down the sarcopenia process (Morais *et al.*, 2006). However, randomized controlled trials (RCTs) in the healthy elderly showed no benefit from protein supplementation (Roth *et al.*, 2000). New approaches are evaluated such as specific essential amino acids (leucine) supplementation, which plays a major role in the control of protein anabolism (Fujita and Volpi, 2006). Data also suggest a role for vitamin D in the development of sarcopenia. Several studies have shown that reduced serum levels of vitamin D were associated with decreased muscle strength and gait speed, impaired equilibrium, and increased risk of falls and fractures (Gerdhem *et al.*, 2005).

Physical activity decreases with aging, promoting muscle-mass loss and decreased muscle strength. Resistance exercise (when muscle works against an external force) increases muscle strength at all ages, but in a heterogeneous manner. A systematic review of 27 RCTs (Latham *et al.*, 2004) showed that functional improvement is modest (number of falls, capacity to stand up from a chair), as is the favorable effect on autonomy. The American College of Sport Medicine suggested that training at a 70–90% of 1 RM (repetition maximum) on two or more non-consecutive days per week was the appropriate training intensity to produce gains in muscle size and strength, even in frail elderly people (Nelson *et al.*, 2007).

### **Hydration Disorders**

Water is the largest component of body mass. The total body water ranges between 45% and 70% of body mass. This proportion varies according to several factors, for example age, hydration, weight, and disease, and is a difficult component to measure. Because of the dramatic consequences of severe dehydration (both for individual health outcomes and for the health-care system, estimated to be responsible for 5% of hospital expenditure), diagnosis and treatment of hydration disorders should be a prior-

ity. A recent study showed that, since the 2003 heatwave in France, there has been a significant reduction in the prevalence of intracellular hydration disorders, indicating behavioral changes with a positive impact on hydration status (Kettaneh *et al.*, 2010).

Elderly people are more susceptible to dehydration than younger people for many reasons (Thomas *et al.*, 2008; Schols *et al.*, 2009).

With aging there is a decline in total body water. Two-thirds of the water in the body is intracellular, predominantly in lean mass. It is because of the decrease in lean mass that total body water decreases with aging.

Elderly people display reduced thirst sensations. In young adults the osmolarity threshold for thirst is approximately 294 mOsm/L. It increases to 297–300 mOsm/L in the healthy elderly, whereas the amount to be drunk to quench thirst is lower in the elderly. In the case of mild dehydration, elderly people are therefore less able to compensate with adequate fluid intake. These modifications in thirst are minimal in healthy elderly people but are always present in patients with neurologic disorders (such as dementia or stroke).

Furthermore, elderly people often have various disabilities and/or handicaps, such as visual and cognitive impairments and swallowing disorders, which create difficulties in accessing fluids. They also tend to use numerous medications such as diuretics which increase liquid losses. In addition, fear of incontinence may lead some elderly people to limit their liquid intake.

Low dietary intakes also decrease the water intake. It is estimated that 1000 kcal provides 400 mL of water, whereas oxidation of macronutrients produces a significant amount of metabolic water (1.4 g/g of fat and 0.6 g/g of glucose). It is therefore obvious that a reduction in appetite is a risk factor for dehydration.

The physiological decline in renal function associated with aging increases the risk of dehydration. There is an age-related decrease in renal ability to concentrate urine. After a 12-hour period of water deprivation, urine osmolarity is approximately 1200 mOsm/L in the young adult, whereas it is only 800 mOsm/L in a healthy elderly person. The number of active nephrons decreases with aging, leading to a decrease in glomerular filtration rate by half between 20 and 70 years of age. Aging is also associated with relative resistance of the kidney to antidiuretic hormone, diminution of renin activity, and low secretion of aldosterone, all parameters increasing the risk of dehydration.

Dehydration increases the risk of falls, kidney stones, and urinary infections in the elderly (Jequier and Constant, 2009).

Because water spaces are difficult to measure, it is difficult to accurately diagnose hydration disorders. Diagnosis still relies on clinical symptoms that are neither specific nor precise (Thomas *et al.*, 2008). Indeed, dehydration presents in atypical ways such as delirium (Flaherty *et al.*, 2007). The state-of-the-art technique for the measurement of water spaces is tracer dilution (with a minimum of 4–5 hours' equilibration for total body water), which is not compatible with the necessity to treat patients in a timely manner. Bioelectrical impedance analysis is an easy means of assessment, and valid equations have been proposed in the elderly (healthy and with disease) (Ritz *et al.*, 2008). Despite the accuracy of the measurements, there is no database of theoretical values for comparison. In the final analysis, the diagnosis of dehydration is biochemical (Thomas *et al.*, 2008).

Simple interventions such as regularly offering fluids to elderly people have been shown to significantly decrease the frequency with which dehydration develops (Simmons *et al.*, 2001).

## Effects of Nutritional Deficiencies on the Older Population

### Frailty

Frailty is a recent concept, and publications in this domain have increased exponentially over the last 20 years. It is defined as a syndrome resulting from multisystem impairments. Frailty is not part of the normal aging process. It increases the risk of poor outcomes such as the development of disabilities, dementia, falls, institutionalization, hospitalization, and increased mortality.

Although there is a universal, intuitive recognition of frailty by most physicians caring for older people, there is a lack of both consensus definition and of a standardized assessment tool to be used in clinical practice and research. The concept of frailty differs between working groups, and many investigators have treated it as synonymous with disability or dependence whereas others have attempted to describe frailty as a distinct concept.

A recent review of the literature explored trends in research into the concept of frailty and the different frailty models (Abellan Van Kan *et al.*, 2010). Nowadays, there are two main frailty phenotypes coexisting in literature: the physical phenotype, and the multidomain

phenotype, which includes cognitive, functional, and social circumstances.

The phenotype of physical frailty was presented by Fried and colleagues in 2001 and was based on a specific list of five items (exhaustion, weight loss, weak grip strength, slow walking speed, and low energy expenditure). Subjects were considered as frail if they met three or more of the five criteria. The concept of frailty is very difficult to understand, and there is actually no consensual definition. To simplify, there are two phenotypes of frailty: the phenotype of physical frailty proposed by Fried *et al.* (2001), and the multidomain one which considers additional components as part of the syndrome including, for example, cognitive impairment, disability, or poor social conditions.

Even if the physical phenotype could be considered as a gold standard when assessing frailty, controversies still exist in relation to the definition of the frailty components. Many investigators considered additional components such as cognitive impairment, mood disorders, sensory impairment, poor social conditions and support, chronic diseases, and disability as part of the frailty syndrome. This is the concept of the multidomain phenotype. Most of the work performed on this phenotype model is based on comprehensive geriatric assessments, with frailty measures reflecting the accumulation of identified deficits in various domains such as cognition, autonomy, nutrition, mood or social resources. Similarly to sarcopenia, frailty has an ambiguous definition, with many working groups proposing different criteria to define it.

### **Cognitive Decline and Alzheimer's Disease**

Among the complications of Alzheimer's Disease (AD), weight loss is frequent and contributes to adverse outcomes such as mortality, institutionalization, progression of cognitive impairment, and loss of functional autonomy (Gillette-Guyonnet *et al.*, 2005; Vellas *et al.*, 2005; Spaccavento *et al.*, 2009). Some studies have even suggested that weight loss was present before a formal diagnosis has been made (Knopman *et al.*, 2007; Inelmen *et al.*, 2010).

Recent studies suggested that age has a modifying effect on the association between body weight and risk of dementia: being overweight in middle age (40–45 years) increases risk of dementia in later life (Whitmer *et al.*, 2007), while the relation between body weight and risk of dementia in older age (65–75 years) appears to be U-shaped (Luchsinger *et al.*, 2007). In older subjects (76 years old and over), a higher BMI is associated with a decreased risk of dementia

(Luchsinger *et al.*, 2007; Naderali *et al.*, 2009). Furthermore, there is evidence that high adiposity is related to AD, particularly in the middle-aged and in the younger elderly (Luchsinger and Gustafson, 2009).

The onset of dementia is insidious, and the underlying pathologies are believed to be active for many years before the cognitive loss becomes apparent. Cognitive impairment can be influenced by a number of factors, and the potential effect of nutrition has become a topic of increasing scientific and public interest. In particular, various arguments suggest that nutrients (food and/or supplements) can affect the risk of cognitive decline and dementia, especially in frail elderly people at risk of deficiencies.

Experimental, clinical, neuropathological, and epidemiological investigations have implicated oxidative stress as a possible factor in the pathogenesis of cognitive decline and dementia. Antioxidants (such as vitamin E and C) may reduce neuronal damage and cellular death from oxidative reactions by decreasing beta-amyloid toxicity. Several RCTs looking at vitamin E and cognitive decline have been published, but none has found an association between supplementation and decreased risk of cognitive decline. A recent RCT on an antioxidants complex supplementation (including 34 elements) has shown increased cognitive performance during the 4 months of follow-up compared with the placebo group (Summers *et al.*, 2010). A long-term supplementation with  $\beta$ -carotene (50 mg every other day for 18 years) showed a beneficial effect compared with the placebo group (Grodstein *et al.*, 2007). However, a recent meta-analysis (Bjelakovic *et al.*, 2007), studying the effect of antioxidant supplements on mortality in randomized primary and secondary prevention trials, showed that treatment with  $\beta$ -carotene, vitamin A, or vitamin E might increase mortality. According to the authors, the potential impact of vitamin C and selenium on mortality needs further study.

It is now proved that deficiency of vitamin B<sub>6</sub>, vitamin B<sub>12</sub>, and vitamin B<sub>9</sub> (folate), co-factors in the methylation of homocysteine (Hcy), are associated with increased Hcy concentration. Supraphysiological levels of Hcy or deficits in folate and vitamin B<sub>12</sub> should promote amyloid and tau protein accumulation and neuronal death, and also have a direct effect on cognitive decline. Several RCTs tested effects of supplementation with one or more supplementations with folate, vitamin B<sub>12</sub> or vitamin B<sub>6</sub> in healthy individuals or cognitively impaired and demented older individuals. Only one trial has shown a positive effect on cognition: a 3-year folate supplementation (800 mg/day)

significantly improved memory, sensorimotor speed and information processing speed compared with placebo (Durga *et al.*, 2007).

Prevalence of vitamin D deficiency seems to be more frequent in patients with AD (Evatt *et al.*, 2008) than in the general population. Moreover, some studies have found a positive association between decreased vitamin D serum concentrations and decreased cognitive performances (Annweiler *et al.*, 2010; Slinin *et al.*, 2010). However, no RCT on vitamin D supplementation in the prevention of cognitive decline has been published.

Among the macronutrients, fatty acids have been suggested to play a role in modulating the risk of cognitive impairment and dementia based on observational studies. Polyunsaturated fats (PUFA) comprise two major classes: the n-6 class (e.g. linoleic acid and arachidonic acid) and the n-3 class (e.g.  $\alpha$ -linolenic acid, eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]). In addition to their role in the composition and fluidity of neuron membranes and their vascular properties, PUFA have a modulating effect on neuro-inflammation, pro- (n-6) versus anti-inflammatory (n-3). Fatty fish is the primary dietary source of longer chain n-3 fatty acids, EPA and DHA. The main sources of n-6 PUFA are vegetable oils. Data associating dietary fat and cognitive decline or dementia are obtained mainly from observational studies. High intakes of saturated and *trans*-unsaturated (hydrogenated) fats were generally positively associated with increased risk of AD, whereas high intakes of PUFA and monounsaturated fats (MUFA) were protective against cognitive decline in the elderly. Moreover, several studies have found that regular fish consumption (at least once a week) was associated with lower risk of AD. Only one RCT has shown positive results: it examined the effect of n-3 fatty acid supplementation on cognitive functions in patients with mild to moderate AD. However, positive effects were observed in a small group of patients with very mild AD (MMSE >27 points) (Freund-Levi *et al.*, 2006).

Epidemiological analysis of the relationship between nutrient intake and cognitive decline is complex. It is necessary to focus both on food groups and on dietary patterns. One study suggested that undiversified diet increased the risk of dementia (Barberger-Gateau *et al.*, 2007). In this study, daily consumption of fruits and vegetables and regular consumption of n-3 PUFA-rich oils or fish was associated with decreased risk for dementia, and regular consumption of n-6 PUFA-rich oils with increased risk for AD and dementia. A recent paper showed that higher adherence to a diet approaching the Mediterranean

diet is associated with reduced risk for AD (Feart *et al.*, 2010). The Mediterranean diet is characterized by a high intake of vegetables, legumes, fruits, and cereals; a high intake of unsaturated fats (mostly in the form of olive oil), but low intake of saturated fatty acids; moderately high intake of fish; low to moderate intake of dairy products; low intake of meat and poultry; and regular but moderate amount of ethanol (primarily in the form of wine during meals). A recent study suggested a synergistic action of Mediterranean diet and physical activity in the prevention of dementia (Scarmeas *et al.*, 2009).

An RCT on the association between physical activity and risk of dementia included subjects with a cognitive complaint but who did not meet criteria for dementia (hence without cognitive impairment). The intervention group received a program of physical activity at home (at least 150 minutes of moderate activity per week). After 24 weeks, patients of the intervention group improved their cognitive performance compared with patients in the placebo group. After 18 months, results were similar (Lautenschlager *et al.*, 2008). In another RCT, the intervention group received a program of aerobic physical activity (treadmill, stationary bike or elliptical, 45–60 minutes/day four times a week). The results showed an improvement in executive functions at 6 months among women of the intervention group (Baker *et al.*, 2010). An RCT testing the effectiveness of multidomain intervention (physical activity, cognitive and social activities, DHA supplementation) on cognitive function in frail elderly people is under way (the Multidomain Alzheimer Preventive Trial, MAPT).

Large studies are necessary to show whether nutritional intervention has an impact on cognitive decline. A policy of nutritional advice similar to that proposed for patients at risk of cardiovascular disease could then be envisaged.

### **Osteoporosis**

Osteoporosis is defined as a systemic skeletal disorder characterized by low bone mass and microarchitectural deterioration of bone tissue. Osteoporosis diagnosis is based on the bone mineral density (BMD) measured by DEXA. A patient is osteoporotic based on a BMD measurement that is 2.5 standard deviations below the mean of the young healthy population. BMD is determined by bone capital accumulated during childhood and especially during growth (peak bone mass) and bone density loss, which begins for women during perimenopause.

Nowadays, osteoporosis is a public health issue because of the increased incidence of fractures related to osteoporosis.

There were an estimated 9 million osteoporotic fractures worldwide in 2000 (Johnell and Kanis, 2006) and some estimates predict a continued increase in the number of hip fractures over the next 40 years (Gullberg *et al.*, 1997). Hip and spine fractures are associated with increased mortality (Ioannidis *et al.*, 2009). Fractures may result in loss of independence, depression, and chronic pain (Poole and Compston, 2006; Adachi *et al.*, 2010).

Increase in and loss of bone density are influenced by genetic and environmental factors over the life course. Among these factors, calcium and vitamin D intakes are determinants because of their role in bone homeostasis: calcium from the bones can be mobilized to maintain calcium plasma concentration, and vitamin D synthesis promotes intestinal calcium absorption and bone mineralization.

In postmenopausal women, and also in aging men, several RCTs have shown a positive association between calcium with and without vitamin D supplementation, by means of increased dietary calcium intake (Daly *et al.*, 2006) or medication (calcium supplements) (Jackson *et al.*, 2006), and increased BMD.

Current data about the benefits of such supplementation in the prevention of osteoporotic fractures are equivocal. In fact it seems difficult to differentiate the respective effects of calcium and vitamin D. A current meta-analysis published results of 45 RCTs (84 585 subjects) with calcium with and without vitamin D supplementation (Avenell *et al.*, 2009). Results have shown that vitamin D supplementation alone is inefficient. Only the supplementation with both calcium and vitamin D was associated with a decrease in hip fractures, particularly in elderly people living in institutions. A recent review of the literature (Marian and Sacks, 2009) provides important information about micronutrients (vitamins and minerals) for older people. Some studies suggested that current vitamin D intakes are low in the majority of older people (Orwoll *et al.*, 2009). Many nutrition experts recommended a daily intake of 800–1000 IU/day to maintain an adequate serum level of 25-hydroxyvitamin D, the best laboratory indicator of vitamin D status (Avenell *et al.*, 2009). Routine monitoring of 25-hydroxyvitamin D levels in high-risk individuals is recommended with the goal of achieving levels  $\geq 30$  ng/mL. Increased sun exposure during summer months and consumption of vitamin D fortified food and/or supplements may help to improve overall vitamin D intakes. Recommendations for calcium (diet plus supplements) in

postmenopausal women are now higher than in the past, approaching 1200–1500 mg/day.

Physical activity has positive effects on BMD in perimenopausal women, especially walking (Bonaiuti *et al.*, 2002). There is no scientific evidence showing that high-intensity exercises (such as running) are more beneficial than moderate-intensity exercises (e.g. walking). For adults, regular physical activity should decrease the risk of hip fractures. In a prospective study in which 61 000 postmenopausal women were included, those walking 4 hours or more per week had 40% less risk of being affected by hip fracture than women walking less than 1 hour per week (Feskanich *et al.*, 2002). It is currently recommended that adults take moderate-intensity activity (ideally walking) at least 30 minutes per day.

## Future Directions

There are attractive hypotheses to support research on the relationships between nutrition and age-related diseases. Research identifying the role of certain nutrients, certain foods or certain dietary behaviors is an indispensable step if we are to propose specific recommendations in the future. The impact of the standard social and cultural determinants of food habits, such as regional cultures, social status and educational level, will obviously need to be considered. It would be of great value to adapt communication strategies and nutritional advice to eating habits and to the stage of aging.

## SPORTS NUTRITION

LOUISE M. BURKE, OAM, PhD, APD

*Australian Institute of Sport, Belconnen, ACT, Australia*

### Summary

Despite the range of physiological challenges and practical considerations that arise between and within sports, there are some common themes shared by all athletes. During training, the athlete needs to eat to achieve an ideal physique for their event, to stay healthy and injury free, and to be able to train hard and recover optimally from each session. Each competitive event involves a physiological challenge; in many cases, nutritional strategies undertaken before and during the event, or in the recovery between games or heats and the final, can help to reduce or delay fatigue and allow the athlete to perform optimally. The practical needs of sports also create special challenges: these include finding opportunities to eat well while travelling, having access to suitable foods and fluids at the strategic times around workouts or competition, and making good decisions regarding supplements and sports foods.

### Introduction

The demands of sport vary greatly according to the type of event, the phase of training or competition, and the individual characteristics of each athlete. However, there are some common threads to the nutritional goals of sport. The aim of this chapter is to provide a summary of these key goals of sports nutrition, and to provide recommendations and strategies that will help the athlete achieve some of these goals. It will also identify emerging or controversial ideas in sports nutrition from which new recommendations in sports nutrition will evolve. Given the breadth of topics that will be covered, it is impossible to provide the depth of information that would allow adequate coverage of any single area. To counter this problem, efforts will be made to cite recent papers in which a more sophisti-

cated review of the current knowledge on a specific area is provided, with particular reference to applications in sport. This is not meant to show disrespect to the pioneers of sports nutrition and the original or seminal papers. Rather, the aim is to provide a connection to literature from which both the historical and current perspectives can be gained.

### **Goal 1: Eat Adequate Energy and Fuel to Cover Your Individual Needs, Tracking Changes in Needs over Different Times of the Sporting Year**

Energy intake provides an important focus for an athlete's training diet since it must provide the carbohydrate cost

of training and recovery, protein needs for growth, repair and adaptation, and sufficient foods to supply any additional requirements for micronutrients and phytonutrients that arise from the commitment to daily exercise. It also plays a direct role in physique changes, and can influence health and injury risks. Energy requirements vary between sports, between athletes in the same sport, and across various times in an individual athlete's periodized training program. Extremes in energy intake and energy demand can be demonstrated. At the low end of the energy spectrum are athletes in sports focused on brief moments of skill/technique rather than prolonged movement (such as archery or shooting), those who need to achieve or maintain a low body mass/fat level (e.g. athletes in weight-division sports or physique-conscious sports), and those in which these two characteristics are combined (e.g. gymnastics, horse-racing). At the high end of the energy range are athletes in sports involving prolonged sessions of high-intensity exercise (e.g. cyclists undertaking a stage race), those supporting growth, large muscle mass or intentional muscle-gain programs (e.g. adolescent basketball players, American football players), and combinations of these (e.g. heavyweight rowers).

High energy needs often require athletes to consume energy in greater amounts than would be provided in culturally determined eating patterns, or dictated by their appetite and hunger. They may also need to consume energy during and after exercise when the availability of foods and fluids, or opportunities to consume them, are limited. Practical issues interfering with the achievement of energy intake goals during post-exercise recovery include loss of appetite and fatigue, poor access to suitable foods, and distraction from other activities. Specialized advice from a sports dietitian is useful in the development of a plan to address the energy intake challenges faced by individual athletes. Valuable strategies include a pattern of frequent eating occasions, good organization in order to ensure access to suitable foods and drinks in a busy day, and a focus on choices that are low in bulk and high in energy density including high-energy fluids and specialized sports foods (Burke, 2001). Alternatively, the athlete with reduced energy needs faces their own practical challenges to meet their nutritional goals and appetite with a smaller energy budget. General principles that may assist in this scenario include behavior modification to reduce unnecessary eating, focus on choices that are high in bulk or satiety, and choosing nutrient-rich foods that can meet nutritional goals with a lower energy cost (Burke, 2001).

Recent updates to sports nutrition guidelines include the recognition that an athlete's energy requirements change from day to day, and across various parts of the sporting calendar, particularly with changes in the energy demands of an athlete's training (or competition) program or strategies to alter physique. There are several advantages in trying to track energy intake with energy needs. For example, a consistently high energy intake is needed during periods of extremely high energy demands since it may be beyond the absorptive capacity of the gut to play "catch up" once a significant energy deficit has accumulated (Saris *et al.*, 1989). Furthermore, a new concept of energy availability has been developed to assess the suitability of an athlete's energy intake. Defined operationally as the energy cost of the athlete's exercise program subtracted from their total energy intake (see Table 43.1), energy availability provides an approximation of the amount of energy that the body can utilize for everyday activities required for good health (Loucks, 2004). Energy availability may be low when an athlete restricts their energy intake to achieve or maintain a light or lean physique, or when they fail to increase their energy intake sufficiently to meet a strenuous exercise load. When energy availability drops below about 30 kcal (125 kJ) per kilogram of the athlete's fat-free mass for as little as 3–5 days, there is impairment of homeostasis and function, including impaired hormone and bone function (Loucks *et al.*, 1998). Therefore, it makes sense for the athlete to adjust their daily energy intake in reasonable harmony with fluctuations in training load. A strategy that can assist with this goal is to consume food and drinks before, during, and after each exercise session. As will be discussed under the heading "Goal 4," this will help to support performance and recovery around the workout or event. However, it is also a practical way to allow energy intake to increase as sessions are increased in duration or frequency, and to remove unnecessary intake when the training load is reduced, especially during injuries or the off-season. Table 43.1 summarizes various levels of energy availability with examples of situations in which it has been increased to allow gain of body mass, as well as scenarios depicting both a healthy and suboptimal approach to energy restriction for weight loss.

## Goal 2: Achieve and Maintain a Physique That Is Associated with Good Performance

Physical characteristics such as height, body mass (BM), lean mass (LBM), and body fat play a role in the perform-

**TABLE 43.1** Calculating energy availability in sport

Situation	Energy availability (= energy intake – energy cost of exercise) per kg fat-free mass (FFM)	Examples
Weight gain, growth, hypertrophy, etc.	>45 kcal (189 kJ)	Swimmer A: 65 kg (20% body fat = 80% FFM); weekly training = 5600 kcal (23.5 MJ); daily energy intake = 3520 kcal (14.7 MJ) energy availability = $(3520 - 800)/(0.8 \times 65) = 52$ kcal/kg FFM (219 kJ)
Weight/physique maintenance	~45 kcal (189 kJ)	Swimmer B: 65 kg (15% body fat = 85% FFM); weekly training = 5600 kcal (23.5 MJ) daily energy intake = 3285 kcal (13.8 MJ) energy availability = $(3285 - 800)/(0.85 \times 65) = 45$ kcal/kg FFM (189 kJ)
Healthy weight loss (or weight maintenance at reduced metabolic rate)	30–45 kcal (125–189 kJ)	Runner C: 55 kg (20% body fat = 80% FFM); weekly training = 5600 kcal (23.5 MJ); daily energy intake = 2340 kcal (9.8 MJ) energy availability = $(2340 - 800)/(0.8 \times 55) = 35$ kcal/kg FFM (164 kJ)
Low energy availability – health implications	<30 kcal (125 kJ)	Runner D: 55 kg (25% body fat = 75% FFM); weekly training = 5600 kcal (23.5 MJ) daily energy intake = 1980 kcal (8.3 MJ) energy availability = $(1980 - 800)/(0.75 \times 55) = 29$ kcal/kg FFM (120 kJ)

ance of many sports (O'Connor *et al.*, 2007). For example, a large BM and LBM are linked with strength, power, and momentum and are important in many football codes, throwing and lifting events, rowing, and track cycling. By contrast, low BM and body fat levels offer biomechanical and “power to weight” advantages to allow athletes to move their bodies over distances, against gravity or in a small space (e.g. distance running, uphill cycling, diving, and gymnastics). Esthetic considerations are important for the subjectively biased outcomes of sports such as gymnastics, figure skating, and bodybuilding; however, many athletes are also motivated by a personal desire to look good in a skimpy or figure-hugging sporting uniform. In combative events (e.g. boxing, wrestling, judo), weight-lifting, and light-weight rowing, athletes compete in weight divisions which attempt to match competitors based on size, strength, and reach. Eligibility for competition is decided at a weigh-in undertaken just before the event, according to specific roles of the sport.

Elite competitors typically reach the optimal physique for their event via the genetic predispositions that have helped to determine their sporting interests and the conditioning effects of nutrition and training. While some appear to achieve this physique easily, others need to

manipulate their training and dietary programs to achieve their desired size and shape. Unfortunately, some athletes embark on extreme weight-loss schemes, often involving excessive training, chronic low energy and nutrient intake, and psychological distress (Beals *et al.*, 2010; O'Connor and Caterson, 2010). Problems arising from these activities include fatigue, inadequate intake of protein and micronutrients (especially iron and calcium), reduced immune status, altered hormonal balance, disordered eating, and poor body image. “Making weight” is another common activity undertaken in weight-division sports whereby athletes, many of whom are already lean, shed kilograms in the hours or days prior to the weigh-in to qualify for a division lighter than their normal BM (Walberg Rankin, 2010). Although this strategy is used to gain advantage in strength or reach over a smaller opponent, it brings disadvantages in terms of dehydration or suboptimal nutritional status resulting from rapid weight-loss techniques. Medical committees and governing organizations have issued guidelines warning against extreme “making weight” activities (Burke, 2007).

Targets for “ideal” BM and body fat should be set in terms of ranges, with each athlete setting individual targets that are compatible with long-term health and

performance, rather than short-term benefits alone. Where it is warranted, loss of body fat should be achieved by a gradual program of sustained and moderate energy deficit. Each athlete should be able to achieve targets while eating a diet adequate in energy and nutrients, and free of unreasonable food-related stress (O'Connor and Caterson, 2010). Most importantly, athletes should not strive for minimal levels of body fat per se, and the characteristics of elite athletes should not be considered natural or necessary for recreational and sub-elite performers. Even then, most elite athletes periodize their body mass and body fat levels, achieving their “race weight” only for times they are at their competition peak. Special nutrition support should be given to athletes in weight-making sports to assist them to choose an appropriate weight division, and to adopt the diet and exercise strategies that achieve their weigh-in targets with minimal negative effects (Burke, 2007).

At the other end of the spectrum are athletes who wish to gain muscle mass. These athletes often focus dietary interests on excessive protein intake and special supplements that make extravagant claims. However, emerging evidence suggests that the key nutritional support for a resistance-training program is well-timed intake of nutrition (Burd *et al.*, 2009). Modest amounts (15–25 g) of high-quality protein (particularly from dairy, eggs or animal sources) consumed close to the workout promote maximal protein synthesis during the immediate recovery period (Moore *et al.*, 2009). Total protein requirements are generally easily met within the high energy intakes typical of athletes undertaking heavy training. Meanwhile, carbohydrate may be needed to fuel training sessions and recovery, and an energy surplus may be needed to promote optimal gain in BM or general growth.

### Goal 3: Eat to Stay Healthy and Injury Free

Staying healthy and injury free is a key ingredient in a sporting career since it supports consistent training and ensures that the athlete can be at their peak for important competitions. However, the intensive exercise programs undertaken by many athletes straddle the fine line between providing the maximum stimulus for performance improvements and increasing the risk of illness and injury. Although we do not have sufficient evidence to set recommendations for nutritional practices that will guarantee good health and minimum down-time due to injury, some

nutritional risk factors for the opposite outcome can be identified.

There is a somewhat contentious belief that athletes are at increased risk of succumbing to infectious illnesses, particularly upper respiratory tract infections, during periods of high-volume training or after strenuous competitive events (Walsh *et al.*, 2011a). However, there is evidence of suppression of markers of acquired immune function during the acute response to a bout of exercise, and it is intuitive that an exacerbation of the duration or severity of such effects could lead to chronic immunosuppression and compromised resistance to common infections (Walsh *et al.*, 2011a). Nutritional factors that may exacerbate this risk include inadequate fuelling (low carbohydrate availability) around exercise sessions, and poor energy availability. Athletes are advised to follow nutritional practices that avoid such deficiencies. Meanwhile, nutritional supplements have been promoted to offer protection with mixed support; there is limited evidence of benefits from supplementation with vitamin C, and from herbal products such as echinacea and glutamine, mixed support for colostrum and probiotics, and some apparent potential associated with polyphenolic compounds such as quercetin (Walsh *et al.*, 2011b).

Injuries generally occur via two mechanisms: acute problems occurring following a collision or contact impact, or chronic problems that arise from inadequate resilience to continual impact. Nutritional factors may be indirectly involved with some aspects of acute injury if inadequate nutrition contributes to the fatigue that facilitates poor concentration and technique or an increased risk of accidents (Brouns *et al.*, 1986). Nutritional factors are often involved in the development of stress fractures since low bone density is a risk factor in the development of this chronic injury (Bennell *et al.*, 1996). Reduced bone density in athletes seems contradictory, since exercise is an important protector of bone health. However, a serious consequence of low energy availability and menstrual disturbances frequently observed in female athletes is the high risk of either direct loss of bone density, or failure to optimize the gaining of peak bone mass that should occur during the 10–15 years after the onset of puberty (Kerr *et al.*, 2010). The female athlete triad is a term first coined to describe the coincidental presence of eating disorders, amenorrhea, and osteoporosis in female athletes, and the relationships between these problems (Otis *et al.*, 1997). However, the syndrome has been updated to describe the interrelatedness

of three issues of energy availability, menstrual health and bone health in female athletes (Nattiv *et al.*, 2007). Each of these factors is seen to exist in a continuum between optimal function and a clinical disorder (as in the previous definition). However, female athletes are now encouraged to regard movement toward the negative end of any of these spectra as unwelcome, and to seek early intervention for such changes.

The reduced “medicalization” of the triad may be important in encouraging athletes to recognize and address problematic nutrition at an early stage; for example, we now know that low energy availability can arise through the lack of recognition of increased energy requirements when energy expenditure is high rather than requiring the stigma of the label of eating disorder/disordered eating (Loucks, 2004). Healthy bones require an environment of adequate energy availability, hormone function and adequate calcium intake, with suggestions that calcium recommendations be increased to 1300–1500 mg/day in female athletes with impaired menstrual function, as is the case for post menopausal women (Kerr *et al.*, 2010). Where adequate calcium intake cannot be met through dietary means, usually through use of low-fat dairy foods or calcium-enriched soy alternatives, a calcium supplement may be considered. Low bone density is also seen in male athletes, with high-risk groups including elite cyclists; this presumably results from the low energy availability associated with heavy energy expenditure and a desire for low body fat levels, but may be exacerbated by the lack of bone loading during cycling activities (Campion *et al.*, 2010).

Vitamin D deficiency or insufficiency is now recognized as a community health problem with consequences including impairment of bone health, muscle function, and immune status. Education campaigns target people at high risk to seek assessment and reversal of inadequate vitamin D status. Some athletes may be vulnerable to such problems (Larson-Meyer and Willis, 2010); risk factors include indoor training (e.g. gymnasts, swimmers), residing at latitudes greater than 35 degrees, training in the early morning or late evening thus avoiding sunlight exposure, wearing protective clothing or sunscreen, and consuming a diet low in vitamin D. Athletes with these characteristics should seek professional advice and have their vitamin D status monitored. Although there is dispute over optimal vitamin D status, vitamin D supplementation may be required to prevent or treat insufficiency (Larson-Meyer and Willis, 2010).

#### **Goal 4: Understand the Physiological Limitations to Performance in an Event, and Eat Before and During the Event to Reduce or Delay the Onset of Such Fatigue**

To achieve optimal performance, an athlete should identify potentially preventable factors that contribute to fatigue during an exercise task and undertake nutritional strategies before, during, and after the event that minimize or delay the onset of this fatigue. This is obviously important during competition, but athletes should also practice such strategies during key training sessions, both to support technique and intensity during the workout as well as to fine-tune the nutritional plan for a specific event. The nutritional challenges of competition vary according to length and intensity of the event, the environment, and factors that influence the recovery between events or the opportunity to eat and drink during the event itself (see Table 43.2).

Carbohydrate reserves for the muscle and central nervous system limit the performance of prolonged (>90 minutes) submaximal or intermittent high-intensity exercise, and play a permissive role in the performance of brief or sustained high-intensity work (Coyle, 2004). Competition eating should target strategies to consume carbohydrate before and during such events so as to meet these fuel needs. Carbohydrate should be consumed over the day(s) leading up to an event commensurate with the muscle glycogen requirements of the task. The trained muscle is able to normalize its high resting stores with as little as 24 hours of rest and carbohydrate intake (see Table 43.3), and extending the time and carbohydrate ingestion to 24–48 hours can achieve a super-compensation of muscle glycogen commonly known as carbohydrate loading and improve performance of events of more than 90 minutes' duration (Hawley *et al.*, 1997). Carbohydrate eaten in the hours prior to an event can also ensure adequate liver glycogen, especially for events undertaken after an overnight fast (Hargreaves *et al.*, 2004). Although general recommendations can be provided for the pre-event meal (Table 43.3), the type, timing, and amount of carbohydrate-rich foods and drinks will need to be chosen with consideration of practical issues such as gastrointestinal comfort, individual preferences, and catering arrangements in the competition environment. Sustained-release (low-glycemic-index) carbohydrate sources, or foods

**TABLE 43.2** Factors related to nutrition that could produce fatigue or suboptimal performance during sports competition

Factor	Description	Examples of high risk/common occurrence in sports
Dehydration	Mismatch between sweat losses and fluid intake during an event. May be exacerbated if an athlete begins the event in fluid deficit	Events undertaken in hot conditions, particularly involving high-intensity activity patterns and/or heavy protective garments. Repeated competitions (e.g. tournaments) may increase risk of compounding dehydration from one event to the next. Athletes in weight-making sports may deliberately dehydrate themselves to achieve their weigh-in target, with insufficient time between weigh-in and the start of their event to restore fluid levels
Muscle glycogen depletion	Depletion of key muscle fuel due to high utilization in a single event and/or poor recovery of stores from previous activity/event. Typically occurs in events longer than 90 minutes of sustained or intermittent high-intensity exercise	Occurs in endurance events such as marathon and distance running, road cycling, and Ironman triathlons. May occur in some team sports in “running” players with large total distances covered at high intensities (e.g. midfield players in soccer, Australian Rules football). Repeated competitions (e.g. tournaments) may increase risk of poor refueling from one match to the next
Hypoglycemia	Reduction in blood glucose concentrations due to poor carbohydrate availability. However, not all athletes are susceptible to feeling fatigue when blood glucose concentrations become low  Note that even when the central nervous system is not fuel deprived, intake of carbohydrate can promote a “happy brain,” allowing the muscle to work at a higher power output	Low blood-glucose concentrations may occur in athletes with high carbohydrate requirements (see above) who fail to consume carbohydrate during their event  Events of 45–75 minutes’ duration may benefit from intake of even small amounts of carbohydrate which stimulate the brain and central nervous system. This includes half-marathons, 40-km cycling time trial, many team sports
Disturbance of muscle acid–base balance	High rates of H <sup>+</sup> production via anaerobic glycolytic power system	Prolonged high-intensity activities lasting 1–8 minutes, e.g. rowing events, middle-distance running, 200–800m swimming, track cycling team pursuit. May also occur in events with repeated sustained periods of high-intensity activity – perhaps in some team games, racquet sports

**TABLE 43.2** (Continued)

Factor	Description	Examples of high risk/common occurrence in sports
Depletion of phosphocreatine	Inadequate recovery of phosphocreatine system of ATP regeneration leading to gradual decline in power output in subsequent efforts	Occurs in events with repeated efforts of high-intensity activity with short recovery intervals – perhaps in some team games, racquet sports
Gastrointestinal disturbances	These include vomiting and diarrhea which directly reduce performance as well as interfering with nutritional strategies aimed at managing fluid and fuel status	Poorly chosen intake of food and fluid before and/or during event. Risks included consuming a large amount of fat or fibre in pre-event meal, consuming excessive amounts of single carbohydrates during the event or becoming significantly dehydrated
Salt depletion(?)	Inadequate replacement of sodium lost in sweat. There is anecdotal evidence that salt depletion may increase the risk of a specific type of whole-body muscle cramp	Salty sweaters: individuals with high sweat rates and high sweat sodium concentrations who may acutely or chronically deplete exchangeable sodium pools
Water intoxication/hyponatremia (low blood sodium)	Excessive intake of fluids leading to hyponatremia ranging from mild (often asymptomatic) to severe (can be fatal). While this problem is more of a medical concern than a cause of fatigue, symptoms can include headache and disorientation, which can be mistaken as signs of dehydration	Athletes with low sweat losses (e.g. low-intensity exercise in cool weather) who overzealously consume fluid before and during the event. This has most often been seen during marathons, ultra-endurance sports, and hiking

Adapted from Burke (2011).

**TABLE 43.3** Summary of recommendations for carbohydrate intake by athletes

	Situation	Carbohydrate targets	Comments on type and timing of carbohydrate intake
<i>Daily needs for fuel and recovery:</i> these general recommendations should be fine-tuned with individual consideration of total energy needs, specific training needs, and feedback from training performance			
Light	Low-intensity or skill-based activities	3–5g/kg of athlete's body mass (BM)/day	<ul style="list-style-type: none"> <li>Timing of intake may be chosen to promote speedy refuelling, or to provide fuel intake around training sessions in the day. Otherwise, as long as total fuel needs are provided, the pattern of intake may simply be guided by convenience and individual choice</li> </ul>

(Continued)

TABLE 43.3 (Continued)

	Situation	Carbohydrate targets	Comments on type and timing of carbohydrate intake
Moderate	Moderate-exercise program (i.e. ~1 hour/day)	5–7 g/kg/day	<ul style="list-style-type: none"> <li>Protein- and nutrient-rich carbohydrate foods or meal combinations will allow the athlete to meet other acute or chronic sports nutrition goals</li> </ul>
High	Endurance program (e.g. 1–3 hours/day moderate- to high-intensity exercise)	6–10 g/kg/day	
Very high	Extreme commitment (i.e. >4–5 hours/day moderate- to high-intensity exercise)	8–12 g/kg/day	
<i>Acute fuelling strategies: these recommendations promote high carbohydrate availability to promote optimal performance in competition or key training sessions</i>			
General fuelling up	Preparation for events <90 minutes' exercise	7–12 g/kg per 24 hours as for daily fuel needs	<ul style="list-style-type: none"> <li>Athletes may choose compact carbohydrate-rich sources that are low in fiber/residue and easily consumed to ensure that fuel targets are met, and to meet goals for gut comfort or lighter "racing weight"</li> </ul>
Carbohydrate loading	Preparation for events >90 minutes' sustained/intermittent exercise	36–48 hours of 10–12 g/kg BM per 24 hours	
Speedy refuelling	<8 hours' recovery between two fuel-demanding sessions	1–1.2 g/kg/hour for first 4 hours then resume daily fuel needs	<ul style="list-style-type: none"> <li>There may be benefits in consuming small, regular snacks</li> <li>Compact carbohydrate-rich foods and drink may help to ensure that fuel targets are met</li> </ul>
Pre-event fuelling	Before exercise >60 minutes	1–4 g/kg consumed 1–4 hours before exercise	<ul style="list-style-type: none"> <li>Timing, amount and type of carbohydrate foods and drinks should be chosen to suit the practical needs of the event and individual preferences/experiences</li> <li>Choices high in fat/protein/fiber may need to be avoided to reduce risk of gastrointestinal issues during the event</li> <li>Low glycemic index choices may provide a more sustained source of fuel for situations where carbohydrate cannot be consumed during exercise</li> </ul>
During brief exercise	<45 minutes	Not needed	

**TABLE 43.3** (Continued)

	Situation	Carbohydrate targets	Comments on type and timing of carbohydrate intake
	During sustained high-intensity exercise	45–75 minutes Small amounts including mouth rinse	<ul style="list-style-type: none"> <li>• A range of drinks and sports products can provide easily consumed carbohydrate</li> </ul>
	During endurance exercise including “stop and start” sports	1–2.5 hours 30–60 g/hour	<ul style="list-style-type: none"> <li>• Opportunities to consume foods and drinks vary according to the rules and nature of each sport</li> <li>• A range of everyday dietary choices and specialized sports products ranging in form from liquid to solid may be useful</li> <li>• The athlete should practice to find a refueling plan that suits their individual goals including hydration needs and gut comfort</li> </ul>
	During ultra-endurance exercise	>2.5–3 hours Up to 90 g/hour	<ul style="list-style-type: none"> <li>• As above</li> <li>• Higher intakes of carbohydrate are associated with better performance</li> <li>• Products providing multiple transportable carbohydrates (glucose/fructose mixtures) will achieve high rates of oxidation of carbohydrate consumed during exercise</li> </ul>

Reproduced with permission from Burke (2011).

consumed just prior to the start of the competition will also provide an ongoing source of glucose from the gut during exercise (O’Reilly *et al.*, 2010).

According to the specific logistics and culture of a sport, athletes can continue to consume carbohydrate during an event from a range of specialized sports products (e.g. carbohydrate-electrolyte sports drinks, gels, bars) or everyday foods (soft drinks, fruit, confectionery). Until recently, refuelling recommendations for athletes during exercise encouraged the development of a personalized nutrition plan for events of >60 minutes that combined carbohydrate intake of 30–60 g/hour and adequate rehydration with the practical opportunities for intake during the session (Sawka *et al.*, 2007). Opportunities for a more systematic approach to specific carbohydrate needs for different types of situations were, however, discouraged by prevailing beliefs including the capping of the oxidation rate of exogenous carbohydrate at 60 g/hour, the concern that larger intakes might cause gastrointestinal distress, and the lack of evidence of a dose response to carbohydrate

intake during exercise (Burke *et al.*, 2011). New information has allowed a differentiation of strategies for both non-endurance (45–75 minutes) and ultra-endurance (>3–4 hours) events.

There is now robust evidence that intestinal absorption provides the limits to the provision of an exogenous supply of carbohydrate to the working muscle, and that this can be overcome by consuming a mixture of carbohydrate sources that use different intestinal transport mechanisms, such as fructose and glucose (Jeukendrup, 2010). Such mixes allow better gastrointestinal comfort and higher rates of oxidation of ingested carbohydrate with higher rates of intake. The emerging evidence of a dose response between carbohydrate intake and performance benefits in ultra-endurance exercise (Smith *et al.*, 2010a,b) has led to separate recommendations for such events (Table 43.3). The optimal feeding rates may be up to 80–90 g/hour with these carbohydrate targets provided in absolute amounts since the absorptive capacity of the gut appears to be independent of body size (Jeukendrup, 2010). Athletes are

also encouraged to practice intake during training sessions, since this may also be associated with an adaptation of the gut to promote greater exogenous fuel use (Cox *et al.*, 2010).

Events of ~60 minutes' duration are not associated with limitations of muscle fuel supply when adequate preparation has been achieved. However, new research has shown that intake of small amounts of carbohydrate, even in the form of frequent rinsing of the mouth with a carbohydrate-solution, are associated with better performance in such protocols (Jeukendrup and Chambers, 2010). It appears that there is communication between receptors in the mouth/throat and centres of reward and motor control in the central nervous system (Chambers *et al.*, 2009). These findings have been incorporated into new recommendations for athletes (Table 43.3) although further work is required to investigate whether the effect is dampened by the consumption of a pre-event carbohydrate-rich meal (Jeukendrup and Chambers, 2010).

Other major nutritional strategies during exercise involve replacement of the fluid and electrolytes lost in sweat (see Figure 43.1). Sweat losses vary during exercise according to such factors as the duration and intensity of exercise, environmental conditions, and the acclimatization of the athlete, but typically range between 500 and 2000 mL/hour (O'Reilly *et al.*, 2010). As the resulting fluid deficit increases, however, it gradually increases the stress associated with exercise such as the drifting increase in heart rate and perception of effort (Montain and Coyle,

1992) The point at which this causes a noticeable or significant impairment of exercise capacity and performance will depend on the individual, their environment (effects are greater in the heat or at altitude), and the type of exercise (Chevront *et al.*, 2003; Goulet *et al.*, 2008) In events lasting longer than ~45 minutes there may be opportunities to consume fluids during the session and advantages in doing so. The general recommendations are that athletes use the opportunities that are specific to their sport to replace as much of their sweat loss as is practical during the event, and particularly to keep the fluid deficit below 2% of body mass in stressful environments (Sawka *et al.*, 2007; Shirreffs and Sawka, 2011). Depending on the event, there may be opportunities to drink during breaks in play (i.e. half time, substitutions or time-outs in team games) or during the exercise itself (from aid stations, handlers or self-carried supplies). Checking body mass before and after the session, then accounting for the weight of drinks and foods consumed during the session, will allow the athlete to calculate sweat rates, rates of fluid replacement, and the total sweat deficit over the session (Maughan and Shirreffs, 2008). This can be useful in developing and fine-tuning an individualized hydration plan that is specific to an event and its conditions (Chevront *et al.*, 2003; Goulet *et al.*, 2008).

The need to replace sodium losses during exercise is debated. The inclusion of modest amounts of salt in commercial carbohydrate–electrolyte beverages (sports drinks) improves the taste and voluntary intake of a beverage.

**FIG. 43.1** Considerations for managing fluid balance during an exercise session of >1 hour's duration. Adapted from Burke and Cox (2011).

Large salt losses are documented in the case of athletes who experience large losses of sweat during prolonged sessions of exercise in the heat (Godek *et al.*, 2005) and/or excrete “salty sweat” (Godek *et al.*, 2010). There is anecdotal evidence that pro-active replacement of salt during and between exercise sessions may prevent the development of whole body cramps during exercise in the heat in some individuals (Eichner, 2007), but this hypothesis is disputed by others (Schwellnus, 2009). Similarly, the contribution of large salt losses to the development of hyponatremia or low plasma salt concentrations has been a contentious topic. Modeling of salt and fluid changes during exercise shows that sodium losses can contribute to a worsening of plasma sodium homeostasis for any given level of dehydration/fluid replacement (Montain *et al.*, 2006). However, we now recognize that the most important risk factor for the development of this potentially fatal syndrome is excessive intake of fluids compared with fluid losses (Almond *et al.*, 2005; Noakes *et al.*, 2005). This has created scrutiny (Noakes and Speedy, 2007c) and continual evolution (Shirreffs *et al.*, 2004; Sawka *et al.*, 2007) of the recommendations for hydration during exercise (see controversy 1 below).

Other strategies to attenuate the physiological factors causing fatigue during sport include the use of ergogenic aids such as caffeine, the buffering agents beta-alanine and bicarbonate, and creatine (see Goal 6).

### **Goal 5: Eat Strategically After Training and Competition Sessions to Recover Optimally**

Recovery is a major challenge for the elite athlete, who undertakes two or even three workouts each day during certain phases of the training cycle with 4 to 24 hours between each session. But it can also be a concern for recreational athletes who train once or twice a day in preparation for a special endurance event such as a marathon or triathlon. Recovery may also be important in determining the outcome of multi-bout or multi-day competitions such as tournaments, stage races, and events with heats and finals. Recovery involves a complex range of processes of restoration of homeostasis and adaptation to the physiological stress of exercise, including factors related to the maintenance of health and function covered in Goal 4. Other recovery goals include the restoration of fluid balance following the loss of fluid and electrolytes in sweat (Shirreffs *et al.*, 2004), replacement of fuel stores including

muscle and liver glycogen and intramuscular triglycerides (Burke *et al.*, 2004), and the synthesis of new protein for muscular development, adaptation, and repair (Burd *et al.*, 2009). A relatively robust research base allows recommendations to be provided for each of these goals, and each athlete needs to individualize recovery eating strategies after each workout based on the nutritional stress or challenges of the specific session, the recovery period until the next session, and their “bigger picture” nutrition goals such as physique management. In all cases, there may be practical impediments to consuming the foods and drinks needed to achieve recovery eating goals, such as loss of appetite after intense exercise, lack of availability of suitable choices, and distraction from other post-competition activities (e.g. performance debriefs, drug tests, equipment management, and media commitments).

Recommendations for carbohydrate intake in the everyday diets and specific recovery eating strategies of athletes have evolved over the past decade. While early sports nutrition recommendations proposed a seemingly ubiquitous “high carbohydrate diet” for athletes (Coyle, 1991), later refinements discouraged the terminology of expressing carbohydrate intake as a percentage of energy intake in favour of guidelines scaled to the size of the athlete and the fuel cost of their exercise program (Burke *et al.*, 2004). An athlete’s carbohydrate status is best considered in terms of whether their total daily intake and the timing of its consumption in relation to exercise maintain an adequate supply of carbohydrate substrate for the muscle and central nervous system (“high carbohydrate availability”) or whether carbohydrate fuel sources are depleted or limiting for the daily exercise program (“low carbohydrate availability”) (Burke *et al.*, 2011). While high carbohydrate availability is important for situations where the athlete needs to perform optimally, especially with exercise of high intensities, in real life there may be practical reasons why athletes undertake some training sessions with low carbohydrate availability. Whether there may be some advantages gained by deliberately training in this way is a topical question (see Controversy 2).

Table 43.3 summarizes the current recommendations for carbohydrate intake in the athlete’s everyday recovery diet including strategies to enhance post-exercise refueling by commencing intake soon after the completion of the exercise bout. Another remodeling of key messages regarding everyday carbohydrate intake is that the athlete’s needs are not static, but rather move between these categories according to changes in the daily, weekly, or seasonal goals

and exercise commitments in a periodized training program (Burke *et al.*, 2011). It can be useful to adjust an athlete's carbohydrate intake by strategically consuming meals/snacks providing carbohydrate and other nutrients around important exercise sessions. This allows nutrient and energy intake to track with the needs of the athlete's exercise commitments as well as specifically promoting the potential for high carbohydrate availability to enhance performance and recovery at key times (Burke *et al.*, 2011).

Recommendations regarding rehydration and consumption of protein to promote muscular development, adaptation, and repair are provided in Table 43.4. New insights into protein needs in response to exercise are a particularly fertile area of current sports nutrition research

(Phillips and van Loon, 2011). Many of the adaptations to training result from the synthesis of new proteins during the recovery from each individual exercise bout (Hawley *et al.*, 2011), with the various types of protein (myofibrillar, sarcolemmal, mitochondrial, cytosolic, etc.) being determined by the characteristics of the exercise stimulus. To maximize the functional output of training (i.e. growth in muscle size and strength, enhancement of aerobic or anaerobic metabolism), the athlete needs to enhance the protein synthetic response to the exercise stimulus; recent studies show, at least with regard to resistance exercise, that muscle protein synthesis is optimized with the intake of 20–25 g of high-quality protein close in time to the exercise bout (Moore *et al.*, 2009).

**TABLE 43.4** Recommendations for rehydration and repair/adaptation following exercise

Issue	Summary of current recommendations
Rehydration	<ul style="list-style-type: none"> <li>• Fluid intake equal to 125–150% of a post-exercise fluid deficit will be needed to accommodate further sweat and urine losses and restore fluid balance</li> <li>• Thirst may not guarantee adequate fluid intake: when the fluid deficit is &gt;2% body mass, an athlete should have a fluid plan and access to a supply of palatable beverages               <ul style="list-style-type: none"> <li>◦ Sweetened, cool drinks encourage voluntary intake of fluids</li> </ul> </li> <li>• Rehydration requires replacement of the electrolytes lost in sweat, especially sodium. Fluid intake in the absence of electrolyte replacement will reduce plasma osmolarity and result in large urine losses               <ul style="list-style-type: none"> <li>◦ Sodium can be replaced via special drinks such as oral rehydration solutions (50–80 mmol/L) or higher-salt-containing sports drinks (30–35 mmol/L)</li> <li>◦ Alternatively, sodium can be consumed in foods or added to the meals eaten in conjunction with fluid intake</li> </ul> </li> <li>• Where possible, it is better to space fluid intake over a period rather than consuming large volumes at a single time: this pattern will reduce urine losses and maximize fluid retention</li> </ul>
Repair and adaptation (protein synthesis)	<ul style="list-style-type: none"> <li>• Protein should be consumed soon after an exercise session to promote the synthesis of new proteins as dictated by the specific exercise stimulus               <ul style="list-style-type: none"> <li>◦ An intake of 20–25 g of protein is sufficient to optimize the response to exercise</li> <li>◦ Protein intake should include high-quality proteins such as animal sources (e.g. dairy, eggs, meats)</li> </ul> </li> <li>• Although previous discussions on increased protein requirements for athletes remain unresolved, it is likely that all needs can be met from intake of 1.2–1.6 g/kg/day               <ul style="list-style-type: none"> <li>◦ Recommendations for the spread of protein over the day are not yet available, but there is logic in consuming protein in modest amounts (20–25 g) spread over a number of eating occasions to take advantage of the increased potential for muscle protein synthesis in the 24 hours after an exercise bout</li> </ul> </li> </ul>

**FIG. 43.2** Balance sheet for considering the use of commercially available sports foods and sports drinks.

## Goal 6: Make Good Choices Regarding Specialized Sports Foods and Supplements

Given that the podium places at important sporting competitions are decided by milliseconds and millimeters, it is understandable that elite athletes are in constant search for any product or intervention that might improve performance by even a small margin. However, even recreational athletes are seduced by the multitude of sports foods and supplements that promise to enhance speed, increase endurance, improve recovery, reduce body fat levels, increase muscle mass, or otherwise make them a better athlete. Some of these products target the provision of known nutrient needs in a practical form to suit intake around exercise or in an athlete's busy lifestyle, while others contain special ingredients that are claimed to directly achieve performance-enhancing effects. The commercial market for these products is both crowded and lucrative, and provides a challenge to stay abreast of the number of products, the marketing claims, and the evi-

dence base for their real contribution to an athlete's sporting goals. There is potential for both positive and negative outcomes related to the use of supplements and sports foods, and each athlete is encouraged to make a well-considered decision based on consideration of their specific situation and issues (see Figure 43.2).

The Australian Institute of Sport has developed a system to provide guidance about the efficacy of products or supplement ingredients which is continually updated based on evolving knowledge (see Table 43.5). Nutritional ergogenic aids that are supported by clear evidence of performance benefits include caffeine for delaying the perception of fatigue (Burke, 2008), bicarbonate as an extracellular buffering agent (McNaughton *et al.*, 2008), and creatine as a fuel for repeated sprint efforts with short recovery intervals (Mujika and Padilla, 1997; Hespel and Derave, 2007). Meanwhile products with emerging evidence include nitrate (including dietary sources such as beetroot juice) (Bailey *et al.*, 2009) and beta-alanine as an intracellular buffer (Derave *et al.*, 2010). Athletes and coaches should, however, be aware that these benefits are limited

**TABLE 43.5** Overview of Australian Institute of Sport (AIS) Sports Supplement Program ([www.ausport.gov.au/ais/nutrition/supplements](http://www.ausport.gov.au/ais/nutrition/supplements))

Supplement category	Supplement characteristics	Examples of products included in category
Group A – supported for use by athletes	<ul style="list-style-type: none"> <li>• Provide a useful and timely source of energy and nutrients in the athlete's diet</li> <li>• Or have been shown in scientific trials to provide a performance benefit, when used according to a specific protocol in a specific situation in sport</li> </ul>	<ul style="list-style-type: none"> <li>• Sport drinks (carbohydrate–electrolyte drinks)</li> <li>• Protein supplements (especially whey-based products)</li> <li>• Liquid meal supplements</li> <li>• Sport gels and jellies</li> <li>• Sport bars</li> <li>• Caffeine</li> <li>• Creatine</li> <li>• Bicarbonate</li> <li>• Multivitamin and mineral supplement</li> <li>• Iron supplement</li> <li>• Calcium supplement</li> <li>• Probiotics used for gut protection</li> <li>• Vitamin D</li> <li>• <math>\beta</math>-Alanine</li> <li>• Carnitine</li> <li>• Hydroxy-methylbutyrate (HMB)</li> <li>• Nitrate/beetroot juice</li> <li>• NO stimulators</li> <li>• Fish oils</li> <li>• Antioxidant vitamins C and E</li> <li>• Quercetin and other polyphenols/phytonutrients</li> <li>• Probiotics used for immune system protection</li> <li>• Chromium picolinate</li> <li>• Coenzyme Q10</li> <li>• Cordyceps</li> <li>• Cytochrome C</li> <li>• Gamma-oryzanol and ferulic acid</li> <li>• Ginseng</li> <li>• Inosine</li> <li>• Lactaway</li> <li>• Oxygenated waters</li> <li>• Pyruvate</li> <li>• Rhodiola rosea</li> <li>• Vitamin supplements and free-form amino acids when used in situations other than summarized in Group A</li> <li>• Zinc monomethionine aspartate (ZMA)</li> </ul>
Group B – considered for use by AIS athletes only under a research trial	<ul style="list-style-type: none"> <li>• Have received some scientific attention, sometimes in populations other than highly trained athletes, or have preliminary data which suggest possible benefits to performance</li> <li>• Are of topical interest to athletes and coaches</li> </ul>	
Group C – little proof of benefits	<ul style="list-style-type: none"> <li>• This category includes the majority of supplements and sports products promoted to athletes</li> <li>• These supplements, despite enjoying a cyclical pattern of popularity and widespread use, have not been proven to provide a worthwhile enhancement of sports performance. Although we can't categorically state that they don't "work," current scientific evidence shows that either the likelihood of benefits is very small or that any benefits that occur are too small to be useful</li> <li>• In fact, in some cases, these supplements have been shown to impair sports performance, with a clear mechanism to explain these results</li> </ul>	

**TABLE 43.5** (Continued)

Supplement category	Supplement characteristics	Examples of products included in category
Group D – should not be used	<ul style="list-style-type: none"> <li>• We have named a few of the products that belong in this category, but others that have not been named in our supplement system more than likely belong here</li> <li>• These supplements are either directly banned by the World Anti-Doping Agency code or provide a high risk of producing a positive doping outcome due to the potential for contamination with banned substances</li> </ul>	<ul style="list-style-type: none"> <li>• Androstenedione and related compounds</li> <li>• DHEA</li> <li>• 19-norandrostenedione and 19-norandrostenediol</li> <li>• Tribulus terrestris and other herbal testosterone supplements</li> <li>• Ephedra</li> <li>• Strychnine</li> <li>• Methylhexanamine</li> <li>• Glycerol used for hyperhydration (has recently been added to WADA List of Banned Substances as a plasma expander)</li> </ul>

to specific situations. Furthermore, the range of disadvantages associated with the use of supplements includes, for elite athletes who compete in sports governed by an anti-doping code, the possibility of ingestion of contaminants including prohibited substances that can lead to an inadvertent doping outcome (Geyer *et al.*, 2008).

## Future Directions

### **Controversy 1: “Train Low” for Optimal Training Adaptations**

Although current recommendations promote exercise under conditions of high carbohydrate availability to enhance performance, increase capacity at high intensity, or improve technique, there is recent interest in the potential advantages of training with low carbohydrate availability. Many of the signaling cascades that drive the adaptation to training appear to be up-regulated when an exercise stimulus is applied in a low-carbohydrate environment (low glycogen and/or low exogenous carbohydrate availability) (Philp *et al.*, 2011). Several studies have shown

that this can enhance the increase in proteins associated with exercise metabolism (e.g. oxidative enzymes and regulatory proteins such as transcription factors), even in well-trained individuals (Hawley and Burke, 2010; Philp *et al.*, 2011). However, to date, only one study has shown that this translates into better exercise capacity, with this investigation involving previously untrained subjects (Hansen *et al.*, 2005). There are some caveats to apply to the interest among athletes and coaches in “training low.” The first is to note that these benefits have not been achieved by exposing the exercising individual to chronic periods of a low-carbohydrate diet. In fact, the favorable protocols involve a short period of carbohydrate depletion in an otherwise carbohydrate-replete daily environment: either by undertaking exercise in an overnight fasted situation without carbohydrate intake during the session, or by scheduling two sessions of exercise close together such that the second bout is undertaken with reduced glycogen stores due to the lack of refuelling from the first bout (Burke, 2010a). This limits the total exposure of the body to the disadvantages of low carbohydrate availability and could allow the athlete to periodize their training so that

only some workouts are undertaken with the “train low” stimulus. The potential disadvantages of “training low” (Burke, 2010a) include an increase in the perception of effort and a reduction in training intensity (e.g. speed, power outputs), a potential for down-regulation of metabolic pathways promoting carbohydrate utilization and high power outputs during exercise, and an increased risk of injury, illness, and over-reaching. “Training low” may have greater application to populations who exercise to overcome problems of metabolic syndrome and metabolic inflexibility, allowing such individuals to “train smarter” (derive greater benefits from the same exercise stimulus). However, as noted previously (Burke, 2010a), it may already occur in the periodized training and nutritional programs practiced by athletes in real life, and deliberate implementation of such strategies requires further study.

### **Controversy 2: Are Fluid Guidelines Useful or Harmful?**

Fluid mismatches during competitive events mostly err on the side of a fluid deficit (Sawka *et al.*, 2007). However, it is possible for some athletes to overhydrate if they drink excessively during events in which sweat rates are actually low (Almond *et al.*, 2005). This situation is generally unnecessary and may even be dangerous if it leads to the potentially fatal condition of hyponatremia (low blood sodium concentration; often known as water intoxication) (Noakes, 2003; Noakes and Speedy, 2007b). The recognition of this problem and the justifiable publicity surrounding deaths in some community participation events has led some sports scientists to blame guidelines for fluid intake or the marketing of sports drinks as a contributing cause (Noakes and Speedy, 2007a,c). Indeed, there has been a gradual evolution of recommendations for fluid intake over the past 30 years in view of the recognition of the unsuitability of prescriptive advice and the implication from previous guidelines that athletes should drink as much as possible during exercise (Casa *et al.*, 2000; Sawka *et al.*, 2007). As stated above, the current guidelines warn against overdrinking but encourage an individualized fluid plan that keeps the fluid deficit to an acceptable level.

It should be noted that even these recommendations have been subjected to the criticism of being unnecessary, complicated and still capable of leading to hyponatremia (Noakes, 2003; Noakes and Speedy, 2007c). Instead, it has been argued that athletes should simply drink according to their thirst (Noakes and Speedy, 2007c). The opinion of this author is that thirst or *ad libitum* intake of fluid

provides a reasonable starting point for developing a fluid plan. However, there are often good reasons to improve on these subjective dictates. For example, in sports where opportunities for fluid intake are limited, the athlete may need to drink at the available opportunities early in an event (i.e. “ahead of their thirst”) to better pace total fluid intake over the session. In addition, as long as it does not require an excessive fluid intake, athletes may consume beverages such as sports drinks to meet carbohydrate refueling targets. Finally, it is possible that some individuals have poor judgment of portion control or thirst response and may need some guidance regarding appropriate fluid volumes.

### **Controversy 3. Anti-oxidants: Friend or Foe?**

Exercise is known to increase the production of free oxygen and nitrogen radical species (RNOS) which in excess are thought to contribute to acute impairment of the muscle’s ability to produce force as well as longer-term inflammation, damage and soreness (Konig *et al.*, 2001). While increasing cellular antioxidant capacity via supplementary intake of antioxidants seems a logical approach to counteract the negative effects of RNOS on muscle force capability, the results of studies of supplementation with antioxidant vitamins in association with acute or chronic exercise models have been unclear with respect to muscle damage or performance outcomes (Fisher-Wellman and Bloomer, 2009). Newer insights now find that it is only excessive oxidative damage that is problematic, and that small and confined oxidative changes in the muscle fulfil an important role in the adaptation to exercise; for example, inducing signaling cascades and up-regulating the endogenous oxidative defense system, which consists of complex interactions of compartmentalized antioxidants (Hawley *et al.*, 2011). In fact, some recent studies have found that supplementation with isolated antioxidants such as vitamin C and/or E can actually reduce the benefits of exercise training (Gomez-Cabrera *et al.*, 2008; Ristow *et al.*, 2009). The most recent recommendations for athletes promote the benefits of a varied diet including a range of antioxidant- and phytochemical-containing fruits and vegetables, although research continues to investigate potential benefits from the specific consumption of polyphenols such as quercetin and epigallocatechin-3-gallate (EGCG), which may contribute a range of functions including effects on the immune system, the anti-inflammatory response, and mitochondrial biogenesis (Hawley *et al.*, 2011).

## NUTRIENT REGULATION OF THE IMMUNE RESPONSE

PHILIP C. CALDER<sup>1</sup>, PhD, DPHIL, RNUTR AND PARVEEN YAQOOB<sup>2</sup>, MA, DPHIL, RNUTR

<sup>1</sup>University of Southampton Faculty of Medicine, Southampton, UK

<sup>2</sup>University of Reading, Reading, UK

### Summary

There is a bidirectional interaction between nutrition, infection, and immunity: undernutrition decreases immune defenses, making an individual more susceptible to infection, but the immune response to an infection can itself impair nutritional status and alter body composition. Practically all forms of immunity are affected by protein–energy malnutrition, but non-specific defenses and cell-mediated immunity are more severely affected than humoral (antibody) responses. Micronutrients are required for an efficient immune response, and deficiencies in one or more micronutrients diminish immune function, providing a window of opportunity for infectious agents. Essential fatty acids play a role in the regulation of immune responses since they provide precursors for the synthesis of eicosanoids. Deficiencies in essential amino acids impair immune function, but some non-essential amino acids (e.g. arginine and glutamine) may become conditionally essential in stressful situations. Probiotic bacteria enhance immune function in laboratory animals and may do so in humans. Prebiotics may also have these effects but research in this area is not conclusive. Breast milk has a composition that promotes the development of the neonatal immune response and may protect against infectious diseases.

### Introduction

Associations between famine and epidemics of infectious disease have been noted throughout history: as early as 370 BC Hippocrates recognized that poorly nourished people are more susceptible to infectious disease. In general, undernutrition impairs the immune system, suppressing

immune functions that are fundamental to host protection against pathogenic organisms (Chandra, 1991; Scrimshaw and SanGiovanni, 1997; Calder and Jackson, 2000). Undernutrition leading to impairment of immune function can be due to insufficient intake of energy and macronutrients and/or due to deficiencies in specific micronutrients. These may occur in combination. The

impact of undernutrition is greatest in developing countries, but it is also important in developed countries, especially among the elderly, individuals with eating disorders, alcoholics, patients with certain diseases, premature babies and those born small for gestational age. Although it has proven difficult to identify the precise effects of individual nutrients on different aspects of immune function, it is now clear that many nutrients have an important role in maintaining the immune response. Thus, the functioning of the immune system is influenced by nutrients consumed as normal components of the diet, and appropriate nutrition is required for the host to maintain adequate immune defenses towards bacteria, viruses, fungi, and parasites. This chapter begins with an overview of the key components of the immune system, concentrating on the cells that participate in immune responses and the mechanisms by which they communicate. The role of nutrients in the immune system is examined using specific examples, and the cyclic relationship between infection and nutritional status is discussed. The main body of the chapter is devoted to an evaluation of the influence of individual micronutrients and macronutrients on immune function. The content of this chapter is based on Yaqoob and Calder (2011).

## The Immune System

The immune response acts to protect the host from infectious agents that exist in the environment (bacteria, viruses, fungi, parasites) and from other noxious insults. It is a complex system involving various cells that are distributed in many locations throughout the body and that move between these locations in the lymph and the bloodstream. In some locations the cells are organized into discrete lymphoid organs. These can be classified as primary lymphoid organs where immune cells arise and mature (bone marrow and thymus) and secondary lymphoid organs (lymph nodes, spleen, gut-associated lymphoid tissue) where mature immune cells interact and respond to antigens. The immune system has two functional divisions: the innate (or natural) immune system and the acquired (also termed specific or adaptive) immune system (see Figure 44.1).

### *Innate Immunity*

Innate immunity consists of physical barriers, soluble factors and phagocytic cells, which include granulocytes (neutrophils, basophils, eosinophils), monocytes, and

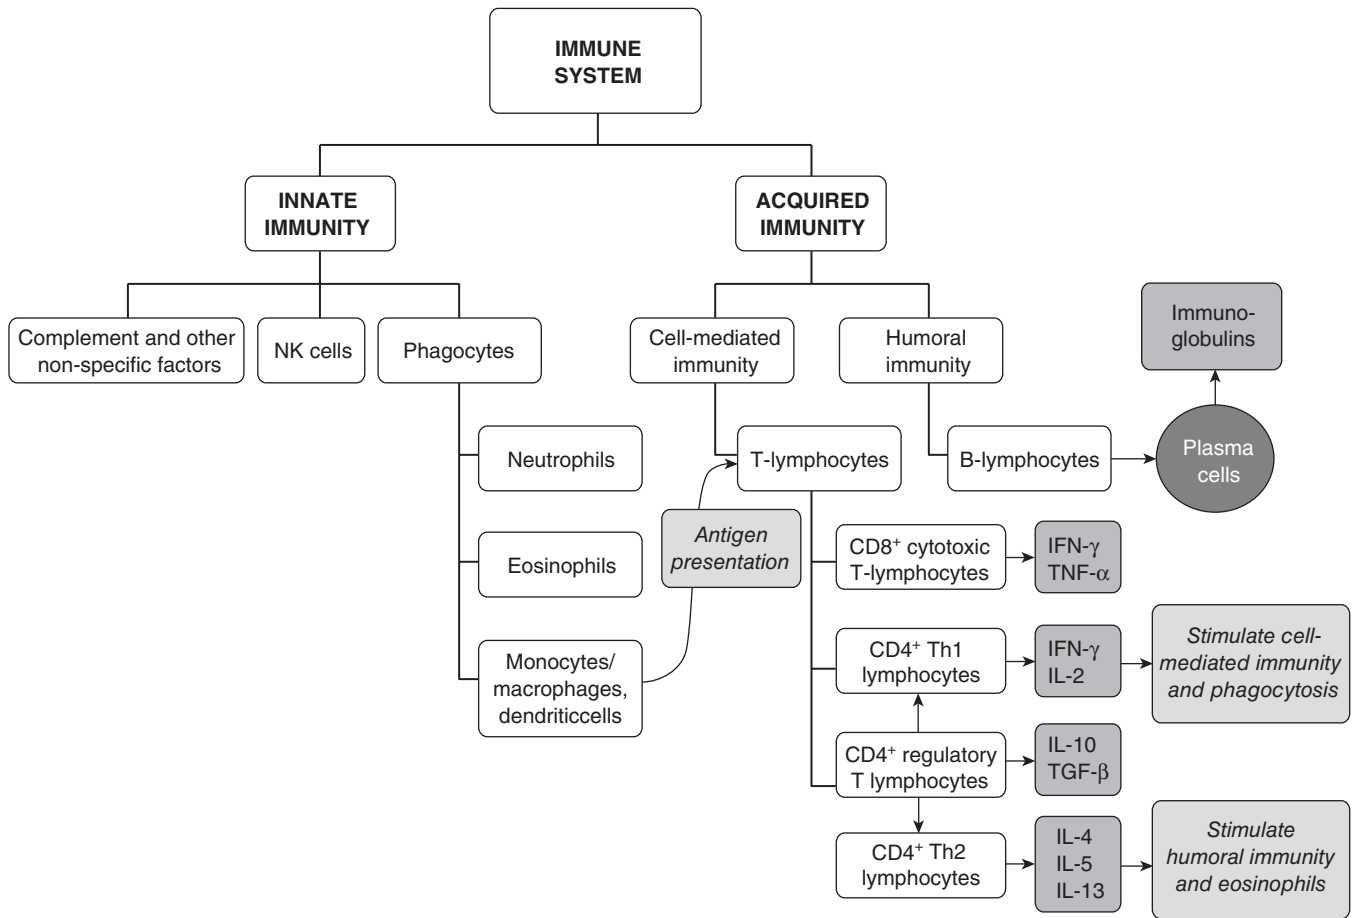

macrophages (Table 44.1). Innate immunity has no memory and is therefore not influenced by prior exposure to an organism. Phagocytic cells, the main effectors of innate immunity, express surface receptors that recognize certain structures on bacteria; the receptors are termed pattern recognition receptors and the bacterial structures are termed microbe-associated molecular patterns. Binding of bacteria to the receptors triggers phagocytosis (engulfing) and subsequent destruction of the pathogenic microorganism by toxic chemicals, such as superoxide radicals and hydrogen peroxide. Natural killer cells also possess surface receptors and destroy their target cells by the release of cytotoxic proteins. In this way, innate immunity provides a first line of defense against invading pathogens. However, an immune response often requires the coordinated actions of both innate immunity and the more powerful and flexible acquired immunity.

### *Acquired Immunity*

Acquired immunity involves the specific recognition of molecules (termed antigens) on an invading pathogen which distinguish it as being foreign to the host. Lymphocytes, which are classified into T- and B-lymphocytes (also called T-cells and B-cells), are responsible for this form of immunity (Figure 44.1). All lymphocytes (indeed all cells of the immune system) originate in the bone marrow. B-lymphocytes undergo further development and maturation in the bone marrow before being released into the circulation, while T-lymphocytes mature in the thymus. From the bloodstream, lymphocytes can enter peripheral lymphoid organs, which include lymph nodes, the spleen, tonsils, and gut-associated lymphoid tissue. Immune responses occur largely in these lymphoid organs, which are highly organized to promote the interaction of cells and invading pathogens.

Since each lymphocyte carries surface receptors for a single antigen, the acquired immune system is highly specific. However, acquired immunity is extremely diverse; the lymphocyte repertoire in humans has been estimated at recognition of approximately  $10^{11}$  antigens. The high degree of specificity, combined with the huge lymphocyte repertoire, means that only a relatively small number of lymphocytes will be able to recognize any given antigen. The acquired immune system has developed the ability for clonal expansion to deal with this. Clonal expansion involves the proliferation of a lymphocyte once an interaction with its specific antigen has occurred, so that a single lymphocyte gives rise to a clone of lymphocytes, all of

**FIG. 44.1** Schematic representation of the immune system. IFN, interferon; IL, interleukin; NK, natural killer; TGF, transforming growth factor; Th1, type 1 helper; Th2, type 2 helper; TNF, tumor necrosis factor.

**TABLE 44.1** Components of innate and acquired immunity

	Innate	Acquired

Circulating molecules	Complement	Antibodies
Cells	Granulocytes Monocytes/macrophages Natural killer cells	Lymphocytes (T and B)
Soluble mediators	Macrophage-derived cytokines	Lymphocyte-derived cytokines

which have the ability to recognize the antigen causing the initial response. The acquired immune response becomes effective over several days after the initial activation, but it also persists for some time after the removal of the initiating antigen. This persistence gives rise to immunological memory, which is also a characteristic feature of acquired immunity. It is the basis for the stronger, more effective, immune response to re-exposure to an antigen (i.e. reinfection with the same pathogen) and is the rationale for vaccination. Eventually, the immune system will re-establish homeostasis using self-regulatory mechanisms which involve communication between cells.

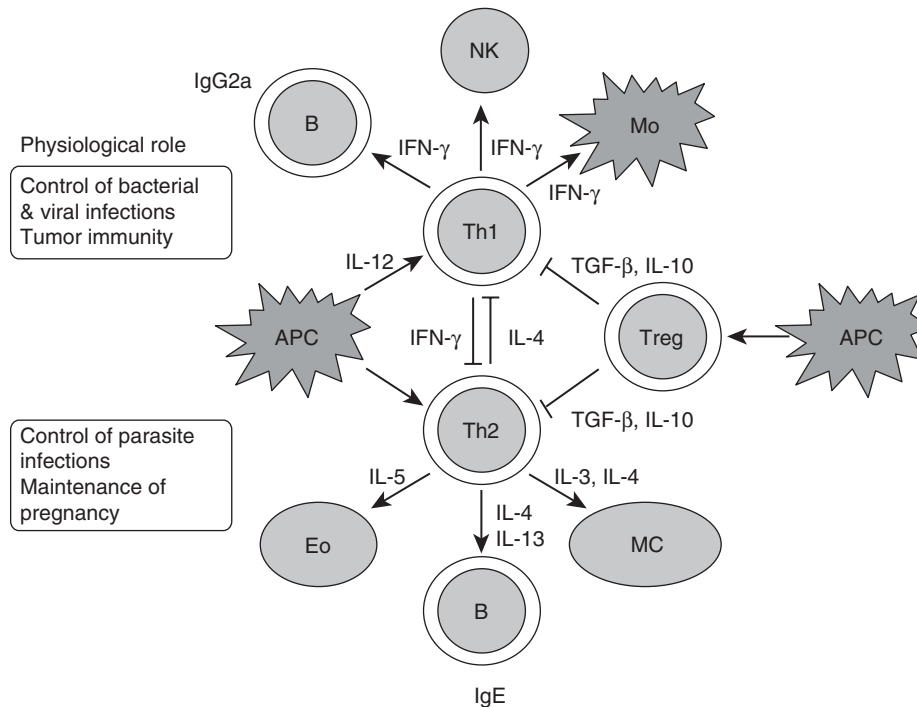

### **B- and T-Lymphocytes**

B-lymphocytes are characterized by their ability to produce antibodies (these are soluble antigen-specific immunoglobulins). This form of protection is termed humoral immunity. B-lymphocytes also carry immunoglobulins, which are capable of binding an antigen, on their cell surface (Figure 44.1). Binding of immunoglobulin with antigen causes proliferation of the B-lymphocytes and subsequent transformation into plasma cells, which secrete large amounts of antibody with the same specificity as the parent cell.

There are five major classes of immunoglobulin (IgA, IgD, IgG, IgM, and IgE), each of which elicits different components of the humoral immune response. Antibodies work in several ways to combat invading pathogens. They can “neutralize” toxins or microorganisms by binding to them and preventing their attachment to host-cells, and they can activate complement proteins in plasma, which in turn promote the destruction of bacteria by phagocytes. Since they have binding sites for both an antigen and for receptors on phagocytic cells, antibodies can also promote the interaction of the two components by forming physical “bridges,” a process known as opsonization. The type of phagocytic cell bound by the antibody will be determined by the antibody class; macrophages and neutrophils are specific for IgM and IgG, while eosinophils are specific for IgE. In this way, antibodies are a form of communication between the acquired and the innate immune response; although they are elicited through highly specific mechanisms, they are ultimately translated to a form that can be interpreted by the innate immune system, enabling it to destroy the pathogen.

Humoral immunity deals with extracellular pathogens. However, some pathogens, particularly viruses, but also certain bacteria, infect individuals by entering cells.

These pathogens will escape humoral immunity and are instead dealt with by cell-mediated immunity, which is conferred by T-lymphocytes. T-lymphocytes express antigen-specific T-cell receptors (TCR) on their surface, which have an enormous antigen repertoire. However, unlike B-lymphocytes, they are only able to recognize antigens that are presented to them on a cell surface (the cell presenting the antigen to the T-lymphocyte is termed an antigen presenting cell); this is the distinguishing feature between humoral and cell-mediated immunity. Activation of the TCR results in entry of T-lymphocytes into the cell cycle and, ultimately, proliferation. Activated T-lymphocytes also begin to synthesize and secrete the cytokine interleukin-2 (IL-2), which further promotes proliferation and differentiation. Thus, the expansion of T-lymphocytes builds up an army of antigen-specific T-lymphocytes in much the same way as that of B-lymphocytes. Effector T-lymphocytes have the ability to migrate to sites of infection, injury, or tissue damage. There are three principal types of T-lymphocytes; cytotoxic T-cells, helper T-cells, and regulatory T-cells. Cytotoxic T-lymphocytes carry the surface protein marker CD8 and kill infected cells and tumor cells by secretion of cytotoxic enzymes, which cause lysis of the target cell. Helper T-lymphocytes carry the surface protein marker CD4 and eliminate pathogens by stimulating the phagocytic activity of macrophages and the proliferation of, and antibody secretion by, B-lymphocytes. Helper T-lymphocytes have traditionally been subdivided into two broad categories according to the pattern of cytokines they produce, although new categories have recently been identified (Figure 44.2). Helper T-cells that have not previously encountered antigen produce mainly IL-2 upon the initial encounter with an antigen. These cells may differentiate into a population, sometimes referred to as Th0 cells, which differentiate further into either Th1 or Th2 cells. This differentiation is regulated by cytokines: IL-12 and interferon-gamma (IFN- $\gamma$ ) promote the development of Th1 cells, while IL-4 promotes the development of Th2 cells. Th1 and Th2 cells have relatively restricted profiles of cytokine production: Th1 cells produce IL-2 and IFN- $\gamma$ , which activate macrophages, natural killer cells, and cytotoxic T-lymphocytes and are the principal effectors of cell-mediated immunity. Interactions with bacteria, viruses, and fungi tend to induce Th1 activity. Th2 cells produce IL-4, which stimulates IgE production, and IL-5, an eosinophil-activating factor. Th2 cells are responsible for defense against helminthic parasites, which is due to IgE-mediated activation of

**FIG. 44.2** Schematic representation of the roles of helper T-cells in regulating immune responses. APC, antigen presenting cell; B, B-cell; Eo, eosinophil; IFN, interferon; Ig, immunoglobulin; IL, interleukin; MC, mast cell; NK, natural killer cell; TGF, transforming growth factor; Th1, type 1 helper T-cell; Th2, type 2 helper T-cell; Treg, regulatory T-cell. Adapted from Calder *et al.* (2006).

mast-cells and basophils. The patterns of cytokine secretion by Th1 and Th2 lymphocytes were first demonstrated in mice. Human helper T-lymphocytes do show differences in cytokine profile, the divisions are not as clear, with the majority secreting a mixture of Th1 and Th2 cytokines in differing proportions. Thus, the terms “Th1 dominant” and “Th2 dominant” are commonly used to describe the cytokine profiles of these cells. More recently characterized categories of helper T-cells include Th17 cells, which appear to play an important role in autoimmunity (where the immune system attacks host tissues inappropriately). However, the range of activities of these new categories of helper T-cells is not yet fully understood. Regulatory T-cells ( $CD4^+CD25^+FoxP3^+$ ) produce IL-10 and transforming growth factor- $\beta$  and suppress the activities of B-cells and other T-cells, preventing inappropriate activation.

### **The Gut-associated Immune System**

The immune system of the gut (sometimes termed the gut-associated lymphoid tissue) is extensive and includes

the physical barrier of the intestine as well as components of innate and adaptive immune responses (Mowat, 2003). The physical barrier includes acid in the stomach, peristalsis, mucus secretion, and tightly connected epithelial cells, which collectively prevent the entry of pathogens. The cells of the immune system are organized into specialized lymphoid tissue, termed Peyer’s patches, which are located directly beneath the epithelium in the lamina propria (Mowat, 2003). This also contains M cells, which sample small particles from the gut lumen. Other lymphocytes are also present in the lamina propria, as well as associated with the epithelium itself. Because the gut-associated immune system of humans is inaccessible and requires invasive techniques for study, it is relatively poorly understood and much of our understanding of the influence of nutrition on this aspect of immunity comes from animal studies.

### **The Immune System in Health and Disease**

Clearly, a well-functioning immune system is essential to health and serves to protect the host from the effects of

ever-present pathogenic organisms. Cells of the immune system also have a role in identifying and eliminating cancer cells. There are, however, some undesirable features of immune responses. First, in developing the ability to recognize and eliminate foreign antigens effectively, the immune system is responsible for the rejection of transplanted tissues. Secondly, the ability to discriminate between “self” and “non-self” is an essential requirement of the immune system and is normally achieved by the destruction of self-recognizing T- and B-lymphocytes before their maturation. However, since lymphocytes are unlikely to be exposed to all possible self-antigens in this way, a second mechanism termed “clonal anergy” exists, which ensures that an encounter with a self-antigen induces tolerance. In some individuals there is a breakdown of the mechanisms that normally preserve tolerance; a number of factors contribute to this, including a range of immunological abnormalities and a genetic predisposition in some individuals. As a result, an inappropriate immune response to host tissues or to normally benign environmental antigens is generated and this can lead to autoimmune and inflammatory diseases, which are typified by ongoing chronic inflammation and a dysregulated T-cell response.

## Factors Influencing Immune Function

Many factors influence immune function and resistance to infection, leading to great variability in immune responses within the population (Calder and Kew, 2002; Cummings *et al.*, 2004). These factors include genetics, sex, early life events, age, and hormonal status. Immunological “history” also plays a role in the form of previous exposure to pathogens, vaccination history, and chronic disease burden (accumulating conditions over time). Other factors influencing immune function include stress (environmental, physiological, and psychological), exercise (acute and chronic), obesity (see below), smoking, alcohol consumption, gut microbiota, and nutritional status. In a newborn baby, immunologic competence is gained as the immune system encounters new antigens and so matures and expands. Some of these early encounters with antigens play an important role in ensuring tolerance, and a breakdown in this system can lead to increased likelihood of childhood atopic diseases and perhaps also to certain inflammatory conditions later in life (Calder *et al.*, 2006). At the other end of the lifecycle, older people experience a progressive dysregulation of the immune system, leading to decreased

**FIG. 44.3** The interrelationship between undernutrition and infection. Adapted from Calder and Jackson (2000).

cell-mediated immunity and a greater susceptibility to infection (Castle, 2000; Burns and Goodwin, 2004; Agarwal and Busse, 2010). Innate immunity appears to be less affected by aging; indeed, there is a progressive increase in chronic inflammation during aging.

## Impact of Infection on Nutrient Status

Undernutrition decreases immune defenses against invading pathogens and makes an individual more susceptible to infections. However, the immune response to an infection can itself impair nutritional status and alter body composition (Scrimshaw and SanGiovanni, 1997; Calder and Jackson, 2000). Thus, there is a bidirectional interaction between nutrition, infection and immunity (Figure 44.3).

Infection impairs nutritional status and body composition in the following ways:

- Infection is characterized by anorexia. Reduction in food intake (anorexia) can range from as little as 5% to almost complete loss of appetite. This can lead to nutrient deficiencies even if the host is not deficient before the infection and may make apparent existing borderline deficiencies.
- Infection is characterized by nutrient malabsorption and loss. The range of infections associated with nutrient malabsorption is wide and includes bacteria, viruses, protozoa, and intestinal helminths. Infections that cause diarrhea or vomiting will result in nutrient loss. Apart from malabsorption, nutrients may also be lost through the feces as a result of damage to the intestinal wall caused by some infectious agents.

**FIG. 44.4** Effects of infection on the host which can decrease nutrient status. Adapted from Calder and Jackson (2000).

- Infection is characterized by increased resting energy expenditure. Infection increases the basal metabolic rate during fever: each 1°C increase in body temperature is associated with a 13% increase in metabolic rate, which significantly increases energy requirements. This places a significant demand on nutrient supply, particularly when coupled with anorexia, diarrhea, and other nutrient losses (e.g. in urine and sweat).
- Infection is characterized by altered metabolism and redistribution of nutrients. The “acute-phase response” is the name given to the metabolic response to infections, and it includes the onset of fever and anorexia, the production of specific acute-phase reactants, and the activation and proliferation of immune cells. This catabolic response occurs with all infections, even when they are subclinical, and serves to bring about a redistribution of nutrients away from skeletal muscle and adipose tissue and towards the host immune system. This redistribution is mediated by the production of proinflammatory cytokines by leukocytes and associated endocrine changes. Amino acids, mobilized from skeletal muscle, are used by the liver for the synthesis of acute-phase

proteins (e.g. C-reactive protein) and by leukocytes for the synthesis of immunoglobulin and cytokines. The average loss of protein over a range of infections has been estimated to be 0.6–1.2 g/kg body weight per day.

It is clear that the inflammatory cytokines mediate many of the effects that lead to compromised nutritional status following an infection, including anorexia, increased energy expenditure, and redistribution of nutrients, while malabsorption and maldigestion are brought about by the pathogen itself. The result is that an increased nutrient requirement coincides with reduced nutrient intake, reduced nutrient absorption, and nutrient losses (Figure 44.4).

### Why Should Nutrients Affect Immune Function?

Although the immune system is functioning at all times, specific immunity becomes activated when the host is challenged by pathogens. This activation is associated with a marked increase in the demand of the immune system

for substrates and nutrients to provide a ready source of energy, which can be supplied from exogenous sources (i.e. from the diet) and/or from endogenous pools. The cells of the immune system are metabolically active and are able to utilize glucose, amino acids, and fatty acids as fuels (Calder, 1995). Energy generation involves electron carriers and a range of coenzymes, which are usually derivatives of vitamins. The final component of the pathway for energy generation (the mitochondrial electron transfer chain) includes electron carriers that have iron or copper at their active site. Activation of the immune response gives rise to the production of proteins (immunoglobulins, cytokines, cytokine receptors, adhesion molecules, acute-phase proteins) and lipid-derived mediators (prostaglandins, leukotrienes). To respond optimally there must be the appropriate enzymic machinery in place (for RNA synthesis and protein synthesis and their regulation) and ample substrate available (nucleotides for RNA synthesis, the correct mix of amino acids for protein synthesis, polyunsaturated fatty acids [PUFAs] for eicosanoid synthesis). An important component of the immune response is oxidative burst, during which superoxide anion radicals are produced from oxygen in a reaction linked to the oxidation of NADPH. The reactive oxygen species produced can be damaging to host tissues and thus antioxidant protective mechanisms are necessary. Among these are the classic antioxidant vitamins (vitamins E and C), glutathione, the antioxidant enzymes superoxide dismutase and catalase, and the glutathione recycling enzyme glutathione peroxidase. The antioxidant enzymes all have metal ions at their active site (manganese, copper, zinc, iron, selenium). Cellular proliferation is a key component of the immune response, providing amplification and memory: before division there must be replication of DNA and then of all cellular components (proteins, membranes, intracellular organelles, etc.). In addition to energy, this clearly needs a supply of nucleotides (for DNA and RNA synthesis), amino acids (for protein synthesis), fatty acids, bases, and phosphate (for phospholipid synthesis), and other lipids (e.g. cholesterol) and cellular components. Although nucleotides are synthesized mainly from amino acids, some of the cellular building blocks cannot be synthesized in mammalian cells and must come from the diet (e.g. essential fatty acids, essential amino acids, minerals). Amino acids (e.g. arginine) are precursors for the synthesis of polyamines, which have roles in the regulation of DNA replication and cell division. Various micronutrients (e.g. iron, folic acid, zinc, magnesium) are also involved in

nucleotide and nucleic acid synthesis. Thus, the roles for nutrients in immune function are many and varied, and it is easy to appreciate that an adequate and balanced supply of these is essential if an appropriate immune response is to be mounted.

## Assessment of the Effect of Nutrition on Immune Function

There is a wide range of methodologies by which to assess the impact of nutrients on immune function (Cummings *et al.*, 2004; Albers *et al.*, 2005; Calder, 2007a). Assessments can be made of cell functions *ex vivo* (i.e. of the cells isolated from animals or humans subjected to dietary manipulation and studied in short- or long-term culture) or of indicators of immune function *in vivo* (e.g. by measuring the concentrations of proteins relevant to immune function in the bloodstream or the response to an immunological challenge). Box 44.1 lists some examples of approaches used for the assessment of immune function. However, the biological relevance of these markers of immune function remains unclear, and there is no single marker that can be used to draw conclusions about modulation of the immune system as a whole, apart from infection as a clinical outcome. An expert group identified measures of delayed-type hypersensitivity (DTH; the cell-mediated immune response to controlled application of an antigen usually through the skin), the response to vaccination, and the production of secretory IgA as the most suitable assessments of immune function in humans (Albers *et al.*, 2005).

## Obesity and Immune Function

Comparisons between lean and obese individuals suggest that obesity is associated with impairments of the bacterial killing capacity of granulocytes, T-lymphocyte proliferation, natural killer cell activity, and delayed-type hypersensitivity, with increased susceptibility to infection, and with poorer outcome from infection (Marti *et al.*, 2001). Obesity was identified as one of the major co-morbidities associated with death from H1N1 influenza infection during the 2009–2010 pandemic (Lucas, 2010). Factors derived from adipose tissue, such as the cytokine-like hormone leptin, may play a role in immune regulation and may explain some of the effects of obesity on immunity (Matarese *et al.*, 2010). Adipose tissue is infiltrated with immune cells, notably, but not exclusively, macrophages,

**BOX 44.1 Approaches used to assess the effect of nutrition on immune function*****In vivo measures***

Size of lymphoid organs  
 Cellularity of lymphoid organs  
 Numbers of cells circulating in bloodstream  
 Cell surface expression of molecules involved in immune response (e.g. antigen presentation)  
 Circulating concentrations of Ig specific for antigens after an antigen challenge (e.g. vaccination)  
 Concentration of secretory IgA in saliva, tears, and intestinal washings  
 Delayed-type hypersensitivity response to intradermal application of antigen  
 Response to challenge with live pathogens (mainly animal studies – outcome usually survival)  
 Incidence and severity of infectious diseases – widely used in human studies

***Ex vivo measures***

Phagocytosis by neutrophils and macrophages  
 Oxidative burst by neutrophils and macrophages  
 Natural killer cell activity against specific target cells (usually tumor cells)  
 Cytotoxic T-lymphocyte activity against specific target cells  
 Lymphocyte proliferation (following stimulation with an antigen or mitogen)  
 Production of cytokines by lymphocytes and macrophages  
 Production of immunoglobulins by lymphocytes  
 Cell surface expression of molecules involved in cellular activation

and releases a range of inflammatory mediators (Tilg and Moschen, 2006). As such, obesity is a state of chronic low-grade inflammation.

**Protein–Energy Malnutrition and Immune Function**

Protein–energy malnutrition, although often considered a problem solely of developing countries, has been described in even the most affluent nations. It is important to recognize that protein–energy malnutrition often coexists with micronutrient deficiencies, and poor outcome of intervention can result from a lack of awareness of multi-

ple deficiencies. Practically all forms of immunity may be affected by protein–energy malnutrition, but non-specific defenses and cell-mediated immunity are more severely affected than humoral (antibody) responses (Chandra, 1991; Kuvibidila *et al.*, 1993; Woodward, 1998, 2001). Protein–energy malnutrition causes atrophy of the lymphoid organs (thymus, spleen, lymph nodes, tonsils) in laboratory animals and humans. There is a decline in the number of circulating lymphocytes, which is proportional to the extent of malnutrition, and the proliferative responses of T-lymphocytes to mitogens and antigens is decreased by malnutrition as is the synthesis of IL-2 and IFN- $\gamma$  and the activity of natural killer cells. Production of cytokines by monocytes (TNF- $\alpha$ , IL-6, and IL-1 $\beta$ ) is also decreased by malnutrition, although their phagocytic capacity appears to be unaffected. The *in vivo* skin DTH response to challenge with specific antigens is reduced by malnutrition. However, numbers of circulating B-lymphocytes and immunoglobulin levels do not seem to be affected or may even be increased by malnutrition; underlying infections may influence these latter observations.

**The Influence of Individual Micronutrients on Immune Function**

Much of what is known about the impact of single nutrients on immune function comes from studies of deficiency states in animals and humans, and from controlled animal studies in which the nutrients are included in the diet at known levels. There is now overwhelming evidence from these studies that particular nutrients are required for an efficient immune response and that deficiencies in one or more of these nutrients diminish immune function and provide a window of opportunity for infectious agents. It is logical that multiple nutrient deficiencies might have a more significant impact on immune function, and therefore resistance to infection, than a single nutrient deficiency. What is also apparent is that excess amounts of some nutrients also impair immune function and decrease resistance to pathogens. Thus, for some nutrients, there may be a relatively narrow range of intake that is associated with optimal immune function.

***Vitamin A***

The vitamin A (or retinoid) family includes retinol, retinal, retinoic acid, and esters of retinoic acid. There is a transi-

tory decrease in serum retinol during the acute-phase response which follows infection, which is likely to be due to decreased synthesis of retinol binding protein (RBP) by the liver, and therefore decreased release of retinol-RBP by the liver, and also to increased vascular permeability at sites of inflammation, allowing leakage into the extravascular space. For these reasons, serum retinol cannot be used as an indicator of vitamin A status in individuals with an active acute-phase response.

Vitamin A is essential for maintaining epidermal and mucosal integrity; vitamin A-deficient mice have histopathological changes in the gut mucosa consistent with a breakdown in gut barrier integrity and impaired mucus secretion, both of which would facilitate entry of pathogens through this route. One of the key changes caused by vitamin A deficiency is the loss of mucus-producing goblet cells; the resulting lack of mucus diminishes resistance to infection by pathogens that would otherwise be trapped and washed away. Vitamin A regulates keratinocyte differentiation, and vitamin A deficiency induces changes in skin keratinization, which may explain the observed increased incidence of skin infection. Many aspects of innate immunity, in addition to barrier function, are affected by vitamin A (Semba, 1998, 1999, 2002; Stephensen, 2001; Villamor and Fawzi, 2005). It modulates gene expression to control the maturation of neutrophils; in vitamin A deficiency there are increased neutrophil numbers, but decreased phagocytic function. Macrophage-mediated inflammation is increased by vitamin A deficiency, but the ability to ingest and kill bacteria is impaired. Vitamin A deficiency may therefore lead to more severe infections, coupled with excessive inflammation. Natural killer cell activity is diminished by vitamin A deficiency. The impact of vitamin A on acquired immunity is less clear, but there is some evidence that vitamin A deficiency alters the Th1/Th2 balance, decreasing the Th2 response, but often without affecting the Th1 response (Stephensen, 2001). This area requires further research.

The impact of vitamin A deficiency on infectious disease has been studied widely in the developing world (Scrimshaw and SanGiovanni, 1997; Semba, 1999; Calder and Jackson, 2000; Stephensen, 2001; Villamor and Fawzi, 2005). Vitamin A deficiency is associated with increased morbidity and mortality in children, and appears to predispose to respiratory infections, diarrhea, and severe measles. Although vitamin A deficiency increases the risk of infec-

tious disease, the interaction is bidirectional such that infections can lead to vitamin A deficiency: diarrhea, respiratory infections, measles, chickenpox, and human immunodeficiency virus infection are all associated with the development of vitamin A deficiency.

Replenishment of vitamin A in deficient children by provision of supplements decreases mortality in areas of the world where deficiency is a problem. In general, frequent small doses tend to decrease mortality more dramatically than infrequent high doses. Vitamin A supplements improve recovery from measles and decrease the duration, risk of complications, and mortality from the disease. Because measles is an acute, immunosuppressive viral infection, it is often associated with secondary opportunistic bacterial infections, and it is not clear whether vitamin A improves recovery from the measles itself, the secondary infection, or both. The ability of vitamin A to promote the regeneration of damaged mucosal epithelium and phagocytic activity of neutrophils and macrophages results in a reduction in the incidence and duration of diarrhea, which may be of particular benefit to infants who are not breast-fed.

### **B Vitamins**

B vitamins participate as coenzymes in the synthesis of nucleic acids and proteins, pathways which are crucial for many aspects of immune function. There is some suggestion that folate supplementation of elderly individuals improves immune function, and, in particular, natural killer cell activity, although this is not conclusive (Troen *et al.*, 2006). Elderly subjects supplemented for 4 months with a combination of folic acid (400 µg/day), vitamin E (120 IU/day), and vitamin B<sub>12</sub> (3.8 µg/day) were reported to have increased natural killer cell activity and fewer infections in one study (Bunout *et al.*, 2004). Elderly individuals tend to be at risk of vitamin B<sub>12</sub> deficiency, and studies have shown that subjects >65 years with low serum vitamin B<sub>12</sub> concentrations have impaired antibody responses to vaccination (Fata *et al.*, 1996). Patients with vitamin B<sub>12</sub> deficiency also have decreased numbers of lymphocytes and suppressed natural killer cell activity, which may be reversed with supplementation (Tamura *et al.*, 1999). Vitamin B<sub>6</sub> deficiency in laboratory animals causes thymus and spleen atrophy, and decreases lymphocyte proliferation and the DTH response. In a study in healthy elderly humans, a vitamin B<sub>6</sub>-deficient diet (3 µg/kg body weight per day or about 0.17 and 0.1

mg/day for men and women, respectively) for 21 days resulted in a decreased percentage and total number of circulating lymphocytes, decreased T- and B-cell proliferation in response to mitogens, and decreased IL-2 production (Meydani *et al.*, 1991). Repletion at 15 or 22.5 µg/kg body weight per day for 21 days did not return the immune functions to starting values; however, repletion at 33.75 µg/kg body weight per day (about 1.9 and 1.1 mg/day for men and women, respectively) returned immune parameters to starting values. This comprehensive study indicates that vitamin B<sub>6</sub> deficiency impairs human immune function, and that the impairment is reversible by repletion.

### Vitamin C

Vitamin C is a water-soluble antioxidant found in high concentrations in circulating leukocytes and appears to be utilized during infections. High circulating levels of vitamin C are associated with enhanced antibody responses, neutrophil function, and antiviral activity in animal studies. In humans, supplementation studies have often been conducted in athletes. The interest in athletes is due to the fact that exercise induces an increase in the numbers of neutrophils and their capacity to produce reactive oxygen species, which, if prolonged, can be immunosuppressive and reduce neutrophil activity in the recovery period following exercise. Since neutrophils form an important part of the defense against viruses, the suppression of neutrophil activity after strenuous exercise may explain why upper respiratory tract infections are often noted to coincide with this. Because of its antioxidant capacity, vitamin C could potentially counteract the exercise-induced generation of reactive oxygen species and limit the post-exercise immunosuppression. However, randomized controlled trials (RCTs) have often been limited by lack of statistical power and do not conclusively show an effect of vitamin C on cell numbers, neutrophil function, or reactive oxygen species production (Wintergerst *et al.*, 2007).

Several studies suggest a modest benefit of vitamin C supplementation at doses ranging between 1000 and 8000 mg/day in reducing the duration, but not the incidence, of respiratory infections (Douglas *et al.*, 2007). However, the incidence of common colds and pneumonia has been shown to be reduced by vitamin C in those individuals who regularly engage in strenuous physical activity, and also in those who live in crowded conditions. The potential benefits and risks of vitamin C supple-

mentation at doses above 8000 mg/day, and the role of vitamin C in non-respiratory infections, have not been investigated.

### Vitamin D

The active form of vitamin D (1,25-dihydroxyvitamin D<sub>3</sub>) is referred to here as vitamin D. Vitamin D receptors have been identified in most immune cells, and some cells of the immune system can synthesize the active form of vitamin D from its precursor, suggesting that vitamin D is likely to have immunoregulatory properties. Some reports suggest immune defects in vitamin D-deficient patients and experimental animals, and there is anecdotal evidence that individuals with rickets are particularly prone to infection. A recent study reported that individuals with low vitamin D status had a higher risk of viral respiratory tract infections (Sabetta *et al.*, 2010). Supplementation of Japanese schoolchildren with vitamin D (1200 U/day) for 4 months during winter decreased by about 40% the risk of influenza (Urashima *et al.*, 2010). These studies suggest that vitamin D acts to improve immune function. However, there is, paradoxically, a large body of literature supporting an immunosuppressive role for vitamin D and related analogs (Griffin *et al.*, 2003; Hayes *et al.*, 2003; Cantorna *et al.*, 2004; van Etten and Mathieu, 2005; Bruce *et al.*, 2010). The current view is that under physiological conditions vitamin D probably facilitates immune responses, but that it may also play an active role in the prevention of autoimmunity and that there may be a therapeutic role for vitamin D in some immune-mediated diseases. Vitamin D acts by binding to its receptor and regulating gene expression in target cells. Its effects include promotion of phagocytosis, superoxide synthesis, and bacterial killing, but it is also reported to inhibit T-cell proliferation, production of Th1 cytokines, and B-cell antibody production, highlighting the paradoxical nature of its effects. The role of vitamin D in autoimmunity is particularly interesting; there is increasing evidence, mainly from animal studies, that vitamin D deficiency is linked with autoimmune diseases such as multiple sclerosis, rheumatoid arthritis, and inflammatory bowel disease. The inhibition by vitamin D of Th1-type immune activity, which underlies many autoimmune conditions, is thought to be key to this link (Lemire *et al.*, 1995; Bruce *et al.*, 2010). In addition, a polymorphism in the vitamin D receptor gene has been associated with increased risk of Crohn's disease. Taken together, the evidence suggests

that vitamin D is a selective regulator of immune function and the effects of vitamin D deficiency, vitamin D receptor deficiency or vitamin D supplementation depend on the immunological situation (e.g. health, infectious disease, autoimmune disease).

### **Vitamin E**

Vitamin E is the major lipid-soluble antioxidant in the body and is required for protection of membrane lipids from peroxidation. Free radicals and lipid peroxidation are immunosuppressive; thus, it is considered that vitamin E should act to optimize and even enhance the immune response (Meydani and Beharka, 1998; Meydani *et al.*, 2005). Indeed, a positive association exists between plasma vitamin E levels and DTH responses, and a negative association has been demonstrated between plasma vitamin E levels and the incidence of infections in healthy adults over 60 years of age (Chavance *et al.*, 1989). There appears to be particular benefit of vitamin E supplementation for the elderly (Meydani *et al.*, 1990; Pallast *et al.*, 1999), with studies demonstrating enhanced Th1 cell-mediated immunity at high doses. A comprehensive study demonstrated increased DTH responses in elderly subjects supplemented with 60, 200, and 800 mg/day of vitamin E, with maximal effect at a dose of 200 mg/day (Meydani *et al.*, 1997). This dose also increased the antibody responses to hepatitis B, tetanus toxoid and pneumococcus vaccinations. This "optimal" dose of 200 mg/day of vitamin E is well in excess of the recommended dietary intake; thus, it appears that adding vitamin E to the diet at levels beyond those normally recommended may enhance some immune functions above normal, and it has even been argued that the recommended intake for vitamin E is not adequate for optimal immune function. However, RCTs do not consistently support a role for vitamin E supplementation in reducing the incidence, duration or severity of respiratory infections in elderly populations (Graat *et al.*, 2002), although one large study did show benefit specifically for upper respiratory tract infections (Meydani *et al.*, 2004).

### **Zinc**

Zinc is important for DNA synthesis and in cellular growth and differentiation and antioxidant defense. Zinc deficiency impairs many aspects of innate immunity, including phagocytosis by macrophages and neutrophils, natural killer cell activity, and respiratory burst and com-

plement activity, all of which could be important contributors to increased susceptibility to infection (Fraker *et al.*, 1993; Scrimshaw and SanGiovanni, 1997; Shankar and Prasad, 1998; Calder and Jackson, 2000; Prasad, 2002, 2008; Fraker and King, 2004). Zinc deficiency has a marked impact on bone marrow, decreasing the number of nucleated cells and the number and proportion of cells that are lymphoid precursors (Fraker and King, 2004). In patients with zinc deficiency related to sickle-cell disease, natural killer cell activity is decreased, but can be returned to normal by zinc supplementation. In acrodermatitis enteropathica, which is characterized by reduced intestinal zinc absorption, thymic atrophy, impaired lymphocyte development, and reduced lymphocyte responsiveness and DTH are observed (Shankar and Prasad, 1998). Moderate or mild zinc deficiency or experimental zinc deficiency (induced by consumption of <3.5 mg zinc/day) in humans results in decreased thymulin activity, natural killer cell activity, lymphocyte proliferation, IL-2 production, and DTH response; all can be corrected by zinc repletion (Beck *et al.*, 1997).

Low plasma zinc levels can be used to predict the subsequent development of lower respiratory tract infections and diarrhea in malnourished populations (Calder and Jackson, 2000; Prasad, 2002; Fischer Walker and Black, 2004). Indeed, diarrhea is considered a symptom of zinc deficiency and several studies show that zinc supplementation decreases the incidence, duration, and severity of childhood diarrhea. Effects of zinc on respiratory tract infections are less clear. Most (but not all) studies fail to show a benefit of zinc supplementation in respiratory disease in malnourished populations, and available trials on the effect of zinc on the common cold in non-malnourished populations report conflicting results (Marshall, 2000; Turner and Cetnarowski, 2000). Very high zinc intakes can result in copper depletion, and copper deficiency impairs immune function and increases susceptibility to infection (Failla and Hopkins, 1998; Percival, 1998).

### **Iron**

Iron deficiency has multiple effects on immune function in laboratory animals and humans (Sherman and Spear, 1993; Kuvibidila and Baliga, 2002; Weiss, 2002). However, the relationship between iron deficiency and susceptibility to infection remains controversial (Oppenheimer, 2001; Weiss, 2002; Schaible and Kaufmann, 2004). Furthermore, evidence suggests that infections caused by organisms that

spend part of their life cycle intracellularly, such as plasmodia, mycobacteria, and invasive salmonellae, may actually be enhanced by iron therapy. In the tropics in children of all ages, at doses of  $>2$  mg/kg/day, iron has been associated with increased risk of malaria and other infections, including pneumonia. For these reasons, iron intervention in malaria-endemic areas is not advised, particularly high doses in the young, those with compromised immunity (e.g. HIV infection), and during the peak malaria transmission season. Iron treatment for anemia in a malarious area must be preceded by effective antimalarial therapy and should be oral rather than parenteral. The detrimental effects of iron administration may occur because microorganisms require iron and providing it may favor the growth and replication of the pathogen. Indeed, it has been argued that the decline in circulating iron concentrations that accompanies infection is an attempt by the host to “starve” the infectious agent of iron. There are several mechanisms for withholding iron from a pathogen in this way. Lactoferrin has a higher binding affinity for iron than do bacterial siderophores, making bound iron unavailable to the pathogen. Furthermore, once lactoferrin reaches 40% saturation with iron, it is sequestered by macrophages. It is notable that breast milk contains lactoferrin, which may protect against the use of free iron by pathogens transferred to an infant. It is important to note that oral iron supplementation has not been shown to increase risk of infection in non-malarious countries (Oppenheimer, 2001).

### **Selenium**

Selenium is essential for an effectively functioning immune system. Deficiency in laboratory animals affects both innate and adaptive immunity, particularly neutrophil function (Stabel and Spears, 1993; McKenzie *et al.*, 1998). It also increases susceptibility to bacterial, viral, fungal, and parasitic challenges. Lower selenium concentrations in humans have also been linked with increased virulence, diminished natural killer cell activity, increased mycobacterial disease, and HIV progression. Selenium supplementation has been shown to improve various aspects of immune function in humans (Kiremidjian-Schumacher *et al.*, 1994; Roy *et al.*, 1994; Hawkes *et al.*, 2001), including the elderly (Peretz *et al.*, 1991; Roy *et al.*, 1995). Selenium supplementation (50 or 100  $\mu$ g/day) in adults with low selenium status improved some aspects of their immune response to a poliovirus vaccination (Broome *et al.*, 2004).

## **Dietary Fat and Immune Function**

### ***Eicosanoids: A Link between Fatty Acids and the Immune System***

Fatty acids can affect immune function through a variety of actions, including alterations in membrane structure, cell signalling mechanisms, and gene expression (Calder, 2008). However, the best described mechanism of action of polyunsaturated fatty acids (PUFAs) is through influencing the production of a class of lipid mediators termed eicosanoids that play important roles in regulating immunity and inflammation (Tilley *et al.*, 2001). The membranes of most immune cells contain large amounts of arachidonic acid, which is the principal precursor for eicosanoid synthesis. Arachidonic acid in cell membranes can be mobilized by various phospholipase enzymes, most notably phospholipase A<sub>2</sub>, and the free arachidonic acid can subsequently act as a substrate for cyclooxygenase enzymes (COX), forming prostaglandins (PGs) and related compounds, or, for one of the lipoxygenase (LOX) enzymes, forming leukotrienes (LTs) and related compounds. Di-homo- $\gamma$ -linolenic acid and eicosapentaenoic acid are also precursors for eicosanoid synthesis, and the mediators produced from each different substrate have different structures and different biological potencies. Eicosanoids are formed in a cell-specific manner and may have opposing effects to one another, so the overall physiological or pathophysiological effect will be governed by the nature of the cells producing the eicosanoids, the concentrations of the different eicosanoids, the timing of their production, and the sensitivities of target cells to their effects.

### ***Essential Fatty Acid Deficiency and Immune Function***

Animal studies have shown that deficiencies in both linoleic and  $\alpha$ -linolenic acids result in decreased thymus and spleen weight, and reduced lymphocyte proliferation, neutrophil chemotaxis, macrophage-mediated cytotoxicity, and DTH response. Thus, the immunological effects of essential fatty acid deficiency appear to be similar to the effects of single micronutrient deficiencies, although there are no human studies to confirm this (essential fatty acid deficiency is very rare in humans). Essential fatty acid deficiency probably has its effects because cells of the immune system require PUFAs for membrane synthesis and as precursors for the synthesis of eicosanoids.

### **Amount of Dietary Fat and Immune Function**

High-fat diets have been reported to result in diminished immune cell functions (both natural and cell-mediated immunity) compared with low-fat diets in both humans (Barone *et al.*, 1989; Kelley *et al.*, 1992; Han *et al.*, 2003) and experimental animals, but the precise effect depends on the exact level of fat used in the high-fat diet and its source.

### **Effect of Specific Fatty Acids or Fatty Acid Families on Immune Function**

Saturated fatty acids appear to have little impact on humoral or cell-mediated immune function, but cell culture, animal model, and human epidemiological studies all indicate that some saturated fatty acids promote inflammation. N-6 PUFAs are also believed to promote inflammation through the actions of eicosanoids, but human studies do not fully support this contention. Cell culture and animal model studies have shown that marine n-3 PUFAs (eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]) suppress both inflammation and cell-mediated immune responses (Calder, 2003, 2006), acting through a variety of mechanisms including altered:

- membrane structure;
- membrane and intracellular signalling processes;
- gene expression profiles;
- production of eicosanoids.

EPA and DHA also give rise to resolvins and related lipid mediators that have potent anti-inflammatory and inflammation-resolving activities (Serhan *et al.*, 2008).

Epidemiological studies in humans, and studies in which human subjects are given marine n-3 PUFAs, demonstrate that these fatty acids are anti-inflammatory, but less consistent effects of cell-mediated immunity are demonstrated. Consistent with their anti-inflammatory effects, marine n-3 PUFAs have some treatment efficacy in certain chronic inflammatory conditions (Calder, 2009a,b). Animal studies show variable effects of marine n-3 PUFAs (and indeed other fatty acids) on the ability to handle pathogens (Anderson and Fritsche, 2002) and there is little information on fatty acids and infection in humans.

## **Dietary Amino Acids and Immune Function**

### **Sulfur Amino Acids**

Sulfur amino acids are essential in humans. Deficiency in methionine and cysteine results in atrophy of the thymus,

spleen and lymph nodes, and prevents recovery from protein–energy malnutrition (Gross and Newberne, 1980; Grimble and Grimble, 1998; Grimble, 2002). When combined with a deficiency of isoleucine and valine, also essential amino acids, sulfur amino acid deficiency results in severe depletion of gut lymphoid tissue, very similar to the effect of protein deprivation (Gross and Newberne, 1980). Glutathione is a tripeptide that consists of glycine, cysteine, and glutamate. It is recognized to have antioxidant properties. Glutathione concentrations in the liver, lung, small intestine, and immune cells fall in response to inflammatory stimuli (probably as a result of oxidative stress), and this fall can be prevented in some organs by the provision of cysteine in the diet. Although the limiting precursor for glutathione biosynthesis is usually cysteine, the ability of sulfur amino acids to replete glutathione stores is related to the protein level of the diet. Glutathione can enhance the activity of cytotoxic T-cells, while depletion of intracellular glutathione diminishes lymphocyte proliferation and the generation of cytotoxic T-lymphocytes (Peterson *et al.*, 1998).

### **Arginine**

Arginine is a non-essential amino acid in humans and is involved in protein, urea, and nucleotide synthesis, and adenosine triphosphate (ATP) generation. It also serves as the precursor of nitric oxide, a potent immunoregulatory mediator that is cytotoxic to tumor cells and to some microorganisms. In laboratory animals arginine decreases the thymus involution associated with trauma, promotes thymus repopulation and cellularity, increases lymphocyte proliferation, natural killer cell activity, and macrophage cytotoxicity, improves DTH, increases resistance to bacterial infections, increases survival to sepsis and burns, and promotes wound healing (Evoy *et al.*, 1998; Duff and Daly, 2002). There are indications that arginine may have similar effects in humans, although these have not been tested thoroughly.

### **Glutamine**

Glutamine is the most abundant amino acid in the blood and in the free amino acid pool in the body; skeletal muscle is considered to be the most important glutamine producer in the body. Once released from skeletal muscle, glutamine acts as an inter-organ nitrogen transporter. One important user of glutamine is the immune system. Plasma glutamine levels are lowered (by up to 50%) by sepsis, injury, and burns, and following surgery. Furthermore, the skeletal muscle glutamine concentration is lowered by

more than 50% in at least some of these situations. These observations indicate that a significant depletion of the skeletal muscle glutamine pool is characteristic of trauma. The lowered plasma glutamine concentrations that occur are likely to be the result of demand for glutamine (by the liver, kidney, gut, and immune system) exceeding the supply, and it has been suggested that the lowered plasma glutamine contributes, at least in part, to the impaired immune function that accompanies such situations. It has been argued that restoring plasma glutamine concentrations in these situations should restore immune function. As with arginine, there are animal studies to support this (Calder and Yaqoob, 1999; Calder and Newsholme, 2002). Clinical studies, mainly using intravenous infusions of solutions containing glutamine, have also reported beneficial effects for patients undergoing bone marrow transplantation and colorectal surgery, patients in intensive care, and low-birth-weight babies, all of whom are at risk from infection and sepsis (Calder, 2007b). In some of these studies, improved outcome was associated with improved immune function. In addition to a direct immunological effect, glutamine, even provided intravenously, improves gut barrier function in patients at risk of infection. This would have the benefit of decreasing the translocation of bacteria from the gut and eliminating a key source of infection.

### Probiotics, Prebiotics and Immune Function

Indigenous bacteria are believed to contribute to the immunological protection of the host by creating a barrier against colonization by pathogenic bacteria. This barrier can be disrupted by disease and by the use of antibiotics, so allowing easier access to the host gut by pathogens. It is now believed that this barrier can be maintained by providing supplements containing live “desirable” bacteria; such supplements are termed probiotics. Probiotic organisms are found in fermented foods including traditionally cultured dairy products and some fermented milks. The organisms used commercially as probiotics are typically lactobacilli or bifidobacteria. These organisms only colonize the gut temporarily, making regular consumption necessary. In addition to creating a barrier effect, some of the metabolic products of probiotic bacteria (e.g. lactic acid and a class of antibiotic proteins termed bacteriocins produced by some bacteria) may inhibit the growth of pathogenic organisms. Probiotic bacteria may also compete

with pathogenic bacteria for nutrients and may enhance the gut immune response to pathogenic bacteria. Probiotics have various routes for internalization by the gut epithelium and contact with underlying immune tissues; it is through these interactions that probiotics are thought to be able to influence immune function. However, the nature of this regulation is not very well understood. A number of studies have examined the influence of various probiotic organisms, either alone or in combination, on immune function, infection and inflammatory conditions in humans (Lomax and Calder, 2009a). Probiotics appear to enhance innate immunity (particularly phagocytosis and natural killer cell activity), but have lesser effects on adaptive immunity. In children, probiotics have been shown to reduce the incidence and duration of diarrhea, although the effects depend on the nature of the condition. In adults, some studies demonstrate a reduction in the risk of traveller’s diarrhea. The effect on other infectious outcomes is much less clear. There is some evidence that probiotics could be beneficial in ulcerative colitis, irritable bowel syndrome, and allergy. One of the difficulties in interpreting results is that there may be significant species and strain differences in the effects of probiotics, as well as differences in doses used, duration of treatment, and subject characteristics.

Prebiotics are typically, though not exclusively, carbohydrates which are not digestible by mammalian enzymes but which are selectively fermented by gut microbiota, leading to increased numbers of beneficial bacteria within the gut. Although there is growing evidence for potential immunomodulatory effects of prebiotics (Lomax and Calder, 2009b), it is not clear whether they are direct effects, or manifested through alteration of the gut microbiota.

### Breastfeeding and Immune Function

#### *The Composition of Breast Milk*

Breast milk is the best example of a foodstuff with immune-enhancing properties. Breast milk contains a wide range of immunologically active components, including cells (macrophages, T- and B-lymphocytes, neutrophils), immunoglobulins (IgG, IgM, IgD, sIgA), lysozyme (which has direct antibacterial action), lactoferrin (which binds iron, so preventing its uptake by bacteria), cytokines (IL-1, IL-6, IL-10, IFN- $\gamma$ , TNF- $\alpha$ , transforming growth factor- $\beta$ ), growth factors (epidermal growth factor, insulin-like growth factor), hormones (thyroxin), fat-soluble vitamins

(vitamins A, D, E), amino acids (taurine, glutamine), fatty acids, amino sugars, nucleotides, gangliosides, and prebiotic oligosaccharides (Emmett and Rogers, 1997; Bernt and Walker, 1999). Breast milk also contains factors that prevent the adhesion of some microorganisms to the gastrointestinal tract and so prevents bacterial colonization. Human breast milk contains factors that promote the growth of useful bacteria (e.g. bifidobacteria) in the gut. The content of many factors varies among milks of different species, and is different between human breast milk and infant formulas.

### **Breastfeeding and Infection**

Breastfeeding is thought to play a key role in the prevention of infectious disease, particularly diarrhea and gastrointestinal and lower respiratory infections, in both developing and developed countries (Golding *et al.*, 1997a,b,c). In addition to preventing infectious disease, breastfeeding enhances the antibody responses to vaccination. A meta-analysis of studies that examined the effect of breastfeeding versus formula-feeding on risk of death due to infectious diseases in developing countries identified that infants who are not breast-fed have a six-fold greater risk of dying from infectious diseases in the first 2 months of life than those who are breast-fed. However, it appears that this protection decreases steadily with age, as infants begin complementary feeding, so that, by 6–11 months, the protection afforded by breastfeeding is no longer apparent. Breastfeeding may provide better protection against diarrhea (up to 6 months of age) than against deaths due to respiratory infections. There are also geographical influences on the protection afforded by breastfeeding; in some continents, protection can be observed throughout the first year of life, whereas in others it is much more short-lived.

### **Other Considerations**

Deficiencies of total energy or of one or more essential nutrients, including vitamins A, B<sub>6</sub>, B<sub>12</sub>, C, and E, folic acid, zinc, iron, copper, selenium, essential amino acids, and essential fatty acids, impair immune function and increase susceptibility to infectious pathogens. This occurs because each of these nutrients is involved in the molecular and cellular responses to challenge of the immune system. Providing these nutrients to deficient individuals restores immune function and improves resistance to infection. For

some nutrients the dietary intakes that result in greatest enhancement of immune function are greater than recommended intakes. However, excessive intake of some nutrients also impairs immune responses. It is often assumed, when considering the relationship between nutrient intake and immune function, that all components of the immune system will respond in the same dose-dependent fashion to a given nutrient. This is not correct, at least as far as some nutrients are concerned, and it appears likely that different components of the immune system show an individual dose–response relationship to the availability of a given nutrient, meaning that the overall impact of the nutrient is difficult to predict.

Although outside the scope of this chapter, it is important to consider the role of hormones in regulating immune function during malnutrition. An inadequate supply of nutrients to the body may cause physiological stress, leading to an elevation in the circulating concentrations of glucocorticoids and catecholamines. Both classes of hormones have an inhibitory effect on immune function and may therefore be important factors when considering the relationship between nutrient supply and immunological outcome.

It is now appreciated that the supply of nutrients that are not considered to be essential according to traditional criteria may also influence immune function; this is particularly notable for the amino acids glutamine and arginine, and may indicate that a re-evaluation of the definitions of essentiality, nutrient requirements, and nutrient status is required for some dietary components.

Finally, an early point of contact between nutrients and the immune system occurs within the intestinal tract. Relatively little is known about the relationship between nutrient status and the function of the gut-associated immune system. This is of particular relevance when considering adverse reactions to foods: the role of immunoregulatory nutrients in responses to food components and in sensitization to food-borne allergens is largely unknown. An understanding of the interaction between nutrients, the types of bacteria that inhabit the gut, and gut-associated and systemic immune responses is only now beginning to emerge.

The term “optimal immune function” is often used in the literature without careful thought about its definition. An optimal immune response to any given nutrient measured by one marker will not necessarily be optimal according to a second marker of immune function. Furthermore, the effect of a given nutrient on immune response may be

altered by levels of other nutrients. For these reasons, the desire to “optimize” the immune response may not be realistic. At best, it is reasonable to expect that correction of marginal deficiencies will improve immunity, but further enhancement using supplements cannot be guaranteed and in excessive doses is likely to be detrimental. At the other extreme, there is interest in the potential therapeutic effect of nutrients in diseases involving dysregulation of the immune system (e.g. n-3 fatty acids in rheumatoid arthritis). In some but by no means all cases, there is supportive evidence for this approach. Between these extremes there are many unanswered questions, but it is clear that the modulation of immune function by nutrients has important implications in both developing and developed countries.

## Future Directions

Impaired immunity, in part related to poor nutrition, remains a major public health problem (Calder and Jackson, 2000). Diseases involving dysregulated immunity are of great clinical significance, with evidence that certain dietary components may have some influence on these conditions (Calder *et al.*, 2009). Thus, it is highly likely that significant research activity in the area of nutritional immunology will continue for the foreseeable future, that advances in identifying the effects of individual nutrients, combinations of nutrients, and particular foodstuffs will be made, and that these will be coupled with advances in the understanding of mechanisms of action involved (Calder *et al.*, 2002) and of the determinants that confer an individual’s sensitivity to the immunomodulating activity of particular nutrients (Calder and Kew, 2002). The discovery of new immune cell subtypes (e.g. regulatory T-cells, Th17 cells) and new mediators of immunity and inflammation (e.g. resolvins) is opening new avenues of research that will aid our understanding of the nutrition–immunity axis. Recognition of the chronology of events and of the factors that contribute to the acquisition of immune competence early in life (Calder *et al.*, 2006) and to the decline in immune competence with aging (Castle, 2000; Burns and Goodwin, 2004; Agarwal and Busse, 2010) will provide opportunities for studying and then targeting nutrition towards vulnerable periods of the life cycle. Awareness of immune impairments associated with obesity (Marti *et al.*, 2001) and that obesity and chronic diseases of aging such as cardiovascular disease have an

inflammatory component (Calder *et al.*, 2009) will focus attention on the interaction between nutrition, the immuno-inflammatory response, and other lifestyle, as well as genetic, factors. Finally the role of the gut microbiota in shaping host immune maturation and immune responses is beginning to be defined (Calder *et al.*, 2006), but the exact nature of the bacteria–host interaction is not yet well described; it is likely that this area will become a focus of research in nutritional immunology, and it is anticipated that great advances will be made fairly quickly (Saulnier *et al.*, 2009).

## OBESITY AS A HEALTH RISK

SUE D. PEDERSEN<sup>1</sup>, MD, FRCPC, ANDERS SJÖDIN<sup>2</sup>, MD, DMSc, AND  
ARNE ASTRUP<sup>2</sup>, MD, DMSc

<sup>1</sup>*LMC Endocrinology Centre, Calgary, Alberta, Canada*

<sup>2</sup>*University of Copenhagen, Frederiksberg, Denmark*

### Summary

Obesity is defined as a state of excess body fat and is classified by body mass index, though body fat distribution should also be taken into consideration. The prevalence of obesity has reached epidemic proportions globally. The etiology of most cases of obesity rests in a complex interplay between environmental, genetic, and psychosocial contributors, with endocrinological causes of obesity being responsible for only a minority of cases. Obesity carries with it many medical co-morbidities, including diabetes mellitus, several cardiac risk factors, an increased risk of malignancy, obstructive sleep apnea, osteoarthritis, and several psychosocial issues. Through these co-morbidities, obesity has a pronounced impact on disability and mortality. While an effective means of obesity prevention continues to evade us on a population level, a hypocaloric diet, a sustained commitment to physical activity, and attention to individual psychosocial and environmental contributors to obesity can be successful in weight reduction and maintenance of a healthy body weight.

### Introduction

Obesity has become the major nutrition-related disease of this century, and is defined as a condition of excessive body fat accumulation to an extent that increases the risk of complicating diseases. Overweight and obesity are responsible for the majority of new cases of type 2 diabetes, and contribute to high blood pressure, adverse blood lipid profile, infertility, birth complications, arthritis, and several cancers, and can amplify asthma and generally worsen overall health status. Although obesity should theoretically be preventable through changes in lifestyle, especially diet, physical activity, sleep, and psychological

stress, there are many powerful environmental and genetic drivers of obesity that can make effecting these changes and successfully preventing the disease exquisitely challenging.

### Epidemiology of Obesity

#### **Definition and Measurement of Obesity**

Obesity is not a single entity, but it is most commonly classified by a single measure, the body mass index (BMI), a ratio of weight and height ( $BMI = \text{weight (kg)}/\text{height}^2 (\text{m}^2)$ ). The World Health Organization (WHO) classifies

**TABLE 45.1** The international classification of adult underweight, overweight and obesity according to body mass index (BMI)

Classification	BMI (kg/m <sup>2</sup> )
Underweight	<18.5
Normal range	18.5–24.9
Overweight	≥25
Obese	≥30
Class I	30–34.9
Class II	35–39.9
Class III	≥40

underweight, normal weight, overweight and obesity according to categories of BMI (Table 45.1). This height-independent measure of weight allows comparisons to be made more readily within and between populations of the same ethnic origin. The definition of the “normal” range of BMI is based on Caucasian mortality data. For Asian populations the categories are: 18.5 kg/m<sup>2</sup> underweight; 18.5–23 kg/m<sup>2</sup>, increasing but acceptable risk; 23–27.5 kg/m<sup>2</sup>, increased risk; and 27.5 kg/m<sup>2</sup> or higher, high risk.

The body mass index has limitations, however, as it does not distinguish fat from lean tissue or water, nor does it identify whether the fat is accumulated in particular sites such as the abdomen, where it has more serious metabolic consequences. Techniques such as bioelectric impedance to estimate body fat, and DEXA (dual energy X-ray absorptiometry) scans to separate body mass into fat-free mass and fat mass, are increasingly used. DEXA, MR (magnetic resonance), and CT (computer tomography) scans are used for an accurate assessment of intra-abdominal adipose tissue, although BMI in combination with simple waist circumference is increasingly recognized as an easy and valid measure of overall cardiovascular risk. Waist to hip ratio and skinfold thickness may also be used to verify fatness in individuals.

### **Prevalence and Time Trends of Overweight and Obesity**

The prevalence of the problem of excess body weight is staggering, with over 1.5 billion overweight or obese adults worldwide. The steep increase in the prevalence of obesity that has been seen in recent decades has prompted this development to be called an epidemic, and, because it is worldwide, a pandemic. In 2010, 15% of adult men and 18% of women in Denmark were obese, and in the UK,

21% of men and 24% of women were obese, and a further 47% of men and 33% of women were overweight (BMI 25–30 kg/m<sup>2</sup>). Rates of overweight and obesity range from 10% to 20% in northern Europe and are higher still in southern Europe – from 20% to as high as 36% in parts of southern Italy. There is a higher than expected level of obesity among certain ethnic groups living in Europe, probably due to increased genetic susceptibility to the European lifestyle. Obesity rates are highest among people of Indian, Pakistani, and black Caribbean origin, and the prevalence of obesity in young people of Asian origin is three to four times higher than among Caucasians.

In the United States, the situation is even more extreme. In 2010, the prevalence there of obesity was 34%, though this obesity prevalence may now represent a plateau (Flegal *et al.*, 2010). Europe is following the track of the USA, but is about 10 years behind, so in 10 years can expect to reach the same level of obesity that exists in the USA today.

Obesity is now apparent in even some of the poorest countries of the world. Normally the obesity problem first appears in a country in the more affluent parts of the population, but in recent decades obesity is characteristically higher among groups with low levels of education, low income, and low social class.

The proportion of obese people increases with age until around the age of retirement. Beyond this age, the impact of obesity-related premature death and disease-related weight loss leads to a modest decline in the proportion of obese adults. People who today are in their 60s or older were born at a time of austerity and limited food supplies. Younger people have largely grown up in a world where a greater variety of food than ever before has become available, and at relatively low cost, and so they are more prone to develop obesity at a younger age.

Attention is increasingly focused on young people, where the problem of overweight and obesity has become more pronounced. Among young Danish males attending draft boards, there has been a dramatic increase in the prevalence of obesity, from 0.1% in 1955 to about 8% in 2000, corresponding to an 80-fold increase. In the United Kingdom in 1997, among 4- to 18-year-olds 4% were obese and a further 15% were overweight, with a higher rate of obesity among young people in Scotland and Wales relative to England. Childhood obesity was first recognized as a major problem in industrialized countries, but a sharp increase in the number of obese children in subpopulations of developing countries has more recently been

observed, particularly in urban areas. In heavily populated countries such as India and China, this poses a huge future health challenge unless the present trend is effectively halted. The decrease in the age of onset of obesity that is currently being observed is likely to lead to an increase in the number of years that subjects suffer from obesity-related morbidity and disability.

## Childhood Obesity

Obesity in children is one of the most important health challenges of our time. Even in young children, obesity is associated with higher blood pressure and LDL-cholesterol, in addition to an increased risk of steatohepatitis, type 2 diabetes, and psychosocial and musculoskeletal problems (Lobstein and Jackson-Leach, 2006; Puder and Munsch, 2010). However, for the majority of moderately obese children, the negative health consequences are mainly related to the risk of ongoing obesity into later life, and the concomitant risk of serious associated diseases (e.g. diabetes, cardiovascular disease, and cancer) (Adair, 2008). Appropriate strategies for identification of children at risk, coupled with effective treatment and prevention, are therefore of utmost importance, given the alarming increase in the prevalence of childhood obesity over the last 20 to 30 years.

Defining overweight and obesity in a meaningful way in the growing child is a particular challenge due to normal growth, which affects the BMI calculation. BMI normally increases sharply during the first 9–12 months after which it falls until around the age of 6–7 years, when it again increases through childhood and continues to do so during puberty, though with some gender differences. Overweight and obesity in children are therefore better assessed using BMI percentile curves (see [www.cdc.gov/growthcharts/cdc\\_charts.htm](http://www.cdc.gov/growthcharts/cdc_charts.htm)). From these curves, age- and sex-specific cut-off values are generally used to assess obesity prevalence, though many different methods are utilized clinically around the world. A slightly different pattern of adiposity compared with BMI is also seen when measured by skinfold thickness. Early on, fat is predominantly found subcutaneously, whereas intra-abdominal fat depots increase with age.

Interestingly, longitudinal studies have shown that an early rise in BMI before the age of 5 years, after the initial fall during the preschool years (i.e. adiposity rebound), is a risk factor for later obesity (Rolland-Cachera *et al.*,

2006). The combination of early growth retardation and later fatness, a condition typical in many developing countries, may be especially dangerous with regard to the risk of developing cardiovascular disease later in life.

Genetic factors alone, rare diseases such as Prader-Willi syndrome, and endocrine disorders can only explain a minority of the present obesity prevalence seen among children, though common genetic allelic variants may set the stage for obesity within an obesogenic environment. A cluster of factors linked to psychosocial and environmental contributors is most likely to be blamed for the recent development of obesity in the vast majority of affected children (see next section).

## Etiology

### *Environmental Contributors to Obesity*

It is a truism that the development of obesity results from excess energy intake that is not balanced by sufficient energy expenditure. Thus, lack of physical activity and increased consumption of foods rich in fat and sugar are easy to blame for the development of obesity. However, meta-analyses exploring the effects of dietary fat content and physical exercise suggest that these two conventional factors are likely to explain only a limited amount of weight gain, and it has become increasingly clear that obesity is a multifactorial condition with a complex and diverse pathogenesis. For instance, it has been shown that the risk of being overweight or obese is clearly higher for both children and adults who have a number of non-traditional risk factors (e.g. short sleep duration and less calcium in the diet) compared with those reporting traditional risk factors such as high-fat diets and lack of physical exercise (Chaput *et al.*, 2006, 2010a). It is therefore important to look beyond the traditional risk factors in order to develop successful strategies to counteract the increasing prevalence of obesity and its co-morbidities.

Recent studies have emphasized the importance of other dietary factors than fat, and there is solid evidence that demonstrates that sugar-rich soft drinks and a diet rich in total carbohydrates (instead of protein) and refined carbohydrates (instead of whole-grain and low-glycemic-index carbohydrates) promotes weight gain, as well as weight regain following weight loss (Larsen *et al.*, 2010).

Perhaps no other demographic group in history has undergone such significant transformation in lifestyle than our younger generations over recent decades. This

transition coincides with a sharp increase in body weight that has resulted in an *obesity epidemic*. The typical sedentary lifestyle, which is a result of our modern environment and way of living, is problematic in regard to the maintenance of energy balance. Physical activity is no longer a natural component of work and transportation for most people; rather, it is limited to those who are engaged in structured physical exercise in their leisure time. The problem of positive energy balance is not, however, only a matter of the low amount of calories expended, but also that many of the sedentary activities that we are involved in seem to promote overconsumption of food (Chaput *et al.*, 2010b). In a sedentary environment characterized by an abundance of affordable, easily accessible, highly palatable, energy-dense foods and beverages served in large portion sizes and intensively marketed, such stimuli are likely to have substantial effects on energy balance. In childhood, the number of hours of TV and computer time is positively associated with a high consumption of calorie-dense, low-fiber foods, and with less time spent physically active.

Mainly based on associations found in epidemiological studies, a number of environmental factors with hypothesized mechanisms that may directly or indirectly affect both sides of the energy balance equation have been identified. The term *obesogenic environment* is often used to describe this cluster of factors. The potential causative effects of these factors are often difficult to validate in experimental studies, and these factors often have a very complex, multifaceted association with obesity. Confounding and reverse causality may therefore easily confuse our understanding of their actual contribution to obesity. However, recent studies have given us a better understanding of this emerging research field.

The effects of short sleep duration and mental stress on the predisposition to obesity are two novel areas of investigation. According to the US National Sleep Foundation, the prevalence of young adults sleeping less than 7 hours per night has risen from 16% to 37% in 40 years, while obesity has increased from 13% to 32% during the same time period (Kutson *et al.*, 2010). Several epidemiological studies have described a strong association between short sleep and obesity (Chaput *et al.*, 2010c). Additionally, short-term partial sleep restriction has been shown to negatively affect glucose metabolism and regulation of food intake in young adults (Grandner *et al.*, 2010).

Mental stress has been shown to result in increased energy intake. This has been demonstrated in the absence

of alteration in perceived hunger or changes in appetite hormones, suggesting an influence on the hedonic aspects of regulation of food intake (Chaput *et al.*, 2010b). It could be speculated that there may be common mechanisms explaining the effects of stress on food intake and the associations between obesity and attention disorders, depression, and psychosocial issues. In an environment characterized by high cognitive demands rather than physical challenges, this is important knowledge needed to develop effective strategies for prevention of obesity, but represents a challenging area of study.

The environment in which we eat has also been shown to affect how much we eat. Distractors such as watching TV or playing computer games while eating increase food intake and attenuate the development of feelings of fullness during that meal. Interestingly, engaging in these activities (particularly playing video games) also leads to more snacking later on. Other distractors such as music can also affect our eating depending on rhythm and volume, while our eating company affects us as well. We generally tend to eat more with friends than alone or with strangers, and we tend to eat more or less in order to mimic our mealtime companions.

Finally, it should be noted that the present trend in overweight and obesity is not limited to humans but is also present in a number of animals, ranging from domesticated dogs and cats to wild rats living in close contact with us, suggesting that they may be affected by many of the same factors as humans (Klimentidis *et al.*, 2010). This trend also holds true for laboratory animals that have not been feeding from our leftovers, but fed with strictly controlled ad libitum diets with constant composition for decades, and without any obvious concomitant changes in physical activity habits. These observations suggest the possibility of additional obesogenic factors in our common environment. Several studies have shown a positive correlation between accumulation of lipid-soluble organochlorines in our bodies and BMI, suggesting that these environmental pollutants may play a role (Major *et al.*, 2007). Increases in plasma organochlorine levels found during weight loss have been shown to decrease energy expenditure, potentially via a decrease in thyroid hormone levels.

### Genetics

In only a minority of cases is obesity caused by a chromosome abnormality or a mutation in a single gene. However,

there exists a complex genetic predisposition towards obesity in each individual, with pathogenetic mechanisms that operate within this genetic framework to affect both body-fat content and body-fat distribution.

The increasing activity within the field of genome-wide association studies for disease susceptibility genes has led to the identification of approximately 30 loci influencing body mass index, one of the most well known being the fat mass and obesity-associated (FTO) gene. The effect of each gene on body weight is small, though it may be as much as 2–3 kg for certain genes identified. At least 15 loci influencing visceral patterns of fat distribution have also been identified, many showing stronger associations in women than in men (McCarthy, 2010). Epigenetic influences during pregnancy may have a significant role in the etiology of obesity as well; chemicals or hormones transferred from mother to fetus during pregnancy may program the offspring to be susceptible to obesity and the metabolic syndrome.

The genetic contribution to common obesity is not such that obesity is fixed in the genes from the outset and not amenable to change. Rather, the genetic component is perceived as a predisposition, which is expressed only when certain environmental factors are favorable. The most important obesity-triggering environmental factors that are generally acknowledged are a diet high in fat and refined carbohydrate, and a low level of physical activity. It is still not precisely known how the genetic component is expressed physiologically, although a number of studies suggest that abnormal lipid metabolism, altered appetite regulation or taste preference, and a reduced ability to spontaneously increase physical activity during periods of overeating, are the most important candidates.

Prader-Willi syndrome is the most common (though still very rare) chromosomal obesity disorder, caused by either a deletion or a double maternally derived region of chromosome 15, and manifest by hyperphagia, cognitive impairment, and several dysmorphic features. Other less common congenital disorders include Bardet-Biedl, Alström, and Cohen's syndromes.

Single gene mutations that cause obesity in humans are extremely rare. A deficit of the satiety hormone leptin is characterized by severe hyperphagia, and responds with considerable weight loss when treated with leptin injections. The most common form of obesity due to a single gene mutation involves mutations in the melanocortin-4 receptor, which occur in 3–4% of children with severe obesity. Other mutations, such as in the proopiomelano-

cortin and the prohormone convertase 1 genes, are similarly associated with obesity.

### **Medical Conditions**

Although several endocrine disorders can cause weight gain, these conditions are responsible for only a minority of cases of obesity. Hypothyroidism is often accompanied by weight gain, which can be attributed to the fact that energy expenditure falls proportional to the degree of hypothyroidism. Despite effective treatment, it is often difficult to shed the excess pounds and return to baseline body weight. With thyrotoxicosis, weight loss is most commonly seen, but increase in weight often occurs with treatment and return to a euthyroid state. Return to a euthyroid state can result in a weight gain of 5–7 kg within a year, or more if the patient becomes transiently hypothyroid as a consequence of treatment. This weight gain may be exacerbated if treatment is targeted to render the patient biochemically euthyroid in the lower end of the normal range, as this may result in a subnormal energy expenditure (Jacobsen *et al.*, 2006).

Cushing's syndrome, which is a condition of excess cortisol production, often results in weight gain, particularly in the abdominal fat distribution. Other features of Cushing's syndrome include type 2 diabetes, hypertension, dyslipidemia, and oligomenorrhea. It can be challenging clinically to distinguish Cushing's syndrome from a patient with visceral obesity and the metabolic syndrome, as many of the clinical features overlap. However, it is crucial to make this distinction clinically, as the treatment of Cushing's syndrome is directed at the cause of the excess cortisol production (usually a tumor of the pituitary or adrenal gland).

Growth hormone deficiency is an uncommon condition, usually caused by a pathologic disturbance of the pituitary gland, such as a tumor, damage from radiation therapy, or infiltrative disease. Lean body mass is decreased, and fat mass (particularly visceral fat) is increased in untreated adults who are deficient in growth hormone, compared with those who have normal growth hormone secretion. These parameters improve with growth hormone therapy.

There are several medications which may provide an iatrogenic contribution to obesity (Box 45.1), and the use of alternative agents should be considered carefully by the prescribing physician (Leslie *et al.*, 2007). For example, in the realm of antidepressive agents, tricyclic antidepressants are associated with significant weight gain, whereas some

### BOX 45.1 Etiologic contributors to obesity

#### Environmental contributors

- Increased availability of highly processed, calorie-dense food sources
- Increased portion sizes
- Sedentary modern lifestyle
- Decreased sleep
- Increased mental/cognitive stressors
- Environmental pollutants

#### Genetic factors

- Common genetic polymorphisms (e.g. FTO gene variations)
- Epigenetic factors
- Genetic syndromes (e.g. Prader-Willi syndrome)
- Rare single gene mutations (e.g. leptin deficiency)

#### Medical conditions

- Hypothyroidism
- Cushing's syndrome
- Growth hormone deficiency

#### Iatrogenic

- Oral hypoglycemic agents
- Insulin
- Tricyclic antidepressants
- Glucocorticoids
- Antipsychotic agents
- Antiepileptic agents
- Beta blockers

#### Psychosocial contributors

- Depression
- Binge eating disorder
- Low socioeconomic status

selective serotonin reuptake inhibitors have been associated with weight loss. The antiepileptic drugs valproate and carbamazepine are associated with weight gain, whereas the antiepileptic drug topiramate is currently under study in combination with an amphetamine, phentermine, as a potential combination weight-loss agent. First-generation antipsychotic agents have been shown to cause several kilograms of weight gain after only a few months of therapy. Glucocorticoids, which are used to treat a wide array of conditions, cause weight gain and a Cushing's phenotype.

## Co-Morbidities of Obesity

### *Diabetes Mellitus*

Type 2 Diabetes mellitus is a condition that arises when the pancreas does not produce enough insulin to overcome

the insulin resistance in the peripheral tissues, leading to hyperglycemia. Type 2 diabetes is distinguished from type 1 diabetes, which is an autoimmune disease characterized by absolute failure of pancreatic insulin production. Overweight and obesity are the major causes of the development of type 2 diabetes, though individuals with normal body weight but a high genetic susceptibility towards insulin resistance can develop type 2 diabetes as well. The genetic predisposition is an important determinant as to whether an obese individual develops type 2 diabetes or not, and many morbidly obese subjects without the genetic predisposition maintain normoglycemia throughout life.

The health impact of diabetes is serious, and may arguably be the most important medical consequence of obesity. Diabetes is a common condition, affecting over 8% of the US population, and accounts for almost 14% of American health-care expenditures. Chronic hyperglycemia is associated with microvascular complications affecting the eyes (retinopathy), kidneys (nephropathy), and nerves (neuropathy), and macrovascular complications affecting the heart, brain, and peripheral circulation. Diabetes is a leading cause of myocardial infarction, stroke, kidney failure, blindness, and amputation, and may reduce life expectancy by as much as 8–10 years.

The foundation of diabetes prevention and treatment among overweight individuals is weight loss. It is possible to put diabetes into remission with weight loss in some cases, though this is less likely if the genetic predisposition to type 2 diabetes is strong, or the diabetes has persisted for too long a time with irreversible damage to the insulin secretory capacity of pancreatic  $\beta$  cells (Harder *et al.*, 2004). In those cases, there is still an improvement in the severity of type 2 diabetes with weight loss, by virtue of a concomitant decrease in the degree of peripheral insulin resistance. In patients with prediabetes, which can be manifest as impaired glucose tolerance or impaired fasting glucose, weight loss can prevent or delay development of type 2 diabetes.

In the treatment of a patient with type 2 diabetes, consideration should be given to the effect of various treatment agents on weight. Metformin, which is the first-line therapy for type 2 diabetes, is often associated with mild to moderate weight loss, whereas other commonly utilized oral hypoglycemic agents, such as sulfonylureas and thiazolidinediones, cause weight gain. While insulin causes weight gain, it is often a necessary treatment agent in type 2 diabetes, particularly in later stages or more severe cases of the disease. The incretin-based therapies represent newer

### BOX 45.2 International Diabetes Federation definition of metabolic syndrome

Waist  $\geq 94$  cm (men) or  $\geq 80$  cm (women)<sup>a</sup> plus two or more of:

- Blood glucose  $\geq 5.6$  mmol/L, or diagnosed diabetes
- HDL cholesterol  $< 1.0$  mmol/L (men);  $< 1.3$  mmol/L (women), or on drug treatment for low HDL
- Triglycerides  $\geq 1.7$  mmol/L, or on drug treatment for high triglycerides
- Blood pressure  $\geq 130/85$  mmHg or drug treatment for hypertension

<sup>a</sup>For South Asia and Chinese patients, waist  $\geq 90$  cm (men) or  $\geq 80$  cm (women); for Japanese patients, waist  $\geq 90$  cm (men) or  $\geq 80$  cm (women).

treatment options for type 2 diabetes which are associated with weight loss (in the case of GLP-1 agonists) or weight neutrality (in the case of DPP-IV enzyme inhibitors).

#### Other Cardiovascular Risk Factors

An abundance of literature points to the existence of a particular metabolic syndrome encompassing insulin resistance, hypertension, dyslipidemia, and abdominal obesity. This syndrome is also known as insulin resistance syndrome, since the underlying pathophysiology is that of reduced sensitivity to the action of insulin. A variety of risk factors for the development of cardiovascular disease appear to be associated with this syndrome, which links obesity with the most significant health complications (type 2 diabetes, atherosclerosis, and hypertension). In addition to the degree of obesity, other factors are significantly associated with the metabolic syndrome: pattern of body-fat distribution, level of physical activity, and genetic disposition. The International Diabetes Federation has proposed a definition of the syndrome (Box 45.2).

The way in which overweight and obesity contribute to the metabolic syndrome is not entirely clear, but hormones and substrates secreted by the adipose tissue are thought to be the main cause. Reduced secretion of the hormone adiponectin from fat tissue, increased metabolism of free fatty acids, as well as increased secretion of cytokines and inflammatory mediators such as tumor necrosis factor alpha and interleukin 6, appear to play an important role in the development of insulin resistance and the accompanying metabolic disturbances. Treatment of the meta-

bolic syndrome includes weight loss and physical activity, with close attention to cardiovascular risk reduction.

The risk of developing hypertension is several-fold greater in an obese individual compared with non-obese individuals, and can be seen with or without other manifestations of the metabolic syndrome. Blood pressure is positively correlated with both abdominal circumference and with the degree of obesity. Insulin resistance and hyperinsulinemia appear to be the underlying pathophysiological mechanisms responsible for the hypertension in most cases. Insulin has an anti-natriuretic effect that results in an increase of both extracellular and intravascular volume. Hyperinsulinemia may also have a direct trophic effect on the smooth muscle cells of the arterioles, which can lead to increased vascular tone and arterial vascular resistance.

The hypertension associated with obesity has the same potential consequences as hypertension from other causes, including increased risk of myocardial infarction, stroke, renal damage, and retinal damage. As such it is imperative that blood pressure be managed and controlled to the same targets as in the normal-weight patient. Weight loss is a key component of management of hypertension as even a small weight loss can result in a marked drop in blood pressure.

Following the discussion above, it should come as no surprise that obesity, and abdominal obesity in particular, are associated with a significant increased risk of atherosclerotic complications. The risk of developing ischemic heart disease or stroke is 2.5 and 6 times greater, respectively, with a predominantly abdominal fat distribution compared with individuals with a more even fat distribution. The increased risk portended by abdominal obesity is multifactorial, including a predisposition towards an unfavorable lipid profile, hypertension, insulin resistance and type 2 diabetes, an increase in inflammatory markers such as fibrinogen and C-reactive protein, and reduced fibrinolytic activity. A recent large study has suggested that BMI and waist circumference do not improve cardiovascular risk prediction when blood pressure, diabetes status, and lipid profiles are known, illustrating that the cardiovascular risk of obesity is mediated by these parameters (The Emerging Risk Factors Collaboration, 2011).

Obesity is associated with congestive heart failure, which may be secondary to ischemic heart disease, or may be related to increased cardiac work with subsequent myocardial hypertrophy and dysfunction, severe insulin resistance, excessive fat accumulation in the myocardium,

pulmonary hypertension, or any combination of these factors. Obesity is associated with an increased risk of atrial fibrillation compared with normal-weight individuals (52% and 46% increased risk for men and women, respectively) (Wang *et al.*, 2004).

### **Malignancy**

Obesity is responsible for an increased risk of several types of malignancy, including cancer of solid organs including colon, esophagus, endometrium, kidney, female breast, pancreas, liver, gallbladder, and stomach, as well as hematologic malignancies such as non-Hodgkin's lymphoma and multiple myeloma. It is estimated that overweight and obesity may be responsible for 3% of cancers in men, and 9% of cancers in women.

The mechanisms by which obesity promote tumorigenesis are complex, and vary by site (Darren *et al.*, 2010). Chronic hyperinsulinemia may increase availability of bioactive IGF-1, which can stimulate tumor growth and development. Epidemiologic studies have linked high levels of insulin secretion with increased risk of breast, colon, pancreatic, and endometrial cancer, and these high levels are an adverse prognostic factor for cancer-related mortality. Increased bioavailability of estrogen due to aromatization in adipose tissue is an important mechanism predisposing to an increased risk of breast and endometrial cancer. Polypeptides derived from adipocytes, such as leptin and adiponectin, as well as inflammatory mediators, also play an important and complex role.

The impact of obesity on the risk of death from cancer is even more profound. In men and women with a BMI  $\geq 40$ , the relative risk of dying from cancer compared with normal-weight subjects is 1.5 and 1.6, respectively (Calle *et al.*, 2003). In the United States, it is estimated that overweight and obesity may be responsible for 14% of all cancer deaths in men, and 20% in women. Major weight loss reduces the risk of cancer-specific mortality.

### **Obstructive Sleep Apnea**

Obstructive sleep apnea (OSA) is a disorder that is characterized by obstructive pauses in breathing during sleep, caused by repetitive collapse of the upper airway. Clinical features include restlessness and snoring during sleep, waking feeling unrested, frequent morning headaches, poor concentration, and daytime somnolence. OSA is associated with an increased risk of hypertension, diabetes, myocardial infarction, cardiac arrhythmias, congestive

heart failure, and accidental injury. Patients with untreated severe OSA are at a 3 to 6 times increased risk of death compared with patients without OSA (Marshall *et al.*, 2008; Young *et al.*, 2008).

Obesity is the most well documented risk factor for OSA. The prevalence of OSA progressively increases as the body mass index, neck circumference, and waist-to-hip ratio increase. Inflammatory mediators which are increased in both OSA and obesity, and which contribute to the atherosclerotic complications of OSA, may have an etiologic role in OSA as well.

Other alterations may occur in pulmonary function in the setting of obesity, including a restrictive component with lower lung volumes due to increased chest-wall impedance, and reduced endurance of respiratory muscles.

### **Osteoarthritis**

The risk of osteoarthritis increases with increasing BMI, and accounts for a significant proportion of the total health-care expenditures associated with obesity. Weight-bearing joints are at the highest risk, but non-weight-bearing joints are affected as well, suggesting alterations in the cartilage and/or bone in the setting of metabolic syndrome and obesity that are independent of weight-related trauma. Weight loss is linearly associated with a decreased risk of developing osteoarthritis; one study demonstrated that a BMI reduction of 2 kg/m<sup>2</sup> or more among women in the preceding 10 years decreased the odds of developing osteoarthritis of the knee by 50% (Felson, 1992). Weight loss of even a modest degree can improve joint pain and function in patients with established osteoarthritis.

### **Other Medical Co-Morbidities**

As the physical and metabolic alterations seen with excess weight impact every body system, there are many other medical conditions associated with obesity.

Obesity can have an important impact on the gastrointestinal and hepatobiliary system. Accumulation of fat in the liver can lead to steatohepatitis, which is increasingly recognized as an important cause of liver cirrhosis. There is an increased risk of gallstone formation in obesity. Interestingly, the risk of gallstones increases with weight loss as well, particularly if the weight loss is rapid (>1–1.5 kg per week), as the flux of cholesterol through the biliary system increases in this setting. Obesity is also a risk factor for gastroesophageal reflux disease, and several gastrointestinal cancers (see earlier section on Malignancy).

There is an association between obesity and deep vein thrombosis, which can be life threatening as it can lead to potentially fatal pulmonary embolism. This risk is particularly high in patients with additional risk factors for thromboembolic disease, such as smokers, passengers on long-haul flights, and oral contraceptive users.

Fertility can be significantly impaired in obese patients, often in the context of polycystic ovary syndrome (PCOS). The underlying pathophysiologic defect in PCOS is insulin resistance, which leads to increased testosterone production by the ovaries, resulting in impairment of ovulation, irregular, infrequent, or absent menses, hirsutism, and acne. Although PCOS can occur in normal-weight women, the PCOS symptom complex does worsen with weight gain as this exacerbates the underlying insulin resistance. Treatment is focused on decreasing the insulin resistance, primarily by weight loss in obese or overweight women. For any pregnant woman with obesity, there is an increased risk of several complications, including pregnancy-induced hypertension, gestational diabetes, and delivery by cesarean section.

From a genitourinary perspective, the most important obesity-related complication is renal impairment, which is in turn related to the increased risk of diseases known to cause renal dysfunction, including diabetes and hypertension. There is an increased risk of kidney stones with obesity and with weight gain. Urinary incontinence is an important obesity-related issue for many women as well.

Other conditions associated with obesity include gout, which is characterized by increased serum urate concentrations, leading to precipitation in joints with both acute and chronic sequelae. Excess body weight has been associated with dementia and psoriasis, though a causal association has not been established.

## Psychosocial Issues

A number of studies have examined the relationship between BMI and various aspects of quality of life. A robust finding across these studies has been the negative impact of obesity on physical functioning, such as general health perception and vitality, as well as psychological functioning and social well-being. Obesity was associated with more reports of poor body image, stigmatization, discrimination, diminished social interactions, depression, increased absence from the workplace, and lower socioeconomic status. Physical fitness was, however, shown to be a

strong modifier, attenuating the negative effects of obesity (Castres *et al.*, 2010; Griffiths *et al.*, 2010).

The direction of causality has often been discussed regarding these associations. The interrelatedness between obesity and psychological problems seems in many cases to be bidirectional, potentially adding to the severity and complexity of the problem. It is therefore of critical importance to address not only the weight problem, but also the psychosocial co-morbidities of obesity.

In children as well as adults, psychological distress may foster weight gain at the same time as obesity may lead to psychosocial problems. In a meta-analysis of longitudinal studies including close to 60,000 subjects, it was shown that obese people had a 55% increased risk of developing depression over time, whereas depressed individuals had a 58% increased risk of becoming obese (Luppino *et al.*, 2010). Somewhat weaker associations are also found between overweight and depression.

In terms of the treatment of obesity, a concomitant reduction in co-morbidities, including an improvement in psychosocial aspects, is one important defining aspect of treatment success. Psychosocial factors should be part of pretreatment evaluation of the patient, prior to selection of the most appropriate management strategy (Palmeira *et al.*, 2010).

Weight loss is often, though not uniformly, found to be accompanied by improvement in most aspects of quality of life. An improvement in quality of life is often seen with initial weight loss, regardless of treatment mechanism, but this may regress once a plateau in weight is reached; psychological and physiological mechanisms are hypothesized to be involved. Anecdotal observations also describe frustration when patients realize that life did not “become perfect” following a very successful weight loss, even with achievement of a normal body weight.

The effect of obesity and weight loss on different psychosocial issues may differ considerably, depending on the individual and the context (i.e. different populations and subcultures), and particular consideration for patient-specific factors is therefore of the utmost importance.

Co-morbidities associated with obesity are summarized in Box 45.3.

## Mortality

The complications of obesity and abdominal overweight are poorly recognized, but are responsible for a major

**BOX 45.3 Co-morbidities associated with obesity**

- Type 2 diabetes mellitus
- Cardiovascular disease
  - Atherosclerotic heart disease
  - Congestive heart failure
  - Stroke
  - Hypertension
  - Peripheral vascular disease
  - Deep vein thrombosis/pulmonary embolism
  - Atrial fibrillation
- Malignancy
- Respiratory disease
  - Obstructive sleep apnea
  - Restrictive lung disease
- Musculoskeletal

  - Pregnancy-induced hypertension
  - Gestational diabetes mellitus
  - Increased cesarean-section risk
- Psychosocial
  - Depression
  - Societal discrimination
  - Loss of work days
  - Medical costs

burden on the health system, accounting for an increasing proportion of all health-cost expenditures. Even a normal BMI, but with abdominal fat accumulation, can be responsible for hypertension, hyperlipidemia, type 2 diabetes, and cardiovascular disease, which makes it important to identify increased adiposity as the underlying cause of the condition or disease. The increase in obesity rates has an important impact on the global incidence of cardiovascular disease, type 2 diabetes mellitus, cancer, osteoarthritis, infertility, birth complications, work disability, and sleep apnea. By virtue of these effects, obesity has a pronounced impact on mortality (Berrington de Gonzalez *et al.*, 2010). Obesity amongst 40-year-old non-smokers is estimated to shorten life expectancy by 5.8 years and 7.1 years for males

and females, respectively. For smokers, obesity has an even more profound effect, shortening lifespan by 13.3 years for females, and 13.7 years for males (Peeters *et al.*, 2003). In the United States, obesity is responsible for more deaths than smoking.

**Obesity Prevention**

In light of the obesity epidemic that grips the globe, a wealth of research studies have attempted to find an effective means by which to prevent obesity. On a population level, an effective means of obesity prevention continues to evade us.

Numerous popular diets promote changing diet composition in accordance with principles that are claimed to have a favorable impact on weight maintenance. These claims are generally unsubstantiated, and some may even promote nutritionally insufficient diets. A diet abundant in fiber, vegetables, fruits, and whole grains, which are more satiating for fewer calories, are beneficial in weight maintenance. A large body of experimental human data suggests that protein possesses a higher satiating power per calorie than carbohydrate and fat. A recent large randomized clinical trial in eight European countries demonstrated that both a modestly higher-protein and lower-glycemic-index diet is beneficial in weight maintenance, confirming findings of smaller studies (Larsen *et al.*, 2010). Overall, the balance of the evidence suggests that a low-fat higher-protein, moderate complex-carbohydrate diet seems to be more effective for long-term weight maintenance.

Daily physical activity and exercise are important components of weight maintenance. The impact of exercise for weight control is based on the ability of patients to engage in adequate levels of activity. The minimal level that should be recommended is at least 45–60 minutes of moderate intensity physical activity on most days of the week (Saris *et al.*, 2003). This level of physical activity not only helps to prevent obesity, but also improves health-related factors. A sustained commitment to physical activity is an important part of a lifelong commitment to health.

**Future Directions**

In a world in which obesity has reached epidemic proportions, the impact on morbidity and mortality of our populations, as well as the health-care expenditures associated with managing these co-morbidities, are stag-

gering. Successful strategies are desperately needed to both treat and prevent obesity. Societal strategies are needed that address unhealthy eating tendencies, promote healthier eating habits, and encourage more active lifestyles in an otherwise permissively sedentary environment. New therapies that modify the interplay of satiety and hunger hormones and cues, such as the incretin-based therapies, show promise as medical treatment options for obesity, and research on these and related compounds is ongoing. Bariatric surgery is currently the only treatment of obesity that has been shown to be effective and sustainable in the long term; it may be the most appropriate treatment option for more extreme and refractory cases of obesity, or those cases of refractory obesity associated with significant co-morbidities, particularly type 2 diabetes. Bariatric surgery is associated with variable degrees of success and improvement of co-morbidities, but also carries a variable profile of complications and risks, depending on the type of surgery performed. Further research is needed to determine which type of bariatric surgery provides the optimum balance of benefit in the context of associated risk of complications, and to gain a better understanding of the long-term outcomes of these procedures.

## HYPERTENSION

THOMAS A.B. SANDERS, PhD, DSc

*King's College London, London, UK*

### Summary

Hypertension is an established and independent risk factor for stroke, coronary heart disease, and heart and kidney failure. The relationship between blood pressure and cardiovascular risk is continuous with no threshold. Blood pressure increases with age and is on average higher in men than in women. The cause of elevated blood pressure in most cases is unknown but it is a self-amplifying condition that is more amenable to treatment in its early stages. Consequently, lowering blood pressure in the whole population including normotensive individuals contributes to lowering the burden of cardiovascular disease. Convincing evidence exists for the effects of overweight/obesity and of high intakes of alcohol and salt on increasing blood pressure. Pharmacologically high intakes (>3g/day) of long-chain n-3 polyunsaturated fatty acids lower blood pressure but not intakes within the range of normal dietary intakes (up to 2g/day). There is probable evidence to show that the consumption of low-fat milk products is associated with lower blood pressure and for an increased intake of calcium to be associated with a reduced risk of hypertension. There is a probable relationship between low potassium intake and increased blood pressure, and possible relationships with the intakes of nitrate. Low birth weight and poor growth in early life are associated with an increased risk of developing hypertension. Meta-analyses of randomized controlled trials show convincing evidence that salt reduction, moderation of alcohol intake, and weight loss in the overweight/obese lower blood pressure. An integrated dietary approach involving a global change in dietary pattern appears to be more effective in lowering blood pressure than single dietary interventions.

### Introduction

High blood pressure or hypertension is classified as systolic blood pressure of 140 mm Hg or above and diastolic blood pressure of 90 mm Hg or above, or being on specific treatment (Table 46.1). Elevated blood pressure is a major

modifiable risk factor for cardiovascular disease, and especially stroke. Severe hypertension results in end-organ damage, particularly to the microvasculature of the retina, brain, and kidney, and is an important cause of blindness, dementia, and chronic renal failure (Box 46.1). However, the hazards of cardiovascular disease associated with blood

**TABLE 46.1** Classification of blood pressure (mm Hg) based on seated clinic blood pressure

Condition	Systolic BP	Diastolic BP
Ideal	<120	<80
Pre-hypertension	120–139	80–89
Hypertension	140–159	90–99
Grade 1	140–159	90–99
Grade 2	160–179	100–109
Grade 3	>180	>110

Cardiovascular disease  
 Stroke  
 Coronary heart disease  
 Peripheral vascular disease  
 Renal failure  
 Retinal damage

pressure extend well into the normal range, and the hazards are greater in the presence of other risk factors (increasing age, high blood cholesterol, smoking, diabetes mellitus, and target organ damage). Data from the analysis of prospective cohort studies (Lewington *et al.*, 2002) show that all-cause mortality, stroke, and coronary heart disease (CHD) incidence increase on a doubling scale (log-linear) with increasing blood pressure. This has led to the conclusion that the relationship of blood pressure and risk of cardiovascular disease has no threshold. There is convincing evidence that lowering raised blood pressure using drugs reduces mortality, especially from stroke but also from CHD (Czernichow *et al.*, 2011). It has been difficult to demonstrate benefit from lowering blood pressure below 120/80 mm Hg in high-risk groups such as people with type 2 diabetes (Cushman *et al.*, 2010).

The prevalence of hypertension increases with age so that the majority of people over the age of 50 are at risk or are already hypertensive in economically developed areas of the world; this age group carries the greatest population attributable risk of cardiovascular disease (Lewington *et al.*, 2002). Measuring blood pressure is subject to substantial measurement error and bias. The use of automated sphygmomanometers reduces bias such as digit preference and cut-offs for diastolic blood pressure. However, equipment needs to be regularly calibrated, and elevated read-

ings may be obtained when subjects are stressed (“white-coat hypertension”). Ambulatory blood pressure monitoring devices provide more robust measures of blood pressure, but give values that are 5 mm Hg lower than clinic seated blood pressure (O’Brien *et al.*, 2005). The techniques used to measure blood pressure and appropriate placebos are crucial issues when evaluating diet and lifestyle effects on blood pressure.

Nationwide cross-sectional studies tend to overestimate the prevalence of hypertension because they are made on measurements on a single occasion. It is well known that blood pressure falls in response to repeat measurement, regressing towards the mean. The association of blood pressure with risk of cardiovascular disease tends to be underestimated because of resulting regression dilution bias. Adjusting for regression dilution bias by using multiple measures of blood pressure on different days gives a better estimate of true blood pressure and strengthens the relationship with risk. The absolute risk of hypertension increases markedly with age and it is in the older age groups that the benefits of treating hypertension are greatest because their absolute risk is greatest (Lewington *et al.*, 2002).

High blood pressure usually results from increased resistance to blood flow by small arterioles (resistance vessels). It is a self-amplifying process in which the arterioles develop thicker, more muscular walls in response to the increased pressure which further increases peripheral resistance when stimulated by vasoconstrictor substances or by sympathetic stimulation. Systolic blood pressure (SBP) increases with age whereas diastolic blood pressure (DBP) tends to increase in line with SBP until the sixth decade and then tends to fall. Stiffening of the large arteries occurs with aging and this contributes to hypertension and is emerging as a powerful predictor of vascular events, at least in older people. Women on average have lower blood pressure than men. However, blood pressure rises around/following the menopause, indicating that ovarian hormones, especially oestrogen, have a protective effect. Drug treatment of hypertension becomes warranted when the absolute annual risk of cardiovascular events is greater than 2% or where there is severe elevation of blood pressure (Williams *et al.*, 2004; Jessani *et al.*, 2006). It also takes several years for the full effects of blood pressure lowering treatments to have their maximal effects, as was demonstrated in the ALLHAT study (ALLHAT Investigators, 2002). A high proportion of the population has “pre-hypertension” or “mild hypertension” where the

risk profile does not favor drug treatment. Diet and lifestyle are considered to have their most important influence on the prevention of high blood pressure rather than on the management of established hypertension, and early intervention in the hypertensive process almost certainly helps prevent blood pressure becoming severely elevated. Accelerated hypertension has dramatically reduced in frequency over the last few decades in countries with reasonable health services where high blood pressure detection occurs.

International comparisons show large variations in the prevalence of hypertension and the rate of increase in blood pressure with age. Hypertension is more common in groups of African compared with white European ethnic origin. Early epidemiological studies which were predominantly cross-sectional ecological comparisons showed marked geographical variations in the prevalence of hypertension within countries and within populations that were related to lifestyle. For example, migrants from rural areas of Kenya were found to show large increases in blood pressure when they moved into cities (Poulter *et al.*, 1990). The INTERSALT investigators (Elliott *et al.*, 1996) showed that the age-related increase in blood pressure across a large number of different communities was independently related to body mass index, alcohol intake, and the urinary ratio of sodium/potassium. Later analyses from the INTERSALT group (Elliott *et al.*, 2006) reported an inverse association between vegetable protein intake and blood pressure. As these studies were cross-sectional, they are limited in their ability to adjust for confounding factors. More robust evidence is provided by prospective cohort studies. These consistently show a relationship between hypertension, increased body mass index, and change in body weight. Prospective studies have revealed mixed conclusions regarding salt intake and raised blood pressure. However, estimates of salt intake from dietary records are generally unreliable compared with measures of intake based on the collection of 24-hour urine samples.

Over the past decade, evidence has emerged that blood pressure is falling in many countries (Tunstall-Pedoe *et al.*, 2006), which cannot be attributed to more effective drug management of hypertension. The reason for this decline is unknown. Yet there is some evidence to suggest that early growth development may affect susceptibility to hypertension. Barker *et al.* (2005), in a follow-up of birth and growth records of children born in Hertfordshire, UK, showed a strong relationship between low birth weight, low weight gain in the first year of life, and adult blood

pressure. They went on to show that infants who have low birth weight and have a low body mass index at the age of 2 years but who subsequently gain weight and have a high body mass index at age 11 years are more prone to develop hypertension (Barker *et al.*, 2005). Children in a subsequent longitudinal study who had been small at birth but who gained weight rapidly during early childhood (1 to 5 years) had the highest adult blood pressure at age 22 years. The US Collaborative Perinatal Project (1959–1974) studied 55 908 pregnancies and showed that each 1-kg increase in birth weight increased the odds by 2.19 for raised SBP at 7 years of age and confirmed the finding that those who crossed growth centiles were most at risk (Hemachandra *et al.*, 2007).

## Role of Adult Diet and Lifestyle in Influencing Blood Pressure

Several dietary factors in adult life have been linked to elevated blood pressure, including stress, lack of physical activity, high alcohol intake, high salt intake, obesity, and low dairy and fruit and vegetable intake. Stress acutely influences blood pressure, and this is why measurements need to be made in subjects in a relaxed situation. However, stress management does not appear to be a useful strategy for lowering blood pressure. The population approach to controlling blood pressure focuses on lowering the average population blood pressure, not just in those with hypertension. It aims to decrease exposure to factors that increase risk and to empower individuals to make healthier lifestyle choices. Frost *et al.* (1991) argue that lowering the blood pressure of the whole population is likely to have a greater impact on cardiovascular mortality than focusing on individuals with high blood pressure. In practice a combination of a population approach and a high-risk approach is needed as it would be unethical to deny drug treatment to individuals at high risk. Guidelines (Jessani *et al.*, 2006; Mancia *et al.*, 2007) have been developed to stratify individuals according to their risk of cardiovascular disease where risk is greater than 20% over the next 10 years or if blood pressure is severely elevated. At levels of 160/100 mm Hg, drug treatment is recommended. A healthy diet and lifestyle is advocated for all.

## Body Weight and Blood Pressure

There is a convincing relationship between body mass index and usual blood pressure from the meta-analysis of prospective cohort studies (Whitlock *et al.*, 2009). Results

from a meta-analysis of 25 studies indicates (Neter *et al.*, 2003) that net weight reduction of 5 kg, by means of energy restriction, increased physical activity, or both, reduced SBP/DBP by 4.4/3.6 mm Hg. In this respect a reduction of total fat intake that results in lower energy intake and weight loss lowered blood pressure. However, there is no clear evidence to indicate the superiority of low-calorie diets which contain a higher proportion of fat than carbohydrate. Thus, for each kilogram of weight lost, blood pressure falls by about 1 mm Hg over a range of weight loss of 1–5 kg. The effects of overweight and obesity on blood pressure are associated with changes in insulin sensitivity. How systemic vascular resistance is increased is uncertain, but sympathetic nervous system activation plays a major role linking obesity to the development of hypertension. Part of this effect appears to be mediated via the melanocortin 4 receptor independent of insulin (Greenfield, 2011). The accumulation of fat itself may result in changes in small vessel reactivity (Greenstein *et al.*, 2009; Withers *et al.*, 2011).

### **Dietary Lipids and Blood Pressure**

The INTERMAP study (Ueshima *et al.*, 2007; Miura *et al.*, 2008) has provided some evidence for a relationship between fatty acid intake and blood pressure by using four 24-hour dietary recalls to assess dietary intake and eight clinic BP measurements over 3 weeks in 17 populations in Japan, China, the United Kingdom, and the United States ( $n = 4680$ ). This study concluded that dietary linoleic acid intake may contribute to prevention and control of adverse blood pressure levels in the general population. It was estimated that the systolic/diastolic blood pressure differences with 2 SD higher linoleic acid intake (3.77% kcal) were  $-1.42/-0.91$  mm Hg ( $p < 0.05$  for both) for participants not being treated for hypertension. Similar findings were made for total polyunsaturated fatty acids intake. The same study reported small effects  $<1$  mm Hg for n-3 PUFA, especially those derived from oily fish.

A number of randomized dietary intervention trials have examined the effect on blood pressure of modifying the type of fat and the intake level. However, most studies have not been of sufficient size to detect small variations in blood pressure, and few have used ambulatory blood pressure monitoring, which is a more robust measure of blood pressure. Some studies have reported falls in blood pressure when moving from a diet high in saturated fatty acids to one low in saturated fatty acids. However, a major

criticism of these studies is that they have failed to randomize treatment order. This introduces bias, with the diet rich in saturated fatty acids being administered first in the sequence. This is particularly important as blood pressure tends to regress towards the mean. Some well controlled studies such as the DASH (Appel *et al.*, 1997) and Premier Studies (Appel *et al.*, 2003) discussed below have used a reduced saturated fatty acid intake as part of a multifaceted intervention to lower blood pressure. However, the nature of these studies often resulted in weight loss, making it difficult to attribute changes to a lower saturated fatty acid intake. The OMNIHEART study (Appel *et al.*, 2005) provided evidence to suggest that replacement of carbohydrate with unsaturated fatty acids or protein lowers SBP by 1.3 and 1.4 mm Hg, respectively, compared with carbohydrate, without any change in body weight. A meta-analysis comparing diets high in monounsaturated fatty acids vs. ones high in carbohydrates was unable to demonstrate superiority of monounsaturated fatty acids (Shah *et al.*, 2007). A recent large randomized multicenter controlled trial was unable to show any effect of replacing saturated fatty acids with MUFA or carbohydrate (either of high or low glycemic index) on clinic blood pressure (Jebb *et al.*, 2010).

The blood-pressure-lowering effect of a high intake of long-chain n-3 polyunsaturated fatty acids, usually provided as fish oil supplements, is more consistent, at least at high intakes. Meta-analyses of randomized controlled trials (Geleijnse *et al.*, 2002) indicated that intakes in the region of 2–5 g/day of long-chain n-3 polyunsaturated fatty acids as fish oil lowered both SBP and DBP, particularly in subjects over the age of 45. They concluded, however, that the effects of lower intakes were uncertain; the average fall in SBP/DBP was 2.3/1.5 mm Hg. Most of the studies provided relatively high intakes, and there were insufficient numbers of subjects treated to come to any conclusions regarding lower intakes, i.e. below 2 g/day. Several randomized controlled trials using doses in the range of 0.4–1.8 g/day in participants with pre-existing cardiovascular disease, many receiving blood-pressure-lowering medication, did not report changes in blood pressure (Yokoyama *et al.*, 2007; GISSI-HF Investigators *et al.*, 2008; Kromhout *et al.*, 2010). A recent 12-month double-blind randomized controlled trial in 312 non-smoking adults aged 45–70 years found no effect of doses ranging from 0.45 g/day to 1.8 g/day long-chain polyunsaturated fatty acids using ambulatory blood pressure monitoring (Sanders *et al.*, 2011). Overall it appears that

dietary fat composition has minimal effects on population blood pressure within the normal ranges of dietary intake.

### **Salt**

There is compelling evidence to show an association between dietary salt (sodium chloride) intake and the prevalence of raised blood pressure. In particular, the age-related increase in blood pressure is greater in populations with a high salt intake. The INTERSALT study (Elliott *et al.*, 1996) concluded that an increase in sodium intake of 100 mmol/day was associated with an increase in SBP/DBP of 3–6/0–3 mm Hg. This relationship was found to be true for both men and women, young and old people, and hypertensive and normotensive subjects. Research in chimpanzees has also shown the potent blood pressure raising effects of salt in the diet (Denton *et al.*, 1995). It has been demonstrated that long-term modest salt restriction achieved with dietary advice can yield significant benefits. A meta-analysis concluded that a reduction of 3 g/day of salt predicts a fall in SBP/DBP of 3.6–5.6/1.9–3.2 mm Hg in hypertensives and 1.8–3.5/0.8–1.8 mm Hg in normotensives (He and MacGregor, 2004). The blood pressure lowering effect is likely to be greater in individuals where the renin–angiotensin system is less active. Low renin concentrations are more prevalent in people of black African origin (He *et al.*, 2009), who are more likely to benefit from salt reduction as are people over the age of 50 years. While sodium retention and increased plasma volume are a plausible mechanism for raised blood pressure in older people, it does not readily explain the effects of salt in younger people. There is some emerging evidence to indicate that salt intake may adversely influence endothelial function (Dickinson *et al.*, 2011) and that low birth weight may increase sensitivity to salt intake (Perala *et al.*, 2011). While the relationship between salt intake and blood pressure is well established, there is no clear relationship between measures of salt intake by 24-hour sodium excretion and subsequent cardiovascular mortality. However, a systematic review of prospective cohort studies found a 23% increase in risk of stroke in participants with the highest intake of salt compared with those with the lowest intake (Strazzullo *et al.*, 2009).

Salt intakes have fallen in many developed countries as the consumption of salted and pickled foods has declined while the consumption of fresh, chilled, and frozen food has increased. This is most notable in Japan, where both blood pressure and stroke incidence have fallen (Ueda

*et al.*, 1988). In practice a meta-analysis of dietary advice (Hooper *et al.*, 2004) suggested that lower salt intake leads to only a small reduction in blood pressure (SBP-1/DBP-0.6) with an average reduction in 24-hour urinary sodium excretion of 35.5 mmol/day (about 2 g/day). Providing advice to cut down on salt intake is generally limited in its efficacy as salt in the diet is mainly provided by processed foods such as bread, rather than being added at table or during cooking. Consequently, it has often been argued that it is more important to focus on reducing the levels of salt in commercially processed foods (Anderson *et al.*, 2010). However, there are large cultural differences with regard to the use of salt in domestic food preparation, and in some communities large amounts of salt are added at home.

The UK Government's Food Standards Agency embarked on a policy to persuade food manufacturers to reduce the salt content of processed foods, particularly bread and ready prepared meals, and launched a media campaign to make consumers aware of the salt in processed food. There is some evidence from measurement of 24-hour urine sodium excretion to suggest that salt intakes have fallen in the UK. In contrast a review of measures of salt intake by 24-hour urinary excretion in the USA showed little change in salt intake over the past 50 years (Bernstein and Willett, 2010). Current dietary guidelines advocate that salt intakes should not exceed 6 g/day (100 mmol) for adults in Europe, levels that are achievable. However, in the United States there is a more stringent target of less than 4 g/day (65 mmol/day) in adults over 51 years of age and those with hypertension.

### **Alcohol**

Alcohol intake increases blood pressure acutely in young subjects, and binge drinking can lead to large increases in blood pressure. Heavy alcohol intake is a well known cause of hypertension. Binge drinking is also an important cause of hemorrhagic stroke and sudden cardiac death. The blood-pressure-raising effects of alcohol may decrease with increasing age, and the effect of low to moderate alcohol intake may lower blood pressure. Alcohol acutely suppresses vasopressin (antidiuretic hormone) secretion, thereby having a diuretic effect, but this is followed by a transient increase in renin secretion. It is believed that plasma renin activity is increased as a compensatory reaction to the vasodilatation and diuresis caused by alcohol. Renin catalyzes the conversion of angiotensinogen into

angiotensin I. Angiotensin I is subsequently converted into angiotensin II by the action of angiotensin converting enzyme (ACE) which is expressed in endothelial cells, especially in the lung. Angiotensin II causes vasoconstriction of resistance arterioles and acutely elevates blood pressure. The blood pressure raising effect of alcohol is rapidly reversible and can be inhibited by alpha-adrenergic blockade. Randomized controlled trials have shown that moderation of alcohol intake results in a reduction in blood pressure. A meta-analysis of 15 randomized controlled clinical trials of hypertensive and normotensive heavy drinkers (>3 drinks daily) found that alcohol reduction was associated with a significant reduction in mean systolic BP of 3.3 mm Hg and diastolic BP of 2.0 mm Hg (Xin *et al.*, 2001).

### **Fruit and Vegetable Consumption**

Prospective cohort studies show an association between reported increased intake of fruit and vegetables and lower risk of stroke and CHD (He *et al.*, 2006, 2007). It is widely assumed that this difference may be due to an effect on blood pressure. However, it is not possible to exclude residual confounding caused by the association of a healthy lifestyle with higher intakes of fruit and vegetables. For example, plasma vitamin C concentration is a biomarker of fruit and vegetable intake but is also lowered by tobacco use. Higher plasma vitamin C concentrations are also associated with a lower risk of stroke (Myint *et al.*, 2008) but there is no good evidence from randomized controlled trials to indicate that vitamin C supplementation lowers blood pressure. Advice to increase fruit and vegetable consumption to five portions a day in a general-practice setting was found to lower SBP by 4 mm Hg compared with the control group (John *et al.*, 2002). However, this was an incidental finding and not the planned primary outcome of the study. Furthermore, the intervention was a single session of dietary advice, and the blood pressure measurements were done in clinic. This finding was not confirmed in a randomized controlled trial specifically designed to address this question and using ambulatory blood pressure monitoring (Berry *et al.*, 2010). It had been argued that the beneficial effects of increased fruit and vegetable intake can be at least partly attributed to the resultant increased intake of potassium. However, potatoes are an important source of dietary potassium but are generally not regarded as qualifying as “fruit and vegetables” in many food-based dietary guidelines.

### **Potassium Intake**

Prospective epidemiological studies consistently show a consistent relationship between low potassium intake and increased risk of stroke. A meta-analysis of 33 randomized controlled trials of oral potassium supplements (Whelton *et al.*, 1997) revealed significant heterogeneity between studies, and post hoc analyses indicate a reduction in blood pressure that was only apparent when salt intakes were high (>165 mmol/day). Potassium supplementation lowered SBP in China by about 5 mm Hg (Gu *et al.*, 2001). However, salt intakes are high, and habitual intake of potassium is low in the UK. Two recent randomized controlled trials using ambulatory blood pressure monitoring (Berry *et al.*, 2010; He *et al.*, 2010) failed to show any benefit from potassium supplementation in UK subjects with early hypertension. These findings are in agreement with a Cochrane Review (Dickinson *et al.*, 2006) which found no benefit of potassium supplementation for the treatment of hypertension. It is also possible that there is a threshold effect of potassium intake around 40 mmol/day at which increases in potassium intake may lower blood pressure.

### **Plant Bioactive Materials**

Caffeine has a short-term blood-pressure-raising effect which is mainly a consequence of its effect on heart rate. A meta-analysis of chronic caffeine/coffee intake in randomized controlled trials (Noordzij *et al.*, 2005) found that caffeine intake increased SBP by 2.04 mm Hg (95% CI, 1.10–2.99) and DBP by 0.73 mm Hg (95% CI, 0.14–1.31) without affecting heart rate. A meta-analysis (Ried *et al.*, 2010) of cocoa flavonoids suggests a reduction of SBP/DBP by 3.2/2.0 mm Hg. However, a recent well-controlled trial using theobromine-enriched cocoa resulted in a 3.2 mm Hg higher 24-hour ambulatory SBP (van den Bogaard *et al.*, 2010).

The soy isoflavone genistein when infused into the forearm has a similar effect to estradiol on forearm blood flow, which could be attributed to differences in nitric oxide bioavailability (Walker *et al.*, 2001). A meta-analysis of soy isoflavones and blood pressure reported a 1.92 mm lower SBP with intakes ranging between 25 and 375 mg soy isoflavones (Taku *et al.*, 2010). However, this level of isoflavone intake is well above the exposure of people consuming Western diets. There is a lack of reliable data to support claims for a blood-pressure-lowering effect of other flavonoids and anthocyanins.

### Arginine and Nitrate

Nitric oxide (NO) produced by the vascular endothelium from arginine causes vasodilation and plays an important role in the regulation of vascular tone. Impaired NO-dependent vasodilation is associated with the development of hypertension (Weil *et al.*, 2011); arginine supplements acutely lower blood pressure (Vasdev and Gill, 2008) and conversely inhibitors of arginine metabolism such as N<sup>G</sup>-monomethyl-L-arginine (L-NMMA) raise blood pressure. Dietary intake of arginine is dependent on the level and type of protein consumed. A systematic review (Altorf-van der Kuil *et al.*, 2010) of the effect of protein intake on blood pressure in observational prospective cohort studies and randomized intervention trials indicated a small blood-pressure-lowering effect, especially in the case of plant protein. Plant foods have a higher non-protein nitrogen content than foods of animal origin, and this is mainly due to the presence of nitrate which is well known to lower blood pressure in animals. The blood-pressure-lowering effects of organic nitrates are well established, but recently evidence has emerged to show that dietary inorganic nitrate can acutely lower blood pressure by generating NO (Webb *et al.*, 2008). This effect is apparently a consequence of some bacterial conversion of nitrate to nitrite in the mouth that subsequently results in increased NO (Lundberg *et al.*, 2009; Kapil *et al.*, 2010). In a randomized controlled trial of beetroot juice a reduction in SBP of 5.4 mm Hg was demonstrated. The effects, however, appear to last only a few hours. Currently, there is a lack of evidence from randomized controlled trials of more widely consumed vegetables with an increased nitrate content, and further research in this area is required.

### Dairy Products

A meta-analysis of prospective cohort studies supports the inverse association between low-fat dairy foods and fluid dairy foods and the risk of elevated blood pressure (Ralston *et al.*, 2011). No relationship was found with cheese. As milk products are a major source of dietary calcium, it is not surprising that a similar relationship has been found with calcium intake and blood pressure. It has also been proposed that vitamin D status may influence blood pressure but the few randomized controlled trials to date provide no clear evidence (Geleijnse, 2011). However, a systematic review of combined vitamin D and calcium supplementation (Chung *et al.*, 2009) concluded that supplementation lowered SBP but not DBP by 2–4 mm Hg.

Furthermore a meta-analysis also concluded that calcium supplementation had a beneficial effect in pregnancy on preventing hypertensive disorders (Hofmeyr *et al.*, 2010).

Peptides produced through the fermentation of dairy products with *Lactobacillus helveticus* have blood-pressure-lowering properties (Seppo *et al.*, 2003). These peptides appear to partially inhibit angiotensin converting enzyme and thereby reduce blood pressure. Foods containing these peptides were first marketed in Japan, then Finland and some other European countries. However, using ambulatory blood pressure monitoring as outcomes, two large multicenter studies were unable to confirm the blood-pressure-lowering effects of dairy peptides (van Mierlo *et al.*, 2009). At present, the evidence suggests a possible beneficial effect of reduced-fat liquid milk products in protecting against hypertension, but this requires further investigation because of possible residual confounding.

## An Integrated Dietary Approach to Prevent Hypertension

From the above it can be seen that several dietary factors can influence blood pressure, and in most cases the effects on SBP are in the range of 1–3 mm Hg (Table 46.2). However, these small differences may have additive or synergistic effects when combined. The Dietary Approaches to Stop Hypertension (DASH) study (Appel *et al.*, 1997) compared three diets: a control diet that was low in fruit, vegetables, and dairy products with a fat content typical of the American diet; a diet rich in fruit and vegetables; and a “combination diet” rich in fruits and vegetables and low in saturated fats and added sugars (the diet comprised whole grains, low-fat dairy products, fish, and poultry, with restrictions on the consumption of red meat, sugary drinks, cakes, and biscuits). Blood pressure was measured using ambulatory monitoring on multiple occasions, and the study was statistically well powered. SBP was

**TABLE 46.2** Summary of well-established individual dietary effects on blood pressure (mm Hg)

Dietary factor	Systolic BP	Diastolic BP
5 kg overweight	4.4	3.3
Salt	2.5	1.3
Alcohol	3.3	2
Caffeine	2	0.7

**BOX 46.2 The DASH eating plan**

Emphasizes fruit, vegetables, and low-fat dairy foods  
 Includes whole grains, poultry, fish, and nuts  
 Contains less red meat, sweets, and sugar-containing beverages  
 Minimizes the use of salt  
 Alcohol allowed only in moderation  
 Aims at maintaining a healthy weight

3–4 mm Hg lower for the high fruit and vegetable group compared with the control group, and a much greater reduction in blood pressure was obtained with the “combination diet.” Since the initial DASH study, several further studies have examined the effects of a DASH-style eating plan in combination with other lifestyle interventions. The DASH-2 study (Sacks *et al.*, 2001) examined the effects of different levels of dietary salt reduction in conjunction with the DASH diet. The benefits of the DASH diet for blood pressure reduction were enhanced with a reduction in salt intake. Combined effects on blood pressure of a low salt intake and the DASH diet were greater than the effects of either intervention alone. The combined effect of the DASH diet with a low salt intake resulted in a reduction in SBP of 7.1 mmHg in normotensives and 11.5 mmHg in hypertensives. The modified DASH eating plan is shown in Box 46.2.

The DASH studies, however, were tightly controlled dietary interventions as opposed to tests of the effectiveness of dietary advice. The PREMIER study (Appel *et al.*, 2003) was designed for this purpose and compared the effect of lifestyle advice with and without behavioral therapy on blood pressure in free-living subjects after 6 months of intervention. Participants were given the lifestyle advice with the DASH diet alone or with behavioral therapy, a third group received standard dietary advice (reduce salt intake, lose weight, and cut back on alcohol intake) and behavioral therapy. Dietary advice alone resulted in a reduction in SBP/DBP of 3.7/1.7 mmHg. However, if advice was accompanied by behavioral therapy, reductions in SBP/DBP of 8/4.3 mmHg were observed. In this study similar reductions in blood pressure were obtained with standard advice (reduce salt intake, lose weight, and cut back on alcohol intake) compared with the DASH diet. Most of the changes in blood pressure in the groups that received behavioral intervention could be

attributed to changes in weight (4–5 kg difference compared with advice alone) as intakes of alcohol were low at baseline and sodium intake as estimated from urinary excretion of sodium was only 10 mmol/day lower. The approach adopted by the DASH investigators has been replicated in other countries, and currently appears to be the most effective dietary intervention.

**Conclusions**

Blood pressure shows a continuous relationship with risk of stroke and coronary heart disease. Small reductions in the population average blood pressure translate into a significant reduction in the number of deaths from cardiovascular disease. Decreasing the intake of salt, alcohol, and saturated fat, increasing the intake of fruit and vegetables, and losing weight can lower SBP/DBP by up to 8/4 mmHg. However, lifestyle changes tend to be difficult to adopt, and so in practice dietary advice alone is only likely to result in a 3–4 mmHg change in blood pressure in the short term. Even such small changes in blood pressure can translate into greater reductions in the long term and are likely to substantially reduce the burden of cardiovascular disease in the population. The genesis of hypertension is likely to be during fetal development and early life. Consequently, the prevention of hypertension also needs to consider optimum maternal and infant nutrition.

**Future Directions**

Arterial stiffening is emerging as a major predictor of vascular mortality and contributes to increases in SBP in older people. Further research is needed to understand whether dietary factors such as vitamins D and K are involved in arterial stiffening. The mechanisms by which blood pressure is programmed in early life require further attention, and there is a need for trials in pregnancy to see if risk of hypertension in offspring can be reduced. Confirmation of the blood-pressure-lowering effects of dairy products is required by appropriately powered randomized controlled trials. The role of nitric oxide and dietary nitrate in the regulation of blood pressure continues to be a topic that deserves further research, as are the mechanisms by which the central nervous system influences peripheral vascular resistance.

## INSULIN RESISTANCE AND THE METABOLIC SYNDROME

JENNIE BRAND-MILLER, PhD, FAIFST, FNSA AND STEPHEN COLAGIURI, MD

*University of Sydney, Sydney, New South Wales, Australia*

### Summary

Insulin resistance is a physiological phenomenon that describes impairments or weakness in insulin action. Insulin resistance occurs naturally at puberty and during pregnancy and is usually severe in overweight and obese individuals and those with type 2 diabetes and cardiovascular disease. The “metabolic syndrome” is now a widely recognized yet controversial concept that refers to a clustering of metabolic risk factors, such as raised blood pressure, dyslipidemia (raised triglycerides and lowered high-density lipoprotein cholesterol), raised fasting glucose, and central obesity in the one individual. Insulin resistance is the most accepted unifying theory explaining the origins of the metabolic syndrome. Prevention and management of the metabolic syndrome by lifestyle interventions, including weight loss, a healthy diet, and increased physical activity, represent the best chance of reducing the personal, societal, and economic burden of chronic disease. The molecular basis of insulin resistance, its role in health and disease, and the optimal diet composition for improving insulin sensitivity present continuing challenges to research scientists around the world.

### Introduction

In 1936, Harold Himsworth introduced the concept of “insulin sensitivity,” separating diabetes into two main types, an insulin-sensitive and an insulin-resistant phenotype (Himsworth, 1936). He developed the first method for measuring insulin resistance and began studies to show that diet might influence glucose tolerance by altering insulin sensitivity. Today, being insulin-sensitive is considered instrumental to good health and the prevention of

chronic diseases such as type 2 diabetes and cardiovascular disease. Insulin resistance, the opposite of insulin sensitivity, is a physiological phenomenon that describes impairments of insulin action, usually in respect of glucose metabolism rather than fatty acids or amino acids (Draznin, 2008). Compared with insulin-sensitive individuals, those with insulin resistance require higher concentrations of insulin to facilitate the disposal of glucose in tissues. Insulin-resistant humans and animals therefore develop compensatory hyperinsulinemia in order to ensure normal

utilization of glucose by the insulin target tissues. As a consequence, hyperinsulinemia and insulin resistance go hand in hand (DeFronzo *et al.*, 1992).

Insulin resistance can be a normal, physiological state or pathologically severe. Insulin resistance increases naturally at puberty (Goran and Gower, 2001) and during pregnancy (Butte, 2000), but it is more extreme in overweight and obese individuals, in people with type 2 diabetes and pre-diabetes, and in those with cardiovascular disease (Facchini *et al.*, 2001). Recent research links insulin resistance to many conditions, including fatty liver disease, polycystic ovarian syndrome, sleep apnea, and cancer. Insulin resistance is the most accepted unifying theory explaining the origins of the “metabolic syndrome” (Mikhail, 2009).

The metabolic syndrome is now a widely recognized yet controversial concept that refers to a clustering of metabolic risk factors, such as high waist circumference, low HDL-cholesterol, high serum triglycerides, hypertension, and impaired glucose tolerance, in the one individual. There is a lack of consensus on its practical utility either as a diagnostic or a management tool, and even its definition and diagnostic criteria vary around the world (Table 47.1). While there is general agreement on four of the central components, there is disagreement on waist circumference and how this should be adjusted for use in different ethnic groups. A recent WHO Expert Consultation concluded that it was a premorbid condition rather

than a clinical diagnosis and should exclude individuals with established diabetes or known cardiovascular disease (Simmons *et al.*, 2010).

The clustering of metabolic risk factors with diabetes and cardiovascular disease has been recognized for more than 80 years, but the modern concept of the metabolic syndrome began when Gerald Reaven proposed that apparently unrelated biological parameters were part of a single physiological condition (Reaven, 1988). He argued that insulin resistance provided a common mechanism to link the abnormalities although this remains a subject of debate. The parallel presence of compensatory hyperinsulinemia may well have effects that are distinct from those of insulin resistance *per se*, stimulating or even overstimulating certain aspects of insulin action in various cells and tissues (Low *et al.*, 2004). It is therefore difficult to distinguish between causes and consequences of insulin resistance.

## Prevalence of the Metabolic Syndrome

The prevalence of the metabolic syndrome varies markedly around the world. It has strong lifestyle determinants, which are in turn influenced by socioeconomic status, culture, and education. Depending on the definition, approximately one in four or five adults in industrialized countries meet the criteria for the metabolic syndrome (Ford *et al.*, 2004). It is increasingly common in younger age groups and in developing nations.

Insulin resistance by itself may be a normal physiological response to changes in metabolic circumstances. Both energy restriction and energy surplus cause a decline in insulin sensitivity. Indeed, insulin resistance in one set of tissues may facilitate the redirection of fuels around the body to the tissues in greater need. During lactation, the mammary glands become exquisitely insulin-sensitive, while muscles remain insulin resistant, thus driving uptake of glucose for the synthesis of lactose (Vernon, 1989). Insulin resistance also appears at birth in infants born small or large for gestational age (McMillen and Robinson, 2005).

Insulin resistance is associated with excess visceral fat in the abdomen but not excess subcutaneous fat (Cnop *et al.*, 2002). Surgical removal of visceral fat immediately restores insulin sensitivity. Because skeletal muscle is the largest insulin-sensitive tissue, higher proportions of lean mass are associated with greater insulin sensitivity.

**TABLE 47.1** International Diabetes Federation definition of the metabolic syndrome

Measure	Categorical cut-points <sup>a</sup>
Elevated waist circumference	Population and country-specific definitions (e.g. Euroid $\geq 94$ cm in males, and $\geq 80$ cm in females or China $\geq 85$ cm in males, $\geq 80$ cm in females)
Elevated triglycerides	$>150$ mg/dL or 1.7 mmol/L
Reduced HDL-cholesterol	$<40$ mg/dL or 1.0 mmol/L in males, $<50$ mg/dL or $<1.3$ mmol/L in females
Elevated blood pressure	Systolic $\geq 130$ and/or diastolic $\geq 85$ mm Hg
Elevated fasting glucose	$\geq 100$ mg/dL or 5.5 mmol/L

<sup>a</sup>Drug treatment for any specific parameter is an alternative indicator.

Data from Alberti *et al.* (2009).

Within healthy European populations, the amount of physical activity is the main determinant of insulin sensitivity, accounting for a two-fold range (Balkau *et al.*, 2008; Helmerhorst *et al.*, 2009). Both resistance exercise and aerobic exercise increase insulin sensitivity whereas total time in sedentary activities reduces insulin sensitivity.

Insulin sensitivity also varies from one ethnic group to another. Pima Indians, distinguished by having the highest recorded rate of type 2 diabetes in the world, are among the most insulin resistant even when young and lean (Bogardus, 1993). In some studies, European Caucasians were twice as insulin sensitive as BMI-matched individuals of African-American or Asian origin (Osei and Schuster, 1994; Dickinson *et al.*, 2002) (Figure 47.1). Profound compensatory hyperinsulinemia is evident in response to a realistic carbohydrate meal in lean young adults of Asian origin (Figure 47.2).

Insulin resistance is also influenced by perinatal factors (Hales and Barker, 2001). Young adults who were born prematurely with a very low birth weight are more likely to have insulin resistance, glucose intolerance, and the metabolic syndrome than those who were born with normal birth weight (Hovi *et al.*, 2007). Higher body fat at birth is also associated with greater insulin resistance and type 2 diabetes later in life (Wei *et al.*, 2003). Maternal glucose intolerance, in particular, promotes excess fetal growth and fetal insulin resistance (Luo *et al.*, 2010).

**FIG. 47.1** Differences in insulin sensitivity assessed by the euglycemic-hyperinsulinemic clamp procedure in lean young healthy individuals from four ethnic groups. Drawn from Dickinson *et al.* (2002) and Lillioja *et al.* (1988).

**FIG. 47.2** Postprandial insulin responses to a 75-g carbohydrate portion of white bread in lean young healthy subjects of Southeast Asian origin ( $n = 10$ ) and European Caucasian origin ( $n = 10$ ). The higher insulin response in Asians reflects compensatory hyperinsulinemia stemming from intrinsic insulin resistance (Dickinson *et al.*, 2002).

Together, these effects produce a vicious cycle that promotes higher risk of chronic disease in children and young adults.

## Normal Actions of Insulin

Insulin, the most potent anabolic hormone in the body, exerts a multitude of effects on carbohydrate, lipid and protein metabolism, ion and amino acid transport, nitric oxide (NO) synthesis, and cell proliferation and differentiation (Draznin, 2008). At the onset of eating, insulin is released from the pancreatic beta-cells in order to re-establish euglycemia. Insulin promotes glucose uptake in skeletal muscle by stimulating translocation of glucose transporter 4 (GLUT 4) from the cytosol to the plasma membrane where it facilitates glucose transport into the cell. Concomitantly, insulin stimulates intracellular utilization of glucose by many other tissues as well. In the fasting state, the main physiological function of insulin is to suppress glucose production by the liver and prevent uncontrolled lipolysis and ketogenesis, without which diabetic ketoacidosis would quickly develop. Hence, if either of these aspects of insulin action is impaired, then peripheral or liver hepatic insulin resistance or both are said to be present.

On a cellular level, insulin stimulates glycogen, protein, and lipid synthesis while also inhibiting glycogenolysis, lipolysis, protein degradation and apoptosis. But selective insulin resistance is usually present, affecting one tissue more than others. Insulin resistance usually defines an inadequate strength of insulin signalling from the insulin receptor downstream to the final substrates of insulin action involved in metabolic aspects of cellular function.

## Molecular Mechanisms of Insulin Resistance

Although great strides are being made in our understanding, the molecular mechanisms still remain unclear. The defect in most people appears to lie *downstream* of the insulin receptor. Numerous studies show that the number and function (tyrosine kinase activity) of insulin receptors are usually normal in people with type 2 diabetes. Magnetic resonance spectroscopy studies *in vivo* indicate that there is a defect in insulin-stimulated glucose transport into skeletal muscle. Recent studies consistently show reduced strength in the insulin receptor substrate-1/phosphatidylinositol 3-kinase (IRS-1/PI 3-kinase) pathway (i.e. the pathway responsible for most, if not all, of the metabolic effects of insulin), resulting in diminished glucose uptake and utilization in target tissues (Draznin, 2008). However, the culprit that initiates and sustains the impaired insulin signaling is not known.

Two complementary mechanisms have been suggested to explain reduced strength in this pathway. In the first, increased activity of several serine kinases diminishes insulin signal transduction by phosphorylating serine residues on IRS-1. Excessive phosphorylation interferes with normal conductance of the insulin signal. The trigger could be hyperinsulinemia or hyperglycemia, occurring under conditions of nutrient saturation or nutritional excess. Activation of the transcription factor NF- $\kappa$ B in response to oxidative stress or proinflammatory molecules, including hyperglycemia, also produces insulin resistance via this mechanism. The second molecular mechanism that could lead to insulin resistance is a disruption in the balance between the amounts of the two PI-3 kinase subunits (Draznin, 2008). The regulatory subunit, p85, is tightly associated with the catalytic subunit, p110. Insulin-resistant states could be associated with decreases in the expression of the p85 monomer, causing decreased PI-3 kinase activity. Pregnancy appears to be associated with increased expression of skeletal muscle p85 in response

to increasing concentrations of human placental growth hormone.

Another hypothesis gaining ground is that insulin resistance is caused by mitochondrial dysfunction or reduced numbers of mitochondria with decreased fatty acid oxidation and accumulation of fatty acid acyl CoA and diacylglycerol (Lowell and Shulman, 2005). The mechanism in this case is thought to be activation of novel protein kinase C (PKC), which leads to increased serine phosphorylation of IRS-1. Insulin resistance may therefore be an appropriate response to nutrient excess, i.e. a cellular antioxidant defense mechanism. Indeed, mitochondrial superoxide production has been shown to be a common feature of many different models of insulin resistance in isolated adipocytes, myotubes, and animal models (Hoehn *et al.*, 2009). Insulin resistance can be rapidly reversed by agents that act as mitochondrial uncouplers or inhibitors of the electronic transport chain. In fact, artificial induction of mitochondrial superoxide production causes rapid impairments in insulin action independently of changes in the PI-3 kinase pathway (Hoehn *et al.*, 2009). Mitochondrial superoxide could be described as a metabolic sensor of energy excess.

## Techniques Used to Assess Insulin Action

In healthy, normal individuals, blood glucose concentration is maintained within a narrow range. After an overnight fast or between meals, blood glucose normally falls within the range of 3.5–5.5 mM. Immediately after a meal containing carbohydrate, blood glucose concentration rises to a peak of 6–10 mM followed by a sharp decline back to baseline within 60 minutes. This exquisite control is achieved by a fine balance between glucose absorption from the gut, glucose production by the liver, and glucose extraction from the blood into the cells and tissues.

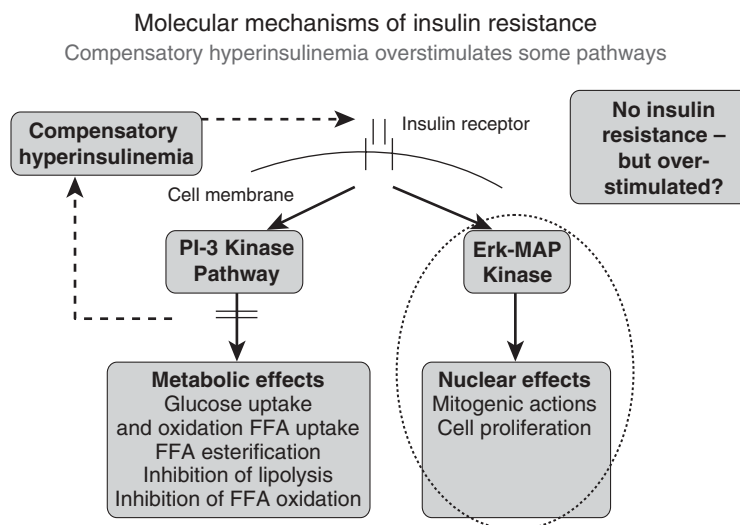

Insulin plays a central role in the regulation of blood glucose concentration by suppressing hepatic glucose production and stimulating peripheral glucose uptake. Most methods used to measure any impairment in insulin action (i.e. insulin resistance) therefore assess the quantitative relationship between a given plasma insulin concentration and some measurable insulin-dependent process, usually at the whole body level. A simple and common marker of insulin resistance is called HOMA-IR (homeostasis modelling assessment-insulin resistance), simply calculated as the product of the fasting glucose in mmol/L and the

fasting insulin in  $\mu\text{U}/\text{mL}$  divided by 22.5 (Matthews *et al.*, 1985). In lean, young, healthy individuals, this value approximates 1, but the range within the normal adult population is around 1 to 4. The top quartile is regarded as being relatively insulin resistant. Obese people and individuals with type 2 diabetes show values in the range 4 to 8. Since HOMA is calculated using fasting glucose and insulin, it reflects mostly hepatic insulin resistance and not the ability to metabolize a large carbohydrate challenge. Others have endeavored to improve on HOMA-IR by using the quantitative insulin sensitivity check index (QUICKI), and the fasting glucose-to-insulin ratio (FG insulin resistance). Techniques such as the frequently sampled intravenous glucose tolerance test (FSIGTT) or Bergman minimal model, endeavor to measure how quickly blood glucose levels return to normal after injection of a given amount of insulin (Bergman *et al.*, 2003). The “gold standard” method for measuring insulin resistance is the euglycemic–hyperinsulinemic clamp (Matthews, 1985), in which a constant intravenous infusion of insulin is balanced by a simultaneous infusion of glucose in a clinical research setting. Because of the invasive, time-consuming nature of the clamp procedure, it is difficult to

use in routine clinical practice or in large epidemiological studies.

## How Does Insulin Resistance Cause Cardiovascular Disease and Type 2 Diabetes?

Under normal circumstances, insulin exerts anti-atherogenic and anti-inflammatory actions in the endothelial cells and vascular smooth muscle cells lining the blood vessels (Wang *et al.*, 2004). Insulin inhibits the expression of adhesion molecules, monocyte chemo-attractant protein-1, and the inflammatory transcription factor, NF-kappa B. However, in the presence of insulin resistance (i.e. with impaired PI 3-kinase signaling), hyperinsulinemia appears to exert adverse effects on the arterial wall. Compensatory hyperinsulinemia becomes pro-atherogenic by stimulating both the MAP-kinase signaling pathway and excessive prenylation of Ras and Rho proteins (Figure 47.3). Hence, management of insulin-resistant individuals must include effective measures to improve insulin sensitivity as well as decrease ambient insulinemia. The metabolic stages in the transition from normal glucose tolerance

**FIG. 47.3** Two major pathways are stimulated when insulin binds to insulin receptors on cell membranes of insulin-sensitive tissues: phosphatidyl inositol-3 kinase and MAP-kinase. Insulin resistance appears to originate downstream of the insulin receptor in the PI-3 kinase pathway involved in the metabolism of carbohydrates, fats, and proteins but not in the MAP-kinase pathway. Compensatory hyperinsulinemia resulting from insulin resistance in the PI-3 kinase pathway can mean overstimulation of the MAP-kinase pathway, with implications for cell growth, multiplication, and differentiation. Modified from Draznin (2008).

**BOX 47.1 How insulin resistance causes type 2 diabetes**

**Stage 1.** Normal glucose tolerance, mild insulin resistance, compensatory hyperinsulinemia

**Stage 2.** Glucose tolerance begins to deteriorate; postprandial hyperglycemia becomes common

**Stage 3.** Impaired glucose tolerance worsens, marked fasting and postprandial hyperinsulinemia

**Stage 4.** Beta-cells begin to fail, fasting and postprandial insulinemia declines, marked fasting and postprandial hyperglycemia

**Stage 5.** Beta-cell mass declines, insulin replacement may be necessary

to beta-cell failure and type 2 diabetes are described in Box 47.1.

## What Can We Do to Maximize Insulin Sensitivity?

The most important environmental and modifiable factors that worsen insulin resistance are excessive body weight, physical inactivity, unhealthy diet, and smoking. Increased muscle mass and lower abdominal fat mass each markedly improve insulin sensitivity. Hence a combination of weight loss and physical activity, particularly resistance exercise, is the ideal lifestyle intervention to reduce the risk of type 2 diabetes and cardiovascular disease.

However, diet composition has been shown to have a separate additional effect. Observational studies and intervention trials have shown that the macronutrient distribution (i.e. the ratio of fat:carbohydrate:protein energy) and the quality of individual macronutrients directly influence insulin sensitivity. In particular, the amount and quality of fat and carbohydrate are factors involved in the development of insulin resistance and type 2 diabetes.

### **Diet Composition and Insulin Resistance**

The effect of dietary fat and carbohydrate on insulin sensitivity have been debated for decades. Some of the controversy stems from divergent findings in animals vs. humans and in differing study designs. Insulin resistance can be induced in animal models by diets high in fat, sucrose, or fructose. However, a single bout of exercise or a high-starch meal can completely reverse the defect. In humans, some studies suggest that a high intake of fat is

associated with impaired insulin sensitivity but this may be modified by the type of fat and by the type of subject. Several studies indicate that a diet high in saturated fat may be especially deleterious in physically inactive, sedentary individuals.

Free fatty acids (FFA) are thought to be involved in the early stages of insulin resistance when subjects are still normoglycemic. In skeletal muscle, FFA inhibit insulin-stimulated glucose uptake at the level of glucose transport and/or phosphorylation through mechanisms that involve intramyocellular accumulation of diacylglycerol and long-chain acyl-CoA, activation of protein kinase C (PKC), and decreased tyrosine phosphorylation of insulin receptor substrate 1/2 (Boden, 2004). In liver, plasma FFA within the physiological range cause insulin resistance along with increased liver diacylglycerol content and higher activity of serine/threonine kinases. Expression of proinflammatory nuclear factors and cytokines is also increased (Boden *et al.*, 2005).

Using clamp studies in humans, Vessby (2000) was the first to show that insulin resistance could be related to the fatty acid composition of the diet. High proportions of saturated fatty acids and low proportions of unsaturated fatty acids characterized the serum cholesterol esters of healthy 50-year-old men who later developed type 2 diabetes. Later, fatty acid composition of the phospholipids in the skeletal muscle cell membranes was found to be directly related to insulin sensitivity in healthy men (Borkman *et al.*, 1993). Specifically, the sum of the proportions of long-chain fatty acids with 20–22 carbohydrate atoms correlated strongly with insulin sensitivity. Unfortunately, the fatty acid pattern of skeletal muscle is influenced not just by diet but also by the degree of physical activity and by muscle fiber composition. None the less, the implication is that if dietary fat composition is changed from more saturated to more unsaturated under strictly controlled isoenergetic conditions, then insulin sensitivity should improve.

Unfortunately, nutrition science is not that simple. Well-designed, but short (usually 3–4 weeks) studies in lean, healthy subjects comparing the effects of changes in dietary fatty acids on insulin sensitivity have uniformly shown negative results (Vessby, 2000). Similarly, placebo-controlled studies on supplementation with fish oil or n-3 fatty acids have shown no effect. Animal studies, however, suggest that n-3 fatty acids improve insulin sensitivity, and it is conceivable that longer timeframes are needed to cause a change in human skeletal muscle phospholipids.

Two well-designed longer-term studies stand out. The KANWU study included 162 healthy subjects who received isoenergetic diets for 3 months containing either a high proportion of saturated fatty acids (SAFA) or monounsaturated (MUFA) acids (Vessby *et al.*, 2001). Within each group there was a second assignment to fish oil supplements or placebo. Insulin sensitivity as assessed by the frequently sampled intravenous glucose tolerance test (FSIVGTT) was significantly impaired by the SAFA diet (−10%) but did not change on the MUFA diet. However, the beneficial effects of MUFA were *not* seen when total fat intake exceeded 37%E (the median level of participants). Addition of n-3 fatty acids did not influence insulin sensitivity, and neither diet altered insulin secretion.

The second study (Due *et al.*, 2008) compared three diets over 6 months. Forty-six obese individuals were randomly assigned to one of three diets after ≥8% weight loss: a diet high in MUFA (40%E as fat, 45% as carbohydrate), a low-fat diet (25%E as fat, 60% as carbohydrate), and a control diet with 35% energy as fat (>15% as saturated fat, 50% as carbohydrate). Protein accounted for 15% of energy in all three diets. At the end of the 6 months, the high-fat/high-MUFA diet had improved insulin resistance (according to the HOMA score) by 12%, while the control diet and the low-fat diet had worsened insulin resistance (by 23% and 16% respectively). This study therefore clearly indicated that both high-carbohydrate and high-saturated-fat diets were each capable of worsening insulin resistance. Taken together, these and other findings suggest that, at fat intake close to average in industrialized nations (i.e. 32–37%E), it is preferable to maintain higher fat intake but increase the proportion of MUFA or PUFA fatty acids, rather than increase the percentage energy derived from carbohydrate.

### **Dietary Carbohydrates and Insulin Sensitivity**

Like fat, the quantity and quality of carbohydrate can influence insulin sensitivity. In a cross-sectional analysis of ~3000 individuals in the Framingham Offspring Study, whole grains, total fiber from all sources, as well as fiber from cereals and fruit, were inversely related to HOMA–insulin resistance (McKeown *et al.*, 2004). There was no relationship with total carbohydrate intake or intake of refined grains. Dietary glycemic index (GI) and glycemic load (GL) were also directly related to insulin resistance, with approximately 10% more insulin resistance in the highest quintile of GI than in the lowest.

*Some* high-carbohydrate diets appear to have beneficial effects on insulin sensitivity. In healthy, young persons, isoenergetic substitution of high-fibre carbohydrate foods (to 57%E as carbohydrate) for saturated fatty acids improved insulin sensitivity within 4 weeks (Perez-Jimenez *et al.*, 2001). In this instance, the proportions of whole grains, simple sugars and dietary GI of this high-carbohydrate diet may have been critical, each with independent effects on insulin sensitivity. Indeed, carbohydrates consumed without fiber may produce detrimental effects (Due *et al.*, 2008). In individuals with diabetes, higher carbohydrate intake has the potential to raise postprandial glucose and increase insulin demand, an effect that might worsen insulin resistance. However, under metabolic ward conditions for 21 days, Garg *et al.* (1988) showed that hepatic and peripheral insulin sensitivity as assessed by the glucose clamp remained unchanged in 10 type 2 patients on either a high-carbohydrate (60%E) or low-carbohydrate (35%E) diet, matched for fiber. The patients in this study were treated with insulin, a factor that may fundamentally affect the ability to metabolize a high-carbohydrate meal.

Higher whole-grain intake has been directly correlated with insulin sensitivity in cross-sectional studies in which insulin sensitivity was assessed by the FSIVGTT (Liese *et al.*, 2003). A well-designed but small intervention study incorporated 6–10 servings of breakfast cereal, bread, rice, pasta, muffins, cookies, and snacks from either whole or refined grains (in both cases mostly ground to flour) in a diet containing 55%E from carbohydrate and 30%E from fat. Using the glucose clamp, insulin sensitivity was higher after 6 weeks on the whole-grain diet compared with a similar period on the refined-grain diet (Pereira *et al.*, 2002). Unfortunately, this finding was not confirmed in the larger WHOLEheart Study in which 60–120 g/day whole-grain foods were ingested for up to 16 weeks (Brownlee *et al.*, 2010). However, the modified QUICKI method used to assess insulin sensitivity may not have been sensitive enough to detect any difference.

### **Sucrose and Fructose**

The effect of fructose and sucrose on insulin sensitivity remains controversial. Studies in animals, often fed extremely high intakes (e.g. 70% of total energy) or in solution in place of water, have shown a detrimental effect of fructose and sucrose compared with starch or glucose (Daly *et al.*, 1997). When fructose and glucose were compared directly, fructose was found to be the culpable moiety.

The evidence in humans, however, suggests that fructose and sucrose in realistic amounts might have beneficial effects on insulin sensitivity. In lean, young, healthy males, a diet containing 25% sucrose produced higher insulin sensitivity as assessed in a two-step clamp procedure than a diet containing 1% sucrose (Kiens and Richter, 1996). Similarly, a study in people with type 2 diabetes showed that a diet with 10% fructose produced a 34% improvement in insulin sensitivity measured by the euglycemic–hyperinsulinemic clamp (Koivisto and Yki-Jarvinen, 1993). In this study, patients lived in a hospital environment and all food was provided. Finally, using the glucose clamp, no effects on insulin sensitivity were noted after 3 months of a 13% fructose vs. sucrose diet (Thorburn *et al.*, 1988). It is conceivable, however, that at very high intakes (>30%E), sucrose and fructose have adverse effects on insulin sensitivity.

### **Low-Glycemic-Index Diets**

Low-glycemic-index (GI) diets in which the carbohydrates are more slowly digested and absorbed, resulting in lower postprandial glycemia, have been associated with improved insulin sensitivity in some studies but not others. Glucose uptake was 45% higher during the clamp procedure in people with type 2 diabetes who ate a low-GI diet for 4 weeks compared with a macronutrient-matched high-GI diet (Rizkalla *et al.*, 2004). The alpha-glucosidase inhibitor, Acarbose, which slows carbohydrate digestion but is not absorbed into the systemic circulation, also produces improvements in insulin sensitivity (Holman *et al.*, 1999). Low-GI diets improved insulin sensitivity in women with polycystic ovary syndrome as judged by the glucose tolerance test-based insulin sensitivity index (Marsh *et al.*, 2010). Low-GI diets did not improve insulin sensitivity as judged by the glucose clamp in lean, active, young males (Kiens and Richter, 1996). In older, obese individuals a 7-day low-GI diet combined with exercise training improved clamp-derived insulin sensitivity just as well as a high-GI diet + exercise although there were greater benefits of the low-GI diet on systolic blood pressure and  $\text{VO}_2$  max (Solomon *et al.*, 2010).

### **Micronutrients and Insulin Sensitivity**

Insulin sensitivity has also been related to intake of specific micronutrients. Magnesium is an important co-factor for enzymes involved in carbohydrate metabolism, and magnesium deficiency as judged by serum and dietary magnesium concentration is associated with insulin resistance

and increased risk of type 2 diabetes (Huerta *et al.*, 2005). In randomized controlled trials, magnesium supplements given to deficient subjects with type 2 diabetes improved HOMA–insulin resistance (Rodriguez-Moran and Guerrero-Romero, 2003).

The ability of chromium to improve insulin sensitivity remains controversial. Chromium is clearly essential for carbohydrate metabolism but it is widely available in the diet and deficiency states are rare. There is growing evidence that chromium supplementation, particularly at higher doses (1000  $\mu\text{g}/\text{day}$ ) in the form of chromium picolinate, is safe and may improve insulin sensitivity and glucose tolerance (Cefalu and Hu, 2004).

Vitamin intake and status may also play a role in maintenance of insulin sensitivity. Lipid oxidation, for example, might be a mechanism contributing to impaired mitochondrial function. Variations in insulin-mediated glucose disposal were observed in healthy individuals according to plasma concentrations of lipid-soluble antioxidant vitamins including lutein, carotenoids, and tocopherols (Facchini *et al.*, 2000). But in other cross-sectional studies, antioxidant vitamins E and C, showed no relationship to insulin sensitivity as judged by the FSIVGTT (Sanchez-Lugo *et al.*, 1997). The concentration of 25(OH)vitamin D correlated independently with clamp-derived insulin sensitivity in a study of 126 healthy, glucose-tolerant individuals living in California (Chiu *et al.*, 2004). Those with hypovitaminosis D were also three times more likely to have the metabolic syndrome. Salt sensitivity of blood pressure, as judged by the difference in blood pressure after a high vs. low sodium diet, was also strongly associated with insulin resistance in lean essential hypertensive patients (Yatabe *et al.*, 2010).

## **Diet and the Metabolic Syndrome**

The best evidence that dietary changes can improve the metabolic syndrome comes from landmark studies in which intensive lifestyle interventions prevented or delayed progression from impaired glucose tolerance to type 2 diabetes mellitus (Tuomilehto *et al.*, 2001; Diabetes Prevention Program Research Group, 2002). Both studies employed low-fat, high-carbohydrate diets (30% of energy from fat, 10% from saturated fat) in combination with physical activity to achieve the goal of weight loss. These findings have since been perceived as a rational basis for recommending low-fat, high-carbohydrate diets. Unfortunately, weight loss *per se* likely played the most

important role, and the superiority of low-fat diets for those with the metabolic syndrome is questionable.

In intervention trials, increased carbohydrate intake is well known to increase serum triglycerides and lower HDL, two markers of the metabolic syndrome (Garg, 1998). Indeed the similarity implies that high-carbohydrate diets of a certain nature play an etiological role in the metabolic syndrome. Several meta-analyses and reviews have concluded that low-carbohydrate, high-protein diets (Halton and Hu, 2004), low-glycemic-index (GI) or low-glycemic-load (GL) diets (Thomas *et al.*, 2007; Livesey *et al.*, 2008; Thomas and Elliott, 2009), and Mediterranean-style diets (Shai *et al.*, 2008) may be more effective (or just as effective) for improving components of the insulin resistance syndrome as traditional low-fat, high-carbohydrate diets. This higher effectiveness holds true over both the shorter and the longer term. Some studies suggest that these alternative dietary approaches may also be more successful for preventing weight regain than low-fat, high-carbohydrate diets.

In prospective observational studies, carbohydrate intake (whether high or low) is not usually an independent predictor of the development of type 2 diabetes or cardiovascular disease. In meta-analyses, however, quality of carbohydrate intake as assessed as the GI or GL shows a consistent positive relationship to the risk of type 2 diabetes and CVD despite non-significant findings in some individual prospective studies (Barclay *et al.*, 2008). The highest relative risks (>2) were observed among those with both a higher dietary GI or GL and lower (cereal) fiber intake. Recently, some prospective cohort studies have demonstrated that higher intake of high-GI carbohydrates, but not low-GI carbohydrates, is associated with greater risk of developing CVD (Sieri *et al.*, 2010). Similarly, there is increased risk of type 2 diabetes and overweight associated with dietary patterns that are characterized by higher intakes of refined grains or white bread, ready-to-eat breakfast cereals, sugar-sweetened beverages, potatoes or French fries, sweets or sweet bakery products (Buyken *et al.*, 2010). In contrast, a protective pattern commonly included carbohydrate choices such as fruits, vegetables, legumes, wholemeal or whole-grain bread, and high-fiber breakfast cereals. Finally, greater adherence to the "Alternative Healthy Eating Index," a set of dietary guidelines which targets fruits, vegetables, the ratio of white to red meat, the ratio of polyunsaturated to saturated fat, fiber, nuts, soy, and alcohol intake, was associated with reversion of the metabolic syndrome over a 5-year period

of study in participants in the Whitehall II Study (Akbaraly *et al.*, 2010).

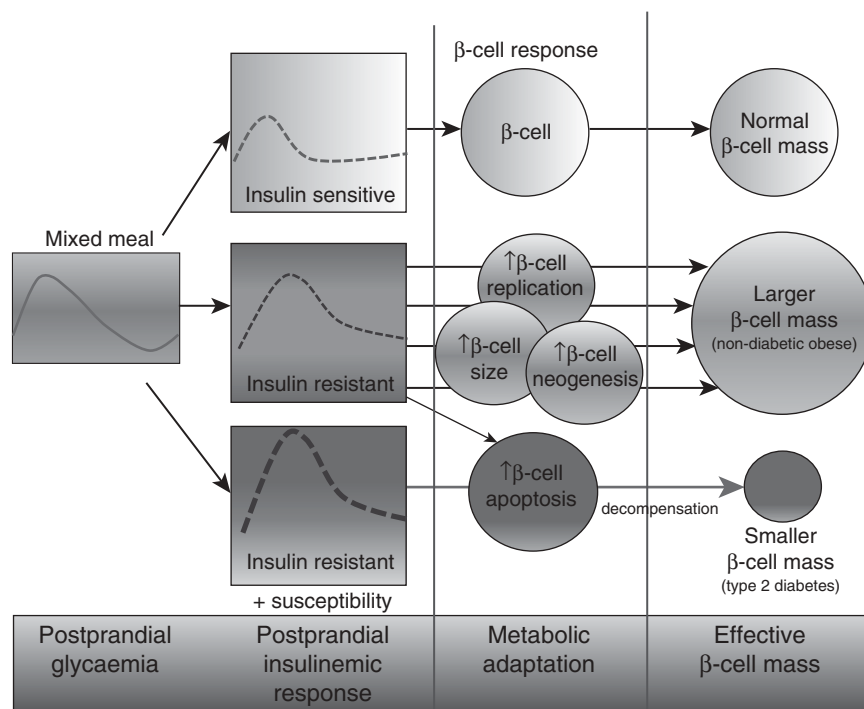

Taken together, these studies imply that dietary approaches that reduce the risk of developing type 2 diabetes or CVD share a unifying mechanism of reduced postprandial glycemia and insulinemia despite variable macronutrient distribution. It is possible that a diet that facilitates reduced glycemia without increasing dyslipidemia is likely to improve insulin sensitivity and the metabolic syndrome, and relieve the burden on the beta-cell. The least effective (or even most damaging) diet would be one that increased postprandial glycemia and placed extra demands on beta-cell function (Figure 47.4). These adverse effects will be most detrimental for individuals with insulin resistance. Conventional low-fat, high-carbohydrate diets may therefore not be the optimal dietary approach for persons at risk of developing the metabolic syndrome and its sequelae.

## Implications for Management

The triad of metabolic syndrome, insulin resistance, and overweight/obesity are strongly associated. Reducing weight in people who are overweight/obese compared with their population norm results in improvement in insulin resistance and the clinical manifestations of the metabolic syndrome. Therefore the aim of management should be weight reduction and sustained weight-loss maintenance through increased physical activity and dietary modification. Reduction in total energy intake is usually required to achieve weight loss. While research continues into other specific dietary recommendations, some general conclusions can be drawn from the literature. Salt reduction will assist with blood-pressure lowering. Reducing saturated fat and total carbohydrate intake will assist with controlling the typical lipid abnormalities seen in the metabolic syndrome. Avoiding high total carbohydrate intake, increasing fiber intake, and preferentially consuming low-GI carbohydrates will assist with controlling the glucose intolerance associated with the metabolic syndrome and help prevent progression to type 2 diabetes.

## Future Directions

The molecular basis of insulin resistance, its role in health and disease, and the role of diet composition in worsening or improving insulin sensitivity present continuing challenges to research scientists the world over. The recogni-

**FIG. 47.4** A tenuous balance exists between insulin resistance and an effective beta-cell mass. For the most part, the beta-cell mass adapts adequately to compensate for changes in the metabolic load. However, beta-cells can be pushed too far in susceptible individuals. Poor diets can worsen insulin resistance and contribute to an overwhelming metabolic load. Eventually the beta-cell mass fails to compensate for insulin resistance, and type 2 diabetes ensues. This failure may be caused by a marked increase in beta-cell apoptosis, most likely induced by a combination of chronic postprandial hyperglycemia and hyperlipidemia, and/or cytokines that interfere with the signaling pathways that maintain normal beta-cell growth and survival. Of all tissues, the beta-cells in particular are especially sensitive to endoplasmic reticulum and oxidative stress caused by high throughput through the mitochondrial chain. The net effect is a reduction in functional beta-cell mass in the type 2 diabetic state. Data from Rhodes (2005). Adapted from Buyken *et al.* (2010).

tion of a “metabolic syndrome” might prompt some health professionals to assess related risk factors when one risk factor is detected. However, a recent WHO Expert Consultation (Simmons *et al.*, 2010) recommended that

the metabolic syndrome not be applied as a clinical diagnosis. Rather, it should be considered as a premorbid condition, and individuals with established diabetes and known CVD should be excluded.

### Summary

Atherosclerotic cardiovascular disease (CVD) is initiated by a non-resolving inflammatory response, and later develops into a chronic disease in which genetic predisposition, diet, and lifestyle promote onset and progression. Modifiable CVD risk factors include overweight/obesity, elevated total cholesterol, low-density-lipoprotein (LDL) cholesterol and triglycerides, and low high-density-lipoprotein (HDL) cholesterol, elevated blood pressure, hyperglycemia, physical inactivity, cigarette smoking, stress, and an unhealthy dietary pattern. Effects of the macronutrients and selected vitamins, minerals, and antioxidants on CVD risk are reviewed. Combinations of various nutrients significantly reduce CVD risk factors. Furthermore, modifications in dietary patterns have been shown to reduce CVD risk by as much as 40%. Food-based dietary guidelines for reducing CVD risk are presented from various national and global health organizations. Efforts to manage co-morbidities such as obesity and diabetes also significantly impact disease risk. The need for population-wide strategies to curtail incidence of this epidemic is briefly discussed.

### Introduction

Atherosclerotic cardiovascular disease is a leading cause of mortality, resulting in a third of all deaths globally, with 85% of the disease burden and mortality currently borne by low- and middle-income countries (WHO, 2004a). It is a multifactorial, chronic disease in which genetic predisposition, diet, and lifestyle are instrumental in its onset and disease progression. The term *atherosclerosis*, derived from the Greek words “*athere*” for gruel and “*skleros*” for

hard, was first coined by the German physician Felix Marchand in a paper he presented at the 21st Congress for Internal Medicine in 1904. More than a century later, this term is used to define the build-up of waxy plaque in an artery that leads to the occlusion of blood flow. Atherosclerosis is a “maladaptive, nonresolving inflammatory response” (Moore and Tabas, 2011) produced by the interactions among modified lipoproteins, monocyte-derived macrophages, and T-lymphocytes in the arterial wall (Glass and Witztum, 2001). The thrombus that is

formed in response to a ruptured or eroded atherosclerotic plaque leads to the progression of cardiovascular disease (CVD) and can result in a myocardial infarction or a stroke (Naghavi *et al.*, 2003a,b; Spagnoli *et al.*, 2004).

The role of nutrition in the initiation, progression, and reversal of CVD is well established. A heart-healthy diet has long been a focal point in prevention and treatment of CVD. As our knowledge base has expanded, it has become evident that nutrition affects CVD in a multitude of ways by targeting important risk factors. Moreover, although our understanding of the mechanisms by which diet affects CVD has increased impressively, there still are many frontiers of inquiry that remain to be resolved. In addition, the combination of nutrition and lifestyle changes also has proven beneficial. The purpose of this chapter is to review our current understanding of the role that nutrition plays in the prevention and treatment of CVD, and to provide an overview of the lifestyle behaviors that are recommended to decrease the risk of CVD.

## Pathophysiology of Atherosclerotic Cardiovascular Disease (CVD)

### **Atherosclerotic Disease Progression**

CVD is a chronic inflammatory disease mediated by endothelial damage and circulating blood lipids. An elevated cholesterol level is a contributing factor in atherogenesis (atherosclerotic plaque development) (Glass and Witztum, 2001). Low-density lipoprotein (LDL) modification, particularly by oxidation, contributes importantly to atherogenesis. Intrinsic factors such as antioxidant content, fatty acid composition, and particle size (small and dense sub-fractions of LDL are more susceptible to oxidation), and extrinsic factors including the surrounding pH, local antioxidant concentrations, and transition metal availability, increase the susceptibility of LDL to oxidation (Young and McEneany, 2001). LDL modification allows for its cellular uptake via the scavenger receptor and consequent promotion of atherogenesis. LDL oxidation is mediated in part by 15-lipoxygenase, myeloperoxidase, or nitric oxide synthase (NOS) (Glass and Witztum, 2001; Yoshida and Kisugi, 2010). Oxidized LDL (OxLDL) is atherogenic and is a direct and indirect chemoattractant for circulating monocytes (Quinn *et al.*, 1987), with the latter occurring via the release of monocyte chemoattractant protein-1 (MCP-1) from the endothelium (Cushing *et al.*, 1990). OxLDL inhibits the movement of the resident macrophages (Quinn *et al.*, 1987) and in turn

promotes the differentiation of monocytes into tissue macrophages via the release of macrophage colony-stimulating factor from the endothelial cells (Rajavashisth *et al.*, 1990). It also is a chemoattractant for T-lymphocytes (McMurray *et al.*, 1993) and is immunogenic, unlike its native form (Palinski *et al.*, 1989), in that it is cytotoxic to several cell types such as endothelial cells (Hessler *et al.*, 1983) and consequently may promote the loss of endothelial integrity (Young and McEneany, 2001). OxLDL also stimulates the release of interleukin-1 $\beta$  from macrophages (Thomas *et al.*, 1994), inhibits tumor necrosis factor expression (Hamilton *et al.*, 1990), inhibits endothelial cell-dependent arterial relaxation (Ohgushi *et al.*, 1993), and activates matrix-digesting enzymes that promote plaque instability (Xu *et al.*, 1999).

### **Endothelial Injury**

Figure 48.1a shows the initiation of arterial plaque accumulation. Several events occur during the development of an atherosclerotic plaque and its progression towards a thrombotic event. The endothelium is sensitive to shear stress and the various hemodynamic conditions including branching, reverse flow, and low and oscillating shear stress which promote atherogenesis (Cunningham and Gotlieb, 2005). Susceptible blood vessels may contain lesion-prone regions consisting of leaky, activated, and dysfunctional endothelium (Davies *et al.*, 1988), where atherosclerotic lesions may develop. De-endothelialized or denuded areas may appear over advanced lesions as a result of the loss of endothelial cells, resulting in exposed sub-endothelial tissue with or without platelets adhering to the surface (Davies *et al.*, 1988). Lipoprotein particles (i.e. LDL) and other plasma molecules traverse the damaged endothelium into the intima or sub-endothelial space (Falk, 2006). Within the intima the lipoproteins are sequestered and modified, thereby contributing to their chemotactic, pro-inflammatory, cytotoxic, and pro-atherogenic properties (Falk, 2006), thus initiating atherogenesis.

### **Inflammatory Response**

The endothelium is activated by several atherogenic and pro-inflammatory particles (Falk, 2006) found in the circulation (Figure 48.1b). The endothelium in turn has increased expression of various cell adhesion molecules, such as the vascular cell adhesion molecule-1 (VCAM-1), which results in the recruitment of monocytes and T-lymphocytes (Falk, 2006). Other molecules also participate in the recruitment of blood-borne cells to the

**FIG. 48.1 (a) Endothelial injury.** The endothelium is sensitive to shear stress and varying hemodynamic conditions. Susceptible regions of the endothelium contain lesion-prone areas with leaky, activated, and dysfunctional endothelial cells. Lipoprotein particles extravasate through the defective endothelium into the intima or sub-endothelial space. Within the intima the lipoproteins are retained and oxidized. Oxidization occurs via 15-lipoxygenase, myeloperoxidase, or nitric oxide synthase (NOS). OxLDL is highly chemotactic, cytotoxic, pro-inflammatory, and pro-atherogenic. **A** – lumen, **B** – blood flow, **C** – reverse flow, **D** – endothelial cell, **E** – LDL particle, **F** – dysfunctional endothelial cell, **G** – intima, **H** – 15-lipoxygenase, myeloperoxidase, nitric oxide synthase (NOS), **I** – oxidized LDL (OxLDL), **J** – internal elastic lamina, **K** – media, **L** – smooth muscle cell. **(b) Inflammatory response.** The activated endothelium increases its expression of vascular cell adhesion molecule-1 (VCAM-1) and the release of monocyte chemoattractant protein-1 (MCP-1) to enable the recruitment of monocytes and T-lymphocytes. Adhesion to the endothelium is followed by trans-endothelial migration into the intima. OxLDL and MCP-1 are the most potent atherogenic chemoattractants. Monocytes within the intima differentiate into macrophages and undergo receptor-mediated endocytosis of oxLDL via their scavenger receptors. These LDL-laden macrophages further release the pro-inflammatory cytokine known as interleukin 1- $\beta$  and later develop into foam cells; foam cells are white in appearance due to the presence of several lipid-containing vacuoles. **A** – lumen, **B** – monocyte chemoattractant protein-1 (MCP-1), **C** – release of MCP-1, **D** – monocyte, **E** – T-lymphocyte, **F** – vascular cell adhesion molecule -1 (VCAM-1), **G** – monocyte extravasation, **H** – macrophage, **I** – scavenger receptor, **J** – receptor-mediated endocytosis, **K** – interleukin-1 $\beta$ , **L** – OxLDL, **M** – intima. **(c) Fatty streak development and thrombosis.** Foam cells endocytose until death by either apoptosis or necrosis. Death of the foam cells forms a soft, unstable, lipid-rich core and results in the release of tissue factor and various matrix-degrading, proteolytic enzymes. The smooth muscle cells respond to the injury by migrating to form a collagen-rich matrix to stabilize the lipid-rich core or fatty streak. Release of tissue factor into the bloodstream initiates coagulation by the rapid recruitment of platelets and clotting factors to result in the formation of a fibrin-rich cap over the damaged endothelium and fatty streak. This fibroproliferative process eventually leads to thrombosis, with an obstruction of blood flow within the arterial lumen. **A** – lumen, **B** – tissue factor, **C** – platelet, **D** – aggregation, **E** – fibrin, **F** – intima, **G** – necrosis or apoptosis, **H** – migrated smooth muscle cell, **I** – tissue factor, **J** – smooth muscle cell, **K** – collagen, **L** – necrotic foam cell, **M** – fatty streak, **N** – media.

atherosclerotic lesion, including intercellular adhesion molecule-1 (ICAM-1), E selectin, and P selectin (Libby, 2002; Hansson, 2005). Adhesion to the endothelium is followed by trans-endothelial migration mediated via one or more chemotactic cytokines (Falk, 2006). OxLDL and MCP-1 are the most potent atherogenic chemoattractants (Libby, 2002). In the intima the monocytes differentiate into macrophages and undergo receptor-mediated endocytosis of the atherogenic lipoproteins through their scavenger receptors and develop into foam cells. These scavenger receptors differ from the native LDL receptor in that their expression is not down-regulated with an increased cholesterol accumulation (Falk, 2006). In an abundance of atherogenic lipoproteins the activated macrophages or foam cells endocytose until death by either apoptosis or necrosis. Death of the foam cells leads to the formation of a soft and unstable lipid-rich core within the atherosclerotic plaque (Falk, 2006). In conditions of low LDL and high HDL levels, the foam cells may shrink through the efflux of cellular cholesterol to extracellular HDL mediated by membrane transporters (Glass and Witztum, 2001; Lewis and Rader, 2005), creating the initial step in reverse cholesterol transport (RCT). This process was first described by Glomset in 1968 in relation to the shuttling of peripheral cholesterol (Cuchel and Rader, 2006). Moderate to high levels of HDL have been found to be cardioprotective since the risk of atherosclerosis is inversely related to HDL levels (Tall *et al.*, 2000) with the protective effect due to the mediation of RCT by HDL (Burgess *et al.*, 2006). In this process HDL particles remove free cholesterol from the macrophages and transport these to the liver for excretion in the bile (Burgess *et al.*, 2006). Since HDL-mediated RCT contributes to a decrease in tissue cholesterol levels, increased RCT stimulates atheroregression and decreases the risk of atherosclerotic plaque development.

### Fatty Streak and Plaque Formation

Progression of atherosclerosis occurs as the result of the development of a foam-cell lesion known as a fatty streak (Falk, 2006), as shown in Figure 48.1c. This is accompanied by a fibro-proliferative response mediated by the intimal smooth muscle cells (Falk, 2006). The smooth muscle cells produce a collagen-rich matrix that stabilizes the atherosclerotic plaques. With further progression, endothelial cells, macrophages, and smooth muscle cells die by either apoptosis or necrosis, and it is the breakdown

of the foam cells and the smooth muscle cells that leads to the development of a destabilized lipid-rich core with a fragile, fibrous cap (Geng and Libby, 2002). Breakdown of foam cells also is detrimental in that tissue factor is released and several matrix-degrading (proteolytic) enzymes are expressed, such as matrix metalloproteinases, which further destabilize the plaque and induce thrombogenesis (Libby, 2002). A relatively large atherosclerotic plaque is prone to plaque rupture where a defect or gap occurs in the fibrous cap leading to the loss of the separation between its lipid-rich core and the circulating blood (Schaar *et al.*, 2004). This results in a cascade of events beginning with plaque rupture followed by platelet aggregation to the exposed sub-endothelial tissue and fibrin formation over the ruptured plaque. The rapid onset of platelet aggregation creates an obstruction leading to a decrease in blood flow (Falk, 2006). Plaque rupture is the cause of about 76% of all fatal heart attacks worldwide that are caused by coronary thrombosis (Falk *et al.*, 2004).

## Coronary Heart Disease, Stroke, and Peripheral Vascular Disease

Cardiovascular disease is defined as any disease plaguing the heart and its associated blood vessels. These include a variety of diseases including coronary heart disease, stroke, and peripheral vascular disease.

*Coronary heart disease* (CHD), also known as coronary artery disease (CAD), is disease of the coronary arteries, which provide the heart's oxygen and nutrient requirements (Morrow and Gersh, 2007). These arteries are at high risk for narrowing when cholesterol deposits (i.e. plaques) build up inside the artery. With significant narrowing of the coronary arteries the heart's blood supply is significantly decreased, resulting in pain or angina. If the plaque ruptures, a thrombus (blood clot) forms and may obstruct the artery, thereby decreasing blood flow and frequently causing a myocardial infarction or stroke. The stoppage of blood flow to the heart also causes the affected muscle to die, resulting in diminished function of the heart.

Stroke, also known as a cerebrovascular accident, is another form of cardiovascular disease that exists in two forms. Ischemic stroke results when the formation of a plaque blocks the blood flow within the artery leading to the brain, while hemorrhagic stroke results after the rupture of a blood vessel, and is characterized by uncontrolled bleeding into the surrounding tissue; ischemic and

**TABLE 48.1** Modifiable and non-modifiable risk factors for atherosclerosis

Non-modifiable	Modifiable	Goals for modifiable risk factors
Age	Weight	BMI: 18.5–24.9 kg/m <sup>2</sup>
Sex	Lipid profile	Total cholesterol: <200 mg/dl (5.2 mmol/L)
Family history/ genetics		LDL-C <sup>a</sup> : Very high-risk individuals, <70 mg/dl (1.8 mmol/L) High-risk individuals, <100 mg/dl (2.6 mmol/L) with optional goal of <70 mg/dl (1.8 mmol/L) Moderate-risk individuals, <130 mg/dl (3.4 mmol/L) with optional goal of <100 mg/dl (2.6 mmol/L)
Race/ethnicity		HDL-C: Men: ≥40 mg/dl (1.0 mmol/L) Women: ≥50 mg/dl (1.3 mmol/L)
		Triglycerides: <150 mg/dl (1.7 mmol/L)
	Blood pressure	Systolic: <120 mmHg Diastolic: <80 mmHg
	Glycemic control	Fasting blood glucose: <100 mg/dl (5.6 mmol/L)
	Physical activity	150 minutes of moderate activity or 75 minutes of vigorous activity per week
	Smoking	Stop smoking
	Diet	Follow a healthy diet
	Stress	Keep stress as low as possible

<sup>a</sup>Goals for LDL-C levels are those recommended by the National Cholesterol Education Program Adult Treatment Panel III (Grundy *et al.*, 2004). Very high-risk individuals are persons with established CHD, who also have diabetes, metabolic syndrome or other poorly controlled CVD risk factors. Individuals at high risk are those with established CHD, diabetes, or with two or more CVD risk factors which cause a greater than 20% risk of developing CHD within a 10-year period. Individuals at moderate risk refer to those with two or more risk factors for CHD, giving a 10–20% risk of developing CHD within a 10-year period.

hemorrhagic stroke represent ~80% and ~20% of all global cases respectively (World Health Organization, 2004b). Stoppage of blood flow for more than a few seconds leads to the loss of oxygen to cells within the brain, causing cell death and permanent brain damage.

*Peripheral vascular disease* is disease of the blood vessels outside of the brain and heart (World Health Organization, 2004b). Inflammation, tissue damage, and plaque accumulation cause narrowing of the blood vessels leading to the periphery – the arms, legs, stomach, and kidneys – and results in damage to these organs and tissues.

### Risk Factors for Atherosclerosis

Atherosclerosis is affected by abnormal blood lipid and lipoprotein levels, elevated blood pressure, and smoking,

as well as other risk factors (Glass and Witztum, 2001). Approximately 20–25% of initial vascular events occur in patients with one major CVD risk factor, with about one-half of those having elevated LDL cholesterol (LDL-C) (Ridker *et al.*, 2004). Recommended nutrition and medical interventions target modifiable risk factors and can significantly reduce the progression of atherosclerosis and CVD. These modifiable and non-modifiable risk factors are presented in Table 48.1 (Glass and Witztum, 2001; Sacco, 2011).

Persons diagnosed with metabolic syndrome (MetS) are at increased risk for developing cardiovascular disease. An individual with MetS, also known as insulin resistance syndrome, is classified by the International Diabetes Federation (IDF, 2006) as having central obesity, defined as a waist circumference of ≥94 cm for European men and ≥80 cm for European women, and any two of the four

**TABLE 48.2** Inclusion criteria for metabolic syndrome diagnosis

International Diabetes Federation	World Health Organization	American Heart Association and National Heart, Lung, and Blood Institute
Individual must have central obesity classified as having a waist circumference of $\geq 94$ cm (37 in) for Europid men or $\geq 80$ cm (32 in) for Europid women <sup>a</sup> , plus any two of the following factors:	Large waist circumference: $\geq 94$ cm (37 in) in men and women Waist-to-hip ratio $>0.9$ BMI $\geq 30$ g/m <sup>2</sup>	Large waist circumference: Men $\geq 40$ in Women $\geq 35$ in
Blood pressure $\geq 130/85$ mmHg or treatment for previously diagnosed hypertension	Blood pressure $\geq 140/90$ mmHg	Blood pressure $\geq 130/85$ mmHg
Triglycerides $\geq 150$ mg/dL (1.7 mmol/L) or treatment for this lipid abnormality	Triglycerides $\geq 150$ mg/dL	Triglycerides $\geq 150$ mg/dL
HDL-cholesterol $<40$ mg/dL (1.03 mmol/L) for men and $<50$ mg/dL (1.29 mmol/L) for women or treatment for this lipid abnormality	HDL-cholesterol: $<35$ mg/dL for men and women	HDL-cholesterol: $<40$ mg/dL for men $<50$ mg/dL for women
Fasting plasma glucose $\geq 100$ mg/dL (5.6 mmol/L) or previously diagnosed type 2 diabetes	Fasting blood glucose $\geq 100$ mg/dL	Fasting blood glucose $\geq 100$ mg/dL

<sup>a</sup>Specific values for waist circumference are provided for other ethnic groups (International Diabetes Federation, 2006).

criteria listed in the left panel in Table 48.2. The World Health Organization classifies a person with metabolic syndrome as having either high insulin levels, an elevated fasting blood glucose level or an elevated post-meal glucose level alone, along with at least two of the criteria listed in Table 48.2 in the center panel (Alberti and Zimmet, 1998). The American Heart Association (AHA) and the National Heart, Lung and Blood Institute (US Department of Human and Health Services) classify individuals with MetS as having three or more of the following factors shown in Table 48.2 in the right-hand column (Grundy *et al.*, 2005).

High levels of LDL-C, as well as elevated total cholesterol concentrations, are potent contributors to atherogenesis (Glass and Witztum, 2001). The risk of atherosclerosis is inversely related to HDL levels (Tall *et al.*, 2000); the protective effect is due to the mediation of reverse cholesterol transport (Burgess *et al.*, 2006). Cigarette smoking is a major risk factor for the development of atherosclerosis; the main mechanisms involve endothelial dysfunction, inflammation, and an unfavorable lipid profile (CDC, 2010). Smoking is associated with increased triglyceride and decreased HDL-C concentrations (CDC, 2010). Another major risk factor for atherosclerosis, high blood pressure, causes endothelial injury through shear stress and micro-tears in the artery wall

(AHA, 2011). Other risk factors, such as weight, blood glucose, physical inactivity, and diet, play a major role in the progression of atherosclerosis. A chronic state of inflammation presented as elevated levels of C-reactive protein and other pro-inflammatory cytokines, along with decreased levels of anti-inflammatory cytokines, also has been found to promote atherosclerotic plaque development (Falk, 2006). Targeting these risk factors is central to reducing coronary artery disease (CAD). Table 48.3 shows the effects of targeted lifestyle and dietary changes on mortality risk in persons with CAD. Beneficial effects on reducing mortality risk are also achievable within the general population via combined dietary changes ( $-45\%$ ), incorporation of moderate-intensity physical activity at 40–60%  $VO_2$  max for at least 30 minutes per day on at least 5 days per week ( $-25\%$ ), moderation of alcohol intake to 2 drinks per day for women and 3 drinks per day for men ( $-20\%$ ), and cessation of smoking ( $-45\%$ ) (Iestra *et al.*, 2005). The aforementioned combined dietary changes include two or more of the following factors: limiting saturated ( $\leq 10\%$  E) and *trans* fatty acid intake ( $\leq 1\%$  E), consumption of 1–2 portions of oily fish per week, regular fruit and vegetable intake ( $>400$  g/day), sufficient intake of fiber-containing grain products, legumes and/or nuts ( $\geq 3$  U/day), and decreased salt intake ( $<2,400$  mg/day).

**TABLE 48.3** Effects of targeted diet and lifestyle interventions on mortality risk in individuals with coronary artery disease (CAD): evidence from prospective cohort studies and randomized controlled trials. Adapted from Iestra and colleagues, 2005

Intervention	Reduction in mortality risk for individuals with CAD
Combined dietary changes <sup>a</sup>	45%
Moderate-intensity physical activity <sup>b</sup>	25%
Moderation of alcohol intake <sup>c</sup>	20%
Smoking cessation	45%

<sup>a</sup>Represents a combination of  $\geq 2$  of the following factors: limiting saturated fat intake ( $\leq 10\%$  E) and *trans* fatty acid intake ( $\leq 1\%$  E); regular consumption of fish (1–2 portions of oily fish per week); regular fruit and vegetable intake ( $\geq 400$  g/day); sufficient intake of fiber-containing grain products, legumes and/or nuts ( $\geq 3$  U/day); reduction of salt intake ( $\leq 2,400$  mg/day).

<sup>b</sup>Moderate-intensity physical activity (40–60% of  $VO_2$  max) for at least 30 minutes per day on at least 5 days per week.

<sup>c</sup>A maximum of 2 drinks per day for women and 3 drinks per day for men (Iestra *et al.*, 2005). Adapted with permission from Iestra *et al.* (2005).

### Ranking of the Strength of the Scientific Evidence

There has been extensive primary research conducted on the effect of various nutrients on CVD risk factors as well as several evidence-based reviews on their overall mechanisms of action for reducing CVD risk. Expert panels rank such evidence to create national-policy public-health recommendations. Table 48.4 presents the 2010 Dietary Guidelines for Americans conclusion and grading system used by the expert panel to determine the strength of the current evidence. Specifically this system was used for the macronutrients, sodium and potassium. For the reader, this conclusion and grading system is also applicable to the strength of the evidence provided by the Institute of Medicine (IOM) and the American Heart Association (AHA) for magnesium, the B-vitamins, vitamin D, and the antioxidant vitamins C and E.

### Role of the Macronutrients in Atherosclerosis

The macronutrient composition of dietary patterns affects lipids and lipoproteins and, consequently, CVD risk. A key question that has been addressed by many researchers concerns which macronutrient should replace calories provided by saturated fats. A meta-analysis of 60 controlled trials by Mensink and colleagues (2003) found that, rela-

tive to carbohydrates (CHO), SFAs increased LDL-C and HDL-C. Monounsaturated fatty acids (MUFAs) were associated with increasing HDL-C levels while significantly lowering LDL-C levels relative to CHO. Polyunsaturated fatty acids (PUFAs) resulted in the greatest LDL-C reduction with a slight but significant increase in HDL-C. The total cholesterol:HDL-C (TC:HDL-C) ratio did not change when SFA was replaced with CHO; however, the ratio decreased when SFA was replaced with MUFA or PUFA. In contrast, *trans* fatty acid (TFA) did not increase HDL-C relative to carbohydrate, but produced the greatest increase in LDL-C, resulting in the most detrimental TC:HDL-C ratio. Lastly, replacing carbohydrates with any type of fatty acid resulted in a lower triglyceride (TG) level. Additional dietary factors, including omega-3 (n-3) and omega-6 (n-6) fatty acids, the glycemic index, fiber content, and protein intake, also affect CVD risk through a variety of mechanisms that will be discussed in the following sections.

### Saturated Fatty Acids

Strong evidence indicates a positive association between dietary SFA intake and increased total cholesterol and LDL-C, as well as increased CVD risk (DGAC, 2010b). As such, reducing SFA intake is a primary focus of dietary interventions to lower LDL-C (Lichtenstein *et al.*, 2006a). Regression analyses indicate that for every 1% increase in energy from SFAs, LDL-C increases by 0.033–0.045 mmol/L and HDL-C by 0.011–0.013 mmol/L (Mensink and Katan, 1992; Hegsted *et al.*, 1993; Clarke *et al.*, 1997). A meta-analysis of randomized controlled trials reported that all long-chain SFAs with the exception of stearic acid (18:0) increase LDL-C and HDL-C relative to carbohydrate (Mensink *et al.*, 2003). Stearic acid has been excluded from the category of cholesterol-raising fatty acids since it does not increase LDL-C compared with the other long-chain SFAs (DGAC, 2010a). Consequently, high stearic acid vegetable oils have been developed as a source of solid fat that is considered a healthy alternative in food applications requiring solid fat (Hunter *et al.*, 2010).

Reducing dietary SFAs typically is associated with an increase in some other macronutrient. The nutrient(s) replacing SFA(s) will differentially affect blood lipid levels and therefore influence the risk of atherosclerosis and CVD. Clinical evidence has consistently shown that replacing SFA with unsaturated fat improves lipid levels and decreases CVD risk. Consumption of PUFA (Chung

**TABLE 48.4** Guidelines for determining the strength of evidence

Elements	Strong	Moderate	Limited	Expert opinion only	Grade not assignable
<i>Quality:</i>					
Scientific rigor and validity	Studies of strong design	Studies of strong design with minor methodological concerns	Studies of weak design for answering the question	No studies available	No evidence that pertains to question being addressed
Study design and execution	Free from design flaws, bias, and execution problems	Or only studies of weaker design for question	Or inconclusive findings due to design flaws, bias, or execution problems	Conclusion based on usual practice, expert consensus, clinical experience, opinion, or extrapolation from basic research	
<i>Consistency:</i>					
Consistency of findings across studies	Findings generally consistent in direction and size of effect or degree of association, and statistical significance with very minor exceptions	Inconsistency among results of studies with strong design Or consistency with minor exceptions across studies of weaker design	Unexplained inconsistency among results from different studies Or single study unconfirmed by other studies	Conclusion supported solely by statements of informed nutrition or medical commentators	NA
<i>Quantity:</i>					
Number of studies	One large study with a diverse population or several good quality studies	Several studies by independent investigators	Limited number of studies	Unsubstantiated by published research studies	Relevant studies have not been done
Number of study participants	Large number of subjects studied Studies with negative results have sufficiently large sample size for adequate statistical power	Doubts about adequacy of sample size to avoid Type I and Type II errors	Low number of subjects studied and/or inadequate sample size within studies		
<i>Impact:</i>					
Importance of studied outcomes	Studied outcome relates directly to the question	Some doubt about the statistical or clinical significance of the effect	Studied outcome is an intermediate outcome or surrogate for the true outcome of interest	Objective data unavailable	Indicates area for future research
Magnitude of effect	Size of effect is clinically meaningful Significant (statistical) difference is large		Or size of effect is small or lacks statistical and/or clinical significance		
<i>Generalizability:</i>					
Generalizability to population of interest	Studied population, intervention and outcomes are free from serious doubts about generalizability	Minor doubts about generalizability	Serious doubts about generalizability due to narrow or different study population, intervention or outcomes studied	Generalizability limited to scope of experience	NA

*et al.*, 2004; Lichtenstein *et al.*, 2006b; Kralova Lesna, 2008) and MUFA (Yu-Poth *et al.*, 2000; Lichtenstein *et al.*, 2006b; Berglund *et al.*, 2007) in place of SFA decreases LDL-C. Replacing SFA with carbohydrate also lowers LDL-C; however, TG increases and HDL-C decreases compared with PUFA and MUFA replacement (Mensink *et al.*, 2003; Berglund *et al.*, 2007). Also, the type of carbohydrate replacing SFA contributes to the overall CVD risk. For example, replacing SFA with refined carbohydrate may increase the number of small LDL particles, another CVD risk factor, even though total LDL-C may be lowered slightly (Mensink *et al.*, 2003; Krauss *et al.*, 2006; Siri-Tarino *et al.*, 2010). Small, dense LDL particles are more atherogenic due to a greater ability to penetrate the endothelial wall and initiate foam cell formation (Gardner *et al.*, 1996; Stampfer *et al.*, 1996; Lamarche *et al.*, 1997).

Previous epidemiological evidence reported adverse associations between SFA and lipid and lipoprotein levels (Skeaff and Miller, 2009). SFAs were positively correlated with total cholesterol, as well as CVD incidence in different populations (Posner *et al.*, 1991; Hu *et al.*, 1997). However, recent epidemiological studies challenge these results and suggest that SFAs may not be associated with CVD risk. Skeaff and Miller (2009) conducted a meta-analysis using results from prospective cohorts to evaluate the associations between fatty acids and CVD risk. SFAs were not significantly associated with CHD events (RR 0.93 [95% CI: 0.83–1.05]) or CHD death (RR 1.14 [95% CI: 0.82–1.60]). However, the authors stated that the evidence available was unsatisfactory and unreliable. Many of the studies included in the analysis used a 24-hour recall to assess dietary intake, a particularly imprecise method for determining long-term dietary habits (Beaton *et al.*, 1979). Another recent meta-analysis of prospective studies by Siri-Tarino and colleagues (2010) also found that SFAs were not significantly related to CHD (RR 1.07 [95% CI: 0.96–1.19]). Only six of the 16 studies included in this analysis reported a positive association with CHD. However, the authors did not define CHD or separate CHD into events versus fatalities. Not unlike Skeaff and Miller (2009), many of the studies that were included (more than half) used 24-hour recalls or some other dietary assessment method with known limitations. The use of 24-hour recalls to assess long-term dietary habits raises questions about the reliability of the results, and through regression dilution bias may reduce the strength of association (Katan *et al.*, 2010).

Jakobsen and colleagues (2009) conducted a pooled analysis of prospective cohort studies from both Europe and the United States reporting that the substitution of PUFA for SFA was associated with a decreased risk of CHD events (HR 0.87 [CI: 0.77–0.97]) and CHD death (HR 0.74 [95% CI: 0.61–0.89]). In contrast, substitution of MUFA or carbohydrate for SFA was associated with an increased risk of CHD events (HR 1.19 [CI: 1.00–1.42] and HR 1.07 [CI: 1.01–1.14]), but not CHD death. These results suggest that PUFAs are the preferred substitute for SFAs over MUFAs or carbohydrate, in order to reduce CHD risk. The authors pointed out that no differentiation was made between carbohydrate sources of different glycemic indexes, which significantly influence CHD risk (Jakobsen *et al.*, 2009). Also, adjustments for TFA in the foods may have been incomplete and, in fact, possibly included in the hazard ratio estimations for MUFA intake. In contrast, Mente and colleagues (2009) pooled prospective cohort studies and found strong evidence for an inverse relationship between MUFA and CHD risk (RR 0.80 [CI: 0.67–0.930]), and a positive relationship between TFA and CHD risk (RR 1.32 [95% CI: 1.16–1.48]). These investigators also reported no significant relationship for SFAs (RR 1.06 [CI: 0.96–1.15]) and CHD. However, unlike the other recent studies, PUFAs (RR 1.02 [CI: 0.81–1.23]) were not related to CHD.

The inconsistencies among recent epidemiological studies may indeed be due to differences in the method of assessment of dietary SFA intake. As well, more clinical and observational studies may be used to determine why epidemiological evidence varies from that seen in clinical trials. None the less, strong clinical evidence indicates an association between SFA intake and increased CVD risk.

### Monounsaturated Fatty Acids

There is strong evidence in support of MUFA replacement of SFA for an improvement in blood lipids (DGAC, 2010b). Clinical evidence has shown that MUFA substitution for SFA decreases LDL-C (Yu-Poth *et al.*, 2000; Lichtenstein *et al.*, 2006b; Berglund *et al.*, 2007). When replacing SFA with MUFA, compared with PUFA or carbohydrate, HDL-C is either less reduced or unchanged (Rudel *et al.*, 1998; Mensink *et al.*, 2003). Both MUFA and carbohydrate lower LDL-C levels when replacing SFA, but MUFA can increase HDL-C levels versus carbohydrate, lower the TC:HDL-C ratio, and potentially decrease apolipoprotein B levels (apo B), the main apolipoprotein

in LDL-C (Garg, 1998; Mensink *et al.*, 2003). Evidence demonstrates that diets high in MUFAs versus PUFAs also may protect against LDL oxidation (Garg, 1998). MUFAs have a lower susceptibility to spontaneous oxidation compared with PUFAs and are less likely to form oxidative derivatives in the circulation (Ashton *et al.*, 2001; Hargrove *et al.*, 2001; Ahuja *et al.*, 2003). Therefore, MUFAs may protect against smooth muscle cell proliferation and oxidative stress (Colette *et al.*, 2003).

Primate studies have shown that MUFAs are more atherogenic than PUFAs, eliciting effects similar to SFAs (Rudel *et al.*, 1995, 1998). Rudel and colleagues (1995) fed atherogenic diets (35% fat, 0.8 mg cholesterol/kcal) high in SFAs, PUFAs, or MUFAs to adult male African green monkeys for 5 years to assess the effects on plasma lipoproteins and coronary artery atherosclerosis (CAA); CAA is the development of atherosclerotic plaques within the coronary arteries. Monkeys fed the PUFA and MUFA diets had significantly lower LDL-C levels than the monkeys fed the SFA diet, whereas HDL-C levels, while similar for the SFA and MUFA groups, were significantly lower in monkeys fed the PUFA diet. CAA was comparable in the MUFA and SFA groups, but significantly less in monkeys fed the PUFA diet. The authors concluded that the SFA and MUFA diets were more atherogenic than the PUFA diet. Interestingly, the diets high in SFA and MUFA elicited similar atherogenic effects. Unlike the group fed PUFA, cholesteryl oleate was the primary cholesterol ester accumulating in the coronary arteries in the SFA and MUFA groups. It was noted that LDL in animals fed MUFA was significantly enriched in cholesteryl oleate, which shifted the melting point of LDL above body temperature (Rudel *et al.*, 1995). This shift may have decreased the ability to hydrolyze and clear cholesterol ester droplets, thereby contributing to CAA. However, clinical studies have not shown MUFA consumption to be harmful, and the 2010 Dietary Guidelines for Americans state that PUFA or MUFA in place of SFA reduces CVD risk (DGAC, 2010a).

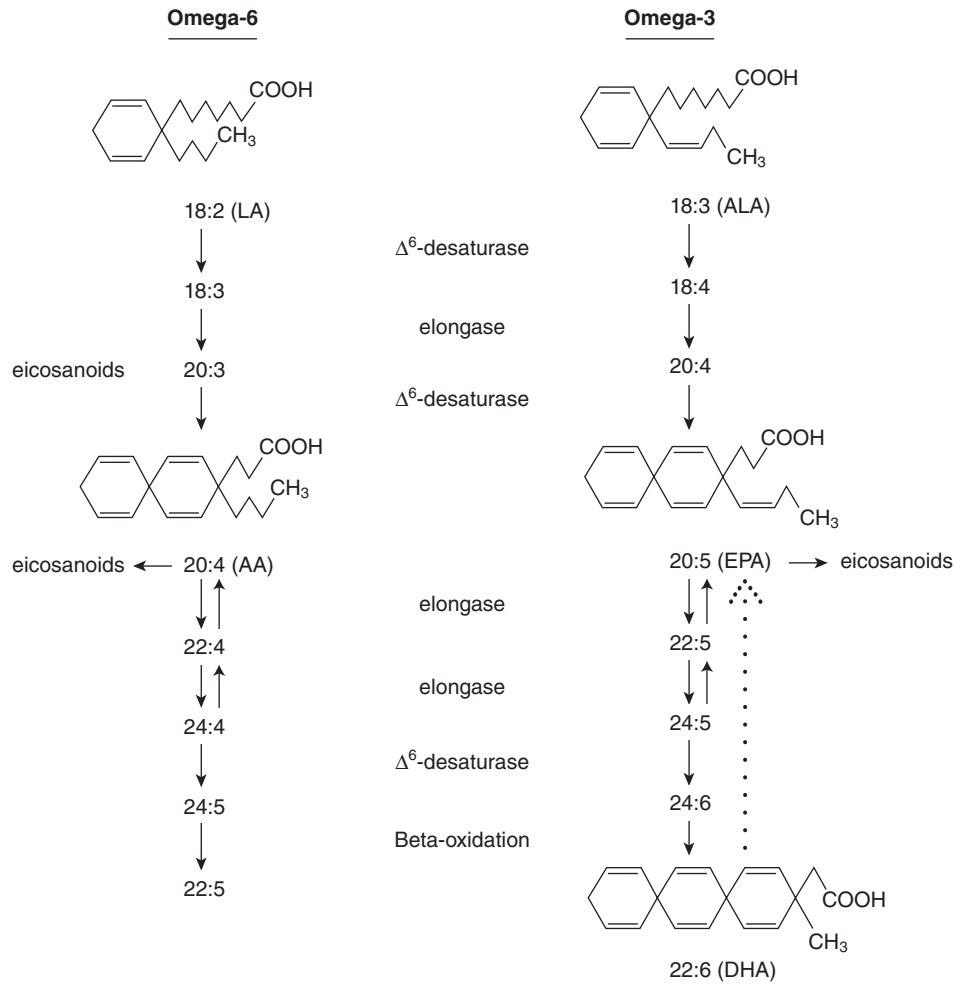

A recent meta-analysis by Cao and colleagues (2009) reported that moderate-fat (MF; average 23.6% of total kcal as MUFA) and low-fat (LF; average containing 11.4% of total kilocalories as MUFA) diets both lowered TC and LDL-C similarly. However, MF diets increased HDL-C [2.28 mg/dL (95% CI: 1.66–2.90)  $p < 0.0001$ ] and decreased TG [−9.36 mg/dL [CI: −12.16, −6.08]  $p < 0.00001$ ] vs. LF diets. Thus, the TC:HDL-C ratio was significantly reduced after MF diets (−0.36,  $p < 0.0001$ )

with a  $-0.30 \pm 0.09$  ( $p < 0.001$ ) difference between MF and LF diets. Predicted changes in CVD risk estimated that MF diets led to greater reductions in CVD risk compared with LF diets for both men and women (−6.37% and −9.34%, respectively). Additional research is needed to explain why animal studies (in particular, those involving non-human primates) and human studies differ in how MUFAs affect CVD risk.

Epidemiological evidence for substituting MUFA in place of SFA has also been inconsistent with regard to CVD risk, as previously discussed. A recent pooled analysis of prospective cohort studies reported a positive association between substitution of MUFA for SFA and CHD events (HR: 1.19 [95% CI: 1.00–1.42]). In contrast, another pooled analysis of prospective cohort studies reported an inverse relationship between MUFA and CHD risk (RR 0.80 [CI: 0.67–0.93]). Further research is needed to clarify discrepancies associated with MUFA and CVD risk. The DGAC report states that a 5% energy replacement of SFA with MUFA can decrease the risk of CVD and type 2 diabetes (DGAC, 2010b). Therefore, substituting MUFA for SFA, TFA, and/or carbohydrate can improve the lipid and lipoprotein levels and other biomarkers of CVD risk.

### Polyunsaturated Fatty Acids

There is strong and consistent evidence in support of the association between intake of polyunsaturated fatty acids (PUFAs) and an improvement in blood lipids, particularly when PUFAs replace SFAs and TFAs in the diet (DGAC, 2010b). PUFAs have multiple double bonds and consequently are more fluid than saturated fatty acids. Omega-3 (n-3) and omega-6 (n-6) PUFAs have their first double bond at 3 and 6 carbons from the omega end of the fatty acid, respectively. These are essential nutrients that cannot be synthesized by humans due to the lack of an enzyme required to insert a *cis* double bond into a carbon backbone (Institute of Medicine, 2002). Humans can synthesize long-chain (LC) n-3 or n-6 fatty acids from the essential, parent fatty acids obtained from the diet, albeit at a low rate. The parent fatty acid for the n-3 series is  $\alpha$ -linolenic acid (ALA; 18:3n-3), and the parent fatty acid for the n-6 series is linoleic acid (LA; 18:2n-6). Bioconversion of these PUFAs leads to the production of several LC fatty acids including eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:4n-6) in the n-3 series, and arachidonic acid (AA; 20:4n-6) in the n-6 series. However, the bioconversion of the n-3

**FIG. 48.2** The metabolism of omega-3 and omega-6 PUFAs. Modified and reproduced with permission from Harris *et al.* (2008). Questions remain about whether DHA is retroconverted to EPA, as shown by the dotted arrow.

series to these very long-chain FAs is low (Hussein *et al.*, 2005; Goyens *et al.*, 2006).

Figure 48.2 displays the metabolism of both n-3 and n-6 FAs, which primarily includes desaturase enzymes that remove hydrogen atoms to create a double bond, and elongase enzymes that add carbons to the backbone of the fatty acid. n-3 and n-6 FAs utilize the same enzymes for elongation and desaturation, and consequently there is competition between the fatty acid groups for these rate-limiting enzymes, most notably for the  $\Delta^6$ -desaturases. Enzymatic competition is part of the basis for recommending decreased n-6 FA intake to improve the metabolism of short-chain dietary n-3 fatty acids (FAs) and to theoretically increase blood levels of EPA and DHA. Liou and colleagues (2007) addressed the effects of lowering the

n-6:n-3 ratio in a randomized cross-over study in men ( $n = 22$ ). They compared two diets given for 4 weeks: a high-LA diet (7.0–15.8% total energy; approximately 10:1 LA/ALA ratio) with a low-LA diet (2.9–5.2% energy; 4:1 ratio) and found a decrease in phospholipid EPA and an increase in the AA:EPA ratio when participants consumed the high-LA diet, but no increase in phospholipid AA (Liou *et al.*, 2007). This suggests that the n-3 FA content in cell membranes may be affected by a high intake of n-6 FA, but perhaps only when consuming primarily shorter chain n-3 PUFAs.

The cardioprotective benefits of marine n-3 fatty acids were discovered in the 1970s by Danish researchers assessing the fish-rich diet and low CVD occurrence of Greenland Inuits (Dyerberg and Bang, 1979). Since this ecological

observation, population, clinical, and basic investigations have confirmed the protective effect of both marine- and plant-derived n-3 FAs against CVD (Agency for Healthcare Research and Quality, 2004). The evidence for plant-based n-3 FAs (rich in ALA) is less conclusive than that for marine-based, longer-chain, n-3 FAs, EPA, and DHA (Wang *et al.*, 2006). Flaxseed, walnuts, flaxseed oil, walnut oil, and canola oil are sources of ALA, and cold-water fish such as salmon, mackerel, herring, and sardines are the species of seafood that are the richest sources of EPA and DHA (Harris *et al.*, 2008; DGAC, 2010a).

**Plant-Based n-3 Fatty Acids:  $\alpha$ -Linolenic Acid.** There is limited but supportive evidence that a higher intake of n-3 FAs from plant sources reduces CVD-related mortality among persons with existing CVD (DGAC, 2010b). Based on epidemiological studies, an intake of between 1.5 and 3 g/day of ALA is considered cardioprotective (Albert *et al.*, 2005; Mozaffarian *et al.*, 2005). In an 18-year follow-up of women (30–55 years at baseline) in the Nurses' Health Study ( $n = 76\,723$ ), women in the top two quintiles for ALA intake (median: 1.16 and 1.39 g/day) had a 38–40% lower risk of sudden cardiac death vs. women in the lowest quintile (median: 0.66 g/day) (Albert *et al.*, 2005). This trial, however, showed no relationship between ALA intake and other types of fatal CHD or non-fatal myocardial infarction. After 14 years of follow-up, male participants in the Health Professionals Follow-Up Study ( $n = 45\,722$ ) with little or low EPA and DHA intake (<100 mg/day) had a 47% reduction in the risk of CHD incidence for every 1 g/day increase in ALA intake (Mozaffarian *et al.*, 2005); however, this association was not seen in participants with higher EPA and DHA intakes ( $\geq 100$  mg/day). Several clinical studies have investigated the effects of high ALA intake on CVD and mortality but the results have not been conclusive (Natvig *et al.*, 1968; de Lorgeril *et al.*, 1999; Harris, 2005). The Mediterranean (Lyon) Diet Heart Study demonstrated a 50% reduction in CHD risk over 4 years of follow-up in a secondary prevention population when the diet followed was increased in ALA ( $\approx 1$  g/day). However, causality could not be determined because there were multiple dietary components that were altered between diets, including breads, fruits, vegetables, legumes, deli and regular meats, butter, cream, and margarine (de Lorgeril *et al.*, 1999). Natvig and colleagues (1968) supplemented middle-aged men ( $n = 13\,578$ ; 50–59 years) with 5.5 g/day ALA or sunflower seed oil for 1 year and did not find any differences

in CVD endpoints between groups. The death rate in this study was lower than anticipated (0.4%), which decreased statistical power to detect a difference between groups (Natvig *et al.*, 1968).

Although ALA can be converted to long-chain FAs such as EPA and DHA, these rates are very low in humans, with values between 0.01 and 8% for EPA and less for DHA (Brenna, 2002; Plourde and Cunnane, 2007). The ALA conversion rate also is affected by age, gender, genetics, and overall dietary intake, as well as competition for enzymes catalyzing the conversion of LA to arachidonic acid (AA) as previously described. Due to the high intake of LA in the average American diet, a greater conversion of LA to AA often occurs, blunting the conversion of ALA to EPA and DHA (Chan *et al.*, 1993). Therefore, the recommendation to increase EPA + DHA levels by dietary ALA often includes the simultaneous recommendation to decrease LA intake. Recent studies have shown that daily supplementation of between 2.4 and 3.7 g of ALA for 12 weeks significantly increased erythrocyte EPA and docosapentaenoic acid (DPA), but not levels of DHA (Brenna, 2002; Harper *et al.*, 2006; Barcelo-Coblijn *et al.*, 2008). Despite the studies that show lower conversion rates of ALA to longer chain n-3 fatty acids (principally EPA) when LA is high, it is generally accepted that, if consumption of EPA and DHA meets current recommendations, modifications in LA intake (as well as ALA) are not necessary for the purposes of increasing production of longer chain n-3 fatty acids. The DGAC 2010 report concludes that the evidence currently available on ALA is insufficient to make recommendations for increasing intake of this n-3 fatty acid to reduce CVD risk (DGAC, 2010b). The adequate intake recommendation for ALA made by the Institute of Medicine is based on nutrient adequacy and is 1.6 and 1.1 g/day for men and women, respectively (Institute of Medicine, 2005).

**Marine-Derived n-3 Fatty Acids: EPA and DHA.** There is a moderate body of evidence for an association between the consumption of two 4-oz (113 g) servings of seafood per week, providing a total of 250 mg/day of long-chain n-3 FAs, and reduced mortality from CHD or sudden death in persons with and without CVD (DGAC, 2010b). The association between CHD mortality and fish intake was assessed in a meta-analysis of over 220 000 persons who were followed for an average of 11.8 years (He *et al.*, 2004b). In contrast to non-fish-eating individuals, persons

who consumed fish  $\geq 5$  times per week had a 38% decrease in CHD mortality risk. In addition, for every 20 g/day increase in fish intake there was a 7% decrease in risk of mortality due to coronary events. Also, a moderate intake of 1–3 servings of fish each month significantly reduced the risk of stroke (9%) and CHD mortality (11%) (He *et al.*, 2004a,b). The Diet and Reinfarction Trial (DART) reported that male myocardial infarction survivors who consumed 200–400 g/week of fatty fish, which provided an additional 500–800 mg/day of n-3 FAs, had a 29% reduction in 2-year, all-cause mortality (Burr *et al.*, 1989). However, in their study in men with angina, Burr and colleagues (2003) found that, in the group advised to eat oily fish (2 servings/week) and those supplied with fish-oil capsules (3 capsules/day), there was a higher risk of cardiac death (HR: 1.26 [95% CI: 1.00–1.58],  $p = 0.047$ ), indicating possibilities for adverse events in particular subgroups of the population. Results from this study were unexpected given previous clinical and epidemiological findings. There were major concerns about the levels of compliance given that participants received dietary advice only. Participants were seen at baseline and at 6 months, but use of plasma EPA levels as a direct measure of compliance was only determined in 68 of the 3114 participants. Mailings and phone follow-up contacts were used for subsequent measures of compliance, but these are indirect and there may have been over-reporting of the capsules taken or the amount of fish consumed over time (Kris-Etherton and Harris, 2004). Mortality was determined after 3–9 years using National Health Service records, but it must be noted that, with any effectiveness trial of long duration, there is a tendency for participants to adopt high-risk behaviors if they view the intervention as preventive (Kris-Etherton and Harris, 2004). Several variables may have influenced the mortality rate, and, given the weak study design, only replication of these results in more controlled clinical studies would prompt revision of current recommendations for fish and fish-oil intake specifically for patients with angina.

Indeed, many intervention trials that have utilized fish-oil capsules instead of fish have noted significant reductions in CHD risk. The GISSI Prevention Study was a large prospective clinical trial that tested the efficacy of n-3 FAs for secondary prevention of CHD (GISSI-Prevenzione Investigators, 1999). Subjects randomized to the EPA + DHA supplement group (850 mg/day of n-3 ethyl esters) experienced a 15% reduction in the primary endpoint of death, non-fatal myocardial infarction and non-fatal

stroke ( $p < 0.02$ ). All-cause mortality was reduced by 20% ( $p = 0.01$ ), and sudden death was reduced by 45% ( $p < 0.001$ ) compared with the control group. Compared with baseline, no significant changes among groups were reported for TC, LDL-C, or HDL-C levels after 6 months; compared with controls, however, TG levels significantly decreased in patients receiving the EPA + DHA supplement (GISSI-Prevenzione Investigators, 1999). More recently, the Japan EPA Lipid Intervention Study (JELIS) (Yokoyama *et al.*, 2007), a primary prevention study investigating the effects of EPA on CHD, assigned patients ( $n = 18\,645$ ) with elevated TC ( $>6.5$  mmol/L) to receive treatment of either a statin alone or together with 1800 mg/day of EPA (no DHA). At mean follow-up of 4.6 years, EPA in combination with statin therapy reduced coronary events by 19% compared with statin alone ( $P = 0.011$ ). Non-fatal coronary events and unstable angina also were significantly reduced in the EPA group (19% and 24%, respectively); however, the reduced risk did not apply to coronary death or sudden cardiac death. In addition, the reduced risk of coronary events in the EPA group was similar at different LDL-C levels, indicating that EPA benefits are independent of LDL-C reduction.

Recent trials on n-3 FAs have reported results inconsistent with previous findings. A Cochrane meta-analysis of 48 randomized controlled studies (RCTs) and 41 cohort studies reported no evidence that dietary or supplemental n-3 FAs reduce CVD events or total mortality (Hooper *et al.*, 2004). However, there have been many concerns regarding the analysis. The Cochrane report included a study of questionable science (DART 2), omitted many relevant cohort and biomarker-based studies, and used contradictory search criteria. Not surprisingly, the DGAC 2010 report did not include this analysis in their evidence-based review of n-3 fatty acids. More recently, the Alpha Omega Trial (Kromhout *et al.*, 2010) tested the effect of EPA + DHA in addition to ALA on the rate of CHD events in post-myocardial infarction patients. A low dose of EPA + DHA (mean: 376 mg/day), ALA (mean: 1.9 g/day), or both, in margarines had no significant effect on the occurrence of CVD events after 40 months of supplementation. Factors responsible for the lack of effect may include the low treatment dose and improvements in cardioprotective drug treatments, particularly statin therapy. Similarly, the addition of 1 g/day of EPA + DHA ethyl esters to current guideline-adjusted treatment (revascularization, clopidogrel, beta-blockers, statins and ACE-inhibitors, and rehabilitation lifestyle changes) for 1 year

in a secondary prevention population ( $n = 3851$ ) did not decrease mortality by sudden cardiac death (Rauch *et al.*, 2010). The potency of the current guideline-adjusted treatment for secondary prevention affected these results by decreasing the number of deaths and the statistical power to detect the effect of the EPA + DHA supplement. A higher dose of n-3 ethyl esters (8 g/day for 1 week; 3 g/day for 24 weeks) was not effective in treating atrial fibrillation as compared with a placebo in an adult population ( $n = 258$ ) with atrial fibrillation but no structural heart disease (Kowey *et al.*, 2010). Finally, there was no effect of daily EPA + DHA supplements (600 mg) or B-vitamins (folate, 560  $\mu$ g; vitamin B<sub>6</sub>, 3 mg; vitamin B<sub>12</sub>, 20  $\mu$ g) on secondary prevention of myocardial infarction in a 5-year, double-blind, placebo-controlled, randomized controlled trial (Galan *et al.*, 2010). However, the dose of EPA + DHA in this trial did not meet the recommended amount for secondary prevention, and the death rate was lower than expected, thereby decreasing the statistical power of the intervention. While these results may raise uncertainties about the expectations for EPA + DHA supplements as preventative treatments for CVD patients, they do not disprove the previous studies, and have limitations that affected their ability to assess the efficacy of the intervention. The 2010 DGAC report concludes that “moderate evidence shows that consumption of about 8 ounces per week of a variety of seafood, which provide an average consumption of 250 mg per day of EPA and DHA, is associated with reduced cardiac deaths among individuals with and without pre-existing cardiovascular disease” (DGAC, 2010b).

The mechanism(s) of action for EPA + DHA in preventing cardiac events have been studied intensely in both animal models and randomized controlled clinical trials. EPA + DHA have been shown to reduce the susceptibility for cardiac arrhythmias (Campbell *et al.*, 1981; Stevenson *et al.*, 1993; Billman *et al.*, 1999; Leaf *et al.*, 2003; Schrepf *et al.*, 2004; Christensen *et al.*, 2005; Raitt *et al.*, 2005), stabilize atherosclerotic plaques (Thies *et al.*, 2003), favorably affect serum lipid levels and cholesterol, especially triglycerides (Stevenson *et al.*, 1993; Roche and Gibney, 1996; Nestel, 2000), modestly reduce blood pressure (Shimokawa and Vanhoutte, 1989; Yin *et al.*, 1991; Chu *et al.*, 1992; McVeigh *et al.*, 1994; Geleijnse *et al.*, 2002), produce less aggregatory eicosanoids compared with those from the n-6 FA family (Goodnight *et al.*, 1981; Sanders *et al.*, 1981; von Schacky *et al.*, 1985; Calder, 2004; Mori and Beilin, 2004), and decrease markers of systemic

inflammation and oxidative stress (Chinetti *et al.*, 1998; Finstad *et al.*, 1998; Marx *et al.*, 1998; Baumann *et al.*, 1999; Massaro *et al.*, 2002; Lopez-Garcia *et al.*, 2004; Zampelas *et al.*, 2005; Zhao *et al.*, 2005; Richard *et al.*, 2008; Ambrozova *et al.*, 2010; Calzada *et al.*, 2010). The mechanisms by which EPA + DHA exert their effects relate mainly to their structure; they contain multiple double bonds that increase membrane fluidity. The specific conformations of EPA and DHA make them suitable ligands for many receptors, i.e. PPAR, that inhibit pro-inflammatory, cell-signaling cascades for subsequent production of inflammatory molecules, and EPA metabolites (eicosanoids) are known to have a vast number of beneficial functions in the body.

New avenues of research include measuring blood levels of n-3 FAs in clinical practice, determining the individual effects of EPA and DHA, and discovering sustainable and non-marine sources of longer-chain n-3 FAs. The omega-3 index is a novel biomarker of CHD risk that is currently used in both clinical and research settings. It represents long-term n-3 FA status and is measured as the percentage of EPA + DHA on the basis of total fatty acid content in erythrocyte membranes (Harris, 2008). An omega-3 index  $\geq 8\%$  has the greatest cardioprotective effect, while an index  $\leq 4\%$  is associated with a ten-fold increase in risk for sudden cardiac death. Since the development of purified EPA and DHA oils, new avenues of research also have focused on studying the separate mechanisms of action for EPA and DHA. Currently, DHA has been found to decrease blood pressure, heart rate and the number of total and small dense LDL particles, while EPA is known as the source for most eicosanoids and their action (Adkins and Kelley, 2010). Higher doses (8–14 g/day) of ALA have reportedly reduced inflammatory markers and adhesion molecules, but these amounts are 6 to 11 times greater than commonly consumed levels (Harris, 2005). It is not known as to whether there is a specific mechanism by which ALA may reduce CHD risk, independent of its conversion to EPA + DHA. In addition, stearidonic acid (SDA) has attracted much attention because it is a plant-derived n-3 FA that is more easily converted to EPA than ALA. This is because it is the product of ALA and the  $\Delta^6$ -desaturase, and therefore bypasses the rate-limiting step during conversion. In a randomized, double-blind, placebo-controlled study ( $n = 252$ ), 4.2 g/day of SDA raised EPA levels in erythrocyte membranes to a similar extent as 1 g/day of EPA during 12 weeks of supplementation and oil use (Lemke *et al.*, 2010).

***n-6 Fatty Acids: Linoleic and Arachidonic Acid.*** Linoleic acid (LA) is the primary n-6 FA in the diet, accounting for 85–90% of n-6 PUFA intake (Harris *et al.*, 2009). It is metabolically converted to arachidonic acid (AA); however, the amount of AA in cell membranes is tightly regulated so that only about 0.2% of LA is converted (Hussein *et al.*, 2005). AA is provided by meat, poultry, eggs, and some species of fish, while LA is found in vegetable oils such as corn, soybean and safflower oil, as well as many seeds and nuts.

Results from a meta-analysis of 60 feeding studies indicated that substituting PUFAs (between 0.6% and 28.8% energy from n-6 FAs) for carbohydrate produced favorable effects on the ratio of total to HDL cholesterol in comparison with other fatty acids (Mensink *et al.*, 2003). When n-6 FAs replace 10% of calories from SFAs, there is an 18 mg/dL decrease in LDL-C (Mensink and Katan, 1992). Other improvements in CVD risk factors can be attributed to both higher serum LA levels, such as decreased blood pressure (Grimsgaard *et al.*, 1999), and increased LA intake, as well as improved insulin sensitivity (Summers *et al.*, 2002) and reduced incidence of diabetes mellitus (Salmeron *et al.*, 2001). Overall, results from metabolic studies, studies in non-human primates, and randomized controlled trials have shown that an n-6 FA intake between 10% and 21% of energy reduces CHD risk without adverse events (Harris *et al.*, 2009).

Suggestions to decrease LA intake have been based on the inflammatory nature of CHD and the fact that AA is a major substrate for the production of several pro-inflammatory molecules (Libby, 2006). While many eicosanoids derived from AA are pro-inflammatory, vasoconstrictive and pro-aggregatory, several other metabolic products of AA have anti-inflammatory and anti-aggregatory properties (Node *et al.*, 1999; Serhan, 2005). In addition, the conversion from LA to AA in cell membranes is tightly regulated, independent of the amount of LA consumed, as previously mentioned. Despite this, diets high in LA have been found to increase the *ex vivo* susceptibility of LDL to oxidation (Tsimikas *et al.*, 1999). Moreover, results from an angiographic study have shown a relationship between PUFA intake and luminal narrowing in women with CHD (Mozaffarian *et al.*, 2004b). In summary, the evidence for the benefits of n-6 FA intake and CHD risk is greater than the evidence to prove otherwise. Currently, there is limited evidence in support of a net pro-inflammatory or pro-atherogenic effect of n-6 intake, with greater evidence suggesting that decreasing

current recommended levels of intake (5–10% energy) may increase, rather than decrease, CVD risk (Harris *et al.*, 2009). The American Heart Association (AHA) recommends a daily n-6 PUFA intake of 5% to 10% of total energy, along with other AHA dietary and lifestyle recommendations (Harris *et al.*, 2009).

***The n-3:n-6 Ratio.*** Estimates show that the ratio of n-6 to n-3 FAs in the human diet has changed over time from a ratio of 1:1 to 10:1 or greater, the latter of which is representative of that found in a typical Western diet (Simopoulos *et al.*, 2000; Kris-Etherton *et al.*, 2002). This switch is thought to be due to the combination of decreased fish consumption, since fish is a potent source of n-3 FAs, and an increased use of vegetable oils rich in n-6 FAs (Simopoulos, 1999). Proponents for reducing n-6 intakes, namely that of LA, assume that, since the n-6 FA, arachidonic acid (AA), is a substrate for the synthesis of many pro-inflammatory molecules, higher levels would contribute to the inflammatory state found in CVD (Harris *et al.*, 2009). However, AA also serves as a substrate for many anti-inflammatory and anti-aggregatory molecules (Node *et al.*, 1999), indicating its wide array of functions within the body. In addition, it is well established that the metabolic pathways for n-3 and n-6 FAs utilize the same enzymes, and intake of a large amount of n-6 FAs has been shown to decrease the rate of conversion of short- to long-chain n-3 FAs in those with a low intake of long-chain n-3 FAs (Liou *et al.*, 2007). However, there are multiple factors that affect the conversion of ALA to EPA and DHA besides n-6 FA intake, and tracer studies have shown that the extent of LA conversion to AA is only  $\approx 0.2\%$  (Hussein *et al.*, 2005). Results from human trials are intriguing. Increased levels of n-6 PUFAs, particularly AA, have been associated with decreased levels of pro-inflammatory markers and increased levels of anti-inflammatory markers (Ferrucci *et al.*, 2006). In another study by Kusumoto and colleagues (2007), daily supplementation of AA (840 mg/day) for 4 weeks had no effect on inflammatory markers or platelet aggregation (Kusumoto *et al.*, 2007). Results from observational studies in US adults showed that increased n-6 PUFA intake was associated with either lower or unaltered levels of inflammatory molecules (Pischon *et al.*, 2003).

In a European epidemiological study, participants ( $n = 4902$ ) were classified as fish-eaters, meat-eaters, vegetarians, or vegans, based on a 7-day dietary record (Welch *et al.*, 2010). Intakes of ALA, EPA, DHA, and LA, as well

as the circulating blood levels of these and their precursor-product ratios as an estimate of conversion, were compared between the groups. Not surprisingly, the fish-eaters consumed the most EPA + DHA, and the vegans ate high levels of LA and no EPA + DHA. Yet, the blood levels of total EPA + DHA in vegan women were higher than in female fish-eaters, and the difference between male fish-eaters and vegans was smaller than expected, albeit statistically significant. Women with the highest LA intake and lowest EPA + DHA intake still had the highest blood levels of EPA + DHA; the sample of vegan women was, however, very small ( $n = 5$ ). Still, estrogen has been shown to promote the gene expression of  $\Delta^5$ - and  $\Delta^6$ -desaturases, increasing the efficiency of conversion to EPA + DHA. Indeed, the factors affecting the bioconversion of shorter-chain n-3 and n-6 FAs to longer-chain FAs and their effects on each other are beyond our current knowledge. The Joint FAO/WHO Expert Consultation on Fats and Fatty Acids in Human Nutrition (2008) concludes that “there is no rationale for a scientific recommendation for n-6:n-3 ratio, or LA to ALA ratio, if intakes of n-6 and n-3 fatty acids lie within the recommendation established in this report,” referring to acceptable macronutrient distribution ranges (AMDR) of 2.5–9% total energy for n-6, and 0.5–2% total energy for n-3 PUFAs (Joint FAO/WHO Expert Consultation, 2008).

When recommending a decrease in one macronutrient, it is important to specify the foods or nutrients that should replace it. PUFAs generally are recommended as a replacement for SFAs and some CHO. Intake of long-chain n-3 FAs is still the most efficient way to increase blood levels of EPA + DHA and thereby decrease risk for CHD, regardless of LA intake. Reducing the amount of n-6 FAs available to improve n-3 conversion in the blood will not attain levels of EPA and DHA that have been shown to achieve cardiovascular benefits. Thus, increasing long-chain n-3 FAs rather than reducing n-6 FAs is recommended (Harris, 2006). Indeed, the vast majority of the clinical trials have proven the benefit of increased n-3 FA consumption over n-6 FA reduction. Nevertheless, populations that consume low levels of EPA + DHA, such as vegans and vegetarians, may benefit from decreasing LA intakes in order to improve their n-3 FA metabolism (Liou *et al.*, 2007).

The body of evidence indicates that the type of fat and what it replaces in the diet affect CVD risk. Consumption of SFAs and TFAs is associated with an unfavorable lipid profile that increases CVD risk, while unsaturated fatty

acids, namely MUFAs and PUFAs, are protective against CVD. Isocaloric substitution of SFAs and TFAs by MUFAs and PUFAs provides the greatest cardiometabolic benefits.

### Trans Fatty Acids

*Trans* fatty acids are classified as unsaturated fatty acids containing at least one unsaturated, non-conjugated, double bond in the *trans* configuration. Industrial TFAs are produced during partial hydrogenation of vegetable oils. Conjugated fatty acids, formed as intermediates or by-products from the biohydrogenation of linoleic acid by ruminal microbes, are found within the tissues of ruminants and in the meat and dairy products they provide (Bauman *et al.*, 2003). Vaccenic acid, the most commonly occurring TFA isomer in ruminant fats, represents 30–50% of the *trans*-isomers (Mozaffarian *et al.*, 2009). Humans metabolize vaccenic acid to 9c,11t conjugated linoleic acid (CLA), a *trans* fat with two double bonds separated by a single, conjugated bond (Tricon *et al.*, 2006). TFA consumption is of particular concern given the range of its effects on CVD risk. Observational studies and RCTs have shown adverse effects on lipids such as increased LDL-C levels, reduced HDL-C levels, and increased TC:HDL-C ratio, a pro-inflammatory response with elevated IL-6 and CRP levels, and TNF- $\alpha$  activity, as well as endothelial dysfunction (Mozaffarian *et al.*, 2009).

Epidemiological and clinical studies have shown consistently that TFAs increase cardiovascular risk and adversely affect blood lipids (Ascherio *et al.*, 1999), and there is strong and consistent evidence for improving blood lipids by substituting PUFAs for TFAs (DGAC, 2010b). TFAs have the most detrimental effects on blood lipid levels compared with all other dietary fatty acids, including SFAs. Saturated and TFAs similarly increase LDL-C; however, TFAs lower HDL-C compared with SFAs (Ascherio *et al.*, 1999). Meta-regression analysis of randomized clinical trials has shown that a 2% increase in TFA raises the ratio of LDL to HDL cholesterol (LDL-C:HDL-C) by 0.1 unit, which corresponds to a 53% increase in CHD risk (Ascherio *et al.*, 1999). In addition, compared with an equivalent amount of SFAs, a diet enriched in TFAs doubles the ratio of LDL-C:HDL-C, which demonstrates their highly atherogenic properties (Ascherio *et al.*, 1999). Studies also have shown that high TFA intakes are associated with increased CHD incidence (Oomen *et al.*, 2001; Oh *et al.*, 2005b), increased levels of inflammatory markers, and impaired endothelial func-

tion (de Roos *et al.*, 2003; Mozaffarian *et al.*, 2004a). Recognition of the detrimental health effects of TFA led to demands for their removal from the food supply and resulted in the Food and Drug Administration mandating that all manufacturers of conventional and functional foods list all non-conjugated TFAs on the nutrition facts panel. Nutrition labeling provides consumers with knowledge of the TFAs in foods so they can make informed purchasing decisions in order to decrease TFA intake and lower their risk of CHD. In addition, food manufacturers are motivated to decrease TFAs in their products as a result of TFA labeling regulations.

Previous experimental animal studies indicated that CLA not only lowered total cholesterol, LDL-C and triglyceride levels, but also reduced the LDL-C:HDL-C and TC:HDL-C ratios (Lee *et al.*, 1994). Using cholesterol-fed hamsters, Lock and colleagues (2005) found that supplementation with vaccenic acid and CLA significantly altered the plasma cholesterol profile by reducing total cholesterol, LDL-C and very-low-density lipoprotein (VLDL), as well as lowering the ratio of atherogenic to anti-atherogenic plasma lipoproteins. However, meta-analyses by Brouwer and colleagues (2010) have shown that all TFAs, including CLA, had the same effect on raising the LDL-C to HDL-C ratio in humans. The authors reviewed 39 studies for their analyses that evaluated the effects on the LDL-C:HDL-C ratio due to industrial TFAs and ruminant fatty acids, as well as CLA. Industrial TFAs were found to increase the LDL-C:HDL-C ratio by 0.055 for every 1% dietary energy replacement of *cis*-monounsaturated fat. In addition, with every 1% energy replacement of *cis*-MUFA, industrial TFAs increased LDL-C by 0.048 mmol/L and decreased HDL by  $-0.01$  mmol/L. Replacement of 1% dietary energy from *cis*-MUFA with ruminant fatty acids also increased the LDL to HDL ratio by 0.038, increase LDL levels by 0.045 mmol/L, and decrease HDL by  $-0.009$  mmol/L. Replacement of 1% dietary energy from *cis*-MUFA by CLA increased the LDL to HDL ratio by 0.043, as well as LDL levels by 0.038 mmol/L, and reduced HDL levels by  $-0.008$  mmol/L. These analyses demonstrate an increase in the LDL to HDL ratio by all three classes of TFA, with a modest increase in response to CLA intake, to result in an increased risk for coronary heart disease (Brouwer *et al.*, 2010). However, given that ruminant TFAs are consumed in low levels within the population ( $\approx 1$ – $2$  g/day) representing  $<0.5\%$  total energy intake (DGAC, 2010b), and the fact that they cannot be entirely removed from the diet, their associated risk with CHD is

viewed as low (Mozaffarian *et al.*, 2009). There is currently a limited body of evidence to support a prominent biological difference in adverse health effects between ruminant and industrial TFAs when ruminant TFAs are consumed at levels between 7 to 10 times higher than the average level of intake (DGAC, 2010b). The differences in chemical structure also present a need for more studies on their metabolic effects. The stance of the European Food Safety Authority is that there is “no convincing evidence that any of the conjugated linoleic acid isomers in the diet play a role in prevention or promotion of diet-related diseases” (EFSA Panel on Dietetic Products Nutrition and Allergies, 2010b), while the FAO’s Expert Consultation on Fats and Fatty Acids in Human Nutrition concludes that there should be an upper limit of  $<1\%$  dietary energy from TFAs to reduce the risk of chronic disease. All non-conjugated TFAs are required to be listed on food labels, including the naturally occurring vaccenic acid (Joint FAO/WHO Expert Consultation, 2008). There is currently no requirement by the Food and Drug Administration (FDA) to list amounts of the conjugated *trans* fatty acid CLA on food labels.

### Dietary Cholesterol

A moderate body of evidence from epidemiological studies shows a relationship between dietary cholesterol and several clinical markers for CVD (DGAC, 2010b). Dietary cholesterol generally increases blood cholesterol levels; however, the effect of dietary cholesterol on lipid levels and CVD risk varies as a function of diet response to cholesterol. Randomized clinical trials on dietary cholesterol often use eggs as the dietary source (DGAC, 2010b), as reduction in egg consumption is a common method for lowering cholesterol intake. Typically, dietary cholesterol suppresses the activity of LDL receptors, thereby inhibiting cholesterol clearance from plasma and increasing LDL-C levels (Katan, 2006). However, individuals known as hyper-responders are likely to have greater increases in LDL-C levels following the intake of dietary cholesterol than others who are hypo-responders (Katan *et al.*, 1986). An overview of epidemiological studies reported no association between eating one egg a day ( $\approx 200$  mg cholesterol) and CVD risk in non-diabetic men and women (Kritchevsky and Kritchevsky, 2000). In contrast, several cohort studies have shown that persons with type 2 diabetes who consume one or more eggs a day have up to a two-fold increase in CVD risk over type 2 diabetics who consume less than one egg per week (Hu *et al.*, 1999;

Tanasescu *et al.*, 2004; Djousse and Gaziano, 2008b). Furthermore, consumption of two or more eggs a day has been associated with a greater risk of heart failure among male physicians [1.64 (95 % CI: 1.08–2.49),  $p < 0.006$  for trend] (Djousse and Gaziano, 2008a). The DGAC 2010 report states that one egg per day ( $\leq 7$  eggs per week) does not adversely affect lipid/lipoprotein levels or increase CVD risk in healthy adults, but does increase CVD risk in individuals with type 2 diabetes (DGAC, 2010b). Therefore, recommended dietary cholesterol intake is lower ( $< 200$  mg/day vs.  $300$  mg/day) for persons with or at high risk for CVD or type 2 diabetes (DGAC, 2010b).

### Carbohydrate

The proportion of total fat and carbohydrate (CHO) intake in isocaloric diets can be tailored to target certain CVD risk factors, such as overweight and obesity, central obesity, glycemic control, and plasma lipids, especially TG. In clinical studies, an increase in dietary energy from carbohydrates usually is associated with a moderate increase in fasting plasma TG levels, a reduction in HDL cholesterol levels, and an increased fraction of small, dense LDL, all of which impact adversely on CVD risk. However, no clear evidence has shown that the quantity of dietary carbohydrates alters the risk of CVD independently.

The Ornish diet ( $< 10\%$  energy from fat) and the Atkins diet ( $< 20$  g CHO/day) represent very low-fat and very low-carbohydrate diets respectively, and both have beneficial effects on CVD risk factors with weight loss (Ornish *et al.*, 1998, 1990; Samaha *et al.*, 2003; Seshadri *et al.*, 2004; Dansinger *et al.*, 2005). Generally, very low-carbohydrate diets restrict energy from carbohydrate to  $< 20$ – $30$  g/day, while very low-fat diets restrict total fat intake to  $< 10$ – $20\%$  of energy. A number of weight-loss studies have shown that carbohydrate-restricted diets improve metabolic syndrome characteristics more effectively than low-fat diets (Sharman *et al.*, 2004; Shai *et al.*, 2008; Volek *et al.*, 2008, 2009). A meta-analysis of five randomized controlled trials found that very low-carbohydrate diets were more effective than very low-fat diets only for short-term weight loss ( $\approx 6$  months), and induced more favorable changes in TG and HDL-C levels compared with low-fat diets, but low-fat diets elicited greater reductions in total cholesterol and LDL-C levels overall (Nordmann *et al.*, 2006). Results from the Pounds Lost study showed that, when macronutrients were kept within the recommended ranges (except for total fat for which an upper level was tested) and used in reduced-calorie diets of either low fat

(20%) or high fat (40%), average protein (15%) or high protein (25%), or a range of carbohydrate levels (35%, 45%, 55%, and 65%), weight loss was similar with each diet after 2 years (Sacks *et al.*, 2009). All diets decreased CVD risk factors at 2 years, and lowered TG levels by similar amounts ranging between  $-12\%$  and  $-17\%$  (Sacks *et al.*, 2009), indicating cardioprotection in the long term. After 2 years, LDL-C levels were significantly ( $p < 0.05$ ) lowered by the low-fat ( $-5\%$ ) and high-carbohydrate ( $-6\%$ ) diets over the high-fat ( $-1\%$ ) and low-carbohydrate diets ( $-1\%$ ) respectively, while there was a significant increase in HDL levels by the lowest carbohydrate diet (9%) over the highest carbohydrate diet (1%). All diets but the highest carbohydrate diet decreased serum insulin levels by  $-6\%$  to  $-12\%$ , and blood pressure was lowered by  $-1$  mm Hg to  $-2$  mm Hg for all diets (Sacks *et al.*, 2009).

In addition to weight-loss studies on low-carbohydrate diets, an isocaloric weight-maintenance study (the OmniHeart Randomized Trial) showed that partial substitution of carbohydrate (about 10% of energy substitution, from 58% to 48%) with either protein or MUFA further lowered blood pressure, improved lipid levels, and reduced estimated CVD risk (Appel *et al.*, 2005). These results are consistent with evidence showing that high-carbohydrate weight-maintenance diets can induce atherogenic dyslipidemia, traditionally characterized by higher TGs, decreased HDL-C levels, and smaller LDL particle size (Cuchel and Rader, 2006). The potential adverse effects of low-fat, high-carbohydrate diets are supported by data from 16 clinical trials reporting that, for every 5% decrease in total fat, there would be a decrease in HDL-C by  $-2.2\%$  and an increase in TGs by 6% (Trumbo *et al.*, 2002). A recent meta-analysis also shows that moderate-fat diets had greater estimated reductions in predicted CHD risk in men ( $-6.37\%$ ) and women ( $-9.34\%$ ) compared with low-fat, higher-carbohydrate diets, of  $-6.37\%$  and  $-9.34\%$ , respectively (Cao *et al.*, 2009).

Although low-carbohydrate diets have risen in popularity, evidence from intervention trials on the benefits and risks of low-carbohydrate diets to achieve weight loss and modify CVD risk factors is limited. Furthermore, little is known about the long-term health effects of these diets; micronutrient inadequacy may occur when carbohydrate intake is very low (Bolton-Smith and Woodward, 1995). In conclusion, consuming a diet too high or too low in either fat or carbohydrate may result in adverse health effects, and the relative proportions of the two within the diet should target specific CVD risk factors and personal

preferences within current dietary recommendations. The acceptable macronutrient distribution range (AMDR) for carbohydrate (45–65 % of energy) promotes achieving nutrient adequacy and attaining a healthy lipid and lipoprotein profile.

### Glycemic Index and Glycemic Load

A question of interest with respect to carbohydrate research is the determination and characterization of the most healthful types for inclusion in the diet. Examples of health-based classifications include the glycemic index or glycemic load, fiber-rich carbohydrates, available and resistant carbohydrates, and rapidly versus slowly digested starch. Use of health-based characterization versus structural characterization including starch, sugar, monosaccharides, and oligosaccharides, may convey more effective public-health messages.

Glycemic index (GI) and glycemic load (GL) quantify the postprandial blood glucose response to foods containing carbohydrate (Jenkins *et al.*, 1981). Specifically, glycemic index is used to compare the potential of foods with the same carbohydrate content to increase blood glucose levels (Ludwig, 2002), while the glycemic load is obtained by multiplying the glycemic index of a food by the amount of carbohydrate it contains in grams, and dividing this product by 100 (Liu and Willett, 2002). A high-GI diet may lead to postprandial hyperglycemia and hyperinsulinemia, which are found to increase CVD risk by producing oxidative stress (Lefebvre and Scheen, 1998). Hyperinsulinemia and insulin resistance are predictors of CHD risk (Pyorala *et al.*, 1998a,b), but the role of insulin as an independent CVD risk factor is uncertain. The evidence for an association between high GI or GL and CVD risk remains limited and inconclusive (DGAC, 2010b). Dietary recommendations currently do not include advice on GI or GL (DGAC, 2010a).

Recently, three reports from the Nurses' Health Study demonstrated positive associations between high GL and CVD, but two of them found positive associations only in women with BMIs greater than 23 kg/m<sup>2</sup> and 25 kg/m<sup>2</sup> (Liu *et al.*, 2000; Oh *et al.*, 2005a; Halton *et al.*, 2006). In another follow-up study on middle-aged women, a positive association between GL and stroke was found, but the positive association between GI or GL and CHD was found only in women with a BMI greater than 25 kg/m<sup>2</sup> (Beulens *et al.*, 2007). A prospective cohort study of 36 246 Swedish, middle-aged men found that GI and GL were not associated with ischemic cardiovascular disease or

mortality, but that GL was associated with a greater risk of stroke after 5 years of follow-up (Levitan *et al.*, 2007). Two other observational studies found no significant association between GI or GL with CVD (Van Dam *et al.*, 2000; Levitan *et al.*, 2007). One case-control study reported no significant association between GI and GL and the risk of non-fatal acute myocardial infarction (Tavani *et al.*, 2003). Discrepancies between these findings may be due to differences in the populations studied, short-term follow-up in some studies, and variations in the dietary contributions to GI and GL. Furthermore, assigning a GI or GL value to a food is difficult because of the large variability in glycemic response to carbohydrate between individuals (Vega-López *et al.*, 2007). Based on recent evidence, the DGAC 2010 report concludes that the GI or GL values of a food do not meaningfully improve carbohydrate selection, and suggests that consumers ultimately focus on caloric intake, caloric density, and fiber content (DGAC, 2010b).

### Fiber and Whole Grains

Dietary fiber is defined as non-digestible carbohydrate and lignin that are intrinsic in plants (Trumbo *et al.*, 2002). The DGAC 2010 report states that there is a moderate body of evidence for a protective effect of dietary fiber from whole foods, and therefore recommends consumption of 14 g dietary fiber per 1000 kcal, or 25 g for adult women and 38 g for adult men per day (DGAC, 2010b). Observational and intervention studies have shown that dietary fiber lowers blood pressure, improves serum lipid levels, and reduces inflammation (Brown *et al.*, 1999; Ajani *et al.*, 2004; Pereira *et al.*, 2004; Streppel *et al.*, 2005; Whelton *et al.*, 2005; Ma *et al.*, 2006; King *et al.*, 2007). However, the food source of fiber (cereal, fruits and vegetables, or functional foods) related to CVD risk is not clear. For example, the NIH-AARP Diet and Health Study found that high intake of dietary fiber significantly reduced risk of all-cause death after 9-year follow up in 567 169 men and women in the United States (Park *et al.*, 2011). Upon further analysis, only fiber from grains and not that from other sources (fruits, vegetables, and beans) was significantly and inversely related to both total and CVD mortality (Park *et al.*, 2011). Similarly, Wolk and colleagues (1999) found that women with the highest fiber intake (22.9 g/day) had a 47% reduction in risk for CVD events compared with women with the lowest intakes (11.5 g/day) (RR: 0.53, 95% CI: 0.40–0.69). Again, when sources of fiber were analyzed, only cereal

fiber was associated with a reduction in CVD risk (RR: 0.63, 95% CI: 0.49–0.81) (Wolk *et al.*, 1999).

Cereal fiber is traditionally equated with whole grains and is distinct from refined grain products. However, Jacobs and colleagues (2000) found this assumption to be faulty after assessing the relationship between cereal fiber intake from either refined or whole grains and overall mortality in 11 040 postmenopausal women over 11 years of follow-up (Jacobs *et al.*, 2000). Despite matching total cereal fiber intake, the women consuming whole grains had a 17% lower mortality rate as compared with those eating refined grains. The synergy of nutritional components in whole grains, such as lignin, sterols, and phenolic compounds, is thought to account for the protective effects that extend beyond cereal fiber. Indeed, there is great variability among various grains in their nutrient content and bioactive components, and grain is not necessarily an excellent source of fiber (De Moura *et al.*, 2009). De Moura and colleagues (2009) found that broadening the concept of whole grain beyond the FDA's definition would provide more convincing evidence for the current CVD health claim through support from 14 observational and 15 interventional studies. However, the variability of individual grains used in these studies (oat bran, oatmeal, oat cereal, wheat, rice, barley) makes it difficult to dissociate the effects of various grain components. Currently there is moderate evidence from prospective cohort studies for a protective effect of whole-grain intake against CVD (DGAC, 2010b). Further investigations on the assessment of fiber in whole grains, as well as the health benefits of whole grains contributed by different grain components, are needed.

There is sufficient evidence showing beneficial effects of dietary fiber and whole-grain intake on CVD risk factors. However, questions on the differences in physiological effects between fiber from cereal vs. other sources, as well as other nutritional factors in whole grains found to provide these protective effects, still remain.

### Resistant and Available Carbohydrate

Measurements of resistant and available CHO are used to characterize CHO bioavailability within the small intestine (Englyst *et al.*, 2007). Resistant CHO has chemical bonds that are not accessible to digestive enzymes and therefore is not absorbed in the small intestine, i.e. fiber and resistant starch. Available CHO is digested easily and absorbed in the small intestine because of its bond structure, i.e. sugars and starch. The concept of resistant and

available starch is consistent with the GI and GL concepts of characterizing CHO by the glucose response they elicit in the body. Englyst and colleagues (2003) found that the GI value may be explained by the content of rapidly or slowly available glucose, which measures the rate of glucose release from foods. The resistant starch or slowly digested starch content in food also contributes to a lower GI value (Goni *et al.*, 1997). Although several studies have evaluated the physical effects of starches as categorized by their digestion rates, the structural properties and potential health benefits of slowly digested starches are not well understood. It must be noted that this classification scheme is determined under laboratory-controlled conditions and is related to the structure of the carbohydrate, making the characterization more consistent and reliable than GI values. In addition to defining carbohydrates by their digestibility, their source should also be considered, since evidence for the health effects of plant-based fiber in comparison with industrially processed fiber is not available.

Regardless of how carbohydrates will be characterized in the future, minimally processed plant sources of carbohydrate, such as whole grains, legumes, fruits, and vegetables, are an integral part of the dietary recommendations to reduce CVD risk.

### Protein

High-protein diets ( $\approx 34\%$  of energy) have consistently been shown to lower CVD risk through weight reduction, which favorably affects blood lipids, glucose, insulin, and other CVD risk factors (Clifton *et al.*, 2008). In a study conducted to investigate the short-term (4-month) effects of a calorie-restricted, reduced-carbohydrate ( $\approx 40\%$  of energy), higher-protein ( $\approx 30\%$  of energy) diet compared with a higher-carbohydrate ( $\approx 55\%$  of energy), moderate-protein ( $\approx 15\%$  of energy) diet, there was no difference in total weight loss between diets, but a greater reduction in fat mass of  $-22\%$  with the high-protein diet (Layman *et al.*, 2009). The same study evaluated the sustained long-term (8-month) effects of adherence to the two diets without calorie restriction. Both diets sustained long-term weight loss, but the high-protein diet had significantly greater improvements in body composition, TG, HDL-C, and the TG:HDL-C ratio (Layman *et al.*, 2009). Moderate- to high-protein (22–90% of energy) diets tend to increase energy expenditure, maintain lean body mass, and increase satiety, all of which are important factors for weight maintenance, energy balance, and the prevention

of co-morbidities associated with weight gain (Westerterp-Plantenga *et al.*, 1999; Mikkelsen *et al.*, 2000; Feinman and Fine, 2003). Although higher-protein diets, such as the Atkins and Zone diets, commonly induce quick weight loss, the American Heart Association does not endorse high-protein diets that severely restrict carbohydrates and limit food choices (St. Jeor *et al.*, 2001). The current acceptable macronutrient distribution range (AMDR) for protein, set forth in the dietary reference intakes (DRIs), is 10–35% of calories from protein (Institute of Medicine, 2005). The AHA Science Advisory takes a more modest stance, and recommends that diets contain 15–20% of calories from protein (St. Jeor *et al.*, 2001). Higher-protein diets must be planned carefully to incorporate important nutrients found in fruits, vegetables, and whole grains and to avoid protein-rich foods excessively high in total fat, saturated fat, and dietary cholesterol.

Evidence suggests that isocaloric diets higher in protein (22–25% of energy), at the expense of carbohydrates, have beneficial effects on CVD risk factors in both normolipidemic and hypercholesterolemic individuals (Wolfe and Giovannetti, 1991; Appel *et al.*, 2005). A diet with 25% of energy from protein (half from plant sources) and 48% energy from carbohydrates, compared with a diet with 15% energy from protein and 58% energy from carbohydrates, significantly decreased total cholesterol (−7.8 mg/dL), LDL-C (−3.3 mg/dL), TG (−15.7 mg/dL), and HDL-C (−1.3 mg/dL), as well as systolic (−1.4 mm Hg) and diastolic (−1.2 mm Hg) blood pressure (Appel *et al.*, 2005).

There has been much discussion about the health effects of plant protein versus animal protein. There is limited and inconsistent evidence from prospective cohort studies for an association between intake of animal protein products and CVD; however, there has been more supportive evidence for an association between processed meat intake and CVD (DGAC, 2010b). A moderate body of evidence from prospective cohort studies has provided inconsistent results on a relationship between animal product intake and blood pressure (DGAC, 2010b). On the other hand, a moderate body of evidence from both cross-sectional and cohort studies has linked vegetable protein intake with lower blood pressure; due to inconsistent results, there is limited evidence suggesting a protective effect of vegetable protein against CVD (DGAC, 2010b). Additionally, vegetarians who consume all protein from plant sources tend to have lower mortality from CHD compared with non-vegetarians (Key *et al.*, 1999;

Fraser, 2009). In accordance with this observation, the lysine:arginine (Lys:Arg) ratio has been a popular topic of research because animal protein is high in lysine whereas plant protein is typically high in arginine. Studies investigating the cholesterol-lowering effects associated with substituting plant protein (soy) for casein and other animal proteins indicate a small but significant TC-lowering (−2.5%) and LDL-C-lowering (−3.0%) effect in humans (Balk *et al.*, 2005). In a 5-week, crossover, controlled-feeding trial of individuals ( $n = 12$ ) fed a moderate-fat (30% of energy), low-cholesterol (<100 mg/day) diet supplemented with either arginine (1.2 g/day) or placebo, arginine supplementation resulted in a significant reduction in both serum cholesterol and LDL-C (Kohls *et al.*, 1987). In contrast, a 35-day, randomized, controlled, cross-over trial evaluating a low-Lys:Arg (0.70) diet vs. a high-Lys:Arg (1.41) diet reported no reduction in cholesterol or LDL-C with a low-Lys:Arg ratio diet (Vega-López *et al.*, 2010). Given these inconsistencies, further clinical studies on the applicability of the Lys:Arg ratio are needed.

In a trial investigating the effects of protein supplementation (40 g/day) in pre-hypertensive and hypertensive individuals (mean BP: 126.7/82.4 mm Hg), using either soy or milk protein and a high-GI carbohydrate control, there was a significant reduction ( $p < 0.01$ ) in systolic blood pressure of −2.0 mm Hg and −2.3 mm Hg due to the soy and milk protein supplementation, respectively, with no difference between the protein interventions (He *et al.*, 2011). A reduction in diastolic blood pressure due to the protein supplementation also was demonstrated, but was not statistically significant (He *et al.*, 2011). In this study, He and colleagues (2011) demonstrated a blood-pressure-lowering effect of substituting carbohydrate with protein (via supplementation), whether plant or animal based, in pre-hypertensive and hypertensive individuals.

Higher-protein diets (22–34% of energy), both isocaloric and calorie-restricted, have demonstrated favorable effects on body composition and CVD risk factors. Further intervention studies are needed to investigate the safety, efficacy, and feasibility of long-term adherence to high-protein/low-carbohydrate diets.

### **Roles of Select Micronutrients and Antioxidants in Atherosclerosis**

Some micronutrient deficiencies have been shown to increase the risk of atherosclerotic cardiovascular disease.

These nutrients act through gene–nutrient pathways to influence CVD risk and progression (Houston, 2010). There are several mechanisms by which micronutrients reduce CVD risk. Sodium, potassium, and magnesium have blood-pressure-lowering effects; magnesium also increases insulin sensitivity. Vitamin D lowers CVD risk via several mechanisms including down-regulation of the renin–angiotensin system and preservation of endothelial cell function. A recent cross-sectional study also has shown an independent association of vitamin D with blood pressure levels and with hypertension and prehypertension. The mechanisms by which vitamins B<sub>6</sub>, B<sub>12</sub> and folate beneficially affect CVD risk (i.e. by decreasing homocysteine levels) are unclear based on findings from large clinical trials. Niacin is, however, used therapeutically to improve the lipid and lipoprotein profile, and reduce CVD risk. Clinical studies have not demonstrated the efficacy of the antioxidant vitamins C and E.

### Sodium

Sodium is an essential nutrient, and a strong body of evidence indicates that decreases in sodium intake decrease blood pressure in adults (DGAC, 2010b). Changes in sodium intake influence blood volume; increased sodium levels cause an increase in water retention resulting in an increase in blood volume and blood pressure (Sheng, 2000; Institute of Medicine, 2004). As summarized in the 2010 DGAC report, reduced sodium intake results in fewer strokes and CVD events and in decreased mortality. In the Dietary Approaches to Stop Hypertension (DASH) trial, a multicenter randomized controlled-feeding study, researchers evaluated the effects of a diet high in fruits and vegetables, and low-fat dairy products on blood pressure (Appel *et al.*, 1997). In hypertensive (Stage 1) participants fed the DASH diet, high in fruits and vegetables (8–10 servings per day; 75th percentile of US consumption) and low-fat dairy products (2–3 servings per day) and low in saturated fat (6%) and total fat (27%), there was a decrease in systolic (–5.5 mm Hg) and diastolic (–3.0 mm Hg) blood pressure. In the DASH-Sodium trial, three levels of sodium were evaluated in the context of the DASH diet; a high target of 150 mmol/L (150 mEq/L), an intermediate target of 100 mmol/L (100 mEq/L), and a low target of 50 mmol/L (50 mEq/L) (Sacks *et al.*, 2001). The combination of the DASH diet and sodium reduction (<5 g/day) resulted in a larger decrease in systolic (–11.5 mm Hg) and diastolic (–6.3 mm Hg) blood pressure (Sacks *et al.*, 2001). A meta-analysis of 13 cohort studies by Strazzullo and colleagues

(2009) reported that an increased sodium intake increased risk for stroke and cardiovascular disease, a 2000 mg/day increase in intake resulting in a 23% higher risk for stroke (Strazzullo *et al.*, 2009). Other evidence, however, has shown that a restricted sodium intake (1840 mg/day) in persons with heart failure significantly increased hospitalization and mortality when compared with persons on an intake of 2760 mg/day (Cohen *et al.*, 2008), indicating that restriction may be harmful in certain populations (Jessup *et al.*, 2009). Researchers have questioned these results since sodium intake was assessed by a single 24-hour recall. Despite these latter findings, there is general agreement that increasing sodium intake is accompanied by an increase in blood pressure, which increases risk for stroke and coronary heart disease. Results from the DASH and DASH-Sodium trials contributed importantly to the current dietary recommendations for sodium as well as fruits and vegetables, and low-fat dairy products for normotensive and hypertensive individuals. The DGAC 2010 guidelines recommend a daily sodium intake of less than 2300 mg and less than 1500 mg for persons at high risk including those over the age of 51, African-Americans, and persons with hypertension, diabetes or chronic kidney disease.

### Potassium

There is a moderate body of evidence for an association between potassium intake and blood pressure levels (DGAC, 2010b). A higher potassium intake has been associated with lower blood pressure in adults (Cappuccio and MacGregor, 1991; Whelton *et al.*, 1997; Whelton and He, 1999; Geleijnse *et al.*, 2003; Houston and Harper, 2008), and several observational studies have shown that an increase in potassium intake decreases the risk of stroke and coronary heart disease (DGAC, 2010a). Meta-analyses of clinical and cohort studies showed that an increase in potassium intake, for an average supplemental level between 44 and 86 mmol/day, significantly lowered systolic (–2.4 to –5.9 mm Hg) and diastolic (–1.5 to –3.4 mm Hg) blood pressure (Cappuccio and MacGregor, 1991; Geleijnse *et al.*, 2003). A meta-analysis by Whelton and colleagues (1997) showed average net systolic/diastolic blood pressure reductions of –4.4/–2.5 mm Hg for hypertensive persons and –1.8/–1.0 mm Hg for non-hypertensives from a 2 g/day increase in urinary potassium excretion. Increased potassium intake also may attenuate the adverse effects of sodium on blood pressure (DGAC, 2010a), as seen in the DASH trial where a diet rich in vegetables and fruits and low-fat dairy products, and therefore rich in

potassium, lowered blood pressure (Appel *et al.*, 1997). Many trials have evaluated the effects of supplemental potassium (mostly as potassium chloride) and potassium provided by food. The blood-pressure-lowering effects of potassium are greater when sodium intake is high versus when it is low (DGAC, 2010a). A response in blood pressure due to a change in sodium chloride intake has been shown to vary between individuals, with the concept of “salt sensitivity” used to describe blood pressure that is directly associated with sodium chloride intake (Weinberger, 1996; Morris *et al.*, 1999). This “salt sensitivity” was shown to be a risk for hypertension and mortality due to CVD, even in non-hypertensive persons (Morimoto *et al.*, 1997; Weinberger *et al.*, 2001), and its expression was found to be modulated by the intake of dietary potassium (Morris *et al.*, 1999; Schmidlin *et al.*, 1999). Potassium, irrespective of the accompanying anion (van Buren *et al.*, 1992), acts on the renal tubule to increase urinary sodium chloride excretion (Brandis *et al.*, 1972; Stokes, 1982). Thus, evidence exists for the mitigation of the pressor effect of sodium chloride by potassium supplementation (Iimura *et al.*, 1981; Morgan *et al.*, 1984). The current Institute of Medicine recommendation is 4700 mg/day for an adult.

### Magnesium

Epidemiological evidence has reported that populations with a low intake of magnesium have an increased incidence of hypertension (McCarron, 1983; Joffres *et al.*, 1987; Witteman *et al.*, 1989; Ascherio *et al.*, 1992; Ma *et al.*, 1995). Low magnesium status is associated with cardiac arrhythmias, electrocardiographic changes, and increased sensitivity to cardiac glycosides (Rude, 1993). The anti-arrhythmic effect of magnesium sufficiency is related to its role in maintaining intracellular potassium levels (Matsuda, 1991a,b). Magnesium competes with sodium for binding sites on vascular smooth muscle cells to induce vasodilatation and reduce blood pressure (DGAC, 2010a). Some epidemiological, observational, and clinical trials have shown that dietary magnesium ranging from 500 to 1000 mg/day is associated with lower blood pressure, but the evidence has not been as consistent as that for sodium and for potassium (Widman *et al.*, 1993; Houston and Harper, 2008). A diet rich in fruits and vegetables that increased dietary magnesium from around 176 mg/day to 423 mg/day significantly lowered blood pressure in non-hypertensive adults (systolic blood pressure <140 mm Hg/diastolic blood pressure <95 mm Hg) (Appel *et al.*, 1997). However, foods with high levels of magne-

sium often have high levels of potassium and fiber, making the determination of an independent blood-pressure-lowering effect of magnesium difficult (Institute of Medicine, 1997). Results from intervention studies with hypertensive patients on magnesium therapy also are not conclusive. Whereas several studies have reported a blood-pressure-lowering effect with magnesium supplementation (Dyckner and Wester, 1983; Motoyama *et al.*, 1989; Widman *et al.*, 1993; Geleijnse *et al.*, 1994; Witteman *et al.*, 1994), other studies have not (Cappuccio *et al.*, 1985; Wallach and Verch, 1986; Zemel *et al.*, 1990; Sacks *et al.*, 1995; Yamamoto *et al.*, 1995). The evidence for an effect of magnesium supplementation on reducing CVD risk is supportive but limited; more research on the relationships between markers of magnesium status, magnesium intake, and CVD is needed (Institute of Medicine, 1997).

Magnesium also influences insulin sensitivity (DGAC, 2010a); a decrease in insulin sensitivity has been associated with low magnesium status (Ma *et al.*, 1995). This is of particular interest as CVD is a common complication of type 2 diabetes. Results from the Framingham Offspring Cohort study ( $n = 2708$ ) indicated that higher magnesium intake was associated with lower fasting insulin levels as well as post-glucose challenge plasma insulin levels and improved insulin sensitivity after adjusting for potential risk factors for type 2 diabetes mellitus and insulin resistance (McKeown, 2004). Clinical studies also have shown that insulin sensitivity in patients with type 2 diabetes is improved by magnesium supplementation (Paolisso *et al.*, 1989, 1992), which would decrease CVD risk. In a 1999 recommendation by the American Diabetes Association (ADA) “routine evaluation of blood magnesium level is recommended only in patients at high risk for magnesium deficiency. Levels of magnesium should be repleted [replaced] only if hypomagnesemia can be demonstrated” (ADA, 1999). Recommended dietary allowances by the Institute of Medicine range between 310 and 320 mg/day for women and between 400 and 420 mg/day for men.

### Vitamin D

Prospective observational studies and randomized controlled clinical trials have shown that moderate to high doses of vitamin D supplementation ( $\approx 1000$  IU/day) may reduce CVD risk (Wang *et al.*, 2010). Epidemiological studies in particular have shown an association between low serum 25-hydroxyvitamin D levels and higher rates of CVD morbidity (Giovannucci *et al.*, 2008; Wang *et al.*, 2008b) and mortality (Wolf *et al.*, 2007; Dobnig

*et al.*, 2008; Melamed *et al.*, 2008; Pilz *et al.*, 2008; Wang *et al.*, 2008a). A recent cross-sectional study ( $n = 7228$ ) also has shown that serum concentrations of 25-hydroxyvitamin D (22.3–22.9 ng/mL) and parathyroid hormone (42.7–49.8 pg/mL) were independently associated with blood pressure, hypertension, and prehypertension (Zhao *et al.*, 2010). Vitamin D preserves endothelial cell function (Levin and Li, 2005), downregulates the renin–angiotensin system (Li *et al.*, 2004; Rammos *et al.*, 2008), inhibits proliferation of vascular smooth muscle cells (Carthy *et al.*, 1989), and improves insulin sensitivity and secretion (Maestro *et al.*, 2000; Chiu *et al.*, 2004). Randomized trials using vitamin D supplements versus a placebo have shown a statistically nonsignificant reduction in CVD risk due to vitamin D supplementation at moderate doses (100 000 IU every 4 months) (Trivedi *et al.*, 2003) and high doses (1000 IU/day) (Prince *et al.*, 2008). Other randomized trials evaluating the effects of vitamin D supplementation in conjunction with calcium supplementation did not show changes in CVD event risk (Brazier *et al.*, 2005; Hsia *et al.*, 2007). Renal disease patients tend to have a compromised vitamin D status and typically are treated with vitamin D supplements (Wang *et al.*, 2010). While not representative of the population at large, the association between vitamin D supplementation and CVD mortality in these patients has been evaluated (Marco *et al.*, 2003; Shoji *et al.*, 2004; Teng *et al.*, 2005; Wolf *et al.*, 2007; Naves-Diaz *et al.*, 2008). Reductions in CVD mortality with vitamin D supplementation have been reported in prospective studies of dialysis patients (Wang *et al.*, 2010). The pooled relative risk of CVD in these randomized trials was 0.90 (CI: 0.77–1.05) (Wang *et al.*, 2010). These findings suggest a protective effect of moderate to high doses of vitamin D on CVD risk (Wang *et al.*, 2010). However, given these limited and inconclusive findings, further intervention trials are needed to confirm causality and to determine the efficacy of vitamin D supplementation at different doses in various subpopulations. The 2010 DGAC report, assuming minimal sun exposure, recommends 600 IU/day of vitamin D for children and adults, and 800 IU per day for adults over age 70 (DGAC, 2010b). The Food and Nutrition Board of the Institute of Medicine issued dietary reference intakes of 600 IU/day (15  $\mu$ g cholecalciferol) for children and adults, with a recommended intake of 800 IU/day (15–20  $\mu$ g cholecalciferol) for persons over age 70, and an upper limit of 4000 IU/day (Institute of Medicine, 2010). This Institute of Medicine review was

jointly commissioned by the US and Canadian governments, with Health Canada (Ottawa) recommending intakes of 600 IU/day for children and adults, 800 IU/day for persons over 70, daily supplemental intake of 400 IU/day (10  $\mu$ g cholecalciferol) for persons over 50, and an upper limit of 4000 IU/day (Health Canada, 2010).

### B-Vitamins

Elevated plasma homocysteine levels are associated with increased risk of atherosclerosis (Gerhard and Duell, 1999; Martí-Carvajal *et al.*, 2009). Homocysteine levels are affected by vitamins B<sub>6</sub>, B<sub>12</sub>, and folate. Folate coenzymes catalyze the synthesis of methionine from homocysteine; homocysteine levels increase in folate deficiency (Gerhard and Duell, 1999). Homocysteine levels also are under the control of vitamins B<sub>6</sub> and B<sub>12</sub>. Vitamin B<sub>12</sub> acts as a co-factor for methionine synthase, an enzyme that catalyzes the conversion of homocysteine to methionine (Homocysteine Lowering Trialists, 1998). Vitamin B<sub>6</sub> is a cofactor for two enzymes involved in an alternative homocysteine pathway involving the conversion of homocysteine to cysteine (Folsom *et al.*, 1998). Each of the pathways involves the utilization of homocysteine, thus regulating plasma levels. Consequently, supplementation of these vitamins was hypothesized to lower homocysteine levels and decrease CVD risk (Folsom *et al.*, 1998; Gerhard and Duell, 1999). Martí-Carvajal and colleagues (2009) reviewed eight randomized controlled trials ( $n = 24\,210$ ) to determine the effects of B<sub>6</sub>, folate, and B<sub>12</sub> supplementation in either primary or secondary prevention interventions. The authors found no evidence that a decrease in homocysteine levels in response to B-vitamin supplementation decreased stroke or myocardial infarction, or reduced mortality in individuals with CVD (Martí-Carvajal *et al.*, 2009). Despite the inverse association between homocysteine concentration and folate intake, the body of evidence for an association between homocysteine concentration and CVD risk is inconsistent (Institute of Medicine, 1998). The American Heart Association Nutrition Committee concluded that there is inadequate evidence in support of the use of the B-vitamins for lowering CVD risk (Lichtenstein *et al.*, 2006a).

Therapeutic doses of niacin, or nicotinic acid, are prescribed primarily for TG-lowering and increasing HDL-C. Pharmacological doses of nicotinic acid (3 g/day) result in a global improvement in the lipid profile (Chapman *et al.*, 2010) including a reduction in total cholesterol and triglycerides, and a decreased risk of cardiovascular events

(Canner *et al.*, 1986). Niacin and derivatives decreased plasma triglyceride levels by  $-35\%$  and LDL-C by  $-15\%$ , and increased HDL-C by  $25\%$  (Chapman *et al.*, 2010). In addition, nicotinic acid ( $1\text{--}3\text{ g/day}$ ) shifted the size and density of LDL particles from being small and dense to large and buoyant (Guyton and Capuzzi, 1998). The modulation of the lipid profile by niacin was reported to be dose-dependent, with  $1.5\text{ g/day}$  providing the most tolerable and efficacious dose (Watts and Karpe, 2011). However, in their study on an antioxidant combination of vitamin E, vitamin C, selenium, and  $\beta$ -carotene, Cheung and colleagues (2001) found that the use of this antioxidant supplement cocktail blunted the effects of simvastatin–niacin therapy on HDL-C in persons with CAD and decreased HDL-C levels, indicating potential adverse antagonistic effects (Cheung *et al.*, 2001). In another study on CHD prevention, Brown and colleagues (2001) showed that, when an antioxidant cocktail (vitamin E, vitamin C,  $\beta$ -carotene, selenium) was administered with simvastatin and niacin, the clinical benefits of the lipid therapy (simvastatin and niacin alone), including a lowered frequency of occurrence for a first cardiovascular event, were no longer evident. In addition, this combination caused a significant reduction in HDL sub-fraction levels including one of the main fractions involved in reverse cholesterol transport, indicating a blunting of the main cardioprotective effect of the statin–niacin therapy (Brown *et al.*, 2001). People should be under the care of a health-care provider when taking therapeutic doses of niacin for the management of lipid disorders, and should avoid taking antioxidant supplements. The Institute of Medicine recommends  $14\text{ mg/day}$  of niacin equivalents (NEs) for women and  $16\text{ mg/day}$  NEs for men to achieve nutrient adequacy.

### The Antioxidant Vitamins—Vitamins C and E

A diet high in fruits and vegetables has been found to be protective against CVD, and so the bioactive compounds that offer this cardioprotection are of great interest. Since CVD development and progression are influenced in large part by oxidative stress, the potential action of the antioxidant vitamins has been a major area of study. Vitamin C (ascorbic acid) and vitamin E ( $\alpha$ -tocopherol) have been shown to protect against free radical production *in vitro* (Bagchi *et al.*, 1997) and may consequently reduce lipid peroxidation and formation of oxidized LDL (Knekt *et al.*, 2004). In addition, vitamin C may facilitate the regeneration of oxidized vitamin E (Knekt *et al.*, 2004), providing a synergistic scavenger effect. Generally, studies of these

antioxidants have focused on both their dietary and supplemental forms and their effects on CVD risk.

Clinical evidence of cardioprotective roles of vitamins C and E have been limited and inconclusive. In a review of 67 ( $n = 232\,550$ ) randomized controlled trials, Bjelakovic and colleagues (2008) assessed the effects of antioxidant supplements on overall mortality in primary and secondary prevention clinical trials. The authors found no evidence in support of antioxidant supplements in primary or secondary prevention measures for lowered mortality due to CVD. When a selection of 47 trials ( $n = 180\,938$ ) with low risk for bias was used, there was a significant increase in relative risk for total mortality due to vitamin E of 1.04 (CI: 1.01–1.07), and a non-significant increase in relative risk for total mortality due to vitamin C of 1.06 (CI: 0.94–1.20) (Bjelakovic *et al.*, 2008).

In an analysis of nine prospective cohort studies ( $n = 293\,172$ ), Knekt and colleagues (2004) found that persons with no pre-existing CHD, who were on supplemental vitamin C regimens ( $>700\text{ mg/day}$ ), had a lower relative risk for CHD incidence of 0.75 (CI: 0.60–0.93) vs. persons not taking these supplements. Ye and Song (2008) also conducted a meta-analysis of 15 cohort studies ( $n = 374\,488$ ) to evaluate the relationship between intakes of vitamin C and CHD risk. Their results showed that dietary intake of vitamin C, but not supplemental vitamin C, had an inverse relationship with CHD risk (Ye and Song, 2008). In another randomized controlled trial, using over 14 000 men who took part in the Physician's Health Study II, daily vitamin C supplementation ( $500\text{ mg/day}$ ) had no significant effect on CVD events, myocardial infarction or mortality due to CVD (Sesso *et al.*, 2008). However, this study was limited in that all participants were 50 years or older, with about 5% having pre-existing heart disease, which probably resulted in a diminished preventive effect against CVD progression. Several studies also have shown improved vasodilation with supplemental vitamin C ( $500\text{ mg}$ ) (Carr and Frei, 1999; Gokce *et al.*, 1999; Frikke-Schmidt and Lykkesfeldt, 2009; Versari *et al.*, 2009), and some, but not all, studies have shown a blood-pressure-lowering effect with supplemental vitamin C (Ness *et al.*, 1997). In their study with 69 hypertensive individuals supplemented for 6 weeks with vitamin C ( $500\text{ mg/day}$ ), Ward and colleagues (2005) found a significant ( $p < 0.05$ ) decrease in systolic blood pressure ( $-1.8\text{ mm Hg}$ ) in comparison with a placebo (Ward *et al.*, 2005). Given the inconsistencies in the evidence, further replication in larger, controlled clinical trials is needed.

In their meta-analysis of nine prospective cohort studies ( $n = 293\,172$ ), Knekt and colleagues (2004) also found that high dietary vitamin E intakes (100–249 mg/day) were associated with a lower CHD risk after accounting for age and energy intake. In the meta-analysis of 15 cohort studies ( $n = 374\,488$ ) by Ye and Song (2008), both dietary and supplemental intake of vitamin E were inversely associated with CHD risk. In the Alpha-Tocopherol–Beta-Carotene Cancer Prevention study ( $n = 299\,133$ ), vitamin E supplementation (50 mg/day) in a group of Finnish male smokers slightly lowered mortality of CHD (ischemic heart disease by  $-4\%$  and ischemic stroke by  $-1.3\%$ ), but had no effect on incidence of non-fatal myocardial infarction (Alpha-Tocopherol–Beta Carotene Cancer Prevention Study Group, 1994). The Cambridge Heart Antioxidant Study (CHAOS) on secondary prevention by vitamin E supplementation (400 or 800 IU per day for 1.5 years) in patients with CHD ( $n = 2002$ ) showed a significant reduction in risk for recurrent myocardial infarction ( $-77\%$ ), but no effect on CVD mortality, and a non-significant increase in total mortality (Stephens *et al.*, 1996). Other large-scale clinical trials in patients with established CHD also have not shown protective effects of vitamin E supplementation on future CVD events (GISSI-Prevenzione Investigators, 1999; Yusuf *et al.*, 2000), indicating the need for further study in different populations before conclusions are drawn.

Discrepancies between these studies have been attributed to the overall healthy lifestyles of persons on antioxidant vitamin regimens; for example, high serum ascorbic acid levels may be associated with high fruit and vegetable intake (Ye and Song, 2008). There also may have been discrepancies in CHD risk between persons in randomized controlled trials versus those in cohort studies, since the latter tend to recruit younger persons who are fairly healthy whereas controlled trials often study persons at high risk (Ye and Song, 2008). Toxicity with increased levels of supplement intake in smokers or persons with pre-existing CHD also is possible. Poor study design and distinct methods of analysis also may have contributed to the discrepancies in the overall findings (Traber *et al.*, 2008).

The Institute of Medicine (2000) states that data on the preventive effects of vitamins C and E, either dietary or supplemental, on CVD risk are both inconsistent and insufficient; the Academy of Nutrition and Dietetics provides no recommendation for routine supplementation

of either vitamin due to the lack of strong evidence at this time.

## Dietary Prevention and Treatment of Cardiovascular Disease

### **Current Dietary Guidelines for the prevention of CVD**

Over the years, specific nutrient recommendations have been issued in dietary guidelines reports from health-related institutions worldwide. More recently, with growing evidence on the role of dietary patterns and specific foods and food groups on health, there has been a transition from nutrient-based to food-based recommendations (Mozaffarian and Ludwig, 2010), as evidenced in the food-based dietary guidelines from several countries. A basic premise of these dietary guidelines is that nutrient needs should be met primarily through foods.

### **Food-Based Dietary Guidelines for Worldwide Application**

The Department of Nutrition for Health and Development of the WHO (World Health Organization), in collaboration with the FAO (Food and Agriculture Organization of the United Nations), continually reviews new research and information from around the world on human nutrient requirements. The results of this work provide the foundation for all countries to develop food-based dietary guidelines for their populations. Food-based dietary guidelines from different countries share basic recommendations that are consistent with WHO guidelines. However, national dietary guidelines often contain unique features, which are designed to address the priorities of each country. A selection of food-based guidelines by region and country is given in Box 48.1. A summary of the recommendations, both shared and differing between countries, is shown in Box 48.2. Common recommendations include limiting salt intake, eating fruit and vegetables daily, eating foods rich in starch and fiber, and maintaining a healthy body weight.

For promoting cardiovascular health, the Joint WHO/FAO Expert Consultation published a technical report on Diet, Nutrition and the Prevention of Chronic Diseases in 2002 which provides general diet recommendations for the prevention of death and disability from major nutrition-related chronic diseases, including obesity, diabetes, several forms of cancer, osteoporosis, dental disease, and cardiovascular disease (Joint FAO/WHO Expert

**BOX 48.1 Summary of a selection of food-based dietary guidelines by region (FAO)**

<b>Africa</b>	Namibia	Eat a variety of foods; Eat vegetables and fruit every day; Eat more fish; Eat beans or meat regularly; Use whole-grain products; Use only iodized salt, but use less salt; Eat at least three meals a day; Avoid drinking alcohol; Consume clean and safe water and food; Achieve and maintain a healthy body weight. <i>(Ministry of Health and Social Services, Namibia)</i>
	Nigeria	Total food intake should be balanced with the level of physical activity; Individuals who do manual work need to consume more food than those who do sedentary work; Limit fat intake from animal foods; The diet should consist of as wide a variety of foods as possible, e.g. cereals, legumes, roots/tubers, fruits, vegetables, fish, lean meat, local cheese (wara); Limit intake of salt, bouillon cubes and sugar; Liberal consumption of whatever fruit is in season is encouraged. <i>(Ministry of Health, Abuja, Nigeria)</i>
	South Africa	Enjoy a variety of foods; Be active; Make starchy foods the basis of most meals; Eat dry beans, split peas, lentils and soya regularly; Chicken, fish, milk, meat or eggs can be eaten daily; Drink lots of clean, safe water; Eat plenty of vegetables and fruits every day; Eat fats sparingly; Use salt sparingly; Use food and drinks containing sugar sparingly and not between meals; If you drink alcohol, drink sensibly. <i>(Department of Health, Directorate: Nutrition, Pretoria, South Africa)</i>
<b>Asia and the Pacific</b>	China	Eat a variety of foods, with cereals as the staple; Consume plenty of vegetables, fruits and tubers; Consume milk, beans, or dairy or bean products every day; Consume appropriate amounts of fish, poultry, eggs, and lean meat; Reduce fatty meat and animal fat in the diet; Balance food intake with physical activity to maintain a healthy body weight; Choose a light diet that is also low in salt; If you drink alcoholic beverages, do so in limited amounts; Avoid unsanitary and spoiled foods. <i>(Chinese Nutrition Society)</i>
	India	Eat a variety of foods to ensure a balanced diet; Ensure provision of extra food and health care to pregnant and lactating women; Promote exclusive breastfeeding for 6 months and encourage breastfeeding until 2 years; Feed home-based, semi-solid foods to infants after 6 months; Ensure adequate and appropriate diets for children and adolescents both in health and sickness; Ensure moderate use of edible oils and animal foods and very much less use of ghee/butter/vanaspati; Overeating should be avoided to prevent overweight and obesity; Use salt in moderation/Restrict salt intake to minimum; Ensure the use of safe and clean foods; Practice good cooking methods and healthy eating habits; Drink plenty of water and take beverages in moderation; Minimize the use of processed foods rich in salt, sugar and fats; Include micronutrient-rich foods in the diets of elderly persons to enable them to be fit and active. <i>(National Institute of Nutrition, Indian Council of Medical Research, India)</i>
	Japan	Enjoy your meals; Establish a healthy rhythm by keeping regular hours for meals; Eat well-balanced meals with staple foods, as well as main and side dishes; Eat enough grains such as rice and other cereals; Combine vegetables, fruits, milk products, beans, and fish in your diet; Avoid too much salt and fat; Learn your healthy body weight and balance the calories you eat with physical activity. <i>(Japan Dietetic Association)</i>

*(Continued)*

	Singapore	Achieve and maintain body weight within the normal range; Eat sufficient amounts of grains, especially whole grains; Eat more fruits and vegetables every day; Choose and prepare food with less fat, especially SFA; Choose and prepare foods with less salt and sauces; Choose beverages and food with less sugar; If you drink alcoholic beverages, do so in moderation. <i>(Health Promotion Board, Singapore)</i>
	Thailand	Eat a variety of foods from each of the five food groups and maintain proper weight; Eat adequate amounts of rice or alternative carbohydrate sources; Eat plenty of vegetables and fruits regularly; Eat fish, lean meat, eggs, and legumes and pulses regularly; Drink milk in appropriate quality and quantity for one's age; Eat a diet containing appropriate amounts of fat; Avoid sweet and salty foods; Eat clean and safe foods; Avoid or reduce the consumption of alcoholic beverages. <i>(Department of Health, Thailand)</i>
<b>Europe</b>	Bulgaria	Eat a nutritious diet with a variety of foods; Do eat regularly, take enough time and enjoy your food in a friendly environment; Consume cereals as an important source of energy; Choose whole-grain bread and other whole-grain products; Eat a variety of vegetables and fruits, more than 400g every day, preferably raw; Choose milk and dairy products with low fat and salt content; Choose lean meat, replace meat and meat products often with fish, poultry or pulses; Limit total fat intake, especially animal fat; Replace animal fats with vegetable oils when cooking; Limit the consumption of sugar, sweets and confectionery, avoid sugar-containing soft drinks; Reduce intake of salt and salty foods; If you drink alcoholic beverages, you should consume moderate quantities; Maintain a healthy body weight and be physically active every day; Drink plenty of water every day; Prepare and store food in a way to ensure its quality and safety. <i>(Ministry of Health, Bulgaria)</i>
	France	Increase consumption of fruits and vegetables, regardless of its form (fresh, frozen, canned, cooked), in order to achieve consumption of at least 5 fruits and vegetables daily; Consume food sources of calcium in sufficient quantity to achieve the recommended dietary allowances, or 3 dairy products per day; Limit consumption of fat, especially saturated fat; Increase intake of starch, including food grains, potatoes, legumes, etc. – have these with every meal; Eat meat, fish, seafood or eggs 1–2 times a day on alternate days; Choose meat with less fat and consume fish at least twice a week; Limit salt intake and always choose iodized salt; Limit alcohol consumption to a maximum of 2 glasses per day for women and a maximum of 3 glasses a day for men; Increase daily physical activity to at least 30 minutes of brisk walking or equivalent and reduce sedentary time, especially in children; Enjoy the benefits of sunlight without excess and monitor weight regularly. <i>(The Ministry of Health, Family and the Disabled, France)</i>
	Ireland	Enjoy your food; Eat a variety of foods, using the Food Pyramid as a guide; Eat the right amount of food to be a healthy weight, and exercise regularly; Eat 4 or more portions of fruit and vegetables every day; Eat more foods rich in starch – breads, cereals, potatoes, pasta, and rice – aim for at least 6 servings a day; Eat plenty of foods rich in fibers – breads and cereals (especially whole grain), potatoes, pasta and rice, fruit and vegetables; Reduce the amounts of fatty foods you eat, especially saturated fats – grill, boil, oven-bake or stir-fry in very little fat instead of deep-frying; If you drink alcohol, keep within sensible limits; Use a variety of seasonings, try not to always rely on salt to flavor foods – use herbs, spices and black pepper as alternatives. <i>(The Irish Nutrition and Dietetic Institute)</i>

	The Netherlands	<p>Eat a variety of foods; Be moderate with fat; Eat plenty of carbohydrates and fiber; Have 3 meals a day and do not snack more than 4 times in-between meals; Be careful with salt; Drink 1.5L of fluid daily, but be moderate with alcohol; Keep body weight at its correct level; Prevent food-borne infections by good hygiene; Keep in mind the presence of harmful substances in foods; Read the information on the food label.</p> <p><i>(The Netherlands Bureau for Food and Nutrition Education)</i></p>
	Poland	<p>Ensure you eat a variety of foods; Beware of overweight and obesity – be physically active; Cereal products should be the main source of calories; Drink at least 2 large glasses of low-fat milk daily – milk could be substituted for yogurt, kefir and partly for cheese also; Eat in moderation; Eat a lot of vegetables and fruits every day; Limit intake of fats, particularly of animal ones, and all foods containing cholesterol; Be moderate in intake of sugar and sweets; Limit salt intake; Avoid alcohol.</p> <p><i>(Ministry of Health, Poland)</i></p>
	United Kingdom	<p>Enjoy your food; Eat a variety of different foods; Eat the right amount to be a healthy weight; Eat plenty of foods rich in starch and fiber; Eat plenty of fruits and vegetables; Don't eat too many foods that contain a lot of fat; Don't have sugary foods and drinks too often; If you drink alcohol, drink sensibly.</p> <p><i>(Health Education Authority, London, UK)</i></p>
Latin America and the Caribbean	Chile	<p>Consume dairy products like milk, yogurt or cheese 3 times daily, preferably as low- or non-fat versions; Eat at least 2 dishes of vegetables, and 3 fruit of different colors each day; Eat beans, chickpeas, lentils or split peas at least 2 times per week as a replacement for meat; Eat fish at least 2 times per week cooked either by baking, steaming or grilling; Choose foods with less saturated fat and cholesterol; Reduce your intake of sugar and salt; Consume 6–9 glasses of water a day.</p> <p><i>(Ministry of Health, Chile)</i></p>
	Cuba	<p>A varied diet during the day is enjoyable and necessary for your health; Eat vegetables every day – fill your life; Eat fresh fruit to increase vitality; Choose vegetable oils – butter is more costly to your health; Fish and chicken are the healthiest of meats; Reduce sugar intake; Reduce salt intake – start by not adding it at the table; A good day starts with breakfast; Find a healthy weight for your height – stay in shape.</p> <p><i>(Ministry of Public Health, Cuba)</i></p>
	Commonwealth of Dominica	<p>Start the day with breakfast; Always try to eat a variety of foods every day; Eat more vegetables and fruits daily; Reduce fat and oil intake; Choose less sweet foods and drinks; Use less salt, salted foods, seasonings, and salty snacks; Make physical activity a part of your daily life; Drink water several times a day; If you use alcohol, do so in moderation.</p> <p><i>(Ministry of Health and Social Security, Dominica)</i></p>
	Grenada	<p>Eat a variety of foods; Eat larger amounts of fruits and colored vegetables; Eat less fatty, oily, greasy, and barbecued foods; Choose to use less sweet foods and drinks; Use less salt, salty foods, salty seasonings and salty snacks; Drink more water – it's the healthier choice; Drink little or no alcohol; Be more physically active every day – get moving.</p> <p><i>(Grenada Food and Nutrition Council)</i></p>

(Continued)

Mexico	<p>Try to eat healthily, accompanied by family and/or friends, and make eating an enjoyable time; Eat raw vegetables and fruits in season; Have moderate consumption of fats (margarine, vegetable oils, and mayonnaise among others), sugars (soft drinks, honey, jam, sweets and table sugar) and salt; Eat according to your needs and conditions, neither more nor less; Eat moderate amounts of animal foods, choose legumes; Combine grains (tortillas, bread or pasta) with legumes such as beans, peas, or lentils; Try to choose whole grains such as corn tortillas, bread, oatmeal, and amaranth instead of refined versions; Try eating fish twice a week and skinless chicken instead of red meat; If using eggs, keep it in moderation; Avoid alcoholic beverages or consume them only sporadically since, among other factors, they are high in calories. <i>(National Institute of Medical and Nutrition Science, Mexico)</i></p>	
St. Vincent and the Grenadines	<p>Eat a variety of foods; Eat more fruits and vegetables everyday; Reduce fats and oils by cutting back on fatty, oily, and greasy foods; Reduce the intake of sugar – use less sugar, sweet foods and drinks; When cooking, use less salt and salted seasonings – eat less salted foods and snacks; Water is essential – drink it several times a day; If you use alcohol, do so sparingly, both in drinking and in food preparation; Get moving – increase physical activity daily. <i>(Ministry of Health and the Environment, St. Vincent and the Grenadines)</i></p>	
Venezuela	<p>Eat foods from all the basic groups; Breast milk is the only irreplaceable food for children under 6 months; Increase consumption of vegetables, fruits, legumes and cereals; Moderate your intake of sugar, salt, and alcohol; Eat foods of animal origin in moderation; Practice hygienic habits during food preparation; Water maintains health and is essential for life; Manage your money well during the selection and purchase of food; Take 30 minutes of physical activity daily. <i>(National Institute of Nutrition, Bolivarian Republic of Venezuela)</i></p>	
<b>Near East</b>	Egypt	<p>Limit red meat and dairy products; Use low fat milk; Do not fry; Consume plenty of fruits, vegetables, legumes and whole grains; Consume olive oil, nuts, plant proteins, and fish; Limit candies and soft drinks; Avoid salty, canned, preserved, and fast food; Establish and maintain at least 30 minutes of moderate-intensity physical activity on 5 or more days per week. <i>(The Egyptian Hypertension Society)</i></p>
	Oman	<p>Vary your diet by making it healthy and balanced; Choose whole grains and cereals, and consume potatoes with their skin; Consume 3–5 servings of vegetables daily; Consume 2–4 servings of fruits daily; Consume fish, poultry, eggs or lean meat; Consume 1 serving of legumes daily; Consume milk or dairy products daily; Limit your fat intake and choose snacks wisely; Follow the five keys to safer food: keep everything clean, separate raw and cooked foods, cook foods thoroughly, keep food at safe temperatures, and use safe water and raw materials; Be active, exercise regularly and drink plenty of water. <i>(Ministry of Health, Oman)</i></p>

**North America**

## Canada

Eat at least one dark green and one orange vegetable each day; Choose vegetables and fruit prepared with little or no added fat, sugar, or salt; Have vegetables and fruit more often than juice; Make at least half of your grain products whole grain each day; Choose grain products that are lower in fat, sugar, or salt; Drink skim, 1% or 2% milk each day; Select lower fat alternatives; Have meat alternatives such as beans, lentils, and tofu often; Eat at least 2 servings of fish each week; Select lean meat and alternatives prepared with little or no added fat or salt; Include a small amount (2 to 3 tbsp) of unsaturated fat each day; Use vegetable oils such as canola, olive and soybean; Choose soft margarines that are low in saturated and *trans* fats; Limit butter, hard margarine, lard and shortening; Drink water regularly; Build 30 to 60 minutes of moderate physical activity into daily life; Enjoy eating with family and friends.  
(Health Canada)

**For First Nations, Inuit, and Métis:** Eat at least one dark green and one orange vegetable each day; Choose vegetables and fruit prepared with little or no added fat, sugar or salt; Have vegetables and fruit more often than juice; Make at least half of your grain products whole grain each day; Choose grains that are lower in fat, sugar or salt; Drink 2 cups (500 mL) of skim, 1% or 2% milk each day; Select lower fat milk alternatives – drink fortified soy beverages if you do not drink milk; Have meat alternatives such as beans, lentils, and tofu often; Eat at least 2 servings of fish each week; Select lean meat and alternatives prepared with little or no added fat or salt; Most of the time, use vegetable oils with unsaturated fats, including canola, olive and soybean oils – aim for a small amount (2 to 3 tbsp) each day; Traditional fats that are liquid at room temperature such as seal and whale oil, or ooligan grease, also contain unsaturated fats – these can be used as all or part of the recommended 2 to 3 tbsp per day; Choose soft margarines that are low in saturated and *trans* fats; Limit butter, hard margarine, lard, shortening and bacon fat; For strong body, mind and spirit, be active every day.  
(Health Canada)

**BOX 48.2 Summary of global food-based dietary guidelines***Basic dietary recommendations shared among many countries*

Eat a variety of foods

Eat vegetables and fruit every day

Limit salt intake

Moderate fat intake, reduce cholesterol intake

Eat poultry, fish, beans, and dairy products regularly

Eat plenty of foods rich in starch and fiber

Limit consumption of foods containing added sugars

Avoid drinking alcohol or, if alcohol is consumed, do so responsibly

Achieve and maintain a healthy body weight

*Unique features*

Consume clean and safe water and food (some developing countries)

Use only iodized salt (some developing countries)

Eat soya regularly (some African and Asian countries)

Eat eggs regularly (South Africa, China)

Drink plenty of liquids every day (South Africa, Bulgaria)

Consume iron-rich foods (some developing countries)

Eat breakfast every day (some developing countries)

**TABLE 48.5** Joint WHO/FAO Expert Consultation dietary recommendations for CVD prevention

Recommendations	How to achieve
<i>Fat intake (%E):</i> SFA <7%; TFA <1%; 6–10% of PUFAs (n-6: 5–8%, n-3: 1–2%); MUFAs ≈15–30% <i>Dietary cholesterol:</i> <300 mg/day	Limit intake of fat from dairy and meat sources; avoid use of hydrogenated oils and fats in cooking and manufacturing of food products; using appropriate edible vegetable oils in moderation; regular intake of fish (1–2 times per week) and/or plant sources of ALA (n-3 PUFAs); utilize non-frying food preparation methods
<i>Fruits and vegetables:</i> 400–500 g/day is recommended to reduce the risk of CHD, stroke and high blood pressure <i>Sodium:</i> 1.7 g of sodium per day (equivalent to a daily sodium chloride intake of 4 g/day) is beneficial in reducing blood pressure and is not associated with adverse effects	Daily intake of fresh fruit and vegetables (including berries, green leafy and cruciferous vegetables, legumes) in adequate quantities Restrict daily salt (sodium chloride) intake to less than 5 g/day; minimize other forms of sodium consumption through food additives and preservatives, such as monosodium glutamate (MSG)
<i>Potassium:</i> Dietary intake sufficient to maintain sodium: potassium ratio close to 1, i.e. at daily potassium intake levels of 70–80 mmol/day	Adequate daily consumption of fruits and vegetables
<i>Fish:</i> Consumption of fish and other marine foods should provide over 200 mg/day of DHA and EPA <i>Dietary fiber:</i> Increase intake.	Regular fish consumption, as consumed on a weekly basis  Adequate intake of fruits, vegetables and whole-grain cereals
<i>Alcohol:</i> Moderate consumption.	Regular low to moderate consumption of alcohol

Consultation, 2002). The primary aim of this report was to provide “effective and sustainable policies and strategies to deal with the increasing public health challenges related to diet and health.” A summary of the recommendations specifically focused on CVD prevention is shown in Table 48.5.

### Dietary Guidelines for Americans 2010

The first edition of *Nutrition and Your Health: Dietary Guidelines for Americans*, issued in 1980, provided guidance on total fat, saturated fat, cholesterol, sodium, sugar, starch, and fiber intake, as well as the maintenance of an ideal body weight and appropriate alcohol consumption, all of which are related to CVD risk. The most recent Dietary Guidelines for Americans 2010 (DGAC 2010a) continues to promote CVD prevention by providing food-based recommendations.

Generally, a healthy eating pattern limits the intake of sodium, solid fats, added sugars, and refined grains, and emphasizes nutrient-dense foods. The DGAC 2010 Report identified certain foods and food components that are consumed in excessive amounts and should be reduced in order to decrease the risk of overweight and certain chronic diseases, including major sources of sodium, SFAs, added sugar, solid fats, dietary cholesterol, refined grains, and alcohol (Box 48.3). Besides limiting these foods, the Dietary Guidelines for Americans (2010) also make recommendations for certain foods that should be increased, including vegetables and fruits, whole grains, fat-free or low-fat dairy products, seafood, lean meat and poultry, eggs, beans and peas, soy products, unsalted nuts and seeds, plant oils, and foods that provide more potassium, calcium, vitamin D, and dietary fiber. Of these foods and food groups that the DGAC recommends be increased or

**BOX 48.3 Dietary components currently over- and underconsumed by the American population (DGAC, 2010a)**

<b>Overconsumed</b>	Adults	Total energy intake, particularly energy intake from solid fats and added sugars; sodium; percentage of total energy from saturated fats; total cholesterol (in men); and refined grains
	Children	Energy intake from solid fats and added sugars; sodium; percentage of total energy from saturated fats; total cholesterol (only in boys, aged 12–19 years); and refined grains
<b>Underconsumed</b>	Entire population, on average	Americans of all ages consume too few vegetables, fruits, high-fiber whole grains, low-fat milk and milk products, seafood, and oils, and have low intakes of fiber, potassium, calcium, and vitamin D

decreased, most are related to a reduced risk of CVD; see Table 48.6 (DGAC, 2010a).

**American Heart Association (AHA) Diet and Lifestyle Recommendations and 2020 Impact Goals**

In 2006, the American Heart Association (AHA) released the Diet and Lifestyle Recommendations Revision for reducing CVD risk (Lichtenstein *et al.*, 2006a); overall, these diet and lifestyle recommendations are similar to those provided by the WHO and FAO. In 2010, the American Heart Association (AHA) issued the 2020 Impact Goals to achieve the following: “By 2020, to improve the cardiovascular health of all Americans by 20% while reducing deaths from cardiovascular diseases and stroke by 20%” (Lloyd-Jones *et al.*, 2010). The dietary intake goals are “in the context of a diet that is appropriate in energy balance, pursuing an overall dietary pattern that is consistent with a DASH-type eating plan” (Lloyd-Jones *et al.*, 2010). Specific food and nutrient recommendations to achieve the AHA 2020 Impact Goals are summarized in Table 48.7.

**European Food Safety Authority (EFSA) Panel on Dietetic Products, Nutrition and Allergies (NDA) Scientific Opinion on Dietary Reference Values**

In 2009 the EFSA Panel on Dietetic Products, Nutrition and Allergies issued reports to the European Commission on the Population Reference Intakes for the European population. The primary goal of these reports was to update the first dietary reference intake values set in 1993. Reference intakes for carbohydrate, dietary fiber, and water were assessed, as well as those for fat, the latter of which

included SFAs, MUFAs, PUFAs, *trans* fats and cholesterol (EFSA Panel on Dietetic Products Nutrition and Allergies, 2010a,b). These recommendations are shown in Tables 48.8 and 48.9. Advice on the reference intakes for protein, energy, vitamins, and minerals is forthcoming.

The EFSA’s review of the literature and subsequent recommendations provide a model for countries and regions with very distinct food patterns. Recommendations could be made that are more sensitive to the culture and geographical region of interest in order to present the most cost-effective measures for the maintenance of overall health.

**Dietary Patterns for Prevention**

Both the DGAC 2010 and global recommendations focus on three dietary patterns designed for the prevention of chronic diseases, specifically CVD. Clinical and epidemiological evidence shows that the Dietary Approaches to Stop Hypertension (DASH) diet, a Mediterranean-style diet, and a vegetarian diet all reduce risk factors associated with CHD (DGAC, 2010a). The American Heart Association’s Therapeutic Lifestyle Changes (TLC) diet is designed for the prevention and treatment of CHD, other cardiovascular diseases, diabetes, insulin resistance, metabolic syndrome, and elevated LDL-C (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). With these healthful dietary patterns, there are many options to accommodate individual preferences to enhance adherence to current guidelines for reducing CVD risk.

**TABLE 48.6** Foods and food components recommended for increased or reduced consumption in the diet by the 2010 Dietary Guidelines for Americans (DGAC, 2010a)

Food	Recommended amount	Reduces risk of:
<i>Increase:</i>		
Vegetables and fruits	At least 2½ cups per day	CVD, cancer
Whole grains	At least half of recommended total grain intake or 3 oz equivalents per day	CVD, overweight, type 2 diabetes
Milk and milk products	3 cups per day of fat-free or low-fat milk and milk products for adults and children and adolescents ages 9–18 years, 2½ cups per day for children ages 4–8 years, and 2 cups for children ages 2–3 years	CVD, high blood pressure, type 2 diabetes
Protein foods	Consume a balanced variety of protein foods	CVD
Seafood	An intake of 8 oz or more per week (less for young children), which provide an average consumption of 250 mg per day of EPA and DHA	CVD
Oils	Replace solid fats with oils, rather than add oil to the diet, and use oils in small amounts	CVD
<i>Reduce:</i>		
Sodium	Less than 2300 mg and further reduce to 1500 mg among persons who are 51 and older and those of any age who are African-American or have hypertension, diabetes, or chronic kidney disease	High blood pressure, CVD, congestive heart failure, kidney disease
Saturated fat intake	Consume less than 10% and further reduce to 7% of calories from saturated fat (for persons at increased risk) and replace these with monounsaturated and/or polyunsaturated fat	Elevated LDL cholesterol, CVD
<i>Trans</i> fatty acids	As low as possible (<1% calories)	Elevated LDL cholesterol, CVD
Cholesterol	Less than 300 mg per day of cholesterol and further reduce to 200 mg per day for individuals at high risk of CVD	Elevated LDL cholesterol, CVD
Solid fats	Reducing sources of excess solid fats in the diet results in reduced intake of saturated fats, <i>trans</i> fats, and calories	Excess caloric intake, colorectal cancer, CVD
Added sugars	Reducing consumption of sources of added sugars lowers the calorie content of the diet without compromising its nutrient adequacy	Excess caloric intake
Refined grains	No more than 3 oz equivalents per day; at least half of all grains eaten as whole grains; reduce consumption of refined grain products that also are high in solid fats and/or added sugars, such as cakes, cookies, donuts, and other desserts	Excess caloric intake
Alcohol	Moderate alcohol consumption recommended for persons who consume alcohol; this is defined as up to 1 drink per day for women and up to 2 drinks per day for men	Cirrhosis of the liver, hypertension, stroke, type 2 diabetes, cancer of the upper gastrointestinal tract and colon, increased body weight, impairment of cognitive function, injury, and violence

**TABLE 48.7** Food and nutrient recommendations to achieve the American Heart Association (AHA) 2020 Impact Goals; these are based on a 2000-calorie/day diet

Food goals and metrics	Recommended servings
<i>Primary dietary metrics</i>	
Fruits and vegetables	≥4.5 cups per day
Fish (preferably oily fish)	≥Two 3.5-oz servings per week
Fiber-rich whole grains (≥1.1 g of fiber per 10g of carbohydrate)	≥Three 1-oz-equivalent servings
Sodium	<1500mg per day
Sugar-sweetened beverages	≤450kcal (36oz) per week
<i>Secondary dietary metrics</i>	
Nuts, legumes, and seeds	≥4 servings per week
Processed meats	None or ≤2 servings per week
Saturated fat	<7% of total energy intake

**TABLE 48.8** European Food Safety Authority (EFSA) reference intakes for carbohydrate, dietary fiber and water

Nutrient	Recommendation	Rationale
Carbohydrate	45–60% of energy intake for adults and children	To promote energy balance
Dietary fiber	25g/day for adults	Promotes normal bowel function Evidence for reduced risk of CVD and type 2 diabetes and promotion of weight maintenance with higher levels
Water	Adequate intakes of 2L/day for women and 2.5L/day for men.	To ensure adequate hydration and to prevent water intoxication

**Dietary Approaches to Stop Hypertension (DASH) Dietary Pattern**

The DASH dietary pattern emphasizes fruits, vegetables, and low-fat dairy products; incorporates whole grains, fish, nuts, and poultry; and reduces intake of red meats, sweets, and sugar-sweetened beverages (Appel *et al.*, 1997).

Consequently, nutrient targets are higher for potassium (4700 mg/day), magnesium (500 mg/day), and calcium (1240 mg/day) and lower for total fat (27% total energy), saturated fat (6% total energy), and cholesterol (150 mg/day) in a diet providing 2100 kcal/day; carbohydrate and protein comprise 55% and 18% of total energy, respectively (Appel *et al.*, 1997). Other DASH-style dietary patterns have been evaluated with higher unsaturated fat content and higher protein content (Appel *et al.*, 2005).

The DASH diet has been shown to decrease CVD risk factors, including: systolic and diastolic blood pressure (−5.5 and −3.0 mmHg, respectively), total cholesterol (−13 mg/dL), and LDL-C (−10.7 mg/dL) compared with a typical American diet (Appel *et al.*, 1997; Obarzanek *et al.*, 2001). The blood-pressure-lowering effect of the DASH dietary pattern compared with typical US dietary intake was significant in all populations studied, with this effect being greater in persons with stage 1 hypertension over those who were normotensive (Appel *et al.*, 1997). The total and LDL-cholesterol-lowering effects of the diet did not differ by race or baseline lipid concentration; however, the net reduction in total and LDL-cholesterol were several units greater for men over women (a further −10.3 and −11.2 mg/dL reduction for total and LDL-cholesterol respectively in men over women) (Obarzanek *et al.*, 2001). Overall, the DASH diet decreased 10-year CHD risk by −18% compared with the control diet, i.e. the typical American diet (Chen *et al.*, 2010).

In a study that evaluated the original DASH diet, a higher-unsaturated-fat DASH diet (37% fat, 15% protein, 48% carbohydrate), and a higher-protein DASH diet (27% fat, 25% protein, 48% carbohydrate), all three diets reduced systolic (−8.2 to −9.5 mmHg) and diastolic (−4.1 to −5.2 mmHg) blood pressure and total (−12.4 to −19.9 mg/dL) and LDL-cholesterol (−11.6 to −14.2 mg/dL) concentrations in pre-hypertensive and stage 1 hypertensive individuals (Appel *et al.*, 2005). HDL-C significantly decreased in both the original DASH diet (−1.4 mg/dL) and the higher-protein DASH diet (−2.6 mg/dL), while HDL-C remained unchanged during the higher-fat DASH diet (Appel *et al.*, 2005). The higher-protein and higher-fat DASH diets both significantly decreased triglycerides (Appel *et al.*, 2005). Another study evaluating various DASH dietary sodium levels found that a low sodium intake of 1150 mg/day (50 mmol/day) compared with a high sodium intake of 3450 mg/day (150 mmol/day), the latter of which represents an average American diet, reduced systolic and diastolic blood pressure by −3.0 mmHg and

**TABLE 48.9** European Food Safety Authority (EFSA) reference intakes for fat and cholesterol

Nutrient	Recommendation	Rationale
Total fat	20–35% energy intake for adults	For maintenance of good health, body weight and for proper absorption of fat-soluble dietary components such as vitamins
Saturated fats	Intake should be as low as possible within a nutritionally adequate diet	SFAs are synthesized in the body and are not required in the diet
<i>cis</i> -MUFAs	No reference value set	MUFAs are synthesized in the body and have no specific role in either the prevention or promotion of diet-related diseases
<i>n</i> -3 PUFAs	Adequate intake levels of 250mg/day of EPA + DHA as a primary preventive measure for healthy adults Adequate intake levels of 0.5% energy for ALA	<i>n</i> -3 PUFA supplementation or oily fish consumption (1–2 meals per week) decrease risk of mortality from CHD and sudden cardiac death ALA is considered an essential fatty acid as it cannot be synthesized in the body and is required for the maintenance of metabolic integrity
<i>n</i> -6 PUFAs	Adequate intake level of 4% energy from LA No dietary reference intake value set for AA	LA is an essential fatty acid that cannot be synthesized in the body and is required to maintain metabolic integrity AA is not an essential fatty acid and there is no consistent evidence for its promotion of diet-related diseases
<i>Trans</i> fatty acids	Intake should be as low as possible within a nutritionally adequate diet.	TFAs are not synthesized by the body and are not required in the diet High intakes increase risk of CHD TFA intake increases total cholesterol and LDL-C levels in a dose-dependent manner TFAs also decrease HDL levels and increase the total cholesterol: HDL ratio Evidence indicates that TFAs from ruminant sources have similar adverse effects as those from industrial sources when consumed in equivalent amounts
Conjugated linoleic acid	No dietary reference intake value set	No convincing evidence that CLA isomers are important in either the prevention or promotion of a diet-related disease
Cholesterol	No dietary reference value set	Cholesterol is synthesized in the body and is not required in the diet Positive dose-dependent association is seen with cholesterol intake and LDL-C levels; however, main determinant of LDL-C levels is SFA intake Most foods containing cholesterol are also significant sources of SFAs. Therefore, reference intake value for SFAs should first be considered

−1.6 mm Hg, respectively (Sacks *et al.*, 2001). Sacks and colleagues (2001) also showed that, when the low-sodium DASH diet was compared with the high-sodium average American diet (control), there was a significant reduction in systolic blood pressure of −7.1 mm Hg in pre-hypertensive individuals, with an even greater reduction of −11.5 mm Hg in hypertensive individuals. However, there is also evidence to suggest that humans self-regulate dietary sodium intake via hormonal and central nervous system mechanisms, leading some scientists to argue that current guidelines for sodium intake are below the physiologic set-point of 2.7 to 4.9 g/day, and are impractical for long-term adherence to recommendations (McCarron *et al.*, 2009). Overall, the original DASH dietary pattern, the higher-protein DASH diet, the higher-unsaturated-fat DASH diet, and the DASH diet with reduced sodium all favorably affect blood pressure, blood lipids, and CVD risk (DGAC, 2010a).

### **Mediterranean-Style Eating Patterns**

The Mediterranean-style eating pattern represents the unique dietary patterns of many countries surrounding the Mediterranean Sea. Some common attributes of the Mediterranean diet include: increased consumption of fruits, vegetables (specifically root vegetables), whole grains, legumes, nuts, seeds, and olive oil; low to moderate consumption of wine (non-Islamic countries), fish, poultry, and dairy products; and decreased consumption of red meat (Kris-Etherton *et al.*, 2001). Diets from the Mediterranean area tend to be higher in monounsaturated fat and lower in saturated fat. Due to the diversity of the Mediterranean diet, scoring indices have been developed based on dietary components that are inherent to all variations of the diet; higher scores indicate greater adherence to the Mediterranean-style diet (Kourlaba and Panagiotakos, 2009).

Epidemiological and clinical evidence both show benefits of a Mediterranean-style diet for CVD risk factors. In a prospective cohort study of a Greek population, greater adherence to a Mediterranean diet was associated with decreased total mortality, CHD death, and cancer death (Trichopoulou *et al.*, 2003). In the Nurses' Health Study, women who followed a Mediterranean diet most closely were at a lower relative risk for CHD (RR 0.71 [95% CI: 0.62–0.82]) and stroke incidence (RR 0.87 [95% CI: 0.73–1.02]) and total CVD mortality (RR 0.61 [95% CI: 0.49–0.76]) compared with women with the lowest adherence (Fung *et al.*, 2009). A recent meta-analysis confirmed these results, reporting decreased total

mortality (RR 0.92 [95% CI: 0.90–0.94]) and CVD-related incidence or mortality (RR 0.90 [95% CI: 0.87–0.93]) with a 2-point increase in the Mediterranean diet scoring index (Sofi *et al.*, 2010).

The PREDIMED (Mediterranean Diet in the Primary Prevention of Cardiovascular Disease) clinical trial implemented a nutrition education intervention in free-living participants to evaluate the difference between a low-fat diet and a Mediterranean diet; subjects in the Mediterranean diet group were supplemented with either virgin olive oil (1 L/week) or nuts (30 g/day). Results after 3 months indicated that a Mediterranean diet supplemented with nuts (hazelnuts, almonds, and walnuts) significantly reduced fasting glucose (−5.4 mg/dL), systolic (−7.1 mm Hg) and diastolic (−2.6 mm Hg) blood pressure, total cholesterol (−6.2 mg/dL), triglyceride concentration (−13.0 mg/dL), and the total cholesterol:HDL-C ratio (−0.26), and increased HDL-C (1.6 mg/dL) compared with a low-fat diet (Estruch *et al.*, 2006). The Mediterranean diet supplemented with olive oil significantly reduced fasting glucose (−7.0 mg/dL), systolic (−5.9 mm Hg) and diastolic (−1.6 mm Hg) blood pressure, and the total cholesterol:HDL-C ratio (−0.38), and increased HDL-C (2.9 mg/dL) compared with a low-fat diet (Estruch *et al.*, 2006). The same trial reported that a Mediterranean diet, supplemented with olive oil or nuts, reduced the incidence of diabetes by −52% compared with a low-fat diet in individuals with high cardiovascular risk after 4 years of follow-up (Salas-Salvadó *et al.*, 2011). As summarized by the DGAC 2010 report, individuals with a higher Mediterranean diet scoring index tend to have reduced total mortality, CVD risk factors, and CVD incidence (DGAC, 2010a).

### **Vegetarian Dietary Pattern**

Vegetarian dietary patterns represent a spectrum of food intake practices. “Vegetarian” is a broadly encompassing term used for a variety of different categories: ovo-lacto-vegetarians do not consume meat or fish; ovo-vegetarians do not consume meat, fish, or dairy products; lacto-vegetarians do not consume meat, fish, or eggs; vegans do not consume any animal products; while raw vegans, Su vegetarians, and fruitarians do not consume any animal products or vegetables in the *Allium* family (e.g. onions, garlic) (Li, 2011).

Vegetarian diets emphasize fruits, vegetables, whole grains, legumes, nuts, seeds, and soy foods and include little or no animal products. Vegetarians typically consume

increased fiber, carbohydrates, potassium, magnesium, folic acid, n-6 PUFAs, non-heme iron (the less biologically absorbable form of iron found predominantly in plants) and vitamin C, and have decreased total calories, total fat, SFAs, cholesterol, and sodium compared with non-vegetarians (Duo *et al.*, 2000; DGAC, 2010a). Important nutrients that vegetarian diets may lack include: heme iron (the more biologically absorbable form of iron found in animal products), zinc, vitamin B<sub>12</sub>, vitamin A, vitamin D, and n-3 PUFAs (Li *et al.*, 2000).

Vegetarians tend to have lower mortality from CHD, specifically, a -24% decrease in mortality from ischemic heart disease (IHD) compared with non-vegetarians (Key *et al.*, 1999; Fraser, 2009). In a group of Seventh Day Adventists, risk of fatal IHD was 2.31-fold greater in men who consumed beef  $\geq 3$  times per week as compared with vegetarian men, but this trend was not observed in women (Fraser, 1999). A recent British prospective trial reported no significant differences in mortality rates for ischemic heart disease and cerebrovascular disease between vegetarians and non-vegetarians (Key *et al.*, 2009). The authors attribute this discrepancy to the recruitment of relatively health-conscious non-vegetarians. Epidemiological data indicate that vegetarians have a decreased prevalence of diabetes and hypertension (Fraser, 1999, 2009) and a significantly lower BMI than non-vegetarians (Fraser, 1999, 2009; Haddad *et al.*, 1999; Li *et al.*, 2000). Cross-sectional studies consistently show decreased total cholesterol and LDL-C in individuals consuming plant-based diets as compared with the general population, with vegans experiencing the lowest cholesterol levels (Ferdowsian and Barnard, 2009).

Clinical interventions show decreased total cholesterol (-7.6 to -26.6%) and LDL-cholesterol (-9.2 to -37.4%) in participants randomized to a plant-based diet versus a typical Western diet (Ferdowsian and Barnard, 2009). A vegan combination diet (plant sterols 1.2 g/1000 kcal, soy protein 16.2 g/1000 kcal, viscous fiber 8.3 g/1000 kcal, almonds 16.6 g/1000 kcal) has been shown to decrease total cholesterol (-26.6% vs. -9.9%), LDL-C (-35.0% vs. -12.1%), the total cholesterol: HDL-C ratio (-20.8 vs. -2.6), and the LDL:HDL-C ratio (-30.0 vs. -5.1) compared with a low-fat control diet and similarly to first-generation statin drug therapy (Jenkins *et al.*, 2003). The improved lipid and lipoprotein profile may account for the -31.7% decrease in CHD mortality witnessed in individuals who follow plant-based, vegetarian, and vegan diets (Jenkins *et al.*, 2003).

A concern for vegetarians, especially vegans, is that they typically have lower levels of circulating serum ferritin and vitamin B<sub>12</sub> and decreased phospholipid-incorporated n-3 PUFAs (Haddad *et al.*, 1999; Li *et al.*, 2000; Elmadfa and Singer, 2009). Vegetarians also show elevated blood homocysteine levels (Elmadfa and Singer, 2009) which have been associated with increased risk of atherosclerosis (Gerhard and Duell, 1999). Individuals consuming vegetarian diets should therefore monitor their B<sub>12</sub> levels, consume B<sub>12</sub>-fortified foods, and consider taking a B<sub>12</sub> supplement. In addition, decreased intake of dietary n-3 PUFAs (especially longer-chain n-3 fatty acids) in vegetarians may contribute to platelet aggregation and platelet structural changes, which may be associated with an increased tendency for thrombosis (Li, 2011).

The CHD-related benefits of plant-based, vegetarian, and vegan diets have been demonstrated repeatedly in epidemiological and clinical trials and are endorsed by the US Department of Agriculture (USDA) as one of several healthy diets. Specialized food-guide pyramids for vegetarian and vegan diets also have been developed. Well-planned, plant-based diets can provide sufficient macronutrients and micronutrients to meet current dietary recommendations for all stages of life.

### **Therapeutic Lifestyle Changes (TLC)**

The National Cholesterol Education Program TLC diet is designed for individuals with elevated LDL-C, lipid disorders, cardiovascular disease, diabetes, insulin resistance, and/or metabolic syndrome. The diet emphasizes decreased saturated fat (<7% of calories) and cholesterol (<200 mg) intake, and provides two therapeutic options of increasing soluble fiber (10–25 g/day) and plant sterol/stanol (2 g/day) intake to further reduce LDL-C. Macronutrient intake recommendations are as follows: total fat (25–35%), MUFAs (up to 20%), PUFAs (up to 10%), carbohydrate (50–60%), and protein ( $\approx$ 15%) (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). Total calorie intake should be balanced with energy expenditure to maintain weight and prevent weight gain. The TLC program also recommends moderate physical activity to expend at least 200 kcal/day. The TLC diet can be achieved through a variety of dietary intake patterns and may be based on individual preferences. For the most part, the DASH diet, Mediterranean diets, and vegetarian diets all meet the TLC diet recommendations for saturated fat and dietary cholesterol intake.

When plant sterols (1g/1000kcal), viscous fiber (8.2g/1000kcal), and plant protein ( $\approx$ 25g/1000kcal) were incorporated into a diet already low in dietary cholesterol (99mg/1000kcal) and saturated fat (7.7% of energy), both normal and hyperlipidemic subjects had a significant decrease in total cholesterol (−22.3%), LDL-C (−29.0%), the total cholesterol: HDL-C ratio (−19.8%), and the LDL-C:HDL-C ratio (−26.5%) compared with baseline (Jenkins *et al.*, 2002). Based on these blood lipid results, the calculated CHD risk reduction of this Portfolio Diet is −30.0% (Jenkins *et al.*, 2002). In a community intervention trial, the TLC diet, in conjunction with lifestyle modifications such as stress management, smoking cessation, and physical activity, significantly decreased systolic (−6 mm Hg) and diastolic (−3 mm Hg) blood pressure in pre-hypertensive individuals (Bavikati *et al.*, 2008). The blood-pressure-lowering effect was greater in women than men and greater in normal and overweight individuals than in obese individuals; there were no racial differences in blood pressure change. The TLC diet can effectively contribute to the prevention and treatment of elevated cholesterol levels, and thereby lower CVD risk.

## Functional Foods and Nutrition Labeling Terminology

### Functional Foods

Functional foods have received much attention for their potential in disease risk reduction and optimal health promotion. Numerous definitions exist for the term “functional food,” making it difficult to develop consistent terminology. The International Food Information Council defines functional food as any food or food component that may have health benefits beyond basic nutrition (Stevens *et al.*, 2008). In the case of CVD, foods such as fatty fish, flaxseed, oats, psyllium, grapes, garlic, and tea, as well as sterol/stanol-enhanced margarines, have been found to significantly modify CVD risk (Hasler *et al.*, 2000). Peer-reviewed evidence of their effectiveness in modifying CVD risk is ranked and interpreted for the development of appropriate food and nutrient recommendations.

The Academy of Nutrition and Dietetics (AND), formerly known as the American Dietetic Association (ADA), considers all foods functional at some biochemical level, but specifically classifies functional foods as those that provide additional health benefits beyond necessity (ADA, 2009). Functional foods are divided into four categories: conventional foods (i.e. whole foods), modified foods,

medical foods (e.g. phenylketonuria formulas), and foods for special dietary use (e.g. hypo-allergenic foods) (ADA, 2009). Modified foods include subcategories of fortified, enriched, and enhanced food products. Fortified food products have additional nutrients incorporated during processing that do not naturally occur in the food, such as calcium-fortified orange juice. Enriched food products have naturally occurring nutrients reincorporated into the food that were lost during processing (e.g. folate-enriched breads), while enhanced food products are enhanced with bioactive nutrients (e.g. phytosterol-enhanced margarines) (ADA, 2009).

### Food and Nutrition Recommendations

Health and governmental organizations, including the FDA and the AND, provide specific nutrient and food recommendations for reducing the risk of disease. The FDA bases unqualified Health Claims on significant scientific agreement that a food or nutrient decreases the risk of a specific disease (FDA, 2003). The FDA allows Qualified Health Claims when significant scientific agreement is not reached but emerging evidence suggests a favorable relationship between a food or nutrient and the risk of a specific disease (FDA, 2003). Since they are regulated by the FDA, unqualified and Qualified Health Claims can be used in food labeling when appropriate. The AND has a rating system based on strong, fair, weak, consensus, and insufficient evidence ratings to advise clinical practitioners on how to make recommendations for patients (ADA, 2004a). Conventional and modified foods that decrease the risk of CHD are listed in Table 48.10.

## World Health Organization and Food and Agriculture Organization Summary on the Strength of the Evidence for Dietary and Lifestyle Factors for CVD Risk

The WHO Programme on CVD is focused on preventing, monitoring, and managing CVD globally. The main aims are to develop global approaches for lowering the rates of incidence, morbidity, and mortality due to CVD. The 2002 WHO report states that there is sufficient evidence that the mortality rates of CVD have been associated with behavioral risk factors such as poor dietary habits, increased tobacco use, and inadequate amounts of physical activity

**TABLE 48.10** Strength of evidence for specific foods and nutrients associated with CHD risk reduction

Type of food	Bioactive component	Recommended amount	FDA health claim <sup>a</sup>	AND evidence <sup>b</sup>
Whole oats	$\beta$ -glucan soluble fiber	3 g/day soluble fiber	Unqualified (A)	Strong (fiber)
Barley	$\beta$ -glucan soluble fiber	3 g/day soluble fiber	Unqualified (A)	Strong (fiber)
Psyllium husk	Soluble fiber	7 g/day soluble fiber	Unqualified (A)	Strong (fiber)
Fortified margarines/ salad dressings	Plant sterols/ stanol esters	2 g/day sterols/ stanols	Unqualified (A)	Strong (stanols/ sterols)
Soy protein	Plant protein	25 g/day	Unqualified (A)	Fair (soy protein)
Nuts	Unsaturated fatty acids, vitamin E	1.5 oz/day	Qualified (B)	Fair (nuts)
Walnuts	Omega-3 fatty acids <sup>c</sup>	1.5 oz/day or 1 tbsp/day oil	Qualified (B)	Fair (nuts) Fair (omega-3 FA)
Fatty fish	Omega-3 fatty acids	8 oz/week	Qualified (B)	Fair (omega-3 FA)
Flaxseed	Omega-3 fatty acids <sup>c</sup>	0.5 tbsp/day or <1 tsp/day oil	Qualified (B)	Fair, (omega-3 FA)
Canola oil	Unsaturated fatty acids, omega-3 fatty acids <sup>c</sup>	1.5 tbsp/day	Qualified (C)	Fair (omega-3 FA)
Olive oil	Monounsaturated fatty acids	2 tbsp/day	Qualified (C)	N/A
Corn oil	Unsaturated fatty acids	1 tbsp/day	Qualified (D)	N/A

(Cardiovascular Disease Programme, 2002). The biological factors contributing to increased CVD risk are being overweight, and having central obesity, elevated blood pressure, diabetes, and dyslipidemia (Cardiovascular Disease Programme, 2002). These are often coupled with increased intake of SFAs, refined carbohydrates and salt, and low intake of fruits and vegetables (Cardiovascular Disease Programme, 2002). In their joint report published in 2002, the WHO and the FAO of the United Nations summarized the strength of the evidence for the various dietary and lifestyle factors associated with CVD risk (Joint FAO/WHO Expert Consultation, 2002). An adaptation of this summary is given in Box 48.4.

## Major Co-Morbidities of Cardiovascular Disease

### Obesity

There is convincing evidence that being overweight or obese increases risk for CVD (Lloyd-Jones *et al.*, 2010). A shift towards more urbanized ways of life as well as increased industrialization in most countries has resulted in marked changes in diet, behavior, and lifestyle, with diet becoming more energy-dense and high in fat, and lifestyles trending towards being more sedentary. In countries going through an economic transition, the rising rates of obesity may occur alongside increased prevalence of chronic

**BOX 48.4 Summary of the evidence on dietary and lifestyle factors associated with CVD risk (Joint WHO/FAO Expert Consultation, 2002)**

<b>Convincing evidence</b>	Decreased risk	EPA and DHA, LA intake, vegetables and fruits (including berries), potassium, low to moderate alcohol intake, regular physical activity
	Increased risk	<i>Trans</i> fatty acids, high sodium intake, myristic and palmitic acids, high alcohol intake, overweight
<b>Probable evidence</b>	No relationship	Vitamin E supplementation
	Decreased risk	ALA, oleic acid intake, dietary fiber, whole-grain cereals, nuts (unsalted), plant sterols/stanols, folate
	Increased risk	Dietary cholesterol, unfiltered boiled coffee (this contains a terpenoid lipid known as cafestol that is found to raise total and LDL-cholesterol levels)
<b>Possible evidence</b>	No relationship	Stearic acid
	Decreased risk	Flavonoids, soy products
	Increased risk	Fats rich in lauric acid, $\beta$ -carotene supplements
<b>Insufficient evidence</b>	No relationship	–
	Decreased risk	Calcium, magnesium, vitamin C
	Increased risk	Carbohydrates, iron
	No relationship	–

undernutrition (Joint FAO/WHO Expert Consultation, 2002). In low-income countries, obesity occurs in persons of higher-economic status, most likely due to a higher energy intake, whereas in higher-income countries obesity is widespread in lower socioeconomic groups (Joint FAO/WHO Expert Consultation, 2002), which may be related to the low relative cost of high-energy and nutrient-poor foods. However, this trend is expanding across groups in higher-income countries. Since the risk of hypertension, CVD, and diabetes are all associated with increased weight, the prevention of obesity plays a pivotal role in the prevention and management of several chronic diseases (Lloyd-Jones *et al.*, 2010). There is strong evidence to suggest that moderate to high fitness levels greatly reduce the risk of CVD, and all-cause mortality, regardless of BMI level, and results from epidemiological studies have shown that ongoing physical activity, regardless of body weight, is protective against chronic disease (Nocon *et al.*, 2008; Shiroma and Lee, 2010). Prevention of weight gain would therefore greatly decrease CVD risk and allow for better management of CVD with age.

**Childhood Obesity**

There is a worldwide trend towards increased prevalence of childhood obesity (Steyn *et al.*, 2005), which would play a significant role in children’s nutritional and health outcomes as they enter adulthood. Strong associations

between childhood obesity and early-onset hypertension, dyslipidemia, and insulin resistance have been reported (Raghuveer, 2010), and studies have shown that the childhood onset of obesity and the associated co-morbidities adversely affect the vasculature, resulting in premature onset and accelerated progression of atherosclerosis (Berenson *et al.*, 1998; Freedman *et al.*, 2008). Clinical manifestations of atherosclerotic cardiovascular disease have not been observed in obese children, and so assessment of subclinical markers is needed to evaluate disease risk, progression and monitoring of the effects of interventions implemented (Raghuveer, 2010). Our primary aim should be to prevent the premature onset of the disease before the development of clinical disease events (Balagopal *et al.*, 2011). Thus, efforts to curb the rate of incidence, as well as morbidity and mortality due to CVD, are needed at an early age.

**Diabetes**

The current global estimate for diabetes cases is 150 million, and this number is expected to double by the year 2025 (Joint FAO/WHO Expert Consultation, 2002). Type 2 diabetes, previously a disease of the middle- and older-aged, is now detected in all age groups including adolescents and children (Cardiovascular Disease Programme, 2002). Diabetes increases risk for stroke,

peripheral vascular disease, and CHD (Grundey *et al.*, 1999; Goldberg, 2000). Similar numbers of people are thought to have impaired glucose tolerance, which is associated with a two- to three-fold increase in risk for vascular disease (Liao *et al.*, 2001; DECODA Study Group (International Diabetes Epidemiology Group), 2002). CVD is the most common complication of type 2 diabetes (Cardiovascular Disease Programme, 2002); diabetes is associated with an increased prevalence of hypertension and dyslipidemia (Grundey *et al.*, 1999; Goldberg, 2000). Efforts to curb the risk of mortality due to CHD or CVD may be therefore be thwarted by rapid increases in the incidence of diabetes (Cardiovascular Disease Programme, 2002). Also, overweight and obesity increase risk of diabetes, thus indicating a critical need for healthy dietary and lifestyle behaviors for preventing and reducing overweight and obesity, as well as CVD risk and the risk of type 2 diabetes (Cardiovascular Disease Programme, 2002). A summary of the recommendations for reducing diabetes risk given by the Joint WHO/FAO Expert Consultation on Diet, Nutrition and the Prevention of Chronic Diseases (2002) is presented in Box 48.5.

## Healthy Lifestyle Behaviors

Behavioral patterns play significant roles in one's health status; unhealthy behaviors account for 40% of premature deaths (Schroeder, 2007). Physical activity recommenda-

tions aim to reduce the risk of disease and increase overall health. The World Health Organization (WHO) recommends at least 30 minutes of moderate-intensity physical activity on most days to reduce CVD and other disease risks (Waxman, 2004). The US Department of Health and Human Services (USDHHS) recommends the equivalent, 150 minutes of moderate-intensity aerobic activity or 75 minutes of vigorous-intensity aerobic activity each week, for adults (Tay *et al.*, 2008). Evidence strongly suggests that adherence to these guidelines reduces CHD risk, via a decrease in triglycerides and LDL-C levels, as well as an increase in HDL-C levels (Thornburg *et al.*, 1995). Moreover, adherence to these recommendations lowers risk for chronic diseases such as CHD, stroke, metabolic syndrome, type 2 diabetes, and some cancers by allowing one to achieve appropriate energy balance, manage weight, lower blood pressure, achieve a favorable lipid profile, and prevent premature death (Office of Disease Prevention and Health Promotion, 2008). A summary of the physical activity recommendations provided in the WHO Global Strategy on Diet, Physical Activity and Health Report (WHO, 2004) is given in Table 48.11.

The recommendations for moderate-intensity physical activity refer to exercises that include brisk walking (>3 miles/hour), water aerobics, cycling (<10 miles/hour), and tennis (doubles); equivalent vigorous-intensity exercises include jogging or running, swimming laps, cycling (≥10 miles/hour), and tennis (singles) (Tay *et al.*, 2008). These aerobic activities should be done in addition to daily baseline activity, defined as the activity required for everyday living, and in at least 10-minute intervals to be considered physical activity for the purpose of improving health. If these recommendations are unattainable for physical or other reasons, health benefits are still gained with lesser amounts of activity; any amount of exercise is better than remaining inactive (Tay *et al.*, 2008). Additional benefits may be gained by exceeding these recommendations.

Additionally, the USDHHS recommendations include muscle strength training, which should be done at least two days of the week for all major muscle groups. Strength training provides additional health benefits beyond those obtained from aerobic exercise, including improvements in muscular tone and bone strength. Examples of strength exercises include weightlifting, calisthenics, push-ups, and sit-ups. Flexibility exercises such as stretching also are encouraged (Tay *et al.*, 2008).

The advantages of regular physical activity for children and older adults are similar to those for adults. Children

### BOX 48.5 Recommendations for reducing diabetes risk (Joint FAO/WHO Expert Consultation, 2002)

Prevention and treatment of overweight and obesity  
 Maintaining an optimum BMI (21–23 kg/m<sup>2</sup>) and avoiding weight gain (>5 kg) in adulthood  
 Voluntary weight reduction in the overweight and obese with impaired glucose tolerance  
 Participating in an endurance activity at moderate or greater level of intensity (e.g. brisk walking) for 1 hour or more per day on most days per week  
 Saturated fat intake <10% total energy with an intake of <7% for high-risk groups  
 Adequate dietary fiber intakes through regular consumption of fruits, vegetables, whole-grain cereals, and legumes. Minimum daily intake of 20 g

**TABLE 48.11** Summary of the World Health Organization Physical Activity Recommendations (WHO, 2004)

Age group	Recommendation
Children 5–17 years	Accumulate at least 60 minutes of moderate- to vigorous-intensity physical activity daily; amounts greater than 60 minutes will provide additional health benefits. Most daily physical activity should be aerobic; vigorous intensity activities should also be incorporated, including those that strengthen muscle and bone at least 3 times per week: bone loading activities can be a part of playing games, running, turning or jumping.
Adults 18–64 years	Accumulate at least 150 minutes of moderate-intensity aerobic physical activity throughout the week or at least 75 minutes of vigorous-intensity aerobic physical activity during the week or an equivalent combination of moderate-and vigorous-intensity activity. Aerobic activity should be performed in bouts at least 10 minutes in length; additional health benefits can be achieved by increasing moderate-intensity aerobic physical activity to 300 minutes or to 150 minutes of vigorous-intensity aerobic physical activity per week, or an equivalent combination of moderate- and vigorous-intensity activity.
Adults >65 years	Be as physically active as possible with all abilities and health conditions; accumulate at least 150 minutes of moderate-intensity aerobic physical activity throughout the week or at least 75 minutes of vigorous-intensity aerobic physical activity during the week, or an equivalent combination of moderate- and vigorous-intensity activity. Aerobic activity should be performed in bouts at least 10 minutes in length; additional health benefits can be achieved by increasing moderate-intensity aerobic physical activity to 300 minutes or to 150 minutes of vigorous-intensity aerobic physical activity per week, or an equivalent combination of moderate- and vigorous-intensity activity. Older adults with poor mobility should perform physical activity to enhance balance and prevent falls on 3 or more days per week. Muscle strengthening activities involving major muscle groups should be performed on at least 2 or more days per week. Physical activity can include walking, dancing, gardening, hiking, swimming, cycling, household chores, play, games, sports, planned exercise, and occupational activity if the individual works.

should engage in at least 60 minutes of physical activity per day to promote health; the majority of activity should be aerobic, but also include muscle and bone-strengthening exercises (Tay *et al.*, 2008). Guidelines for older adults are equivalent to those for younger adults; however, older adults may experience obstacles due to physical limitations. Older adults can include exercises that improve balance to decrease the risk of falls. Those seeking to maintain or lose weight may require increased physical activity duration and/or intensity based on individual needs and abilities.

Another behavioral pattern found to increase CVD risk is sleep. Sleep deprivation (<7 hours per night) is associated with CVD, obesity, and type 2 diabetes; both short and long durations of sleep increase glucose intolerance,

obesity, and hypertension, all risk factors for CVD (Institute of Medicine, 2006). Obstructive sleep apnea (OSA), a sleep disorder that involves breathing pauses of >10 seconds due to obstruction of the airway during sleep, is associated with CVD and related risk factors (Institute of Medicine, 2006); OSA results in severe and intermittent oxygen loss and carbon dioxide retention during sleep (Somers *et al.*, 1993), and if repetitive can cause vasoconstriction of the peripheral blood vessels and a sharp increase in blood pressure (Somers *et al.*, 1989a,b, 1995). Additionally, CVD and diabetes are risk factors for OSA (Sin *et al.*, 1999). The National Sleep Foundation recommends 7–9 hours of sleep for adults and 8.5–9.25 hours of sleep for adolescents to achieve optimal health (National Sleep Foundation, 2011).

## Diet and Lifestyle Interventions Complement Drug Therapy

Diet has significant additive effects on reducing CVD risk factors, particularly LDL-C and systolic blood pressure (SBP), especially when adopted early in life and maintained across the lifespan. Individually, each dietary recommendation may have a relatively small effect, but in combination can affect treatment options in terms of the drug therapy and dose needed. A combination of these recommendations has been shown to reduce LDL-C in amounts similar to those gained from standard, first-generation statins (National Cholesterol Education Program Expert Panel, 2002). For example, a diet with  $\leq 30\%$  total fat,  $< 10\%$  SFA, and  $< 300$  mg cholesterol per day lowered LDL-C levels by  $-8\%$  compared with an average American diet (Yu-Poth *et al.*, 1999). In Table 48.12 we see the estimated LDL-C-lowering effects of various diet recommendations and their estimated cumulative effect in the range of  $-20\%$  to  $-30\%$  (Jenkins *et al.*, 2000).

For those individuals on drug therapy, there are additive benefits for also implementing a TLC diet (National Cholesterol Education Program Expert Panel, 2002). Hunninghake and colleagues (1993) found a further  $-5\%$  reduction in LDL-C levels when diet therapy (SFA  $< 7\%$ ; cholesterol  $< 200$  mg/day) was used in combination with

lovastatin, 20 mg/day, an effect similar to that attained when the statin dose is doubled (National Cholesterol Education Program Expert Panel, 2002). Studies using plant sterols (3–5.1 g/day) as a part of diet therapy, in persons on statin treatment, showed between  $-17\%$  and  $-20\%$  reductions in LDL-C levels (Gylling *et al.*, 1997; Blair *et al.*, 2000). The combination of diet and drug therapy is preferred over increasing statin doses over time (National Cholesterol Education Program Expert Panel, 2002).

Hypertension is a major CVD risk factor; treatment of hypertension significantly reduces CVD morbidity and mortality (Chobanian *et al.*, 2003). Several diet and lifestyle modifications have been shown to effectively reduce SBP, which is a strong indicator of CVD risk (Chobanian *et al.*, 2003). These include reducing intake of sodium (Chobanian and Hill, 2000; Sacks *et al.*, 2001; Vollmer *et al.*, 2001); adopting a Dietary Approaches to Stop Hypertension (DASH) eating pattern that is high in fruits and vegetables and in potassium, and utilizes low-fat dairy products (Sacks *et al.*, 2001); weight loss in overweight or obese individuals (Trials of Hypertension Prevention Collaborative Research Group, 1997; He *et al.*, 2000); increased physical activity (Kelley and Kelley, 2000; Whelton *et al.*, 2002); and moderation in alcohol consumption (Xin *et al.*, 2001). Indeed, cessation of smoking is imperative for CVD risk reduction (DGAC, 2010a). The SBP-lowering effects of these recommendations are presented in Table 48.13. Combined diet and lifestyle interventions would significantly lower SBP, and allow for increased efficacy of anti-hypertensive drug therapy, and decrease CVD risk (Chobanian *et al.*, 2003).

Possible additive effects of dietary strategies can be utilized in persons undergoing drug therapy. Persons at high risk for CVD due to increased LDL-C levels and hypertension, who are on drug regimens, may lower their recommended doses, prevent increases in doses over-time, and reduce occurrences of adverse side-effects of pharmacotherapy with recommended diet therapy. For example, LDL-C lowering by diet would decrease the dose of statin required and, in the case of n-3 fatty acids and phytosterols, also boost the pharmacokinetic action of these drugs (Bruckert and Rosenbaum, 2011). Reductions in sodium intake are manageable and can significantly decrease blood pressure (He *et al.*, 2000), allowing for more effective management of hypertension. Physical activity also may decrease insulin resistance, preventing weight gain, increas-

**TABLE 48.12** Approximate and cumulative LDL-cholesterol reductions achievable by dietary and lifestyle modifications

Dietary component	Recommendation	Approximate LDL reduction
<b>Major:</b>		
Saturated fat	$< 7\%$ calories	8–10%
Dietary cholesterol	$< 200$ mg/day	3–5%
Weight reduction	Lose 10 lb (4.5 kg)	5–8%
<b>Other:</b>		
Viscous fiber	5–10 g/day	3–5%
Plant sterol/stanol esters	2 g/day	6–15%
Cumulative estimate		20–30%

Adapted and reproduced from the Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults – Adult Treatment Panel III (National Cholesterol Education Program Expert Panel, 2002).

**TABLE 48.13** Approximate systolic blood pressure (SBP) reductions achievable by diet and lifestyle modifications

Factor	Recommendation	Approximate SBP reduction range
Sodium intake	Reduce dietary sodium to no more than 2400 mg or 6 g of sodium chloride daily	2–8 mm Hg
Adopt DASH <sup>a</sup> eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of total and saturated fat	8–14 mm Hg 13–19 mm Hg*
Weight reduction	Achieve and maintain a normal body weight; BMI: 18.5–24.9 kg/m <sup>2</sup>	5–20 mm Hg/ 10 kg weight loss
Physical activity	Achieve regular aerobic physical activity for at least 30 minutes each day, most days of the week	4–9 mm Hg
Alcohol consumption	Limit consumption to no more than 1 drink per day for women, and no more than 2 drinks per day for men	2–4 mm Hg

<sup>a</sup>Dietary Approaches to Stop Hypertension (Appel *et al.*, 1997).

\*Adherence to the DASH diet in combination with a weight management program may further reduce SBP levels (Blumenthal *et al.*, 2010).

Adapted from National High Blood Pressure Education Program (2003).

ing HDL, and lowering total cholesterol levels, as well as managing blood pressure (He *et al.*, 2000; Durstine *et al.*, 2001; Whelton *et al.*, 2002; Saris *et al.*, 2003), and dyslipidemia (DGAC, 2010a). Given these findings, medical advice aimed at maximizing compliance to both diet and drug regimens would allow for significant reduction of CVD risk in the long term. Overall lifestyle modification, which includes healthful dietary patterns, smoking cessation, and physical activity for weight loss and manage-

ment, would be most beneficial for decreasing CVD incidence in high-risk individuals on drug therapy (Yu-Poth *et al.*, 1999; Bruckert and Rosenbaum, 2011).

## A Need for Population-Based Approaches

There have been major improvements in socioeconomic status and increased urbanization in many countries, coupled with distinct changes in lifestyle, including increased caloric and saturated fat intake, increased tobacco use, and reduced physical activity levels, all of which increase risk factors for CVD (Joint FAO/WHO Expert Consultation, 2002). Deaths due to CVD now account for between 35% and 65% of all deaths, and exceed deaths due to infections and malnutrition worldwide (Gersh *et al.*, 2010). In the USA there has been a steady decrease in age-adjusted CHD (–2%) and in stroke mortality (–3%) per year, mainly attributable to the control of risk factors and the use of therapeutics (Ford and Capewell, 2007); management of CVD prevalence is attainable. However, with increased global prosperity and urbanization, epidemics of hypertension, obesity, and diabetes are more widespread (Balkau *et al.*, 2007), and these factors in combination increase risk for CVD dramatically. Results from the INTERHEART study, a case-control study on 25 countries, showed that more than 90% of the attributable risk of myocardial infarction or heart attacks was due to nine modifiable risk factors: hypertension, diabetes, smoking, abdominal obesity, the apolipoprotein B/apolipoprotein AI ratio, fruit and vegetable intake, exercise, regular alcohol consumption, and a psychosocial index (Yusuf *et al.*, 2004; Joshi *et al.*, 2007; Anand *et al.*, 2008; Teo *et al.*, 2009). These results illuminate the value of a global risk assessment for an individual (Cardiovascular Disease Programme, 2002), which aims to look at the complement of factors contributing to development of the disease.

Epidemiological theory proposes that, for conditions of high risk and prevalence within the population, small improvements in the population distribution of risk would have a greater impact on disease reduction than the intensive, individual treatment of high-risk patients (Rose, 2001). Examples of these include decreasing the amount of salt used in food processing, removing certain fats from the food chain, or having a smoke-free environment.

Ideally, a combination of both high-risk and population-wide strategies would be the best approach for treatment and prevention (Mendis, 2001) versus the traditional, clinic-based strategy focused on high-risk groups (Gersh *et al.*, 2010); indeed, persons without elevated risk factors but with chronic disease would also benefit. However, the lack of resources in many areas, coupled with the burden of non-communicable diseases, pose a challenge for health-care delivery (Mayosi *et al.*, 2009). None the less, public health responses may utilize several combinations of the main components of prevention that include either individual level prevention, the use of an integrated health-care system, or policy and societal changes (Gersh *et al.*, 2010). Such population-based approaches are thought by many to be especially cost-effective and allow for a shift towards a more primary, preventive, and community-based form of health care.

## Future Directions

Atherosclerotic cardiovascular disease is a leading cause of all global deaths, with a major proportion of these now occurring within the growing populations of low- and middle-income countries (WHO, 2011). Traditionally, the burden of CVD has been largely in the developed countries, but as developing countries achieve economic growth the emerging burden of this disease is evident in their vulnerable population groups (Novotny, 2005). The health inequalities already present in low- to middle-

income countries may only amplify the impact of CVD among the population (Ezzati *et al.*, 2005) and early attempts should be made to address this possible public health challenge, as recommended by the WHO global strategy for diet, physical activity, and health (Ziraba *et al.*, 2009).

The search for targeted interventions aimed at both the prevention and treatment of CVD has focused on identifying healthy dietary and lifestyle practices. The evolution of new science will facilitate the identification of the best nutrition practices for preventing CVD. Globally, these are consistent dietary recommendations for reducing CVD risk. However, this chapter also has identified several areas for which there is scientific controversy about diets, nutrients, and supplements. In the future, it will be important to resolve these controversies to evolve better dietary recommendations and determine how these may be used with lifestyle modifications and pharmacological treatments. It is likely that dietary recommendations will be individualized even more in the future to accommodate genetic differences in diet responsiveness, as well as identifying approaches that can be followed and enjoyed for a lifetime. In addition, it will be essential to effectively translate nutrition messages to the public, and worldwide, to achieve current dietary recommendations and attain the associated public health benefits. It is evident that, to achieve these goals that result in marked changes in dietary patterns, there needs to be a broad-based effort that shifts the demand for foods that make up a heart-healthy diet.

### Summary

Glycemic control and reduction of cardiovascular disease risk are the major treatment goals for all types of diabetes. In addition to nutritional management (termed medical nutrition therapy [MNT] in the United States), these goals are accomplished through several modalities including a variety of pharmacological agents, close personal and laboratory monitoring, and care provided by a team of health professionals. All of these elements, integrated and coordinated, are essential in the management of diabetes.

There is not one diet for individuals with diabetes. Nutritional management should be based on individual assessment and development of an individualized treatment plan. The distribution of macronutrient intake may vary based on a number of factors, including matching insulin to lifestyle in type 1 diabetes (T1D) and weight loss in type 2 diabetes (T2D). Assessing micronutrient status is needed for patients in poor control, with complications, or with other evidence of being at risk.

This chapter will discuss the etiology, diagnosis, and attainment of glycemic control (with an emphasis on MNT) of T1D, T2D, and gestational diabetes (GDM). It will then discuss the role of nutrition in the prevention of complications and reduction of chronic disease risk factors for both T1D and T2D and the role of specific dietary components including herbal and other supplements and micronutrients in diabetes care. The chapter will conclude with a discussion of global public health issues relating to diabetes, and research needs and future direction of the role of nutrition in this complex disorder.

### Introduction

According to the American Diabetes Association (ADA), diabetes is a group of metabolic disorders resulting from defects in insulin secretion, insulin action, or both, that

results in hyperglycemia (American Diabetes Association, 2010a). Despite major advances in our understanding about and treatments for diabetes, this multifactorial condition continues to pose major challenges to individuals, families, communities, and nations throughout the world.

The present burden of diabetes, both in the United States and worldwide, is significant: an estimated 23.6 million people in the United States and 366 million people worldwide have diabetes (Centers for Disease Control and Prevention, 2008; International Diabetes Federation, 2011). Because of the growing public health burden of diabetes in the United States and throughout the world, three general approaches to reduce the burden of diabetes are now being considered: (1) *primary prevention* of diabetes in high-risk individuals through weight management and increasing physical activity; (2) *secondary prevention* of the onset and/or severity of complications (i.e. controlling metabolic disorders associated with diabetes); and (3) *tertiary prevention* of morbidity and mortality resulting from complications (US Department of Health and Human Services, 2010). Nutrition has a critical role to play at each level of prevention.

Four classes of diabetes are currently recognized by the ADA (American Diabetes Association, 2010a). *Type 1 diabetes (T1D)*, formerly known as insulin-dependent or juvenile diabetes, which represents approximately 5–10% of known cases of diabetes (American Diabetes Association, 2010a). *Type 2 diabetes (T2D)*, formerly known as non-insulin-dependent or adult-onset diabetes, which represents the majority (90–95%) of known cases of diabetes (American Diabetes Association, 2010a). *Gestational diabetes (GDM)*, which is defined as hyperglycemia identified during pregnancy (American Diabetes Association, 2010a). The last class of diabetes accounts for approximately 1–5% of known diabetes cases and includes diabetes resulting from genetic defects (monogenic diabetes) and diabetes that is secondary to other diseases or drug- or chemically induced diabetes (American Diabetes Association, 2010a). In some instances, the class of diabetes is not clear, but may become more apparent over time.

The overall goal of therapy for diabetes (T1D, T2D, and GDM) is to normalize macronutrient metabolism (particularly of carbohydrates and lipids) in order to prevent both acute (e.g. hyperglycemia and ketoacidosis) and chronic (e.g. microvascular, macrovascular, and neuropathic) complications. Results from clinical trials in individuals with both T1D and T2D indicate that improving metabolic control (glycemia, blood pressure, and lipids) greatly reduces the development and progression rates for microvascular, macrovascular, and neuropathic complications (Diabetes Control and Complications Trial Research Group, 1993; Harris and Eastman, 1998; UK Prospective Diabetes Study Group, 1998a,b,c). Despite

similarities in complications and risk factors, the primary prevention, underlying etiology, and treatment approaches differ among T1D, T2D, and GDM.

## Type 1 Diabetes (T1D)

T1D is characterized by severe insulin deficiency requiring exogenous insulin to prevent ketoacidosis, coma, and death. Although T1D may occur at any age, onset usually occurs during childhood, adolescence, or early adulthood, with peak age of diagnosis at age 10 to 14 years. The SEARCH for Diabetes in Youth Study is a population-based, multicenter observational study of youth with clinically diagnosed diabetes in the United States (SEARCH for Diabetes in Youth Study Group, 2006). Based on data from 2002 to 2003, approximately 15 000 youth are newly diagnosed with T1D annually (SEARCH for Diabetes in Youth Study Group, 2006; Centers for Disease Control and Prevention, 2008). The incidence of T1D is higher in whites than in other ethnic/racial groups, with the greatest discrepancy at younger ages (SEARCH for Diabetes in Youth Study Group, 2006).

### Prevention

Currently there are no established approaches for primary prevention of T1D; studies are ongoing to better understand environmental triggers as well as the potential role of immunosuppressive therapy and various other approaches.

### Etiology and Diagnosis

T1D is characterized by T-cell-mediated autoimmune destruction of the beta-cells in the islets of Langerhans within the pancreas. Markers of this destruction include islet cell autoantibodies, autoantibodies to insulin, autoantibodies to GAD (GAD65), and autoantibodies to the tyrosine phosphatases IA-2 and IA-2 $\beta$  (American Diabetes Association, 2010a). Furthermore, T1D appears to be associated with particular histocompatibility leukocyte antigen (HLA) alleles (Atkinson, 2005). Often these antibodies can be found in the serum prior to the onset of clinical disease, and so it is important when considering the etiology of T1D to distinguish between the onset of autoimmunity, which can occur years before the onset of hyperglycemia, and the onset of the clinical disease (Atkinson, 2005; Muntoni and Muntoni, 2006). Testing for the presence of these antibodies can be used in a clinical setting to confirm a T1D diagnosis.

Although all immune-mediated forms of T1D share this common autoimmune destruction of beta-cells, the underlying etiology of this immune response involves a complex interaction of genetic and environmental factors, which is currently not well-established. For example, the factor(s) initiating autoimmunity are not clearly known (Atkinson, 2005) nor are the factor(s) influencing the rate of beta-cell destruction. Toxins or viral exposures have been suggested (Atkinson, 2005), but more recently the possibility of specific food ingredients at a critical time of life has been explored. Both the BABYDIAB and DAISY studies (Norris *et al.*, 2003; Ziegler *et al.*, 2003) suggested that there is a link between infant diet and the development of early autoimmunity against pancreatic beta-cells. Furthermore, the timing of this exposure (between 3 and 7 months) has been identified as a period of considerable vulnerability in the initiation of autoimmunity, particularly in so-called genetically high-risk individuals. Two particular types of food have been implicated: cow's milk (Mayer *et al.*, 1988; Bodington *et al.*, 1994; Norris and Scott, 1996; Norris *et al.*, 1996; Virtanen *et al.*, 1998; Vaarala *et al.*, 1999) and gluten-containing cereals (Norris *et al.*, 2003; Ziegler *et al.*, 2003; Virtanen *et al.*, 2006), including the timing of introduction of these and other complementary foods to infant diet.

Over the past several years, interesting hypotheses have been proposed regarding whether the absence of breastfeeding and/or early exposure to infant formula (i.e. a cow's milk protein) might be involved in the initiation of autoimmunity (Atkinson, 2005; Vaarala, 2005). Cross-sectional epidemiologic studies indicate a link between early introduction of cow's milk formula and development of T1D. Possible mechanisms suggested for this association include: (1) triggering autoantibody reactivity to the milk protein; and (2) almost by accident in an "innocent bystander" scenario in genetically susceptible individuals, a protein structure in the beta-cell with great similarity to the cow's milk protein is recognized as foreign and thus attacked. Equally important may be the absence of the immunoprotection of breastfeeding (Yoon and Jun, 2005).

One ecological study of the 37 world areas reporting a 3% yearly increase of T1D evaluated diabetes incidence in relation to dietary patterns using the Food and Agriculture Organization's Food Balance Sheets (Muntoni and Muntoni, 2006). The incidence of diabetes appeared to be related to the milk supply from 1961 to 2000. Several molecular, genetic, and clinical studies addressing

the possible role of protein in cow's milk are ongoing, and a large-scale epidemiologic project called TRIGR is examining, on a population basis, a possible relationship between cow's milk and T1D (Akerblom *et al.*, 2005; TRIGR Study Group, 2007). Should a relationship be established, it may be relevant only in persons with genetic susceptibility to autoimmunity, and thus broader versus targeted recommendations for breastfeeding would need to be resolved.

Several nutritional factors have been proposed as playing a role in beta-cell function including n-3 polyunsaturated fatty acids, vitamin D, and vitamin E. Genetically susceptible infants with higher intakes of n-3 fatty acids have been shown to have reduced risk of beta-cell autoimmunity (Norris *et al.*, 2007). Maternal vitamin D consumption during pregnancy has also been associated with reduced beta-cell autoimmunity in infants (Fronczak *et al.*, 2003). A prospective study looking at vitamin D supplementation during infancy found a reduced risk of diabetes in those infants receiving vitamin D (Hyppönen *et al.*, 2001), further lending support to a potentially protective effect of vitamin D on the development of diabetes. Similar to vitamin D, vitamin E may also have a protective effect against T1D risk (Knekt *et al.*, 1999; Costacou *et al.*, 2008). The SEARCH Nutrition Ancillary Study (SNAS) will examine the effects of certain nutritional factors on sustaining beta-cell function in a large cohort of youth with clinically diagnosed T1D in the United States.

In addition to testing for the antibodies described previously, four criteria for the diagnosis of diabetes (both T1D and T2D) are currently used by the ADA: a hemoglobin A1c (A1C; World Health Organization, 2011) of at least 6.5% (when performed using a National Glycohemoglobin Standardization Program-certified and Diabetes Control and Complications Trial-standardized assay); a fasting plasma glucose (FPG) of at least 7.0 mmol/L (126 mg/dL); a 2-hour post-oral glucose tolerance test (2-h OGTT) plasma glucose of at least 11.1 mmol/L (200 mg/dL); or a random plasma glucose of at least 11.1 mmol/L (200 mg/dL) when accompanied by symptoms of diabetes (e.g. hyperglycemia) (American Diabetes Association, 2010b).

Screening of individuals for T1D is not currently recommended by the ADA, though testing for autoantibodies to identify individuals at risk of developing T1D is possible if other risk factors are present (such as prior transient hyperglycemia or relatives with T1D) (American Diabetes Association, 2010b).

### Achieving Glycemic Control

Glycemic control and restoration of normal metabolism is the major treatment goal for all classes of diabetes. This task is accomplished using several modalities including a variety of pharmacological agents, close personal and laboratory monitoring (e.g. self-blood glucose testing, A1C, and renal function testing), and careful assessment by a variety of health professionals. All these elements, integrated and coordinated, are essential in the management of diabetes and are beyond the scope of this update on the nutritional dimensions of diabetes (Box 49.1). The reader is referred to ADA and European Association for the Study of Diabetes (EASD) publications to review specific recommendations (Rydén *et al.*, 2007; American Diabetes Association, 2010b). This section will focus on nutritional aspects of glycemic control for individuals with T1D.

#### BOX 49.1 Summary of current American Diabetes Association (ADA) nutrition recommendations

- Achieve and maintain blood glucose as near to normal range as is safely possible by balancing dietary intake and physical activity with each other and with any antidiabetic medications.
- Achieve and maintain optimal serum lipid levels that reduce the risk of vascular disease.
- Achieve and maintain blood pressure as near to normal range as is safely possible.
- Provide adequate energy intake for achieving or maintaining a reasonable weight in adults, normal rate of growth and development in children and adolescents, and optimal nutrition during pregnancy and lactation or during recovery from catabolic illnesses.
- Prevent acute complications such as severe hypoglycemia or hyperglycemia.
- Prevent or treat long-term complications such as cardiovascular disease (including hypertension, dyslipidemia, and other risk factors), renal disease, and neuropathy (especially gastroparesis) by modifying dietary intake and physical activity.
- Consider personal and cultural preferences and willingness to change when addressing individual nutrition needs.
- Maintain pleasure of eating by limiting food choices only when supported by scientific evidence.

Adapted from American Diabetes Association (2008).

The Diabetes Control and Complications Trial (DCCT) was conducted in individuals with T1D to compare the effects of intensive versus standard glycemic control (Diabetes Control and Complications Trial Research Group, 1993). Intensive treatment reduced the mean A1C from 9% to 7.2%, and greater attention to dietary strategies accounted for almost one-fourth of the glycemic improvement (Diabetes Control and Complications Trial Research Group, 1988). The risk of development and progression of retinopathy, albuminuria, and neuropathy was reduced by between 50% and 75% over 8 years. Reduction in the risk of complications was linearly related to the reduction in A1C, indicating that risk reduction can be achieved by improving glycemic control, even if a perfect or normal metabolic state is not achieved (Diabetes Control and Complications Trial Research Group, 1988). These accomplishments, as well as efforts to attenuate the two- to three-fold increase in severe hypoglycemia and weight gain, were largely due to educational and nutritional strategies (Delahanty and Halford, 1993; Diabetes Control and Complications Trial Research Group, 1993).

Most recently, longer-term follow-up of the DCCT cohort in the Epidemiology of Diabetes Interventions and Complications (EDIC) study has documented a continued differential in the risk of microvascular (Genuth *et al.*, 2005) and macrovascular (Nathan *et al.*, 2005) complications, even though A1C levels in the two groups have been similar for approximately 8 years.

#### Medical Nutrition Therapy (MNT)

For all classes of diabetes, the first goal of MNT is to assist in the achievement and maintenance of metabolic normality, including blood glucose, lipid, and lipoprotein levels (Box 49.2). For T1D, this means coordinating an individual's insulin regimen with his/her food choices and physical activity (American Diabetes Association, 2008), as well as moment-to-moment measures of blood glucose levels throughout the day with self-blood-glucose monitoring. Multiple insulins are available (Table 49.1) and are often used in various combinations. A typical approach in terms of insulin use is a "basal-bolus" regimen, either via subcutaneous insulin infusion (SCII or pump therapy) or multiple daily injections (MDI) in which insulin is delivered as a bolus before meals in amounts matched to total carbohydrate intake, with basal insulin on board consistently over time. There are other approaches to MDI, which utilize different types of insulin. Patients can either vary their insulin dose to match the amount of food

### BOX 49.2 Summary of medical nutrition therapy (MNT) implementation strategies by class of diabetes

#### Type 1 Diabetes (T1D)

- Assess usual lifestyle, focusing on eating and physical activity habits.
- Plan insulin therapy to match insulin action to lifestyle.
- Monitor blood glucose levels while keeping lifestyle consistent.
- Adjust insulin and lifestyle to achieve blood glucose levels in the target range.
- Create algorithms for adjusting insulin for lifestyle flexibility and to correct blood glucose levels that are not in the target range.

#### Type 2 Diabetes (T2D)

- If overweight, reduce calorie intake to achieve 5% to 10% weight loss.
- Increase physical activity.
- Monitor blood glucose approximately four times per day to assess pattern of glycemic control.
- If postprandial glucose level is high, spread food intake throughout the day (using five or six small meals/snacks rather than having fewer larger ones).
- Reduce and/or modify type of fat to achieve weight and lipid goals.

#### Gestational diabetes (GDM)

- Plan calorie intake to achieve desired weight gain based on desirable body weight.
- Balance carbohydrate intake throughout the day (usually 40–50% of calories).
- Monitor glucose approximately seven times per day; adjust intake to achieve glucose levels in target range.
- Add exogenous insulin if target glucose levels are not achieved by diet alone.

#### Secondary diabetes

- Assess interrelationship between primary disease(s) and secondary diabetes to establish treatment priorities.
- Institute diabetes treatment as needed to avoid short- and long-term complications.

**TABLE 49.1** Insulin preparations: onset, peak, and duration of action

Insulin	Brand name	Onset of action	Peak action	Duration of action
<i>Very rapid acting</i>				
Insulin aspart analog	NovoLog	10–20 minutes	0.5–2.5 hours	3–5 hours
Insulin lispro analog	Humalog			
Regular insulin	Humulin R Novolin R	30–40 minutes	2–4 hours	5–7 hours
<i>Intermediate acting</i>				
NPH insulin	Humulin N Novolin N	1–3 hours	4–10 hours	14–24 hours
Lente insulin	Humulin L	2–4 hours	4–15 hours	16–24 hours
<i>Long acting</i>				
Ultralente insulin	Humulin U	3–4 hours	8–14 hours	18–24 hours
Insulin glargine	Lantus Levemir	1–2 hours	No peak	Approx. 24 hours

Data from Wylie-Rosett *et al.* (2006).

consumed, with additional considerations for physical activity; or meals and physical activity can be held constant in order to match a constant dosing of insulin from day to day. Reduction of insulin dosage is the preferred method of preventing hypoglycemia during and/or after exercise, but this requires planning physical activity ahead of time. For unplanned exercise, increased carbohydrate intake may be needed (American Diabetes Association, 2008). Self-blood-glucose monitoring, education, and experience allow the individual to learn how to keep all of this in balance.

The approaches to nutritional interventions in the DCCT can be a powerful example of ideal nutrition counseling for patients with T1D. Dietary behaviors associated with better glycemic control in the intensively treated group included adherence to an overall meal plan (timing and amount of carbohydrate), appropriate treatment of hypoglycemia (avoiding excess consumption of carbohydrate to treat symptoms), prompt intervention for hyperglycemia (more insulin and/or less food), and consistent consumption of planned evening snacks (Delahanty and Halford, 1993). The mean level of weight gain in the intensively treated group was reduced by 50% after the intervention staff focused on strategies to control weight gain (e.g. avoiding excessive food consumption to prevent and treat hypoglycemia) (Diabetes Control and Complications Trial Research Group, 1988).

The American Dietetic Association has developed and evaluated MNT for patients with T1D (American Dietetic Association, 2002). In the randomized field test, specific guidelines for nutrition counseling were used by dietitians with 24 patients, and results were compared with those of 30 patients receiving “usual counseling” as the control treatment condition. The mean A1C in the guidelines-treated patient group was significantly reduced compared with the control group (1.0% vs. 0.3%) (American Dietetic Association, 2002).

The Dose Adjustment for Normal Eating (DAFNE) study saw improvements in A1C, quality of life, psychological well-being, and satisfaction with treatment in individuals with T1D who learned to use glucose testing to better match insulin to carbohydrate intake despite an increase in the number of daily glucose tests and insulin injections (DAFNE Study Group, 2002; American Diabetes Association, 2008). These quality-of-life results were well-maintained at approximately 4 years, though the glycemic control outcomes were maintained to a lesser extent (Speight *et al.*, 2010).

The process of intensifying T1D management to improve glycemic control involves several stages and individualization of insulin, physical activity, monitoring, and nutrition therapy. The initial stage, usually lasting three or four visits, focuses on basic skills needed by newly diagnosed patients and those with little or no previous nutrition knowledge or a history of poor glycemic control. Nutrition counseling emphasizes consistency of carbohydrate intake and eating times. Blood glucose monitoring provides information about the patterns of response. Patients need to gain a basic understanding of the relationship between insulin action and lifestyle before moving on to more complex planning to achieve better glycemic control and a more flexible lifestyle. An initial bolus dose of insulin is often estimated to provide one unit per 15 g of carbohydrate. Gradually, algorithms are developed to adjust insulin for changes in carbohydrate intake or physical activity. After mastering insulin adjustment and supplementation, patients learn to adjust insulin for changes in food or activity using a ratio of carbohydrate intake to insulin dosage.

### Specific Dietary Considerations

In addition to the ADA, several international societies have developed nutritional guidelines for the management of diabetes (Mann *et al.*, 2004; American Diabetes Association, 2008; Canadian Diabetes Association Clinical Practice Guidelines Expert Committee, 2008). The conclusions drawn by these independent reviews are very similar and so this section will focus on the recent technical review and position statement of the ADA (American Diabetes Association, 2008). Where applicable, additional recommendations developed by the EASD will be presented (Mann *et al.*, 2004).

**Protein.** Recommendations for protein intake in individuals with all classes of diabetes and normal renal function are based on the review for Daily Recommended Intakes by the Institute of Medicine, and are similar to recommendations for the general public: 15–20% of energy intake from protein (Institute of Medicine, 2005); EASD recommends 10–20% of energy intake from proteins in individuals with T1D or T2D and without established nephropathy (Mann *et al.*, 2004). Protein intake needs to be adequate for normal growth, development, and maintenance of body functions. Individuals who may need more than 20% of energy intake from protein include those in a catabolic state, those with growth needs

(children, adolescents, and pregnant women), and individuals on very-low-energy diets to achieve weight loss. In select patients with diabetes and micro- or macroalbuminuria (chronic kidney disease), the ADA recommends reducing protein intake to 0.8–1.0 g per kg body weight per day (American Diabetes Association, 2008) based on evidence that lowering protein intake is associated with improved renal function (urine albumin excretion rate and glomerular filtration rate) in select patients (Dullaart *et al.*, 1993; Pomerleau *et al.*, 1993; Narita *et al.*, 2001; Hansen *et al.*, 2002; Pijls *et al.*, 2002). The EASD recommends a reduction of protein intake to the lower end of this range (0.8 g per kg body weight per day) for individuals with T1D and established nephropathy (Mann *et al.*, 2004). Neither the ADA nor the EASD makes specific recommendations regarding the type of protein (Mann *et al.*, 2004; American Diabetes Association, 2008).

**Fat.** In considering the amount of fat in the diet, one must take into account postprandial glycemic excursions (American Dietetic Association, 2002; Sheard *et al.*, 2004; American Diabetes Association, 2010b). One recent case-control study of 652 individuals with T1D found that higher fat intake was associated with poor glycemic control (Snell-Bergeon *et al.*, 2009). However, whether or not *total* fat intake plays a role in postprandial glucose or overall glycemic control remains controversial. In contrast, it is now well-established that the *type* of fat consumed can influence long-term risk for chronic disease, and therefore the ADA recommends that all individuals with diabetes (T1D, T2D, and GDM) limit their saturated fat to less than 7% of total energy, minimize *trans* fat intake, and limit dietary cholesterol intake to less than 200 mg per day. In addition to these recommendations, the ADA also recommends consumption of two or more servings of fish per week in order to increase intake of n-3 fatty acids, which may contribute to improved cardiometabolic risk factor outcomes, a topic discussed later on in this chapter. Similar to the ADA, the EASD recommends limiting saturated and *trans* fat intakes (less than 10% of total energy intake, less than 8% if LDL cholesterol is elevated); limiting total fat intake to less than 35% of total energy intake (less than 30% if overweight or obese); limiting cholesterol intake (less than 300 mg/day); and consuming two to three servings of fish per week (Mann *et al.*, 2004).

**Carbohydrates.** Dietary carbohydrate is the major determinant of postprandial glucose concentration and is there-

fore integral to glycemic control. The ADA now recognizes *total* carbohydrate as the major determinant of postprandial glucose concentration with the type of carbohydrate as an additional determinant. The restriction of table sugar or sucrose is often used in an attempt to improve glycemic control. However, studies conducted in the 1970s and 1980s indicated that glycemic response to mono- and disaccharides (“table sugars”) did not result in a higher postprandial glycemic response than polysaccharides (“starches”) (Franz *et al.*, 2002). Although fructose has been shown to reduce postprandial hyperglycemia when it is substituted for sucrose or starch, the long-term consequences of high fructose intake on plasma lipids and other complications is unknown. A recent meta-analysis of 16 trials found that the effects of fructose intake on blood lipids in individuals with T2D are heterogeneous (Sievenpiper *et al.*, 2009), and therefore this substitution is not currently recommended by the ADA or EASD (Mann *et al.*, 2004; American Diabetes Association, 2008). The ADA’s nutrition recommendations indicate that glycemic control is not contingent on restricting sucrose and suggest that the decision about sugar consumption should be based on overall nutrition considerations (Franz *et al.*, 2002; Sheard *et al.*, 2004; American Diabetes Association, 2010b). None the less, consumption of large quantities of sugars (e.g. high-fructose corn syrup in soft drinks and other beverages) is a major source of excess calories (Howard and Wylie-Rosett, 2002; Wylie-Rosett *et al.*, 2004).

The glycemic effect of carbohydrate-containing foods has been studied extensively and is the source of considerable debate with respect to the effects of a low-glycemic-index diet on glycemic control and weight (Franz *et al.*, 2002; Brand-Miller *et al.*, 2003; Sheard *et al.*, 2004; Wylie-Rosett *et al.*, 2004). The concept of *glycemic indexing* of food was developed to compare the effects of the quality of carbohydrate while keeping the amount of carbohydrate standardized. The estimated *glycemic load* of foods, meals, and dietary patterns is calculated by multiplying the glycemic index by the amount of carbohydrate in each food and then totaling for all of the foods in a meal or dietary pattern. The role of the glycemic index and/or glycemic load remains very controversial (Schulz *et al.*, 2005), although modifying the type as well as the amount of carbohydrate can improve glycemic control (Kripke, 2005). In a randomized study of a measured carbohydrate exchange diet versus a flexible low-glycemic-index diet, children with T1D on the low-glycemic diet

had significant improvements in A1C and quality of life compared with children with T1D on the measured carbohydrate exchange diet (Gilbertson *et al.*, 2001). Recent results of randomized controlled trials in individuals with T2D have found mixed results: a 6-month trial found a moderate decrease in A1C (Jenkins *et al.*, 2008) while a 1-year trial found no improvements in A1C (Wolever *et al.*, 2008). A third trial found a decrease in A1C in both the low-glycemic diet group and the ADA diet education group at 1 year (Ma *et al.*, 2008). Meta-analysis results have also been mixed: a Cochrane review and a review by Brand-Miller *et al.* found significant decreases in A1C levels while on low-glycemic diets (Brand-Miller *et al.*, 2003; Thomas and Elliott, 2009) whereas Anderson *et al.* found no significant difference in A1C levels between a low- and a high-glycemic diet (Anderson *et al.*, 2004b). These inconsistent results may be due to the inclusion of studies of both T1D and T2D, the small number of included studies due to differences in outcome reporting (e.g. A1C vs. fructosamine vs. both), or other factors. Taking this evidence into account, the ADA and EASD recognize that considering the glycemic index of carbohydrates may provide additional benefit over considering total carbohydrate alone, provided that the overall attributes of the carbohydrate are taken into account (Mann *et al.*, 2004; American Diabetes Association, 2008). They therefore recommend dietary patterns including carbohydrates from whole-grain cereals, fruits, vegetables, legumes, and low-fat milk (Mann *et al.*, 2004; American Diabetes Association, 2008).

In further examining the effects of the amount and type of dietary carbohydrate in diabetes management, it has been documented that *intrinsic variables* can influence the degree of glucose excursions (Sheard *et al.*, 2004). These intrinsic variables include the physical form of the food (i.e. juice vs. whole fruit, mashed potato vs. whole potato), ripeness, degree of processing, type of starch (i.e. amylose vs. amylopectin), style of preparation (e.g. cooking method and time, amount of heat or moisture used), and the specific type (e.g. fettucine vs. macaroni) or variety (e.g. long-grain rice vs. short-grain rice) of the food. *Extrinsic variables* that may influence glucose response include fasting or preprandial glucose level, degree of insulin resistance, and the macronutrient distribution.

Findings from several randomized controlled trials (Jenkins *et al.*, 2002; Lu *et al.*, 2004; Cho *et al.*, 2005b; Tapola *et al.*, 2005; Ziai *et al.*, 2005; Clark *et al.*, 2006; Flammang *et al.*, 2006; Vuksan *et al.*, 2007; Magnoni

*et al.*, 2008) indicate that fiber supplements (additional 4–19 g/day) do not improve glycemia or cardiovascular disease risk factors and therefore the recommended dietary intake for the general public is also recommended for people with diabetes: 14 g per 1000 kcal by the ADA and 20 g per 1000 kcal by the EASD (Mann *et al.*, 2004; American Diabetes Association, 2008). In essence, given the many factors that can affect glucose metabolism, including those beyond nutrition *per se* (e.g. medicines, activity), it is often problematic to predict the exact plasma glucose response to specific carbohydrate-containing foods. Certainly, blood-glucose self-monitoring and experience can help predict the glycemic effects of food products. Furthermore, a variety of methods can be used to estimate the nutrient content of meals, including carbohydrate counting, the exchange system, and experience. With emerging evidence of the relations among postprandial glycemia and cardiovascular disease (Tushuizen *et al.*, 2005), postprandial glucose levels are of increasing importance.

Several important dimensions of “carbohydrates and diabetes” deserve additional consideration.

First, because diabetes complications are associated with tissue-protein glycation, and because heated foods containing sugar can also form glycation end products (Howard and Wylie-Rosett, 2002; Vlassara *et al.*, 2002), concern has been expressed about the possible role of these ingested glycated products in the pathogenesis of diabetes complications. Although only about 10% of ingested advanced glycation end products enter the circulation, they are excreted slowly, especially in patients with diabetes. However, considerably more research is needed to determine whether such dietary components can alter the risk of diabetes complications.

The second consideration is the role of “carbohydrate substitutions.” Fructose, mannitol, and sorbitol are often substituted for sucrose in “sugar-free” products. In experimental studies, these products can shift the balance from oxidation of fatty acids to esterification of fatty acids in the liver, which can in turn increase very-low-density lipoprotein synthesis (Franz *et al.*, 2002). Although the effects on serum lipids are inconsistent, susceptible individuals may have a worsening of dyslipidemia. These sweeteners appear to offer no documented advantage in the management of diabetes over other carbohydrate sources.

Third, reading dietary-product labeling about carbohydrates can be confusing. Many food products list the “net” or “impact” carbohydrate on the front of the label, a value

considerably lower than the “total” carbohydrate listed in the nutrient facts panel. Fiber or fiber plus the sugar alcohols is usually subtracted to obtain the net or impact carbohydrate value, but there is no standardization. If patients with diabetes use these products, monitoring is needed to determine the effects on blood glucose (Wylie-Rosett *et al.*, 2004).

Fourth is the possible role of sugar or fat substitutes. “High-intensity sweeteners” are widely used as a replacement of various types of sugar in food and beverage products. Currently approved intense sweeteners include aspartame, saccharin, acesulfame K, and sucrolose. Patients with diabetes use products containing these sweeteners to control energy and carbohydrate intake (Franz *et al.*, 2002). Fat substitutes mimic one or more of the roles of fat in a food; they may be protein-based (usually from egg white or whey), carbohydrate-based (from modified starches, dextrans, or maltodextrins), or fat-based (from emulsifiers replacing triglycerides with mono- or disaccharides or from modification to achieve a partially absorbable or non-absorbable fat). Patients with diabetes may encounter difficulty eating fat substitutes if food products containing them are higher in energy density than the original product or when carbohydrate calculations are not adjusted (Franz *et al.*, 2002).

Fifth, alcohol consumption among persons with diabetes and the possible impact on both carbohydrate and fat metabolism needs to be considered. In general, the recommendations with regard to alcohol intake are similar to those for the general public, and moderate intake (the equivalent of two or fewer drinks) does not have a major effect on metabolic control (Franz *et al.*, 2002). However, alcohol can inhibit hepatic glucose production and cause hypoglycemia if consumed without food in patients taking insulin or sulfonylureas. Conversely, consuming large amounts of alcohol can raise blood glucose levels, especially in the presence of severe insulin deficiency. Finally, alcohol intake should be avoided or significantly limited by patients with pancreatitis, severe hypertriglyceridemia, severe neuropathy, myocardiopathy, or renal failure.

## Gestational Diabetes (GDM)

### *Etiology and Diagnosis*

In the past, GDM has been defined as glucose intolerance with onset during pregnancy (American Diabetes Association, 2010a). However, due to the high prevalence of T2D and undiagnosed diabetes, the ADA, in conjunc-

tion with the International Association of Diabetes and Pregnancy Study Groups (IADPSG), recommends that women diagnosed with diabetes at their first prenatal visit receive a diagnosis of overt diabetes (not GDM) and then only when the diabetes is resolved upon delivery should the diabetes be classified as gestational.

Approximately 7% of pregnancies are complicated by GDM. The ADA therefore recommends that risk assessment be carried out during the first prenatal visit for all women and that women deemed “very high risk” should be screened as soon as possible thereafter. Criteria for very high risk include: severe obesity, history of GDM or large-for-gestational-age neonate, presence of glycosuria, diagnosis of polycystic ovarian syndrome (PCOS), and strong family history of T2D (American Diabetes Association, 2010b). Women deemed “above low risk” at this visit should be tested at 24 to 28 weeks’ gestation (American Diabetes Association, 2010b). According to the ADA, in order for a woman to be classified as “low risk” and therefore not require GDM screening, she must have *all* of the following characteristics: age less than 25 years, normal weight before pregnancy, member of racial/ethnic group with low diabetes prevalence, no known diabetes in first-degree relatives, no history of abnormal glucose tolerance, and no history of a poor obstetrical outcome (American Diabetes Association, 2010b).

The IADPSG now recommends that *all* women without prior diabetes undergo a 75 g oral glucose test between 24 and 28 weeks’ gestation (American Diabetes Association, 2010b). In 2010 the ADA was planning on collaborating with obstetrical organizations in the United States to consider adopting these IADPSG guidelines. Though this change would result in a significant increase in prevalence of diagnosed GDM, it may be appropriate because evidence shows that treating even mild GDM reduces maternal and neonatal morbidity (Landon *et al.*, 2009). Diagnostic cut points for the fasting, 1-hour, and 2-hour post-glucose load tests were developed using data from the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study (Leary *et al.*, 2010). In order to be diagnosed with GDM, a woman must have two of the following abnormal values: fasting of at least 5.3 mmol/L (95 mg/dL), 1-hour of at least 10.0 mmol/L (180 mg/dL), 2-hour of at least 8.6 mmol/L (155 mg/dL), and 3-hour of at least 7.8 mmol/L (140 mg/dL) (American Diabetes Association, 2010b). Importantly, it is now established that women with GDM are at very high risk for subsequent T2D after delivery. It is therefore recommended by the ADA that all women with

GDM receive a non-pregnant oral glucose tolerance test 6 to 12 weeks postpartum (American Diabetes Association, 2010b). The risk of developing T2D in women with GDM appears to be reduced by proper nutrition, activity, and possibly medication (Jovanovic and Pettit, 2004).

In addition to the adverse consequences for the mother, there appear to be important, long-term, adverse consequences to the child. Results from the HAPO study indicate that maternal glucose is significantly positively associated with neonatal adiposity, a relationship possibly mediated by neonatal hyperinsulinemia (HAPO Study Cooperative Research Group, 2009). Other results from the HAPO study indicate that maternal hyperglycemia is associated with increased levels of fetal umbilical cord blood C-peptide and increased risk of large for gestational age birth weight (HAPO Study Cooperative Research Group *et al.*, 2008).

### **Achieving Glycemic Control**

The goal of therapy in GDM is to achieve and maintain euglycemia in order to improve pregnancy outcomes; reduce risks to the fetus/baby, such as macrosomia and perinatal complications; and perhaps reduce chances of fetal malnutrition, with subsequent increased risk for adult chronic diseases. Women with GDM actually have nutrition requirements similar to those of other pregnant women but are much more likely to also be overweight. The Fourth International Workshop/Conference on Gestational Diabetes Mellitus recommended the following caloric intake per kilogram of present pregnant weight: 167 kJ (40 kcal)/kg if less than 80% desirable body weight (DBW); 126 kJ (30 kcal)/kg if 80–120% DBW; 100 kJ (24 kcal)/kg if 121–150% DBW; and 50 kJ (12 kcal)/kg if more than 150% DBW. A weight gain of 6.8 kg (15 lb) or less is recommended for women who are 150% or more DBW (Jovanovic, 1998). The recommendations addressed the effects of carbohydrate on the 1-hour postprandial glucose level, suggesting limiting carbohydrate to approximately 40% of energy intake and distributing intake across six feedings, with 10–15% for breakfast, 20–30% for lunch, 30–40% for dinner, and 10% for each of three between-meal snacks (Jovanovic 1998).

In addition to reducing caloric intake as described above, the euglycemic diet recommended for women with GDM (sometimes called the Jovanovic diet) also includes recommendations to restrict carbohydrate intake to less than 40% of calories (minimum of 175 g carbohydrate per day) and allows for 40% of calories to come from fat and

20% from protein. Another component of this diet is to have small breakfasts low in carbohydrates to counter the effects of cortisol (Jovanovic, 2000).

Although experiences with the above approaches to MNT during pregnancy among persons with GDM have stood the test of time, most clinicians and investigators feel strongly that randomized, controlled trials are needed to establish more valid guidelines with respect to dietary composition (amounts and types of carbohydrates and fats), weight gain, and energy and carbohydrate restriction.

## **Type 2 Diabetes (T2D)**

Development of T2D is associated with insulin resistance and inadequate pancreatic beta-cell compensatory insulin production (American Diabetes Association, 2010a). Symptoms and signs associated with T2D are often related to the presence of complications and include poor wound healing, blurred vision, recurrent gum or bladder infections, and changes in hand or foot sensation. T2D may be present for several years before a clinical diagnosis is made (Harris *et al.*, 1992). Many individuals are asymptomatic and their glucose elevation may be detected as the result of a routine blood test.

T2D is rare in children under the age of 10, but accounts for an increasing proportion of cases as age increases (SEARCH for Diabetes in Youth Study Group, 2006). Results from the SEARCH for Diabetes in Youth Study indicated that, in 2001, the prevalence (per 1000) of T2D was 0.01 in children less than 10 years of age and 0.42 in children 10–19 years of age (SEARCH for Diabetes in Youth Study Group, 2006).

### **Prevention**

MNT plays a critical role in the primary prevention of T2D: the goal of MNT for individuals at high risk of developing T2D is to improve food choices and physical activity and achieve sustained weight loss and increased beta-cell sensitivity (Tuomilehto *et al.*, 2001; Knowler *et al.*, 2002). Over the past 10 years, studies have been conducted that establish the validity of efforts in primary prevention among those at high risk of developing T2D and the critical role of addressing overweight, obesity, and physical inactivity (Pan *et al.*, 1997; Diabetes Prevention Program Research Group, 2002; Lindström *et al.*, 2003; Uusitupa *et al.*, 2003; Anderson *et al.*, 2004a; Avenell

*et al.*, 2004; Centers for Disease Control and Prevention Primary Prevention Working Group, 2004; Mayer-Davis *et al.*, 2004; Norris *et al.*, 2005; Orchard *et al.*, 2005; Uusitupa, 2005; Wylie-Rosett *et al.*, 2006).

The Da Quing Diabetes Prevention Study was a 6-year lifestyle intervention (diet, exercise, or diet plus exercise) in 577 adults with impaired glucose tolerance in China. The results of this study provided preliminary evidence that diet and exercise interventions can lower the conversion to overt diabetes (Pan *et al.*, 1997). The 20-year follow-up results showed that individuals in the combined intervention group had a 43% lower incidence of diabetes over the 20-year period and spent an average of 3.6 fewer years with diabetes compared with control-group participants (Li *et al.*, 2008).

The Finnish Diabetes Prevention Study (FDPS) was a randomized controlled trial in 522 individuals with impaired glucose tolerance randomized to one of two groups: lifestyle intervention or control (Tuomilehto *et al.*, 2001). The lifestyle intervention involved a low-fat (less than 30% of calories from fat; less than 10% of calories from saturated fat), high-fiber (at least 15 g/1000 kcal) diet in conjunction with moderate-intensity exercise for at least 30 minutes per day (Tuomilehto *et al.*, 2001). After an average follow-up of 3.2 years, results of the FDPS showed a 58% reduction in the incidence of T2D with lifestyle intervention (Lindström *et al.*, 2003; Uusitupa *et al.*, 2003; Uusitupa, 2005). There were small but significant reductions in total cholesterol, triglyceride, and systolic blood pressure and an increase in HDL cholesterol in the lifestyle intervention group but not in the control group, and PAI-1 (an inflammatory marker associated with increased cardiovascular disease risk) levels fell significantly in the lifestyle group in proportion to weight reduction (Uusitupa *et al.*, 2003). Studies from the FDPS of candidate genes affecting energy metabolism showed the importance of genetic polymorphisms in defining responses to lifestyle interventions (Uusitupa, 2005).

The Diabetes Prevention Program (DPP) was a randomized controlled trial conducted in 3234 individuals with impaired glucose tolerance randomized to one of three groups: standard lifestyle recommendations plus metformin, standard lifestyle recommendations plus placebo, or intensive lifestyle modification (Knowler *et al.*, 2002). The intensive lifestyle modification involved a healthy, low-calorie (subtracted 500 to 1000 calories from estimated amount of calories needed to maintain baseline weight), low-fat (25% of calories from fat) diet in conjunc-

tion with at least 150 minutes of moderate-intensity physical activity per week with an overall goal of achieving and maintaining a weight reduction of at least 7% of initial body weight (Diabetes Prevention Program Research Group, 2002; Knowler *et al.*, 2002). The program consisted of a 16-session core curriculum in which participants received individualized advice on how to reach their goals (Diabetes Prevention Program Research Group, 2002).

After an average follow-up period of 2.8 years, results of the DPP showed that the incidence of diabetes was reduced by 58% in the intensive lifestyle intervention group compared with only 31% in the metformin group (Diabetes Prevention Program Research Group, 2002; Centers for Disease Control and Prevention Primary Prevention Working Group, 2004; Mayer-Davis *et al.*, 2004; Wing *et al.*, 2004; Orchard *et al.*, 2005; Wylie-Rosett *et al.*, 2006). Further analysis revealed that weight loss was the dominant predictor of the observed reduced diabetes incidence: when adjusted for changes in diet and physical activity, each kilogram of weight loss resulted in a 16% reduction in diabetes risk (Hamman *et al.*, 2006). Furthermore, a lower percent of calories from fat and increased physical activity accounted for the weight loss, indicating that it was through these intermediates that the diabetes risk reduction was accomplished (Hamman *et al.*, 2006). Treatment effects did not differ by sex, race, or ethnic group. Recent 10-year follow-up of the DPP found that the cumulative incidence of diabetes remained the lowest in the intensive lifestyle intervention group (Gillis *et al.*, 2009).

Unlike the intensive lifestyle intervention, which was effective across the entire baseline body weight and fasting glucose ranges, metformin was ineffective in those with a BMI less than 30 kg/m<sup>2</sup> and minimally effective in those with a BMI less than 35 kg/m<sup>2</sup> or with a fasting glucose level less than 6.1 mmol/L (110 mg/dL). As in the FDPS, insulin sensitivity improved in the intensive lifestyle intervention group, with a smaller increase in the metformin group, but did not change in the placebo group. Insulin secretion decreased in all groups, but was associated with improved beta-cell function only in the intensive lifestyle intervention group. The intensive lifestyle intervention resulted in a lower prevalence and need for medical treatment of hypertension and dyslipidemia. It also lowered inflammatory biomarkers (CRP and PAI-1) associated with increased cardiovascular disease risk. In the placebo group, of the participants who did not have metabolic

syndrome at baseline, 51% had developed it at the study's end. The lifestyle intervention reduced the prevalence by 33%; metformin reduced it by only 15%.

The simulated lifetime cumulative incidence of microvascular and macrovascular complications and life expectancy for the DPP indicated that, compared with placebo, the lifestyle intervention would reduce the cumulative incidence of blindness by 39%, end-stage renal disease by 38%, amputation by 35%, stroke by 9%, and coronary heart disease by 8%, and would increase life expectancy by 0.5 years (Wylie-Rosett *et al.*, 2006). Compared with the placebo intervention, the lifestyle intervention cost per quality-adjusted life-years would be approximately \$1100 (Wylie-Rosett *et al.*, 2006). For metformin, the cost per quality-adjusted life-years was calculated using costs of the generic form of the drug as \$1800 (Wylie-Rosett *et al.*, 2006).

Both the DPP and FDPS asked participants to self-monitor their food intake (Lindström *et al.*, 2003; Uusitupa *et al.*, 2003; Mayer-Davis *et al.*, 2004). In the FDPS, participants were asked to complete 3-day food records four times per year; in the DPP, participants were asked to self-monitor their activity, food intake, calories, and fat grams daily during the first 24 weeks and then at least 1 week per month thereafter. In the DPP, the frequency of dietary self-monitoring was related to success at achieving both the physical-activity goal and the weight-loss goal. Moreover, participants who were 65 or older were more likely to complete self-monitoring records, report a lower percentage of calories from fat, and meet the activity and weight-loss goals than those who were less than 45 years old (Mayer-Davis *et al.*, 2004). Thus, it is not surprising that older participants had a greater (71%) risk reduction in the development of diabetes with lifestyle intervention (Knowler *et al.*, 2002; Wing *et al.*, 2004). Lifestyle coaches in the DPP taught the participants to use a problem-solving approach to manage high-risk situations (stress, vacations, eating out) and used a toolbox approach to deal with barriers to lifestyle change (Diabetes Prevention Program Research Group, 2002).

Studies independent of the FDPS and DPP have found that an increase in fiber and whole-grain consumption may help prevent or delay the onset of diabetes (American Diabetes Association, 2008). Furthermore, the inclusion of an emphasis on increased fiber consumption in the FDPS and DPP lifestyle intervention groups lends support to a possible role of fiber consumption in the primary prevention of T2D.

Thus, current efficacy data from large randomized controlled trials (FDPS and DPP) support a moderately low-fat diet as part of a lifestyle intervention for weight loss and primary prevention of T2D. It is not unreasonable to consider other dietary strategies and distributions of macronutrients for achieving weight-loss goals (Davis *et al.*, 2009). A meta-analysis of randomized controlled trials that compared low-fat diets with non-energy-restricted low-carbohydrate diets found that the latter are effective and safe alternatives for weight loss (Nordmann *et al.*, 2006). Furthermore, a recent randomized trial (PREDIMED study) observed a lower 4-year incidence of diabetes in the two Mediterranean diet groups compared with the low-fat group in the absence of significant changes in weight (Salas-Salvado *et al.*, 2011).

The HEALTHY study was a randomized, controlled, multicenter study in middle-school-aged children in the United States, designed to reduce risk factors associated with T2D development (Gillis *et al.*, 2009). Preliminary results indicate that, although there was a decrease in the combined prevalence of overweight and obesity in schools (primary outcome), there were no differences between intervention and control schools. Intervention schools did, however, have significantly greater decreases in BMI z-scores, percentage of students with a waist circumference at or above the 90th percentile, fasting insulin levels, and obesity prevalence (HEALTHY Study Group *et al.*, 2010). The efficacy of the intervention in prevention of T2D will require additional participant follow-up and further testing.

### **Etiology and Diagnosis**

The etiology of T2D, similar to T1D, is likely a complex interaction between environment and genetic predisposition, as indicated by the wide variability in the prevalence of T2D in cross-sectional and prospective studies (Permutt *et al.*, 2005; Roche *et al.*, 2005). Further complicating matters is the fact that, unlike T1D, the incidence of T2D shows strong social patterning due to differential exposure to obesogenic environments (Whiting *et al.*, 2010). Many indigenous populations are lean and have low rates of T2D, but the rates of diabetes and obesity dramatically increase with lifestyle or environmental changes (Wild *et al.*, 2004; Centers for Disease Control and Prevention, 2008).

Android fat distribution is associated with greater insulin resistance than gynoid fat distribution. Abdominal girth of at least 89 cm (35 in) in women and at least 102 cm

(40 in) in men is considered an indicator of increased insulin resistance, hypertension, and dyslipidemia (Obesity Education Initiative Expert Panel, 1998). Insulin resistance increases with age, and the incidence of diabetes rises sharply in the elderly (American Diabetes Association, 2010a).

In a few patients, genetic mutations appear to be associated with T2D (Roche *et al.*, 2005; American Diabetes Association, 2010a). For example, recent work using the DPP data has led to the identification of 27 single nucleotide polymorphisms (SNPs) in the SLC30A8 gene (codes for a protein that transports zinc molecules into insulin granules in beta-cells, which is essential for insulin storage and processing) that are associated with T2D (Billings *et al.*, 2010). A “thrifty genotype” that favors energy efficiency and could be maladaptive in an environment with an energy-dense food supply and low level of physical activity is another genetic concept being considered (Prentice *et al.*, 2005). Finally, metabolic adaptations in the fetus of a malnourished and/or hyperglycemic mother may be associated with a “thrifty phenotype” in the newborn and subsequent insulin resistance and increased risk for T2D (Bateson *et al.*, 2004).

There have been numerous studies examining the role of various nutritional (or activity) factors and the incidence of T2D. From the most general perspective, these studies can be divided into three categories: studies focusing on specific dietary components (examples include nuts, coffee, and fiber [Freeman, 2005; Lovejoy, 2005; Murakami *et al.*, 2005; van Dam and Hu, 2005]), studies examining total calories/weight loss (Pan *et al.*, 1997; Diabetes Prevention Program Research Group, 2002; Lindström *et al.*, 2003; Uusitupa *et al.*, 2003; Centers for Disease Control and Prevention Primary Prevention Working Group, 2004; Jack *et al.*, 2004; Mayer-Davis *et al.*, 2004; Wing *et al.*, 2004; Uusitupa, 2005; Orchard *et al.*, 2005; Wylie-Rosett *et al.*, 2006), and studies examining meal patterns (examples include Mediterranean diets [Karantonis *et al.*, 2006; Esposito *et al.*, 2009] and vegetarian diets [Barnard *et al.*, 2009]). In general, the studies that have identified specific food ingredients as related to T2D incidence have been large observational studies that particularly address the statistical significance of relative risk as the determinant of importance (Lovejoy, 2005; Murakami *et al.*, 2005; van Dam and Hu, 2005). The randomized trials that address total calories consumed along with accompanying increased physical activity and meal patterns address absolute risk and “numbers needed

to treat” as indicators of public health importance (Pan *et al.*, 1997; Diabetes Prevention Program Research Group, 2002; Lindström *et al.*, 2003; Uusitupa *et al.*, 2003; Centers for Disease Control and Prevention Primary Prevention Working Group, 2004; Jack *et al.*, 2004; Mayer-Davis *et al.*, 2004; Wing *et al.*, 2004; Orchard *et al.*, 2005; Uusitupa, 2005; Wylie-Rosett *et al.*, 2006).

Three categories of increased risk of developing diabetes are currently recognized by the ADA: an FPG between 5.6 and 6.9 mmol/L (100 and 125 mg/dL), defined as having impaired fasting glucose (IFG); a 2-h OGTT between 7.8 and 11 mmol/L (140 and 199 mg/dL), defined as having impaired glucose tolerance (IGT); an A1C between 5.7 and 6.4% with values between 6.0 and 6.4 considered very high risk (American Diabetes Association, 2010a).

It is estimated that approximately one-fourth of individuals with diabetes in the United States are currently undiagnosed. Therefore, it is recommended that all individuals, regardless of age, with a BMI  $\geq 25$  kg/m<sup>2</sup> and at least one other risk factor are tested for diabetes. Risk factors include physical inactivity, a first-degree relative with diabetes, hypertension (blood pressure of at least 140/90 mm Hg or on therapy for hypertension), a high-density lipoprotein (HDL) cholesterol level less than 35 mg/dL (0.90 mmol/L) and/or a triglyceride level greater than 250 mg/dL (2.82 mmol/L), an A1C of at least 5.7%, IFG, IGT, other clinical conditions associated with insulin resistance (e.g. acanthosis nigricans), a history of cardiovascular disease, women with PCOS, women who delivered a baby weighing more than 9 lb (4.1 kg) or who were diagnosed with GDM, and being a member of a high-risk ethnic population (e.g. African-American, Latino, Native American, Asian-American, Pacific Islander) (American Diabetes Association, 2010a). In the absence of any risk factors, it is recommended that testing begin at 45 years of age. If tests are normal, then testing should occur every 3 years. Testing should occur in a health-care setting and is equivalent to screening because the tests for diagnosis and for screening are the same.

Consistent with the guidelines for testing for T2D in adults, the ADA recommends testing overweight children (defined as BMI greater than the 85th percentile for age and sex, weight for height greater than the 85th percentile, or weight greater than 120% of ideal for height) who also have any two of the following risk factors: family history of T2D (first- or second-degree relative), maternal history of diabetes or GDM during child’s gestation, member of high-risk race/ethnicity group (Native American, African-

American, Latino, Asian-American, Pacific Islander), or signs/symptoms associated with insulin resistance (e.g. acanthosis nigricans, hypertension, dyslipidemia, PCOS, small for gestational age birth weight) (American Diabetes Association, 2000).

### **Achieving Glycemic Control**

The United Kingdom Prospective Diabetes Study (UKPDS) examined the benefit of metabolic control (glucose and blood pressure) in patients newly diagnosed with T2D (UK Prospective Diabetes Study Group, 1998a,b,c). Fundamentally, the UKPDS confirmed that the findings of the DCCT also applied to T2D. There was a reduction in macrovascular and microvascular complications, and the best results were achieved in those individuals who had both glucose and blood-pressure control. Similarly, there was a clear dose–response relationship between metabolic and blood-pressure control and the risk of diabetes complications.

The Lifestyle Over and Above Drugs in Diabetes (LOADD) randomized, controlled trial in New Zealand looked at the impact of intensive nutritional counseling over a period of 6 months in patients with T2D ( $n = 93$ ). Significant reductions in the intervention group were observed in A1C, weight, BMI, and waist circumference compared with the control group (Coppell *et al.*, 2010).

### **Medical Nutrition Therapy (MNT)**

Similar to T1D, glycemic control and restoration of normal metabolism in T2D is accomplished using several modalities including a variety of pharmacological agents, close personal and laboratory monitoring, and careful assessment by a variety of health professionals. MNT for treatment of T2D progresses from prevention, primarily through weight loss, to improving insulin sensitivity, to improving metabolic control of glucose, lipids, and blood pressure. Among efforts to establish normal metabolism to prevent longer-term diabetes complications, reducing cardiovascular disease risk is a primary goal for MNT and the overall management of T2D, as well as T1D; a topic that will be discussed in more detail later on in this chapter (American Diabetes Association, 2010b). Diet and exercise are considered to be the first step to achieve euglycemia, with focus often on the health risks associated with overweight and obesity. However, medical care standards and experience with T2D indicate that, to reduce both cardiovascular and microvascular risk, patients often must take five or more medications to achieve blood glucose,

blood pressure, and cholesterol goals, as well as low-dose aspirin. Supporting the benefits of MNT, the amount of medication needed is likely to be less with a modest weight loss of 5–10% of body weight (Obesity Education Initiative Expert Panel, 1998; Norris *et al.*, 2004; American Diabetes Association, 2010b). The impact of weight loss is most dramatically demonstrated by bariatric surgery, a procedure for selected patients with T2D and obesity. However, the effects of bariatric surgery appear to be largely independent of weight loss and may be due to changes in hormonal metabolism (Buchwald *et al.*, 2004).

Guidelines for MNT in T2D, focusing particularly on controlling glycemia, dyslipidemia, and hypertension, have been validated and supported by a randomized trial (American Dietetic Association, 2002). Furthermore, the Look-AHEAD (Action for Health in Diabetes) Study, an ongoing multicenter, randomized controlled trial of an intensive lifestyle intervention in 5145 patients with T2D, found that a weight loss of 8.6% was associated with improved diabetes control, as indicated by reductions in diabetes medication use and A1C levels (Look AHEAD Research Group *et al.*, 2007). Four-year results of the Look-AHEAD study indicate that the improvements in weight (loss of 6.15%), fitness, and A1C observed in the intensive lifestyle intervention group compared with the control group were sustained (Look AHEAD Research Group, 2010). When lifestyle changes or MNT do not achieve euglycemia, combinations of oral agents (Table 49.2) with or without concomitant insulin may be prescribed to improve insulin secretion and/or insulin sensitivity, with the starting medication typically metformin. Likewise, for both hypertension and hyperlipidemia a variety of agents exist and are increasingly being used in combination to treat T2D (American Diabetes Association, 2010b).

Dietary fat composition may require additional consideration in individuals with T2D. Decreasing dietary fat and increasing carbohydrate intake can potentially worsen the dyslipidemia of T2D by lowering HDL cholesterol levels and increasing the level of VLDL cholesterol, triglyceride, and LDL cholesterol – effects that can be ameliorated by weight loss (American Dietetic Association, 2002; Institute of Medicine, 2005). Studies that looked at the effect of supplementation of n-3 fatty acids in individuals with T2D have found mixed results: four randomized, controlled trials found that n-3 fatty acid supplementation increased fasting plasma glucose by a small (but significant) amount (Woodman *et al.*, 2002; Pedersen *et al.*, 2003; Mostad *et al.*, 2006), whereas one

**TABLE 49.2** Oral antidiabetic medications: mechanism of action and side-effects

Medication class and mechanism of action	Generic name	Brand name	Comments and side-effects
<i>Sulfonylureas</i> Stimulate the pancreatic beta-cells to secrete more insulin	Chlorpropamide (first-generation)	Diabinese	Hypoglycemia risk, especially when using Chlorpropamide and Glyburide compared with other sulfonylureas or in the elderly
	Glyburide (second-generation)	Micronase, Diabeta, Glynase Pres Tab	Weight gain (approximately 2 kg) upon treatment initiation common
	Glipizide (second-generation)	Glucotrol, Glucotrol XL	Higher doses should be avoided
	Glimepiride (third-generation)	Amaryl	
<i>Meglitinides (glinides)</i> Stimulate the pancreatic beta-cells to secrete more insulin	Repaglinide	Prandin	Must be administered more frequently than sulfonylureas
	Nateglinide	Starlix	Hypoglycemia risk, less than with sulfonylureas for Nateglinide Weight gain similar to sulfonylureas
<i>Biguanides</i> Reduce output of glucose from the liver	Metformin	Glucophage	May have gastrointestinal side-effects Interferes with B <sub>12</sub> absorption but rarely associated with anemia Contraindicated in patients with renal dysfunction Check creatinine clearance if over 65 years of age
<i>Alpha-glucosidase inhibitors</i> Decrease rate of digestion of carbohydrate-containing foods	Acarbose	Precose	Reduced risk of hypoglycemia compared with other drug classes
	Miglitol	Glyset	Gastrointestinal side-effects, including gas and diarrhea
<i>Thiazolidinediones</i> Enhance insulin sensitivity	Rosiglitazone	Avandia	Fluid retention, which can lead to congestive heart failure in the elderly or other high-risk patients
	Pioglitazone	ACTOS	Contraindicated in liver disease. Check liver enzymes on an ongoing basis Weight gain
<i>Dipeptidyl peptidase 4 inhibitors</i> Prevent breakdown of GLP-1	Sitagliptin	Januvia	Do not cause hypoglycemia Upper respiratory tract infection risk

Data from Nathan *et al.* (2009).

small study found that supplementation significantly decreased A1C (Pooya *et al.*, 2010). A meta-analysis conducted using trials up to 2008 found no significant effect on glycemia or insulinemia in individuals receiving n-3 fatty acids vs. placebo supplements (Hartweg *et al.*, 2009).

## Approaches to Reduce Complications of Chronic Disease Risk Factors in Type 1 and Type 2 Diabetes

Cardiovascular disease and its complications are by far the greatest cause of death in individuals with diabetes. Therefore, reduction in cardiovascular disease risk factors is a major treatment goal for all patients with diabetes.

### **Glycemic Control to Reduce Complications of Chronic Disease Risk Factors in T2D**

The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study was a randomized controlled trial that looked at the effects of intensive glycemic control (target A1C less than 6%) vs. standard glycemic control (target A1C between 7 and 7.9%) in 10 251 patients with extant diabetes on cardiovascular disease outcomes. The treatment arm receiving intensive control of blood pressure and lipids did not have a significant improvement over controls (Ismail-Beigi *et al.*, 2010). Results from two other large, randomized, controlled trials, the ADVANCE study and the Veterans Affairs Diabetes Trial (VADT), also found no significant reduction in cardiovascular disease risk with intensive glycemic control (ADVANCE Collaborative Group *et al.*, 2008; Duckworth *et al.*, 2009). The reader is referred to the ADA's position statement on intensive glycemic control and the prevention of cardiovascular events for more information on this topic (Skyler *et al.*, 2009). Together, the results of these three trials indicate that intensive treatment may not provide any additional benefit, at least in the time period of treatment and populations observed in these studies (Skyler *et al.*, 2009).

### **MNT to Reduce Complications of Chronic Disease Risk Factors in T1D and T2D**

The Look-AHEAD Study also looked at the effect of achieving and maintaining weight loss on cardiovascular disease risk reduction. One-year results of the intervention indicated that the clinically significant weight loss (8.6%) was associated with reductions in cardiovascular disease risk factors as indicated by blood pressure, triglycerides, HDL cholesterol, and urine albumin-to-creatinine ratio

(Look AHEAD Research Group *et al.*, 2007). Reductions in C-reactive protein have also been observed (Belalcazar *et al.*, 2010). Four-year results of the study indicate that the improvements in systolic blood pressure and HDL cholesterol levels observed in the intensive lifestyle intervention group compared with the control group were sustained (Look AHEAD Research Group, 2010).

Results from a recent 2-year study of weight loss on a low-carbohydrate diet found significant increases in HDL cholesterol and significant decreases in total cholesterol in comparison with a low-fat diet (Shai *et al.*, 2008). This study also observed significant increases in insulin sensitivity in individuals with diabetes on a Mediterranean diet in comparison with a low-fat diet (Shai *et al.*, 2008).

Although MNT treatment guidelines focus on glycemic control, it is recognized that achieving an optimal lipid and lipoprotein profile and blood pressure level are also very important aspects of diabetes treatment. For the treatment and management of cardiovascular disease risk, the ADA recommends dietary patterns high in fruits, vegetables, whole grains, and nuts, low sodium intake (for patients with diabetes and symptomatic heart failure less than 2000 mg per day; in normotensive and hypertensive patients less than 2300 mg per day), and, for most individuals, a modest amount of weight loss (American Diabetes Association, 2008). To date, there are no large-scale randomized controlled trials of overall MNT recommendations and cardiovascular disease risk reduction in individuals with diabetes. However, improvements in glycemic control (as measured by A1C) in individuals with both T1D (DCCT) and T2D (UKPDS) have been associated with cardiovascular disease risk reduction (Stratton *et al.*, 2000; Nathan *et al.*, 2005).

### **Specific Dietary Components**

**Fat.** There is little evidence to support suggestions that changing the percent of calories from fat (e.g. total fat intake) has any influence on cardiovascular disease risk factors in individuals with diabetes. However, as with glycemic control, the type of fat may play an important role. The ATP III guidelines classify most individuals with diabetes as being at high risk for cardiovascular disease within the next 10 years – that is, diabetes is a cardiovascular disease “risk factor equivalent” (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). Thus, the goals of treatment are lower than in the absence of diabetes: serum low-density lipoprotein level less than 2.6 mmol/L (100 mg/dL) and dietary

goals with less than 7% of calories from saturated fat, minimal *trans* fat intake, and less than 200 mg of cholesterol per day.

Both monounsaturated and polyunsaturated fatty acids reduce LDL cholesterol levels, but they may differ with respect to their effect on HDL cholesterol levels. Reducing intake of total fat and saturated fatty acids in particular tends to further reduce a low HDL cholesterol level associated with insulin resistance and diabetes. However, weight loss may ameliorate this effect. In a meta-analysis of dietary intervention studies in patients with T2D, Garg (1998) reported that diets high in monounsaturated fats reduced the VLDL cholesterol and triglyceride levels by 22% and 19% respectively and did not adversely affect body weight.

Hydrogenation of the *cis*-isomer of fatty acids in oils creates *trans* isomers that function like more saturated fatty acids in food products and potentially in the human body. Epidemiological studies have linked *trans* fat consumption to increased cardiovascular disease risk, but to date there are no intervention studies that specifically address the extent to which *trans* fat intake may increase the risk of cardiovascular disease. Individuals with diabetes and/or other risk factors for cardiovascular disease should keep *trans* fat intake as low as possible (Christiansen *et al.*, 1997).

Considerable interest exists in the intake of fish and n-3 fatty acids (Connor, 2004). For example, the rates of diabetes and of cardiovascular disease are lower in population groups with a high fish intake, perhaps because fatty acids from fish and other sources that have the double bond in the n-3 position reduce triglyceride production (Nettleton and Katz, 2005). A recent meta-analysis of clinical trials of fish oils conducted in patients with T2D showed a 7% reduction in fasting triglyceride levels accompanied by a slight increase in LDL cholesterol (Hartweg *et al.*, 2009). Overall, the current evidence supports a possible role of n-3 fatty acid supplementation in decreasing triglyceride levels in individuals with diabetes, but a potential role in LDL and/or HDL levels is not clear.

**Carbohydrates.** The American Heart Association (AHA) recently released a scientific statement concerning the role of dietary sugar intake in cardiovascular health (Johnson *et al.*, 2009). Although clinical trial evidence linking additional consumption of sugars with adverse outcomes is missing, observational data indicate that increased intake of added sugars (the majority of which is in the form of sugar-sweetened beverages) is associated with increased energy intake and higher body weight along with decreased

intake of essential vitamins. Based on this evidence and the fact that intake of added sugars greatly exceeds the 2005 United States Dietary Guidelines for discretionary calories (Institute of Medicine, 2005), the AHA now recommends limiting intake of added sugars to half discretionary calories, which equates to no more than 100 calories per day for women and no more than 150 calories per day for men (Johnson *et al.*, 2009). It is important to note that this recommendation is intended as a pragmatic way to limit caloric intake and is not based on a particular problem caused by carbohydrate or sugar intake.

## Micronutrients and Supplements

The relations between diabetes and micronutrients are reciprocal: micronutrients can affect diabetes, and diabetes and its complications can alter the metabolism and impact of micronutrients. Poorly controlled diabetes can alter vitamin and mineral status, and micronutrients can affect glucose and overall energy homeostasis.

Studies indicate that many patients with diabetes consume supplements and do not alert their health-care professionals about this use (Venters *et al.*, 2004). Consultation regarding the use of supplements should help patients with diabetes evaluate the potential risks and benefits of these products (Barringer *et al.*, 2003; Cefalu and Hu, 2004; Cicero *et al.*, 2004; Liu *et al.*, 2004; Narendhirakannan *et al.*, 2005; Schwartz *et al.*, 2005). One clinical study that evaluated the effects of a multivitamin supplement on quality of life and missed days of activity found some benefit for the subgroup with diabetes and those over 65 years of age (Barringer *et al.*, 2003). Although antioxidant nutrients appear to play a role in reducing oxidative stress and possibly in insulin sensitivity, there is insufficient evidence at present to warrant making any specific recommendation about use of the substances in diabetes management (American Diabetes Association, 2010b). This level of uncertainty has been raised by two large randomized controlled trials that failed to demonstrate a positive impact of antioxidant vitamins on cardiovascular disease, including patients with diabetes (Toole *et al.*, 2004; Lonn *et al.*, 2005). A survey of providers of alternative therapies used in diabetes found that the 10 most commonly recommended nutrient supplements were biotin, vanadium, chromium, vitamin B<sub>6</sub>, vitamin C, vitamin E, zinc, selenium, alpha-lipoic acid, and fructooligosaccharides, and the 10 most commonly recommended herbal supplements were gymnema, psyllium,

fenugreek, bilberry, garlic, Chinese ginseng, dandelion, burdock, prickly pear cactus, and bitter melon (Cicero *et al.*, 2004). Although these products may have some blood-glucose-lowering effects, a patient's use of these products is not generally evaluated as part of his or her medical or dietary history. Having an open dialog about the use of alternative therapies provides the opportunity to explore how they may interact with prescribed medications, either beneficially or harmfully (Cicero *et al.*, 2004).

Some of these supplements have received more attention – in the laboratory, clinical world, and media – than others. Although some research suggests that chromium supplementation may improve insulin sensitivity and glucose metabolism in patients with diabetes, research results are mixed. Limitations of the chromium studies to date include inadequate sample size, short duration, non-randomized design, lack of information about the pre-study chromium status of the study population, and different doses of chromium supplementation – all of which may account for the variability of the findings (Cefalu and Hu, 2004). Long-term clinical trials are needed to examine chromium in relation to diabetes using well-defined outcomes (e.g. T2D and cardiovascular disease) and metabolic parameters and to assess the safety of long-term chromium supplementation (Cefalu and Hu, 2004).

Magnesium modulates glucose transport across cell membranes, and poorly controlled diabetes can induce hypomagnesemia by increasing urinary excretion, with possible increased insulin resistance (Franz *et al.*, 2002). The clinical usefulness of supplementation, usually by intake of magnesium-based antacids, for patients with T2D and insulin resistance, is not, however, established. As another example of the present disconnect between laboratory and clinical studies, in laboratory experiments zinc and antioxidant requirements increase during wound healing (Franz *et al.*, 2002), but the need for supplementation for every patient postsurgery or with a foot ulcer remains to be confirmed (American Diabetes Association, 2010b).

Other inorganic trace elements such as vanadium, copper, iron, potassium, sodium, and nickel may play an important role in the maintenance of normoglycemia by activating the beta-cells of the pancreas. Sources of these elements are often contained in various alternative/complementary medications. For example, analysis of the mineral content of the leaves from four plants used in Asian traditional medicine (*Murraya koenigii*, *Mentha piperita*, *Ocimum sanctum*, and *Aegle marmelos*) yielded mod-

erate levels of copper, nickel, zinc, potassium, and sodium (which may account for the reported therapeutic benefit if the basic food supply is inadequate) (Narendhirakannan *et al.*, 2005). However, the need for this supplementation, should the nutrients in the dietary pattern recommended in the 2005 Dietary Guidelines be accomplished, is not apparent among persons with diabetes based on more valid clinical studies.

The B-vitamin group is a final category of “supplements” to consider, particularly thiamin, riboflavin, niacin, and vitamin B<sub>6</sub>, all of which are involved in glucose metabolism. Among persons with poorly controlled diabetes and polyuria associated with hyperglycemia, requirements may be altered by excess excretion in the urine. Ironically, nicotinic acid itself can worsen glycemic control when it is used to treat hyperlipidemia; however, uncontrolled studies suggest that it may also help to protect beta-cell function from autoimmune destruction. Folate and vitamin B<sub>12</sub> levels play a role in homocysteine metabolism, and plasma levels of these nutrients are inversely related to homocysteine levels. In patients with T2D, plasma homocysteine concentration is a significant predictor of cardiovascular events and death, perhaps due to worsening of endothelial dysfunction and/or structural vessel properties induced by oxidative stress (Huijberts *et al.*, 2005). Elevated fasting homocysteine levels appear to be a biomarker for subsequent development of T2D in women (Cho *et al.*, 2005a). However, to confirm that a particular measurement is actually a risk factor (versus a risk marker), it is desirable that a randomized, controlled trial be conducted to show that the alteration in the compound being measured is associated with benefits to patients. Such clinical trials are being completed, and results do not indicate a relationship between homocysteine perturbations and subsequent stroke or myocardial infarctions (Bønaa *et al.*, 2006; Lonn *et al.*, 2006).

## Other Types of Diabetes

### **Monogenic Diabetes**

Monogenic diabetes is a class of diabetes associated with genetic defects in beta-cell function. They are frequently associated with early onset of hyperglycemia (typically before 25 years of age). Three common forms of monogenic diabetes include maturity-onset diabetes of the young (MODY) and mutations in KIR6.2 (KCNJ11) and SUR1 (ABCC8). MODY is an autosomal dominant disorder associated with mutations on one of six common

genetic loci. A mutation on chromosome 12 in the hepatocyte transcription factor, HNF-1 $\alpha$ , is the most common form of the disorder. Individuals with MODY have impaired insulin secretion but normal insulin action. Mutations in the ATP-sensitive potassium transporter genes, KCNJ11 and ABCC8, are associated with glucose intolerance (van Dam *et al.*, 2005). In the majority of cases, these forms of diabetes are best managed with sulfonylureas rather than insulin, and glycemic control is typically not difficult to achieve.

### Secondary Diabetes

Disorders directly affecting the pancreas can secondarily cause diabetes (American Diabetes Association, 2010a). Diabetes can also be secondary to endocrinopathies leading to increased counter-regulatory hormone production [e.g. acromegaly (excess growth hormone), Cushing's syndrome (excess cortisol), glucagonoma (excess glucagon), and pheochromocytoma (excess epinephrine)]. Pharmacological agents can also create insulin resistance or damage to the pancreatic beta-cells. Steroids and novel antipsychotic medications that increase insulin resistance and visceral fat may increase insulin requirements beyond endogenous capacity (American Diabetes Association, 2004, 2010a; Centers for Disease Control and Prevention, 2008).

Cystic fibrosis-related diabetes (CFRD) is the most common co-morbidity in people with CF. The addition of diabetes to CF is associated with poorer nutrition outcomes in addition to more severe inflammatory lung disease and greater mortality from respiratory failure, especially in women (American Diabetes Association, 2010b).

### Global Public Health Issues

It is estimated that approximately 366 million people worldwide currently have diabetes (International Diabetes Federation, 2011). In 2011, approximately 4.6 million deaths were estimated to be attributable to diabetes (International Diabetes Federation, 2011). These high-prevalence and mortality estimates have led the International Diabetes Federation (IDF) to conclude that diabetes is "one of the most challenging health problems in the 21st century" (International Diabetes Federation, 2009). Approximately 70% of diabetic individuals live in low- and middle-income countries and it is now widely recognized that these countries carry the greatest diabetes

burden (International Diabetes Federation, 2009). It has been proposed that this heavy burden is the result of population aging, urbanization, and the resulting changes in diet and physical activity. However, there is growing evidence that, in some middle-income countries, especially including India and China, the prevalence in rural areas is approaching that in urban areas, perhaps related to mechanization (Yang *et al.*, 2010).

The estimated direct medical cost for prevention and treatment of diabetes worldwide was approximately US\$376 billion in 2010 and will exceed US\$490 billion by 2030 (Zhang *et al.*, 2010). Total costs are substantially higher due to loss of productive years of life, particularly in developing countries.

Achieving population-level impact in the primary, secondary, and tertiary prevention of diabetes is a complex task. Addressing nutrition issues at all three levels requires collaborations involving a wide variety of partners to ensure an appropriate balance between efforts to prevent and treat diabetes complications and efforts to prevent the onset of diabetes. Clearly, factors beyond what occurs in a doctor's office have a dramatic impact on both preventive and management strategies for chronic diseases, including all classes of diabetes. In the United States, insurance status, federal and state policies, opportunities for proper nutrition and activity at schools, reimbursement strategies, and federal deficits can all have a significant impact on the individual health provider and/or patient in terms of how well diabetes can be prevented and/or treated. Typically, these are not issues that are discussed in the office, but they must be included in larger efforts to address all aspects of nutrition and diabetes (Jack *et al.*, 2004; Ogilvie and Hamlet, 2005). The ability to capitalize on prevention opportunities requires a strong infrastructure to plan and support interventions, nurture partnerships, and monitor and evaluate progress. Much of the effort to date has targeted identifying individuals at risk for diabetes and also diabetes complications, and increasing public awareness of diabetes risks, especially in communities with populations at high risk of developing diabetes.

In the United States, many efforts within the voluntary, professional, academic, and private sectors address these challenges of diabetes. The National Diabetes Education Program (NDEP), a partnership of the National Institutes of Health and the Centers for Disease Control and Prevention (CDCP), tries to serve as a "coordinating entity" among more than 200 public and private organizations. In addition, the CDCP's Division of Diabetes

Translation is addressing community infrastructure and environmental issues to reduce the burden of diabetes, including public health surveillance systems for diabetes, applied translational research, state-based diabetes control programs, and public information (Murphy *et al.*, 2004). The National Institutes of Health has also expanded the focus of research to address how environmental factors and community infrastructure are related to obesity and the risk of diabetes and other chronic diseases. The ADA, an active member of NDEP, is partnering with the American Cancer Society and the American Heart Association to provide unified public messages and recommendations that address the role of nutrition in reducing chronic disease burden (Eyre *et al.*, 2004).

On an international scale, the World Health Organization has developed the Diabetes Programme, with the primary aims of setting international norms and standards, promoting surveillance, and encouraging prevention, especially in low- and middle-income communities and with a particular emphasis on developing countries. Advocacy work within this program has led to the development of Diabetes Action Now, a program in partnership with IDF that aims to increase awareness of diabetes and promote prevention in developing countries (World Health Organization and International Diabetes Federation, 2004).

With the growing awareness of the worldwide burden of diabetes, as well as the fact that scientific and economic studies, both in the care and prevention arenas, indicate that this burden does not have to occur, societal approaches need to be developed to complement clinical strategies to address diabetes in all of its complexities.

## Future Directions

Understanding of gene–gene, gene–nutrient, and gene–nutrient–environment interactions can provide insights into the molecular basis of the metabolic dysregulation associated with diabetes (Permutt *et al.*, 2005; Roche *et al.*, 2005; Phillips *et al.*, 2008). This genetic heterogeneity is matched by clinical heterogeneity and the impact of various medications (e.g. steroids, novel antipsychotic agents) (American Diabetes Association *et al.*, 2004).

There is considerable evidence on the effectiveness of MNT and the role of nutrition in the primary and secondary prevention of diabetes and diabetes complications. However, additional research is needed to address environmental factors related to the rapid rise in the prevalence

of obesity and to develop effective techniques to reduce the obesity and physical inactivity epidemics – both of which are mutable (unlike age or race/ethnicity) and contribute to the increased prevalence of diabetes. Research is also needed to examine how nutritional factors other than energy balance may affect the risk of developing diabetes.

Current research will yield additional evidence to assess the long-term effectiveness of weight-loss lifestyle interventions in preventing diabetes and the development of diabetes complications. In the United States, not only is MNT an important component in the “ABCs” campaign to achieve goals for A1C, blood pressure, and cholesterol, but nutrition also is integral to current clinical trials addressing these risk factors.

Of particular practical need is a better understanding of how to both prevent and control weight gain. Evidence-based overweight and obesity guidelines were developed in 1998 by the National Heart, Lung, and Blood Institute (1998). Updates to these guidelines are currently being developed and will be released in the fall of 2011. Updates on progress can be found on the following website: <http://www.nhlbi.nih.gov/guidelines/obesity/obesity2/index.htm>. The guidelines recommend a comprehensive assessment that includes measuring and evaluating relative body weight or BMI, measuring body fat distribution (waist circumference as an index of visceral fat accumulation), evaluating overall risk status (for diabetes and related factors), and evaluating motivation to lose weight (National Heart, Lung, and Blood Institute, 1998). Although weight is frequently measured, BMI evaluation is often not recorded, and few practice settings measure waist circumference and assess weight-loss motivation. Research is needed to evaluate barriers to assessing weight, especially with respect to body-fat distribution and motivation. The more recent diabetes prevention trials strongly support a 5–10% weight loss in 6 months with a comprehensive approach that combines dietary, physical-activity, and behavioral interventions. Analysis from the DPP suggests that there may be a benefit of lifestyle changes even if no weight loss is achieved (Murphy *et al.*, 2004; Wing *et al.*, 2004; Wylie-Rosett *et al.*, 2006).

Another issue related to body weight is sustaining weight loss. A small, randomized trial of meal replacement in patients with T2D found a greater weight loss using a liquid-formula meal-replacement approach than with individualized meal planning. However, previous research suggests that providing menus may be as effective as

providing food (Wing and Jeffery, 2001; Look AHEAD Research Group, 2003). Therefore, more research is needed to determine the extent to which being provided with a structure to avoid making food decisions facilitates achieving energy intake goals and weight loss. Further research on the short- and long-term effects of these formulas on metabolic parameters in individuals with diabetes is also needed.

Research needs to address how nutrition interacts with diabetes risk across the broad spectrum of this complex disorder to address primary prevention (how to curb the obesity epidemic and reduce the concomitant diabetes incidence), secondary prevention (how nutrition can help improve metabolic control and risks of developing complications), and tertiary prevention (how nutrition can help treat and control complications). These broad research needs will require multiple methods of research ranging from studies in nutrition–gene interaction and effects on cell metabolism to research that explores how community, state, national, and international policy may impact the prevalence of obesity and diabetes.

The long-term goal of MNT in diabetes is to prevent and/or delay complications by restoring metabolism as close to normal as possible. The focus for all classes of diabetes is on reducing cardiovascular risk factors such as hypertension and dyslipidemia. The distribution of macronutrient intake may vary based on a number of factors, including matching insulin to lifestyle in T1D and weight loss in T2D. Assessing micronutrient status is needed for patients in poor control, with complications, or with other evidence of being at risk.

There is no one diet for individuals with diabetes. MNT should be based on individual assessment and development of a treatment plan. Ideally, a registered dietitian who consults with the health-care team and the patient assesses the patient's needs and develops an individualized treatment plan that considers overall health needs in addition to ameliorating the metabolic effects of diabetes and its complications. Clearly, nutrition has and will continue to have a major role among persons with extant diabetes.

The importance of nutrition concepts and strategies has become even more important given the solid and convincing evidence of the ability to prevent T2D among high-risk individuals. The risk for developing diabetes is closely linked to lifestyle and obesity. Thus, the next great challenge for many will be to convert the important primary prevention science into active, practical, and widely available behavioral programs. These efforts will require more

than just traditional nutrition science; they will also require the involvement of public health, industry, government, and society at large.

## OSTEOPOROSIS

JOHN J.B. ANDERSON, PhD

*University of North Carolina, Chapel Hill, North Carolina, USA*

### Summary

Advances in understanding of the roles of nutrient requirements for bone health in older populations have been achieved over the last decade. This chapter focuses on the nutritional requirements that impact on osteoporosis late in life. Calcium needs have been established as more critical than other single nutrients as determined by several meta-analyses of randomized controlled trials. Several other nutrients, including phosphorus, vitamin D, vitamin K, and protein, remain important for bone health and the prevention or delay of osteoporosis and fragility fractures. Healthy diets providing balanced intakes of all nutrients continue to be the preferred way to promote bone health of older adults along with other healthy lifestyles, such as participating in routine physical activities, not smoking, and consuming only moderate amounts of alcohol per day, if any. Physical activity helps maintain muscle mass, equilibrium/balance, and the general overall health of organ systems. Together, sound diet and regular activity help promote bone health and delay or prevent osteoporosis and associated fractures of elders.

### Introduction

Early-life skeletal development is critical for late-life bone health. The individual bone models created by early-life events suggest that skeletal tissue is highly plastic until the early teens or even during the pre-teens in females, who are more developmentally advanced than males. The nutritional needs of growing children and adolescents required for the achievement of optimal bone mass and skeletal architecture remain, along with physical activity, the cornerstone for the prevention or delay of late-life osteoporosis (Weaver and Heaney, 2008).

Although osteoporosis usually manifests itself late in life, it is a disorder of bone growth greatly influenced by diet and lifestyle during the first two decades of life. The etiology of osteoporosis is complex and it is greatly affected by environmental factors, both dietary and usual lifestyle behaviors, as well as by genetic factors that are only recently being recognized. Osteoporosis is, therefore, a disease of multifactorial etiology, but not, strictly speaking, solely a disease of calcium deficiency.

Genetic analyses suggest that environmental factors contribute approximately 20% to the variance in bone density measurements (Ralston and Uitterlinden, 2010).

Diet and physical activity represent almost equal contributions to bone health. Therefore, the contribution of exercise needs to be factored into studies examining the effects of diet on skeletal development and maintenance. The functions of the musculoskeletal system in ambulation and other activities are critically linked in the maintenance of bone health during adult life and the elder years, perhaps even more so than dietary determinants.

The genetic determinants of bone health are significant, i.e. as much as approximately 80% of the variance in bone measurements is linked to heredity. Racial and ethnic differences in bone metabolism have been identified, but genetic factors governing mechanisms contributing to the metabolic differences have not been established. In fact, specific genes that govern bone tissue, both in development and in later maintenance, have remained elusive. Many genes are considered to be involved in orchestrating the functions of bone cells and, hence, bone tissue. Nutrient–gene interactions in the context of bone tissue are, however, poorly understood.

## Definitions of Osteoporosis and Osteopenia

A combination of low bone mass and micro-architectural defects of both the organic matrix and mineral phases characterizes osteoporosis. Low bone mineral content (BMC) or low bone mineral density (BMD) are measured using dual-energy X-ray absorptiometry (DXA), whereas architectural defects are assessed by histomorphometry and physical tests of bone strength. Osteoporosis is distinguished from osteopenia by the degree of bone loss measured by DXA; the World Health Organization (WHO) cut-points below normal DXA bone scans of healthy young adults (20–29 years old) are listed in Table 50.1.

**TABLE 50.1** World Health Organization bone mineral density cut-points below normal DXA scans of healthy young adults (20–29 years old)

Category of bone status	Individual BMD values compared to healthy young adult
Normal	>1 SD below mean for gender
Osteopenic	1–2.5 SDs below mean for gender
Osteoporotic	<2.5 SDs below mean for gender

BMD, bone mineral density; DXA, dual-energy X-ray absorptiometry; SD, standard deviation.

The public health costs of osteoporotic fractures are enormous: an estimated \$17 billion a year was expended in the United States in 2005 (National Osteoporosis Foundation, 2010). Hip fractures represent the majority of this entire amount, as they typically require major medical care, hospitalization, and rehabilitation. Mortality of patients with hip fractures approaches an estimated 20% by 12 months post-fracture, an enormous toll. Spinal fractures, while much more common, generally require less medical care and cost, and mortality is very low.

## Epidemiology of Osteoporosis

The epidemiology of osteoporosis is complicated by the definitions used.

DXA measurements classify osteoporosis of the lumbar spine and the proximal femur, two major sites of bone fractures, but not all osteoporotic subjects have fractures despite their low measurement values. Therefore, other factors not detected by DXA scans must contribute to prevent or to enhance fracture occurrence. Diet in the broadest sense may be one of these factors, and physical activity or musculoskeletal fitness is clearly a fracture-preventive factor. Other environmental factors, such as cigarette smoking and excessive alcohol consumption, are typically negative, as is early-life ovarian failure. The frequency of falls that may lead to fractures in older adults is another critical component impacting on osteoporotic subjects.

### *Incidence and Prevalence Rates*

The statistics of osteoporosis are based on estimates of fractures, since relatively few bone measurements using DXA are made among older subjects. Prevalence rates in the United States of approximately two million older adults who have been hospitalized are estimated to be 70% hip fractures and 30% lumbar spinal and other fractures. However, most spinal fractures go unreported so that total fracture estimations are not accurate. New cases of hip fractures of older adults per year are much more accurate because nearly all patients are admitted to hospitals. The numbers of total (hip and other) fractures were reported in 2005 to be 300 000 in the United States (National Osteoporosis Foundation, 2008). Total US cases of osteoporosis were estimated to be 12 million by 2010 (National Osteoporosis Foundation, 2010) and the ratio is approximately four fractures in women to every one in men over age 50. In the developing world the rates are anticipated

**TABLE 50.2** Selected nutritional risk factors for osteoporosis: deficient and excessive intakes of nutrients

Nutrient variable	Intake concern		Adverse skeletal consequences or effects
	Deficient	Excessive	
Calcium	X		Low bone mass, fracture
Phosphorus	X	X	Arterial calcification, renal stones Low bone mass, fracture
Vitamin D	X	X	Hyperparathyroidism, bone loss Osteomalacia, low bone mass
Protein	X	X	Hypervitaminosis D, mineral deposits Low bone matrix, poor mineralization
Animal		X	Increased acid load, bone loss (?)
Vitamin K	X		Low osteocalcin maturation, low bone mass
Vitamin A	X	X	Not established Decreased bone formation
Magnesium	X	X	Increased bone resorption Not established
Fluoride	X	X	Not established Low bone mass (?) Fluorosis

to increase even more as life expectancies continue to increase.

### **Environmental and Dietary Risk Factors**

Many environmental risk factors for osteoporosis exist, such as inadequate physical activity throughout the life cycle. The nutritional risk factors are also numerous, and a few nutrients are briefly noted here (Table 50.2). Dietary macronutrients clearly are needed for healthy bone tissue, but a chronically excessive amount of acid-generating animal protein may have adverse effects on bone by promoting hypercalciuria (Kerstetter *et al.*, 2003), though this issue remains controversial. Adequate amounts of high-quality protein sources, however, are needed to maintain bone collagen and other matrix proteins and, hence, bone strength.

Insufficient calcium, phosphorus, and vitamin D intakes have been well established as major determinants of low bone mass and osteoporosis, but the metabolic relationships of these nutrients to bone are complex (see below under Pathophysiology of Osteoporosis). Too little protein in the diet, especially from high-quality sources, may have a negative impact on bone health in later life. An insufficiency of dietary vitamin K may also have an adverse effect on bone health, but only a few prospective trials have been reported on the linkage between vitamin K and bone

(Knapen *et al.*, 2007). Insufficiency of essential omega-3 fatty acids has also been suggested as contributing to sub-optimal bone health, but this relationship has not yet been supported by clinical trials. The effects on bone health resulting from deficits of other nutrients are limited by a paucity of human investigations.

### **Pathophysiology of Osteoporosis**

Functional declines of several organ systems contribute to the onset of osteoporosis, but the serum concentration of at least one hormone, i.e. parathyroid hormone (PTH), typically increases within the reference range late in life. Each of the major functional changes affecting bone tissue briefly described here increases with advancing age.

### **Declines in Estrogen and Androgen Production**

Gender-related hormones generally decline in late life. Estrogens from the ovaries fall more precipitously beginning in the 40s and reach minimal levels by the early 50s, the typical onset of the postmenopausal period. Androgens, mainly testosterone, decline more gradually, beginning typically in the 60s. Each of these hormones has anabolic effects on the retention of bone mass. The decline or loss of these hormones hastens bone loss in the late decades of life.

### **Bone Tissue Changes: Declines in Mass and Organization**

Bone turnover in late life favors bone resorption over bone formation, with the net result of gradual loss of both bone mass and microscopic architecture. This contributes to an increase in bone fragility and the risk of fracture, especially of trabecular or cancellous bone tissue (Figure 50.1A, B). The increase in the resorption rate and, hence, bone turnover, relates not only to diminished sex hormones, but also

**FIG. 50.1** Increased bone fragility and the risk of fracture, especially of trabecular or cancellous bone tissue, as shown by scanning electron micrographs. (A) Normal trabecular microarchitecture with health struts (cross-pieces) and vertical bars. (B) Osteoporotic trabecular bone with losses of connectivity as struts or bars have undergone resorption. Reproduced with permission. Copyright Dr David W. Dempster 2001.

to a chronic elevation of serum PTH concentration. An increase in dietary calcium intake will lower the PTH concentration within the normal reference range (McKane *et al.*, 1996), and it will have a beneficial effect in reducing the risk of fracture. (See later in this chapter.)

### **Declines in Intestinal Calcium Absorption**

A steady decline in intestinal calcium absorption has been reported as starting in postmenopausal women without a decline in serum 25-hydroxyvitamin D (Nordin *et al.*, 2004). Whether the decline in intestinal calcium absorption results from a decrease in effectiveness of the vitamin D hormone, calcitriol, on the absorbing cell capacity for producing calcium-binding protein, or whether modification of other mechanisms, perhaps vitamin D-independent, might be responsible for this decline in calcium absorption, has not been established. Presumably, renal production of the calcitriol hormone from its precursor, calcidiol, remains optimal at late ages of life. Since renal function typically declines with age, the production of calcitriol would be expected to be compromised in those with renal deficits (see below).

Whereas calcium absorption may decline in efficiency in late life, no decline in phosphate absorption is thought to occur in older adults. Because of the delay in calcium absorption compared with phosphate entry into blood and the reduced calcium absorptive efficiency, the early postprandial PTH response is likely to be greater in older individuals (Anderson, 1991).

### **Declines in Renal Function**

The major decline in renal function that may have a significant impact on bone is the lowering of the glomerular filtration rate (GFR), which may result in hyperphosphatemia and secondary hyperparathyroidism. An acute elevation in serum phosphate concentration helps lower serum calcium and it may also directly stimulate PTH secretion, as observed in younger adult and premenopausal women (Calvo *et al.*, 1990; Kemi *et al.*, 2009). Whether this phenomenon occurs in adults over 50 years has not been established. The net effect of this dietary excess of phosphorus is bone loss resulting from increased PTH-directed osteoclast-mediated resorption, especially in those with lowered GFR.

### **Increased Secretion of Parathyroid Hormone**

PTH has a strong minute-to-minute regulatory role in maintaining the serum calcium concentration, really the

**FIG. 50.2** Actions of parathyroid hormone that maintain homeostatic regulation of serum calcium ion concentration. Upward arrows represent increases and downward arrows represent decreases. Adapted from Ontjes, in Anderson *et al.* (2011).

ionic calcium concentration, at its physiological set concentration (1.25 mmol/L). When dietary calcium is low, serum calcium will decline and stimulate an increase in PTH secretion from parathyroid gland stores. Normocalcemia is restored by two PTH-mediated actions: calcium release from the bone envelope, including possibly also bone resorption, and increased renal tubular calcium reabsorption. In addition, serum phosphate ion concentrations are lowered by an increase in PTH. Figure 50.2 illustrates the actions of PTH on bone, kidney, and, indirectly, the small intestine. Reciprocal PTH effects occur in response to meals rich in calcium sources. Together these homeostatic changes result in tight regulation of the serum ionized calcium concentration.

### **Reduced Renal Formation of 1,25-Dihydroxyvitamin D**

The second major adaptation operates more slowly to achieve appropriate calcium balance: positive in growing children and approximately zero balance in adults. During periods of low calcium intake (<500 mg/day), mild hypocalcemia leads to an increase in PTH secretion and then to an increase in calcitriol formation from its precursor, calcidiol. Higher serum concentrations of calcitriol, the hormonal form, act on intestinal absorbing cells to increase calcium absorption and reestablish calcium balance. This

genetic effect of the vitamin D hormone results in the intestinal cell synthesis of calcium-binding protein, which enhances calcium uptake in the blood. The renal capability of producing the calcitriol hormone remains fairly well intact in late life in individuals with normal renal function, i.e. normal GFR. Those with age- or disease-related declines in GFR have reduced synthesis of calcitriol in response to low calcium intakes.

### **Experimental Animal Model and In Vitro Studies of Nutritional Factors Affecting Bone**

Many animal models have been studied in efforts to determine the effects of dietary components, especially calcium, on bone at various stages of the life cycle.

Rodent studies have been helpful in understanding bone concepts, but rodent bone metabolism differs too greatly from human bone tissue turnover to be useful for long-term studies. Unlike human bone, the skeletal growth of rodents continues throughout life. Rats and mice, therefore, are not useful models for the study of osteoporosis. Dog and swine models have served as more appropriate models for the study of bone metabolism, especially for short-term investigations. Their use as osteoporosis models, however, is limited.

Primate models have been utilized to investigate late-life bone loss following the loss of reproductive cycling in a few species of monkeys, but these models are not equivalent in most respects to human metabolism. Also, the great cost of these studies limits their use.

In summary, results of animal research on diet–bone relationships have been helpful, but they have not been overwhelmingly instructive for advancing human understanding of the metabolic aspects of osteoporosis development. In vitro studies are limited to the study of cell perturbations resulting from nutrient media content and hormones or factors that may have roles in osteoporosis.

### Studies of Nutritional Factors Affecting Bone of Older Adults

Several nutrients have been shown to have important effects on bone health, but the emphasis in this chapter is placed on calcium, phosphorus, vitamin D, protein, and vitamin K. Other nutrients relating to bone health are briefly noted.

#### Observational Reports

Elderly female subjects who have been consuming recommended amounts of calcium on a daily basis have long been considered to have skeletal benefits, but the study designs were not sufficiently rigorous by current standards to be meaningful. For example, a report by Nordin (1960) suggested that calcium intakes of 800–1000 mg of calcium were optimal for bone health of practically all populations and that Asian diets containing 500 mg or so per day were grossly inadequate.

An instructive survey by Matkovic *et al.* (1979) supported the benefit of consuming a high-calcium diet based on milk and other dairy foods on bone mass compared with a non-dairy-consuming population in Yugoslavia. This study stimulated great increase in research on the calcium–bone linkage, but it essentially ignored the potential skeletal benefit of the higher-quality protein intake by the dairy consumers. Clinical investigations in fact support the enhancement of bone repair by elderly subjects supplemented with protein (Bonjour, 2005).

#### Randomized Controlled Trials (RCTs)

Many prospective investigations have been undertaken. A few examples of these RCTs are selected to demonstrate the effects of calcium plus vitamin D compared with calcium alone.

#### Calcium plus Vitamin D

A high-quality report that illustrates the positive effects of calcium supplements on bone is probably the largest study yet published. One arm of healthy postmenopausal subjects (62 years of age at initial screen) in the Women's Health Initiative (WHI) trial was administered calcium (1000 mg/day) plus vitamin D (400 IU/day) for an average period of 7 years (Jackson *et al.*, 2006). (Both groups of women were quite health-conscious, and a large percentage were consuming adequate intakes of both calcium and vitamin D because of self-selection of supplements.) Compared with the placebo control group, the treated subjects did have at 7 years modestly greater BMD at the hip, but no reduction in hip fractures. No significant reductions were found in vertebral fractures or in fractures at other sites in the supplemented women. One adverse effect of the calcium and vitamin D treatment was an increase in the risk of renal stones.

Several other well-designed RCTs using calcium and vitamin D have been reported. An original study by Meunier's group based in Lyon, France, found that non-vertebral fractures were reduced following 1 year of therapy with daily calcium phosphate and vitamin D supplements in older women in nursing homes (Chapuy *et al.*, 1992). The amounts of the each nutrient were 1000 mg for calcium, 600 mg for phosphorus, and 800 IU for vitamin D. A compliance rate of almost 100% was reported.

An additional investigation using this nutrient combination (with carbonate instead of phosphate as the anion) in Boston by Dawson-Hughes *et al.* (1997) provided similar results in both older women and men, but the reductions of fracture rates were not as impressive as in the Chapuy study. Numerous studies in other nations have arrived at similar conclusions.

Finally, a systematic review of trials of combined vitamin D and calcium supplementation supports the finding of skeletal gains when both nutrients are consumed at reasonable amounts, i.e. >300 IU of vitamin D and >1000 mg of calcium (Chung *et al.*, 2009).

#### Calcium Alone

Trials using calcium alone have also been reported generally to improve BMD. Most of these have used supplements containing 1000 mg of calcium or more per day. Reid and colleagues (2006), who performed an RCT in postmenopausal women living in Auckland, New Zealand, used calcium supplementation (1000 mg/day as the citrate), which resulted in significant reductions of bone

loss and turnover but no changes in fractures of the hip or other sites after 5 years. The authors stated in their conclusions that poor compliance reduced the effectiveness of the calcium supplements.

Riis and co-researchers in Denmark showed that calcium (1000 mg per day) supplementation helped slow bone loss in postmenopausal women, and they retained more bone mass than placebo-treated subjects (controls) over a period of 2 years (Riis *et al.*, 1987). Fractures were not significantly decreased in the calcium treatment group.

Similar studies by other investigators (Chevalley *et al.*, 1994; Recker *et al.*, 1996) have reported that calcium supplements prevented vertebral fractures in postmenopausal women. Reductions of fractures with calcium treatment alone, however, have not been supported by meta-analyses. (See next section.)

### Meta-Analyses

A comprehensive meta-analysis of several trials examining calcium supplementation (>1200 mg/day) alone on fracture risk found that older subjects (>50 years) had the greatest reduction of fractures ( $p < 0.05$ ) when they had low baseline calcium intake (<700 mg/day) and low serum 25-hydroxyvitamin D (<25 nmol/L), assuming good compliance (Tang *et al.*, 2007). This meta-analysis included data from 17 randomized trials that presented fractures.

Reid *et al.* (2008) first reported that elevated intakes of calcium alone (>800 mg/day) significantly lowered the risk of non-vertebral fractures. In a later analysis they showed that vitamin D supplementation alone was not beneficial in fracture reduction (Reid *et al.*, 2010a).

Two additional meta-analyses arrived at a similar conclusion that vitamin D alone did not reduce fracture risk or fractures in older women (Avenell *et al.*, 2010; DIPART analysis, 2010). Earlier vitamin D trials, however, were quite robust in supporting a beneficial effect of vitamin D supplementation on bone.

A meta-analysis of calcium plus vitamin D supplements by Boonen *et al.* (2007) found that both nutrients, calcium and vitamin D, were needed to reduce fracture risk in older women. This older analysis conflicts with the more recent analyses cited above, which suggest that calcium alone may be utilized by bone tissue for remodeling and that extra dietary vitamin D may be superfluous for bone formation when calcium intake and its absorption are both sufficient.

A previous Cochrane meta-analysis on the benefit of calcium supplementation alone for bone has been with-

drawn (Shea *et al.*, 2002) and a new report of a revised meta-analysis by this group is awaited. The 2002 publication concluded that calcium was statistically beneficial, though weak in its quantitative effect on bone, and that fracture reduction was not demonstrated with statistical confidence. Bone strength is more related to the organic matrix, especially collagen, than it is to the hydroxyapatite mineral phase of bone, as measured by DXA. The lack of improvement in fracture rate by calcium/vitamin D supplementation alone may help explain this anomaly, since no appropriate measurement of the organic status of bone is readily available.

### Interpretation of Human Studies

From a dietary perspective, calcium intakes may represent the single most important nutritional variable affecting bone health and preventing fractures. An adequate vitamin D status helps primarily in adaptation to low calcium intake and therefore to serum calcium concentrations at the low end of the normal range. Inadequate dietary phosphorus, although rare in the US population, may also contribute to osteoporosis. The major issue relating to phosphorus is that, at high chronic intakes typical in the United States, an elevated serum phosphate concentration exerts a lowering effect on serum calcium and thereby triggers the secretion of PTH which may adversely affect bone mass, even in premenopausal women with high calcium intakes (Kemi *et al.*, 2010). Except for phosphorus, other nutrients such as magnesium have not been sufficiently studied to suggest that their intakes are as critical for bone maintenance and health as calcium and vitamin D. Vitamin K clearly enhances the generation of the matrix protein, osteocalcin, but too few well designed trials have been reported.

Concern about excessive calcium supplementation in older subjects has arisen because of a report of increased risk of cardiovascular disease in a population of women in Auckland, New Zealand (Bolland *et al.*, 2008) and a meta-analysis on this association (Bolland *et al.*, 2010). Reid *et al.* (2010b) in their review of the adverse cardiovascular effects of long-term calcium supplementation have concluded that total calcium intakes from foods and supplements need to be more carefully monitored in efforts to both enhance bone status and reduce the risk of cardiovascular morbidity and mortality.

The latter reports raise the question of what should be reasonable intakes of calcium, i.e. total calcium from foods

and supplements, in older subjects who are, because of age, low BMI, or other factors, at increased risk of fracture. The tolerable upper intake levels (ULs), i.e. presumably maximum safe calcium intakes, are set at 2500 mg/day across the life cycle (Institute of Medicine, 1997), but more recent data provided in the reports by Bolland (2008 and 2010) and Daly and Ebeling (2010) suggest that the UL may be safer when lowered to ~1500 mg/day. (A recent IOM report [Institute of Medicine, 2011] has reduced the UL for calcium in men and women 51 and older to 2000 mg/day.) The window of healthy calcium intakes would then range between ~800 and 1500 mg/day, slightly below the current adequate intakes for older adults of 1200 mg/day. Daily intakes of calcium above 1500 mg may increase the risk first of coronary artery calcification and then of cardiovascular morbidity and mortality.

A finding that older subjects who have high serum calcium concentrations are more likely to have increased carotid plaque thickness suggests that arterial calcification is occurring in many elderly individuals (Rubin *et al.*, 2006), but the mechanism(s) for the increase in carotid artery thickness or coronary artery calcification remain(s) elusive.

## Future Directions

New RCTs are needed of postmenopausal women and elderly men that fine-tune our current understanding of the critical nutrients needed to support bone health in late life with or without concurrent physical activity programs (aerobic, etc.), and of diverse racial and ethnic groups. Most studies by far have included Caucasian subjects, but the nutrient requirements of other ethnic groups, especially African-Americans who have PTH responses to calcium challenges that differ from those of Caucasians (Cosman *et al.*, 2000) need greater understanding.

Several prospective RCT investigations of single nutrients or combinations of nutrients, beyond simply calcium and vitamin D, would advance understanding of the essential roles of these nutrients. For example, high phosphate intakes (and low calcium intakes) lasting 1–2 years would provide new information on the potentially chronic adverse effect of this altered diet ratio (by weight) on bone mass and density, and possibly rule in a major role of the phosphate regulatory hormone, fibroblast growth factor 23 (FGF23), in phosphate homeostasis.

Similarly, prospective RCTs of vitamin K in two or three different forms would help clarify the interchangeability of these molecules in the support of bone matrix proteins

Protein itself from high-quality sources rich in sulfates and phosphates needs to be examined in prospective RCTs to establish the beneficial effect of this macronutrient on matrix molecules and to rule out any adverse effect of a potential acid load generated by amino acid metabolism.

The role of magnesium in bone metabolism has been woefully underinvestigated, as only a very few prospective RCTs have been undertaken.

Finally, a combination of several nutrients, i.e. vitamin K and magnesium, provided as a supplement at modest doses of each nutrient along with calcium and vitamin D at RDA levels in a multi-arm prospective RCT would provide very useful data on older subjects, especially women, of all racial/ethnic groups. The study design would also benefit from incorporation of other arms receiving lesser amounts of supplemental calcium and vitamin D than 100% of the RDAs. Sources of calcium containing carbonate in some arms and phosphate in others would be desirable.

Advances in understanding of the roles of nutrient needs for bone health in older populations have been achieved over the last decade. Calcium needs have been established as being more critical for bone maintenance than other individual nutrients as determined by several meta-analyses of RCTs and other studies. Calcium supplementation, alone or with vitamin D, may also reduce fracture risk, but study results are inconsistent on this issue. Other nutrients, however, remain important for bone health and the prevention or delay of osteoporosis and fragility fractures. Further data from RCTs employing additional bone-related nutrients may help expand our understanding.

Healthy diets providing balanced intakes of all nutrients continue to be the optimal way to promote bone health along with other healthy lifestyles, such as participating in routine physical activities, not smoking, and consuming only moderate amounts of alcohol per day, if any.

Physical activity helps maintain muscle mass, equilibrium/balance, and the general overall health of organ systems. Together, sound diet and regular activity help promote good bone health and delay or prevent osteoporosis.

## CANCER

HOLLY NICASTRO, PhD AND JOHN A. MILNER, PhD

*National Cancer Institute, Rockville, Maryland, USA*

### Summary

Evidence continues to mount that dietary habits can significantly influence one's cancer risk and/or tumor behavior. Experimental evidence using a variety of models substantiates the importance of multiple components in the diet that modify one or more cancer-related processes. Nevertheless, clinical intervention studies have been less compelling and make it difficult to draw firm conclusions about what adjustments in eating behaviors are needed. Inconsistencies in the literature may reflect individuality in response and therefore the need to better understand the quantity of the bioactive constituent needed to bring about a response, the timing of exposure for best response, and how genetics and biological insults including excessive energy and associated radicals, environmental contaminants, viruses and/or bacteria may modify the response. Regardless, exciting opportunities exist for identifying and validating biomarkers that can be used to identify who will benefit most or be placed at risk as a result of dietary change. While characterizing responsive individuals will not be easy, the societal benefits are enormous.

### Introduction

Cancer is a collection of complex diseases characterized by abnormal cellular growth. Cancer cells exhibit several physiological hallmarks resulting from various genetic alterations that distinguish them from healthy cells: self-sufficiency in growth signals, insensitivity to growth-inhibitory signals, evasion of programmed cell death, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis (Hanahan and Weinberg, 2000). Carcinogenesis is a multi-step process involving multiple genetic or epigenetic alterations that confer sur-

vival advantages to cells, usually over the course of many decades. The American Cancer Society estimated that there would be approximately 1 596 670 new cases of cancer and 571 950 cancer deaths in the United States in 2011 (American Cancer Society, 2011). Worldwide, cancer accounts for 13% of all deaths, with that figure expected to increase.

Cancer is caused by endogenous and/or environmental factors. Endogenous factors, which account for a minority of cancers, include inherited germ-line mutations, inflammation, or hormones. Cancer also has several environmental causes, including radiation, viruses, bacteria, parasites,

tobacco use, and exposure to carcinogens, and/or improper diet. The majority of cancers are caused by environmental factors; this suggests that modifying environmental exposures such as diet could reduce the risk of developing cancer. The World Cancer Research Fund and American Institute for Cancer Research estimate that 34% of common cancers, and up to 70% of certain cancers including esophageal and endometrial cancers, are preventable if there is appropriate food, nutrition, physical activity, and body fatness (WCRF/AICR, 2007). Mounting evidence continues to highlight dietary change as an effective and cost-efficient approach for reducing cancer risk and for modifying the biological behavior of tumors. This chapter discusses the current knowledge on diet and cancer, current approaches to studying the relationship between food components and cancer development, and challenges and future directions in the field.

## Studying Nutrition and Cancer

### *Intakes/Exposures*

#### **Diversity of Foods and Compounds**

More than 25 000 different bioactive components are believed to occur in the foods that humans consume. At least 500 of these compounds have already been identified as possible modifiers of the cancer process, and others will likely surface with the use of high-throughput screening of natural products and improved detection methods. These bioactive food components may arise from plants (phytochemicals), animal sources (zoochemicals), fungi (fungochemicals), or the metabolism of food components by bacteria within the gastrointestinal tract (bacterochemicals) (Milner, 2006). This diverse array of dietary constituents may modify, either positively or negatively, cancer risk and tumor behavior (WCRF/AICR, 2007). Defining which food component is instrumental in bringing about a phenotypic change is exceedingly challenging because of the complexity of foods and the myriad of sites where food components may function. For example, some of the anti-cancer benefits of tomatoes and tomato products may be attributed not only to lycopene, but also to other carotenoids, flavonoids, vitamins, and minerals (Tan *et al.*, 2010). Likewise, interactions among foods may influence the overall response. For example, combining vitamin D<sub>3</sub> and genistein was more effective in suppressing the growth of prostate cancer cells at biologically achievable concentrations than was either agent alone. This response appears to result from the ability of genistein to inhibit CYP 24

and thereby to increase the half-life of vitamin D<sub>3</sub> (Krishnan *et al.*, 2007). It is likely that many other interactions among food constituents are occurring which have yet to be fully defined.

#### **Methods of Assessing Exposure**

Rapid, accurate, and inexpensive methods for assessing the intake of specific bioactive food components, both essential and non-essential nutrients, are fundamental to unraveling the relationship between dietary habits and cancer risks, yet represent a major methodological challenge. Errors in estimating food intakes and incomplete data about nutrient content or interactions among food components limit the usefulness of self-reported food consumption data. Because eating behaviors are exceedingly complex and may involve foods that are consumed intermittently and irregularly, self-reports are particularly prone to measurement error. Food frequency questionnaires (FFQ) are convenient, measure long-term behaviors and are relatively inexpensive, but they are limited by knowledge about particular foods and are hampered by the inability of individuals to accurately report their intakes retrospectively. A 24-hour recall, while providing more in-depth information about the types and amounts of foods consumed, provides a rather poor estimate of long-term usual intakes. Despite the increased subject burden and cost, a 7-day diary has been found to provide a far better estimate of exposure to dietary constituents including protein and potassium than found with the use of an FFQ (McKeown *et al.*, 2001; Davis and Milner, 2007). However, these methods do not account for variables such as absorption, metabolism, distribution, or excretion that influence the amount of food components that reach target sites. Increasingly, the combined use of intake assessment and biomarker measurements is being employed to provide insight into individual responsiveness to individual and long-term exposures (Jenab *et al.*, 2009).

The complexity of foods also presents challenges for analysis of intake. Reference standards for foods are not always available, and phytonutrient content of foods can vary considerably based on growth conditions, storage, or processing of the food. The genotype of plants may also be an important variable as evident in broccoli where glucoraphanin concentrations have been reported to vary more than 25-fold (Martin, 2007). In addition, the food matrix can have a profound effect on bioavailability of foods and dietary supplements (D'Archivio *et al.*, 2010). Form or speciation is another factor which likely influ-

ences bioavailability. Overall, concentration in a food is only one factor that may influence the relationship between diet and cancer prevention.

### Timing

Timing and duration of exposures are also important factors in determining the overall response to foods or supplements. In rats, the timing of exposure to dietary genistein exposure was determined to be exceedingly important in determining mammary cancer risk (Lamartiniere *et al.*, 2002). In this mammary model, treatment with genistein was protective after prepubertal and combined prepubertal and adult genistein treatments, but was not effective after prenatal- or adult-only treatment. Humans may also respond best with prolonged or early exposures, since, in a case-control study, an inverse relationship was observed between soy food intake in adolescents and breast-cancer incidence later in life; however, protection was not evident when intakes began later in life (Boyapati *et al.*, 2005). Admittedly, this is an area of investigation that deserves additional attention, especially as it might relate to fluctuations in epigenetic processes.

Data from the General Population Trial in Linxian, China, demonstrated that individuals who received a supplement containing  $\beta$ -carotene, vitamin E, and selenium, had a 13% reduction in cancer mortality. Post-intervention follow-up found that the beneficial effects of the supplement were evident and were magnified up to 10 years after termination of the supplementation program (Qiao *et al.*, 2009). The benefits were greater in individuals who were <55 years at the beginning of the intervention. Cancer risk appeared to increase in those who started supplements usage when beyond 55 years of age. These findings suggest that sustained exposure may not always be necessary to bring about a desired outcome. It is conceivable that the observed variation in risk as a function of age possibly reflected differences in the early-stage transformed cells.

The Women's Intervention Nutrition Study (WINS) provides evidence that long-term exposure may be needed to detect a biological response to dietary change (Chlebowski *et al.*, 2006). In this randomized, prospective, multicenter clinical trial the effect of a dietary intervention designed to reduce fat intake in women with resected, early-stage breast cancer receiving conventional cancer management was tested. This study provided evidence that approximately 4 years was required to detect a response to the reduced consumption of dietary fat. The hazard ratio of relapse events in the reduced fat intervention group

compared with the control group was 0.76. Additionally, this study provided evidence that a subgroup of individuals, namely estrogen receptor (ER) negative individuals, were most responsive to a reduction in dietary fat. It should be noted that the Women's Health Initiative provided similar evidence that a reduction in fat (9%) was associated with a slight reduction in breast cancer risk (~24%) that was not observed until after more than 4 years.

Still other studies provide evidence of biological effects after short-term exposures, by monitoring changes in transcriptional mRNA expression (transcriptomics) by food components. Lin *et al.* (2007) have reported that consumption of a low-fat, low-glycemic-load diet can lead to marked changes in the expression of over 20 genes in human prostatic tissue for 6 weeks. These investigators suggest that a molecular approach to health and disease may help individualize appropriate interventions based on cellular signature changes brought about by diet. Significant changes in expression can occur within a few hours after consuming a food, as reported by van Erk *et al.* (2006). Breakfast cereals with different macronutrient profiles resulted in differential blood leukocyte gene expression in men after 2 hours. Thus, a bolus approach to a food or component may represent a relatively inexpensive approach to determine if a nutritional intervention strategy is appropriate, especially if the price of chips continues to decrease. A better understanding of temporal relationships will be needed if appropriate preemptive models are to be forthcoming.

Overall, time appears to be an important variable, yet the best time for intervention remains unresolved. Nevertheless, it does appear that several options are available for using dietary interventions to reduce cancer risk and modify tumor behavior (Table 51.1).

### Interindividual Variability

In order to make specific recommendations to the public about nutrition and cancer prevention, research will need to focus on identifying responders and non-responders. Studying interindividual variability is fundamental to establishing which subpopulations and ideally individuals will derive benefits from dietary intervention and which will not. An important objective is the identification of those individuals who might be placed at risk as a result of dietary change. Since increasing evidence points to excess exposure to a wide array of food components including  $\beta$ -carotene, iron, zinc, selenium, vitamin D, indole-3

**TABLE 51.1** Summary of current diet-related recommendations for cancer prevention from the 2007 WCRF/AICR Report

Category	Recommendations
Body fatness	Be as lean as possible within the normal range of body weight
Physical activity	Be physically active as part of everyday life
Food and drinks that promote weight gain	Limit consumption of energy-dense foods and avoid sugary drinks
Plant foods	Eat mostly foods of plant origin
Animal foods	Limit intake of red meat and avoid processed meat
Alcoholic drinks	Limit alcoholic drinks
Preservation, processing, preparation	Limit consumption of salt and avoid moldy grains or legumes
Dietary supplements	Aim to meet nutritional needs through diet alone (without dietary supplements)

Data from WCRF/AICR (2007).

carbinol, etc., to produce a “J-” or “U-” shaped response curve, it is extremely important that vulnerable subpopulations are also identified. Such knowledge will come from examining how diet-induced phenotypic responses depend on an individual’s background (nutrigenetics), the expression of genes (epigenomics and transcriptomics), changes in the amounts and activities of proteins (proteomics), changes in small molecular weight compounds (metabolomics) or changes in the number or diversity of microbes in the gastrointestinal tract (the microbiome).

Epidemiological studies continue to provide important clues about the likely importance of multiple foods and components as deterrents to cancer. However, controlled-intervention studies, such as the Alpha-Tocopherol, Beta-Carotene (ATBC) study, the Polyp Prevention Trial, the Women’s Healthy Eating and Living study (WHEL), etc., provide mixed messages about the physiological significance of dietary change (Wong *et al.*, 2003; Abrams *et al.*, 2005; Slattery *et al.*, 2007). For example, according to the 2008 World Cancer Research Report (WCRF/AICR 2007), there are 11 studies that have observed a decreased risk of colorectal cancer with increased intake of calcium, yet the response was statistically significant in only three

cases; furthermore, in one case, higher intake was linked with an increased risk in women but not in men. When meta-analysis was restricted to eight studies, a summary estimate was 0.95 per 200 mg/day with no evidence of heterogeneity (WCRF/AICR, 2007). Thus, while calcium was associated with protection, the overall response was relatively modest. While even a relative small change can have profound implications in a large population, it is possible that the change in risk is really a reflection of a large response in a subpopulation.

### Nutrigenetics

Polymorphisms in genes may be one explanation for these modest responses in a large population but greater responses in a subpopulation. For example, inadequate calcium intake is associated with increased colorectal cancer risk in those with the Ff and ff genotypes for vitamin D receptor (VDR) FOK1 polymorphism (Wong *et al.*, 2003). A polymorphism in this receptor involving a T to C substitution at position 2 exon 2 has been identified with lower calcium accretion in children (Abrams *et al.*, 2005). The biological basis by which this polymorphism might influence cancer risk remains to be determined. Regardless, these data suggest that vulnerable individuals with inadequate calcium consumption may have an almost three-fold higher risk of developing colon cancer; again considerably greater than the roughly 20% reduction seen in population studies with greater calcium exposures. Recently, the association of VDR haplotypes has been examined in two large case-control studies (Slattery *et al.*, 2007). While the CDX2 polymorphism was not independently associated with colon or rectal cancer nor several dietary components, the bLFA haplotype (*Bsm1* b, or B, poly(A) L, *Fok* F, and CDX2 A polymorphisms) was associated with an increased risk of colon cancer. It is important to recognize that the frequency of a polymorphism can vary markedly across populations as evident in a frequency of the A allele of the CDX2 polymorphism which occurred in 19% of non-Hispanic whites, 21% of Hispanics, 76% of African-Americans, and 47% of Asians. These data suggest that haplotype analysis that encompasses different domains of the VDR gene might further enhance understanding of the importance of dietary calcium as a deterrent to cancer. The use of polymorphism information may offer opportunities for identifying individuals who will benefit maximally or be placed at risk because of dietary change.

Polymorphisms may influence the metabolism and excretion of dietary cancer-preventive compounds and thereby alter their ability to induce or suppress metabolizing enzymes or transporters (El-Soheby, 2007; Steck *et al.*, 2007; Yu and Kong, 2007). Differential response to dietary cancer-preventive compounds may also relate to the variant of the enzyme being modified. For example, garlic appears to lead to an autocatalysis of CYP2E1, but does not appear to influence other CYP450s in the same manner (Davenport and Wargovich, 2005). Likewise, polymorphisms in the regulator region of metabolizing enzymes/transporters, such as AhR, CAR, and PXR, may also influence the overall response to bioactive food components (Okey *et al.*, 2005; Yu and Kong, 2007).

Understanding gene constitution–nutrient interactions is further complicated by variations that can occur in copy number, either by deletion or amplification of large regions of specific chromosomes. Copy number is the most prevalent structural variation in the human genome, and may account for as much as 20% of the variation among individuals. Thus it may contribute significantly to genetic heterogeneity and may be a significant determinant of whether a diet is appropriate or not (Pinto *et al.*, 2007). Variation in copy number has been reported for  $\alpha$ -amylase, several cytochrome P450 genes, and Her2/Neu (Slamon *et al.*, 1987; Ingelman-Sundberg *et al.*, 2007; Perry *et al.*, 2007) and likely occurs in many others. Typically, increases in copy number are associated with an increase in enzyme activity, and vice versa. This variation in enzymatic activity likely contributes significantly to some of the differential response to food components across individuals.

### Epigenetics

Epigenetic modification regulates expression and activity of genes without modifying genomic sequences. Mechanisms include DNA methylation, histone modifications, gene silencing by microRNA, and chromosome stability. Genes involving cell cycle regulation, DNA repair, angiogenesis, and apoptosis can all be inactivated by the hypermethylation of their respective 5' CpG islands. Key regulatory genes – including the cell cycle inhibitors *p21<sup>WAF1/CIP1</sup>* and *p16<sup>INK4a</sup>*, pi-class glutathione S-transferase, the tumor suppressors cyclin-dependent kinase 2 (*CDKN2*) and *PTEN* – are all susceptible to control by DNA hypermethylation. The intake of multiple food components ranging from vitamin A to zinc may influence epigenetic processes. Actually, several non-essential and essential

nutrients have been reported to influence DNA methylation patterns (Ross, 2003). Classical studies have demonstrated that methyl-deficient diets lead to marked changes in methylation patterns, at least some of which are consistent with alterations observed when a normal cell transforms to a neoplasm (Pogribny *et al.*, 2006). Diets low in folate are linked with increased risk of several cancer types. This effect is believed to be due to abnormal DNA synthesis and methylation (Li and Tollefsbol, 2010). Restoring proper methylation may represent a fundamental process by which some bioactive food components may function to influence gene expression patterns. For example, (-)-epigallocatechin-3-gallate (EGCG) from green tea can reactivate methylation-silenced genes by inhibiting the enzymatic activity of DNA methyltransferase 1 (Fang *et al.*, 2003).

Silencing and unsilencing of genes can also occur through modification of histones (Myzak and Dashwood, 2006; Glozak and Seto, 2007; Holloway and Oakford, 2007). In addition to factors that govern the overall recruitment and release of histones (histone occupancy); there is a complex interplay of reversible histone modifications that govern gene expression, including histone acetylation, methylation, phosphorylation, ubiquitination, and biotinylation. Modification of histone deacetylase (HDAC) has surfaced as one strategy for changing tumor behavior (Myzak and Dashwood, 2006; Glozak and Seto, 2007). Several food components including butyrate, diallyl disulfide, and sulforaphane have been reported to function as weak ligands for this enzyme and lead to reduced in vitro activity (Myzak and Dashwood, 2006; Dashwood and Ho, 2007). Addition of sulforaphane, an isothiocyanate found in cruciferous vegetables, to cell cultures leads to a concomitant increase in global and local histone acetylation status including the promoter regions of p21 and BAX genes. Most recently Dashwood and his research team have demonstrated that sulforaphane feeding markedly changes HDAC activity in humans (Dashwood and Ho, 2007). Impressively, these changes occurred within minutes after consumption of broccoli sprouts and persisted for a significant amount of time but within 24 hours returned to baseline values. How this temporal relationship is influenced by ingestion of multiple food components known to influence epigenetic process remains to be determined. Likewise, what impact these shifts in epigenetic regulation have on physiologically relevant processes in normal and cancerous cells remains to be clarified.

### Transcriptomics

Transcriptomics is the study of the transcriptome, which represents the set of all cellular RNA molecules including mRNA, rRNA, tRNA, and other non-coding RNA. The transcriptome is roughly fixed for a given cell type, although mutations are recognized to influence the quantity of these molecules. A variety of environmental factors, including one's diet, can influence the transcriptome. Monitoring mRNA transcripts is increasingly being examined as a molecular biomarker for the detection of disease risk and/or effectiveness of preventive or therapeutic agents, both dietary components and drugs. Such analyses offer the potential of earlier and more accurate prediction/diagnosis of disease and its progression. Since whole blood mRNA shares more than 80% of the transcriptome with major tissues, it appears to be a good surrogate tissue for predicting events in a target tissue (Liew *et al.*, 2006).

Transcriptomic profiling allows for a simultaneous monitoring of the expression of literally thousands of genes. While microarray technologies provide an important tool to discover expression changes influenced by diet and potentially the regulation of cellular processes, it must be remembered that any response may vary between healthy and diseased conditions. Studies using animals are beginning to identify specific sites of action of bioactive food components (Sunde, 2010). For example, the nuclear factor E2 p45-related factor 2 (Nrf2) and the Kelch domain-containing partner Keap1 are modified by sulforaphane (Cheung and Kong, 2010). Gene expression patterns from wild-type and Nrf2-deficient mice fed sulforaphane have highlighted several novel downstream events and thus clues about the true biological response to this food component. The up-regulation of glutathione S-transferase, nicotinamide adenine dinucleotide phosphate: quinone reductase, gamma-glutamylcysteine synthetase, and epoxide hydrolase, occurring because of release of Nrf2 from its cytosolic complex, likely helps explain the ability of sulforaphane to influence multiple processes including those involving xenobiotic metabolizing enzymes, antioxidants, and biosynthetic enzymes of the glutathione and glucuronidation conjugation pathways (Zhao *et al.*, 2010). Variation in *nfr2* also appears to be involved in explaining the ability of caloric restriction to depress cancer risk (Martin-Montalvo *et al.*, 2011).

Mammals are known to adapt to excess exposure to foods and their components through shifts in absorption, metabolism or excretion. Thus, the quantity and duration of exposure to foods or their constituents must be consid-

ered when evaluating the response in gene expression patterns. Since microarray technologies provide only a single snapshot, over-interpretation of their physiological significance is possible. The cost of using mRNA microarray technologies has decreased and thus they have become more commonplace for analysis in population studies which are aimed at characterizing subjects and their response to agents including nutrients (Ornish *et al.*, 2008; Al Tamimi *et al.*, 2010). Transcriptomic technologies have been used to examine the relationship between diet and cancer risk among native Japanese and second-generation Japanese-American men as a function of consumption of animal fat and soy (Marks *et al.*, 2004). This technology was able to discriminate differences between those men with cancer and those who were cancer free. However, it should be noted that the number of clinical nutrition studies that incorporate transcriptomic technologies remain relatively sparse. Impressively van Erk *et al.* (2006) found that relatively short-term exposures were sufficient to cause significant changes in the human transcriptome, and suggested that this technology can be used to discriminate the effects of types of diets on gene patterns. Overall, it may be possible to use a bolus exposure to determine whether or not key cancer-related processes are responsive or not responsive to foods with proposed anti-cancer activity.

Recent discoveries of embryonic stem cell identity in poorly differentiated tumors suggest that cancer prediction using embryonic stem cell signatures may be an important direction for further research (Ben-Porath *et al.*, 2008; Zhu *et al.*, 2010). Increasing evidence points to the ability of several dietary components to influence stem cells (Trosko, 2008; Alexander *et al.*, 2010; Langelier *et al.*, 2010). The differential transcriptomic response between normal and cancer stem cells represents an exciting area of investigation that may ultimately have a major impact on our understanding of the food components that hold the greatest promise for retarding the recurrent of cancers.

### Proteomics

Proteomics has been widely embraced by multiple biomedical disciplines including nutrition as a tool to identify biomarkers of health, disease and/or prevention/treatment responses (Thongboonkerd, 2007; Xiao *et al.*, 2009; Rahman *et al.*, 2010). High-throughput capabilities allow for the simultaneous examination of numerous proteins, and offer insights into subtle shifts in proteins in cells,

tissues and/or biofluids. Unlike the genome, the proteome is dynamic and varies according to cell type and functional state of the cell, thus raising important issues about what biological specimens are best to monitor the response to foods or their components. It is interesting to note that gene expression patterns do not always correlate with protein expression patterns, and thus the examination of a protein profile may have particular physiological relevance to teasing apart responders from non-responders.

Proteomic studies are already beginning to provide valuable evidence about the pleiotropic effects of food components on cellular processes. For example, a proteomic study using F344 rats revealed that providing quercetin in the diet (10 g/kg for 11 weeks) markedly influenced the expression of proteins in the colon which are involved in energy metabolism, cytoskeleton organization, and apoptosis. (Dihal *et al.*, 2008). Evidence was provided that the response to quercetin shifted the balance from glycolysis towards fatty acid oxidation, possibly by reducing the expression of four proteins involved in glycolysis including fructose 1,6-biphosphate aldolase A(1,6-PAA), glyceraldehyde-3-phosphate dehydrogenase (GADPH),  $\alpha$ -enolase, and pyruvate kinase isoenzyme M2 (PKM2). Resveratrol, which is found in grapes and peanuts, and genistein from soy have also been demonstrated to have a marked effect on multiple cellular networks (Cecconi *et al.*, 2008; Yan *et al.*, 2010). It is unclear if the response to these foods or food components reflects one or possibly a combination of changes in selected proteins.

Stable isotope labeling with amino acids in cell culture (SILAC) phosphoproteomic approaches have been used to investigate the specific effects of genistein on signaling pathways (Yan *et al.*, 2010). Remarkably, the tyrosine phosphorylation of 174 among 181 identified proteins was reduced by treatment with genistein. Other studies in leukemia HL-60 cells that investigated the proteomic response to genistein documented dose-dependent (50  $\mu$ M >20  $\mu$ M) inhibition of heterogeneous nuclear ribonucleoproteins C1/C2 (hnRNP C), stathmin, and GTP-binding Ras-related protein-14, and activation of hnRNP H1 and Hsp70 protein-8. The expression of these proteins was also influenced by time of exposure, with levels of HnRNP C and Rab 14 protein decreasing, and those of HnRNP H1, Hsp70 protein-8, increasing from 24 to 72 hours after treatment with genistein (Zhang *et al.*, 2007). Additional studies are needed to determine if the shifts in a protein are due to changes in synthesis/degradation/modification and if these reflect a progressive (rheostat or off/on switch)

response and the compensatory mechanisms which come into play following more prolonged exposures.

A few human trials have begun to examine the impact of eating behaviors on proteomic profiles. For example, the effect of 300 g Brussels sprouts was examined on proteomic profiles of the white blood cells from five subjects (Hoelzl *et al.*, 2008). Up-regulation of manganese superoxide dismutase (MnSOD), which is induced by the transcription factor Nrf2, and repression of Hsp70, which inhibits apoptosis, were among the more significant findings. Proteomic investigations may be particularly useful for determining gene–nutrient interactions such as the intake of cruciferous vegetables and possibly other foods and better cancer-protective effect in GSTM1- and GSTT1-null individuals compared with those with a wild-type gene profile (Lampe, 2007).

Clinical proteomic studies also support the pleiotropic effects of food components. In a study with healthy postmenopausal women, soy isoflavones (50 mg for 8 weeks) reduced expression of four proteins including galectin-1, which is involved in cell-cycle progression, pleckstrin, an aconitase 2 precursor, and RNA polymerase III transcription initiation factor B in peripheral blood mononuclear cells (Fuchs *et al.*, 2007b). Conversely, genistein increased the level of 25 proteins including Hsp70 and filamin-A, which are known to suppress TNF $\alpha$  activity; 26S protease-8, which has been shown to inhibit NF $\kappa$ B activation; and cytosolic NADP<sup>+</sup>-dependent isocitrate dehydrogenase, which influences overall mitochondria function (Fuchs *et al.*, 2007a). It is unclear if disease conditions will influence the proteomic profile that occurs following soy isoflavone exposure, but based on these finding such studies are warranted.

Proteomic studies may be useful for identifying processes which may influence overall cancer risk such as inflammation. Recently the anti-inflammatory properties of fish oils were examined as a modifier of proteins related to inflammation (de Roos *et al.*, 2008). The authors discovered a reduction of acute-phase proteins haptoglobin, haemopexin, and  $\alpha$ -1-antitrypsin. A combination of two-dimensional and matrix-assisted laser desorption/ionization/time-of-flight mass spectrometric (MALDI TOF MS) technologies were able to identify haptoglobin  $\alpha$ 2 chain as an up-regulated serum protein in glioblastoma patients with levels of the protein increasing as the tumor grade increased (Kumar *et al.*, 2010). Since haptoglobin is known to be expressed in at least six phenotypes, proteomics may be useful for the systematic monitoring of isoforms

and testing of efficacy of dietary interventions with fish oils or other interventions for specific subpopulations (Shah *et al.*, 2010).

While nutritional proteomics is in its infancy, it holds promise to provide a wealth of information for assessing how changes in dietary habits can influence critical cellular processes. Research in this area should allow for a greater understanding of the regulatory mechanisms for maintaining normal cellular homeostasis during normal, limited or excess exposures, and of the pathogenic mechanisms caused or modified by nutritional inadequacies; it should also help to define molecular targets of bioactive food components that can be used for predicting the response to diet. It will be important to characterize these proteins or groups of proteins that play a key part in cellular networks, define the physical boundaries (i.e. nuclear versus cytosolic) and establish their relationships with opposing biological processes (i.e. proliferation versus apoptosis). While biomarkers emanating from proteomic analyses cannot automatically be adopted for their clinical use, they are beginning to provide a biological base for predicting a response (Scott *et al.*, 2010).

### Metabolomics

The metabolome refers to all of the low molecular weight compounds in a biological sample in a given context. The study of metabolomics has enormous potential for validating intake assessment methods or measuring biological changes in response to bioactive food components. Changes in amounts of metabolites generally appear more quickly than changes in amounts of DNA, RNA, or protein. This may allow researchers to detect changes early in the cancer process and determine any influence that dietary compounds have over the process (Kim and Maruvada, 2008). Measuring metabolites provides an additional advantage over measuring mRNA or protein, as a single metabolite may be a substrate of multiple enzymes with varying isoforms (Ellis *et al.*, 2007). Challenges of using metabolomics as a tool include the high number of metabolites and the decision of which metabolites are the most important to study. These can be addressed by measuring a metabolic fingerprint, or a subset of metabolites that provides a snapshot of the metabolome at a given time point.

Researchers have used metabolomic methods to profile cells at various stages in carcinogenesis based on shifts in glucose metabolism (Gatenby and Gillies, 2007). This has potential for allowing researchers to study how food com-

ponents influence these metabolic profiles, which could lead to information on molecular targets of compounds. Measuring metabolites may also assist in determining mechanism of action or bioavailability, as illustrated by a study which measured urinary metabolites in premenopausal women who consumed soy in the form of textured vegetable protein (conjugated isoflavone glucosides) or miso (unconjugated isoflavones). Changes in metabolites in response to miso were greater than those from textured vegetable protein, suggesting that composition of isoflavones may influence any biological effects (Solanky *et al.*, 2005).

### Microbiomics

The microbiota in the human gastrointestinal tract consists of over 100 trillion microorganisms of over 500 bacterial species (Davis and Milner, 2009). Certain strains are associated with increased cancer risk, while others are associated with decreased risk. Therefore, it is important to identify dietary factors that promote the growth of beneficial bacteria while limiting the growth of harmful bacteria. Through metabolism of dietary components, the microbiota, depending on its composition, can form new bioactive compounds that influence cancer processes, either positively (hydrogen sulfide and secondary bile acids) or negatively (equol from soy isoflavones or urolithins from ellagic acid) (Larrosa *et al.*, 2006; O'Keefe *et al.*, 2009; Lampe, 2010).

The composition and activity of the microbiota can be modified by diet. Certain food compounds, particularly oligosaccharides found in vegetables, are not digested by humans, but rather by the microflora. These compounds, called prebiotics, promote selective growth or metabolic activity of beneficial bacteria such as lactobacilli and bifidobacteria. Probiotics, or live bacteria found in yogurts, cheeses, or functional foods and supplements, can colonize the gastrointestinal tract for short periods following consumption. Synbiotics include combinations of probiotics and prebiotics to enhance the survival and activity of the probiotic.

### Physiological versus Pathological Conditions

A fundamental issue remains about the circumstances under which bioactive food components bring about their primary effect; namely, are they maintaining normal cellular function, influencing the transition of the normal to

the neoplastic state, or altering the biological behavior of the neoplasm? Evidence exists that all three conditions can have importance in influencing cancer risk and tumor behavior, but that the biological mechanisms may be unique for each.

A wealth of evidence points to the ability of several bioactive food components to modify phase I and II enzymes and thereby help maintain normalcy in a cell (Milner, 2006; Yu and Kong, 2007). Modifying carcinogen metabolism and disposition is one of the major mechanisms by which dietary compounds can reduce cancer risk. The expression of phase I enzymes, which activate many carcinogens, is established by xenobiotic-sensing nuclear receptors such as AhR, CAR, PXR, and RXR. Phase II enzymes catalyze the conjugations of carcinogens and frequently are transcriptionally controlled by the Nrf2/ARE signaling pathways. Thus, the Nrf2/ARE signaling pathway likely represents a major target for several bioactive food components. The excretion of carcinogens and their metabolites is likely mediated by phase III transporters, which share common regulatory mechanisms with phase I/II enzymes. In addition to transcriptional regulation, the activities of phase I/II enzymes and phase III transporters could be directly activated or inhibited by dietary compounds.

There is limited evidence that bioactive food components can also influence the transition of normal to neoplastic cells. Classically, feeding a methyl-donor-deficient diet precipitates increased liver cancer, even in the absence of carcinogen exposure (Pogribny *et al.*, 2006). More recently, studies have demonstrated that feeding a diet high in fat, but low in calcium and vitamin D and thus similar to that consumed as part of a Western diet, markedly increases colon cancer in rodents (Yang *et al.*, 2007). It is unclear why there are few cases where deficiencies or inadequacies lead to cancer, but the paucity of cases may be related to the ability of the cell to adjust and survive through changes in autophagic homeostasis (Bergamini *et al.*, 2004).

Multiple studies also indicate that several food components can alter cancer cell proliferation, as well as programmed cell death (apoptosis) (Enciso and Hirschi, 2007; Martin, 2007; Moriarty *et al.*, 2007; Meeran and Katiyar, 2008). Key transitions in the cell cycle are known to be regulated by the activities of various protein kinase complexes composed of cyclin and cyclin-dependent kinases (CDK) molecules and to be influenced by multiple dietary components. Evidence that both essential and non-

essential dietary agents can modulate cell cycle checkpoints, and thus contribute to reduced tumor proliferation, continues to mount (Milner, 2006; Enciso and Hirschi, 2007; Moriarty *et al.*, 2007; Meeran and Katiyar, 2008). Diverse agents such as apigenin (celery, parsley), curcumin (turmeric), (-)-epigallocatechin-3-gallate (green tea), resveratrol (red grape, peanuts, and berries), genistein (soybean), and allyl sulfur (garlic) have been shown to markedly influence the cell cycle, possibly by differing mechanisms. At least some of these changes may be associated with post-translational changes including shifts in the phosphorylation of key regulatory factors of cell division. (Knowles and Milner, 2003). Dietary components can modulate apoptosis through shifts in protein expression and function or mRNA expression, either directly or indirectly, to modulate gene expression in both the extrinsic and mitochondrial-mediated apoptotic pathways (Kim *et al.*, 2007; Martin, 2007; Miyoshi *et al.*, 2007). At least some bioactive components may cause apoptosis by enhancing free radical formation in the cell (Kim *et al.*, 2007; Miyoshi *et al.*, 2007). While there is evidence that multiple dietary components can induce apoptosis, the concentrations used in many of these studies are excessive and may not reflect any effects of more physiological exposures.

## Sites of Action

Current information suggests that changes in multiple cellular processes may account for the response to bioactive food components and thus represent a pleiotropic response, unlike that which frequently occurs with drugs. Multiple processes including carcinogen metabolism, DNA repair, cell proliferation, programmed cell death, inflammation, differentiation, and angiogenesis are likely modified by bioactive food components (Figure 51.1) (Milner, 2006, 2008; Davis and Milner, 2007). Since multiple biological changes can occur simultaneously, it is difficult to determine which is most critical in dictating the overall response. The ability of multiple nutrients to influence the same process suggest synergistic, as well as antagonistic, interactions may occur depending on exposures.

The use of animal models, transgenic and knockout, will be fundamental to elucidating the specific site(s) of action of bioactive food components. Knockout mice have already assisted in identifying the nuclear factor E2 p45-related factor 2 (Nrf2) and the Kelch domain-containing partner Keap1 as the complex that is modified

**FIG. 51.1** Bioactive food components can influence multiple cancer processes. It remains unclear if the ability of food components to influence cancer relates to changes in one or a combination of effects on cellular processes.

by sulforaphane (Juge *et al.*, 2007; Yu and Kong, 2007). Gene expression profiles from wild-type and Nrf2-deficient mice fed sulforaphane have shown several novel downstream events and thus provided more clues about the true biological response to this food component. Another potential target for retarding cancer recurrence that has surfaced is the overexpressed human epidermal growth factor receptor 2 (HER-2/neu), which is treated by the monoclonal antibody Herceptin. Recent studies by Yee *et al.* (2005) suggest that fish oil may be as beneficial in retarding overexpression of Her2/neu as is Herceptin. These data suggest that copy number may also be an important determinant of the response to foods and their components.

## Current Recommendations

The 2007 Report of the World Cancer Research Fund/American Institute for Cancer Research on Food, Nutrition, Physical Activity, and the Prevention of Cancer (WCRF/AICR, 2007) reviewed all relevant research on diet and cancer risk and provided recommendations for overall cancer prevention in the general public based on this research. The eight recommendations are summarized in Table 51.1. Because many foods and food components have been reported to have effects on particular cancers and not others, the report also includes summaries specific to cancer site. While reduced intake of red meat, processed meat, and alcohol are the only foods that have associations

**TABLE 51.2** Summary of factors that modify the risk for colorectal cancers based on strength of evidence

Strength of evidence	Increases risk	Decreases risk
Convincing	Red meat Processed meat Alcoholic drinks (men) Body fatness Abdominal fatness Adult attained height	Physical activity
Probable	Alcoholic drinks (women)	Foods containing dietary fiber Garlic Milk Calcium
Limited, suggestive	Foods containing iron Cheese Foods containing animal fat Foods containing sugars	Non-starchy vegetables Fruits Foods containing folate Foods containing selenium Fish Foods containing vitamin D Selenium

Adapted from WCRF/AICR (2007).

with overall cancer prevention, there is sufficient data to draw further conclusions on the effects of foods and specific cancer sites, particularly cancers of the colon and rectum. Table 51.2 summarizes the findings of the report on food, nutrition, physical activity, and colorectal cancers. It is clear from a close examination of the available studies that there remains a dearth of controlled interventions to truly assess the ability of foods or their components to influence cancer risk and tumor behavior. It is also abundantly clear that considerable variability occurs in the literature. While current recommendations are appropriate, it is clear that not all individuals will respond identically to foods or food components. Additional research is needed to determine the best foods/components to consume and when during life to get maximum benefits. It is logical to assume that genetic and epigenetic events along with the microbiome will have a significant impact on the response to what is eaten (Figure 51.2).

**FIG. 51.2** An individual's genome, epigenome, and associated downstream events in transcriptomics, proteomics, and metabolomics, in concert with the microbiome, can markedly influence, either positively or negatively, the response to foods or food components. Three types of biomarkers are needed to adequately understand the role of diet in cancer prevention, namely (1) exposure, (2) effect (molecular target), and (3) susceptibility (genome–nutrient and nutrient–nutrient interactions).

### Future Directions

It is becoming increasingly appreciated that the chances of developing cancer are significantly influenced by one's lifestyle. Since ancient times a host of food items have been touted for their medicinal value including the prevention of diseases such as cancer. A wealth of experimental evidence using a variety of models substantiates the importance of the diet in modifying cancer risk due to carcinogens or to genetic predisposition. The concept that foods and food components can serve as effective agents for cancer risk and tumor behavior has advanced the field markedly. Unfortunately, preclinical studies have not always been substantiated in clinical intervention studies. The reason

for these inconsistencies remains elusive, but may relate to the quantity of the bioactive constituent consumed, the timing of exposure, genetics, and biological insults including excessive energy and associated radicals, environmental contaminants, viruses and/or bacteria. Exciting opportunities exist for identifying and validating biomarkers that can be used to identify the exposures, predict the molecular target needing modification, and identify those susceptible to the merits or risk associated with intervention (both genetic–nutrient and nutrient–nutrient interactions). While identification of those who will benefit most will not be easy, the societal benefits are enormous.

## NUTRITION AND GASTROINTESTINAL ILLNESS

ALAN L. BUCHMAN<sup>1</sup>, MD, MSPH, FACP, FACG, FACN, AGAF AND  
STEPHEN A. MCCLAVE<sup>2</sup>, MD, AGAF

<sup>1</sup>*Feinberg School of Medicine, Northwestern University, Chicago, Illinois, USA*

<sup>2</sup>*University of Louisville School of Medicine, Louisville, Kentucky, USA*

### Summary

The role of nutrition therapy has evolved to become a primary intervention in a number of disease states in the gastrointestinal system. Attention to nutrient agents that may ameliorate symptomatology and/or reverse pathophysiologic processes often serves to change the course of illness and hospitalization and improve patient outcomes.

### Introduction

Nutritional issues, including development of macro- and micronutrient deficiencies as well as therapeutic nutrition, are important in a wide range of gastrointestinal disorders involving every organ of the gastrointestinal tract in addition to the liver and gallbladder. The role of disease-specific malnutrition in a variety of ailments as well as directed nutritional therapy is described below. This chapter is not meant to serve as a comprehensive encyclopedia of all the effects of nutrition and malnutrition on the gastrointestinal system. Nor do we describe the important role of the digestive tract in the digestion, absorption, assimilation, and metabolism of nutrients,

which are covered elsewhere in this book. Rather, specific disease states for which nutrition has a profound role in medical and/or surgical management are used as examples. These include diseases that affect the esophagus (eosinophilic esophagitis and gastroesophageal reflux disease), the small intestine (celiac disease, inflammatory bowel disease, and intestinal failure), and the pancreas (acute and chronic pancreatitis). In some cases, nutrition may have a role in the pathogenesis and treatment of disease (eosinophilic esophagitis, gastroesophageal reflux disease, celiac disease, and Crohn's disease), and in others nutritional issues arise as a result of the disease (Crohn's disease, celiac disease, intestinal failure, and pancreatitis).

## Esophagus

### **Eosinophilic Esophagitis**

Eosinophilic esophagitis (EoE) is a relatively recently recognized disorder of the esophagus. Most subjects are male Caucasians who present with long-standing dysphagia or food impactions (Liacouras *et al.*, 2011). Many patients have evidence of atopy, including asthma, allergic rhinitis, eczema, abnormal skin testing or peripheral eosinophilia (Liacouras *et al.*, 2011). Histologically, tissue injury as well as the presence of eosinophils (>15–20 per high-powered field) in the squamous epithelium of the esophagus are observed; submucosal fibrosis may be evident. Environmental allergens, including food, have been implicated in the pathogenesis of EoE. The combination of skin prick and patch testing may be useful in the identification of offending food allergens in up to 70% of cases (Furuta *et al.*, 2007), although poor test standardization remains a limiting factor (Liacouras *et al.*, 2011). Although the mainstay of treatment in this evolving field has been topical corticosteroids (Liacouras *et al.*, 2011), dietary management through the use of a free amino acid-based “elemental” formula, generally delivered via a nasogastric tube because of poor taste (Markowitz *et al.*, 2003) has also been useful. More recently, Kagalwalla *et al.* (2006) proposed the use of food elimination diets; this has been successful in case series. In their series of 35 children, elimination of cow’s milk protein, soy, wheat, eggs, peanuts, and seafood led to significant improvement in esophageal inflammation in 74%.

### **Gastroesophageal Reflux Disease**

Gastroesophageal reflux disease (GERD) is perhaps the most common gastrointestinal disorder (Locke *et al.*, 1977). Transient relaxation of the lower esophageal sphincter (LES) is one of the mechanisms underlying the disorder’s pathophysiology. This leads to reflux of acid into the esophagus where the mucosal lining may be damaged. Several foods have been associated with increased GERD symptoms. These include dietary fat, peppermint, coffee, caffeine, onions, citrus products, wine, and carbonated beverages because of relaxation of the LES. However, dietary modification has met with variable success for control of both GERD-like symptoms as well as objective evidence of pathology, and studies of specific food triggers have met with conflicting results (Karamanolis and Tack, 2006). High-fat-containing foods may, in addition to lowering the LES pressure, result in delayed gastric emptying

with a resultant enhancement of gastric acid secretion (Karamanolis and Tack, 2006). The incidence of GERD is also increased in obesity (Locke *et al.*, 1999; Ruhl and Everhardt, 1999), although this association has not been demonstrated in all studies (Lagergren *et al.*, 2000). The pathophysiology underlying this observation remains speculative, however. Factors including increased intra-abdominal pressure (Sugerman *et al.*, 1997) and increased basal and food-stimulated acid secretion (Mercer *et al.*, 1987; Wisen *et al.*, 1987) have been proposed. The role of weight loss in the management of GERD is currently undefined, although some studies have suggested an improvement in objective measures of GERD (Tolonen *et al.*, 2006).

## Small Intestine

### **Celiac Disease**

Better understanding of the disease prevalence, the nature of the immunologic responses, the long-term course, and the susceptibility to complications has contributed to improved management of the patient with celiac sprue (See and Murray, 2006; Green and Cellier, 2007). Celiac disease or sprue is a chronic disease in genetically predisposed individuals as a result of a potent immune response to the gluten protein contained in wheat, rye, and barley. Innate immune responses lead to the immediate reaction of increased permeability and release of inflammatory cytokines (interleukin, IL-15). Acquired responses promote further immune sensitivity, loss of tolerance, and development of chronic inflammation (See and Murray, 2006). The proinflammatory Th-1 response that characterizes celiac sprue perpetuates the elicitation of tumor necrosis factor and interferon- $\gamma$ . The proximal small bowel is affected to a disproportionately greater degree than the distal small bowel and colon, as it sees the highest concentration of injurious peptides contained in the toxic grains. The extent of injury can involve from as little as 1% to as great as 100% of the length of the small bowel. The net effect of the chronic inflammation is a defect in the ability to absorb both micro- and macronutrients. Symptoms are fairly classic, with weight loss, diarrhea, steatorrhea, and, in children, failure to thrive. While patients are at risk for multiple micronutrient deficiencies (such as folate, B<sub>12</sub>, and fat-soluble vitamins), iron deficiency is probably most common. Because of the variable involvement of the small bowel, however, there may be wide variation in symptomatology. It is not uncommon for patients who may even be

obese or have no evidence of diarrhea to present with iron deficiency alone.

Extraintestinal manifestations of celiac sprue include infertility, peripheral neuropathy, ataxia and epilepsy, dermatitis herpetiformis, aphthous ulcers in the mouth, abnormalities of the dental enamel, and abnormalities of bone mineralization (See and Murray, 2006). Osteopenia is present in as many as 40% of newly diagnosed cases, with osteoporosis present in up to 26% of new cases (Mora *et al.*, 2001). Patients with celiac disease are at increased risk for autoimmune disorders compared with the general population.

The diagnosis can be made through a serologic panel of antibodies and by biopsies of the small bowel. The most sensitive and specific antibodies are the anti-tissue transglutaminase and the anti-endomysial antibodies (See and Murray, 2006). Anti-gliadin IgG and IgA antibodies are not as sensitive or specific. Because an IgA deficiency can occur concomitantly in a small number of patients with celiac sprue, falsely normal levels of anti-tissue transglutaminase and anti-endomysial antibodies may be seen. Small bowel biopsy helps confirm the case in a patient on a regular diet who shows loss of villous height and evidence of an intense inflammatory infiltrate (especially plasma cells) in the lamina propria of the small bowel.

An interesting mnemonic, “**CELIAC**,” helps remind clinicians of the six key steps in the management of the patient with celiac sprue (James, 2005; See and Murray, 2006). The **C** stands for consult with a dietitian, the **E** for education about celiac disease, and the **L** for lifelong adherence to a gluten-free diet; **I** is for identification and treatment of nutrient deficiencies; **A** is for access to support groups; and the second **C** stands for continuous long-term support (James, 2005; See and Murray, 2006). Only dietary restriction of gluten and a gluten-free diet lead to resolution of symptoms and histology. However, non-compliance is a huge problem in management, an issue which is most often related to poor education.

In evaluating the patient on initial assessment, such factors as a dietary history, the support system and family situation, who prepares the food, and lifestyle travel and business responsibilities are all factors that need to be filtered into the management (See and Murray, 2006). Quantitation of the intake of gluten is not necessary. Patients should be encouraged to switch from grains which contain gluten (such as wheat, rye, barley, and bran) to gluten-free grains such as corn, oats, rice, soybeans, and potatoes. There is some concern about cross-contamination

with oats which is commonly stored with wheat on farms. A gluten-free diet focuses instead on plain meats, dairy, vegetables, fruits, and rice (James 2005; See and Murray, 2006).

General counseling for these patients includes recommendations that they avoid non-food sources of gluten such as toothpaste, mouthwash, and medication capsules. They should plan ahead when traveling or going to a friend's house for dinner. Celiac patients should avoid prepared foods and should be encouraged to “make foods from scratch.” They should be educated about reading labels. When eating out, attendance at the same restaurants is to be encouraged in order to increase familiarity with the menu and avoid hidden sources of gluten. The highest risk of hidden gluten content occurs in sauces, seasoned food, and combination platters (Fine *et al.*, 1997; See and Murray, 2006).

Patients should be reminded that non-compliance increases the chance of bone disease and the risk of lymphoma. Intestinal lymphoma may occur in as high as 10–15% of cases where patients are non-compliant (Catassi *et al.*, 2002). If they are able to obtain lifelong compliance with a gluten-free diet, their risk for intestinal lymphoma should be no different from that of the general population. Finally, absence of symptoms does not guarantee that the patient is free from occult damage to the gastrointestinal tract occurring in response to exposure to gluten products.

### **Inflammatory Bowel Disease**

Generalized protein-calorie malnutrition with weight loss is common in patients with Crohn's disease, albeit is less common in those with ulcerative colitis. Micronutrient deficiencies may also occur, generally because of decreased intake, malabsorption and/or increased losses, and, in some cases, increased requirements. Deficiencies of fat-soluble vitamin D are present in the vast majority of patients with Crohn's disease, even in those whose disease is in remission. Vitamin A deficiency is encountered less frequently, and vitamin E and K deficiencies are rare. Serum vitamin E concentration may be decreased, solely related to the decrease in serum total lipid concentration. Water-soluble vitamin deficiencies, with the exception of cobalamine (vitamin B<sub>12</sub>) are rare. Vitamin B<sub>12</sub> deficiency may develop in those patients with chronically active disease in their terminal ileum, or in those who have had resections of their terminal ileum totaling >60 cm (Behrend *et al.*, 1995). The reduced bile-salt pool that occurs in

conjunction with terminal ileal disease or resection leads to fat maldigestion and can result in deficiency of essential fatty acids and of fat-soluble vitamins (Bousvaros *et al.*, 1999). Vitamin K deficiency remains rare because the majority is synthesized by normal colonic flora, although this may be disrupted in patients with Crohn's colitis who receive antibiotic therapy. Bacterial overgrowth may also occur proximal to strictures, and the resultant bacteria compete with the enterocytes for nutrient absorption. Folate deficiency has been described in upwards of a third of patients with Crohn's disease (Elsbord and Larsen, 1979) and in those patients taking folic acid antagonists such as methotrexate or medications that decrease folic acid uptake (sulfasalazine). Folic acid's use in chemoprevention for colon cancer is controversial (Levine and Burakoff, 2007). Zinc deficiency may be observed in upwards of 40% of patients with Crohn's disease because of fecal loss of zinc in diarrhea (Valberg *et al.*, 1986). Deficiency can be difficult to determine based on measurement of serum zinc concentration because zinc is bound to albumin, other proteins, and amino acids, concentrations of which may be depressed in active Crohn's disease because of the presence of a protein-losing enteropathy. Similarly, conventional measures of iron deficiency may not be relevant in patients with active Crohn's disease or ulcerative colitis because ferritin, as an acute phase reactant, is often elevated in active disease, and the total iron binding capacity (TIBC) may be decreased.

In general, patients with Crohn's disease, in the absence of an intestinal obstruction, should consume a diet liberal in protein, and with sufficient energy to gain back lost weight, or to maintain a normal weight. There is no benefit to a low-carbohydrate or low-residual diet except in the presence of an intestinal obstruction. There is also no proven benefit from a diet with increased content of unrefined carbohydrate (Ritchie *et al.*, 1987). Potentially, diets high in complex carbohydrates and soluble fiber may be beneficial to patients with colitis because of the effects on colonic mucosa of short-chain fatty acids formed from the fermentation of dietary substrate, such as butyrate, acetate, and propionate. Data from studies using enteral nutritional support have suggested diets or formula high on long-chain triglycerides may be associated with an increased relapse risk in patients with Crohn's disease (Middleton *et al.*, 2005).

Dietary oxalate should be restricted in patients with steatorrhea from chronically active disease involving the terminal ileum or because of a terminal ileum resection.

Normally, dietary oxalate is bound by calcium. However, in the setting of steatorrhea, calcium binds preferentially to free fatty acids. Oxalate then passes into the colon where it is absorbed, possibly related to enhanced colonic permeability caused by the presence of bile salts which normally would have been reabsorbed in the terminal ileum. The oxalate is then filtered in the kidneys where it binds to calcium with the creation of calcium oxalate nephrolithiasis (Dobbins and Binder, 1977; Dharmasathaphorn *et al.*, 1982; Sangaletti *et al.*, 1989).

Exclusionary diets have been utilized in the management of Crohn's disease, although not ulcerative colitis. The concept of the exclusionary diet was based on patient reports of specific foods triggering relapse of their Crohn's disease. In studies by Jones *et al.* (1985), Persson *et al.* (1992), and Riordan *et al.* (1993), patients were made *nil per os* in a research setting, and each day an additional self-described food trigger was added to their diet. Wheat, dairy, and some cruciferous vegetables, as well as mustard greens were found to trigger diarrhea and other gastrointestinal complaints consistent with their symptoms of Crohn's disease. Similar foods were reported by Andresen (1942) to trigger the development of ulcerative colitis. Although wheat bran is an excellent water-holding and fecal bulking agent, dairy products can cause diarrhea and other symptoms in lactase-deficient individuals, and many vegetables have significant biomass, these products, as well as eggs, also contain relatively high concentrations of sulfur. In animal models, sulfur exerts toxic effects on colonocytes (Ohkusa, 1985; Roediger *et al.*, 1993). In one study, the percentage of patients with active Crohn's disease who maintained remission was greater in the exclusionary diet group than in those who received corticosteroids. One epidemiological study found a substantially greater likelihood of the development of Crohn's disease among individuals who consumed fast food at least twice weekly (Persson *et al.*, 1992).

Omega-3 fatty acids, named as such because of the double bond that exists between the third and fourth carbon atoms away from the fatty acid chain's methyl group ending, have been evaluated in several studies for the induction of remission and maintenance of remission in both Crohn's disease and ulcerative colitis. Current data taken in aggregate do not support the use of fish oils in the management of either disease (Lorenz-Meyer *et al.*, 1996; Feagan *et al.*, 2008). Similarly, several small studies in which glutamine was used as a therapy for Crohn's disease do not support its use as a therapeutic agent in

irritable bowel disease (IBD); one rodent study suggested inflammation was worsened with glutamine supplementation (Shinozaki *et al.*, 1997; Akobeng *et al.*, 2000).

There are many small studies in which di- and tripeptide-based or free amino acid-based formulas have been used for nasoenteric feeding. The concept behind the use of these products arose because such non-protein-based products would decrease the antigenic load on the gut. However, studies with intact protein-based formulas showed equal efficacy. All of these enteral formulas were sterile, however, and may have resulted in a change in gut flora – perhaps species or total bacterial mass (Buchman, 2005). It must be understood, however, that, even if efficacy of enteral feeding as a primary treatment for Crohn's disease is inferior to treatment with corticosteroids or other pharmacologic interventions (Lochs *et al.*, 1991), enteral nutritional support (or parenteral, if indicated), is useful in the treatment and prevention of nutritional deficiencies and deficits and, in children, prevention and treatment of growth retardation.

The use of parenteral nutrition was based on the concept that so-called “bowel rest” would allow damaged mucosa to heal. Many studies were uncontrolled, and/or retrospective in disease, or used historic controls. Short-term remission rates approaching 64% after 3–6 weeks of therapy were achieved, which are better than with most medical therapies (Lashner *et al.*, 1989). However, long-term remission rates were less impressive and approached those following use of corticosteroids. Most studies have shown similar short- and long-term remission rates when enteral nutritional support was compared with the parenteral route. Although there is little data on the use of enteral nutritional support in the management of enterocutaneous fistulas, findings would suggest short-term closure rates are similar to that with infliximab, although long-term closure is rare (Afonso and Rombeau, 1990). There are certainly appropriate indications for parenteral nutrition in IBD: these include intestinal obstruction, bowel perforation, prolonged postoperative ileus, or use as part of a regimen to manage proximal entero-enteric or enterocutaneous fistulas.

### **Intestinal Failure**

Nearly all macro- and micronutrient absorption occurs in the small intestine, with a lesser component absorbed in the colon. Intestinal failure results when nutrient and/or fluid intake and absorption are insufficient to meet basal requirements. Most commonly, intestinal failure results

### **BOX 52.1 Causes of short bowel syndrome and intestinal failure**

#### *In adults*

- Catastrophic vascular accidents
  - Superior mesenteric venous thrombosis
  - Superior mesenteric arterial embolism
  - Superior mesenteric arterial thrombosis
- Intestinal resection for tumor
- Midgut volvulus
- Multiple intestinal resections for Crohn's disease
- Trauma
- Radiation enteritis<sup>a</sup>
- Refractory sprue\*
- Scleroderma and mixed connective tissue disease\*
- Chronic intestinal pseudo-obstruction\*

#### *In children*

- Congenital villus atrophy<sup>a</sup>
- Extensive aganglioneurosis<sup>a</sup>
- Microvillus inclusion disease
- Gastroschisis
- Jejunal or ileal atresia
- Necrotizing enterocolitis
- Midgut volvulus
- Chronic intestinal pseudo-obstruction
- Multiple intestinal resections for Crohn's disease
- Trauma

\*Functional short bowel syndrome may also occur in conditions associated with severe malabsorption, in which the bowel length is often intact.

from short bowel syndrome – an anatomic reduction in the length of functional intestine (Figure 52.1). Loss of bowel may occur congenitally, or may result from one of more surgical resections as a result of trauma or mesenteric vascular compromise (Box 52.1). Many although not all patients with short bowel syndrome will require parenteral infusion of nutrients, and/or fluid and electrolytes. Some patients with short bowel syndrome may remain nutritionally autonomous, or may be successfully weaned from parenteral support with proper medical and/or surgical management (Figure 52.2). Intestinal failure may also result from a “functional” short bowel syndrome because of severe malabsorption (Box 52.1).

Nutritional complications of intestinal failure include fluid and electrolyte depletion and acidosis, as well as macro- and micronutrient deficiencies (Table 52.1); supplementation may be required in large doses (Table 52.2).

**FIG. 52.1** The three common types of intestinal resection and anastomosis observed in patients with short bowel syndrome: ileocolonic anastomosis, jejunocolonic anastomosis, and end-jejunostomy.

**TABLE 52.1** Daily stomal or fecal losses of electrolytes, minerals, and trace elements in severe short bowel syndrome<sup>a</sup>

Element	Concentration
Sodium	90–100 mEq/L
Potassium	10–20 mEq/L
Calcium	772 (591–950) mg/day
Magnesium	328 (263–419) mg/day
Iron	11 (7–15) mg/day
Zinc	12 (10–14) mg/day
Copper	1.5 (0.5–2.3) mg/day

<sup>a</sup>For sodium and potassium, the average concentration per liter of stomal effluent is given. The values for minerals and trace elements are mean 24-hour losses, with the range in parentheses.

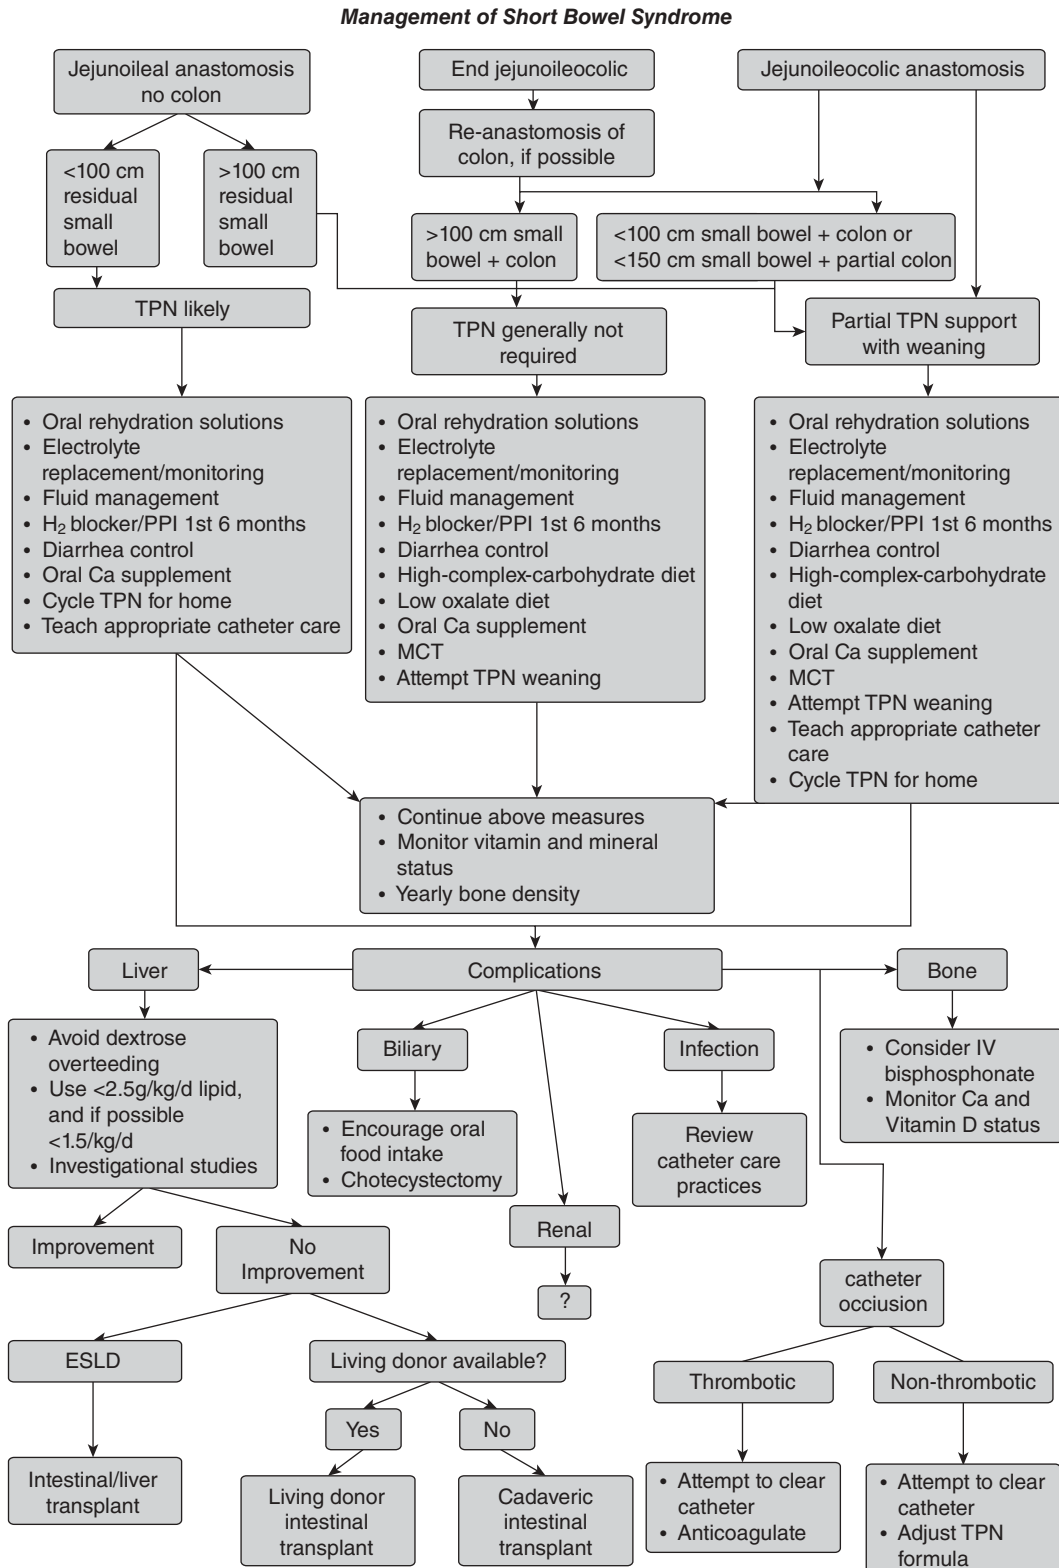

**TABLE 52.2** Vitamin and mineral requirements<sup>a</sup> in patients with a short bowel syndrome

Vitamin A	10000–50000 units daily <sup>a</sup>
Vitamin B <sub>12</sub>	1000 µg SC monthly for patients with terminal ileal resection or disease
Vitamin C	200–500 mg daily
Vitamin D	50000 units weekly to daily as 25 (OH) <sub>2</sub> - or 1,25(OH) <sub>2</sub> -D <sub>3</sub>
Vitamin E	30 IU daily
Vitamin K	10 mg weekly; not always necessary if colon in continuity given bacterial synthesis
Calcium	1000–2000 mg daily
Magnesium	Variable – generally needs to be administered IV
Iron	As needed; absorbed in the duodenum, not always necessary
Selenium	60–150 µg daily
Zinc	220–440 mg daily (sulfate or gluconate form)
Bicarbonate	As needed

Note: the table lists rough guidelines only. Vitamin and mineral supplementation must be monitored routinely and tailored to the individual patient, because relative absorption and requirements may vary. Supplements may be taken orally unless otherwise indicated.

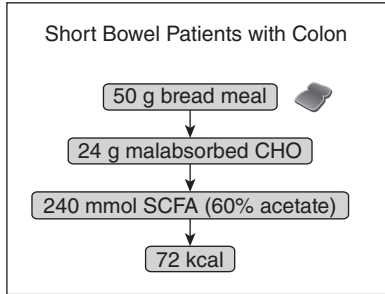

<sup>a</sup>Use cautiously in patients with cholestatic liver disease because of the potential for liver toxicity.

The goals of nutritional therapy are to treat and prevent these deficiencies, and to encourage intestinal adaptation, during which parenteral fluid and nutritional support are progressively weaned if possible. The first step towards nutritional autonomy involves maximization of residual intestinal absorptive function. This entails re-anastomosis

**FIG. 52.2** Management of short bowel syndrome. ESLD, end-stage liver disease; MCT, medium-chain triglyceride; PPI, proton pump inhibitor; TPN, total parenteral nutrition. Reproduced with permission from Buchman *et al.* (2003).

of residual small bowel to colon in order to allow for carbohydrate salvage. Such salvage involves the bacterial fermentation of unabsorbed carbohydrates, including starches and soluble fibers, in the distal residual small intestine and colon (Figure 52.3). Byproducts of the fermentation process include short-chain fatty acids such as butyrate,

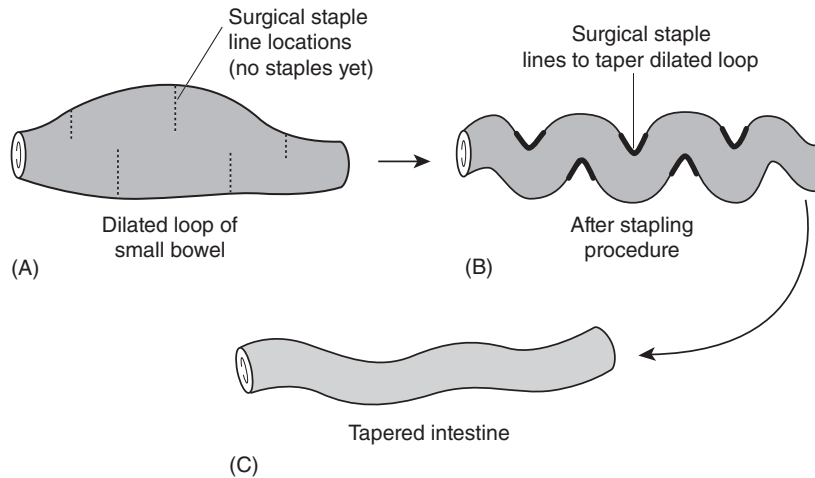

**FIG. 52.3** Colonic absorption of malabsorbed carbohydrates (CHO) in a hypothetical patient with short bowel syndrome following ingestion of a 50-g bread meal. Unabsorbed carbohydrates, non-starch polysaccharides, and soluble fiber are fermented by colonic bacterial flora to hydrogen, methane, carbon dioxide, sulfides, and short-chain fatty acids (SCFAs), including acetate, butyrate, and propionate. By comparison, normal individuals absorb approximately 220–720 mmol SCFA from fermentation of 30–60 g nonstarch polysaccharides.

acetate, and propionate, which serve as energy substrates for colonocytes.

If dilated segments of small intestine are present, dysmotility often leads to bacterial overgrowth and decreased nutrient assimilation via maldigestion and impaired absorption. The dilated segments of intestine can be tapered using a STEP (serial transverse enteroplasty, Figure 52.4) or a Bianchi procedure. The intestine is lengthened, and although the absorptive surface area does not increase, absorption improves because the segment becomes more functional. Although residual intestinal absorptive capacity is the chief predictor of nutritional autonomy, in general a minimum of 100 cm of intestine, ending in an end ileostomy, or 40–60 cm of small bowel with colonic continuity, is required to achieve and maintain independence from parenteral nutrition requirements (Buchman *et al.*, 2003). The ileocecal valve functions to decrease intestinal transit time and thereby increase nutrient–mucosa contact time, which in turn effects greater absorption but also helps prevent the translocation of colonic bacteria to the distal small bowel where they may compete with enterocytes for nutrient assimilation.

Regardless of the surgical approach to reconstruction of the gastrointestinal tract, enteral nutrient assimilation is needed, preferably via the oral route because of the salivary release of epidermal growth factor (EGF) (Piludu *et al.*, 2003). Most nutrient absorption occurs within the initial

**FIG. 52.4** Serial transverse enteroplasty (STEP), an intestinal tapering procedure that can be used to transform a dilated segment of intestine with little motility into a more functional segment with enhancement of fluid and nutrient absorption, most likely due to elimination of conditions favorable for bacterial overgrowth. (A) Diagrammatic depiction of a dilated intestinal segment, (B) staple line positions which lead to (C), a lengthened, but tapered and functionalized intestinal lumen.

100–150 cm of intestine (Borgstrom *et al.*, 1957). Notable exceptions include vitamin B<sub>12</sub> (absorbed in the terminal ileum), and water and sodium, which are absorbed throughout the small intestine and colon; iron and calcium are generally absorbed in the duodenum while some medium-chain triglyceride, calcium, and amino acid absorption may also occur in the colon. Although fat and fat-soluble vitamin A absorption occurs in the proximal jejunum, bile salt re-absorption in the terminal ileum is a necessary component of fat absorption. Bile salts, produced in the liver and stored in the gall bladder, are released into the bile duct in response to food, especially fatty foods. These bile salts mix with fat and create micelles, which serve to solubilize fat and lead to enhanced absorption. Although there is little data in humans because of the inability to study individuals prior to an intra-abdominal catastrophe or prior to the onset of inflammatory bowel disease, a plethora of animal studies have indicated that, during the adaptation process following resection, the intestine lengthens somewhat, but, more importantly, villus height and crypt depth increase, thereby increasing mucosal surface area and absorption. This process is largely complete by 6–12 months, or at most (in general) 24 months in humans (Cisler and Buchman, 2005).

Individuals who develop permanent intestinal failure will require long-term home parenteral nutrition. This nutritional therapy is typically provided in the form of an overnight infusion whereby the patient connects themselves to an intravenous infusion pump using a long-term indwelling central venous catheter. The parenteral nutrition solutions infuse overnight and the patient disconnects the following morning. Patients may require parenteral nutrition between 2 and 7 nights weekly.

The mainstay of medical treatment of short bowel syndrome, and, in some cases, non-short bowel intestinal failure, is control of diarrhea and maintenance of adequate hydration. Furthermore, oral intake needs to increase to 1.5–2 times pre-resection intake; this is termed *hyperphagia* (Crenn *et al.*, 2004). Although enteral supplementation with tube feeding may help achieve this goal, tube feeding presents additional challenges to the patient who already has to maintain themselves on parenteral nutrition. Not only does nutrient malabsorption occur in patients with intestinal failure, but medication malabsorption as well, and higher than conventional doses of medications may often be necessary. Furthermore, narcotics such as tincture of opium or codeine may be necessary to induce

a delay in gastrointestinal transit. Because of gastric hypersecretion for the initial 6 months following a massive enterectomy (Hyman *et al.*, 1986), high-dose proton pump inhibitor therapy is recommended to decrease gastric fluid losses. Increased gastric acid secretion that passes into the duodenum may acidify the normally alkaline duodenal fluid and lead to deconjugation of bile salts and inactivation of lipase, resulting in worsened carbohydrate maldigestion and fat malabsorption.

Recent studies have suggested a role for glucagon-like peptide II (GLP-II) in the enhancement of absorption of fluids and, to a lesser degree, nutrients, and studies have shown significantly enhanced fluid absorption in patients past the normal post-enterectomy adaptation phase with exogenous GLP-II administration (Jeppesen *et al.*, 2001, 2005). The data for growth hormone is less compelling, but does suggest that its use leads to enhanced fluid retention, although probably on the basis of enhanced renal tubular reabsorption of sodium (Byrne *et al.*, 2005).

Potential complications related to intestinal failure include hepatobiliary disease (steatohepatitis, cholestasis, calculous or non-calculous cholecystitis), metabolic bone disease, nephrolithiasis, and nephropathy. Additional complications related to therapy include catheter sepsis and other infections (exit site/subcutaneous cuff and tunnel); mechanical issues including catheter breakage and malpositioning; as well as catheter occlusion and/or occlusion of the vein through which parenteral solutions were infused (thrombotic/non-thrombotic) related to the indwelling catheter required for parenteral fluid administration (Buchman, 2001).

Successful intestinal transplantation was first successfully performed in 1989 (Hansmann *et al.*, 1989). It is currently approved for the treatment of patients with intestinal failure who have required parenteral nutrition but who have developed significant and potentially life-threatening complications, including, most frequently, intestinal failure-associated liver disease (IFALD), loss of venous catheter access, or recurrent infections or dehydration (Buchman *et al.*, 2003). As long-term survival improves, intestinal transplantation may become a viable option for patients with less severe complications of intestinal failure.

Patients who require only partial parenteral nutrition and/or fluid support should be encouraged to consume oral rehydration solutions. These solutions have high sodium concentration (90–100 mmol/L), which is designed to replace fecal sodium losses (Atia and Buchman,

**FIG. 52.5** Mechanism of solute-coupled Na<sup>+</sup> co-transport. Sodium contained in oral rehydration solutions replaces diarrhea-associated Na<sup>+</sup> losses and promotes water absorption by means of solvent drag. This schematic diagram illustrates the active, Na<sup>+</sup>-coupled co-transport of solute into the jejunal enterocyte, where the solute may be glucose (GLU), glucose polymers, galactose, oligopeptides, or L-amino acids. S, solute.

2009). They also contain substantial concentrations of glucose or similar sugars. Absorption of both sodium and glucose is an active process that occurs largely in the jejunum and utilizes the same transport mechanism (Banks and Farthing, 2002). As sodium and glucose enter the enterocyte, water passively diffuses, leading to enhanced fluid absorption and lessening the likelihood of dehydration (Figure 52.5).

It is also recommended that patients consume a high complex-carbohydrate diet if they have residual colon in continuity with small bowel (Buchman *et al.*, 2003; Atia *et al.*, 2011). In the absence of duodenal or proximal jejunal resections, lactose restriction is not necessary and deprives the patient of the major dietary calcium source. Micronutrient status, most notably the fat-soluble vitamins, essential fatty acids (linoleic) zinc, and, to a lesser degree, selenium status, should be followed at regular intervals (at least twice yearly and more frequently if clinically indicated). Vitamin B<sub>12</sub> should be administered by the sublingual, intranasal, or intramuscular route if >60 cm of terminal ileum has been resected.

## Pancreas

### Acute Pancreatitis

Evolution in our understanding of the factors that contribute to the systemic inflammatory response syndrome (SIRS), which characterizes acute pancreatitis, has led to dramatic changes in management (McClave, in press). The sentinel acute pancreatitis event (SAPE) hypothesis described by Schneider and Whitcomb (2002) suggests that an innocuous injury to the pancreatic acinar cells (such as high triglyceride levels, alcohol consumption, passage of a common bile-duct stone, or toxic drug) leads to a sentinel event. The sentinel event refers not to the injurious agent, but to the cascading, self-perpetuating, proinflammatory event that ensues. Increased vascular permeability, aggressive recruitment of neutrophils into the area of the pancreatic acinus, and elaboration of inflammatory cytokines, set up a vicious cycle of inflammation (the sentinel event) which leads to destruction of the acinar cells and autodigestion of the gland (Pandol *et al.*, 2007). This sentinel event represents a final common pathway of many different etiologic agents, with the difference between acute and chronic pancreatitis determined by whether the patient is able to resolve the injury and turn off the inflammation. Specific genetic defects (such as the SPINK-1 cystic fibrosis gene, and others) and the patient's overall antioxidant defense system are key factors in whether the sentinel event goes on to continuity, scar tissue, fibrosis, and chronic pancreatitis (Schneider and Whitcomb, 2002).

Nutritional therapy, primarily through delivery of early enteral nutrition (EN), improves the patient's capability for handling oxidative stress (McClave, in press). Providing early EN maintains gut integrity and prevents increases in gut permeability (Figure 52.6). Failure to provide luminal nutrients helps set up a gut–lung conduit of inflammation, where a cytokine storm produced at the level of the gut releases proinflammatory agents into lymphatic channels that pass directly up to the capillary system of the lungs (Alverdy *et al.*, 2003) (Figure 52.7). In this sense, EN actually protects the patient against acute respiratory distress syndrome (ARDS) and pneumonia. EN down-regulates the systemic immune response by decreasing activation of macrophages and neutrophils of the innate system and stimulating a line of CD-4 Th-2 anti-inflammatory lymphocytes which emerge from the gut and pass out to distant sites throughout the body (Figure 52.6). EN also promotes the role of commensal bacteria,

**FIG. 52.6** Delivery of early enteral nutrition (EN) helps diminish the primary systemic inflammatory response syndrome (SIRS) caused by pancreatitis. EN maintains gut integrity, prevents increases in intestinal permeability, and exerts anti-inflammatory effects through stimulation and release of Th2 CD4 helper lymphocytes from the lamina propria. Both commensal and virulent organisms are present, but the overall effect is beneficial, stimulating heat shock proteins and maintaining tight junctions between epithelial cells.

which act on carbohydrate and fiber to produce short-chain fatty acids, which impact on butyrate receptors in the colon, exerting a further anti-inflammatory effect (Alverdy *et al.*, 2003; McClave, in press).

In fact the focus of management has shifted from being centered on pancreatic rest to maintaining gut integrity and modulating the immune response. The outcome ben-

efits from early EN are profound when compared with parenteral nutrition (PN), with significant decreases in infection, multiple organ failure, hospital length of stay, need for surgical intervention, and mortality (McClave *et al.*, 2006). These benefits cannot be attributed to a deleterious effect of PN, as early studies of EN vs. standard therapy (where no specialized nutritional therapy is

**FIG. 52.7** Failure to utilize the gut in severe acute pancreatitis leads to disruption of intestinal barrier function and increased intestinal permeability. Quorum sensing by virulent organisms leads to their emergence and subsequent adherence to the gut wall. A cytokine “storm” results, with the release of inflammatory cytokines from the intestinal epithelial cells into lymphatic channels. The exit of pro-inflammatory Th1 CD4 helper lymphocytes from the lamina propria further up-regulates immune responses and leads to late complications via a subsequent secondary systematic inflammatory response syndrome (SIRS) response.

provided) have shown a potential mortality benefit when patients operated on for complications of pancreatitis are placed on tube feeding the day after surgery (McClave *et al.*, 2006).

PN clearly has a role in acute pancreatitis in patients for whom EN is not feasible. Results from two early studies

suggest that immediate initiation of PN may have an adverse effect (Sax *et al.*, 1987; Xian-Li *et al.*, 2004). Therefore, in an appropriate candidate, PN should be initiated 4–5 days after admission if EN is not feasible. After the first week of hospitalization, tolerance issues that result in hypocaloric enteral feeding insufficient to meet

energy requirements may necessitate the addition of supplemental PN.

Candidates for early EN in acute pancreatitis are those patients who have a severe degree of illness as indicated by APACHE II scores of  $\geq 8$ , the presence of three or more Ranson criteria, and/or evidence of pancreatic necrosis on computerized tomography (CT) scan (McClave and Ritchie, 2000). Deep jejunal access has been used most often for successful EN in these patients. Two studies now would suggest that gastric feeding is tolerated equally as well as jejunal feeding, particularly if it can be initiated within the first 48 hours of onset of disease. It is important to ensure full volume resuscitation before initiation of EN. A mean arterial pressure of  $\geq 65$  mm Hg, a central venous pressure of 8–12 mm Hg, urine output of  $>0.5$  mL/kg/hour, and a mixed venous  $O_2$   $\geq 65\%$  would suggest that a patient is fully resuscitated and is thus a candidate for initiation of EN. The presence of pancreatic ascites, pseudocyst, necrosis, or fluid collection within the pancreas are not contraindications to EN. The only true contraindications would include documented intolerance (clear stimulation of the SIRS response to EN), fear of ischemia, or mechanical obstruction of the gastrointestinal (GI) tract. Early initiation of feeds within the first 48 hours helps minimize problems with ileus and delayed gastric emptying. Tolerance should be monitored closely for evidence of stimulation of the pancreas, the presence of which would necessitate shifting the level of infusion lower in the GI tract and possibly switching to a formula that has protein in the form of small peptides, and fat in the form of medium-chain triglycerides (MCTs). Serum amylase and lipase levels provide little prognostic information, but they may provide valuable feedback regarding evidence of stimulation of the inflamed pancreas. Variation in the serum levels from day to day should be expected with either pancreatic enzyme, but a steady rise in both enzymes in response to EN may indicate potential intolerance (McClave and Ritchie, 2000).

Three adverse scenarios may result from early EN in acute pancreatitis and include an asymptomatic stimulation of enzyme output, an uncomplicated exacerbation of symptoms (abdominal pain, nausea), and the more concerning increase in the SIRS response. Placing the level of infusion of formula lower in the GI tract (preferably below the ligament of Treitz), or switching to either a small-peptide/medium-chain triglyceride (MCT) oil formula or fat-free formula, usually resolves intolerance and allows the continuation of feeds.

For those patients identified to be appropriate candidates for PN, intravenous fat is tolerated well, but triglyceride levels of the blood should be followed closely. Triglyceride levels should be kept below 400 mg/dL. Moderate glucose control is important: the blood sugar should be kept between 80 and 150 mg/dL. These patients are at risk for refeeding syndrome, so the PN should be advanced slowly over several days, with close monitoring of serum potassium, phosphorus, and magnesium.

### **Chronic Pancreatitis**

Issues related to nutritional therapy shift dramatically with the chronicity of fibrotic calcific pancreatitis. Factors develop over time which promote protein-energy malnutrition. These include maldigestion, food aversion, hypermetabolism, poor oral intake secondary to abdominal pain or nausea/vomiting, continued alcohol abuse, abnormalities of gastric emptying, and development of clinical diabetes mellitus (Scolapio *et al.*, 1999). These same factors increase the risk for micronutrient deficiencies. The absence of pancreatic proteolytic enzymes to remove the  $B_{12}$ -binding R-factor leads to deficiencies of vitamin  $B_{12}$ . Chronic inflammation depletes the level of a patient's antioxidants, promoting deficiencies of selenium,  $\beta$ -carotene, lycopene, and vitamins A and E. Malabsorption of fat-soluble vitamins leads to a vitamin D deficiency and development of osteomalacia and osteoporosis. Vitamin K deficiencies occur less frequently (Petersoen and Forsmark, 2002).

Nutritional management of these patients necessitates abstinence from alcohol and control of abdominal pain. Control of abdominal pain alone stimulates appetite and promotes increases in oral intake. High-carbohydrate, low-fat, high-protein diets are best suited for the patient with chronic pancreatitis. Vegetable fat may be tolerated better than animal fat. Pancreatic enzymes should be taken with meals so that the enzymes and the food are present together in the lumen of the GI tract at the same time (Meier, 2002). Whereas non-enteric-coated pancreatic enzymes are better for controlling abdominal pain in chronic pancreatitis (due to feedback mechanisms in the duodenum), enteric-coated enzymes which are protected as they pass through the stomach are probably better suited to control the maldigestion seen with steatorrhea and chronic pancreatitis (Meier, 2002). Enteric-coated enzymes should not be used in the patient who requires acid suppression from proton pump inhibitors (due to interference with dissolution of the capsule encasing the enzymes). Enzyme

supplements should provide 10% of the volume of enzyme output normally produced by the pancreas, such that approximately 30 000 IU of lipase are needed per meal (Meier, 2002). Enzymes with the highest trypsin content are required to control pain (>50 000 IU). Those patients most likely to respond to enzyme therapy and achieve pain relief are females with small-duct, less-advanced disease that is non-alcoholic in etiology. Fat restrictions in the diet may be needed in the patient for whom enzymes fail to control steatorrhea. Meals may be supplemented with oral small-peptide/MCT oil formulas. For the patient with recurrent pain, weight loss, continued steatorrhea, and frequent hospital admissions, a direct percutaneous endoscopic jejunostomy tube may be utilized to promote nutritional status, control pain, and reduce the number of hospital admissions per year. It is important to rule out small-bowel bacterial overgrowth, which can contribute to the diarrhea and be present in as many as one-third of patients with chronic pancreatitis. A daily antioxidant cocktail is valuable in minimizing the number of painful attacks and reducing the number of hospital admissions per year. Such cocktails should include vitamin E (270 IU/day), vitamin C (0.54 g/day), selenium (600 mg/day),  $\beta$ -carotene (9000 IU/day), and methionine (2 g/day) (De las Heras Castano *et al.*, 2000).

## Future Directions

Although the evidence of a role for dietary intake in the pathogenesis of IBD has been largely epidemiological, and studies of various nutritional programs to treat IBD have met with some, albeit not overwhelmingly positive results, new evidence suggests the possibility of a more substantial role for nutrition. That role is a more indirect one, and may be modulated through intestinal bacteria. Diet as well as specific nutrients may be determinant factors for the presence or absence of specific bacterial species, which themselves may have a causative effect on intestinal inflammation. Not limited to environmental factors, gastrointestinal disease is likely related to interactions between diet and genetics, as well as other environmental factors including toxins and proteins and what is probably a very complex relationship. This relationship becomes even more complex with the finding of single or multiple single nucleotide polymorphisms (SNPs) in the DNA sequence. Host genetic-based responses may be environmentally influenced, particularly by diet. Indeed, the burgeoning fields of “DNA-driven nutrition,” nutrigenetics, and

nutrigenomics have suggested that gene expression may be influenced by diet. Similarly, a given nutritional therapy may be variably effective across a population, but more effective for a specific individual. These include cytoprotective, anti-inflammatory, and immunoregulatory effects. Indeed, nutrition and its interaction with other environmental factors as well as genetics may also play an important role in risk stratification as well as the pathogenesis of EoE and pancreatitis; the role in celiac disease is obvious. With regard to the latter, a more sophisticated understanding of the role of gluten and the development of inflammation has allowed for the development of novel therapies for celiac disease, although effectiveness of these therapies awaits completion of rigorous clinical trials. In pancreatitis, the emerging role of pharmacconutrient agents such as arginine to improve vasomotor abnormalities, glutamine to induce heat shock proteins, fish oil to reduce inflammation, and zinc to maintain gut integrity and promote antioxidant defenses all need to be investigated in a prospective randomized fashion.

Intestinal transplantation is also likely influenced by interactions between bacteria, diet, and other environmental factors, as well as genetic factors. Although short-term (i.e. 5-year) survival has improved dramatically in recent years, and rivals that of other organs, long-term survival (e.g. 10 years or more) has not improved substantially as a clear understanding of the pathogenesis of chronic rejection is not yet on the horizon. The potential influence of diet, intestinal bacterial flora, and genetics in development or prevention of chronic rejection cannot be underestimated.

## KIDNEY DISEASE

THIANE G. AXELSSON<sup>1</sup>, RD, MSc, MICHAL CHMIELEWSKI<sup>2</sup>, MD, PhD, AND  
BENGT LINDHOLM<sup>1</sup>, MD, PhD

<sup>1</sup>*Karolinska Institutet, Stockholm, Sweden*

<sup>2</sup>*Medical University of Gdansk, Gdansk, Poland*

### Summary

Chronic kidney disease (CKD) is considered a worldwide public health threat (Levey *et al.*, 2007). In the United States alone, 9.6% of adults are likely to have some degree of CKD (Coresh *et al.*, 2005). Data from Europe, Australia, and Asia also confirm a similar high prevalence of CKD (Coresh *et al.*, 2005; Stevens *et al.*, 2006; Levey *et al.*, 2007). The increasing prevalence of CKD together with its numerous complications make CKD a growing burden in health-related, social, and economic terms all over the world (Hsu *et al.*, 2006; Rutkowski and Król, 2008). In the present review, we describe briefly the causes and consequences of metabolic abnormalities and nutritional deficiencies in CKD, and provide an overview of current therapies.

### Introduction

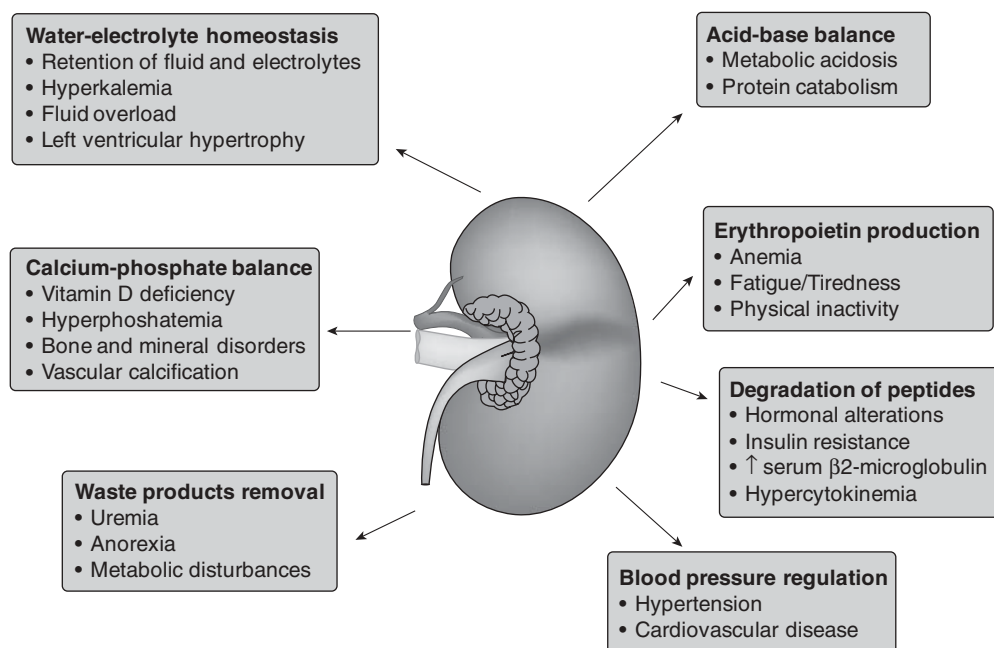

The kidneys play a key role in maintaining fluid and electrolyte homeostasis, in excretion of metabolic waste products, and in the regulation of various hormonal and metabolic pathways. Even a slight reduction in renal function may therefore have metabolic and nutritional consequences.

Patients with manifest CKD consequently display a variety of metabolic and nutritional abnormalities, most prominently protein-energy wasting (PEW) (Young *et al.*, 1991; Qureshi *et al.*, 1998; Heimbürger *et al.*, 2000). Metabolic and nutritional abnormalities arise in CKD from both pathophysiological (e.g. uremic toxicity, altered metabolism) and iatrogenic (e.g. polypharmacy and the

prescription of a low-protein diet to slow disease progression) causes. In the late stage of CKD, defined by the need to start renal replacement therapy (dialysis or kidney transplantation), some of these abnormalities are attenuated, while novel ones may occur (Figure 53.1).

### Basic Kidney Physiology and Pathophysiology

Kidneys play a prominent role in the human organism, providing excretion of metabolic wastes, regulating water–electrolyte and acid–base balance, and secreting hormones. Their importance is reflected by the enormous amount of blood (about 1200 mL) flowing through the kidneys each minute.

**FIG. 53.1** Major roles of the kidney in metabolic regulation.

As the physiological metabolic processes result in formation of numerous metabolites, kidney failure results in accumulation of compounds that are useless or even harmful to the organism. Whereas healthy kidneys remove these waste products by excreting them in the urine, renal insufficiency takes away this function and may also alter metabolic processes, resulting in a state of uremic intoxication. This process, being detrimental *per se*, has a significant impact on the patient's appetite and food intake. Accumulation of metabolic waste products also leads to a state of acidification, which is one of the major factors responsible for increased protein catabolism.

Apart from clearing metabolic wastes, kidneys are responsible for maintaining water–electrolyte balance. Deterioration of their function leads to altered potassium and sodium excretion. This can have a direct impact on cardiac function, and, in cases of severe hyperkalemia, may lead to cardiac arrest and sudden cardiac death, a common cause of death in patients with renal failure. Similarly, sodium removal may be decreased, leading to increased sodium load, and, consequently, to hypertension. The kidneys regulate blood pressure also through their secretory activities. They are the site of renin production, an enzyme involved in the renin–angiotensin–aldosterone system (RAAS). Alterations in RAAS activity are crucial for the development

of hypertension. The secretory abilities of the kidneys are not limited to renin. Another major compound produced in the kidneys is erythropoietin. This hormone plays a major role in production of red blood cells. Therefore, anemia is a typical feature of chronic kidney insufficiency. Finally, the kidneys, by activating vitamin D and removing excess phosphate, regulate calcium–phosphate balance. CKD inevitably results in hypocalcemia, hyperphosphatemia, secondary hyperparathyroidism, and various forms of bone disorders or osteodystrophy.

CKD is often defined as a state of kidney damage and/or decreased glomerular filtration which lasts for at least 3 months. It can be caused by several illnesses, the most common being diabetes mellitus, hypertension, and primary glomerular diseases. CKD can be divided into five stages, depending on the presence of kidney damage, e.g. albuminuria, and on the glomerular filtration rate. CKD, regardless of the underlying pathology, is usually characterized by a progressive course with worsening of renal function, which may lead to stage 5 CKD, often described as end-stage renal disease (ESRD), which requires renal replacement therapy (RRT). There are two major kinds of RRT, dialysis and kidney transplantation. Dialysis is further divided into hemodialysis (HD) and peritoneal dialysis (PD).

As described above, kidneys have several functions that are crucial for the organism. Nutritional interventions play a pivotal role in diminishing metabolic and nutritional abnormalities associated with kidney insufficiency, both in patients treated with RRT, as well as in subjects in earlier stages of CKD.

### Protein-Energy Wasting: Prevalence, Mechanisms and Significance

Among the complications of CKD, progressive loss of body protein mass and energy reserves is one of the most typical and detrimental. This loss has been termed protein-energy wasting (PEW) (Fouque *et al.*, 2008). It is most prevalent in patients with advanced stages of CKD, and may affect up to 75% of subjects with end-stage renal disease.

PEW is to a large extent caused by malnutrition, or, more precisely, by undernutrition. Impaired food intake is a consequence of several overlapping processes. A low-protein diet is advocated in CKD subjects as it has been shown to reduce uremic symptoms and retard the progression of the disease (Fouque and Laville, 2009). However, it may result in negative protein balance, especially in subjects not receiving amino acid and/or ketoacid supplementation. As CKD progresses, anorexia develops (Carrero *et al.*, 2008). This is due to uremic intoxication and hormonal derangements, including an increase in circulating levels of multiple anorexigens such as leptin and a decrease in some orexigens such as ghrelin. Finally, as patients progress towards end-stage renal disease, dialysis is introduced, complicated by significant losses of nutrients into the dialysate in both types of dialysis treatment.

However, malnutrition is not the only culprit for PEW occurrence. Chronic low-grade inflammation seems to be of equal importance (Stenvinkel *et al.*, 2000; Fouque *et al.*, 2008). This prevalent complication of CKD has been shown in several studies to decrease protein generation and to increase protein breakdown, resulting in a highly negative protein balance.

Several other disturbances predispose CKD patients to deteriorations of nutritional status. These include, for example, oxidative stress, acidosis, nutrient losses, social factors such as loneliness and poverty, and co-morbid conditions such as diabetes mellitus, cardiovascular disease, and infections, which are all highly prevalent in CKD patients (Fouque *et al.*, 2008). These and other potential causes of PEW are depicted in Figure 53.2.

It has to be remembered that obesity is a frequent finding in CKD, reflecting the growing prevalence of overweight and obesity in the general population. In fact, obesity is one of the most frequent risk factors for CKD progression (Zoccali, 2009) (also, see Chapter 45). However, PEW is equally frequent and equally detrimental in obese as it is in lean CKD subjects (Honda *et al.*, 2007).

PEW is a strong and independent predictor of cardiovascular and non-cardiovascular mortality in CKD patients. Decreased indices of nutritional status, as albumin, pre-albumin or cholesterol, have been associated with increased risk of death (Kovesdy and Kalantar-Zadeh, 2009). Similarly, decrease in muscle mass, and protein and energy intake, have been linked to worse outcome (Kovesdy and Kalantar-Zadeh, 2009). The importance of PEW as a determinant of poor outcome in the CKD population is reflected by the so-called “reverse epidemiology phenomenon”. For example, in patients with advanced CKD, low (normal) cholesterol and low (normal) body mass index (BMI) predict poor outcome (Kalantar-Zadeh *et al.*, 2007). This stays in contrast to what is observed in the general population, with hypercholesterolemia and obesity being detrimental. Although many potential explanations have been proposed for these paradoxical associations, it seems that the most persuasive is the one in which PEW, resulting in low cholesterol and low BMI, leads to increase in mortality in CKD patients. This shows how crucial it is to prevent PEW in CKD subjects, to diagnose it as soon as it develops, and to treat it effectively.

### Other Nutritional Aberrations in CKD

#### Acidosis

Although malnutrition is an important cause of PEW in CKD patients, other factors, including several hormonal and metabolic alterations related to loss of kidney function, can also predispose these patients to malnutrition. For example, metabolic acidosis, which is a common finding in CKD patients, induces increased protein catabolism with degradation of the essential, branched-chain amino acids and muscle protein. Moreover, metabolic acidosis is also known to suppress synthesis of proteins such as albumin (Ballmer and Imoberdorf, 1995).

#### Appetite

As mentioned above, loss of appetite, or anorexia, often resulting in insufficient intake of macronutrients and/or micronutrients, is also common in CKD and contributes

**FIG. 53.2** Multiple causes of protein-energy wasting. AGEs, advanced glycation end-products.

significantly to malnutrition (Kopple *et al.*, 1989). Anorexia commonly occurs when GFR is less than 10–15% of normal kidney function. One reasonable explanation for the often drastic decrease in appetite is the retention of toxic substances as a result of reduced renal clearance. In accordance with this, most patients improve their appetite when they start renal replacement therapy (RRT) (Bergstrom, 1999). Anorexia in CKD is associated with an increase in morbidity and mortality. Indeed both Kalantar-Zadeh *et al.* (2004) and Carrero *et al.* (2007) investigated maintenance hemodialysis (HD) patients and found that a decrease in appetite was related to greater risk of mortality.

The treatment of anorexia in dialysis patients should be based on a therapeutic strategy that includes several components. Increased dialysis treatment, for example in the form of daily dialysis sessions, and nutritional counseling as well as use of appetite stimulation and administration of nutritional supplements are often effective. Anorexia and nutritional status may be improved by normalization of plasma branched-chain amino acids through branched-

chain amino acid supplementation (Bossola *et al.*, 2009). Megestrol acetate seems to improve anorexia and thereby the nutritional state in maintenance dialysis patients (Rammohan *et al.*, 2005). Subcutaneous ghrelin administration and melanocortin-receptor antagonists appear to be promising future therapeutic interventions.

### **Disorders in Vitamins and Trace Elements**

Inadequate nutritional intake of macronutrients (protein, carbohydrates and fat) is not the only form of malnutrition that exists in CKD patients. They may also suffer from deficiencies of micronutrients, particularly vitamins and trace elements (Kalantar-Zadeh and Kopple, 2003). Inadequate dietary intakes, altered metabolism in uremia, and vitamin loss into the dialysate are likely to contribute to these deficiencies; dialysis treatment results in deficiencies of water-soluble vitamins (Boeschoten *et al.*, 1988; Gilmour *et al.*, 1993). The treatment of mineral and vitamin deficiencies will be discussed further in this chapter.

### **Insulin Resistance and Dyslipidemia**

Diabetes mellitus is now the leading cause of CKD all over the world, accounting for up to 40% of cases of end-stage renal disease in some countries. However, insulin resistance is a typical finding in CKD, also in patients free from diabetes mellitus (also, see Chapter 47). Hypertriglyceridemia is another metabolic abnormality that typically appears as the renal function declines (Axelsson *et al.*, 2004, 2006). While the mechanisms mediating this dysmetabolism remain unclear, it would appear that hypertriglyceridemia represents an early feature of renal failure, usually appearing together with albuminuria and often observed before an elevation of plasma creatinine can be seen (Sechi *et al.*, 2002). Mechanistically, an accumulation of triglyceride-rich lipoproteins in CKD appears mainly to be a result of a decreased catabolism of lipids (Prinsen *et al.*, 2003). As decreased insulin sensitivity occurs (commonly in patients with GFR <30 mL/min/1.73 m<sup>2</sup>), an overproduction of insulin-sensitive very-low-density lipoproteins (VLDL) is likely to contribute to hypertriglyceridemia in CKD patients. However, the role of an increased hepatic production of triglyceride-rich lipoproteins in the pathogenesis of renal dyslipidemia remains a subject of debate (Prinsen *et al.*, 2003; Axelsson, 2008). As consequences of insulin resistance and dyslipidemia, CKD patients commonly suffer from muscle catabolism, cardiovascular disease, decreased appetite, and lipotoxicity.

### **Nutritional Assessment in CKD Patients**

Many methods have been created to identify malnourished and wasted CKD patients, and to grade different degrees of PEW. Unfortunately, there is no single tool that can be used for this purpose; with so many concurrent metabolic and nutritional abnormalities, such a tool has remained elusive. The National Kidney Foundation Clinical Practice Guidelines for Nutrition in Chronic Renal Failure (Kidney Disease Outcomes Quality Initiative, 2000) thus recommend that nutritional status should not be evaluated with only a single measure alone, but instead using a combination of valid, complementary measures. These measures may include biological assessment of protein-energy status, subjective global assessment, dietary intake assessment, and anthropometry measurements.

### **Biomarkers**

Biochemical parameters are routinely used to assess and monitor nutritional status in CKD patients. However,

none of the currently favored biomarkers have been demonstrated to accurately reflect nutritional status in CKD (Ikizler *et al.*, 1999; Stenvinkel *et al.*, 2002; de Mutsert *et al.*, 2009). Instead, strong associations between several biomarkers and mortality seem to derive, at least in part, from their close association with inflammation (de Mutsert *et al.*, 2008), and in part from the important role of the kidney in metabolizing circulating peptides (Naseeb *et al.*, 2008). However, as they are commonly used, we will shortly review the most common biomarkers: plasma concentrations of albumin, pre-albumin, and transferrin (Locatelli *et al.*, 2002; Kamimura *et al.*, 2005).

The amount of serum *albumin* is determined by its synthesis, breakdown, and volume of distribution (Klein, 1990; Jeejeebhoy, 2000). In CKD patients, factors such as overhydration, proteinuria and losses into the dialysate and urine may cause a decrease in plasma protein concentration. Counter-regulatory mechanisms may also influence the serum albumin concentration. Whereas, in the short term, protein deficiency decreases the rate of albumin synthesis (Rothschild *et al.*, 1975), compensation in the long term may occur through a decrease in albumin breakdown and a shift of albumin from the extravascular to the intravascular space. Additionally, albumin has a relatively long half-life (approximately 20 days) and is present in large quantities (Kirsch *et al.*, 1968), limiting the impact of a decreased protein intake on concentrations of albumin. Even in some extreme cases of malnutrition, such as marasmus, serum albumin levels in these patients remain normal (Whitehead and Alleyne, 1972). In kwashiorkor, on the contrary, serum albumin levels are usually low (Davies, 1948; Trowell *et al.*, 1952). However, it is important to keep in mind that kwashiorkor is typically accompanied by infections (inflammatory state) and severe protein intake deficiency (which is usually not the case in the CKD population in most industrialized countries) (Rossouw, 1989; Friedman and Fadem, 2010). In a study by Kaysen *et al.* (2004) low serum albumin levels in dialysis patients were mainly associated with inflammation. Thus, it seems that hypoalbuminemia in CKD patients is rather associated with chronic inflammatory state than with insufficient food intake (Mak and Cheung, 2006). Like albumin, *pre-albumin* is mainly synthesized in the liver, and a reduced protein intake is associated with a decline in serum concentrations which are then restored by re-feeding (Kidney Disease Outcomes Quality Initiative, 1995), due to its lower concentration and shorter half-life (2–3 days) (Chertow *et al.*, 2000; Neyra *et al.*, 2000).

**TABLE 53.1** Recommended values of biochemical parameters, limitations for assessment of nutritional status in CKD

Biomarkers <sup>a</sup>	Reference values	Limitations
Albumin	>4.0 g/dL	Affected by hypervolemia and inflammatory conditions
Pre-albumin	>30 mg/dL	Affected by inflammation, may be influenced by renal catabolism
Transferrin	Unknown	Affected by inflammation and iron metabolism

<sup>a</sup>Note that the relation between these biomarkers and nutritional status is weak or absent in CKD: see text. Reproduced with permission from Kopple (2001).

However, serum pre-albumin levels are also greatly affected by inflammation (Ingenbleek *et al.*, 1972). In CKD, reduced renal catabolism also contributes to altered serum pre-albumin concentrations (Kopple, 2001). Lastly, *transferrin* is a visceral protein the main function of which is to transport iron in the circulation. Its concentration is affected by iron metabolism, much altered in CKD, and inflammation (Ferrari *et al.*, 2011). Thus, transferrin is not a reliable marker of nutritional status in CKD.

Despite the prevailing acceptance of these biomarkers in CKD, circulating levels of albumin and other proteins such as pre-albumin and transferrin are in fact *not* appropriate indicators of the nutritional status (Table 53.1).

### Subjective Global Assessment (SGA)

With limited usefulness of current biomarkers, subjective global assessment (SGA) (Detsky *et al.*, 1987) has been proposed as a simple, inexpensive, and easy-to-apply subjective method of assessing nutritional status in this patient group. SGA is currently considered to be a reliable indicator of PEW in uremic patients (Kidney Disease Outcomes Quality Initiative, 2000; Toigo *et al.*, 2000). Furthermore, SGA uses scoring of a patient's medical history and physical examination to differentiate well-nourished, slightly malnourished, and severely malnourished patients. The attributes scored in the SGA evaluation include the following: gastrointestinal symptoms, dietary intake, body weight, disease state, and functional capacity.

Owing to its strong correlations with PEW (Cooper *et al.*, 2002) and outcomes (Yang *et al.*, 2007), SGA is

recommended as a component of longitudinal monitoring of chronic dialysis patients by, among others, K/DOQI, the National Kidney Foundation Kidney Disease/Dialysis Outcomes and Quality Initiative (2000). Although several studies show that SGA is a useful tool in CKD (Campbell *et al.*, 2007; Steiber *et al.*, 2007), it should be kept in mind that SGA is still a subjective score that may be biased by inter- and intrapersonal differences. As such, it is perhaps best employed in a longitudinal manner by the same trained investigator to follow patients over time.

### Dietary Records

The estimation of dietary intake is of central importance in CKD patients. The most commonly used and easy ways to quantify individual intake of nutrients are the dietary interview, the 24-hour dietary recall, and the dietary record. These tools are especially useful for the estimation of macronutrient intake in the clinical setting. While under- or over-estimation of dietary intake is common using these methods, they have been successfully used in the CKD patient population. In HD patients, dietary protein intake assessed by 7-day food records correlated with intake estimated by normalized protein catabolic rate, and there were significant differences in diets between dialysis and non-dialysis days (Chauveau *et al.*, 2007). In a study investigating the accuracy of food records with regard to energy consumption, energy intake was evaluated using 4-day food diaries, and resting energy expenditure was measured by indirect calorimetry; energy intake based on 4-day food diaries was found to be underestimated (Avesani *et al.*, 2005).

### Body Composition

Theoretically, body composition and the contents of fat, protein, and water should reflect long-term dietary intake and PEW (also, see Chapter 58). While several methods have been employed in CKD patients, they each suffer from the large variation of body water seen in this patient group.

### Bioelectrical Impedance Analysis (BIA)

BIA and bioelectrical impedance spectrometry (BIS) have long been proposed as non-invasive, simple, and quick techniques for measuring body composition. BIA and BIS use measured variations in electrical currents of one or more frequencies passed through the body to estimate body water, fat, and fat-free mass. However, the problem

of determining the amount and distribution of intra- and extracellular water in CKD patients limits the usefulness of this method for nutritional assessment.

### Dual-Energy X-Ray Absorptiometry

A more reliable tool to estimate body composition is dual-energy X-ray absorptiometry (DEXA). DEXA passes low-energy X-rays through the body to measure fat mass, fat-free mass, and bone mineral density (Gotfredsen *et al.*, 1986). While DEXA is relatively good at measuring fat mass (Avesani *et al.*, 2004a), it is not used routinely in the clinical setting because of its high cost and its inaccuracy in severely overhydrated patients (Bhatla *et al.*, 1995). Furthermore, the amount of radiation, although small, is a concern in patients exposed to DEXA repeatedly over many years.

### Anthropometrics

Skinfold thickness is an anthropometric tool widely used in clinical practice because of its low cost, simplicity, and non-invasive nature. It is used to estimate both fat mass and fat-free mass (Durnin and Womersley, 1974). However, skinfold thickness measurements suffer from a large intra- and inter-observer variability, and are only modestly reliable (Avesani *et al.*, 2004a). Another marker used to determine body fat mass is waist circumference. This is again a simple and easy method, which has been suggested to predict survival in CKD patients (Postorino *et al.*, 2009). However, as fat mass does not necessarily reflect PEW in CKD, waist circumference is likely not a good marker of the nutritional deficiencies associated with PEW (Table 53.2).

## Treating Nutritional Deficiencies in CKD Patients

### Renal Replacement Therapy

When patients reach end-stage renal disease, renal replacement therapy (RRT) is introduced. It improves indices of uremia to a different degree, depending on the RRT method applied. While renal transplantation is by far the best method of RRT, fully replacing native kidneys in the case of well-functioning grafts, dialysis has its drawbacks and limitations. Both the dialyzer membrane in HD and the peritoneal membrane in PD patients are far less selective than the kidney's glomerular barrier. Therefore, many essential nutrients are lost into the dialysate, and the dialysis procedure may cause a transitory inflammatory response stimulating protein catabolism. Nevertheless, dialysis has

**TABLE 53.2** Advantages and disadvantages of nutritional assessment methods

Methods	Advantages	Disadvantages
Biomarkers	Widely accepted	Limited reliability, affected by inflammation
Subjective global assessment	Simple, inexpensive, easy to apply	Subjective; inter- and intrapersonal variability
Dietary records	Simple, inexpensive, easy to apply	Subjective; may easily be over- or underestimated
Body composition measurements		
Bioelectrical impedance analysis	Simple, non-invasive	Influenced by hydration status
Dual-energy X-ray absorptiometry	Reliable	Expensive, influenced by hydration status
Skinfold thickness	Simple, inexpensive, non-invasive	High intra- and inter-observer variability; useless in very obese patients

the capability of improving several indices of nutritional status. It has been demonstrated that adequate dialysis is a prerequisite for PEW prevention (Azar *et al.*, 2007). In patients in whom the dialysis dose does not meet their requirements, uremic intoxication and volume overload evolve. These factors play an important role in PEW development. In patients undergoing kidney transplantation, the immunosuppressive therapy, in particular corticosteroids, may lead to metabolic and nutritional alterations including metabolic syndrome and PEW (Ward, 2009).

### Dietary Composition

#### Protein

The European Society of Parenteral and Enteral Nutrition (ESPEN) and the National Kidney Foundation (NKF) guidelines recommend that CKD patients stages 4–5 (GFR <30 mL/min) should keep a moderately reduced protein intake of 0.55–0.60 g/kg BW/day (Cano *et al.*, 2006). A very low protein diet with protein intake of 0.3–0.4 g/kg BW/day is also used in several countries, but patients receiving such a diet should be carefully monitored and supported by supplements with essential amino

acids or keto acids to avoid a negative nitrogen balance (Cano *et al.*, 2006). (The progression of CKD may slow significantly when following a low-protein diet (Fouque *et al.*, 1992; Klahr *et al.*, 1994; Levey *et al.*, 1996; Pedrini *et al.*, 1996). A low-protein diet might have additional benefits in CKD patients, as it would lead to a decrease in hyperkalemia, hyperphosphatemia, and metabolic acidosis, as well as to the attenuation of other electrolyte disorders (Mitch and Remuzzi, 2004). Furthermore, many of the clinical and metabolic disturbances characteristic of uremia may be delayed or prevented by the reduction of nitrogenous wastes and inorganic ions (derived from a diet rich in protein).

When treating CKD patients, it must be kept in mind that the variation in protein requirements is much larger in these patients than in healthy subjects, as a result of additional sources of variability such as endocrine and biochemical abnormalities, anemia, drugs, physical inactivity, and co-morbid conditions. In addition, some non-essential amino acids become essential in CKD because of the loss of conversion in the kidney, and specific effects of the dialytic process may increase protein requirements, especially in HD patients (Bergstrom and Lindholm, 1993). Owing to these factors, it is currently recommended that CKD patients starting dialysis should discontinue a low-protein diet and instead have a protein intake of 1.2–1.3 g/kg BW/day, of which a large part should be of high biological value (Kopple, 2001). It is, however, interesting to note that recent findings suggest that a protein intake of 0.6–0.8 g of protein/kg BW/day may lead to improved preservation of residual renal function without adverse consequences in dialysis patients (Bergström *et al.*, 1993; Jiang *et al.*, 2009). Thus, whereas many patients may require less than 1.2 g/kg BW/day to maintain nitrogen equilibrium (Bergström *et al.*, 1993; Kopple *et al.*, 1995), some patients, e.g. those who develop PEW, may require higher amounts of protein (and energy). Indeed, studies have suggested that some patients may benefit from eating as much as 1.4–2.1 g protein/kg BW/day, especially during the initial months of dialysis treatment (Bergström *et al.*, 1993).

### Fat

Fat is the most energy-dense macronutrient available and thus would seem to be likely to be beneficial to malnourished CKD patients, especially those on a low-protein diet. However, no studies exist that have explored the optimal amount of fat in the CKD diet. The ESPEN and NKF

Kidney Disease Outcomes Quality Initiative Guidelines respectively for CKD patients recommend a total energy intake for adults that is similar to that of the general population, i.e. 35 kcal/kg/day, and for older adults (>60 years) 30–35 kcal/kg/day (Kent, 2005; Cano *et al.*, 2006).

For CKD patients at stages 1 to 3, the energy requirement is based on energy expenditure and depends on the nutritional status of the patient. Thus, those who are underweight need a higher calorie intake than patients who are of normal weight or overweight (Kent, 2005). Not only the quantity but also the quality of the dietary fat is important. In one study unsaturated fat supplementation (430 kcal, 47 g fat, 26.5 g monounsaturated fatty acids, and 3 g marine n-3 polyunsaturated fatty acids per day) in HD patients was associated with normalized blood lipids, reduced systemic inflammation, and improved nutritional status (Ewers *et al.*, 2009).

### Carbohydrates

There is as yet no evidence that the energy requirements of CKD patients are systematically different from those of normal subjects. While most studies (Monteon *et al.*, 1986; Avesani *et al.*, 2004b) have shown normal resting energy expenditure (REE) in both early and late CKD, one study reported decreased REE in non-dialyzed CKD patients (Avesani *et al.*, 2004c). Thus, an energy intake of at least 35 kcal/kg body weight is currently recommended in CKD patients (Kopple, 2001). Importantly, studies show that most CKD patients have a much lower energy intake, and this may contribute to PEW (Avesani *et al.*, 2005). In dialysis patients, HD is mostly energy neutral, while PD patients may absorb about 60% of the daily dialysate glucose load (100–200 g glucose/24 hours) (Heimbürger *et al.*, 1992). See Table 53.3.

### Vitamins

CKD patients commonly suffer from micronutrient deficiencies (Kalantar-Zadeh and Kopple, 2003). Of the

**TABLE 53.3** Recommendation of protein and energy intake for CKD and ESRD patients

Patients	Protein intake	Energy intake <sup>a</sup>
CKD	0.60 g/kg/day	30–35 kcal/kg/day
ESRD	1.2 g/kg/day	30–35 kcal/kg/day

<sup>a</sup>Energy requirement may vary depending on patient's nutritional status and age (Kent, 2005).

ESRD, end-stage renal disease patients undergoing dialysis therapy.

water-soluble vitamins that have been studied, serum levels of ascorbic acid, thiamine (B<sub>1</sub>), pyridoxine (B<sub>6</sub>), and folic acid have all been reported to be low in dialysis patients (Gilmour *et al.*, 1993). Thiamin deficiency with encephalopathy has been described in dialysis patients (Hung *et al.*, 2001) and may be confounded by other neurologic diseases. A common dietary intake of 0.5 to 1.5 mg/day may be supplemented with a daily dose of 1–5 mg of thiamin hydrochloride. Vitamin B<sub>6</sub> coenzymes play a vital role in several aspects of amino acid utilization, and the need for vitamin B<sub>6</sub> is particularly critical if protein and amino acid intake is limited (Kopple *et al.*, 1981). Indeed, changes in fasting plasma amino acid and serum high-density lipoprotein levels after correction of the vitamin B<sub>6</sub> deficiency in dialysis patients indicate its role in the pathogenesis of the abnormal amino acid and lipid metabolism of CKD (Kleiner *et al.*, 1980). The daily requirement of pyridoxine may be higher in dialysis patients than in normal subjects, and dialysis patients should be supplemented with a minimum of 10 mg of vitamin B<sub>6</sub> per day (Kopple *et al.*, 1981). As a water-soluble vitamin, folate is lost in dialysate. Because serum folate levels have been reported to be reduced in CKD, it is recommended to give 1 mg of folic acid daily. High doses of folic acid (5–10 mg/day) have been shown to reduce the markedly elevated plasma homocysteine levels in dialysis patients by about two-thirds, which is still above the normal range (Arnadottir *et al.*, 1993). The question whether these high doses of folate should be prescribed in order to lower plasma homocysteine levels to reduce cardiovascular morbidity and mortality in CKD is still open, and prospective studies are needed in this area. Furthermore, while supplementation with vitamin C has also been recommended in CKD (Boeschoten *et al.*, 1988), a high intake of vitamin C may aggravate hyperoxalemia in dialysis patients (Canavese *et al.*, 2005) and controlled trials are lacking to support this recommendation.

Unlike water-soluble vitamins, supplementation of the fat-soluble vitamins A, D, E, and K is not recommended on a routine basis to CKD patients (Gilmour *et al.*, 1993). Vitamin A tends to accumulate in CKD patients and can potentially have harmful effects. Vitamin D is converted in the kidneys from 25-hydroxyvitamin D to its active form, 1,25-dihydroxyvitamin D. Most patients with advanced CKD, especially CKD stages 4 and 5, are deficient in 1,25-dihydroxyvitamin D (and also in 25-hydroxyvitamin D), and supplementation of active vitamin D is often given on the basis of an evaluation of the bone metabolic status and taking the risks of hyper-

phosphatemia and hypercalcemia into consideration (Jean *et al.*, 2008). In most studies of uremic patients, blood levels of vitamin E have been found to be normal and stable (Clermont *et al.*, 2000). As vitamin K<sub>2</sub> deficiency may play a role in the development of vascular calcification in CKD patients, it is possible that supplementation of vitamin K might be beneficial. Vitamin E is a strong antioxidant compound, and it has been proposed to reduce cardiovascular disease. This was tested in a randomized controlled trial with a high dose of vitamin E (800 IU  $\alpha$ -tocopherol per day) supplementation (Boaz *et al.*, 2000) in CKD patients with high cardiovascular risk. This study found a significant 50% decrease in cardiovascular incidents as compared with placebo.

### Trace Elements

Dietary requirements for trace elements are not well defined in CKD patients (Kalantar-Zadeh and Kopple, 2003). Trace-element metabolism is frequently altered in CKD (Gilmour *et al.*, 1993), and high levels of trace elements have been attributed to impaired renal elimination or contamination of dialysis fluids, while low levels of trace elements may occur as a result of inadequate dietary intake or loss of protein-bound trace elements into the dialysate (Gilmour *et al.*, 1993). Zinc deficiency has been reported to be common in CKD (Rucker *et al.*, 2010); however, it may be alleviated by zinc administration (Rashidi *et al.*, 2009). Nevertheless, these results have not been generally confirmed and the role of zinc deficiency and requirements for extra zinc in CKD patients remain at present controversial (Gilmour *et al.*, 1993).

### Nutrition Counseling

The goal of nutritional management of CKD patients is to delay the need for dialysis by using low-protein diets while maintaining good nutritional status (Fouque and Aparicio, 2007). Thus, the specialized renal dietitian has a fundamental role in the assessment and treatment of CKD patients. In addition, dietary counseling should be offered as part of a multidisciplinary approach (Locatelli *et al.*, 2002).

In CKD, both regular dietary counseling and protein-energy status assessment are of great importance. In order to avoid a decline in nutritional status during CKD progression, a regular schedule with follow-up evaluations by dietitians and nephrologists (Aparicio *et al.*, 2001) is recommended. According to the Kidney Disease Outcomes Quality Initiative K/DOQI Recommendations for Nutri-

tional Management guidelines (Kidney Disease Outcomes Quality Initiative, 2000), dietary interviews and counseling should be performed every 3 to 4 months. In addition, serum albumin level (although, as noted above, its value as a nutritional biomarker is questionable in CKD), together with body weight and SGA, should be monitored every 1 to 3 months. A key reason for monitoring protein-energy status is to adjust nutritional intakes to the patient's nutritional needs, to detect signs of PEW, and to identify patients requiring nutritional support.

### **Intradialytic Nutritional Support**

In order to compensate for nutrient losses during dialysis and to further improve nutritional status of dialysis patients, intradialytic nutritional support can be used in the form of intravenous (in HD) and intraperitoneal (in PD) infusions. Intradialytic parenteral nutrition (IDPN) is an acknowledged method of protein and energy supplementation in HD patients. Typically composed of a mixture of amino acids, dextrose, and lipids, IDPN has been shown to increase protein synthesis and decrease protein degradation, resulting in a highly positive protein balance (Pupim *et al.*, 2002). However, recent studies have demonstrated no clear additional benefit of IDPN over oral nutritional support (Cano *et al.*, 2007). Therefore, current guidelines limit the use of IDPN to wasted subjects in whom oral nutritional support has turned out to be ineffective in improving nutritional status (Fouque *et al.*, 2007).

Protein losses into the dialysate in PD patients are of even greater magnitude than those occurring in HD. Protein intake ought therefore to be increased in these subjects. Moreover, amino acid based peritoneal dialysis fluids have been developed. In this case, amino acids serve also as an osmotic factor (instead of the common osmotic agent, glucose), but, more importantly, they can improve protein balance of PD patients. One exchange with amino acid based fluid daily in wasted subjects treated with PD is usually enough to replace 24 hours of losses of protein and amino acids in PD patients.

### **Improving Appetite and Anabolic Interventions**

As underlined earlier, nutrient losses into the dialysate are not the only culprit for poor nutritional status of dialysis patients. Decreased food ingestion, due to poor appetite, is also a common problem. Several factors are responsible, with inadequate dialysis, hormonal derangements, inflam-

mation, and co-morbidities being the major ones. Poor appetite has been shown to be a strong and independent predictor of mortality in dialysis patients. Therefore, several initiatives to improve ingestion have been introduced. These include: improving dialysis adequacy and treatment of co-morbidities, but also interventions that are targeted directly at improving appetite. Megestrol acetate, a progesterone derivative, has been shown to ameliorate anorexia and improve nutritional status in CKD patients (Monfared *et al.*, 2009; Yeh *et al.*, 2010). Some concerns have arisen with regard to side-effects caused by megestrol acetate (Bossola *et al.*, 2005). However, it remains a useful tool in treating appetite disorders. Ghrelin, a small peptide produced in the stomach, strongly induces appetite. The concentration of its active, acylated form has been shown to be decreased in dialysis patients, especially in those with chronic inflammatory state (Mafra *et al.*, 2010). Subcutaneous injections of ghrelin have been found to be effective in improving energy intake of wasted subjects on HD (Ashby *et al.*, 2009). Similarly, anabolic interventions with growth hormone (GH), GH-releasing hormone, and insulin-like growth factor-1 (IGF-1) have been capable of improving protein and energy status in dialysis patients (Fouque *et al.*, 2000; Feldt-Rasmussen *et al.*, 2007; Niemczyk *et al.*, 2010). However, the results so far should be interpreted with caution, as no large randomized clinical trials (RCTs) evaluating the impact of appetite improvement and/or anabolic intervention on survival have been performed. To date the only RCT to assess the role of GH in outcome in wasted HD subjects has been cancelled because of problems with patient recruitment (Kopple *et al.*, 2008). A simplified algorithm for applying nutritional interventions is depicted in Figure 53.3.

### **Future Directions**

Since the presence of PEW has been shown to be of considerable importance in determining clinical outcomes, trials should be designed to study the possibilities of effective PEW prevention and treatment in CKD patients. It is essential that nutritional requirements be met, but this may not be sufficient for prevention and treatment of PEW. One might assume that appropriate nutritional interventions would have an impact on patient outcome, but the evidence for such an impact is in fact scarce. One important reason is that "pure" malnutrition may not be the main determinant of PEW in CKD patients who suffer from so many other catabolic conditions, e.g. chronic systemic inflammation and co-morbidities, contributing

**FIG. 53.3** Simplified algorithm for applying nutritional interventions in CKD.

to PEW and – by other mechanisms – to poor clinical outcomes. The number of adequately powered RCTs in this field is very limited. The studies that are available were usually of short duration and performed in small patient groups, and they rarely address “hard” end points such as survival. It seems, therefore, that there must be new trials in the future to verify the usefulness of nutritional initiatives in CKD patients. Such trials should aim at evaluating the impact of particular nutritional interventions, not only on nutrition indices but also on mortality of CKD patients.

Again one has to remember that PEW is a multifactorial process, with pure malnutrition being only one of the culprits. Therefore, it appears that only interventions targeted against several factors responsible for PEW could be expected to have a significant impact on patient outcomes. The future should hopefully provide us with such studies and with an answer to the issue of ideal nutritional support in patients with kidney diseases.

## LIVER DISEASE

CRAIG J. MCCLAIN, MD, DANIELL B. HILL, MD, FACP, FAGA, AND  
LUIS MARSANO, MD

*University of Louisville, Louisville, Kentucky, USA*

### Summary

The liver is the largest and most complex metabolic organ of the body, with critical functions for anabolism, detoxification, and protection from gut-derived toxins; these functions are negatively affected in advanced liver disease. Malnutrition in liver disease is multifactorial, and its assessment is difficult because of the overlap of markers of liver disease with those of malnutrition. However, a subjective global assessment plus selective laboratory tests are usually adequate for identification of malnutrition. Advanced liver disease is strongly associated with malnutrition, and the severity of malnutrition correlates with the development of complications of liver disease, as well as mortality. Intense nutritional support can improve malnutrition in patients with liver disease, and may decrease infectious complications, improve cognitive function, and in some instances even decrease mortality.

Some individual nutrients used in high doses have shown beneficial effects in specific liver diseases, and others are promising. For example, vitamin E improved liver enzymes and histology in non-alcoholic steatohepatitis (NASH). Other therapeutic interventions which are considered "complementary and alternative medicine" may have some value, but need more study.

Obesity with insulin resistance is also a widespread problem and frequently leads to non-alcoholic fatty liver disease (NAFLD) and in some instances to NASH and cirrhosis. Indeed, NASH is now recognized as the major cause of cryptogenic cirrhosis. Excessive intake of some specific nutrients, such as n-6 fatty acids and fructose, has been implicated in the development of NASH. Dietary modifications with weight loss, increased physical activity, and bariatric surgery have all been shown to improve the hepatic steatosis.

In patients in need of liver transplantation, both undernutrition and obesity increase the rate of complications and length of stay after liver transplant. Correction of these problems is an important component of the pre-transplant management.

### Introduction

The liver is the largest organ in the body, weighing approximately 1.5 kg in adults, and it is possibly the most complex organ in terms of metabolism. It has a unique dual blood

supply, being perfused by both the portal vein and the hepatic artery, and comprises multiple cell types that have different functions. Hepatocytes make up over 80% of total liver mass and play a critical role in the metabolism of amino acids and ammonia, biochemical oxidation

reactions, and detoxification of a variety of drugs, vitamins, and hormones. Kupffer cells represent the largest reservoir of fixed macrophages in the body. They play a protective role against gut-derived toxins that have escaped into the portal circulation, and are a major producer of cytokines, which can markedly influence nutritional status. Hepatic stellate cells are the major storehouse for vitamin A in the body, and play an important role in collagen formation during liver injury. Other specific cell types also have unique functions (e.g., bile-duct epithelium in bile flow sinusoidal endothelial cells in adhesion molecule expression and endocytosis). The liver plays a vital role in protein, carbohydrate, and fat metabolism as well as in micronutrient metabolism. It synthesizes plasma proteins, non-essential amino acids, urea (for ammonia excretion), glycogen, and critical hormones such as the anabolic molecule, insulin-like growth factor-1. The liver is a major site for fatty acid metabolism, and bile from the liver is needed for fat absorption from the intestine. Thus, it seems obvious that the liver is important for proper nutrition.

A strong association exists between advanced liver disease and malnutrition. However, malnutrition is not always recognized in patients with liver disease, at least in part because weight loss in these patients can be masked by fluid retention. The loss of glycogen stores predisposes patients with advanced liver disease to enter a starvation state within a few hours of fasting that can lead to further protein catabolism and loss of function. Therefore, it is important to recognize malnutrition and initiate nutrition support early in these patients. Moreover, obesity and the metabolic syndrome are increasingly recognized as a major cause of abnormal liver enzymes and a spectrum of non-alcoholic fatty liver disease (NAFLD). Thus, both undernutrition and obesity play important roles in liver disease.

This chapter begins with a discussion of the prevalence of malnutrition and nutritional assessment in patients with liver disease. Causes of malnutrition and cytokine-nutrient interactions are then discussed, followed by a review of nutritional support, including obesity, in liver disease, as well as nutrition and liver transplantation.

## Assessment and Prevalence of Malnutrition

Malnutrition is widely present in liver disease, especially in more severe, chronic forms. When evaluating information concerning the prevalence of malnutrition in cirrhosis, it is important to use tests that accurately define

nutritional status. Unfortunately, assessment of nutritional status in patients with liver disease is often quite difficult. Tests that are most frequently used include serum visceral protein concentrations, some assessment of immunity (total lymphocyte count or delayed hypersensitivity), anthropometry, percentage of ideal body weight, creatinine-height index, dietary history, subjective global assessment, and – in more sophisticated clinical settings – bioelectric impedance and body composition determinations. Unfortunately, almost all of these tests can be influenced either by underlying liver disease or by factors that may be causing the liver disease, such as chronic alcohol consumption or viral infection. Visceral protein concentrations are probably the tests most frequently used by nutritionists in evaluating nutritional status, especially protein malnutrition. The visceral proteins such as albumin, pre-albumin, and retinol-binding protein are all produced in the liver and correlate better with severity of underlying liver disease than with malnutrition (Merli *et al.*, 1987). Alcohol and viral infection can influence immune function, and edema and ascites can influence anthropometry and bioelectric impedance (O’Keefe *et al.*, 1980; Shronts *et al.*, 1987; Shronts, 1988; Guglielmi *et al.*, 1991; McCullough *et al.*, 1991). Impaired renal function frequently occurs in more severe liver disease and influences indicators such as creatinine-height index (Pirlich *et al.*, 1996). Thus, no ideal single indicator of malnutrition in liver disease exists and, often, subjective global assessment in conjunction with a combination of tests most appropriate for the particular patient will provide the best possible evaluation (Baker *et al.*, 1982; Campillo, 2010). As an example, malnutrition is obvious by subjective global assessment in the alcoholic cirrhotic in Figure 54.1A, and malnutrition has markedly improved with two years of abstinence and appropriate nutrition in Figure 54.1B.

Probably the most extensive studies of nutritional status in patients with liver disease are in patients with alcoholic liver disease (ALD), and we will focus on abnormalities of ALD that can be extrapolated to other forms of liver disease. The best recent studies are two large studies in the Veterans Health Administration (VA) Cooperative Studies Program dealing with patients with alcoholic hepatitis (Mendenhall *et al.*, 1984, 1986, 1993, 1995a,b). The first of these studies (#119) demonstrated that virtually every patient with alcoholic hepatitis had some degree of malnutrition (Mendenhall *et al.*, 1984). Patients (284 with complete nutritional assessments) were divided into groups with mild, moderate, or severe alcoholic hepatitis based on

**FIG. 54.1** Patient with alcoholic cirrhosis with severe PEM as determined by subjective global assessment with ascites and muscle wasting (A). This was corrected with abstinence (B).

**TABLE 54.1** Nutritional status in alcoholic hepatitis

Initial laboratory test	Severity of liver disease		
	Mild	Moderate	Severe
Lymphocytes (1000–4000/mm <sup>3</sup> )	2067 ± 14837	1598 ± 90	1366 ± 83
Albumin (35–51 g/L)	37 ± 1	27 ± 1	23 ± 1
Creatinine-height index (% of standard)	75.7 ± 2.84	62.9 ± 3.3	64.0 ± 4.65

clinical and biochemical parameters. Patients had a mean alcohol consumption of 228g/day (with almost 50% of energy intake coming from alcohol). The severity of liver disease was generally correlated with the severity of malnutrition (Table 54.1). Similar data were generated in a follow-up VA study on alcoholic hepatitis (#275) (Mendenhall *et al.*, 1993).

In both of these studies, patients were given a balanced 2500-kcal (10.5-MJ) hospital diet, monitored carefully by

a dietitian, and encouraged to consume the diet. In the second study, patients in the therapy arm of the protocol also received an enteral nutritional support product high in branched-chain amino acids (BCAA), as well as the anabolic steroid oxandrolone (80 mg/day). In neither of these studies were patients fed by tube if voluntary oral intake was inadequate (probably a study design flaw in retrospect). Voluntary oral food intake correlated in a step-wise fashion with 6-month mortality data. Thus, patients who voluntarily consumed over 3000 kcal/day (12.6 MJ/day) had virtually no mortality, whereas those consuming under 1000 kcal/day (4.2 MJ/day) had more than an 80% 6-month mortality (Figure 54.2) (Mendenhall *et al.*, 1995b).

Moreover, the degree of malnutrition correlated with the development of serious complications such as encephalopathy, ascites, and hepatorenal syndrome (Mendenhall *et al.*, 1995b). In the VA Cooperative Studies, the chronic alcohol-consuming control population without liver disease also frequently had some degree of protein-energy malnutrition. This is in contrast to many other studies in which only alcoholics with liver disease demonstrated significant protein-energy malnutrition (Antonow and McClain, 1985).

Because both of these VA studies evaluated patients with acute inflammatory response (hepatitis), it was important

**FIG. 54.2** A direct relationship was noted between voluntary caloric intake in Veterans Health Administration studies in patients with moderate and severe alcoholic hepatitis. It is not known whether providing enteral feeding to patients with inadequate caloric intake would have improved mortality. Reproduced with permission from Elsevier: Lolli *et al.* (1992). to determine nutritional status in patients with stable ALD without alcoholic hepatitis. We evaluated patients with stable cirrhosis followed in an ascites clinic who were not actively drinking, were free of alcoholic hepatitis, and had bilirubin levels under 51 mmol/L (3 mg/dL). They had indicators of malnutrition almost as severe as patients with alcoholic hepatitis (e.g. a creatinine-height index of 71%) (Antonow and McClain, 1985).

It could be argued that alcohol, rather than the underlying liver pathology, is the critical variable in malnutrition in liver disease. There have been several major studies evaluating patients having both alcoholic liver disease and non-alcoholic- (especially viral-) induced liver disease (DiCecco *et al.*, 1989; Lolli *et al.*, 1992; Thuluvath and Triger, 1994; Caregaro *et al.*, 1996; Sarin *et al.*, 1997).

Although the prevalence of malnutrition in liver disease varied somewhat in the different studies, there is a compelling, consistent observation that no difference in malnutrition occurred between alcohol- and non-alcohol-related causes of cirrhosis in the individual studies. In one of the most carefully designed studies, Sarin *et al.* (1997) demonstrated that protein-energy malnutrition was equally severe in alcoholic and non-alcoholic liver disease, and that dietary intake decreased equally in both diseases. Caregaro

*et al.* (1996) from Italy found that the prevalence, characteristics, and severity of protein-energy malnutrition were comparable in alcoholic and viral-induced cirrhosis. Malnutrition was correlated with the severity of the liver disease. Thus, multiple studies now document that the degree of liver injury, rather than the etiology, is critical in the development of nutritional disorders.

## Causes of Malnutrition in Liver Disease

Multiple factors combine to cause malnutrition in patients with liver disease (Box 54.1). Poor nutritional intake can result from gastrointestinal disturbances, prolonged periods eating nothing during hospitalizations for complications of cirrhosis, and iatrogenic causes. Maldigestion and malabsorption can occur in liver disease and play an important role in causing malnutrition. Typical gastrointestinal disturbances in liver disease include dysgeusia, anorexia, nausea, and early satiety (Madden *et al.*, 1997). Although the exact pathophysiology of how liver dysfunction causes these manifestations is still debated, local and systemic neurohormonal mechanisms are likely involved in causing delayed gastric emptying, small-bowel dysmotility and bacterial overgrowth, and constipation (Thuluvath and Triger, 1989; Galati *et al.*, 1994, 1997; Isobe *et al.*, 1994; Quigley, 1996). Liver transplantation improves or reverses many of these gastrointestinal manifestations (Madrid *et al.*, 1997). Concomitant complications typical of liver disease, such as upper gastrointestinal bleeding, portal systemic encephalopathy, and sepsis, also cause prolonged periods of poor oral intake. Dietary management of fluid retention with salt and water restriction, dietary management of encephalopathy with protein

### BOX 54.1 Major causes of malnutrition

- Anorexia
- Diarrhea and malabsorption
- Nausea and vomiting
- Poor food availability and quality
- Metabolic disturbances (e.g. hypermetabolism and catabolism)
- Cytokines
- Liver complications (portal systemic encephalopathy, ascites, gastrointestinal bleed)
- Unpalatable diets (low sodium, protein)
- No feeding (nothing by mouth) for procedures

restriction, and carbohydrate and lipid restrictions used in patients with diabetes mellitus, chronic pancreatic insufficiency, and cholestatic liver disease can all affect diet palatability and can severely restrict patients' food choices.

Impaired lipid metabolism is also multifactorial in liver disease. Decreased intraluminal bile salts, small-bowel bacterial overgrowth, coexistent pancreatic insufficiency or intestinal disease (e.g., inflammatory bowel disease, sprue), and mucosal vascular hypertension and edema can worsen maldigestion and malabsorption. Cholestatic liver disorders are associated with decreased intraluminal concentration of bile salts, resulting in lipid and lipid-soluble-vitamin malabsorption (Vlahcevic *et al.*, 1971). Impaired intestinal capacity for absorption of long-chain fatty acids, interference with lipid absorption by neomycin, binding of bile salts by cholestyramine, and exocrine pancreatic insufficiency may also contribute to lipid malabsorption (Thompson *et al.*, 1971; Malagelada *et al.*, 1974; Cabre *et al.*, 1990). As a result, patients with liver disease may have decreased plasma levels of essential fatty acids and their polyunsaturated derivatives (McClain *et al.*, 1999).

Low-grade endotoxemia facilitated by portal hypertension and gut bacterial translocation leads to a low-grade increase in proinflammatory cytokines that further affects nutrient management and overall metabolism (McClain *et al.*, 1999) (Figure 54.3). Glycogen storage is impaired in cirrhotic livers partly because of hyperglucagonemia. This results in peripheral muscle proteolysis to provide amino acids for gluconeogenesis, thus contributing to protein malnutrition. Liver disease patients with portal hypertension and ascites are at increased risk of developing

a hypermetabolic state (resting energy expenditure >110% of its expected value), which contributes to overall malnutrition (John *et al.*, 1989; Dols *et al.*, 1991; Muller *et al.*, 1992; Ksiazek *et al.*, 1996).

Healthcare providers must exert great care to improve nutritional status rather than inadvertently compounding the problem (e.g., long periods of fasting for procedures, unpalatable low-sodium diets). This concern is highlighted by the fact that 67% of patients in a VA Cooperative Study on alcoholic hepatitis did not consume the recommended 2500 kcal/day (10.5 MJ/day), even though these patients received expert care by nutritionists and hepatologists who knew that nutrition was a major outcome variable of the study (Mendenhall *et al.*, 1995).

### Cytokine–Nutrient Interactions

Dysregulated cytokine metabolism [with elevated proinflammatory cytokines such as tumor necrosis factor (TNF) and interleukin 8 (IL-8)] is well documented in many forms of liver disease; ALD has been studied in the greatest detail (McClain *et al.*, 1999, 2004) (Figure 54.2). The cytokine interferon- $\alpha$  is used to treat both hepatitis B and C. Increased levels of cytokines have been postulated to cause many of the metabolic and nutritional abnormalities observed in liver disease, especially in more decompensated liver disease (McClain *et al.*, 1999, 2004). Thus, abnormalities such as fever, anorexia, muscle breakdown and wasting, and altered mineral metabolism are likely to be at least partially cytokine mediated (Box 54.2). We will briefly review alterations in mineral metabolism, visceral proteins, hypermetabolism, and anorexia in relation to cytokines and liver disease.

**FIG. 54.3** Endotoxemia and oxidative stress occur in virtually all forms of liver disease, especially in alcoholic liver disease. Both endotoxin and reactive intermediates activate the critical redox-sensitive transcription factor NF $\kappa$ B in hepatic Kupffer cells, with subsequent cytokine production. Recent studies also show that certain free fatty acids can activate Toll receptors, with subsequent NF $\kappa$ B activation and inflammation. This activation will lead to further bacterial translocation with endotoxemia and further oxidative tissue injury. Antioxidants may have a role in blocking this cycle of tissue destruction.

**BOX 54.2 Biological activities of cytokines**

Cytokine effects	Metabolic complications of alcoholic hepatitis
Fever	Fever
Anorexia	Anorexia
Neutrophilia	Neutrophilia
Altered amino acids, decreased glutathione, catabolism with muscle wasting	Altered amino acids, decreased glutathione, catabolism with muscle wasting
Hypermetabolism	Hypermetabolism
Decreased serum zinc	Decreased serum zinc
Increased acute-phase reactants	Increased acute-phase reactants
Decreased bile flow	Cholestasis
Decreased albumin	Decreased albumin
Bone loss	Bone loss
Collagen deposition	Collagen deposition
Increased triacylglycerols	Triacylglycerols (Zieve's syndrome)
Increased endothelial permeability	Ascites and peripheral edema
Slow-wave sleep	Encephalopathy

**Mineral Metabolism**

Cytokines such as TNF and IL-1 generally cause a decrease in the serum zinc concentration and an internal redistribution of zinc, with zinc being sequestered in the liver and being lost from other tissues such as bone marrow and thymus (Gaetke *et al.*, 1997). This internal redistribution of zinc is thought to facilitate priority protein synthesis in the liver, and it also makes the plasma a less favorable environment for bacterial growth (zinc withholding) (Gaetke *et al.*, 1997). This zinc stress response can also be associated with loss of zinc from critical zinc finger proteins and loss of functional activity. We have shown that this plays a role in the increased gut permeability, endotoxemia, and fatty liver in ALD (Kang *et al.*, 2009; Zhong *et al.*, 2010a). There is frequently an increase in urinary zinc loss that can contribute to overall zinc deficits in patients with increased cytokine activity. Patients with liver disease regularly have decreased serum zinc concentrations and increased urinary zinc losses (McClain *et al.*, 1992). This zinc deficiency may play a role in the anorexia, sexual dysfunction, and immune impairment in liver

disease. Although the serum and zinc concentrations are decreased with increased cytokine levels, the serum copper level generally increases, as does the binding protein for copper (ceruloplasmin) (McClain *et al.*, 1991). Increased copper can enhance hepatic oxidative stress and worsen liver injury.

**Visceral Proteins**

With increased cytokines, there is generally a depression in plasma proteins that are used as indicators of nutritional status, including albumin, transferrin, pre-albumin, and retinol-binding protein. This reduction in protein occurs initially because cytokines generally cause an increase in endothelial permeability, which then causes a decrease in these visceral proteins (Hennig *et al.*, 1988). Cytokines also generally decrease production (mRNA) of these visceral proteins, which partially accounts for long-term depression of the proteins (Boosalis *et al.*, 1989). At the same time that these visceral proteins decrease, hepatic acute-phase proteins increase. Certain of these acute-phase reactants play a role in attenuating the ongoing toxic effects of cytokines (e.g. alpha-1 acid glycoprotein attenuates the toxic effects of TNF; Libert *et al.*, 1994).

**Hypermetabolism and Hypercatabolism**

Increased cytokine production can induce a hypermetabolic or hypercatabolic state. For example, TNF infusion into experimental animals causes a decrease in protein synthesis with an overall increase in net protein breakdown (Sakurai *et al.*, 1994). This may relate to the hypermetabolism and wasting seen in liver disease (John *et al.*, 1989).

**Anorexia and Decreased Gastric Emptying**

Cytokines frequently induce anorexia; indeed, TNF was initially termed cachectin (McClain *et al.*, 2004). Interferon is used as a therapeutic agent in certain forms of viral hepatitis, and it has anorexia and flu-like symptoms as major side-effects which generally improve as therapy progresses. Several cytokines such as IL-1 and TNF also impair gastric emptying, which occurs as a complication of liver disease (Suto *et al.*, 1994). Some patients will respond to prokinetic agents such as metoclopramide.

**Nutrition Support**

Interest in nutritional therapy in cirrhosis started when Patek *et al.* (1948) demonstrated that a nutritious diet improved the 5-year outcome of patients with cirrhosis

compared with control subjects consuming an inadequate diet. These low-income patients had alcoholic cirrhosis. Several recent studies further support the concept of improved outcome with nutritional support in patients with cirrhosis. Hirsch *et al.* (1993) demonstrated that outpatients supplementing their diet with an enteral nutritional support product [1000 kcal (4.2 MJ), 34 g protein] had significantly improved protein intake and significantly fewer hospitalizations. These same investigators subsequently gave an enteral supplement to outpatients with alcoholic cirrhosis, and observed an improvement in nutritional status and immune function (Hirsch *et al.*, 1999). In the VA Cooperative Study on nutritional support in ALD using both an anabolic steroid and an enteral nutritional supplement, improved mortality was seen with the combination of oxandrolone plus nutrition supplementation in patients who had moderate protein-energy malnutrition (Mendenhall *et al.*, 1995b). Those with severe malnutrition did not significantly benefit from therapy, possibly because their malnutrition was so advanced that no intervention, including nutrition, could help. Studies by Kearns *et al.* (1992) showed that patients with alcoholic liver disease hospitalized for treatment and given an enteral nutritional supplement via feeding tube had significantly improved serum bilirubin levels and liver function as assessed by antipyrine clearance. A multicenter randomized study of enteral nutrition versus steroids in patients with alcoholic hepatitis showed similar overall short-term results (Cabre *et al.*, 2000). Moreover, those receiving enteral nutrition (rich in BCAAs) had a better long-term outcome with fewer infectious deaths. Thus, traditional nutritional supplementation clearly improves nutritional status and, in some instances, hepatic function and other indicators of outcome in cirrhosis.

A defined approach is necessary to achieve appropriate nutritional support in patients with liver disease (Marsano and McClain, 1991, 1992; McCullough, 2000; Campillo *et al.*, 2003; Stickel *et al.*, 2003) (Box 54.3). For the patient who has been actively drinking alcohol, it is useful first to correct electrolyte imbalances and to treat and control withdrawal symptoms when present. (This will facilitate control of electrolyte disorders and decrease the risk of having a feeding tube or parenteral nutrition line pulled out.) An important component of the dietary management of the patient with advanced liver disease is to minimize periods without food intake because these patients rapidly enter into “starvation mode” with decreased glucose oxidation and increased protein and fat catabolism (Owen

### **BOX 54.3 Nutritional recommendations for patients with liver disease**

Early nutrition assessment and regular follow-ups  
 Total energy: 1.2–1.4 × resting energy expenditure  
 Protein: 1.0–1.5 g/kg/day  
 Fat: 30–40% of non-protein energy  
 Formulate water and electrolyte intake to individual needs, renal function, diuretic sensitivity  
 Replace vitamins and minerals (avoid excessive iron and copper intake)  
 Complement daily requirements with enteral feedings (parenteral if enteral route otherwise contraindicated)

*et al.*, 1983). To prevent this starvation, the diet should optimally be divided into three meals (the first early in the morning), three snacks, plus one bedtime supplement. The early breakfast improves cognitive function in patients with subclinical (minimal) hepatic encephalopathy (Vaisma *et al.*, 2010), and the bedtime supplement improves body protein stores. Importantly, an improvement in muscle mass with night-time supplements was demonstrated by Plank *et al.* (2008) who randomized 103 cirrhotic patients to receive two cans of Ensure Plus™ (710 kcal with 26 g of protein) or two cans of Diabetic Resource™ (500 kcal with 30 g of protein), either during the day or at bedtime, for a total of 12 months. Only the patients who received the supplements at bedtime gained lean muscle mass (2 kg) over 12 months (Plank *et al.*, 2008). This points out the great importance of late-night snacking in maintaining muscle mass. Unfortunately, there is a long tradition of protein restriction for patients with advanced liver disease who also have hepatic encephalopathy (HE). This tradition has no solid scientific basis, and recent studies do not support this approach. Cordoba *et al.* (2004), in a prospective randomized study, treated 30 cirrhotic patients who suffered episodic overt hepatic encephalopathy with either a low-protein enteral formula [with increased protein every 3 days (0 g, then 12 g, 24 g, and 48 g)] or a normal protein formula (1.2 g/kg/day) from the first day. Both formulas provided 30 kcal/kg/day. The outcome of hepatic encephalopathy was similar with both formulas (Cordoba *et al.*, 2004). In a second study, Gheorghe *et al.* (2005) treated 153 consecutive cirrhotic patients with overt HE with a diet providing 30 kcal/kg/day with 1.2 g protein/kg/day, divided into five “meals”

from 8:00 a.m. to 10:00 p.m. Most patients improved their HE, with the best results seen in the more severe HE patients (Gheorghe *et al.*, 2005). The HE should be treated with lactulose and with rifaximin, if needed. If the HE persists despite maximal medical therapy and evaluation for other causes of changes in mentation, then protein intake can be decreased to the maximal tolerated, and a BCAA-enriched formula supplement can be administered to complete the nitrogen needs (see below).

BCAA-enriched diets were developed in an attempt to correct the abnormal ratios of BCAAs to aromatic amino acids observed in liver disease (<2.5 vs. 3.5–4 in normal subjects), with even greater disturbances in hepatic coma (0.8–1.2). Theoretical advantages of BCAA-enriched formulas include increased protein synthesis and decreased protein breakdown as a result of high leucine; use of BCAAs as an energy source for brain, muscle, and heart; better regulation of amino acid efflux from muscle during catabolism and hypoinsulinemia; improved ammonia metabolism by skeletal muscle; increased norepinephrine synthesis in brain; and decreased penetration of aromatic amino acids into the brain (BCAAs compete for the blood–brain amino acid transport system).

Because of the high cost of BCAA-enriched formulas and their limited role in hepatic encephalopathy, these formulas unfortunately are not generally considered cost effective in the United States. The major exception may be for the few patients who have chronic stable portosystemic encephalopathy (PSE) who require multiple admissions to the hospital. In these patients, the enteral formula cost is more than offset by the savings of fewer hospitalizations. A large randomized trial of BCAA in advanced cirrhosis from Italy reported that BCAA supplementation attenuated progression of liver disease and improved markers of nutrition (Marchesini *et al.*, 2003). However, compliance was poor and use of this product remains limited in the United States, as noted above (Charlton, 2003; Marchesini *et al.*, 2003).

If the patient cannot take in adequate kilocalories and has a functioning gastrointestinal tract, then a feeding tube should be used and a standard enteral formula should be given following the guidelines already mentioned above. Enteral nutrition is desired over parenteral nutrition because of cost, risk of sepsis of the parenteral nutrition line, preservation of the integrity of the gut mucosa, and prevention of bacterial translocation and multiple organ failure. Moreover, total parenteral nutrition can, in some instances, cause liver disease as one of its complications. If

enteral nutrition is not possible, then total parenteral nutrition (TPN) can be used with the knowledge that it is important to return to the enteral route as soon as the small bowel shows evidence of recovered function. Total parenteral nutrition (TPN) can be started with a standard amino acid formula in amounts that are increased until nitrogen needs are met. If the patients develop PSE, then standard therapy with lactulose, neomycin, or rifaximin must be given. If the patient is still unable to tolerate the amount of amino acids needed to satisfy nitrogen requirements, then the standard amino acids can be replaced by a BCAA-enriched solution specifically designed for liver disease (Charlton, 2003; Marchesini *et al.*, 2003). It is unusual to require either TPN or BCAA formulas, and the primary goal is always aggressive enteral support.

## Individual Nutrients and Complementary and Alternative Medicine

A recent major thrust in therapy for liver disease has been supplementation with individual nutrients, or the use of complementary and alternative medicine (CAM) (Haas *et al.*, 2000; McClain *et al.*, 2003; Hanje *et al.*, 2006). A detailed discussion of CAM is necessary because it is estimated that >40% of the US population uses CAM, and patients with chronic disease processes such as cirrhosis are frequent users of CAM. Moreover, CAM use is frequently not reported to traditional physicians (McClain *et al.*, 2003). A variety of forms of CAM have been used effectively to treat or prevent liver injury in animal models, and preliminary data with some agents suggest efficacy in human liver disease. It is the responsibility of health-care workers to be aware of the potential benefits and toxicities of these agents and to demand well-designed randomized human trials on such products.

The specific CAM agents that will be reviewed in relation to liver disease include vitamin E, glutathione (GSH) pro-drugs and antioxidant cocktails, S-adenosylmethionine (SAM) and betaine, silymarin (milk thistle), and herbals.

### Vitamin E

Vitamin E is a potent antioxidant that is widely used as a nutritional supplement. In patients with alcoholic liver disease and in experimental models of liver disease, depressed serum and hepatic levels of vitamin E have been documented. Vitamin E has been used extensively to protect against experimental models of liver injury, such

as that induced by carbon tetrachloride. Zern's laboratory (Liu *et al.*, 1995) demonstrated that vitamin E inhibited hepatic activation of the oxidative-stress-sensitive transcription factor NFκB in the carbon tetrachloride model, and postulated that inhibition of this critical transcription factor for proinflammatory cytokine production (e.g., TNF) resulted in attenuation of liver injury. Hill *et al.* (1999) treated human peripheral blood monocytes and rat Kupffer cells in vitro with vitamin E, inhibiting both NFκB activation and TNF production. Vitamin E also inhibits activation of hepatic stellate cells and collagen production in vitro (Lee *et al.*, 1995).

Vitamin E was initially reported to have beneficial effects in some but not all studies of patients with fatty liver (non-alcoholic steatohepatitis, NASH) (Lavine, 2000; Hasegawa *et al.*, 2001; Sanyal *et al.*, 2010). A pilot study in children (Lavine, 2000) showed improvement in liver enzymes, and a study from Japan (Hasegawa *et al.*, 2001) showed that vitamin E not only improved liver enzymes but also decreased serum levels of the profibrotic cytokine, transforming growth factor beta. A study in alcoholic hepatitis patients showed improvement in hyaluronic acid (a marker of fibrosis) but no improvement in mortality (Mezey *et al.*, 2004). The most important and compelling vitamin E data are from a large multicenter NIH-funded trial which assigned 247 adults with NASH (without diabetes) to receive pioglitazone at a dose of 30 mg daily (80 subjects), vitamin E at a dose of 800IU daily (84 subjects), or placebo (83 subjects) for 96 weeks (Sanyal *et al.*, 2010). Vitamin E therapy, as compared with placebo, was associated with a significantly higher rate of improvement in NASH (43% vs. 19%,  $p = 0.001$ ). Serum alanine and aspartate aminotransferase levels were reduced with vitamin E and with pioglitazone, as compared with placebo ( $p < 0.001$  for both comparisons). No treatment caused an improvement in fibrosis. Subjects who received pioglitazone gained more weight than did those who received vitamin E or placebo. In conclusion, vitamin E improved liver histology and liver enzymes and was not associated with the weight gain seen with pioglitazone, and 800IU of vitamin E is probably the preferred "drug" therapy for NASH.

### **Glutathione Pro-Drugs and Combined Antioxidants**

GSH is a tripeptide synthesized from glutamate, cysteine, and glycine. Glutathione, in its reduced form, is the main non-protein thiol in cells, and has an important role in

detoxification of electrophiles and in protection against reactive oxygen toxicity. This includes protection against intracellular free radicals, reactive oxygen intermediates, and several endogenous and exogenous toxins (Lauterburg and Velez, 1988). GSH also protects against toxicity from certain drugs (e.g., acetaminophen). GSH cannot be taken up by hepatocytes, but a number of pharmacologic agents have been devised to enhance intracellular pools (e.g. N-acetylcysteine, 2-oxothiazolidine-4-carboxylic acid). There are two distinct intercellular GSH pools: cytosolic (approximately 80%) and mitochondrial (approximately 20%). Mitochondrial GSH detoxifies hydrogen peroxide and other organic peroxides produced in mitochondria. Chronic alcohol consumption has been reported to deplete GSH levels (Lauterburg and Velez, 1988). Moreover, alcohol causes a marked depletion of GSH in the mitochondrial pool, with at least part of that depletion attributed to its impaired transport from the cytosolic pool (Fernandez-Checa *et al.*, 1993). This depletion renders hepatocytes more vulnerable to oxidative stress. The molecular basis for the impaired GSH transport into mitochondria is unclear, but it has been reported that exogenous SAM – but not N-acetylcysteine or other pro-GSH molecules – restores mitochondrial functions, enhances mitochondrial transport, and corrects mitochondrial GSH deficiency.

GSH precursors also can regulate production of proinflammatory cytokines, such as TNF and IL-8, by Kupffer cells and monocytes, with increased GSH levels decreasing cytokine production (Pena *et al.*, 1999). This occurs at least in part, through inhibition of the oxidative-stress-sensitive transcription factor NFκB, which plays a central role in lipopolysaccharide (LPS)-stimulated TNF production.

The glutathione precursor N-acetylcysteine (NAC) has been used clinically for decades to treat acute acetaminophen overdose with good results if administered early (optimally within 12 hours of acetaminophen ingestion). A recent study evaluated the effects of intravenous NAC on transplant-free survival in patients with non-acetaminophen acute liver failure (Lee *et al.*, 2009). In the study, 173 patients received either NAC or placebo. In patients with early-stage non-acetaminophen-related acute liver failure, NAC improved transplant-free survival. This important study supports the use of intravenous NAC in patients with acute liver failure. Unfortunately, combined trials of antioxidants that not only increase glutathione but also provide other antioxidant effects have not shown

efficacy in patients with chronic alcoholic liver disease (Phillips *et al.*, 2006). Thus, there is great scientific rationale for an antioxidant approach, but defining appropriate clinical populations, appropriate doses, and therapeutic intervals appear to be major challenges.

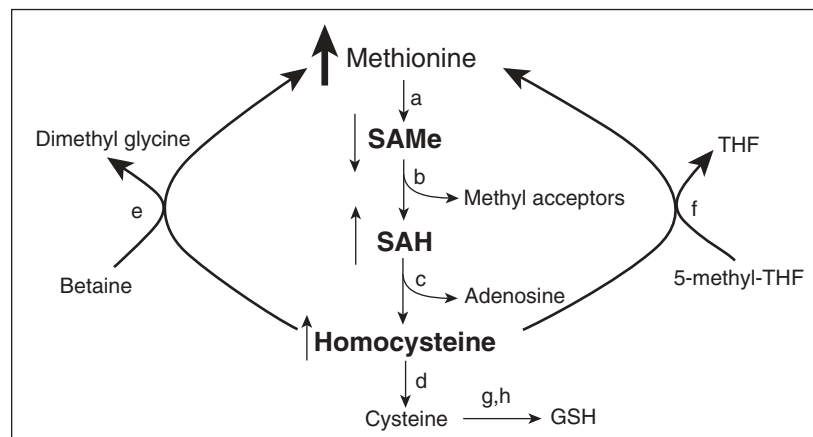

### **S-Adenosylmethionine (SAM)/Betaine**

Elevated methionine and decreased methionine clearance represent a possible therapeutic target for liver disease, especially ALD. In animal models of liver injury, decreased levels of SAM and elevated levels of S-adenosylhomocysteine are regularly observed (Figure 54.4).

In human studies of alcoholic hepatitis and cirrhosis, abnormal hepatic gene expression in methionine and glutathione metabolism occurs and often contributes to decreased hepatic SAM, cysteine, and glutathione levels (Lee *et al.*, 2004). Rodent and primate studies demonstrate that SAM depletion occurred in the early stages of fatty liver infiltration in ALD, and decreased SAM concentration, liver injury and mitochondrial damage can be reversed with SAM supplementation (Lieber, 2002). S-Adenosylmethionine appears to attenuate oxidative stress and hepatic stellate cell activation in an ethanol-lipopolysaccharide-induced fibrotic rat model (Karaa

*et al.*, 2008). Most importantly, a randomized double-blind trial was performed in 123 patients with alcoholic cirrhosis treated using SAM (1200 mg/day, orally) or placebo for two years (Mato *et al.*, 1999). When Child's C cirrhotics were excluded from the analysis, the overall mortality/liver transplantation rate was significantly greater in the placebo group than in the SAM group (20% vs. 12%), and differences between the 2-year survival curves of the two groups (defined as the time to death or liver transplantation) were also statistically significant. A subsequent Cochrane review of SAM and ALD could not find evidence supporting or refuting the use of SAM for patients with ALD (Rambaldi and Gluud, 2006) and the need for long-term, high-quality, randomized trials is clear.

Betaine (trimethylglycine) is a key nutrient in humans and is obtained from a variety of foods and nutritional supplements (Purohit *et al.*, 2007). In the liver, betaine can transfer one methyl group to homocysteine to form methionine. This process removes toxic metabolites (homocysteine and S-adenosylhomocysteine), restores SAM levels, reverses steatosis, prevents apoptosis, and reduces both damaged protein accumulation and oxidative stress (Purohit *et al.*, 2007; Kharbanda, 2009). Betaine also appears to attenuate alcoholic steatosis by restoring phosphatidylcholine generation via the phosphatidyleth-

**FIG. 54.4** Altered methionine metabolism pathway in ALD. (a) Methionine adenosyltransferase (MAT); (b) enzymes involved in transmethylation reactions, including phosphatidylethanolamine N-methyltransferase (PEMT); (c) S-adenosylhomocysteine (SAH) hydrolase; (d) cystathionine- $\beta$ -synthase (CBS); (e) betaine homocysteine methyltransferase (BHMT); (f) methionine synthase (MS); (g) glutamine-cysteine synthetase.  $\uparrow$   $\downarrow$ , effects of alcohol.

anolamine methyltransferase pathway (Kharbanda *et al.*, 2007). Unfortunately, the most definitive human trial thus far (in NASH patients) showed limited benefit (Abdelmalek *et al.*, 2009).

### Zinc

Zinc is an essential trace element that participates in cellular function through hundreds of zinc proteins, including zinc metalloenzymes and critical zinc transcription factors (McClain *et al.*, 1986, 1992). Altered zinc metabolism with zinc deficiency and decreased serum zinc is noted in most forms of clinical liver disease, especially ALD. Stress/inflammation caused by a variety of factors, including LPS/TNF, also causes an internal redistribution of zinc, with loss of zinc from some tissues (deficiency) and redirection to other tissues or organs such as the liver (redistribution). Importantly, zinc deficiency was recently shown to be induced by oxidative stress in which thiol oxidation of zinc-finger transcription factors causes zinc loss, leading to loss of DNA-binding activity (Zhou *et al.*, 2007; Kang *et al.*, 2009; Zhong *et al.*, 2010).

Recent studies from Kang *et al.* (2009) provide major new insights into the molecular mechanisms of altered zinc metabolism in the development and progression of experimental ALD, with important potential therapeutic implications for ALD and other forms of chronic liver disease. In both acute and chronic alcohol-induced hepatotoxicity, alcohol intake and oxidative stress disrupt tight junctions in the intestine, which leads to translocation of bacterial products such as endotoxin (Joshi *et al.*, 2009; Zhong *et al.*, 2010). Endotoxin activates TLR-4 and TNF production, with subsequent oxidative stress and liver injury. Endotoxin and TNF also play a critical role in liver fibrosis. Disruption of tight-junction proteins occurs not only in the intestine but also in the lung and likely at the blood–brain barrier, thus potentially predisposing to lung injury and hepatic encephalopathy (Joshi *et al.*, 2009). Zinc treatment in experimental animals with ALD attenuated the increased gut permeability, endotoxemia, TNF production, oxidative stress, and liver injury, while improving activity of key zinc transcription factors (Kang and Zhou, 2005; Joshi *et al.*, 2009; Kang *et al.*, 2009; Zhong *et al.*, 2010). Thus, zinc supplementation targets most postulated mechanisms for the development of ALD and certain other forms of chronic liver disease such as NAFLD.

A recent human pilot trial also suggests that zinc may stabilize or cause regression of hepatic fibrosis (Takahashi *et al.*, 2007). Polaprezinc, a synthetic zinc-containing com-

pound with 34 mg of elemental zinc, was administered daily for 24 weeks to patients with chronic hepatitis or cirrhosis, and zinc-supplemented patients significantly improved their serum zinc levels and markers of fibrosis.

### Silymarin

Silymarin, the active ingredient extracted from *Silybum marianum* (also known as milk thistle), was shown in experimental animals to protect against multiple types of liver injury, including that induced by carbon tetrachloride, acetaminophen, and iron overload and, very importantly, mushroom poisoning (Luper, 1998). Silymarin is probably the most widely used form of CAM in the treatment of liver disease. Clinically, it has been suggested to have hepatoprotective effects in various forms of toxic hepatitis, fatty liver, cirrhosis, ischemic injury, and viral-induced liver disease (Luper, 1998). It has antioxidant activities, protects against lipid peroxidation, and has anti-inflammatory and antifibrotic effects. Large controlled trials of silymarin performed in Europe have had variable results (Ferenci *et al.*, 1989; Pares *et al.*, 1998). Silymarin may be one of the most popular forms of CAM therapy for liver disease because it has a good safety profile, it has been extensively investigated in multiple forms of experimental liver injury in animals, and some positive results have been reported in humans.

### Herbals

Herbals are widely used for a variety of chronic inflammatory processes such as rheumatoid arthritis, and the use of herbal products for liver disease has been extensively reviewed (Schuppan *et al.*, 1999; Haas *et al.*, 2000; McClain *et al.*, 2003; Hanje *et al.*, 2006). Green tea, green tea polyphenols, and grape-seed polyphenols were reported to have anti-inflammatory properties and to protect against certain forms of experimental liver injury (Yang *et al.*, 1998). Glycyrrhizin is an aqueous extract of the licorice root. It has antioxidant effects, inhibits collagen deposition in animal models of hepatic fibrosis, and decreases procollagen mRNA in hepatic stellate cells in vitro. However, it has aldosterone-like effects and can produce electrolyte abnormalities (McClain *et al.*, 2003) that limit its use. There are multiple herbal preparations that have been used extensively in Asia for hepatitis B and C. However, our understanding of these products is limited by inconsistencies in product preparation/composition and lack of strong randomized trials (Haas *et al.*, 2000; McClain *et al.*, 2003; Hanje *et al.*, 2006).

A major problem with herbals is that they are actually a combination of agents that have been poorly characterized and are not highly reproducible from one lot to the next. Moreover, some herbal compounds cause severe hepatotoxicity (Haas *et al.*, 2000; McClain *et al.*, 2003; Hanje *et al.*, 2006).

## Potential Nutritional Toxicities in Liver Disease: Vitamin, Electrolyte, and Mineral Supplementation

### Vitamins

In liver disease, vitamin deficiencies can occur not only because of decreased dietary intake, but also because of problems with malabsorption, especially of the fat-soluble vitamins. The use of antioxidant vitamins such as vitamin E has been proposed as therapy in some types of liver disease. However, supplementation, especially if large doses of specific vitamins such as vitamin A or niacin are used, can also cause liver toxicity or exacerbate the underlying liver disease.

Malabsorption of the fat-soluble vitamins A, D, E, and K is well described in patients with advanced cholestatic liver disease (Sokol, 1994). The malabsorption and deficiencies have been classically described in patients with primary biliary cirrhosis and primary sclerosing cholangitis. However, cholestasis can occur with advanced liver disease from other etiologies such as alcoholic or viral liver disease. Overt night blindness is unusual; however, subclinical vitamin A deficiency can be detected by testing a subject's dark adaptation (Russell, 2000). Because zinc deficiency can also affect dark adaptation, it must be corrected before the test is valid to test for vitamin A deficiency.

Fortunately, vitamin A deficiency in patients with cholestatic liver disease usually responds to dietary vitamin A supplements. However, parenteral vitamin A may be required for patients with night blindness. Caution must be used in giving vitamin A supplements to alcoholics and patients with alcoholic liver disease (Leo and Lieber, 1999). Vitamin A toxicity can occur even at the dosages of vitamin A present in some multivitamin preparations with the concomitant use of alcohol or with underlying cirrhosis. The stellate cell in the liver is the major storage site for vitamin A in the body.

Vitamin D deficiency can occur because of malabsorption of vitamin D and because the liver produces a metabolite of vitamin D, calcidiol, or 25-hydroxyvitamin D

(Sokol, 1994). Vitamin D deficiency in chronic liver disease is almost universal, with evidence of mild to severe vitamin D deficiency in more than 90% of patients independent of the cause of liver damage (Fisher and Fisher, 2007; Arteh *et al.*, 2010). Because vitamin D is an immunomodulator (von Essen *et al.*, 2010), the relation of vitamin D deficiency to severity of liver damage and response to therapy has been studied in viral chronic hepatitis C. Patients with chronic hepatitis C and low vitamin D levels have been found to have a lower response to interferon-based therapy and to have more liver fibrosis (Petta *et al.*, 2010; Lange *et al.*, 2011). Furthermore, vitamin D supplementation before interferon-based therapy may improve treatment response (Bitetto *et al.*, 2011). Metabolic bone disease is well documented in advanced liver disease, especially in primary biliary cirrhosis and primary sclerosing cholangitis (Bonkovsky *et al.*, 1990). Vitamin D and calcium supplements (discussed below) are frequently given to these patients, especially if there is evidence of osteoporosis. Patients with low plasma calcidiol levels should receive vitamin D supplementation (400–800 IU/day). If plasma calcidiol levels do not normalize on vitamin D, then calcidiol, which is more water soluble, can be given (Sokol, 1994). However, the effectiveness of this practice is not well documented.

Deficiencies in the antioxidant vitamin E may lead to lipid peroxidation and cell membrane instability. Decreased serum levels of vitamin E have been reported in advanced liver disease. If vitamin E is given to children with cholestatic liver disease before age 3 years, neurologic symptoms such as areflexia, ataxia, and sensory neuropathy can be improved (Sokol, 1994). Vitamin E supplementation in the range of 800 IU/day has generally been thought to be safe in liver disease, even long term; however, higher dosages may potentiate the effect of oral anticoagulants and interfere with platelet function. A meta-analysis of vitamin E therapy reported an increased mortality in patients (not liver disease patients) receiving high-dose vitamin E supplementation (Miller *et al.*, 2005). In spite of this concern, recent positive findings using 800 IU of vitamin E per day in NASH patients support its use and safety in liver disease (Sanyal *et al.*, 2010).

Vitamin K malabsorption can occur in cholestatic liver disease and lead to prolongation of the prothrombin time because of deficiencies of vitamin K-dependent coagulation factors (Sokol, 1994). In patients with liver disease and a prolonged prothrombin time, vitamin K is often given parenterally to help determine whether the pro-

longed prothrombin time is due to vitamin K deficiency or malabsorption or to the severity of parenchymal liver disease itself.

Deficiencies of water-soluble vitamins can occur in liver disease. The best dietary sources for most water-soluble vitamins are fruits and vegetables. Patients with liver disease, especially advanced liver disease, can have problems with anorexia and develop dietary deficiencies of these vitamins. Deficiencies of vitamins related to alcohol usage per se can also occur in patients with liver disease. The intake of a daily multivitamin preparation is generally recommended in most patients with liver disease. In addition, we usually give folic acid (1 mg/day) for several months to replete dietary inadequacies. The amount of niacin contained in multivitamins (20 mg niacinamide) is unlikely to cause liver problems. When controlled-release niacin is used as a blood-lipid-lowering agent in dosages of 1 to 3 g/day, a dose-related increase in liver enzymes occurs (Gray *et al.*, 1994). Although hepatotoxicity is infrequent, it can occur with doses above 3 g/day and result in fulminant hepatic failure. Thus, the use of niacin as an antihyperlipidemic agent is contraindicated in patients with liver dysfunction.

The use of antioxidants, including antioxidant vitamins A, C, and E, has become popular because of the hypothesis that they can prevent cancer and slow the aging process by detoxifying toxic free radicals. The use of large doses of some of these agents should be avoided in patients known to have liver disease. As mentioned above, vitamin A toxicity can occur in patients with liver disease and other predisposed individuals. Excessive vitamin C supplementation should be avoided in patients with iron overload states, because vitamin C enhances iron uptake and potentiates free radical generation by transition metals (Sokol, 1996).

### **Electrolytes and Minerals**

Sodium is the primary electrolyte present in body fluids outside cells, with only 5% of the sodium concentration of the body occurring intracellularly. This electrolyte, together with potassium, assists in maintaining the body's electrolyte and water balance. In addition, sodium and potassium play important roles in nerve conduction, muscle contraction, and transport of substances across membranes. Hyponatremia (low serum sodium) is a frequent complication of liver disease (Marsano and McClain, 1989). This usually occurs with normal or increased amounts of sodium being offset by greater increases in total water volume. The increased volume of water and

sodium is expressed as edema or ascites. Many factors contribute to decreased sodium concentrations, with two of the most important being impaired free water clearance and the use of diuretics. In patients with decompensated liver disease, the main way of treating hyponatremia is fluid restriction. Hypernatremia occurs much less frequently in liver disease, and it is usually due to medical interventions with agents such as diuretics or lactulose therapy.

Hypokalemia is frequently observed in liver disease (Marsano and McClain, 1989). Unlike sodium, potassium is predominantly an intracellular electrolyte. Hypokalemia may occur as a result of poor nutrition; losses because of nausea, vomiting, or diarrhea; or use of diuretics to control edema or ascites. Various metabolic factors (e.g., increased insulin levels and respiratory alkalosis) may shift potassium from the extracellular fluid into cells, thus decreasing the serum potassium concentration. Hypokalemia can produce a spectrum of consequences ranging from muscular weakness to cardiac arrhythmias and even cardiac arrest. Hyperkalemia is much less commonly observed in liver disease and usually accompanies renal failure and use of potassium-sparing diuretics. It is vital that patients not be placed on potassium-containing salt substitutes while on potassium-sparing diuretics because severe hyperkalemia can occur.

In liver disease, hypocalcemia can occur because of hypoalbuminemia. If hypocalcemia is due to hypoalbuminemia, there is a reduction in total serum calcium, but the ionized calcium remains normal and no treatment is necessary. However, hypocalcemic crisis due to transient hypoparathyroidism associated with magnesium deficiency has been reported in acute alcoholic fatty liver (Chiba *et al.*, 1987). This hypocalcemia improves with magnesium replacement and improvement in the acute liver disease.

Chronic calcium deficiencies also can occur with liver disease because of dietary insufficiencies and malabsorption. Reduced total and ionized plasma calcium levels can occur with vitamin D deficiency, such as that occurring with cholestatic liver disease, because calcium absorption is reduced with vitamin D deficiency. However, additional factors are thought to be involved in the low-turnover osteoporosis that can occur with cholestatic liver disease, because this osteoporosis can occur despite normal plasma vitamin D and calcium levels (Hay, 1995). Calcium supplementation at a dose of 1500 mg/day is usually given in cholestatic liver disease, although the effectiveness of such therapy is not well documented. This calcium

supplementation is often given along with vitamin D supplementation, especially if plasma calcidiol levels are low.

Hypomagnesemia is frequently observed in liver disease, especially ALD (Flink, 1987). Major causes of the deficiency in liver disease include poor intake, impaired absorption, renal-related losses, and effects of drugs such as diuretics. Moreover, anti-rejection drugs such as cyclosporine and tacrolimus can cause a variety of metabolic and nutritional effects, including hypomagnesemia and hypophosphatemia, alterations in potassium, glucose intolerance, and hyperlipidemia. Hypophosphatemia may occur in very malnourished patients with liver disease and can be exacerbated by refeeding. Thus, serum levels need to be monitored, especially in aggressive refeeding of malnourished patients.

The role of trace elements in liver disease has been reviewed (McClain *et al.*, 1991, 1992). Trace elements are present in the body in amounts equal to or less than those of iron, the most abundant trace metal. Iron overload is a well-documented cause of liver disease. Chronic iron overload can result in fibrosis, cirrhosis, and ultimately even hepatocellular carcinoma. Mechanisms for injury are thought to be multifactorial and most likely relate to oxidative stress and lipid peroxidation. The genetic basis for hereditary hemochromatosis has been identified, and genetic analysis for hemochromatosis is now clinically available (Bacon and Schilsky, 1999; Fleming *et al.*, 2004). Iron deficiency can also occur in liver disease; it is usually caused by gastrointestinal bleeding, especially from esophageal varices or portal hypertensive gastropathy. Care must be taken with iron supplementation in patients with liver disease to avoid iron overload.

Zinc deficiency, as discussed previously, is well documented in liver disease. This is usually due to poor dietary zinc intake as well as increased losses, especially in the urine (McClain *et al.*, 1991, 1992). Zinc deficiency in liver disease may present as neurosensory defects (with alterations in cognitive function, night vision, or appetite), skin lesions, hypogonadism, immune dysfunction, or altered protein metabolism. A major and frequently unrecognized complication of mineral deficiency in cirrhosis is severe muscle cramps. This is often associated with deficiencies of zinc and magnesium, and replacement with these two minerals often improves or corrects these disturbing symptoms.

Increased copper levels may cause hepatotoxicity, the classic example of which is Wilson disease (an autosomal recessive genetic disorder of copper overload) (Harris and

Gitlin, 1996). Copper is excreted in the bile, and cholestatic liver diseases such as primary biliary cirrhosis and sclerosing cholangitis frequently have prominent copper overload. Interestingly, zinc has been used as a therapy for Wilson disease. Zinc blocks copper absorption by inducing intestinal metallothionein, thus preferentially reducing copper absorption at the intestinal level (Brewer, 1999).

Other trace metals of particular relevance to liver disease include selenium (potential antioxidant function), chromium (role in glucose tolerance), and manganese, which is excreted via the biliary route (McClain *et al.*, 1991).

## Obesity and Non-Alcoholic Steatohepatitis

In 1980, the term “NASH” (non-alcoholic steatohepatitis) was coined to describe a new syndrome occurring in patients who usually were obese females (often with type 2 diabetes) who had liver pathology consistent with alcoholic hepatitis but who denied alcohol use (Ludwig *et al.*, 1980). The causes of this syndrome were unknown, and there was no defined therapy. Three decades later, this clinical syndrome is only a little better understood, and there is still no Food and Drug Administration-approved or even generally accepted drug therapy. Men are now proving to be equally affected, and terminology has been expanded to include NAFLD, which encompasses just fatty liver as well as fat plus inflammation/fibrosis (Neuschwander-Tetri and Caldwell, 2003; McClain *et al.*, 2004; Cave *et al.*, 2010). Patients with “primary” NASH typically have insulin resistance syndrome (synonymous with metabolic syndrome, syndrome X, etc.), which is characterized by obesity, type 2 diabetes, hyperlipidemia, hypertension, and, in some instances, other metabolic abnormalities such as polycystic ovary disease (Neuschwander-Tetri and Caldwell, 2003; McClain *et al.*, 2004; Cave *et al.*, 2010). “Secondary” NASH may be caused by drugs such as tamoxifen, certain industrial toxins, rapid weight loss, etc. (Cave *et al.*, 2010). The etiology of NASH remains elusive, but most investigators agree that a baseline of steatosis requires a second “hit” capable of inducing inflammation, fibrosis, or necrosis to develop NASH. Second hits or insults that are thought to be etiologic in the development of NASH include oxidative stress, mitochondrial dysfunction, increased proinflammatory cytokines such as TNF, low levels of the anti-inflammatory adipokine adiponectin, and insulin resistance (McClain *et al.*, 2004; Louthan *et al.*, 2005).

The clinical features of NASH are generally non-specific. Patients are typically diagnosed in the fifth or sixth decade of life, although there is an increasing recognition of NASH in children. Most patients are asymptomatic, although some complain of fatigue and/or right upper quadrant discomfort. Many patients are diagnosed on routine physical examination (mild hepatomegaly) and laboratory evaluation (mild increase in aspartate aminotransferase and alanine aminotransferase <5 times normal). The aspartate aminotransferase/alanine aminotransferase ratio is usually less than 1 in NASH, thus helping to distinguish it from alcoholic steatohepatitis. The natural history of steatosis relates to histologic severity (Brunt, 2001). Fatty liver without inflammation has a relatively more benign course, while the presence of fibrosis and inflammation indicates a more ominous prognosis. Fat may decrease as NASH patients develop cirrhosis. NASH is a major cause of cryptogenic cirrhosis, an increasingly recognized cause of hepatomas, and an indicator for liver transplantation. Lastly, obesity can accelerate the course of other liver diseases such as ALD and hepatitis C (Naveau *et al.*, 1994; Patton *et al.*, 2004).

There is substantial evidence that specific dietary components play a role in the development/progression of NAFLD. As noted above, both steatosis and steatohepatitis appear to be triggered by mechanisms such as dysregulated cytokines/adipokines, lipotoxicity, endotoxemia, alterations in gut microflora, and oxidative stress. These are all mechanisms that are associated with specific dietary habits (e.g. obesity, high-fat diets, excess fructose, diets low in n-3 fatty acids, etc.) (Musso *et al.*, 2003). High-fat diets have frequently been implicated in NAFLD. Indeed, many animal models utilize such a diet (71% of energy from fat) to induce NAFLD (Lieber *et al.*, 2004). These high-fat diets result in several of the metabolic derangements, including alterations in postprandial triglyceride metabolism, increased TNF- $\alpha$ , oxidative stress, circulating free fatty acids (FFA), and insulin resistance, that likely play an etiologic role in NAFLD. Not only is the amount of fat important in the development of NAFLD; the type and ratios of dietary fats also appear to be important. An increased fat intake with an excessive amount of n-6 fatty acids has been implicated in promoting necro-inflammation (Cortez-Pinto *et al.*, 2006). On the other hand, a diet containing MCTs in the absence of LCTs has been reported to be hepatoprotective (Lieber *et al.*, 2008). A large body of literature also exists regarding the role of fructose in the pathogenesis of NAFLD (Ouyang *et al.*, 2008; Lim *et al.*,

2010). Specific sources of fructose, such as soft drinks, have also been implicated (Nseir *et al.*, 2010). Recent animal studies have confirmed that diets containing 30% of fructose, either as free fructose and glucose or as sucrose, induce metabolic syndrome and intrahepatic accumulation of triglycerides. Fructose-induced NAFLD is associated with intestinal bacterial overgrowth and increased intestinal permeability, subsequently leading to an endotoxin-dependent activation of hepatic Kupffer cells and increased MCP-1 and TNF- $\alpha$  (Spruss *et al.*, 2009; Sánchez-Lozada *et al.*, 2010).

Current treatment recommendations for patients with NAFLD include both diet and physical activity for weight reduction and weight-loss surgery for extreme obesity. One year of intensive lifestyle intervention in patients with type 2 diabetes has been shown to reduce steatosis and incident NAFLD (Lazo *et al.*, 2010). Studies examining the effects of dietary interventions reveal that caloric restriction can result in significant changes in both liver fat and volume within a few days (Yki-Järvinen, 2010). The use of low-carbohydrate diets in NAFLD is an area of increasing interest. A low-carbohydrate, ketogenic diet in patients with NASH led to significant weight loss and histologic improvement of fatty liver disease at 6 months (Tendler *et al.*, 2007). Dietary avoidance of lipogenic, simple sugars (i.e., fructose) seems to be universally recommended (Yki-Järvinen, 2010). A reduction in the consumption of sweetened beverages can also lead to significant weight loss owing to a reduction in total calories consumed (Zivkovic *et al.*, 2007). Vigorous exercise may be most beneficial, as it appears that exercise intensity may be more important than duration or total volume (Kistler *et al.*, 2011). Weight loss by bariatric surgery attenuates both steatosis and steatohepatitis, but data supporting improvements in fibrosis are limited (Rafiq and Younossi, 2008). There remains no FDA-approved therapy for NAFLD. Pharmacologic therapies used in NAFLD mostly target components of the metabolic syndrome or oxidative stress associated with the pathogenesis of NASH (Rafiq and Younossi, 2008). As noted previously, a randomized, prospective trial involving adults without diabetes who had NASH reported that vitamin E therapy (800 IU, natural form, once daily) was associated with a significantly higher rate of histologic improvement over placebo (43% vs. 19%,  $p = 0.001$ ) (Sanyal *et al.*, 2010). For this reason, the use of vitamin E 800IU daily has become standard practice (“drug therapy”) in many areas of the country.

## Nutrition and Liver Transplantation

### Malnutrition in Liver Transplantation

Malnutrition is a risk factor for general post-operative morbidity (e.g., poor wound healing, infections, mortality), and this holds true for liver transplantation. In one study, malnutrition was the only variable of six studied that significantly affected outcome and that was potentially alterable and not completely dependent on underlying hepatic function (Shaw *et al.*, 1985). In that study, a risk stratification scoring system, including encephalopathy, ascites, nutritional status, serum bilirubin, prothrombin time, age, and intraoperative blood loss, was used to assign patients a low, intermediate, or high risk for poor outcome following liver transplantation. The actuarial 1-year survival after liver transplantation was significantly poorer for high-risk patients than for intermediate- or low-risk patients (44.5%, 85.2%, and 90.5%, respectively) (Shaw *et al.*, 1985). Moderately to severely malnourished patients had prolonged ventilator times, ICU lengths of stay, total hospital lengths of stay, and total hospitalization costs. Others have validated these data (Moukarzel *et al.*, 1990; Pikul *et al.*, 1994). Mortality increased 3.2-fold when significant loss in body cell mass was present preoperatively (Muller *et al.*, 1992). Using a modified subjective global assessment of malnutrition, Pikul *et al.* (1994) found a 79% incidence of malnutrition in 68 adult liver transplant recipients; in those with moderate and severe malnutrition, they found a significant increase in the number of days requiring ventilatory support, number of days in the ICU and in hospital, and a higher incidence of tracheostomy. In this study, patients with moderate and severe malnutrition had a significantly higher mortality than did those with an adequate status or mild malnutrition. A universal component of chronic liver disease is the loss of muscle mass and strength, and these deficits are associated with impaired health-related quality of life which persists to a lesser degree after liver transplantation (Abbott *et al.*, 2001; Pieber *et al.*, 2006).

The pediatric literature presents similar information. In a study of 119 pediatric liver transplants, malnutrition (assessed as failure to grow in height) was also shown to predict post-operative complications (Moukarzel *et al.*, 1990). Moreover, infants appear to be more susceptible to malnutrition associated with chronic liver disease than do older children; infants show both acute and chronic malnutrition with more severe reductions in weight and fat

body mass because their accelerated growth phase is affected (Roggero *et al.*, 1997).

### Nutritional Intervention Before Liver Transplantation

Dietary restrictions are necessary but often detrimental in maintaining adequate nutritional intake in patients with liver disease. Sodium restriction is probably the single most important restriction in the diet of patients with decompensated portal hypertension, but 1–2 g sodium diets are usually well tolerated and easily followed by well-coached patients. Fluid restriction is sometimes necessary to correct hyponatremia (Lowell, 1996). Restricting protein intake is commonly used to control hepatic encephalopathy, but current evidence does not support protein restriction (Cordoba *et al.*, 2004; Gheorghe *et al.*, 2005). Hepatic encephalopathy can be improved by interventions that include ensuring an adequate intestinal transit time; preventing small- and large-bowel bacterial overgrowth (by decreasing portal hypertension and using broad-spectrum antibiotics and lactulose); replacing electrolytes, vitamins, and minerals; and perhaps by adding casein or vegetable protein to the diet. Maintaining an adequate nutritional status might prevent proteolysis from providing substrate for gluconeogenesis. This would theoretically prevent excessive use of BCAAs for gluconeogenesis, and may prevent worsening hepatic encephalopathy. For example, early breakfast improves cognitive function in patients with covert (minimal) hepatic encephalopathy (Vaisma *et al.*, 2010), and after each food intake alertness improves for a period of time, further supporting the use of frequent small meals in advanced liver disease. A large body of evidence has been accumulated on the use and safety of BCAA preparations in the management of overt hepatic encephalopathy. Some physicians and nutritionists have also extended the use of BCAA preparations to malnourished patients with cirrhosis in an attempt to improve nutritional states. One reviewer summarizes current data regarding that practice: “The cost to benefit ratio makes it impossible to justify the use of BCAA in every malnourished patient with cirrhosis” (Munoz, 1991).

Although a strong body of work suggests that malnutrition is a risk factor for morbidity and mortality after liver transplantation, limited data actually document the benefit of nutritional intervention before this surgery. One of the reasons for this lack of data is that, as the survival after liver transplantation improves, the number of patients needed for such studies grows, making it more difficult to

perform them. Another reason is that, as we have discussed above, the reasons for malnutrition are multiple and vary from patient to patient. Nevertheless, nutritional intervention improves nutritional status in the pediatric population, and post-operative nutritional intervention decreases ICU and ventilatory-support days in adult liver transplant recipients (Reilly *et al.*, 1990; Charlton *et al.*, 1992). Similarly, aggressive bedtime nutrition support can minimize and reverse loss of muscle mass (Plank *et al.*, 2008).

When adequate oral intake cannot be maintained, nutritional goals should be supplemented by using nighttime enteral feedings via small-bore nasogastric tubes. Only in rare instances when the enteral route fails or is contraindicated should total parenteral nutrition be used.

### **Nutrition Support After Liver Transplantation**

Nutrition support after liver transplantation is generally simple because a patient's health improves remarkably rapidly after the surgery. Although increased protein catabolism and a negative nitrogen balance have been documented up to 4 weeks after transplantation, these have not been associated with a poor outcome (Plevak *et al.*, 1994). Immediate enteral feeding was well tolerated by 25 patients who were fed via a nasogastric tube within 12 hours after liver transplantation. When compared with 24 control patients with a sham nasogastric tube, the only significant benefit seen was a decrease in viral infections (Hasse *et al.*, 1995). Nevertheless, nutrition support guidelines have been published for the post-transplant patient (Hasse, 1990). For patients who have a longer ICU stay after transplantation, the experience of Reilly *et al.* (1990) suggests that parenteral nutrition may reduce ICU length of stay (although a shortcoming of this study was that there were no patients fed enterally). Nutrition support will be needed in the minority of patients with complicated post-operative courses and prolonged hospital stays. The rule of using the gut whenever possible stands true in this setting as well.

Starting weeks to months after transplantation, patients are prone to develop hyperglycemia, hypertension, and hypercholesterolemia as drug-related side-effects and weight gain. Necessary traditional nutrition intervention is warranted in these circumstances. Certain foodstuffs may alter immunosuppressive medications (e.g., grapefruit juice increases tacrolimus blood levels), whereas others can cause disease (e.g., raw seafood can transmit bacteria and promote life-threatening infections in immunosuppressed individuals).

In addition, after liver transplantation, there is a period of accelerated loss of bone due to corticosteroid therapy and decreased patient mobility. After this period of accelerated bone loss, there is a progressive increase in bone mineral density that can continue for several years post-transplant (Porayko *et al.*, 1991). Calcium supplementation is important during the period of increased bone formation.

### **Conclusions**

The liver is a unique metabolic organ that metabolizes and detoxifies nutrients, toxins, and drugs from the portal circulation and the arterial blood supply. It is responsible for the production of visceral proteins such as albumin, and anabolic hormones such as insulin-like growth factor-1, and it is the reservoir for the largest source (Kupffer cells) of fixed macrophages, which are responsible for clinical scavenging functions and cytokine production. When liver disease occurs, there are derangements in metabolic functions, with malnutrition being one critical consequence. The prevalence of malnutrition is high and correlates with the severity of liver disease, and the causes of malnutrition are multiple. It is important to initiate early assessment of nutritional status in patients with liver disease and to begin early nutritional support. Patients may have generalized protein calorie malnutrition or more selected depletion of individual nutrients (e.g., zinc, magnesium or folate deficiency). Nutritional supplementation has been shown to improve nutritional status, and in some situations improve liver function or clinical outcome in patients with chronic liver disease.

### **Future Directions**

A vital future direction is a better understanding of the interactions and cross-talk between the liver and other organs/tissues (e.g., the gut–liver axis and liver–adipose tissue axis). The role of the gut microbiome in liver disease as well as obesity and systemic inflammation is a rapidly evolving area. How liver disease alters the gut microbiome, and whether changing the gut microbiome with probiotics/prebiotics attenuates or prevents liver disease, are important areas of active investigation. Clinical trials, including dose-finding studies and appropriate biomarkers, on the impact of nutritional support and individual nutrients (e.g. zinc) on hepatic outcome are needed. Nutrients can dramatically impact gene expression, and nutrient

imbalance in diseases such as ALD may be a major contributor to dysregulated gene expression in liver injury. There is growing interest in the role of epigenetic changes, such as those induced by histone modifications and methylation reactions, that may markedly impact the development of a variety of types of liver disease. It is clear that nutrients and nutritional status may impact these epigenetic changes. Research into the above areas will markedly expand our understanding of mechanisms of various types of liver disease and potential nutritional interventions to prevent or treat liver disease.
