## ALCOHOL: ITS ROLE IN NUTRITION AND HEALTH

PAOLO M. SUTER, MD

*University Hospital, Zurich, Switzerland*

### Summary

In view of the importance of alcoholic beverages in daily life as well as its absolute priority in metabolism, alcohol has considerable potential to affect the nutritional status and metabolism of all essential nutrients including the different energy sources. In view of the great variability among alcohol drinkers in patterns of drinking, amounts ingested, ingestion of other nutrients, metabolic characteristics, genetic factors, and lifestyle characteristics (such as exercise or smoking behavior), the effects of alcohol on nutritional status and disease risk are very heterogeneous. Alcohol-associated malnutrition includes both primary and secondary malnutrition. Because of the comparatively high energy content of alcohol, it displaces other energy sources and thus many essential nutrients in the diet, thereby lowering the intake of most nutrients (primary malnutrition). Gastrointestinal and metabolic complications of heavy alcohol intake (especially liver dysfunction) lead to so-called secondary malnutrition. Anorexia and vomiting from alcoholic gastritis further promote inadequate intakes of food. Malabsorption of nearly all nutrients can develop as a result of mucosal dysfunction, liver insufficiency, and pancreatic insufficiency. Alcoholic liver dysfunction causes a reduced capacity to transport nutrients in the blood, a reduced storage capacity, and an insufficient activation of nutrients such as vitamins. In addition, alcohol increases the excretion of nutrients in the urine and bile. In alcoholic patients, several mechanisms for the development of malnutrition usually occur simultaneously.

The effect of alcohol on morbidity and mortality is biphasic, and the relationship is J-shaped: low levels of ingestion are associated with reduced morbidity and mortality risks, whereas abstinence and higher levels of ingestion are associated with a higher mortality risk due to different cancers, alcoholic liver disease, and cardiovascular diseases such as arrhythmias, alcoholic cardiomyopathy, hypertension, and stroke. The reduced mortality risk at lower intakes is explained by the risk of coronary artery disease and a reduced risk of ischemic stroke. The amount of alcohol ingestion at the nadir of mortality risk is not known and varies from study to study and from one individual to another. The hallmark of excessive alcohol intake is metabolic and structural alterations at the level of the liver, and liver cirrhosis is the leading cause of death in heavy drinkers.

Often, both positive and negative effects occur. In view of the heterogeneity of responses for any given alcohol dose, the formulation of public health recommendations for safe consumption levels is becoming increasingly difficult. In any case, alcohol should not be recommended for health reasons or for health maintenance, especially as long as there are no specific, sensitive predictors for harmful alcohol use and abuse. In the setting of an overall healthy lifestyle with respect to nutrition and physical activity, light to moderate alcohol consumption may add to the quality of life; however, the benefits and risks are not equal for all.

## Introduction

Alcohol is a major part of daily life globally, even in low-income countries. Presently, about 61% of US adults (67% of men and 55% of women) are current drinkers, about 14% are former drinkers, 24% of the adults are lifetime abstainers, and approximately 5% of the adults are classified as heavier drinkers (National Institute on Alcohol Abuse and Alcoholism (NIAAA), 2009; Schoenborn and Adams, 2010). Despite the wide acceptance of alcohol consumption in most societies, it remains an important cause and modulator of disease risk: worldwide, alcohol causes about 2.5 million (3.8% of total) deaths and 69.4 million (4.5% of total) of disability-adjusted life years (DALYs) (World Health Organization, 2010). Unintentional injuries alone account for about one-third of the 2.5 million deaths, whereas neuropsychiatric conditions account for close to 40% of the 69.4 million DALYs (WHO, 2010). With approximately 79 000 deaths per year attributable to excessive drinking, alcohol consumption represents the third leading cause of death after tobacco and poor diet/physical inactivity (Mokdad *et al.*, 2004; NIAAA, 2009). Compared with other food items, alcohol has three characteristic features: depending on the absolute amount and frequency of consumption, it can be regarded as a nutrient, a toxin, or a psychoactive drug. Each consumer determines which aspect of alcohol will prevail for him- or herself.

The energy content of alcohol, compared with other energy sources, is rather high (1 g alcohol = 7.1 kcal = 29.7 kJ), and thus alcohol represents an important source of energy for many alcohol consumers. Alcohol energy contributes, depending on sex and age, to 1.3–5.5% of total energy intake of the US diet (mean for all adult men/women = 4.3%/2.4%), but in heavy drinkers it may contribute up to 50% of the daily energy intake. In view of the importance of alcoholic beverages as a source of energy, alcohol has a high potential to displace other essential nutrients.

Because of its potential toxicity and the inability of the body to store alcohol, it has to be eliminated as quickly as possible from the body. This absolute priority in metabolism is a major cause of the metabolic effects of alcohol on nearly all nutrients, on most if not all organ systems, and, consequently, on disease risks (Figure 55.1).

In view of the great variability among alcohol drinkers in patterns of drinking, amounts ingested, ingestion of other nutrients, and metabolic characteristics, as well as

lifestyle characteristics (such as exercise or smoking behavior), the heterogeneous effects of alcohol on nutritional status and disease risk are not surprising. These effects are further complicated by genetically determined differences in alcohol metabolism (Higuchi *et al.*, 2004; Druesne-Pecollo *et al.*, 2009). For the purposes of this discussion, one “standard” drink corresponds to 0.6 fluid ounces or 14 g of alcohol, the amount contained in approximately 300 mL of beer, 150 mL of table wine (12% by volume), or 45 mL of liquor (40% by volume). A review of alcohol’s effects on selected nutrients and on disease risk follows.

## Alcohol Metabolism

Alcohol is rapidly absorbed from the stomach and the jejunum, and is distributed in the total water compartment of the body. Most of it is metabolized in the liver; however, a small amount may be metabolized in the stomach mucosa (i.e. during the first-pass metabolism) (Paton, 2005). The first-pass metabolism is higher in men than in women, declines with age, and is affected by different drugs such as aspirin, which decreases it. Alcohol can be metabolized via three different enzyme systems and, under usual conditions, depending on the dose and frequency of consumption, is metabolized by two major pathways: for light to moderate levels of intake, alcohol is metabolized in the alcohol dehydrogenase (ADH) pathway; for higher levels of intake, it is predominantly metabolized in the microsomal ethanol oxidizing system (MEOS) (Lieber and DeCarli, 1970). The oxidation of alcohol in both the ADH and the MEOS pathways leads to the production of acetaldehyde, which is further metabolized to acetate by acetaldehyde dehydrogenase (ALDH). Acetate is shuttled to the peripheral tissues and used as a source of energy. The metabolism of alcohol induces a change in the redox potential in the liver. This change contributes to different metabolic and clinical consequences and to functional abnormalities such as suppression of the Krebs cycle, with an increased transformation of pyruvate to lactate, impaired gluconeogenesis and hypoglycemia, greater fatty acid synthesis, reduced urate excretion, and hyperuricemia (Watson and Preedy, 2003).

These alcohol-induced metabolic perturbations depend on the dose of alcohol and the duration of consumption, but most metabolic, endocrine, and functional systems of the body are affected (Figure 55.1). The metabolic consequences of alcohol may be mediated directly or indirectly. Direct alcohol toxicity leads to an alteration in cellular

**FIG. 55.1** Metabolic and functional abnormalities due to alcohol consumption. L-FABP, Liver-type fatty acid binding protein; MEOS, microsomal ethanol-oxidizing system. Reproduced with permission from Lieber (1995).

function resulting from alterations in membrane fluidity and in the intracellular redox potential, and acetaldehyde toxicity. Acetaldehyde elicits many different effects, such as increased free radical production and lipid peroxidation, inhibition of protein synthesis, and impaired vitamin metabolism (Niemelä, 2007; Guo and Ren, 2010).

The metabolism of alcohol shows a wide inter-individual variability that is modulated by different genotypes of the alcohol-metabolizing enzymes ADH and ALDH (Li, 2000; Druesne-Pecollo *et al.*, 2009). Depending on the ADH genotype, higher maximal alcohol and acetaldehyde concentrations and slower elimination of alcohol are found, a situation that may lead to increased direct and indirect alcohol toxicity and thus a different alcohol-related disease pattern. In many people of Asian origin, the activity of ALDH may be low and thus cause a typical facial flushing reaction and headaches after ingestion of even small amounts of alcohol.

Although the capacity to metabolize alcohol varies widely, a healthy person metabolizes alcohol on average at

5 to 7 g/hour. There is no useful and safe strategy (except a high fructose intake leading to a reduced nicotinamide adenine dinucleotide reoxidation) known to increase the rate of alcohol degradation.

## The Nutritional Assessment of the Alcoholic Patient

Nutritional assessment of the alcoholic patient is a challenging task in either the clinical or community setting. The clinical signs of alcohol-related malnutrition depend on the stage of alcoholism, the level of socioeconomic integration, social and familial networks, associated alcohol- and non-alcohol-related diseases (especially liver disease), and concomitant medication intake of the patient (Santolaria-Fernandez *et al.*, 1995). Socioeconomically integrated heavy drinkers, in the absence of any clinically manifested somatic diseases, rarely show signs of malnutrition (Salaspuro, 1993). With the progression of alcoholism, clinical signs from all organ systems and malnutrition

may prevail. Different clinical signs of malnutrition may be found; for example, thin arms and legs due to muscle wasting (Urbano-Marquez and Fernandez-Sola, 2004; Fernandez-Solà *et al.*, 2007), edema (protein deficiency), glossitis (B-vitamin deficiency), and scaly, dry skin (zinc and essential fatty acid deficiency). Spider nevi and multiple hematomas due to easy bruising (vitamin C and K deficiency) may be found on the skin (Smith and Fenske, 2000). The parotid glands are often enlarged due to chronic parotitis. The patients may present with new bone fractures and several old costal fractures, and advanced osteoporosis (especially in men), attributable in part to impaired vitamin D nutrition and metabolism.

Alcohol-associated endocrine pathologies may manifest themselves as gynecomastia, testicular atrophy, and loss of body hair. Neurological signs may be limited to peripheral neuropathy (B-vitamin deficiency), different central nervous system impairments (see section on thiamin), or the full clinical picture of stroke. An impaired dark adaptation due to zinc deficiency is fairly common and should not be misinterpreted as vitamin A deficiency. In general, the nutritional assessment of the alcoholic patient is not different from the assessment of other patients. The biochemical assessment includes measurement of the conventional alcohol markers (i.e. liver transaminase levels and red blood cell mean cell volume) in combination with biochemical markers of nutritional status. Other newly developed biochemical markers for alcohol consumption [such as carbohydrate-deficient transferrin (CDT), fatty acid ethyl esters (FAEEs), or ethyl glucuronide (EtG)] may be helpful (Borucki *et al.*, 2005; Das *et al.*, 2008; Delanghe and De Buyzere, 2009; Mancinelli and Ceccanti, 2009). Chronic alcohol consumption in the range of 50–70 g/day induces hepatocytes to produce a transferrin molecule that is deficient in carbohydrates. The CDT is a marker for sustained and harmful alcohol consumption and returns slowly (the half-life of CDT is approximately 14 days) to normal upon cessation of alcohol intake. CDT measurements may be especially useful for the follow-up of patients in detoxification programs. Elevated levels of high-density lipoprotein (HDL) cholesterol, uric acid, and fasting triacylglycerol levels without other explanation may be signs of excessive alcohol intake.

The assessment of alcohol intake at either the population or individual level is very difficult, especially for drinking in the low to moderate range. Although heavy alcohol intake is detected sooner or later by typical clinical signs or laboratory test results, there is no reliable clinical

sign or biochemical marker for the assessment of light to moderate alcohol intake. Intentional or unintentional underreporting and overreporting often lead to uncontrollable bias in epidemiological and clinical studies. The difficulty in assessing low to moderate levels of alcohol consumption represents probably one of the most important causes of inconsistency in research findings.

## Alcohol and Nutrition

As a function of the amount of alcohol consumed, the duration of intake, and any associated diseases, drinking can impair the status of all nutrients. Alcohol-associated malnutrition includes both primary and secondary malnutrition. Because of the comparatively high energy content of alcohol, it displaces other energy sources and thus many essential nutrients in the diet, thereby lowering the intake of most nutrients (primary malnutrition). Gastrointestinal and metabolic complications of heavy alcohol intake (especially liver dysfunction) lead to so-called secondary malnutrition (Figure 55.1). Anorexia and vomiting from alcoholic gastritis further promote inadequate intakes of food. Malabsorption of nearly all nutrients can develop as a result of mucosal dysfunction, liver insufficiency, and pancreatic insufficiency (Seitz and Suter, 1994). Alcoholic liver dysfunction causes a reduced capacity to transport nutrients in the blood, a reduced storage capacity, and insufficient activation of nutrients such as vitamins. In addition, alcohol increases the excretion of nutrients in the urine and bile. In alcoholic patients, several mechanisms for the development of malnutrition usually occur simultaneously (Table 55.1) (Seitz and Suter, 1994). After gastric bypass surgery bariatric patients with a higher alcohol intake might elicit a higher risk of alcohol-induced nutritional disorders as well as higher alcohol toxicity due to an altered alcohol absorption kinetic, nutrient malabsorption as well as inadequate nutrient intake (Bal *et al.*, 2010; Maluenda *et al.*, 2010).

## Effects of Alcohol on Energy Metabolism

In view of the increasing prevalence of obesity, the effects of alcohol on energy balance and energy metabolism are of great importance (Suter, 2005). Because alcohol is mostly devoid of other nutrients and ingestion is not regulated (in contrast to other substrates, there is no

**TABLE 55.1** Alcohol and nutritional status: possible mechanisms of alcohol-mediated toxicity

Mechanism	Possible causes
Reduced dietary intake	Poverty Displacement of normal food Inappetance due to direct alcohol toxicity and secondarily due to disease (e.g. alcoholic gastritis)
Impaired digestion	Anorexia due to medications Alcoholic gastritis Impaired bile and pancreatic enzymes secretion Direct mucosal damage and impairment of mucosal enzymes (e.g. folyl conjugase)
Malabsorption	Altered gastrointestinal mobility Direct mucosal damage Indirect damage (e.g. due to folate deficiency) Motility changes including accelerated small intestinal transit time and diarrhea Pancreatic insufficiency Interactions with medications
Impaired transport in the circulation	Decreased synthesis of transport proteins due to liver damage
Impaired activation	Liver damage
Decreased storage	Inadequate supply of cofactors Liver pathology Alcoholic myopathy/sarcopenia/cachexia
Increased losses	Increased excretion in urine and bile Increased urinary losses due to medications Increased fecal losses
Increased requirements	Due to the above factors Increased metabolic rate

mechanism such as appetite regulation or hunger), alcohol's calories are unregulated, empty calories (Westerterp-Plantenga and Verwegen, 1999; Caton *et al.*, 2007). The importance of alcohol as a risk factor for weight gain and obesity is disputed (Liu *et al.*, 1994; Sakurai *et al.*, 1997; Suter, 2005). For weight maintenance, the energy balance has to be equilibrated, and alcohol has been reported to affect all components of the energy balance negatively, favoring a positive energy balance (Suter, 2005).

Because moderate drinkers generally add alcohol to their usual food intake, a positive energy balance with an increased risk of weight gain and obesity will result unless

compensated for by other means. This risk is increased by the combination of a high-fat diet and even moderate alcohol intake because of the hyperphagic effect of alcohol (Yeomans, *et al.*, 1999). Alcohol substitution (i.e. the usual food energy sources are substituted by alcohol) is the typical feature of the heavy drinker and will result in malnutrition and weight loss (Figure 55.2).

Depending on the amount and frequency of consumption, alcohol leads to an increase in energy expenditure. In young, moderate drinkers, the addition and the substitution of 25% of their daily energy requirements by alcohol (corresponding to  $96 \pm 4$  g alcohol) leads to an increased 24-hour energy expenditure of  $7\% \pm 1\%$  and  $4\% \pm 1\%$ , respectively (Suter *et al.*, 1992). These increases of energy expenditure correspond to a thermic effect of 20–25% of the energy content of the ingested alcohol. Other studies (Suter *et al.*, 1994; Suter, 2005) reported a thermic effect of alcohol in healthy, moderate consumers in the range of 15–25%, which is rather high compared with other energy sources (e.g. the thermic effect of a mixed meal is approximately 12%).

Presently, it is not clear what fraction of the alcohol energy could be used for adenosine triphosphate (ATP) production. In their classical studies more than 100 years ago, Atwater and Benedict (1902) suggested that alcohol energy seems to be equivalent to the energy of carbohydrates or fat. However, subsequent studies revealed that, as a function of the pathway of the metabolic degradation of alcohol (i.e. ADH vs. MEOS), lower amounts of ATP are produced than theoretical calculations would suggest (Lieber, 1991). Nevertheless, epidemiological and experimental studies suggest that, despite some energy wastage, alcohol calories are largely a usable energy source in the moderate consumer.

Alcohol also affects the energy balance equation by its effects on substrate balance. Independently, whether alcohol is added to or substituted for usual food, lipid oxidation is suppressed approximately by a third (Suter *et al.*, 1992), producing a positive fat balance. The positive fat balance is not caused by a *de novo* lipogenesis from alcohol, but by acetate being used in the peripheral organs (mainly muscle) as a source of energy at the expense of a lower fat oxidation. Use of stable isotope mass spectrometry techniques has shown that most (98%) of the carbons of a moderate alcohol load (25 g) are transported as acetate to the peripheral tissues, and only a negligible amount of the ingested dose (<1%) is used for *de novo* lipogenesis (Siler *et al.*, 1999).

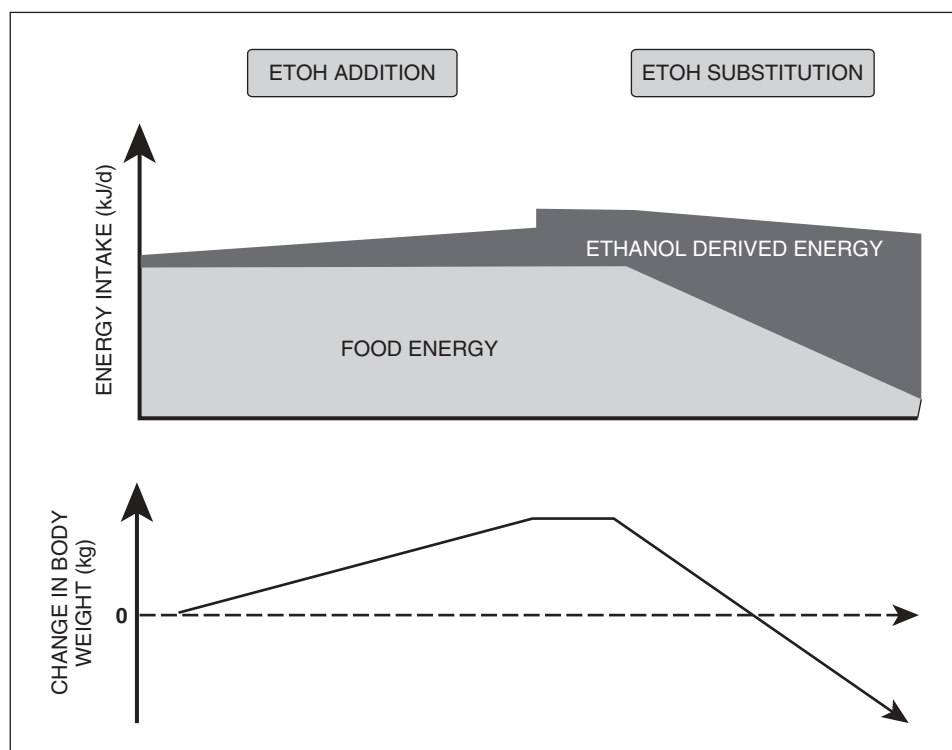

FIG. 55.2 Effect of alcohol on energy intake and body weight.

Despite these effects of alcohol on energy balance, some epidemiological and experimental studies were unable to identify moderate alcohol consumption as a risk factor for obesity (Liu *et al.*, 1994; Rohrer *et al.*, 2005; Wang *et al.*, 2010). Cross-sectional studies described positive or null associations between alcohol intake and body weight in men and inverse or null associations in women. There are only a few prospective studies about this association and they are equally controversial. Data from a 13-year follow-up in the Women's Health Study (Wang *et al.*, 2010) found that initially normal-weight light-to-moderate alcohol-consuming women gained less weight and had a lower risk of becoming overweight and/or obese as compared with non-drinking women. These controversial findings are not surprising in view of the difficulty in assessing alcohol intake and other lifestyle parameters that may compensate for some of the effects of alcohol. Furthermore socioeconomic factors determine alcohol consumption pattern and health behaviors (Schoenborn and Adams, 2010), including coping with factors affecting body-weight changes which explain the controversial outcomes in most if not all studies (Britton *et al.*, 2008). Because of the suppression of lipid oxidation and the

resulting positive energy balance, even moderate amounts of alcohol have to be regarded as a risk factor for weight gain and obesity when not counterbalanced by other means (i.e. reduced energy intake and/or increased energy expenditure by physical activity). To counteract the effects of alcohol on fat oxidation, fat intake should be kept as low as possible and, whenever alcohol is consumed, fat intake has to be reduced, ideally in proportion to the amount of alcohol ingested to remain in substrate balance.

Alcohol enhances the abdominal deposition of fat (Dallongeville *et al.*, 1998), which is associated with several adverse health outcomes such as hypertension or dyslipidemia (Suter *et al.*, 1995; Sakurai *et al.*, 1997), and represents a typical feature of the metabolic syndrome. Again, the later relationship is complicated by epidemiologic findings reporting a lower prevalence of the typical features of the metabolic syndrome in mild to moderate alcohol consumers (Freiberg *et al.*, 2004; Alkerwi *et al.*, 2009).

### Effects of Alcohol on Lipid Metabolism

As a function of the amount consumed, the frequency of drinking, and the presence of concomitant diseases

(especially liver disease, overweight, and obesity), alcohol affects all lipoprotein fractions in the blood (Barona and Lieber, 1998; Brinton, 2010). The development of a fatty liver, a characteristic early sign of alcoholic liver disease, is partly caused by the alcohol-induced suppression of lipid oxidation in the liver, by an increased influx of fat from the peripheral tissues and by alcohol-induced alterations of transcriptional controls of lipid metabolism (Sozio and Crabb, 2008). These early changes are also associated with the typical signs of alcoholic hyperlipidemia, which include elevated serum triacylglycerol levels caused by an increased hepatic secretion of very-low-density lipoproteins (VLDL) and a diminished peripheral removal of the VLDLs resulting from impaired lipoprotein lipase. The rise in triacylglycerol levels is increased by the ingestion of a diet rich in fat. The effects of alcohol on triacylglycerol levels are also seen during the postprandial phase; however, they can be partly counteracted by a concomitant reduction in fat intake and/or higher physical activity before or after the meal (Suter *et al.*, 1999). A recent study described a J-shaped relation between alcohol intake and plasma triacylglycerol levels, findings which are difficult to explain and which need to be confirmed in other studies (Tolstrup *et al.*, 2009). Obviously the response to alcohol might vary in certain subgroups of the population as a function of genetic and/or environmental factors.

The chronic moderate ingestion of alcohol leads to an increase in HDL cholesterol, which may be a major mechanism for the beneficial cardiovascular effects of alcohol (Manttari *et al.*, 1997). The alcohol-associated increase in HDL cholesterol may have multiple causes, including increased hepatic production and secretion of apoproteins, increased peripheral production due to lipid exchange within the different lipoprotein fractions, and decreased catabolism of the HDL particle caused by alcohol's effects on specific enzymes involved in lipid transfer or effects on postprandial lipemia (Sozio and Crabb, 2008). The HDL-raising effects of alcohol are nonlinear, showing a threshold effect on HDL cholesterol (Johansen *et al.*, 2003), and depend on different factors such as gender, body mass index, smoking habits, and genotype (e.g. ADH or apolipoprotein E genotype) (Lussier-Cacan *et al.*, 2002). One study (Lussier-Cacan *et al.*, 2002) reported that alcohol consumption intensifies the increase in low density lipoprotein (LDL) cholesterol and the decrease in HDL cholesterol associated with increasing BMI only in women with the apolipoprotein E genotype  $\epsilon 4/\beta$ . In this context, it should be remembered that obesity (besides physical

inactivity and smoking) represents one of the major causes of low HDL cholesterol.

The effects of alcohol on LDL cholesterol are only minor and less consistent than the effects on the other lipoprotein fractions. In animal studies, alcohol led to a decrease in LDL clearance due to a decreased hepatic LDL-receptor expression and specific effects on signaling pathways in lipid metabolism (Sozio and Crabb, 2008). Alcohol may unfavorably affect the size of the lipoprotein particles, especially LDL particles (Ayaori *et al.*, 1997). During the last few years, evidence has accumulated suggesting that lipoprotein subclass distributions according to particle size may be important modifiers of atherogenic risk. Individuals with a high concentration of small, dense LDL particles and their metabolic precursors, the large VLDL particles, have a higher cardiovascular risk than those with predominantly large LDL particles and small VLDL particles. The role of certain polyphenolic compounds of wine as modulators of LDL oxidation rates *in vivo* is uncertain (Fuhrman *et al.*, 1995), especially given the strong pro-oxidative effects of alcohol and the extremely variable bioavailability and bioefficacy of these compounds (Manach *et al.*, 2005; Ajmo *et al.*, 2008). The atherogenic lipoprotein(a) is lowered by alcohol consumption. A minor fraction of ethanol is metabolized by the formation of fatty acid ethyl esters (FAEEs) (Lange, 1982). Because these FAEEs accumulate in different tissues, they may be of pathophysiologic relevance in the development of alcohol-related pathologies (Petersen *et al.*, 2009), and they may represent useful markers of alcohol intake (Süße *et al.*, 2010).

## Alcohol and Carbohydrate Metabolism

The effects of alcohol on glucose handling are multiple as a function of the dosage, duration of alcohol intake, and overall nutritional status. In healthy, moderate drinkers with normal food intake, alcohol's effects on carbohydrate metabolism are of hardly any clinical relevance. By contrast, excessive alcohol consumption may be associated with the typical clinical entity of alcoholic pancreatitis (Apte *et al.*, 2009), which results in exocrine pancreatic insufficiency with maldigestion and malabsorption. The reduced forms of nicotinamide-adenine dinucleotide (NADH) and acetate produced during alcohol metabolism represent major modulators of glucose metabolism.

The increased production of reducing equivalents caused by the oxidation of alcohol leads to a decrease in

gluconeogenesis (Siler *et al.*, 1998). This decrease may bring about clinically dangerous and life-threatening hypoglycemia, especially in the heavy drinker with an overall inadequate diet and poor intake of carbohydrates (and thus low glycogen stores) (Flanagan *et al.*, 1998). This effect is being reinforced in people with diabetes by the ingestion of oral hypoglycemic agents, insulin, or both (Pedersen-Bjergaard *et al.*, 2005). The alcohol-induced reduction in gluconeogenesis also occurs in the fed state, but is usually compensated for by the glucose in the ingested food. The clinical features of hypoglycemia may share some of the signs of alcohol intoxication, and when it is misdiagnosed as simple alcohol intoxication deleterious health consequences may result. In addition, alcohol produces changes in the secretory response of different counter-regulatory hormones (such as epinephrine or growth hormone), thus resulting in the absence of the potential clinical warning signs of hypoglycemia (Pedersen-Bjergaard *et al.*, 2005). Alcohol also inhibits the storage of glycogen, further increasing the predisposition to hypoglycemia when carbohydrate intake is insufficient.

Light to moderate amounts of alcohol are inversely related to fasting and post-load insulin levels (Crandall *et al.*, 2009), which may represent an additional mechanistic factor for the cardioprotective effects of low-level alcohol consumption. In agreement with this, moderate alcohol intake has been associated with a reduction in coronary heart disease mortality in persons with type 2 diabetes mellitus (Valmadrid *et al.*, 1999) and with a lower risk for the development of the metabolic syndrome (Djousse *et al.*, 2004).

## Effect of Alcohol on Fat-Soluble Vitamins

### Vitamin A

Alcohol may interfere with the metabolism of all fat-soluble vitamins. Retinol (vitamin A), also an alcohol, shares some metabolic pathways with ethanol and thus has a high potential to be affected negatively by alcohol consumption. In light to moderate drinkers, vitamin A metabolism is not altered. Despite low intakes, frank vitamin A deficiency is rarely seen in alcoholics, probably because of the rather large hepatic stores of this vitamin. However, chronic alcohol consumption may lead to low levels of vitamin A in plasma, and, when alcoholic liver disease is present, decreased hepatic vitamin A levels are found. These lower levels are a result of an increased degradation

of the vitamin as a consequence of the induction of microsomal enzymes (Leo and Lieber, 1999) and the alcohol-induced decreased synthesis of retinol-binding protein (McClain *et al.*, 1979). This condition may lead to the prescription of vitamin A supplements; however, higher levels of vitamin A intake (independent of alcohol intake) are associated with considerable hepatotoxicity (Leo and Lieber, 1999), and alcohol represents one of the most important modulators of vitamin A toxicity – especially in the presence of liver disease. In the setting of chronic alcohol consumption, an increased production of polar retinol metabolites seems to be a central mechanism of hepatocellular damage (Dan *et al.*, 2005). A tissue-specific increase in endogenous all-*trans* retinoic acid may contribute to chronic ethanol toxicity (Kane *et al.*, 2010; Wolf, 2010). Further alcohol affects the expression and activation of retinoic acid receptors, thus impairing different signalling pathways (Kumar *et al.*, 2010).

Although the vitamin A precursor  $\beta$ -carotene is thought to bear no toxicity in humans, one epidemiological study reported an increased lung cancer rate in  $\beta$ -carotene-supplemented smokers, especially in those who were also drinking alcohol, an increase most likely due to alcohol-induced alterations in  $\beta$ -carotene metabolism (Albanes *et al.*, 1996). The negative effects of alcohol observed in this study were seen at rather low dosage levels, starting at  $\geq 12.9$  g/day. Although heavy drinkers ( $\geq 200$  g/day) show lower  $\beta$ -carotene plasma concentrations than do control subjects, they show higher  $\beta$ -carotene serum levels than those drinking less (Ahmed *et al.*, 1994). These higher levels may be caused by an impaired utilization or excretion of  $\beta$ -carotene due to liver damage or a partial shift in the degradation of  $\beta$ -carotene from central cleavage to eccentric cleavage (Leo and Lieber, 1999). A recent rat study (Luvizotto *et al.*, 2010) showed that chronic alcohol intake up-regulates the hepatic expression of the carotenoid cleavage enzymes (15,15'-monooxygenase 1 (CMO1)). In view of the present evidence, it is not advisable to routinely prescribe either high-dose  $\beta$ -carotene, other carotenoids (Veeramachaneni *et al.*, 2008) or vitamin A supplements to heavy consumers of alcohol.

### Vitamin E

Levels of vitamin E are reduced in chronic alcohol consumers independent of cirrhosis as a result of reduced intake and higher requirements (Bell *et al.*, 1992). Vitamin E supplementation has been reported to reduce alcohol-induced lipid peroxidation; however, vitamin E

supplementation did not affect laboratory or clinical outcomes (de la Maza *et al.*, 1995; Sario *et al.*, 2007). Tocotrienol, an isoform of vitamin E, has been reported in a rat model to have protective effects on the development of alcoholic neuropathy (Tiwari *et al.*, 2009b) and neuroinflammation (Tiwari *et al.*, 2009a). If vitamin E supplements are given, an adequate vitamin K nutriture should be ensured, given that a high dose of vitamin E may lead to impairment of the vitamin K cycle and an increased tendency to bleed (Machlin, 1989).

### Vitamin K

Data about the effect of alcohol on vitamin K nutriture is scarce. Acute and chronic alcohol consumption has been reported to lead to alterations in gamma-carboxylated molecules such as osteocalcin (Nyquist *et al.*, 1996). In the setting of alcoholic liver disease, vitamin K might have favorable effects on bone health (Shiomi *et al.*, 2002).

### Vitamin D

Heavier alcohol consumption (with and without liver disease) may be associated with an increased fracture risk due to indirect and direct alcohol effects on bone metabolism and on vitamin D metabolism (Nyquist *et al.*, 1997; Alvisa-Negrín *et al.*, 2009; Guañabens and Parés, 2010). Heavier drinkers have a lower intake, absorption, and activation of vitamin D (Laitinen *et al.*, 1990). In addition, because of alcohol's effects on the target organs, tissue-specific vitamin D effects may be impaired. According to animal studies vitamin D deficiency may play a role in alcoholic myopathy (González-Reimers *et al.*, 2010).

## Effects of Alcohol on Water-Soluble Vitamins

The metabolism of all water-soluble vitamins may be affected by the ingestion of alcohol. Alcohol's effects on water-soluble vitamin metabolism are dose dependent, and, in the range of light to moderate alcohol intake in healthy subjects eating a balanced diet, no adverse effects are expected. In heavy drinkers, a deficiency of several vitamins is usually present (Jamieson *et al.*, 1999), therefore the typical clinical signs of a *single* vitamin deficiency are not necessarily seen. In this section, alcohol's effects on a few selected water-soluble vitamins are summarized, but special attention is paid to thiamin and folic acid.

### Thiamin

Excessive alcohol intake represents the major cause of thiamin deficiency in the US population, and alcohol intake has been identified as the major predictor of thiamin status (also, see Chapter 17). Up to 80% of heavy drinkers have impaired thiamin nutriture independent of the presence of liver disease. Insufficient dietary intake is the major cause of thiamin deficiency in alcoholics; in addition, the small amounts of ingested thiamin are malabsorbed (Tomasulo *et al.*, 1968). Low doses of thiamin are absorbed by a carrier-mediated active process or, at high concentrations, by passive diffusion. In the alcoholic, vitamin B<sub>1</sub> intake is generally low so that the vitamin is principally absorbed by the active process, which is, however, impaired by alcohol. The cellular transport of thiamin is mediated by two specific thiamin transporters (THTR1 and THTR2). Chronic alcohol consumption resulted in decreased carrier-mediated thiamin transport across the intestinal basolateral membranes and the renal brush border (Subramanian *et al.*, 2010; Subramanya *et al.*, 2010). Even in non-alcoholic subjects, active thiamin absorption is inhibited by an acute single dose of alcohol. Alcohol also induces a reduction in the activation of thiamin by phosphorylation and an increase in the dephosphorylation of phosphorylated thiamin. These effects are potentiated by the presence of liver disease. In addition, loss of the vitamin in urine may increase by alcohol intake due to a decreased and impaired transport of thiamin across the renal epithelia (Subramanian *et al.*, 2010). The thiamin storage capacity is reduced in the heavy drinker because of liver abnormalities and decreased muscle mass (Preedy *et al.*, 1999). Because of the reduced storage capacity of vitamin B<sub>1</sub> in general and especially in heavy drinkers for the aforementioned reasons, the vitamin has to be ingested regularly, on a more or less daily basis. Alcohol induces specific alterations of thiamin metabolism in the central nervous system (Hazell, 2009; Ke *et al.*, 2009), thereby producing the typical clinical symptoms of Wernicke–Korsakoff syndrome: encephalopathy, oculomotor dysfunction, and gait ataxia (Martin *et al.*, 2003; Harper, 2009; Pitel *et al.*, 2011). Wernicke–Korsakoff syndrome is probably the only medical emergency situation involving vitamin deficiencies: the neurological condition has to be treated immediately with parenteral thiamin (Donnino, *et al.*, 2007). Severe and/or insufficiently treated forms of thiamin deficiency could result in permanent amnesia and ataxia defining the Korsakoff syndrome. The syndrome shows typical clinical features including altered consciousness, ataxia,

oculomotor abnormalities such as nystagmus and eye muscle paralysis, and psychosis. Up to 80% of heavy alcohol consumers show low circulating levels of vitamin B<sub>1</sub> due to low intakes, impaired absorption and storage, and reduced activation of the vitamin by phosphorylation. Autopsy data (reported prevalence of 0.8–2.8%) show that Wernicke's encephalopathy is underdiagnosed, i.e. it is often missed in clinical practice (prevalence based on clinical studies 0.04–0.13%) (Sechi and Serra, 2007). Different endogenous factors (e.g. transketolase enzyme variants with a decreased affinity for thiamin pyrophosphate, ApoE polymorphisms) and exogenous factors (thiamin intake, overall diet, amount of alcohol consumed) determine the risk for the development of a Wernicke–Korsakoff syndrome. During thiamin deficiency the metabolic and morphological changes occur within 10–14 days leading to irreversible structural lesions in the brain. The early diagnosis is thus of major importance; however, it is a very difficult task owing to the fact that classical symptoms are often lacking (Pitel *et al.*, 2011). Therapy should be established also when there is only suspicion of the diagnosis. There is no consensus on the ideal dose, frequency, route of application or duration of the therapy. As an emergency therapy the application of  $\geq 500$  mg dissolved in 100 ml normal saline three times a day for 3 days could be envisioned (Sechi and Serra, 2007; Galvin *et al.*, 2010). Because of the need of vitamin B<sub>1</sub> to metabolize glucose, no glucose infusions should be given to alcohol consumers except with the concomitant administration of thiamin. In view of the difficult diagnosis of Wernicke's encephalopathy and the high prevalence of thiamin deficiency, thiamin should be given to any heavy alcohol consumer independently from the clinical setting, i.e. also as a preventive strategy.

Although no prospective evidence supports the routine administration of several vitamins to alcoholic patients, present evidence suggest a high potential for a benefit of B-vitamin supplementation. Alcohol abstinence brings about an improvement of thiamin absorption (Holzbach, 1996). Research has shown that the neurotoxic effects of alcohol may be potentiated even in subclinical thiamin deficiency (Crowe and Kempton, 1997), and, accordingly, if alcohol abuse cannot be controlled, the preventive supplementation of thiamin and other B vitamins is indicated. Similarly, although controversial, the fortification of alcoholic beverages (e.g. beer) with thiamin might be considered as a mean to reduce the risk of a Wernicke–Korsakoff syndrome. Because of the interrelationship between thiamin and magnesium, an adequate supply of this

mineral should be ensured (McLean and Manchip, 1999). In the alcoholic patient (even when alcohol intake is reduced), thiamin deficiency may represent an important cause of heart failure, especially in combination with diuretics, which increase urinary thiamin losses (Suter and Vetter, 2000a; Keith *et al.*, 2009).

### **Riboflavin**

Riboflavin deficiency is common in the alcoholic patient and is due to low intakes and decreased bioavailability resulting from an alcohol-induced impairment of intraluminal hydrolysis of flavine adenine dinucleotide (FAD) in food sources (Pinto *et al.*, 1987) (also, see Chapter 18). In addition, alcohol inhibits the transformation and activation of the vitamin not only at the level of absorption but also at the level of the peripheral tissues (Ono *et al.*, 1987). Riboflavin is an essential cofactor in the conversion of vitamin B<sub>6</sub> and folate, and thus it represents an important modulator of the overall nutritional status of the B vitamins. Usually, riboflavin deficiency does not occur in isolation but in combination with a deficiency of other B-complex vitamins. Accordingly, the clinical entity is not typical. Because milk and milk products represent one of the major riboflavin sources, the low intake of this vitamin among heavy consumers of alcohol is not surprising.

### **Niacin**

Light to moderate alcohol consumption does not interfere with niacin nutriture (also, see Chapter 19). A deficiency in niacin (vitamin B<sub>3</sub>) is often found in the setting of chronic excessive alcohol consumption, usually together with deficiencies of other B-complex vitamins (Dastur *et al.*, 1976) and other nutrients such as zinc. The prevalence of low plasma niacin levels in chronic alcohol consumers varies widely, probably because niacin can be obtained preformed from food and from synthesis in the liver from tryptophan. In chronic liver disease, the latter synthetic pathway is impaired (Rossouw *et al.*, 1978). In excessive alcohol consumers, a low intake, decreased synthesis from tryptophan and increased urinary excretion, and an increased requirement might be of pathophysiological importance in the development of deficiency. The coenzyme forms of this vitamin (NAD and NADH) play an important role in alcohol metabolism (Hardman *et al.*, 1991). In clinical practice, niacin deficiency symptoms (diarrhea, dermatitis, and dementia) might be confused with the Wernicke–Korsakoff syndrome (Cook *et al.*, 1998). Niacin supplementation might lead to an increase in liver transaminase

levels, which could be misinterpreted as an alcohol-induced increase in transaminase levels. Further pharmacological doses of niacin in the form of a supplement may exacerbate gastric ulcer disease and gout, both conditions that are often found in chronic alcohol consumers. Due to the multivitamin deficiency in excessive alcohol consumers, polyvitamin preparations should be used for therapeutic purposes (Pitsavas *et al.*, 2004) and should include trace elements such as zinc (Vannucchi and Moreno, 1989).

### **Vitamin B<sub>6</sub>**

Depending on liver function, between 50% and 90% of alcoholics show low pyridoxal-5'-phosphate (PLP) serum levels. The PLP content in liver tissue is reduced independent of the presence of liver disease. As for most nutrients, the pathogenesis of the impaired vitamin B<sub>6</sub> nutriture is multifactorial (also, see Chapter 20). The formation of the active vitamin (PLP) in the liver is reduced or even completely blocked by the ingestion of alcohol (Walsh *et al.*, 1966; Mitchell *et al.*, 1976). Acetaldehyde increases the degradation of the vitamin by displacing the vitamin from binding sites and this, in turn, leads to increased catabolism of the free vitamin and consecutively increased urinary loss (Pinto *et al.*, 1987). Because the vitamin has to be activated in a multi-step activation process at the level of the liver, supplementation of this vitamin does not necessarily lead to improved vitamin B<sub>6</sub> nutriture in alcoholics if they continue to ingest alcohol. A population-based cohort study and a recent meta-analysis (Larsson *et al.*, 2005, 2010) reported an inverse association between vitamin B<sub>6</sub> intake and the risk of colorectal cancer, especially in women consuming >30 g/week of alcohol. In agreement, in a meta-analysis the risk of colorectal cancer decreased by 49% for every 100-pmol/mL increase (approximately 2 SDs) in blood PLP levels (RR, 0.51; 95% CI, 0.38–0.69) (Larsson *et al.*, 2010).

### **Folic Acid**

Folate deficiency is one of the most prevalent deficiencies in alcohol consumers (also, see Chapter 21). Up to 50% of heavy alcoholics show low concentrations of serum folate and/or low red blood cell folate (Gloria *et al.*, 1997). Beer consumers may show folate levels somewhat higher than these because of the folic acid content of this beverage. The clinical hallmark of folate deficiency is a megaloblastic anemia caused by damaged cell replication. It is found in all tissues, but especially in those with a high turnover rate, including the gastrointestinal mucosa (Halsted, 1995). The result is functional abnormalities and

clinical symptoms such as diarrhea. Accordingly, folate deficiency leads to a malabsorption of other nutrients, such as other water-soluble vitamins, and also folic acid itself. The malabsorption is further exacerbated by an abnormal enterohepatic circulation. The metabolic transformation to different active folate metabolites is impaired as a consequence of altered liver function and toxic alcohol and acetaldehyde effects on different enzymes. In addition, alcohol increases the urinary losses of this vitamin.

The impairment of absorption at the level of the gut and the kidney may be due to alcohol's effects on specific folate transporters in these tissues (Ross and McMartin, 1996). Because of an alcohol-induced rise in free radical production, the degradation of the vitamin is increased and may cause a tissue-specific deficiency. The alcohol-induced local impairment of folate metabolism may play a role in colorectal carcinogenesis (Hubner and Houlston, 2008). However, the alcohol-associated risk of colorectal carcinogenesis may vary in part according to the genetic polymorphisms of the 5,10-methylenetetrahydrofolate reductase (MTHFR) related to DNA methylation (Le Marchand *et al.*, 2005). The same may also apply to the process of carcinogenesis in other tissues such as oropharyngeal tissue (Capaccio *et al.*, 2005); however, the effects of folate might be also site specific (Duffy *et al.*, 2009). Recent data from the Nurses Health Study reported a lower alcohol-related risk for oral cancer in women with a higher folate intake (Shanmugham *et al.*, 2010). Several studies reported an inverse association between moderate alcohol intake and plasma homocysteine levels, whereas higher alcohol intake is consistently associated with increased plasma homocysteine levels, which are in part mediated by the alcohol-induced deficiency of folate, vitamin B<sub>6</sub> and also vitamin B<sub>12</sub>. The pathophysiological relevance of the alcohol-induced increase of homocysteine is not known. How alcohol might modulate the biphasic effects (Sauer *et al.*, 2009) of folate nutriture on colon cancer risk (i.e. a moderate dietary increase of folate initiated before the establishment of neoplastic foci is protective, whereas excessive intake or increased intake once early lesions are established increases tumorigenesis) is not known (Schernhammer *et al.*, 2010).

## **Effects of Alcohol on Mineral and Trace Element Metabolism**

### **Magnesium**

Low serum and tissue levels of magnesium are a typical feature in heavy drinkers, and these alterations are more

prevalent in the presence of liver disease (Kisters *et al.*, 1997). The magnesium nutriture is impaired as a result of reduced intake, malabsorption, increased urinary losses, secondary hyperaldosteronism, and increased fecal losses due to diarrhea (Romani, 2008). A reduction of alcohol intake is associated with an increase of the magnesium content of red blood cells (Kisters *et al.*, 1997; Romani, 2008). The decreased magnesium content of tissues may play a role in the development and progression of alcohol-associated pathologies (also, see Chapter 30). Magnesium content is especially decreased in heart tissue, a condition that may predispose to cardiac arrhythmias (a typical symptom in magnesium deficiency). Because of magnesium's effects in the maintenance of the membranes, a deficiency may exacerbate the development of organ damage, including liver damage. Magnesium plays a central role in over 300 biochemical reactions, one of them being thiamin phosphorylation. In view of the low toxicity of magnesium, this mineral should be replaced in the medical treatment of heavy drinkers (e.g. by supplementation with 200–300 mg elemental magnesium in chronic mild hypomagnesemia, where 1 mmol = 2 mEq = 24 mg elemental magnesium).

### Zinc

Heavy alcohol consumption is associated with decreased serum zinc and lower hepatic zinc concentrations (Bode *et al.*, 1988) (also, see Chapter 34). The lower zinc levels are correlated with the degree of liver damage, but low zinc levels in serum are also found in less-advanced liver disease, such as fatty liver disease (Bode *et al.*, 1988; Stamoulis *et al.*, 2007). The deficient zinc status results from low intakes, reduced absorption, increased urinary excretion, and an alteration of zinc distribution. Usually, zinc deficiency in the alcoholic is multifactorial, but a low dietary intake is found in most heavy consumers of alcohol. The zinc malabsorption is caused by direct and indirect alcohol effects, such as mucosal damage (Zhong *et al.*, 2010a) and altered synthesis of zinc ligands (such as metallothionein) owing to alcohol-induced impaired protein synthesis. The presence and the degree of exocrine pancreatic insufficiency represent an additional modulator of zinc status. Alcoholic liver disease, especially alcoholic hepatitis, has been identified as the major predictor for metabolic perturbations in zinc nutriture (Stamoulis *et al.*, 2007). The increased urinary excretion of zinc correlates with the degree of liver damage (Rodriguez *et al.*, 1997) and is caused by decreased peripheral tissue zinc uptake and decreased serum levels of albumin. In patients with liver cirrhosis, the increased urinary zinc excretion persists even

after cessation of alcohol intake. The acute ingestion of alcohol among moderate drinkers causes increased urinary zinc excretion, a consequence that suggests direct effects of alcohol on zinc homeostasis at the level of the kidney (Rodriguez *et al.*, 1997). A disruption of the epithelial barrier in the distal small intestine plays an important role in alcohol-induced gut leakiness and consecutively also alcoholic endotoxemia and hepatitis. Zinc deficiency may interfere with the intestinal barrier function by a direct action on tight junction proteins or by sensitizing to the effects of alcohol (Zhong *et al.*, 2010a,b). In a mouse model, zinc supplementation reversed alcoholic steatosis by reactivation of the hepatocyte nuclear factor-4 $\alpha$  (HNF-4 $\alpha$ ) and peroxisome proliferators activated receptor alpha (PPAR- $\alpha$ ) as well as by the inhibition of oxidative stress (Kang *et al.*, 2009). Zinc deficiency has further been implicated in alcohol-induced alveolar-epithelial and macrophage dysfunction (Joshi and Guidot, 2007), and zinc supplementation might correct the dysfunction (Joshi *et al.*, 2009).

Malnutrition in combination with alcohol leads to a higher degree of zinc depletion. It has been suggested that alcohol-induced alterations in zinc metabolism may increase alcohol-associated carcinogenesis (Seitz *et al.*, 1998; Prasad *et al.*, 2009). In view of the multiple effects of zinc, clinical signs of zinc deficiency – abnormalities of taste and smell, hypogonadism, infertility, and an impaired dark adaptation – are often seen in alcoholics. Impaired dark adaptation is a characteristic symptom in alcohol consumers, one generally not caused by vitamin A deficiency but by zinc deficiency. Defective zinc nutriture may increase alcohol toxicity given that the rate-limiting enzyme in alcohol degradation, ADH, is a zinc metalloenzyme.

### Alcohol and Mortality

The effect of alcohol on morbidity and mortality is biphasic, and the relationship is J-shaped: low levels of ingestion are associated with reduced morbidity and mortality risks, whereas abstinence and higher levels of ingestion are associated with a higher mortality risk due to different cancers, alcoholic liver disease, and cardiovascular diseases such as arrhythmias, alcoholic cardiomyopathy, hypertension, and stroke (Gaziano *et al.*, 2000; Hill, 2005; Klöner and Rezkalla, 2007; Djousse *et al.*, 2009; Sadakane *et al.*, 2009; Costanzo *et al.*, 2010; Klatsky, 2010; Mukamal *et al.*, 2010). The reduced mortality risk at lower intakes is explained by risk of coronary artery disease (Rimm *et al.*,

1996; Thun *et al.*, 1997; Gaziano *et al.*, 2000; Hill, 2005; Djousse *et al.*, 2009; Mukamal *et al.*, 2010) and reduced risk of ischemic stroke (Reynolds *et al.*, 2003). The amount of alcohol ingestion at the nadir of mortality risk is not known, and varies from study to study and from one individual to another. An analysis of data from 20 international cohort studies found a substantial variation in the nadir (the level of consumption at which mortality is least) (White, 1999). This meta-analysis estimated the nadir for US men to be 7.7 units of alcohol per week (95% confidence interval (CI) 6.4–9.1). In that study, 1 unit (1 drink) was considered to be 9 g alcohol for US men; 2.9 (95% CI 2.0–4.0) units per week for US women; and 12.9 (95% CI 10.8–15.1) units per week for UK men (White, 1999).

The J-shaped relationship has been reported in different studies, one of them being the American Cancer Society investigation (Thun *et al.*, 1997). In that study in men and in women, light alcohol intake was associated with a reduction in mortality risk because of a lower coronary artery disease risk. However, with increasing alcohol intake (even in the range of moderate intake), mortality risk rose, especially in women, whose risk of breast cancer also increased (Thun *et al.*, 1997).

The hallmark of excessive alcohol intake is metabolic and structural alterations at the level of the liver, and liver cirrhosis is the leading cause of death in heavy drinkers (Thun *et al.*, 1997; Harvey *et al.*, 2009; Rehm *et al.*, 2010). Age-adjusted death rates for liver cirrhosis have been reported as 12.6 and 6.0 per 100 000 for US men and women, respectively. In addition, approximately one-third of all traffic crash fatalities in the United States are alcohol related.

## Alcohol and Cardiovascular Diseases

The protective effect of alcohol on coronary disease risk has been reported in men and women (Thun *et al.*, 1997; Rimm *et al.*, 1999; Hill, 2005; Kloner and Rezkalla, 2007; Sadakane *et al.*, 2009; Sun *et al.*, 2009; Costanzo *et al.*, 2010; Hvidtfeldt *et al.*, 2010; Mukamal *et al.*, 2010), with a risk reduction in the range of 20% to 40% (also, see Chapter 48). A recent study (Mukamal *et al.*, 2010) confirmed in a large US nationwide population the U-shaped relationship between light and moderate alcohol drinking and cardiovascular mortality: compared with lifetime abstainers the relative risk of cardiovascular mortality was 0.69 (95% CI 0.59–0.82) among light consumers (defined

as  $\leq 3$  drinks/week) and 0.62 (95% CI 0.50–0.77) among moderate drinkers ( $>3$  to 7 drinks/week for women,  $>3$  to 14 drinks/week for men). The magnitude of risk reduction was similar in subgroups of age, sex or even baseline health status. However, consumption above these limits led to an increased risk of cardiovascular and non-cardiovascular mortality. The intake levels related to the nadir of risk vary widely in different studies (White, 1999). It is important to recognize that several studies found the protective effects mainly in older people and/or those who do have one or more of the classical cardiovascular risk factors (Thun *et al.*, 1997; Snow *et al.*, 2009; Sun *et al.*, 2009; Hvidtfeldt *et al.*, 2010; Martin *et al.*, 2010). This finding suggests that alcohol may modulate the pathophysiological potential of some of the classic risk factors for coronary artery disease (Britton *et al.*, 2008). The pattern of drinking is an important modifier of the risk modulation. A recent study showed that the cardioprotective effect of moderate alcohol consumption disappears when, on average, light to moderate drinking is mixed with irregular heavy drinking occasions (Roerecke and Rehm, 2010).

The mechanisms of the cardioprotective effects of alcohol (Table 55.2) are not completely elucidated, and about 50% of the potential protection seems to be mediated by the alcohol-induced increase in HDL-cholesterol levels (Criqui, 1998). Favorable effects on fibrinolysis, thrombogenesis, coronary blood flow, postprandial metabolism, prostaglandin and thromboxane synthesis, arterial vasodilatation, other lipoprotein fractions than HDL-cholesterol, anti-inflammatory effects, antioxidative effects, ingestion of non-nutritive protective compounds, ischemic preconditioning, or behavioral aspects have also been suggested (Rimm *et al.*, 1999; Pagel *et al.*, 2004; Bertelli and Das, 2009; Collins *et al.*, 2009; Djousse *et al.*, 2009; Zheng *et al.*, 2010).

The protective effects of alcohol are independent of the beverage type (Rimm *et al.*, 1996; Spaak *et al.*, 2008, 2010; Brown *et al.*, 2009), although studies reported a higher protection in red wine consumers (Renaud *et al.*, 1999) because of its content of polyphenols and flavonoids (Opie and Lecour, 2007; Bertelli and Das, 2009). Red wine consumption may elicit a higher protection that is related to the personality traits (including lifestyle factors, risk control behavior, and socioeconomic factors) of the typical red-wine consumer and the ingestion of red wine mainly with a meal (Trevisan *et al.*, 1987; Mortensen *et al.*, 2001; Britton *et al.*, 2008; Hansel *et al.*, 2010).

**TABLE 55.2** Summary and classification of possible cardioprotective mechanisms of alcohol

Cardioprotective mechanism	Effects
Lipid effects	Increase in HDL cholesterol Decrease in composition, size, and concentration of LDL cholesterol Decrease in lipoprotein(a) LDL-receptor effects Modified fatty acids
Blood coagulation	Modulation of coagulation factors Modulation of thrombogenesis Modulation of fibrinolysis
Endocrine effects	Insulin metabolism (“antidiabetic”) Estrogen metabolism Steroid metabolism
Psychological effects	Control of type A behavior Anti-anxiety effects Stress control
Non-nutritive compounds	Polyphenolic compounds Phytoalexins (e.g. resveratrol)
Miscellaneous effects	Vasoreactivity Ischemic preconditioning Membrane fluidity Liver structure (liver sieve) Modulation of the metabolic syndrome Paraoxonase up-regulation

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

If the cardioprotective effects of alcohol are really causal, then the central questions are, “How much is enough?” and “How much is too much?” A systematic review (using data from England and Wales) reported that the level of alcohol intake with the lowest mortality ranged from 0 units a week in men and women under 35 years of age to 3 units a week in women over 65 years of age and 8 units a week in men over 65 years of age (in this article, 1 unit was defined as 9 g of alcohol) (White *et al.*, 2002). Smoking is a major determinant of health, and the interaction between alcohol and smoking is of great importance. In a prospective cohort study of postmenopausal women (Ebbert *et al.*, 2005), alcohol ingestion among those who had never smoked was inversely associated with coronary heart disease mortality. Among current smokers, no association was found between alcohol ingestion and coronary heart disease mortality, but there was a positive association with cancer incidence among those consuming at least one drink daily. The combination of alcohol drinking and smoking is disadvantageous in any case (Taylor and Rehm,

2006), especially regarding carcinogenesis. Based on data from White *et al.* (2002) it can be concluded that the alcohol consumption levels with the greatest potential benefit are likely to be lower in the future due to a decline in coronary heart disease for reasons unrelated to alcohol intake. This also means that the cornerstone of coronary artery disease prevention remains in the control of the major classic cardiovascular risk factors (i.e. smoking, dyslipidemia, hypertension, and obesity). Despite the potentially favorable effects of alcohol on coronary artery disease risk, alcohol represents an important cause of hypertension (Suter and Vetter, 2000b; Taylor *et al.*, 2009), hemorrhagic stroke (Hillbom and Numminen, 1998; Patra *et al.*, 2010), alcoholic cardiomyopathy, heart insufficiency, and arrhythmias (Fogle *et al.*, 2010; Klatsky, 2010).

The protective effect of alcohol on coronary artery disease risk in the French population has been termed “The French Paradox.” The French do indeed show a more than one-third lower mortality rate for ischemic heart disease than the Americans or British; however, the all-cause mortality rate in France is not much different and the mortality rate for some of the typical alcohol-associated diseases, such as oropharyngeal cancer or liver cirrhosis, is even higher in France than in other countries (Zureik and Ducimetière, 1996). Despite the many associations between alcohol and coronary artery disease mortality, recent data suggest that the protective effect of alcohol may be biased by “good habits” and not “just good wine” (Rimm, 1996), so that the drinker’s habits become more important than the drink (Klatsky, 1999). Several studies reported that moderate alcohol drinkers or wine drinkers do show a healthier diet and behavior compared with other drinkers or abstainers (Klatsky *et al.*, 1990; Tjonneland *et al.*, 1999; Rouillier *et al.*, 2004; Ruidavets *et al.*, 2004). The cardioprotection may thus be mediated by synergistic effects of a low dose of alcohol in combination with health-prone behavior (Hansel *et al.*, 2010).

## Alcohol and Type 2 Diabetes Mellitus

Most studies reported a J-shaped relationship between alcohol intake and the risk of type 2 diabetes in men and women (also, see Chapter 49). The lowest risk was seen in light to moderate consumers, whereas heavier alcohol consumption and binge drinking led to a higher risk for type 2 diabetes (Bantle *et al.*, 2008; Crandall *et al.*, 2009; Pietraszek *et al.*, 2010; Joosten *et al.*, 2011). Recent data from the Health Professionals Follow-up Study showed

that a 7.5 g/day (about half a glass) increase in alcohol consumption over 4 years was associated with lower diabetes risk among initial non-drinkers (multivariable hazard ratio (HR) 0.78; 95% CI 0.60–1.00) and drinkers initially consuming <15 g/day (HR 0.89; 95% CI 0.83–0.96) but not among men initially drinking  $\geq$ 15 g/day (HR 0.99; 95% CI 0.95–1.02; *P* (interaction) <0.01) (Joosten *et al.*, 2011). Light to moderate amounts of alcohol increase insulin sensitivity for up to 24 hours and diminish the postprandial glucose excursion (Greenfield *et al.*, 2005). The improved insulin sensitivity, effects on lipid metabolism and inflammation might play a causal role in the protection (Pietraszek *et al.*, 2010). Some studies could not find a protective effect of alcohol, which may be in part explained by differences in the presence of the other risk factors, differences in the drinking pattern, beverage preference, or body composition and body weight (Pietraszek *et al.*, 2010). In patients with sulfonylurea or insulin treatment, alcohol might increase the risk for hypoglycemia.

## Alcohol and Hypertension

The first description of the relationship between alcohol and blood pressure was published by Lian in 1915. Cross-sectional, prospective, and interventional studies have reported an increase in systolic and diastolic blood pressure with increasing alcohol intake (Klatsky *et al.*, 1977; Huntgeburth *et al.*, 2005; Sesso *et al.*, 2008). Most studies reported a dose–response relationship between alcohol intake and blood pressure without a threshold level of alcohol intake, and cessation of alcohol intake in moderate and heavy consumers led to a reduction in blood pressure (Grobbee *et al.*, 1999). The decline in blood pressure upon cessation of excessive alcohol consumption shows wide variability. Based on a meta-analysis with the exclusive reduction of alcohol intake a significant reduction of mean systolic (2.52 to 4.10 mmHg) and of mean diastolic (1.49 to 2.58 mmHg) blood pressure was achieved (Xin *et al.*, 2001). This decline in blood pressure would result in a 6% reduction of coronary heart disease risk and a 15% reduction in the risk of stroke or transient ischemic attacks (Xin *et al.*, 2001). Blood pressure effects are more pronounced in daily alcohol consumers. Binge drinking may also lead to increased blood pressure. A recent study underlined the importance of the effect of the timing of blood pressure measurements after alcohol intake on the magnitude and direction of the blood pressure change (McFadden *et al.*, 2005), and this may also be a reason for the inconsistent

effects of alcohol on blood pressure in epidemiological and some experimental studies. In one study, alcohol intake was associated with blood pressure and pulse pressure in older men not receiving therapy for hypertension but not in those receiving antihypertensive therapy (Wakabayashi, 2010). However, the potential cardioprotective effects of alcohol are also found in hypertensive subjects. The pathophysiologic mechanisms for the pressor effects of alcohol are not known exactly, and multiple mechanisms involving direct and indirect effects of alcohol on autonomic regulation, neurohumoral effects, effects on peripheral resistance vessels, calcium handling in the vascular smooth muscle cells, and altered stress perception have been suggested. Alterations in liver function may affect the metabolism of antihypertensive drugs. Heavier alcohol consumption is one of the most important reasons for resistant and difficult-to-treat hypertension (also, see Chapter 46).

## Alcohol and Stroke

Alcohol has been identified as an independent risk factor for hemorrhagic stroke (Grobbee *et al.*, 1999; Patra *et al.*, 2010). The increased stroke risk is caused partly by the pressor effects of alcohol as well as by effects on cerebral vasculature (Hillbom and Numminen, 1998; Grobbee *et al.*, 1999; Patra *et al.*, 2010).

Because cardiovascular disease and ischemic stroke share some common pathophysiological features, alcohol may also have protective effects against ischemic stroke. In a study set in a multiethnic, urban society, moderate alcohol consumption (up to two drinks per day) had protective effects on ischemic stroke, with an odds ratio (OR) of 0.51, 95% CI 0.39–0.67) (Sacco *et al.*, 1999). However, excessive drinking, considered to be 7 or more drinks per day (OR 2.96, 95% CI 1.05–8.29) and binge drinking were associated with a two- to four-fold increased risk of ischemic stroke. In addition, risk of ischemic stroke onset is transiently elevated in the hour after alcohol ingestion (Mostofsky *et al.*, 2010). The cardioprotective effects of light alcohol consumption might also be present in stroke patients (Jackson *et al.*, 2003). At present it is controversial as to whether light to moderate alcohol intake increases the risk of atrial fibrillation (Conen *et al.*, 2008), an important risk factor for ischemic stroke. Data from the Health Professional Follow-up Study (Mukamal *et al.*, 2005) reported that intake of two drinks or fewer per day was not associated with an increased risk for ischemic stroke, and that consuming red wine (not other beverages)

was associated with a lower risk. Moderate alcohol consumption (especially wine consumption) is associated with a healthier lifestyle such as increased fruit and vegetable consumption (Klatsky *et al.*, 1990; Tjonneland *et al.*, 1999; Rouillier *et al.*, 2004), and an increased fruit and vegetable intake is associated with a reduced risk of stroke (Lock *et al.*, 2005; Mizrahi *et al.*, 2009). Accordingly a study from western New York showed that wine drinkers had a higher education, higher household incomes, a lower prevalence of smoking, and a higher vitamin intake (McCann *et al.*, 2003). Despite the rather high risk of a recurrent stroke, stroke patients modify their behavior and risk-factor profile insufficiently (Hornnes *et al.*, 2010).

## Alcohol and Cognitive Function

Heavy alcohol consumption is one important cause for short- and long-term impairment of cognitive function. Alcohol elicits direct neurotoxicity and, if applied in large enough quantities for a long enough period, it leads to a multi-domain cognitive impairment that may further develop to ethanol-related dementia (which represents nearly 10% of all causes of dementia). Several studies reported that moderate alcohol consumption is associated with better cognitive functioning and a reduced risk of a cognitive decline with aging (Stampfer *et al.*, 2005; Brust, 2010). The data are controversial and vary according to, among other factors, the time point in life at which alcohol intake was practiced and the cognitive function (Panza *et al.*, 2009; Brust, 2010; Gross *et al.*, 2011). A protective level of consumption cannot be defined at present. Once again, it is not completely clear whether the light alcohol drinking or the behavior of the drinker is the protective principle.

## Alcohol and Liver Disease

Alcoholic liver disease (ALD) includes a wide spectrum of injury, ranging from steatosis, through alcoholic hepatitis, to pathologies. Alcohol is one of the major causes of liver disease worldwide. The mechanisms of alcohol-induced liver injury are multiple and incompletely understood. One key mechanism is the induction of Cyp2E1 which leads to the generation of reactive oxygen species. The alcohol induction of Cyp2E1 predisposes further to xenobiotic induced liver damage due to enhanced biotransformation and increased production of toxic metabolites (Malhi *et al.*, 2010). Further alcohol enhances the genera-

tion of inflammatory cytokines (e.g. TNF- $\alpha$ , IL-1, or IL-6) with local as well as systemic effects (Malhi *et al.*, 2010).

There is a direct relationship between the per capita alcohol consumption (independent of the beverage type) and the death rate from liver cirrhosis. As with other alcohol-related pathologies, susceptibility to developing alcoholic cirrhosis varies from one individual to another as a function of the amount and duration of alcohol intake, gender, genetic predisposition, characteristics of alcohol metabolism, previous hepatitis B or C (Diehl, 2005), and potential nutritional factors (Halsted, 2004; O'Shea *et al.*, 2010). The quantity of alcohol consumed is the most important risk factor for ALD. The risk of developing ALD increases sharply with alcohol consumption over 40 g/day, and the risk for cirrhosis increases considerably in men consuming >60–80 g/day for ten years or longer, and >20 g/day in women (O'Shea *et al.*, 2010). The risk for ALD is higher for consumers of beer and spirits. For women, the threshold dose of alcohol is about half the threshold dosage of men, i.e. they are twice as sensitive to alcohol-induced hepatotoxicity. Further, women develop more severe ALD and within a shorter duration of alcohol exposure. The mechanisms of alcoholic liver damage are multiple, and include direct toxic effects of alcohol, acetaldehyde-mediated toxicity, increased oxygen requirements, and free radical damage. In addition, immune-mediated phenomena such as a proinflammatory state seem to be of central importance. In the development of alcoholic fatty liver, the altered redox potential (NADH/NAD<sup>+</sup>), impaired lipid oxidation, and increased lipogenesis seem to play a central role. The role of oxidative stress and injury in the pathogenesis of alcohol-induced hepatic injury is underlined by an inverse association between the serum alanine transaminase (ALT) and serum concentration of certain nutrients such as vitamin C,  $\alpha$ - and  $\beta$ -carotene, and lutein/zeaxanthin. The nutritional deficiencies (ranging from protein energy malnutrition and multiple micronutrient deficiencies) described in this chapter are commonly found in alcoholic patients and should be corrected by a combination of normal food, targeted supplements and alcohol abstinence. Mortality in ALD increases directly proportional to the degree of malnutrition (Mendenhall *et al.*, 1995) (also, see Chapter 54).

## Alcohol and Cancer

Alcohol consumption is related to an increased prevalence of oropharyngeal, esophageal, liver, colorectal, and female

breast cancers (Seitz and Stickel, 2007). The combination of smoking and drinking increases the risk of the oropharyngeal cancers and of cancers in other locations. Alcohol per se has no direct carcinogenic properties, and the pathophysiologic bases of the alcohol-induced cancers are multiple and include effects of acetaldehyde or effects of alcohol on methyl-group and retinoic acid metabolism (Seitz and Stickel, 2007). A dose–response relationship between alcohol intake and cancer risk can often be found. The mechanisms of ethanol-induced carcinogenesis may vary according to location. Increased alcohol intake, in combination with a low micronutrient intake, increases cancer risk (e.g. colorectal cancer). Alcohol consumption is associated with an increased risk of breast cancer (especially hormone-sensitive cancer types) (Zhang *et al.*, 2007; Li *et al.*, 2010) and breast cancer recurrence, particularly among postmenopausal and overweight/obese women (Kwan *et al.*, 2010). A collaborative analysis (Hamajima *et al.*, 2002) of 53 studies reported that, compared with women who reported drinking no alcohol, the relative risk of breast cancer was 1.32 (1.19–1.45,  $P < 0.00001$ ) for an alcohol intake of 35–44 g/day, and 1.46 (1.33–1.61,  $P < 0.00001$ ) for  $\geq 45$  g/day. The relative risk of breast cancer increased by 7.1% (95% CI 5.5–8.7%;  $P < 0.00001$ ) for each additional 10 g/day intake of alcohol, i.e. for each extra unit or drink of alcohol consumed on a daily basis (Hamajima *et al.*, 2002). Whether small amounts of alcohol intake are associated with an increased risk of breast cancer in women is not exactly known and is controversial. Alcohol has a high potential to modulate estrogen metabolism, leading to higher circulating estrogen levels (Onland-Moret *et al.*, 2005), so the potential detrimental effects of alcohol on estrogen-sensitive cancers is not surprising. Some of the controversy of the data can be explained by genetic factors and/or menopausal status or period of life with alcohol consumption. In view of the current evidence, light alcohol consumption seems to be safe for most women.

Individuals carrying the inactive aldehyde dehydrogenase 2\*2 (ALDH 2\*2) allele have an increased risk for alcohol-related oesophageal cancer. Carriers of other genetic variants (e.g. alcohol dehydrogenase 1C\*1 (ADH1C\*1) homozygotes or methylenetetrahydrofolate reductase (MTHFR) 677CT variants) also have a higher risk for alcohol-related cancers (Druesne-Pecollo *et al.*, 2009). Further lifestyle factors (e.g. smoking, poor oral hygiene, physical activity pattern), certain dietary deficiencies

(e.g. folate, vitamin B<sub>6</sub>, methyl donors) or an excess of certain micronutrients (vitamin A/ $\beta$ -carotene) may potentiate the risk for alcohol-associated tumors (Seitz and Stickel, 2007) (also, see Chapter 51).

## Alcohol and Bone and Muscle

The direct and indirect effects of alcohol on bone and muscle metabolism are multiple and depend on the amount, the duration of alcohol intake, the presence of liver disease, gender, genetic factors and concomitant factors (e.g. dietary factors including protein intake and resistance training). Light to moderate consumption may have favorable effects on bone health (Feskanich *et al.*, 1999; Venkat *et al.*, 2009; Jin *et al.*, 2010). A recent study (Tucker *et al.*, 2009) reported that moderate consumption of alcohol may be beneficial to bone in men and postmenopausal women. In men, high liquor intakes ( $>2$  drinks/day) were associated with significantly lower bone mineral density (BMD), and stronger associations were found between BMD and beer or wine, relative to liquor (Tucker *et al.*, 2009).

In heavy drinkers, the calcium balance is negatively affected by low intakes and malabsorption of calcium due to direct mucosal damage, an impaired vitamin D nutrition, and increased urinary calcium losses (Laitinen and Valimaki, 1993). In heavy drinkers, different structural and functional changes in the bone can be found. Low to moderate amounts of alcohol have no adverse effects on bone mass in postmenopausal women (Feskanich *et al.*, 1999) because of alcohol's effects on endogenous (and exogenous) estrogens (see above). Despite some controversial data that have been reported about the effects of alcohol on bone metabolism, in the clinical setting any unexplained fracture or osteoporosis (especially in men) may point to alcohol-related problems.

Alcohol consumption leads to a dose-dependent negative effect on skeletal muscle, leading to progressive functional and structural alterations of skeletal muscle cells with a concomitant decline in lean body mass (Nakahara *et al.*, 2003; Preedy *et al.*, 2003; Fernandez-Solà *et al.*, 2007). Alcoholic myopathy is a typical clinical feature of the heavy alcohol consumer (Preedy *et al.*, 2003). Importantly these effects are also seen at the level of the heart muscle in the form of alcoholic cardiomyopathy (Laonigro *et al.*, 2009).

## Fetal Alcohol Syndrome

The teratogenic effects of alcohol have been known for centuries. It was not, however, until the late 1960s when it was first reported that heavy alcohol intake during pregnancy might be associated with fetal alcohol syndrome (FAS). FAS is characterized by typical physical and neurobehavioral features (Plant *et al.*, 1999; Calhoun and Warren, 2007; National Institute on Alcohol Abuse and Alcoholism (NIAAA), 2009). Children with FAS show a pre- and postnatal growth retardation, facial dysmorphism, and central nervous system dysfunctions that cause permanent cognitive impairment and learning disabilities (Hofer and Burd, 2009). FAS represents the severe endpoints of a vast spectrum of structural, behavioral, and neurodevelopmental abnormalities caused by exposure to alcohol in utero. Present evidence suggests that alcohol during pregnancy may lead to FAS or to a broader spectrum of defects which are now referred to as fetal alcohol spectrum disorders (FASDs) (NIAAA, 2009; Jones *et al.*, 2010; O'Leary *et al.*, 2010). FAS represents the most severe endpoint of the FASD spectrum. The pathogenesis of the FASDs are multiple and include epigenetic effects, fetal programming, and also the interference of alcohol with nutritional status (Ramsay, 2010). Despite knowledge of the relationship between alcohol and FAS/FASD, approximately 10% of pregnant women reported alcohol use in the past 30 days. Alcohol intake during pregnancy, but also during the week of conception increases the risk of early pregnancy loss. In view of the irreversible lifelong effects of alcohol drinking during pregnancy on the unborn child, pregnancy has to be a period of life during which alcohol intake should be avoided completely. Every woman of reproductive age has to remember that there is no safe amount of alcohol to drink while pregnant, no safe time to drink during pregnancy, and also no safe kind of alcoholic drink.

## Outstanding Issues and Questions

Not only light and moderate but also heavier alcohol drinking is a global issue. Alcohol consumption has “global” effects on all cell and organ systems and should accordingly have “global health priority” at the national and international level (Beaglehole and Bonita, 2009). In addition to the existing tools for assessing hazardous alcohol intake (e.g. AUDIT, T-ACE, TWEAK: <http://pubs.niaaa.nih.gov/publications/aa65/AA65.htm>), more

reliable biomarkers for quantifying alcohol intake should be developed. This would improve the quality of data in all fields of research from epidemiology to clinics. As this chapter has outlined, alcohol affects all nutrients as a function of the consumption pattern, genetic factors, age, and gender, as well as environmental factors. The interactions between these factors and potential positive and negative effects of alcohol on the risks of higher consumption are only incompletely understood. In agreement with recommendations from the NIAAA (2009), nutritional and metabolic aspects of alcohol consumption should be researched across the whole lifespan. Individual differences in benefit and risk should be assessed, and sensitive as well as specific markers and predictors for the differences should be identified. Light consumption may be associated with cardioprotective effects; however, there is nevertheless a need for a randomized trial as is done for any other health recommendation or drug. What are the key modifiers of the protective effects? Is the protection equal for women and men at all ages? What is the contribution of alcohol consumption to the global overweight and obesity pandemic? Strategies and tools to assess the predictive risk for susceptibility to problem drinking have to be researched. Another issue that needs clarification is whether nutritional effects of alcohol are mediators or modifiers of alcohol-related health problems. Furthermore an emerging field of potential high public-health relevance is the study of the interaction between epigenetic mechanisms and alcohol consumption as well as alcohol-associated diseases (Kaminen-Ahola *et al.*, 2010).

## Future Directions

As a function of the amount of alcohol consumed and individual factors (genetic and environmental, including lifestyle and nutritional factors), the health and nutritional effects of alcohol may be positive or negative. Often, both positive and negative effects occur. In view of the heterogeneity of responses for any given alcohol dose, the formulation of public-health recommendations for safe consumption levels is becoming increasingly difficult. In today's world, the best approach to patient and public-health counseling about alcohol consumption is not to forbid it, but to try to formulate safe consumption levels for those wishing to drink. Alcohol should not be recommended for health reasons or for health maintenance,

especially as long as there are no specific and sensitive predictors for harmful alcohol use and abuse.

Evidence suggests that the safe amount may vary considerably from one individual to another, even for those whose alcohol intake is in the light to moderate range. Identifying biochemical and genetic markers for risk assessment related to moderate alcohol consumption may help to formulate and implement specific individual recommendations. In addition, future research activities should focus on strategies for the implementation of safe drinking practices in combination with an overall healthy lifestyle with respect to nutrition and physical activity. In such a setting, light to moderate alcohol consumption may add to the quality of life; however, the benefit and risk are not equal for all.

## EYE DISEASE

ROHINI VISHWANATHAN, PhD AND ELIZABETH J. JOHNSON, PhD

*Tufts University, Boston, Massachusetts, USA*

### Summary

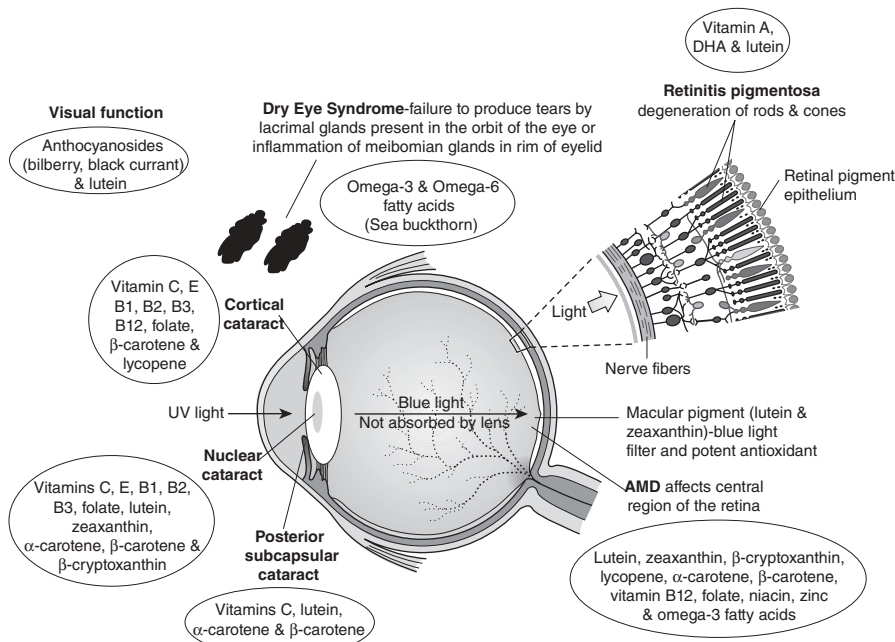

There is biological plausibility for a relationship between certain nutrients and certain eye diseases. This chapter discusses eye diseases and conditions and the beneficial nutrients. Even though evidence from epidemiological and intervention studies have at times yielded conflicting results, it is important to understand that nutrition can have a strong impact on eye diseases such as cataract, age-related macular degeneration (AMD), and retinitis pigmentosa (RP), which together account for ~60% of blindness worldwide. High dietary intake of vitamins C and E, starting early in life, may prevent the incidence of age-related nuclear cataracts as well as AMD. Lutein and zeaxanthin intake may protect against nuclear and posterior subcapsular cataract (PSC), while vitamins B<sub>1</sub>, B<sub>2</sub>, B<sub>3</sub>, and folate may protect against nuclear and cortical cataract. Treatment with the Age-Related Eye Disease Study (AREDS) supplement (a combination of vitamins C and E, β-carotene, zinc, and copper) is beneficial for patients diagnosed with AMD. Apart from the AREDS vitamins, high doses of lutein and zeaxanthin have also been shown to benefit AMD patients. Lutein has also been found to improve visual function because of its role as macular pigment in healthy and also AMD-affected eyes. Among the B vitamins, B<sub>6</sub>, B<sub>12</sub>, and folate have shown some protective indications as a result of their ability to reduce hyperhomocysteinemia, a risk factor for AMD. Apart from increasing consumption of foods rich in the above vitamins and micronutrients, eating a healthy, well balanced diet is equally important in keeping the eyes healthy. Adhering to the Recommended Dietary Guidelines has been found to be associated with a reduced risk of nuclear cataract and advanced AMD. Greater intake of carbohydrates ( $\geq 200$ g/day) is also related to higher odds of cortical cataract. It is critical to eat not just the right amounts, but also the right types of carbohydrates, as high-glycemic-index foods are associated with an increased prevalence of AMD, and of nuclear and cortical cataract. Replacing refined carbohydrates with whole grains and limiting consumption of added sugars would be beneficial. Similarly, the types of fat in the diet could also influence the course of eye diseases. Intake of the omega-3 fatty acids, docosahexaenoic acid and arachidonic acid, is essential for visual development right from birth. Omega-3 fatty acids have also been shown to benefit AMD and RP patients. High intakes of omega-6 fatty acids can offset the omega-3 to omega-6 ratio, which has been shown to increase AMD risk. Adding one to two 3-ounce (85 g) servings of omega-3 rich fatty fish per week to the diet can be beneficial. Omega-3 and omega-6 fatty acids and also antioxidant-rich oils ease dry-eye-related symptoms. RP patients may benefit from taking 15000 IU/day of vitamin A in conjunction with a low vitamin E diet. Even though evidence for beneficial effects of anthocyanosides on visual function is minimal, adding anthocyanoside-rich foods like bilberries to the diet may be helpful because of their antioxidant potential. From the evidence presented in this chapter, it may be more practical to recommend consumption of foods rich in vitamins C and E, B vitamins, lutein and zeaxanthin, omega-3 fatty acids, and zinc, rather than consuming the nutrients in isolation, thus benefiting from the synergistic effects of all the components in the food.

### Introduction

Nutrition has an essential role in the preservation and maintenance of vision. It has long been known that deficiencies of certain essential nutrients can result in visual impairment or blindness. The purpose of this chapter is to review the literature that evaluates the role of dietary components in the prevention of onset or progression of ocular diseases in humans. Figure 56.1 summarizes the nutrients that have been indicated to protect against such diseases, and that are needed in order to maintain normal visual function. Figure 56.2 shows the global causes of blindness. Of these the focus is on diseases for which there is strongest evidence for nutrition playing a role in the prevention and/or treatment. The diseases discussed at length are cataract, age-related macular degeneration, and retinitis pigmentosa. The nutrients of interest are vitamins C and E, carotenoids, B vitamins, omega-3 fatty acids, and zinc. In addition to the diseases of the eye, the possible role of certain nutrients and dietary components in the treatment of dry eye syndrome and visual function is also discussed.

## Cataract

Age-related cataract is one of the major causes of visual impairment and blindness in the aging US population. Approximately 50% of the 30–50 million cases of worldwide blindness result from unoperated cataract (World Health Organization, 1991; Thylefors *et al.*, 1995). A clinically significant cataract is present in about 5% of Caucasian Americans aged 52–64 years and rises to 46% in those aged 75–85 years (Congdon *et al.*, 2004). In the United States, cataract extraction accompanied by ocular lens implant is the most common surgical procedure for the eye (Javitt, 1993). Lens implantation enables many to have reduced dependence on glasses. However, the procedure is costly, accounting for 12% of the Medicare budget and more than \$3 billion in annual health expenditures (Javitt, 1993; Steinberg *et al.*, 1993). For these reasons, the prevention of cataract is a preferred alternative to surgery.

There are three types of cataract, defined by their location in the lens. Nuclear cataract occurs in the center, or

nucleus, of the lens. Cortical cataract begins at the outer rim of the lens, which is referred to as the cortex, and progresses towards the center. Posterior subcapsular cataract (PSC) occurs in the central posterior cortex, just under the posterior capsule, the membrane that envelops the lens. Nuclear cataract is the most common type of cataract (Congdon *et al.*, 2004). It interferes with a person's ability to see distant objects and is usually the result of advancing age. Cortical cataract is most commonly seen in patients who have diabetes. PSC can be present in younger individuals and progresses more rapidly, resulting in glare and blurriness (Asbell *et al.*, 2005). This type of cataract is usually seen in patients who use steroids, or who suffer from diabetes or extreme nearsightedness. Figure 56.3(c) shows a scene viewed by a person affected by cataract.

There are various factors that may be involved in the development of cataracts, such as long-term light exposure, diabetes, smoking, alcohol use, and advancing age (Asbell *et al.*, 2005). Such factors can lead to aggregation

**FIG. 56.3** A scene viewed by a person with (a) normal vision, (b) age-related macular degeneration, (c) cataract, and (d) retinitis pigmentosa. Photographs courtesy of National Eye Institute, National Institutes of Health.

of the lens proteins and osmotic damage, resulting in increased scattering of light and loss of transparency of the lens. Protein aggregation mainly occurs in the lens nucleus, and osmotic damage occurs in the lens cortex (Bunce *et al.*, 1990). Free radicals are generated in the lens during normal metabolic activities and also as a result of photooxidative reactions due to increased UVB exposure (related to cortical cataracts and PSC). These free radicals can also cause electrolyte imbalance and protein aggregation. Innate antioxidant defense mechanisms, enzymes such as superoxide dismutase and glutathione, and non-enzymatic molecules such as vitamins C and E, protect the lens from oxidative stress. Evidence related to nutrients that protect the lens from cataract development is discussed in the sections that follow. For each nutrient the probable mechanism of action, epidemiological evidence pertaining to both dietary intake and serum concentrations of the nutrient of interest, and finally randomized controlled trials, if any, are discussed. The observations are further divided based on the type of cataract (nuclear, cortical, or PSC) and the incidence of cataract extraction.

### Vitamin C

The interest in studying vitamin C for cataract prevention and treatment results from that fact that its accumulation in the lens is 30- to 35-fold greater than in plasma. Not only is vitamin C a strong antioxidant but it also has the ability to absorb UV light (Bunce *et al.*, 1990). Several studies have found that a higher intake of vitamin C, from foods and supplements, was related to decreased risk of nuclear, cortical, PSC, or cataract extraction (Robertson *et al.*, 1989; Jacques and Chylack, 1991; Leske *et al.*, 1991; Hankinson *et al.*, 1992; Mares-Perlman *et al.*, 1995a, 2000; Jacques *et al.*, 1997, 2001; Taylor and Hobbs, 2001; Tan *et al.*, 2008a). The dose of supplementation, duration of either supplement use or intake from foods, age, type of cataract, and certain factors such as smoking, influence the effect of vitamin C on the incidence of cataract. Data from several epidemiological studies reporting a protective relationship have shown the mean range of daily vitamin C intake from diet and supplements to be 104–700 mg in the highest quintile groups, whereas the lowest quintile groups have intakes in the range 33–140 mg (Hankinson *et al.*, 1992; Mares-Perlman *et al.*, 1995a; Jacques *et al.*, 2001). In some studies even the lowest quintile groups had greater vitamin C intake than the RDA of 75 mg/day. On the other hand, intake of ~1000 mg of vitamin C was found to increase the risk of cataract in women aged  $\geq 65$

years from the Swedish Mammography cohort (Rautiainen *et al.*, 2010). Long-term vitamin C intake of  $\geq 10$  years was beneficial in reducing the incidence of cataract, lens opacities and also cataract extraction in all but one study, where the risk of cataract extraction was lower only in women  $< 60$  years and non-smokers (Hankinson *et al.*, 1992; Jacques *et al.*, 1997, 2001; Chasen-Taber *et al.*, 1999; Mares-Perlman *et al.*, 2000; Taylor *et al.*, 2002a; Tan *et al.*, 2008a). In epidemiological studies that had a  $< 10$ -year follow-up, vitamin C intake did not have the same protective effect (Seddon *et al.*, 1994b; Leske *et al.*, 1998; Mares-Perlman *et al.*, 2000). Even with intakes of high doses of vitamin C, women aged  $\geq 60$  years were not protected from cortical cataract and cataract extraction (Leske *et al.*, 1998; Taylor *et al.*, 2002a; Gritz *et al.*, 2006). Summary of data from epidemiological studies on dietary intake of vitamin C is presented in Table 56.1.

Serum ascorbic acid concentrations have been reported to be inversely associated with the prevalence of cataract (Jacques and Chylack, 1991; Simon and Hudes, 1999; Valero *et al.*, 2002; Ferrigno *et al.*, 2005; Dherani *et al.*, 2008; Jalal *et al.*, 2009). Two studies found no association between plasma vitamin C and the risk of nuclear or cortical cataract (Vitale *et al.*, 1993; Nourmohammadi *et al.*, 2008). This may be because the plasma samples were analyzed 4 years prior to the lens examination in one study, and the population size was small in the second study. In contrast, the India–United States case-control study found an increased prevalence of PSC and nuclear cataracts with increased plasma vitamin C but this relationship became protective when vitamin C status was combined with other indices of antioxidant status such as glutathione peroxidase, vitamin E and glucose-6-phosphate dehydrogenase (Mohan *et al.*, 1989). A summary of data from epidemiological studies on serum concentrations of vitamin C is presented in Table 56.2.

There are no randomized control trials to date that have evaluated a vitamin C intervention alone on the incidence of cataract. Intervention studies using vitamin C in conjunction with other antioxidants and vitamins have yielded conflicting results, which are discussed later in the “Intervention Studies” section.

Epidemiologic evidence showed dietary vitamin C to be most beneficial towards nuclear cataract followed by cortical cataract, and lastly PSC (Leske *et al.*, 1991; Mares-Perlman *et al.*, 1995a; Gale *et al.*, 2001; Jacques *et al.*, 2001; Taylor *et al.*, 2002a; Tan *et al.*, 2008b). Vitamin C intake was also associated with reduced risk of cataract

**TABLE 56.1** Dietary intake of vitamin C (from food and supplement) and risk of cataract

Study	Study design	Dietary intake	Study duration	OR/RR/HR <sup>a</sup> (95% confidence interval)	Result	Reference
Robertson <i>et al.</i>	Case-control	S	-	OR = 0.30 (0.12-0.75) P = 0.01	Vitamin C supplement intake was associated with 50% reduction in senile cataract	Robertson <i>et al.</i> (1989)

extraction. In conclusion, long-term vitamin C intake for  $\geq 10$  years may provide protection against cataract, especially in adults  $< 60$  years of age. The optimal dose seems to be  $> 140$  mg/day with doses  $> 300$  mg/day providing no added benefit, possibly due to saturation of eye tissues (Hankinson *et al.*, 1992; Jacques *et al.*, 2001). Supplementation with especially high doses of  $> 1$  g/day may increase the risk of cataract.

### Vitamin E

Vitamin E acts as a strong chain-breaking antioxidant in lipid peroxidation processes in vivo (Bunce *et al.*, 1990). Vitamin E may thus protect the lens from oxidative damage. Epidemiological studies that have evaluated the role of dietary vitamin E from food and supplements in the development and progression of cataracts have yielded mixed results (Table 56.3). Various factors such as supplement use, duration of supplementation, and age play a role in determining the relationship between vitamin E and the incidence of cataract. In the studies that reported a reduced incidence of nuclear cataract with high vitamin E intake, the effect was seen only with vitamin E supplement use for a duration of  $> 10$  years, except one study which showed an effect with  $> 5$  years' supplement use (Mares-Perlman *et al.*, 1995a, 2000; Leske *et al.*, 1998; Jacques *et al.*, 2001, 2005; Christen *et al.*, 2008). In the case of cortical cataract, no such trend was observed. Of the three studies that showed decreased risk of cortical cataract, one was a case-control study that assessed vitamin E intake from foods, the second study only included prior, not current, vitamin E supplement users, the majority of whom had doses of  $< 10$  mg/day, and the third study found an association with plasma vitamin E and not dietary vitamin E intake (Leske *et al.*, 1991; Rouhiainen *et al.*, 1996; Nadalin *et al.*, 1999). Two studies showed a decreased risk of cataract extraction with increased dietary intake of vitamin E from food and supplements (Robertson *et al.*, 1989; Tavani *et al.*, 1996). In studies that showed no relation between vitamin E intake and prevalence of nuclear or cortical cataract, PSC or cataract extraction, the duration of supplement use was  $< 10$  years (Hankinson *et al.*, 1992; Seddon *et al.*, 1994b; Lyle *et al.*, 1999), or the highest dose was  $< 150$  mg/day (Jacques and Chylack, 1991; Taylor *et al.*, 2002a), or the sample size was small (Jacques and Chylack, 1991), or the association was only marginally significant (Valero *et al.*, 2002). In studies that looked at highest versus lowest quintile of vitamin E intake from supplements, the mean vitamin E dose in the high quintile groups were in the

range 90–262 mg/day, whereas the range was 4–6 mg/day in the lowest quintile groups. One study found no significant difference in the prevalence of cataract between persons with vitamin E intake  $> 35.7$  mg/day and those with intakes  $< 8.4$  mg/day (Jacques and Chylack, 1991). The beneficial effects of vitamin E may be attributed to supplemental vitamin E and not to vitamin E from food sources alone.

In six of nine studies examining the relationship between plasma vitamin E and cataract (Table 56.4), increased plasma vitamin E was associated with decreased risk of cataract (Knekt *et al.*, 1992; Vitale *et al.*, 1993; Leske *et al.*, 1995; Rouhiainen *et al.*, 1996; Leske *et al.*, 1998; Nourmohammadi *et al.*, 2008). One study observed that cataract risk was not related to plasma vitamin E concentrations (Gale *et al.*, 2001). In contrast, Mares-Perlman *et al.* (1995c) found increased levels of plasma  $\alpha$ -tocopherol to be a risk factor for nuclear cataract, and a study by Ferrigno *et al.* (2005) found that increased levels of vitamin E were related to increased prevalence of cortical cataract and PSC. A cross-sectional study that analyzed plasma, red blood cells, and lens vitamin E concentrations in cataract patients found no correlation between plasma or RBC-bound vitamin E and vitamin E in the lens (Krepler and Schmid, 2005). This suggests that plasma or RBC vitamin E concentration may not reflect vitamin E status of the lens and cannot be used as a clinically relevant marker to assess cataract risk.

In the only randomized, double-masked, placebo-controlled trial evaluating a vitamin E intervention, pharmacological doses of vitamin E (500 IU or 454 mg/day) for 4 years did not reduce the incidence or progression of nuclear, cortical, or PSC cataracts in subjects aged 55 to 80 years (McNeil *et al.*, 2004). Other intervention studies that evaluated vitamin E supplementation in conjunction with multivitamin or antioxidant supplementation are discussed in the section entitled "Intervention Studies". In conclusion, vitamin E supplementation may be beneficial when consumed for  $> 10$  years and at doses higher than the RDA of 15 mg/day but lower than pharmacologic levels ( $< 300$  mg/day). Associations were protective for nuclear and cortical cataracts and reduction in the incidence of cataract extraction, but not so much for PSC.

### Carotenoids

The human lens contains significant amounts of lutein and zeaxanthin, but not  $\beta$ -carotene and lycopene, which are the dominant carotenoids in serum. Of the total lens

**TABLE 56.3** Dietary intake of vitamin E (from food and supplement) and risk of cataract

lutein and zeaxanthin, 75% is present in the epithelium and cortex (Yeum *et al.*, 1999). Lutein and zeaxanthin, being potent antioxidants, may protect the lens from oxidative stress. Epidemiological studies have evaluated the relationships between intake of lutein/zeaxanthin and also other carotenoids and the incidence of cataract (Table 56.5). All the studies that looked at relations between carotenoid intake and cataract extraction found a significant reduction in the incidence of cataract extraction with higher intake of dietary lutein and zeaxanthin, and not  $\beta$ -cryptoxanthin, lycopene, or  $\alpha$ - and  $\beta$ -carotene (Hankinson *et al.*, 1992; Brown *et al.*, 1999; Chasen-Taber *et al.*, 1999). Of the various carotenoid-rich foods, greens such as spinach, kale, and other cruciferous vegetables, which are rich in lutein, were associated with a decreased risk of cataract extraction rather than foods such as carrots, winter squash, and sweet potatoes (Tavani *et al.*, 1996; Chasen-Taber *et al.*, 1999). Risk of nuclear cataract was lower in the highest quintile intake groups of lutein, zeaxanthin, and  $\beta$ -carotene compared with the lowest quintile intake groups (Mares-Perlman *et al.*, 1995a; Lyle *et al.*, 1999; Jacques *et al.*, 2001). In one study high lutein and zeaxanthin intake was related to reduced prevalence of nuclear opacity but not 5-year change in lens opacity (Jacques *et al.*, 2005). However, this study analyzed data from a subset of the Nurses' Health Study cohort: analyses of the complete cohort showed that those with higher lutein and zeaxanthin intakes had a lower risk of nuclear cataract extraction (Chasen-Taber *et al.*, 1999). Two studies (Mares-Perlman *et al.*, 1995a; Jacques *et al.*, 2001) out of four found high dietary intake of  $\beta$ -carotene to be related to lower risk of nuclear cataract (Chasen-Taber *et al.*, 1999; Lyle *et al.*, 1999). With regard to plasma carotenoids, one study showed the risk of nuclear cataract to be the lowest in people with the highest plasma  $\alpha$ - and  $\beta$ -carotene (Gale *et al.*, 2001), two studies showed no association with any of the measured carotenoids (Vitale *et al.*, 1993; Lyle, 1999), while one study showed increased risk of nuclear sclerosis in women (lutein and lycopene) but decreased risk (lutein,  $\alpha$ -carotene, and  $\beta$ -cryptoxanthin) in men who smoked (Mares-Perlman *et al.*, 1995b).

Dietary intakes of plasma lutein, zeaxanthin, and  $\beta$ -carotene were not found to be related to cortical cataract risk (Vitale *et al.*, 1993; Gale *et al.*, 2001; Taylor *et al.*, 2002a) except in one study in which decreased risk was observed in men with high serum  $\beta$ -carotene whereas increased risk was observed in men with high serum lutein (Mares-Perlman *et al.*, 1995b). Risk of PSC was lower in

women with the highest vs. lowest lutein/zeaxanthin intake and also in individuals with high plasma lutein/zeaxanthin concentrations (Chasen-Taber *et al.*, 1999; Gale *et al.*, 2001). Increased dietary intake of  $\beta$ -carotene (highest quintile group intake level was  $\sim$ 6.6 mg/day) was related to lowered risk of PSC only in women who never smoked (Taylor *et al.*, 2002a). Plasma  $\beta$ -carotene was not related to risk of PSC (Gale *et al.*, 2001). Other carotenoids such as  $\beta$ -cryptoxanthin and lycopene were not found to be related to any type of cataract or incidence of cataract extraction (Brown *et al.*, 1999; Chasen-Taber *et al.*, 1999; Gale *et al.*, 2001; Jacques *et al.*, 2001; Taylor *et al.*, 2002a), except in one study where cortical cataract was lowest in individuals with highest plasma lycopene (Gale *et al.*, 2001).

In a randomized, double-masked, placebo-controlled trial of  $\beta$ -carotene in US male physicians, no overall benefit or harm was observed with  $\beta$ -carotene supplementation (50 mg/day on alternate days) for 12 years to the incidence or extraction of cataract (Christen *et al.*, 2003). However,  $\beta$ -carotene supplementation appeared to lower the risk of cataract by about one-fourth in smokers. In a separate study, no effect was observed on the incidence of cataract extraction in male Finnish smokers supplemented with 20 mg/day of  $\beta$ -carotene (Teikari *et al.*, 1998b). In this study the cataract status at the start of the study was not known. Also, since the endpoint was cataract extraction, many cases of incident cataract that did not require surgery may have been excluded. Other intervention studies of  $\beta$ -carotene in combination with other antioxidants and vitamins are discussed in the "Intervention Studies" section.

In conclusion, there is strong evidence that long-term intake of dietary lutein and zeaxanthin may provide protection against the incidence of nuclear cataract, and to a lesser extent of PSC, but not cortical cataract. Most noteworthy is the fact that pharmacological doses are not necessary: an adequate amount is found in foods such as spinach, kale, and broccoli. The protective associations of  $\beta$ -carotene were strong only in non-smokers as smoking lowers the levels of  $\beta$ -carotene in serum and lens even with high dietary intake (Mosad *et al.*, 2010). Because of this fact, high doses of  $\beta$ -carotene supplements may have attenuated the risk of cataract in smokers (Christen *et al.*, 2003). The positive effects in this study should be interpreted with caution as two different studies have reported increased incidence of lung cancer in heavy smokers and in heavy smokers who were also exposed to asbestos

**TABLE 56.5** Carotenoids (dietary intake from food and supplement and plasma status) and risk of cataract

Study	Study design	Dietary intake or plasma status	Study duration	OR/RR/HR <sup>a</sup> (95% confidence interval)	Result	Reference
NHS	Prospective	F	8 years	OR = 0.73 (0.55–0.97) P < 0.001	Women in the highest quintile intake of carotene had lower odds of cataract extraction compared with lowest quintile intake	Hankinson <i>et al.</i> (1992)
BDES	Retrospective	F	10 years	OR = 0.71 (0.46–1.10) P = 0.064 (β-carotene)	Men in the highest quintile intake for β-carotene who also used multivitamins had lower odds of severe nuclear sclerosis compared with men in the lowest quintile	Mares-Perlman <i>et al.</i> (1995a)
NF-EDSBD	P	–	–	OR = 0.29 (0.10–0.84) P < 0.05 (β-carotene in multivitamin user)	High plasma β-carotene increased the risk of nuclear sclerosis in women. This association was more significant in women who were present smokers	Mares-Perlman <i>et al.</i> (1995b)
				OR = 2.80 (1.21–6.48) P = 0.06 (women)		
				OR = 17.86 (1.47–217.16) P = 0.04 (women smokers)		
				OR = 4.09 (1.67–10.03) P = 0.006 (lutein)		
				OR = 2.26 (0.91–5.63) P = 0.04 (lycopene)		
				OR = 0.27 (0.03–2.70) P = 0.04 (α-carotene)		
BDES	F	10 years	–	OR = 0.04 (0.00–0.41) P = 0.03 (β-cryptoxanthin)	High plasma lutein and lycopene were associated with increased odds of nuclear sclerosis in women	Lyle <i>et al.</i> (1999)
				OR = 0.17 (0.01–1.91) P = 0.05 (lutein)		
				OR = 0.28 (0.06–1.24) P = 0.05 (β-carotene)		
				OR = 4.84 (0.83–28.1) P = 0.03 (lutein)		
				OR = 0.5 (0.3–0.8) P = 0.002		
				Odds of cortical cataract were lower in men with high plasma β-carotene, not lutein		
Persons in the highest quintile of lutein intake in the distant past were half as likely to have an incident of nuclear cataract compared with persons in the lowest quintile of intake						

NHS	Prospective	F	12 years	RR = 0.88 (0.75–1.03) P = 0.04	Women in the highest quintile intake of lutein/zeaxanthin had a 22% decreased risk of cataract extraction than women in the lowest quintile intake	Chasen-Taber <i>et al.</i> (1999)
US-MHP	Prospective	F	8 years	RR = 0.81 (0.65–1.01) P = 0.03	Men in the highest quintile of lutein/zeaxanthin intake had a 19% lower risk of cataract relative to men in the lowest quintile	Brown <i>et al.</i> (1999)
NVP (NHS)	Prospective	F & S	13–15 years	OR = 0.52 (0.28–0.97) P = 0.04 (β-carotene)	Women in the highest quintile intake of β-carotene and lutein/zeaxanthin had reduced odds of nuclear opacity compared with lowest quintile intake	Jacques <i>et al.</i> (2001)
Gale <i>et al.</i>	Cross-sectional	P	–	OR = 0.52 (0.29–0.91) P = 0.03 (lutein and zeaxanthin) OR = 0.5 (0.3–0.9) P = 0.006 (α-carotene)	Risk of nuclear cataract was lowest in people with highest plasma α- and β-carotene.	Gale <i>et al.</i> (2001)
NHS	Retrospective	F & S	13–15 years	OR = 0.7 (0.4–1.4) P = 0.033 (β-carotene) OR = 0.4 (0.2–0.7) P = 0.003 (lycopene) OR = 0.5 (0.2–1.0) P = 0.012 (lutein) OR = 0.29 (0.08–1.05) P = 0.02 (α-carotene)	Risk of cortical cataract was lowest in people with highest plasma lycopene Risk of PSC was lowest in people with highest plasma lutein In women who had never smoked, the odds of PSC in the highest quintile intake of α-carotene, β-carotene, and total carotenoids were lower than the lowest quintile intake	Taylor <i>et al.</i> (2002a)
WHS	Prospective	F	10 years	OR = 0.28 (0.08–0.96) P = 0.02 (β-carotene) OR = 0.19 (0.05–0.68) P = 0.01 (total carotenoids) RR = 0.82 (0.71–0.95) P = 0.045	Women in the highest quintile intake of lutein/zeaxanthin had reduced risk of cataract compared with lowest quintile intake	Christen <i>et al.</i> (2008)

<sup>a</sup>The OR/RR/HR values shown in the table are values obtained for the highest quintile/tertile/quartile group versus the lowest unless stated differently in the results. BDES, Beaver Dam Eye Study; F, food; HR, hazards ratio; NF-EDSBD, Nutritional Factors in Eye Disease of Beaver Dam Eye; NHS, Nurses' Health Study cohort; NVP, Nutrition and Vision Project; OR, odds ratio; P, plasma; PSC, posterior subcapsular cataract; RR, relative risk; S, supplement; US-MHP, US Male Health Professionals Study; WHS, Women's Health Study cohort.

(Heinonen, 1994; Omenn *et al.*, 1996). The effect of supplementation with lutein and zeaxanthin, the only two carotenoids detected in the lens, on the incidence or progression of cataract has not been studied in a large-scale clinical setting. One study showed lutein supplementation (7 mg/day equivalent to lutein in ~100 g of spinach) improved visual acuity and glare sensitivity in people diagnosed with age-related cataract (Olmedilla *et al.*, 2003).

### **B Vitamins**

Flavin dinucleotide (FAD), a cofactor for the enzyme glutathione reductase (GR), is derived from the B vitamin riboflavin. GR is necessary for maintaining the cellular pool of reduced glutathione, which is an important antioxidant that prevents the formation of protein disulfides and maintains transparency of the lens (Bunce *et al.*, 1990). Additionally, riboflavin deficiency has also been shown to interfere with the metabolism of folate, vitamins B<sub>12</sub> and B<sub>6</sub> (Powers, 2003). A summary of studies evaluating B vitamins and cataracts can be found in Table 56.6. There is ample epidemiological data showing reduced prevalence of nuclear opacities with high dietary intake of either one or a combination of two or more B vitamins, which include riboflavin, folate, thiamin or niacin (Leske *et al.*, 1991; Mares-Perlman *et al.*, 1995a; Cumming *et al.*, 2000; Jacques *et al.*, 2001; Kuzniarz *et al.*, 2001; Jacques *et al.*, 2005). Riboflavin (3 mg/day) and niacin (40 mg/day) supplementation reduced the prevalence of nuclear cataract in a rural Chinese population, with the most benefit observed in people aged 65 to 74 years (Sperduto *et al.*, 1993). Riboflavin and niacin treatment in this study was found to have a deleterious effect on PSC, though the number of cases with PSC was small. In observational studies no association was observed between high intake of B vitamins and PSC (Leske *et al.*, 1991; Cumming *et al.*, 2000; Taylor *et al.*, 2002a). Reduced prevalence of cortical cataract was reported with the use of thiamin, riboflavin, niacin, folate, and B<sub>12</sub> supplements in the cross-sectional Blue Mountains Eye Study. In the Lens Opacities Case-Control study, reduced prevalence was observed only with total intake from food and supplements of thiamin, riboflavin, and niacin (Leske *et al.*, 1991; Kuzniarz *et al.*, 2001). A null effect of dietary or supplemental intake of riboflavin on cataract extraction has also been reported (Hankinson *et al.*, 1992).

In most of the studies, the independent effects of the B vitamins, i.e. riboflavin, niacin, and thiamin by themselves, could not be determined as the nutrient intakes

were highly correlated (Sperduto *et al.*, 1993; Mares-Perlman *et al.*, 1995a; Cumming *et al.*, 2000; Jacques *et al.*, 2005). In all the epidemiological studies the doses of riboflavin (>1.3 mg/day), thiamin (>1.2 mg/day), and niacin (>16 mg/day) in the highest quintile groups were at levels much greater than the RDA. In conclusion, B vitamins, especially riboflavin, thiamin, niacin and also folate, from foods and supplements may provide protection against nuclear and cortical cataracts but not PSC.

### **Zinc**

Zinc is a component of antioxidant enzymes such as superoxide dismutase, which is involved in the maintenance of structural integrity of the lens proteins (Flood *et al.*, 2002; Trumbo *et al.*, 2001). Zn<sup>2+</sup> can also specifically interact with  $\alpha$ -crystallin, a major lens protein and molecular chaperone, and enhance its ability to prevent protein aggregation and maintain lens transparency (Biswas and Das, 2007). However, compared with other antioxidants such as vitamins C and E and carotenoids, epidemiological data on zinc intake and cataract prevalence are minimal. The Blue Mountains eye follow-up study showed that above-median intakes of zinc in combination with vitamins C and E and  $\beta$ -carotene were associated with reduced incidence of nuclear cataract but not cortical or PSC cataract (Tan *et al.*, 2008a).

Some studies have suggested a deleterious effect of increased zinc concentrations in the lens and aqueous humor. Two studies reported significantly higher zinc content in the aqueous humor ( $0.243 \pm 0.12 \mu\text{g/mL}$  vs.  $0.154 \pm 0.56 \mu\text{g/mL}$ ,  $P < 0.001$ ) and lens ( $0.51 \pm 0.33 \mu\text{mol/g}$  vs.  $0.32 \pm 0.20 \mu\text{mol/g}$ ,  $P = 0.012$ ) of cataract patients vs. controls (Dawczynski *et al.*, 2002; Nourmohammadi *et al.*, 2006), while another study reported no significant difference (Aydin *et al.*, 2005). Based on this evidence it is unclear if high zinc concentration in the lens is a consequence of cataract or a factor that causes cataract (Nourmohammadi *et al.*, 2006). No positive conclusions of the protective effect of dietary zinc intake on cataract can thus be drawn.

### **Omega-3 Fatty Acids**

The eye is rich in omega-3 fatty acids, especially docosahexaenoic acid (DHA), which is found in very high concentrations in the retina. Although there is no known biological rationale for the role of omega-3 fatty acids in the prevention of cataract, a few observational studies are presented (Hodge *et al.*, 2005). High intakes of dietary

<sup>a</sup>The OR/RR/HR values shown in the table are values obtained for the highest quintile/tertile/quartile group versus the lowest unless stated differently in the results. B<sub>1</sub>, thiamin; B<sub>2</sub>, riboflavin; B<sub>3</sub>, niacin; BDES, Beaver Dam Eye Study cohort; BMES, Blue Mountains Eye Study; F, food; HR, hazards ratio; LOCCS, Lens Opacities Case-Control Study; NHS, Nurses' Health Study cohort; NVP, Nutrition and Vision Project; OR, odds ratio; PSC, posterior subcapsular cataract; RR, relative risk; S, supplement.

omega-3 polyunsaturated fatty acids were shown to reduce the incidence of nuclear cataract in the Blue Mountains Eye Study cohort (Townend *et al.*, 2007). A 16-year prospective study showed that women in the highest quintile intake of long-chain omega-3 fatty acids (0.21% of energy) had a 12% lower risk of cataract extraction compared with those in the lowest quintile intake (0.03% of energy) (Lu *et al.*, 2005). However, in a cohort of the Nurses' Health Study from the Boston, Massachusetts area, higher intake of  $\alpha$ -linolenic acid (ALA) was associated with greater age-related change in lens nuclear density (Lu *et al.*, 2007). There is not enough evidence to conclude that omega-3 fatty acids are protective against cataract.

### Intervention Studies

Based on the epidemiological evidence, several randomized controlled trials (RCTs) have evaluated whether a combination of the above mentioned nutrients can reduce the risk of cataract. The Age-Related Eye Disease Study (AREDS) reported that a combination of high-dose antioxidants (vitamin C, 500 mg; vitamin E, 400 IU;  $\beta$ -carotene, 15 mg) had no apparent effect on the 7-year risk of development or progression of age-related lens opacities or visual acuity loss (Age-Related Eye Disease Study Research, 2001a). The Antioxidants in the Prevention of Cataracts (APC) study also reported no effect of the exact same intervention on the 5-year progression of cataract in a population aged 35 to 50 years from south India (Gritz *et al.*, 2006). The Roche European American Cataract Trial (REACT), which used a similar intervention (vitamin C, 750 mg/day; vitamin E, 600 mg/day;  $\beta$ -carotene, 18 mg/day) found a significant reduction in the measure of lens opacity in the US population diagnosed with early age-related cataract after 3 years of treatment ( $n = 88$  who completed 3 years of follow-up). The same effect was not observed in the UK population of this study due to differences in population characteristics ( $n = 70$  who completed 3 years of follow-up). The UK cohort also included participants with more advanced cataract (Chylack *et al.*, 2002). Intervention with a supplement containing 14 different vitamins and 12 minerals, including vitamin C (180 mg/day),  $\alpha$ -tocopherol (60 IU/day), and  $\beta$ -carotene (15 mg/day) reduced the prevalence of nuclear cataract by 36% in a rural Chinese population aged 65 to 74 years diagnosed with esophageal dysplasia (Sperduto *et al.*, 1993). In the Alpha-Tocopherol Beta-Carotene (ATBC) trial,  $\alpha$ -tocopherol (50 mg/day) and  $\beta$ -carotene (20 mg/day) supplementation was not

found to lower the rates of cataract extraction in male Finnish smokers during a 5- to 8-year follow-up (Teikari *et al.*, 1997). Multivitamin/mineral supplementation (containing 100% RDA of B vitamins, vitamins C and E, no  $\beta$ -carotene) decreased the incidence of nuclear cataract events during a 9-year follow-up in an Italian population aged 55 to 75 years, who started the study with early or no cataract (Clinical Trial of Nutritional Supplements and Age-Related Cataract Study Group *et al.*, 2008). In the same study, the incidence of PSC actually increased with multivitamin/mineral supplementation.

The null findings of some studies could be caused by several factors such as age, nutritional status, overall health and geographic location, all of which influence the diet of study populations. In the case of AREDS, in addition to the multivitamin/mineral intervention, 66% of the population was taking a multivitamin Centrum without lutein (Age-Related Eye Disease Study Research Group, 2001a). Therefore, a majority of the population, whether in the control or treatment group, had an increase in their intake by approximately 100% of the RDA amounts of the nutrients of interest in addition to the study intervention. In the ATBC study, the population were all smokers, and also the true status of cataract at the start of the study was not known. The primary endpoint of the REACT study was change in percent pixels opaque (IPO) (Chylack *et al.*, 2002), which was different from the measures of lens opacity and visual acuity used in the other studies.

In conclusion, supplementation with multivitamins/minerals may reduce the incidence or progression of cataract in older adults with early or no cataract who generally consume diets with nutrients within 100% of the RDA amounts. However, more RCTs are needed to confirm these findings. Nutritional interventions seem to benefit nuclear cataract, which is more common in older adults, more than cortical cataract and PSC. With lutein and zeaxanthin being the major carotenoids found in the lens, more studies need to be done evaluating the effect of lutein and zeaxanthin interventions on cataract.

### Age-Related Macular Degeneration (AMD)

AMD is the leading cause of blindness in adults aged 60 years and over in industrialized countries. The prevalence of AMD increases dramatically with age. Nearly 30% of Americans over the age of 75 years have early signs of AMD, and 7% have advanced AMD, whereas the

respective prevalence is 8% and 0.1% in adults aged 43–54 years (Congdon *et al.*, 2004). None of the current treatment options can reverse the damage caused by AMD. As with cataracts, efforts are focused on preventing incidence and progression of the disease. Nutritional interventions are part of these efforts (Snodderly, 1995).

AMD is a disease that affects the posterior, central region of the retina, called the macula, which contains the densest concentration of photoreceptors and is responsible for sharp central vision. Figure 56.3(b) shows the loss of central vision that is found in AMD patients. Posterior to the photoreceptors is the retinal pigment epithelium (RPE), part of the blood–ocular barrier, which has several functions including phagocytosis of the photoreceptors (Jager *et al.*, 2008). The clinical hallmark and usually the first clinical signs of AMD is the presence of drusen. Drusen are extracellular deposits that accumulate between the RPE and the inner layer of the Bruch’s membrane and appear as pale yellow spots on the retina (Abdelsalam *et al.*, 1999). They are formed as a result of the inability of the RPE to adequately perform its function of phagocytosis. Drusen can also be present in the normal aging eye. AMD can be classified into the following types based on the AREDS classification system: (1) early AMD – presence of few (<20) medium-sized drusen or retinal pigmentary abnormalities; (2) intermediate AMD – the presence of at least one large drusen, numerous medium-sized drusen, or geographic atrophy that does not extend to the center of the macula; (3) advanced or late AMD – can be either neovascular (wet, exudative) or non-neovascular (dry, atrophic, non-exudative). Advanced non-exudative is characterized by drusen and geographic atrophy that extends to the macula (Jager *et al.*, 2008). Advanced exudative is characterized by growth of new blood vessels under the RPE and sometimes into the sub-retinal space. The early stages of AMD are generally asymptomatic. In the later stages there may be distortion of vision or complete loss of visual function, especially central vision (Snodderly, 1995). Although specifics on the pathogenesis of AMD are not completely understood, the mechanisms of importance are chemical and light-induced oxidative stress, blue-light-induced damage to the RPE and photoreceptor rod cells, RPE dysfunction, hemodynamic processes, and also genetic factors. The retina is particularly susceptible to oxidative damage because of its high consumption of oxygen, its high concentration of polyunsaturated fatty acids, and its exposure to visible light (Nolan *et al.*, 2003). Depletion of macular pigment

(discussed in detail under “Carotenoids”) is another predisposing risk factor for AMD that is responsive to nutritional intervention as it cannot be synthesized *de novo*. Since oxidative stress has been implicated in the etiology of AMD, various antioxidant nutrients will be examined for their role in protection against AMD in the sections below. The epidemiological evidence and intervention studies, if any, are organized based on dietary intake from food or supplement and plasma status of the nutrient of interest.

### Vitamin C

Epidemiological evidence examining the relationship between dietary intake of vitamin C, from food and supplements, and plasma vitamin C with AMD is listed in Table 56.7. No protective association was reported between dietary vitamin C or plasma vitamin C concentration and AMD risk in any of the studies (Eye Disease Case-Control Study Group (EDCCSG), 1993; Seddon *et al.*, 1994a; West *et al.*, 1994; Christen *et al.*, 1999; Smith *et al.*, 1999; Cho *et al.*, 2004; Age-Related Eye Disease Study Research Group *et al.*, 2007). In one study, incidence of dry, exudative or non-exudative AMD over 8 years was reduced by 35% in individuals with above-median intake of vitamin C in combination with vitamin E,  $\beta$ -carotene, and zinc (van Leeuwen *et al.*, 2005). In the Blue Mountains Eye Study cohort, higher baseline intake of vitamin C was associated with an increased risk of incident early AMD during a 5-year follow-up period (Flood *et al.*, 2002). There is no conclusive evidence to state that dietary vitamin C in isolation can protect against AMD. Supplementation studies of vitamin C in combination with other antioxidant nutrients are discussed in the “Intervention Studies” section.

### Vitamin E

Being a fat-soluble antioxidant, several studies looked at the relation between vitamin E and the incidence of AMD (Table 56.8). Increased dietary intake of vitamin E, from foods and supplements, was shown to reduce the incidence of AMD in only two studies (VandenLangenberg *et al.*, 1998; van Leeuwen *et al.*, 2005), whereas no such effect was reported in other epidemiological studies (Eye Disease Case-Control Study Group, 1993; Seddon *et al.*, 1994a; Mares-Perlman *et al.*, 1996; Christen *et al.*, 1999; Cho *et al.*, 2004). High plasma vitamin E concentration was associated with reduced prevalence of AMD in some studies (Eye Disease Case-Control Study Group, 1993;

**TABLE 56.7** Vitamin C (dietary intake from food and supplements and plasma status) and risk of age-related macular degeneration (AMD)

Study	Study design	Dietary intake	Study duration	OR/RR/HR <sup>a</sup> (95% confidence interval)	Result	Reference
EDCCSG	Case-control	P	-	OR = 0.7 (0.5-1.2) P = 0.27	Plasma vitamin C was not associated with reduced odds of developing neovascular AMD	EDCCSG (1993)

West *et al.*, 1994), but not in others (Sanders *et al.*, 1993; Mares-Perlman *et al.*, 1995c).

Three double-blind placebo-controlled primary prevention trials have been published that studied the effect of long-term vitamin E supplementation on the incidence or progression of AMD (Teikari *et al.*, 1998a; Taylor *et al.*, 2002b; Christen *et al.*, 2010). The risk of incidence or progression of AMD was not reduced in the vitamin E supplemented groups (doses were 50 mg/day or 75 IU/day, 500 IU/day and 600 IU/2 days) compared with the placebo groups in any of the studies. The doses of vitamin E used in these studies are well over the RDA for vitamin E. High doses of vitamin E ( $\geq 400$  IU/day) have been linked to increased risk of heart failure among people with diabetes or vascular disease (Lonn *et al.*, 2005). The hypothesis is that at such high doses vitamin E could act as a pro-oxidant and displace other fat-soluble antioxidants. In conclusion, there is no strong evidence to support the beneficial effect of vitamin E for the risk of AMD.

Vitamins C and E do not seem to have an independent protective effect on AMD as evidenced from the above reviewed literature. However, some studies have shown that, in combination with each other and with other antioxidants, vitamins C and E can reduce the risk of AMD. High dietary intake of a combination of vitamins C and E,  $\beta$ -carotene, and zinc was associated with a 35% reduced risk of AMD (van Leeuwen *et al.*, 2005). A similar observation was reported in three other studies. One of these looked at a combination of vitamins C and E, carotenoids, and selenium, the second at antioxidant intake, and the third at a combination of plasma vitamins C and E and  $\beta$ -carotene (Eye Disease Case-Control Study Group, 1993; West *et al.*, 1994; Snellen *et al.*, 2002). Studies that looked at supplementation with a combination of vitamins C and E are discussed in the "Intervention Studies" section.

### Carotenoids

Among the carotenoids, lutein and zeaxanthin specifically accumulate in the macula, where they are referred to as macular pigment (Bone *et al.*, 1985). With a maximum absorption of 460 nm, macular pigment (MP) acts as an efficient filter, protecting the underlying photoreceptors and RPE from blue-light damage (Ahmed *et al.*, 2005). Concentrations of lutein and zeaxanthin in the retinas from AMD donors were found to be lower than in controls, suggesting that low MP density could be a risk factor for AMD (Bone *et al.*, 2001). Further evidence for this finding comes from studies that measured MP density in

vivo using a heterochromatic flicker photometer (Wooten *et al.*, 1999). Subjects with advanced AMD in one eye had significantly lower MP density in the fellow eye compared with healthy eyes of subjects without AMD (Beatty *et al.*, 2001). Another study found MP density in the eyes of AMD patients to be 32% lower than in normal disease-free eyes (Bernstein *et al.*, 2002). However, MP density was not related to intermediate AMD in a cross-sectional study of women participating in the Carotenoids in Age-related Eye Disease Study (CAREDS). After an exploratory analysis, the authors suggested that the observations may have been biased in older women, whose diets improved with age. The authors also suggested the possibility that low MP density could be the result, rather than the cause, of damage to the retina with AMD (LaRowe *et al.*, 2008). A similar observation was reported in a subset of the Rotterdam Eye Study, another cross-sectional study that examined MP density in subjects aged 55 years or older with or without AMD (Berendschot *et al.*, 2002). These conflicting observations may be due to the cross-sectional nature of the studies, as prospective data from another study found MP density to be reduced in subjects with late AMD (Schweitzer *et al.*, 2000).

Apart from their role as MP, lutein and zeaxanthin are strong antioxidants and can protect the retina from oxidative-stress-related damage. A number of studies have looked at the relationship between dietary intake of carotenoids, especially lutein and zeaxanthin, and the risk of AMD. High intake of carotenoids, particularly lutein and zeaxanthin, was related to a reduced risk of advanced neovascular AMD (Eye Disease Case-Control Study Group, 1993; Seddon *et al.*, 1994a; Snellen *et al.*, 2002). Cross-sectional data from the CAREDS showed high lutein and zeaxanthin intakes were related to a decreased risk of intermediate AMD in women  $<75$  years, but not in women  $\geq 75$  years (Moeller *et al.*, 2006). Furthermore, the Blue Mountains Eye Study found that high intake of lutein/zeaxanthin reduced the risk of incident neovascular AMD and indistinct soft or reticular drusen during a 5- to 10-year follow-up (Tan *et al.*, 2008b). Lutein and zeaxanthin intake was also associated with a decreased risk of neovascular AMD and large or extensive intermediate drusen when comparing the highest to the lowest quintiles of intakes (Age-Related Eye Disease Study Research Group *et al.*, 2007). However, a nested case-control study of the Beaver Dam Eye Study cohort found no difference in serum lutein and zeaxanthin concentrations between early age-related macular degeneration and age-, sex-, and

smoking-matched controls (Mares-Perlman *et al.*, 1995c). Serum concentrations are not a good measure of long-term dietary intake of lutein and zeaxanthin, which may have caused the null findings. A summary of studies on carotenoid intake and risk of AMD is shown in Table 56.9.

Based on the above observational findings, increased dietary intake of lutein and zeaxanthin, from either foods or supplements, would be a logical strategy in the prevention and/or treatment of AMD. Several studies have shown that increased consumption of lutein/zeaxanthin, from foods such as spinach, corn, and egg yolks (Hammond *et al.*, 1997; Bone *et al.*, 2000; Wenzel *et al.*, 2006; Vishwanathan *et al.*, 2009), and from supplements (Landrum *et al.*, 1997; Bone *et al.*, 2003; Johnson *et al.*, 2008; Connolly *et al.*, 2010), can significantly improve MP density in healthy adults not diagnosed with AMD. In the Lutein Antioxidant Supplementation Trial (LAST), 10 mg/day of lutein for 1 year improved MP density, visual function and subjective results of Amsler grid testing in patients with atrophic AMD (Richer *et al.*, 2004).

In conclusion, lutein and zeaxanthin, because of their specific accumulation in the macula, are important nutrients that may be beneficial in the prevention and treatment of AMD. Studies that used lutein/zeaxanthin in combination with other vitamins and antioxidants as a treatment option are discussed in the “Intervention Studies” section.

### **B Vitamins**

Vitamins B<sub>12</sub> and B<sub>6</sub> and folate are essential for the transsulfuration and remethylation reactions in the metabolic pathway of homocysteine (Selhub and Miller, 1992). Low intakes and blood levels of vitamins B<sub>12</sub> and B<sub>6</sub> and folate have been associated with hyperhomocysteinemia, i.e. increased plasma levels of homocysteine. Also, several observational studies have reported hyperhomocysteinemia to be associated with an increased risk of AMD (Heuberger *et al.*, 2002; Axer-Siegel *et al.*, 2004; Nowak *et al.*, 2005; Vine *et al.*, 2005; Coral *et al.*, 2006; Kamburoglu *et al.*, 2006; Rochtchina *et al.*, 2007; Krishnadev *et al.*, 2010). The mean plasma homocysteine levels were >15 μmol/L in AMD subjects in these studies. In the Blue Mountains Eye Study, in patients with serum homocysteine ≤15 μmol/L, low plasma B<sub>12</sub> was associated with nearly four times higher odds of AMD (Rochtchina *et al.*, 2007). Low plasma vitamin B<sub>12</sub> was also reported to be an independent risk factor for AMD in some studies (Kamburoglu *et al.*, 2006; Rochtchina *et al.*, 2007),

whereas other studies did not find any association (Heuberger *et al.*, 2002; Nowak *et al.*, 2005). The absence of an association of homocysteine with RBC folate and serum vitamin B<sub>12</sub> in the Third National Health and Nutrition Examination Survey was attributed to limited information on changes in the diet and lifestyle of participants, exclusion of persons in an older age group due to missing data, and differences in fasting status at the time of blood draw (Heuberger *et al.*, 2002). However, an inverse association was observed between RBC folate and soft drusen in non-Hispanic Blacks in this study. Folate and vitamins B<sub>6</sub> and B<sub>12</sub> have been explored as a treatment option for AMD as they are capable of reducing plasma homocysteine levels (Woodside *et al.*, 1998). The fact that vitamin B<sub>12</sub> and folate may be independently related to incidence of AMD warrants their investigation in the treatment of AMD.

The Women’s Antioxidant and Folic Acid Cardiovascular Study, a randomized, double-blinded, placebo-controlled study, showed that women at a high risk of cardiovascular disease supplemented with folic acid (2.5 mg/day), vitamin B<sub>6</sub> (50 mg/day), and vitamin B<sub>12</sub> (1 mg/day) for an average of 7.3 years had a statistically significant 35–40% reduced risk of AMD (Christen *et al.*, 2009). After examining a subset of 300 participants for blood levels of homocysteine, the mechanism of action of supplementation was partly attributed to a significant reduction in plasma homocysteine concentrations. Since AMD diagnosis was self-reported and the population was women with a high risk of cardiovascular disease, the authors suggest caution when extrapolating the results to a general population. Other than vitamins B<sub>6</sub> and B<sub>12</sub> and folate, two studies investigated the effect of niacin treatment in AMD patients. Niacin treatment caused vasodilatation of retinal arterioles in one study, and in another study niacin modified choroidal circulation (Metelitsina *et al.*, 2004; Barakat *et al.*, 2006). For a summary of the studies that have evaluated relationships between the B vitamins and AMD, see Table 56.10. In conclusion, vitamins B<sub>12</sub> and B<sub>6</sub> and folate may be beneficial in reducing the risk of AMD, while niacin may help in the treatment of neovascular AMD. More RCTs are needed to confirm these findings.

### **Zinc**

High concentrations of zinc are present in the photoreceptors and RPE compared with other tissues, suggesting that zinc may have an important role in protection against retinal diseases such as AMD (Newsome *et al.*, 1992). Zinc

**TABLE 56.9** Carotenoids (dietary intake from food and supplement, plasma and retina status) and risk of age-related macular degeneration (AMD)

Study	Study design	Dietary intake	Study duration	OR/RR/HR <sup>a</sup> (95% confidence interval)	Result	Reference
EDCCSG	Case-control	P	-	OR = 0.3 (0.2–0.6) P < 0.0001 (total carotenoids)	High levels of total carotenoids in the blood were associated with reduced risk of NV AMD	Eye Disease Case-Control Study Group (1993)

BMES, Blue Mountains Eye Study; NHANES, National Health and Nutrition Examination Survey; P, plasma; RBC, red blood cells; RCT, randomized controlled trial; S, supplement containing folic acid (2.5 mg/day), vitamin B<sub>6</sub> (50 mg/day) and vitamin B<sub>12</sub> (1 mg/day); WAFCS, Women's Antioxidant and Folic Acid Cardiovascular Study.

functions as a cofactor for several ocular enzymes, including superoxide dismutase, a primary antioxidant used to regulate oxidative stress. Because oxidative stress in the retina is involved in the pathogenesis of AMD, the role of zinc in reducing the risk of AMD has been investigated. Further evidence for this hypothesis comes from a study in which zinc levels in the RPE and choroid were found to be significantly reduced by 24% in AMD eyes compared with normal eyes (Erie *et al.*, 2009).

Prospective observational studies on zinc intake and incidence of AMD have reported conflicting results. In the Blue Mountains Eye Study, participants with higher intakes of zinc had relatively reduced incidence of AMD after 5 to 10 years of follow-up (Tan *et al.*, 2008b). However, in the Nurses' Health Study and the Health Professionals Follow-up Study, zinc intake, either from food or as supplements, was not associated with a reduced risk of AMD (Cho *et al.*, 2001b). No association was

observed between zinc intake and prevalence of AMD-related drusen in the cohort of the Nurses' Health Study who also participated in the Nutrition and Vision Project (Morris *et al.*, 2007).

Positive effects of zinc supplementation have been reported in RCTs. Zinc supplementation (100 mg as zinc sulfate) given to an elderly population with early stage AMD resulted in better maintenance of visual acuity than in the control population (Newsome *et al.*, 1988). Supplementation with 50 mg/day of zinc monocyteine was found to significantly improve macular function in individuals with dry AMD (Newsome, 2008). The beneficial effect of zinc supplementation in this study may have been due to the presence of cysteine. Cysteine has the ability to be metabolized into other sulfur-containing compounds such as glutathione, an important antioxidant in the eye. No positive effect of supplementation with 200 mg/day of zinc for 2 years was observed in the healthy eye of patients diagnosed with drusen in one eye (Stur *et al.*, 1996).

A study that tested zinc concentrations in post-mortem eyes found unexpectedly high concentrations of zinc in the sub-RPE deposits, with levels being especially high in eyes with AMD (Lengyel *et al.*, 2007). The authors suggested that zinc may be involved in the formation of sub-RPE deposits and possibly in the development of AMD. However, the fact that zinc was associated with deposit formation does not prove that zinc caused the deposits. There could be a number of reasons for the presence of zinc in the deposits, the simplest being that they are made up of proteins, which may coincidentally, but not harmfully, bind zinc (Newsome and Brewer, 2008). The beneficial effects of zinc cannot be negated, based on the findings of this study. Another study suggested that zinc in low amounts may protect RPE but in high amounts can have the opposite effect based on cell culture data. The authors suggested that zinc supplementation may be beneficial in combination with other antioxidants and not in isolation (Wood and Osborne, 2003). However, clinical evidence would be required to confirm these experimental data on the potential negative effect of high-dose zinc supplementation. Based on data from RCTs, zinc supplementation may be beneficial in reducing the risk of AMD. Further evidence of the protective role of zinc supplementation in combination with other antioxidants and vitamins is described in the "Intervention Studies" section.

### **Omega-3 Fatty Acids**

The rod outer segments of the retina have the highest concentration of DHA compared with any other neural subcellular component, about 30–65% of the total fatty acids (Neuringer *et al.*, 1988). A recent study also suggested that omega-3 fatty acids in the retina have anti-inflammatory effects and, when converted to neuroprotectin, they protect against oxidation-induced apoptosis (Schweigert and Reimann, 2010). Findings from epidemiological studies that examined the relationship of fish intake, omega-3 fatty acids, DHA, and omega-6 fatty acids with incidence of early or late-stage AMD are presented (Table 56.11).

In a prospective 10- to 12-year follow-up of participants in the Nurses' Health Study and the Health Professionals Follow-up Study, consumption of >4 servings of fish per week was associated with a 35% lower risk of AMD compared with ≤3 servings per month (Cho *et al.*, 2001a). Of the individual fish types examined in this study, a significant inverse association was found only with intake of tuna. Similar findings were reported in another prospective study where a 40% reduction in incidence of early AMD was associated with consumption of fish at least once a week, while consumption of fish at least three times a week reduced the incidence of late AMD (Chua *et al.*, 2006). Three case-control studies and two cross-sectional studies also reported positive associations between fish intake and risk of AMD (Seddon *et al.*, 2001, 2006; Age-Related Eye Disease Study Research Group, 2007; Delcourt *et al.*, 2007; Augood *et al.*, 2008). Two other cross-sectional studies failed to find any significant association between fish intake and AMD risk (Mares-Perlman *et al.*, 1995d; Heuberger *et al.*, 2001). The authors of the Beaver Dam Eye Study suggested that fish intakes were low and possibly not varied enough to detect a difference in the risk of AMD (Mares-Perlman *et al.*, 1995d).

Several observational studies including the ones mentioned above also examined associations between omega-3 or omega-6 fatty acids and AMD risk. High dietary intake of omega-3 fatty acids was found to be protective against early and late AMD (Seddon *et al.*, 2001, 2006; Chua *et al.*, 2006; Age-Related Eye Disease Study Research Group, 2007; SanGiovanni *et al.*, 2009). Higher intakes of DHA and eicosapentaenoic acid (EPA) were also associated with lowering the odds of neovascular AMD (Cho *et al.*, 2001a; Augood *et al.*, 2008). Surprisingly, intake of the omega-3 fatty acid, linolenic acid, was associated with

**TABLE 56.11** Dietary intake of fish, long-chain polyunsaturated fatty acids and omega-3 fatty acids and risk of age-related macular degeneration (AMD)

Study	Study design	Dietary intake	Study duration	OR/RR/HR <sup>a</sup> (95% confidence interval)	Result	Reference
NHS HPFU	Prospective	Fish	5–10 years	RR = 0.7 (0.52–0.93) P = 0.05	Intake of >4 servings/week was associated with 35% reduced incidence of AMD compared with ≤3 servings/month	Cho <i>et al.</i> (2001a)
		Tuna		RR = 0.61 (0.45–0.83) P = 0.0007	Of all types of fish, significant association only with tuna	
		DHA		RR = 0.65 (0.46–0.91) P = 0.009	DHA intake had an inverse relation with AMD	
AREDS	Prospective	Omega-3	12 years	OR = 0.65 (0.45–0.92)	Highest intake was associated with 30% less likelihood of geographic and neovascular AMD	SanGiovanni <i>et al.</i> (2009)
EDCCS	Case-control	Fish (≤5.5 g linoleic acid)	–	OR = 0.60 (0.32–1.14) P = 0.05	High fish/DHA intake reduced risk of neovascular AMD only when intake of linoleic acid ≤5.5g	Seddon <i>et al.</i> (2001)
		DHA and EPA (≤5.5 g linoleic acid)		OR = 0.75 (0.44–1.25) P = 0.05

BMES	Prospective	Fish (low linoleic acid intake)	10 years	RR = 0.59 (0.36–0.99) P = 0.12	Increased intake of fish and omega-3 reduced incidence of early AMD only with below median levels of linoleic acid	Tan <i>et al.</i> (2009)
		Omega-3 (low linoleic acid intake)		RR = 0.48 (0.27–0.83) P = 0.01		
BMES	Prospective	Fish	5 years	OR = 0.58 (0.37–0.90)		Chua <i>et al.</i> (2006)
		Fish		OR = 0.25 (0.06–1.00)	At least 1 serving of fish associated with reduced risk of early AMD by 40%	
		Omega-3		OR = 0.41 (0.22–0.75)	At least 3 servings of fish caused significant reduction late AMD risk	
EUREYE	Cross-sectional	DHA	–	OR = 0.32 (0.12–0.87) P = 0.03	High omega-3s reduced risk of incident early AMD	Augood <i>et al.</i> (2008)
		EPA		OR = 0.29 (0.11–0.73) P = 0.02	Reduced odds of neovascular AMD with higher intake of DHA and EPA	
Seddon <i>et al.</i>	Prospective	Fish (≤4.9 g/day linoleic acid)	–	RR = 0.36 (0.14–0.95) P = 0.045	>2 servings of fish reduced risk of late AMD in subjects consuming ≤4.9 g/day linoleic acid	Seddon <i>et al.</i> (2003)

<sup>a</sup>The OR/RR/HR values shown in the table are values obtained for the highest quintile/tertile/quartile group versus the lowest unless stated differently in the result. AREDS, Age-related Eye Disease Study; BMES, Blue Mountains Eye Study; DHA, docosahexaenoic acid; EDCCS, Eye Disease Case-Control Study; EPA, eicosapentaenoic acid; NHANES, National Health and Nutrition Survey; NHS/HPFU, Nurses' Health Study/Health Professionals Follow-up Study.

a relative increase in risk of AMD in the Nurses' Health Study and the Health Professionals Follow-up Study cohort. However, the authors suggested that this could have been a chance finding as many individual fatty acids were assessed and also there is no specific biological mechanism for linolenic acid in the retina (Cho *et al.*, 2001a).

Higher intake of omega-6 fatty acids seemed to negatively influence the protective effect of omega-3 fatty acids. In two prospective studies and one case-control study, reduced risk of early AMD or neovascular AMD associated with fish consumption was observed only among participants consuming low amounts of linoleic acid, an omega-6 fatty acid (Seddon *et al.*, 2001, 2003; Tan *et al.*, 2009). Higher consumption of linoleic acid was also independently associated with greater risk for AMD in the Eye Disease Case-control Study cohort (Seddon *et al.*, 2001). When this study population was stratified by linoleic acid intake ( $\leq 5.5$  or  $\geq 5.6$  g/day), the risk for AMD significantly decreased with high intake of omega-3 fatty acids only among those with low linoleic acid intake. A similar negative effect of above-median intake of linoleic acid on omega-3 fatty acids was reported in the US Twin Study of AMD (Seddon *et al.*, 2006). A higher intake of arachidonic acid (ARA), another omega-6 fatty acid, was also associated with increased odds of neovascular AMD (Age-Related Eye Disease Study Research Group, 2007).

Based on observational findings, higher intake of omega-3 fatty acids, specifically DHA, may be beneficial in reducing the risk of early or late-stage AMD. Incorporating fatty fish in the diet can be a feasible way of increasing dietary omega-3 fatty acid intake. White fish are not rich in omega-3 fatty acids, and increased intake of white fish was not associated with reduced risk of AMD in the POLANUT cross-sectional study (Delcourt *et al.*, 2007). The positive effects of omega-3 fatty acids seem to depend on the intake levels of omega-6 fatty acids. A healthy omega-6/omega-3 ratio (3:1 to 4:1) should be maintained in the diet to obtain protection against AMD (Simopoulos, 2002). The ongoing AREDS 2 study is evaluating the effect of an EPA and DHA intervention on the progression to late AMD.

### **Intervention Studies**

Numerous studies that tested different combinations and doses of the above-mentioned nutrients on MP augmentation and AMD risk are discussed in this section. The AREDS intervention of vitamin C (500 mg), vitamin E (400 IU),  $\beta$ -carotene (15 mg), zinc (as zinc oxide, 80 mg), and copper (as copper oxide, 2 mg) was found to lower the

risk of AMD by 25% in individuals who had intermediate or advanced AMD in one eye but not the other eye (Age-Related Eye Disease Study Research Group, 2001b). In the same high-risk group, these nutrients reduced the risk of vision loss caused by advanced AMD by about 19%. For those subjects who had either no AMD or early AMD, the nutrients did not provide benefit. A daily supplement of 12 mg lutein, 1 mg zeaxanthin, 120 mg vitamin C, 17.6 mg vitamin E, 10 mg zinc, and 40  $\mu$ g selenium for 6 months significantly increased MP density in an older adult population, of which 92.6% exhibited some features of AMD (Trieschmann *et al.*, 2007). In the second treatment arm of the LAST, daily supplementation with 10 mg of lutein in combination with a broad spectrum of vitamins, minerals and other antioxidants for 12 months also improved MP density and visual function in patients with atrophic AMD (Richer *et al.*, 2004). An RCT in individuals with non-advanced AMD in Italy, supplementation with 180 mg vitamin C, 30 mg vitamin E, 22.5 mg zinc, 1 mg copper, 10 mg lutein, 1 mg zeaxanthin, and 4 mg astaxanthin daily for 12 months improved a selective dysfunction in the central ( $0^\circ$ – $5^\circ$ ) retina (Parisi *et al.*, 2008). In addition, two recent systematic reviews found that RCTs did not show that antioxidant supplements prevented early AMD (Chong *et al.*, 2007; Evans and Henshaw, 2008). The AREDS 2 has begun and aims to refine the findings of AREDS by including lutein, zeaxanthin, and omega-3 fatty acids in the test formulation.

In conclusion, supplementation with a combination of vitamins C and E,  $\beta$ -carotene, zinc, and copper or the AREDS supplement may be beneficial in preventing progression of AMD and improving visual function in AMD patients. High doses of lutein/zeaxanthin supplements may also be beneficial as they increase MP density which may prevent further retinal damage in AMD patients. The ongoing AREDS 2 study is evaluating the effect of treatment with 10 mg lutein/2 mg zeaxanthin alone and in combination with omega-3 fatty acids in AMD patients.

### **Dietary Patterns, Cataracts, and AMD**

The above sections focused primarily on the role of single nutrients or combinations of nutrients in the prevention and treatment of cataract and AMD. It is important to determine if adhering to the established Recommended Dietary Guidelines for all nutrients, including macronutrients, might have an impact on the prevention or progression of cataract and AMD. The Healthy Eating Index

(HEI) developed by the USDA is a single, summary measure of diet quality that can be used to monitor changes in dietary consumption patterns (Kennedy *et al.*, 1995). A strong inverse association was reported between adherence to Dietary Guidelines for Americans, measured as HEI score, and the prevalence of nuclear opacities in women from the Nurses' Health Study cohort (Moeller *et al.*, 2004). The same study also observed reduced prevalence of nuclear opacities in women in the highest quartile category of whole-grain intake. The strongest inverse associations were observed with overall HEI score, and not individual components of the diet, such as fruit or vegetable intake alone, stressing the importance of eating an overall well-balanced diet. The Women's Health Initiative also associated high HEI scores with lower prevalence of nuclear cataract (Mares *et al.*, 2010). Consumption of a high-quality diet, measured using an Alternate HEI, also reduced the odds of AMD in a case-control study of men and women diagnosed with advanced AMD (Montgomery *et al.*, 2010).

Dietary carbohydrates have a significant impact on the pathogenesis of both cataract and AMD. Hyperglycemia is thought to cause cataract through polyol pathway disruption, lipid peroxidation, glycation, and glycation-mediated oxidation that could all lead to increased oxidative stress in the lens and cause opacification (Schaumberg *et al.*, 2004; Chiu *et al.*, 2006b). The supply of blood and nutrients, including glucose, to the retina is high. However, glucose is efficiently metabolized as a result of which no glucose is stored in the retina. In cases of AMD, high concentrations of advanced glycation products accumulate in the drusen, probably as a result of impaired metabolism of glucose (Chiu *et al.*, 2006a). Glycemic index (GI), a physiologic measure of the glycemic quality of carbohydrate-containing foods, has also been implicated in the development of cataract and AMD (Jenkins *et al.*, 2002). Foods containing carbohydrates that break down most quickly during digestion have the highest glycemic index. Cross-sectional analysis of the baseline data of the non-diabetic population in the AREDS study showed high dietary GI and high dietary carbohydrate intake to be associated with higher prevalence of nuclear and cortical opacities, respectively (Chiu *et al.*, 2006b). High carbohydrate intake ( $\geq 200$  g/day) was associated with higher odds of cortical but not nuclear opacities, compared with low carbohydrate intake ( $< 185$  g/day) in the Nurses' Health Study cohort (Chiu *et al.*, 2005). Total carbohydrate intake was also associated with pure cortical cataracts in the Melbourne

Visual Impairment project (Chiu *et al.*, 2010). In a prospective study with 12 to 14 years of follow-up, high dietary GI was not found to be related to higher incidence of cataract extraction (Schaumberg *et al.*, 2004).

In a study examining 1036 eyes of participants from the Nurses' Health Study cohort, dietary GI, and not total carbohydrate intake, was significantly related to AMD, specifically with abnormalities in the RPE. Neither total carbohydrate nor dietary GI was related to drusen. Dietary GI may thus be an independent risk factor for AMD (Chiu *et al.*, 2006a). High dietary GI was associated with a higher risk of large drusen, geographic atrophy, and neovascularization when baseline data of the AREDS population was analyzed. There was also a significant positive relation between dietary GI and severity of AMD (Chiu *et al.*, 2007).

In conclusion, adherence to the recommended dietary guidelines may prevent the incidence of cataract and AMD. Consumption of high-carbohydrate diets or high-GI foods could increase the risk of cataract, especially cortical cataract. The risk of AMD may also increase with consumption of high-GI foods.

## Retinitis Pigmentosa

Retinitis pigmentosa (RP) is the leading cause of inherited blindness in the developed world, affecting 50 000 to 100 000 people in the United States and an estimated 1.5 million people worldwide (Berson, 2000; Delyfer *et al.*, 2004). RP refers to a group of inherited retinal disorders that result in the degeneration of rod and cone photoreceptors (Hartong *et al.*, 2006). The disease can be inherited as an autosomal-dominant (30–40% of cases), autosomal-recessive (50–60%), or X-linked (5–15%) trait (Hartong *et al.*, 2006). Mutations in the rhodopsin gene account for ~25% of dominant RP. Mutations in the *USH2A* gene may be the cause of ~20% of the recessive RP (Liu *et al.*, 2007). The *USH2A* gene encodes for the protein usherin and may be important for retinal development and maintaining homeostasis. Mutations in the GTPase regulator gene may account for ~70% of X-linked RP (Hartong *et al.*, 2006). These mutations cause ~30% of all cases of RP. Mutations have also been identified in other genes which include: enzymes of the phototransduction cascade (transducin  $\alpha$ -subunit, guanylate cyclase, cGMP-dependent phosphodiesterase and arrestin); structural or trafficking proteins (peripherin/RD, ABCR); more rarely genes coding proteins involved in vitamin A

metabolism (CRALBP, RPE 65) and phagocytosis of photoreceptor outer segments (McLaughlin *et al.*, 1993; Fuchs *et al.*, 1995; Dryja *et al.*, 1996, 1997; Perrault *et al.*, 1996; Marlhens *et al.*, 1997; Maw *et al.*, 1997; Allikmets, 2000; D'Cruz *et al.*, 2000). Mutations affecting proteins involved in specific biochemical pathways that transduce light can cause hyper-polarization and apoptosis of the rod photoreceptor cells. Clinically, rod cell death translates to night blindness which generally precedes defects in the peripheral visual field, i.e. tunnel vision (Figure 56.3d) by years or even decades. Cones are seldom directly affected by identified mutations. They degenerate secondarily to the rods as the disease progresses, which results in loss of central vision and complete blindness (Delyfer *et al.*, 2004). Many individuals with RP are not legally blind until their forties or fifties, and some even retain some sight throughout life. On the other hand, some RP patients go completely blind during childhood. Since RP affects rods and cones, nutrients that are essential in the normal functioning of these photoreceptor cells will be examined in detail as possible treatment options.

### **Vitamins A and E**

Vitamins A and E are required for the maintenance of normal photoreceptor cell structure and function (Berson, 2000). Vitamin E deficiency results in a chain of oxidative reactions beginning with the highly reactive polyunsaturated fatty acids of the photoreceptor outer segments, followed by massive accumulation of lipofuscin in the RPE. In the absence of vitamin A, the damage resulting from vitamin E deficiency was found to increase (Robison *et al.*, 1979). Vitamin E also protects the stores of vitamin A in the retina from oxidation. Vitamin A deficiency results in loss of photoreceptor cells as the retina requires retinol, an essential structural component of the photoreceptor outer segment membranes (Robison *et al.*, 1980). Further interest in vitamins A and E was based on the observation that RP patients who happened to be taking supplements of vitamin A, vitamin E or both had slower declines in electroretinogram (ERG) amplitudes than those not taking supplements (Berson *et al.*, 1993).

A randomized, controlled, double-masked trial showed that RP patients given high-dose vitamin A (15 000 IU/day) had a significantly slower decline rate in cone ERG amplitude than patients given trace amounts of vitamin A or vitamin E alone. However, the results also suggested that the progression of the disease was faster among patients taking a daily supplement of 400 IU vitamin E

versus those not taking this dose (Berson *et al.*, 1993). Serum vitamin A concentrations were found to be significantly lower in patients given 400 IU of vitamin E (Berson *et al.*, 1993). High vitamin E concentrations may reduce the amount of vitamin A reaching the eye, even though vitamin E may protect vitamin A reserves in the retina. In another study, supplementation of vitamin E (600 IU) in combination with taurine and diltiazem for 3 years decreased the rate of visual field loss in RP patients (Pasantes-Morales *et al.*, 2002). However, the authors attributed the positive effect on RP to taurine/diltiazem combination, while vitamin E was said to protect against any gastric mucosal injury that could be caused by diltiazem. Vitamin E supplementation has been shown to benefit patients with rare forms of RP, which are associated with diseases such as Bassen-Kornzweig disease (low plasma concentrations of apolipoprotein B) and familial isolated vitamin E deficiency (Bishara *et al.*, 1982; Yokota *et al.*, 1997).

Many clinicians recommend that adults with early or middle stages of RP take vitamin A supplementation of 15 000 IU/day and avoid high-dose vitamin E supplementation. No toxic effects were observed for this dose and duration of vitamin A supplementation (Berson *et al.*, 1993). It should be noted that doses of 25 000 IU or more over the long term are considered toxic and, because of the potential for birth defects, women who became pregnant were advised to not take vitamin A at such high doses (Institute of Medicine, 2001).

### **Omega-3 Fatty Acids**

DHA is thought to be important for photoreceptor function since photoreceptor cell membranes containing rhodopsin and cone opsins have very high concentrations of this fatty acid (Fliesler and Anderson, 1983). Red blood cell membrane phosphatidylethanolamine (RBC PE) contents of DHA reflect the levels of DHA in the retina and are on an average lower in patients with RP than in unaffected individuals (Schaefer *et al.*, 1995; Hoffman *et al.*, 2004a). In a randomized, placebo-controlled study in individuals with X-linked RP ( $n = 44$  males), DHA supplementation (400 mg/day) did not slow the progression of the disease. Similar results were obtained in another randomized, double-blind, controlled study of DHA supplementation (1200 mg/day) for 4 years in RP patients who were also given 15 000 IU/day of vitamin A (Berson *et al.*, 2004a). In the same study subgroups were created based on their use or non-use of vitamin A prior to enter-

ing the study. It was found that, in patients not on vitamin A prior to the study, addition of DHA slowed the course of the disease for the first 2 years. This was not, however, observed in the 3- or 4-year follow-up or in patients already on vitamin A prior to entering the study. Also, in the entire control group, those patients eating  $\geq 0.2$  g/day of omega-3-rich oily fish showed significantly less loss of central visual field sensitivity over 4 years (Berson *et al.*, 2004b). The above studies also found that patients with low RBC PE DHA levels (<5% of total RBC PE fatty acids) had a faster rate of decline in visual field sensitivity than those with high RBC PE DHA levels (Berson *et al.*, 2004b; Hoffman *et al.*, 2004a). This observation has led to the recommendation that adults already taking vitamin A supplements should add one or two 3-oz (85-g) servings of omega-3-rich fish per week to their diet to maintain RBC PE DHA levels at 5% of RBC PE fatty acids. The authors estimated that the combination of vitamin A with an oily fish diet would, on average, provide a 60–70% slowing per year that would result in a total of almost 20 years of visual preservation for patients who start this regimen in their mid-30s. The proposed mechanism by which DHA may slow the progression of RP is through enhanced delivery of vitamin A to the remaining cones. Alternatively, vitamin A supplementation may facilitate incorporation of DHA into the retina. Adverse effects on retinal function were observed in RP patients on vitamin A prior to the study and taking 1200 mg/day of DHA for >2 years (Berson *et al.*, 2004b). Therefore, recommendations have been made that patients with typical RP should not take 1200 mg of DHA by capsules for more than 2 years or eat too much oily fish while taking vitamin A supplements (Berson *et al.*, 2004b).

### Lutein

As described in the section on AMD, lutein, together with zeaxanthin, forms macular pigment in the posterior, central region of the retina called the macula. Since this region has the highest concentration of cones and is responsible for sharp, central vision, it was logical to examine the benefits of lutein in RP patients. In the vitamin A clinical trial described in the previous section (Berson *et al.*, 1993), patients taking vitamin A who were also in the highest quintile intake of lutein (3.5–13 mg/day) had a slower rate of decline in the visual field area compared with those in the lower four quintiles (Berson *et al.*, 2010). A beneficial trend was also seen when relating

ERG amplitude to quintile of lutein intake. In the first lutein intervention trial for RP, lutein supplementation (10 mg/day for 12 weeks followed by 30 mg/day for 12 weeks) improved central visual field in a randomized, cross-over, placebo-controlled, double-blind study design in a population of only 34 adults (Bahrami *et al.*, 2006). In another double-blind RCT in 225 non-smoking RP patients aged 18 to 60 years, 4 years of supplementation with lutein (12 mg/day) in addition to vitamin A slowed the loss of mid-peripheral visual field sensitivity (Berson *et al.*, 2010). Maximum slowing of mid-peripheral sensitivity also occurred among those with the highest serum lutein concentration and greatest increase in MP density. However, no significant effect of this intervention was observed on central field sensitivity. The detectable benefit of lutein supplementation preserving mid-peripheral function but not central function in RP may reflect an increased requirement for antioxidants in the photoreceptor outer segments, which are the most impaired. No toxic effects of lutein supplementation were observed in this study. Therefore, lutein supplementation may benefit non-smoking RP patients taking vitamin A. Follow-up of RP patients taking lutein and vitamin A (15000 IU/day) along with a diet containing average amounts of omega-3 fatty acids ( $\sim 0.2$  g/day) is needed to confirm preservation of the mid-peripheral visual field (Berson *et al.*, 2010).

## Beyond Eye Disease

### Dry Eye Syndrome

Dry eye syndrome (DES) is a condition where the eyes do not produce tears, or the tears are not of the correct consistency and evaporate too quickly. This produces dry eyes and increases the risk of inflammation. Published studies indicate that up to 20% of adults aged 45 years or more experience dry eye symptoms (Brewitt and Sistani, 2001). The incidence was observed to increase significantly with age and to be significantly higher in women (Moss *et al.*, 2008). DES can be either evaporative or aqueous deficient, both of which can result in increased tear osmolarity. While the use of artificial tears is the main choice of treatment for DES and allows for temporary relief, it does not resolve the underlying cause.

Recent studies suggest that intake of omega-3 and omega-6 fatty acids may be effective in treating the underlying causes of DES. These fatty acids may improve the lipid layer of the tear film, thereby reducing evaporation. Furthermore, both omega-3 and omega-6 fatty acids are

known to have anti-inflammatory properties (Simopoulos, 2000). In support of omega-3 fatty acids, intake of a high ratio of omega-3 to omega-6 fatty acids was reported to be related to a decrease in the incidence of DES in women (Miljanovic *et al.*, 2005). Pinna *et al.* (2007) evaluated the effect of daily supplementation with two omega-6 fatty acids, linoleic acid (28.5 mg) and  $\gamma$ -linolenic acid (15 mg), for 180 days on meibomian gland dysfunction (MGD), a common cause of DES (McCulley *et al.*, 1982; Driver and Lemp, 1997; Pinna *et al.*, 2007). Supplementation with linoleic acid and  $\gamma$ -linolenic acid caused significant reductions in secretion turbidity and meibomian gland obstruction. The same study also reported that eyelid hygiene alone caused significant reduction in eyelid edema, corneal staining, secretion turbidity, and meibomian gland obstruction. Eyelid hygiene combined with omega-6 fatty acid supplementation significantly reduced all of the above clinical symptoms. Supplementation with omega-6 fatty acids along with proper eyelid hygiene can have a significant positive impact on treating dry eye symptoms.

Sea buckthorn (SB) oil is rich in lipophilic antioxidants, such as vitamin E and carotenoids, while SB seed oil contains high proportions of omega-3 and omega-6 fatty acids (St. George and Cenkowski, 2007). In view of its antioxidant and essential fatty acid composition, the potential of SB oil to relieve DES symptoms was evaluated in a randomized, double-blinded, parallel trial in women and men aged 20 to 75 years with DES. SB oil (2 g/day for 3 months) attenuated the increase in tear-film osmolarity during the cold season and had a positive impact on symptoms of DES (Larmo *et al.*, 2010). The beneficial effect of SB oil can be attributed to the anti-inflammatory properties of the oils contained in SB. The only omega-6 fatty acid in SB oil used in this study was linoleic acid. All previous reports on beneficial effects of linoleic acid have been in combination with  $\gamma$ -linolenic acid (Barabino *et al.*, 2003; Macrì *et al.*, 2003; Pinna *et al.*, 2007). Also, the carotenoids and vitamin E in SB oil may protect the eye from oxidative damage, which leads to activation of inflammatory cascades. Antioxidant supplements containing vitamin E and carotenoids have previously been shown to benefit dry eye symptoms (Blades *et al.*, 2001; Peponis *et al.*, 2002).

In conclusion, omega-3 fatty acids, omega-6 fatty acids (linoleic and  $\gamma$ -linolenic acids), and antioxidant-rich oils such as SB oil may be beneficial in alleviating dry eye symptoms.

## Visual Function Phytonutrients

Bilberries and blackcurrants have been evaluated for their role in visual function as they contain high concentrations of phytonutrients. There is growing interest in studying bilberries to improve visual function after anecdotal reports stated that World War II pilots improved their night vision by eating bilberry jam. The medicinal property of bilberry (*Vaccinium myrtillus*) can be attributed to a class of plant pigments called anthocyanosides, which give purple coloration to fruits, leaves, and stems (Muth *et al.*, 2000; Canter and Ernst, 2004). Anthocyanosides are potent antioxidants that may slow the retinal angiopathy that occurs in AMD and diabetic retinopathy (Trevithick and Mitton, 1999). The possible mechanism of actions on visual apparatus may be the accelerated resynthesis of rhodopsin, modulation of retinal enzyme activity, and improved microcirculation (Canter and Ernst, 2004). In a systematic review of placebo-controlled trials evaluating the effects on night vision of anthocyanosides extracted from bilberry (Canter and Ernst, 2004), four RCTs found no effect (Levy and Glovinsky, 1998; Zadok *et al.*, 1999; Muth *et al.*, 2000; Maysers and Wilhelm, 2001). A fifth RCT and seven non-RCTs reported positive effects on outcome measures related to night vision (Canter and Ernst, 2004). One of the possible reasons for contradictory results could be the differences in the dose of anthocyanosides, which ranged from 36 mg to 2880 mg. Also, the composition of anthocyanosides in these studies was different as the bilberries were cultivated in different geographic locations. Eleven out of 12 studies enrolled subjects with normal or above average eyesight, which may have caused a ceiling effect resulting in no positive effect of the anthocyanosides intervention. The effects on subjects suffering impaired night vision due to pathological eye conditions have not been evaluated. A double-blind, placebo-controlled RCT of anthocyanosides extracted from blackcurrant (*Ribes nigrum*) reported a positive effect on visual fatigue associated with continuous viewing of computer monitors and other video display screens (Nakaishi *et al.*, 2000).

There is not enough data to positively conclude that anthocyanosides improve night vision. More controlled trials of bilberry anthocyanosides in subjects with impaired night vision will be necessary to confirm the positive effects. However, adding anthocyanoside-rich foods to the diet may be advisable as they have not been shown to have any harmful effects.

### Lutein

The role of macular pigment in protecting the retina, and the beneficial effect of lutein supplementation in increasing MP density, are well established (see AMD section). Data are also accumulating that MP may improve visual function. There are two hypotheses that explain the mechanism by which MP improves visual function (Wooten and Hammond, 2002). The acuity hypothesis states that MP reduces the effect of chromatic aberration. The visibility hypothesis states that MP may improve vision through the atmosphere by preferentially absorbing blue haze (short-wave dominant air light that produces a veiling luminance when viewing objects at a distance). It has also been suggested that MP can improve glare disability and photostress recovery because of the light-filtering properties of MP (Stringham and Hammond, 2007). Some biological mechanisms, such as improvement in neuronal signaling efficiency in the eye, have also been suggested by which lutein and zeaxanthin may improve visual function (Stringham and Hammond, 2005). Since lutein intake has been shown to improve MP density, it has been suggested that lutein supplementation may improve visual function measures.

Six months of supplementation with 12 mg/day of lutein was shown to increase MP density in healthy subjects with a mean age of 23 years, and improved visual performance in glare function tests (Stringham and Hammond, 2008). Lutein has been reported to protect against the detrimental effects of long-term computer display light exposure in healthy subjects aged 22 to 30 years of age (Ma *et al.*, 2009). In this study, 12 weeks of supplementation with 12 mg/day of lutein was shown to improve contrast sensitivity. Lutein supplementation (5 mg) in combination with zeaxanthin (1 mg) and black-currant extract (200 mg) was also shown to reduce symptoms of visual fatigue associated with visual proof-reading tasks in healthy subjects aged 22 to 45 years (Yagi *et al.*, 2009).

The effect of lutein supplementation on visual performance has also been evaluated in patients with eye disease. In a double-blind, placebo-controlled study involving cataract patients ( $n = 17$ ), supplementation with 15 mg lutein three times a week resulted in improved visual acuity and glare sensitivity (Olmedilla *et al.*, 2003). In patients with retinal degeneration, lutein supplementation (20–40 mg/day, 26 weeks) improved visual acuity and mean visual-field area, which began 2–4 weeks after the interven-

tion but plateaued at 6–14 weeks (Dagnelie *et al.*, 2000). RCTs involving AMD patients have shown that lutein supplementation, ranging in dose from 8 mg to 15 mg, improved dark adaptation, visual acuity, foveal sensitivity, contrast sensitivity and glare recovery (Falsini *et al.*, 2003; Richer *et al.*, 2004; Cangemi, 2007). In conclusion, dietary intake of lutein seems to improve visual function.

### DHA

Long-chain polyunsaturated fatty acids (LCPUFA) are essential for the normal development of vision (Neuringer *et al.*, 1984). The earliest evidence for the role of DHA in visual function was the observed improvement in visual acuity in preterm infants fed a formula supplemented with DHA (Carlson *et al.*, 1994). The photoreceptor outer segment membranes of the retina contain high concentrations of DHA, which is further reason to investigate the role of DHA in improving visual function (Fliesler and Anderson, 1983). Maternal DHA intake during the prenatal period was shown to play a critical role in the early development of the visual system in children well into the school-age years (Jacques *et al.*, 2011). A number of observational studies on lactating mothers and their infants found that high human milk and/or infant plasma DHA levels were associated with better visual acuity (Innis *et al.*, 2001; Innis, 2003; Jørgensen *et al.*, 2001). Similar associations were also observed in formula-fed infants (Jørgensen *et al.*, 1996; Birch *et al.*, 1998, 2005; Hoffman *et al.*, 2003).

Numerous RCTs have been done to evaluate the effects of supplementation with DHA, as well as ARA, another omega-3 fatty acid, on visual acuity in term infants (Hoffman *et al.*, 2009). A majority of the RCTs reported improved visual acuity in infants supplemented with DHA/ARA ( $\geq 0.3\%/0.64\%$  of total fatty acids) starting near birth to 12 months in most studies (Makrides *et al.*, 1995; Birch *et al.*, 1998, 2002, 2010; Hoffman *et al.*, 2003, 2004b). No improvements in visual acuity were observed with DHA/ARA supplementation in other RCTs (Makrides *et al.*, 1995; Auestad *et al.*, 1997, 2001, 2003). The probable reasons for null effects of some RCTs could relate to the differences in the supplemented doses of DHA/ARA, the duration of supplementation, age of the infant at the time of assessment, the test method used, and the characteristics of the population studied. Trials that used supplemental doses of at least 0.32% DHA (close to the average amounts found in human milk) and

at least 0.64% ARA were more likely to find positive outcomes. The timing of supplementation was also crucial, as DHA supplementation at 1.5, 4, 9, and 12 months improved visual acuity but not at 6 months. This was hypothesized to be due to this being an age at which visual development had temporarily plateaued (Birch *et al.*, 1998). A strong, positive, linear correlation was observed between the length of feeding DHA + ARA and visual function at 1 year of age.

Both DHA and ARA are extremely important for the development of vision in term infants. Several expert groups, such as the American Dietetic Association, the WHO Expert Panel, the European Food and Safety Authority, and the World Association of Perinatal Medicine, recommend that infants who cannot be breast-fed must receive formula supplemented with both DHA and ARA (Hoffman *et al.*, 2009). Infants should receive at least 0.32% fatty acids from DHA and 0.47% ARA, which are the average worldwide levels found in human milk (Brenna *et al.*, 2007).

## Future Directions

Future research needs to take into consideration that a particular nutrient's benefit may be related to the stage at which the disease occurs. It is likely that some eye diseases, particularly those that are age-related, develop over many years and thus the timing of intervention may have a significant impact on the progression of the disease. Studies that evaluate nutritional interventions for prevention of eye disease and not treatment alone are also warranted. More studies are also needed to evaluate the impact of dietary patterns on eye diseases as nutrients are normally consumed as part of a diet and not in isolation. Dietary intervention studies that incorporate nutrient-rich foods rather than supplemental forms of the nutrients need to be done. The nutrient dosage is also a crucial factor in determining the effect on disease progression. At very high doses certain nutrients may have a negative effect. For example, ~1000 mg of vitamin C was related to increased risk of cataract; high intake of omega-6 fatty acids was related to increased risk of AMD; and high vitamin E supplementation was related to progression of RP. Intervention studies that evaluate nutrients at doses found in foods should also be done to determine the ideal beneficial levels. Research evaluating these factors may already be ongoing; in the meantime, eating a healthy diet rich in vitamins C and E, B vitamins, carotenoids, especially

lutein and zeaxanthin, omega-3 fatty acids, and zinc is recommended to maintain visual health.

## SPECIALIZED NUTRITION SUPPORT

VIVIAN M. ZHAO<sup>1</sup>, PharmD AND THOMAS R. ZIEGLER<sup>1, 2</sup>, MD

<sup>1</sup>Emory University Hospital, Atlanta, Georgia, USA

<sup>2</sup>Emory University School of Medicine, Atlanta, Georgia, USA

### Summary

Malnutrition is common in hospitalized patients and is associated with adverse clinical outcomes. A variety of factors common in hospital patients contribute to protein-energy malnutrition and loss of essential vitamins, minerals, and electrolytes. Assessment of nutritional status requires a comprehensive evaluation and integration of medical and surgical history, current clinical and fluid status, dietary intake patterns, body weight changes, gastrointestinal symptoms, physical examination, and selected biochemical tests. Current guidelines suggest that goals for caloric intake between 20 and 25 kcal/kg/day and protein/amino acids between 1.2 and 1.5 g/kg/day are appropriate for most adult hospital patients. Adequate vitamins, minerals, electrolytes, essential amino acids, and essential fats must be provided based on recommended allowances for healthy individuals; however, true requirements in subtypes of hospital patients are unknown. The gastrointestinal (enteral) route should be the first choice for specialized feeding in the hospital setting, with parenteral nutrition modalities, via peripheral or central vein, reserved for those patients in whom adequate enteral nutrition is not possible. Metabolic, infectious, and mechanical complications can occur with both enteral and parenteral feeding modalities, which can be prevented or diminished with careful monitoring and adherence to current standards of practice. Relatively few rigorous, randomized controlled clinical trials (RCTs) have been conducted within the field of specialized feeding in the hospital setting, and many areas of uncertainty remain. However, numerous, large, multicenter RCTs are in progress and will help to define optimal use of these important adjunctive nutritional therapies over the next several years.

### Introduction

The incidence and prevalence of malnutrition, which includes significant loss of lean body mass and/or depletion of essential vitamins and minerals, are quite high in hospitalized patients (Nathens *et al.*, 2002; Luo *et al.*, 2008; McClave *et al.*, 2009; Singer *et al.*, 2009; Barker

*et al.*, 2011; De Luis *et al.*, 2011). Based on various observational studies of total hospital admissions and in intensive care unit (ICU) settings, malnutrition (depletion of essential micronutrients and/or loss of significant lean body mass or body weight) may occur in 20% to as high as 60% of patients (Giner *et al.*, 1996; Pirlich *et al.*, 2006; Barker *et al.*, 2011; De Luis *et al.*, 2011). Further, the

incidence of malnutrition worsens over time in patients requiring a prolonged hospital stay, in part due to inadequate ad libitum food intake and repeated catabolic insults (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; Villet *et al.*, 2005; Pirlich *et al.*, 2006; Patel and Martin, 2008). Protein-energy malnutrition prior to and inadequate nutritional intake during hospitalization are each associated with higher rates of morbidity and mortality (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; Schneider *et al.*, 2004; O'Brien *et al.*, 2006; Zaloga, 2006). The importance of adequate macro- and micro-nutrient intake for optimal cellular, immune, and organ function is outlined elsewhere in this volume. In highly catabolic ICU patients, protein-energy depletion has been associated with higher rates of hospital-acquired infection, poor wound healing, and skeletal muscle weakness (Schneider *et al.*, 2004; O'Brien *et al.*, 2006; Zaloga, 2006; McClave *et al.*, 2009; Singer *et al.*, 2009). Multiple pathophysiologic factors common in hospital patients put these individuals at risk for generalized protein-energy malnutrition and/or micronutrient depletion (Ziegler, 2009; see Box 57.1). The specialized enteral and parenteral nutrition support modalities that are currently available and that are the subject of this chapter have been developed to support vital cell and organ functions, muscle capacity and wound healing. Both enteral nutrition (EN) and parenteral nutrition (PN) formulations provide fluid, calories (as various carbohydrate, protein/amino acid, and fat sources), essential amino acids and fats, electrolytes, vitamins, and minerals, as outlined below.

## Nutritional Assessment

Important aspects of comprehensive nutritional assessment, which involves integration of multiple factors, are outlined in Box 57.2 (Ziegler, 2009). There is currently no “gold standard” for nutritional assessment in hospital patients. For example, blood concentrations of albumin and pre-albumin, which may be useful in outpatient or epidemiologic settings, may be markedly decreased by inflammation, infection, decreased hepatic synthesis, and/or increased clearance from blood in hospital settings. Levels of these proteins in plasma may also be increased during fluid depletion or decreased with fluid overload. Blood concentrations of specific vitamins and minerals, as with blood electrolytes, are useful to follow in certain at-risk patients, but the possibility of changes due to fluid

### BOX 57.1 Major pathophysiologic factors which contribute to malnutrition in hospital patients

- Decreased spontaneous food intake prior to or during hospitalization (e.g. due to anorexia, fatigue, gastrointestinal symptoms, NPO status).
- Increased concentrations of catabolic hormones and cytokines (e.g. cortisol, catecholamines, tumor necrosis factor- $\alpha$ , interleukins).
- Decreased blood levels of anabolic hormones (e.g. insulin-like growth factor-I, testosterone).
- Resistance to anabolic hormones with consequent decreased substrate utilization (e.g. insulin resistance).
- Abnormal nutrient losses (e.g. wounds, drainage tubes, renal replacement therapy, diarrhea, emesis, polyuria).
- Decreased protein synthesis due to physical inactivity (e.g. bed rest, chemical paralysis).
- Drug-nutrient interactions (e.g. diuretics, pressor effects, corticosteroids).
- Increased energy, protein and/or specific micronutrient requirements (e.g. with infection, trauma, oxidative stress).
- Iatrogenic factors (prolonged periods of inadequate enteral or parenteral nutrient provision in relation to metabolic requirements).

NPO = *nil per os* (enteral food restriction due to diagnostic tests or therapeutic procedures).

status and inter-organ shifts necessitate serial monitoring to guide repletion strategies. Body weight often changes dramatically due to fluid status alterations.

A simple method to assess nutritional status, termed “subjective global assessment” (SGA), has been validated as a way to assess nutritional status and to predict clinical outcomes in stable patients without marked fluid shifts (Detsky *et al.*, 1987; Norman *et al.*, 2005). The SGA incorporates patient history regarding body weight loss, usual dietary intake, functional capacity, gastrointestinal symptoms, and physical-examination evidence of malnutrition (loss of muscle or fat mass, presence of edema) to classify patients as well nourished, moderately or suspected of being malnourished, or severely malnourished (Detsky *et al.*, 1987; Norman *et al.*, 2005). In Europe, a method of nutritional risk screening is commonly utilized in hospital settings, which involves scoring risk based on BMI, decrease in % of usual food intake, body weight changes,

### BOX 57.2 Important steps in nutritional assessment of hospitalized patients

- Review past medical and surgical history, tempo of current illness and expected hospital course.
- Determine dietary intake pattern and previous use of specialized nutrition support.
- Obtain body weight history.
- Perform physical examination with attention to fluid status, organ functions, and evidence of protein-energy malnutrition or lesions consistent with vitamin/mineral deficiency.
- Evaluate gastrointestinal tract function to evaluate ability to tolerate enteral feeding.
- Determine ambulatory capacity, mental status.
- Measure or evaluate standard blood tests (organ function indices, electrolytes, pH, triglycerides, and selected vitamins and minerals if at risk for depletion).
- Estimate calorie and protein requirements.
- Evaluate enteral and parenteral access for nutrient delivery.

Patients with involuntary body weight loss of >5–10% of usual body weight in the previous several weeks or months, patients weighing less than 90% of their ideal body weight, or those with a body mass index (BMI) less than 18.5 kg/m<sup>2</sup> should be carefully evaluated for malnutrition.

age, and whether or not the patient is severely ill (Rasmussen *et al.*, 2010). More details regarding comprehensive nutritional assessment can be accessed in the online material from a review by Ziegler (2009).

## Nutrient Intake Goals

Guidelines for energy and protein/amino acid intake in adult hospital patients have been outlined by major professional societies (Heyland *et al.*, 2003; Mirtallo *et al.*, 2004; Kreymann *et al.*, 2006; McClave *et al.*, 2009; Singer *et al.*, 2009). Specific approaches for pediatric patients are beyond the scope of this chapter, but have been recently published (Koletzko *et al.*, 2005; Mehta *et al.*, 2009). It is important to note that energy (calorie) needs in hospitalized patients, especially those who are critically ill, may vary considerably due to serial changes in clinical conditions (Kreymann *et al.*, 2006; McClave *et al.*, 2009; Singer *et al.*, 2009). Optimal caloric and protein/amino acid requirements in hospital patients are unknown due to a relative lack of rigorous, randomized, controlled clinical

trials (McClave *et al.*, 2009; Singer *et al.*, 2009; Yarandi *et al.*, 2011).

Resting energy expenditure (REE) can be determined using serial bedside metabolic cart measurements (indirect calorimetry), but technical issues can cause inaccuracies (Anderegg *et al.*, 2009; McClave *et al.*, 2009). REE can be estimated using standard predictive equations, most commonly the Harris-Benedict equation, which incorporates the patient's age, gender, weight, and height (McClave *et al.*, 2009; Ziegler, 2009). Unfortunately, this method may over- or underestimate REE in certain patients when clinical conditions are changing and/or with body weight changes due to changes in fluid status (Anderegg *et al.*, 2009; Ziegler, 2009). Recently published European and American clinical practice guidelines suggest that an adequate energy goal for most patients can be estimated at 20–25 kcal/kg/day, which is approximately equivalent to measured or estimated REE  $\times$  1.0–1.2. Ongoing RCTs are designed to better define caloric dosing guidelines in ICU patients, as data are particularly conflicting in these settings. Pre-hospital and pre-operative body weight should be used in energy intake estimates because measured body weight in the hospital (especially in the ICU) may reflect fluid status and is typically much higher than recent “dry” weight. An alternative is to use ideal body weight derived from routine tables or equations if recent dry weight is unavailable. In obese subjects, adjusted body weight should be used in the Harris-Benedict equation (Ziegler, 2009).

Studies conducted in the 1980s in ICU patients indicate that protein loads of more than 2.0 g/kg/day are not efficiently utilized for protein synthesis and the excess is oxidized and contributes to azotemia (Shaw *et al.*, 1987; Streat *et al.*, 1987). The commonly recommended protein/amino acid dose range is 1.2–1.5 g/kg/day for most individuals with normal renal and hepatic function (50–100% above the RDA of 0.8 g/kg/day); although some guidelines recommend higher doses (2.0–2.5 g/kg/day) in specific conditions such as burns and in patients requiring renal replacement therapy (McClave *et al.*, 2009; Singer *et al.*, 2009; Ziegler, 2009). The administered amino acid dose should be adjusted downward depending on the degree and tempo of azotemia (in the absence of renal replacement therapy). In patients with evidence of acute liver failure and encephalopathy (who are at risk for amino acid-induced increases in arterial blood ammonia levels), it may be prudent to provide lower doses of PN amino acids (0.6–1.2 g/kg/day), based on the degree of

liver dysfunction, although protein restriction is not currently recommended in stable patients with chronic liver failure.

## Enteral Nutrition Support

Whenever possible, enteral nutrition (EN) in hospital patients should consist of oral diets of regular foods as tolerated, supplemented as indicated with the wide variety of commercially available flavored oral liquid formulations or solid nutrient-rich products. Most hospital patients should also receive a complete multivitamin–mineral product to cover needs, although this recommendation is not evidence-based. Enteral tube feeding is the preferred route of nutritional delivery for patients who have a functional gastrointestinal (GI) tract but are unable to maintain adequate nutrient intake with oral diet alone.

EN is more physiologic, is associated with less severe infectious, metabolic, and mechanical complications, and is less costly than PN (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; McClave *et al.*, 2009). Specific indications for EN in adults and children are described in clinical practice guidelines (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; Heyland *et al.*, 2003; Mirtallo *et al.*, 2004; Koletzko *et al.*, 2005; Kreymann *et al.*, 2006; ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009; McClave *et al.*, 2009; Mehta *et al.*, 2009; Singer *et al.*, 2009). Although not evidence-based, common contraindications to EN include inability to gain access to the GI tract, mechanical or paralytic intestinal obstruction, intractable vomiting, severe diarrhea, diffuse peritonitis, paralytic ileus, bowel ischemia, and hemodynamic instability requiring mid- to high-dose vasopressors (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; McClave *et al.*, 2009; Singer *et al.*, 2009; Ziegler, 2009).

EN administration must be individualized to each patient's specific needs. In order to determine the appropriate EN delivery method, GI tract integrity and functional capacity, presence and degree of malnutrition, underlying disease states, and patient tolerance must be assessed prior to and following the initiation of tube feeding. Gastrointestinal, mechanical, and metabolic complications, as well as pulmonary aspiration of feeds, can occur with enteral tube feeding. It is therefore essential to monitor enterally fed patients closely in order to identify potential complications (ASPEN Board of Directors and

Enteral Nutrition Practice Recommendations Task Force, 2009).

### **Routes for Enteral Tube Feeding**

Successful enteral tube feeding is in part dependent upon careful selection of the appropriate enteral access device and placement technique. Understanding the indications, contraindications, advantages, and disadvantages of each different access device for enteral feedings will allow clinicians to select the best delivery method for patients (Table 57.3). Feeding tubes are usually made of polyurethane or silicone with various diameters, often designated as small-bore (5–12 French) or large-bore ( $\geq 14$  French) (Minard, 1994). The tubes are typically classified according to insertion site (nasal, oral, percutaneous) and location of the terminal end of the enteral device (stomach, duodenum, proximal small bowel) (Table 57.1). Nasoenteral (NE) tubes are often inserted blindly at the bedside by experienced personnel or with the assistance of endoscopy or fluoroscopy. Gastrostomy and jejunostomy tubes can be placed endoscopically, fluoroscopically, laparoscopically, and percutaneously. Surgeons may also place the feeding tube intraoperatively when patients have pre-existing moderate or severe malnutrition and/or are anticipated to ingest inadequate amounts of oral dietary intake for a prolonged period of time after operation (Minard, 1994). Radiographic verification of correct placement of a blindly inserted small- or large-bore feeding tube is mandatory before administering feeding and medications (Minard, 1994; Metheny and Meert, 2004; Baskin, 2006; Metheny *et al.*, 2007). Nasal or oral tubes are usually placed for short-term (<4–6 weeks) use, whereas tube enterostomies are typically placed for long-term ( $\geq 4$  weeks) enteral nutrition support (Minard, 1994; Heyland *et al.*, 2003; Metheny and Meert, 2004; Baskin, 2006; Metheny *et al.*, 2007).

The selection of an enteral access route depends on patient-specific factors, including co-morbidities, GI anatomy with consideration of prior surgery, gastric and intestinal motility and function, risk of aspiration, and the anticipated duration of therapy (Minard, 1994; Heyland *et al.*, 2003; Metheny and Meert, 2004; Baskin, 2006; Metheny *et al.*, 2007; ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009). Gastric feedings generally require a functional stomach without delayed gastric emptying, obstruction, or fistula. Small bowel feedings are most appropriate for patients with gastroparesis, gastric outlet obstruction, pancreatitis, known esophageal reflux, and high aspiration

**TABLE 57.1** Advantages and disadvantages of different enteral nutrition access routes

Route	Indications	Advantages	Disadvantages
<i>Nasoenteric (NE) tube feeding (short term, &lt;4 weeks)</i>	Normal gastric emptying	Easy to place tube	Highest aspiration risk
Nasogastric (NG)	No esophageal reflux	Larger reservoir capacity in stomach	Tube displacement
Nasoduodenal (ND)	Gastroparesis	Lower aspiration risk than NG	May require endoscopic placement
Nasojejunal (NJ)	Impaired gastric emptying	May initiate feedings immediately after injury or operation	Tube displacement
	Esophageal reflux		Potential GI intolerance (bloating, cramping, diarrhea)
	See ND		Potential aspiration
Gastrostomy	Gastric dysfunction	Lower aspiration risk than NG	
	Pancreatitis		
<i>Tube enterostomy (long-term feeding required)</i>	See NG	Can be placed during GI surgery	Surgery is needed for surgical gastrostomies
Percutaneous <sup>a</sup> esophagostomy, gastrostomy (PEG)	No NE route available	No surgery needed for PEG	Requires stoma care
Operative laparoscopic <sup>b</sup> gastrostomy	Persistent dysphasia	PEG less costly than surgical gastrostomy	Potential complications: <ul style="list-style-type: none"> <li>◦ aspiration risk</li> <li>◦ stoma site skin infection</li> <li>◦ skin excoriation at stoma site</li> <li>◦ fistula following tube removal</li> </ul> Requires stoma care
Jejunostomy	See NJ	Lower tube occlusion risk with large-bore tube	
Percutaneous <sup>a</sup> endoscopic jejunostomy (PEJ)	High aspiration risk	Larger reservoir capacity	Tube occlusion with small-bore tube or needle catheter
Needle catheter jejunostomy (NCJ)	Esophageal reflux	Lower aspiration risk	Surgery required for jejunostomy placement
Operative laparoscopic jejunostomy	Inability to access upper GI tract (esophagus, stomach, duodenum)	Can be placed during GI surgery	Potential complications: <ul style="list-style-type: none"> <li>◦ GI intolerance</li> <li>◦ stoma site infection</li> <li>◦ skin excoriation at stoma site</li> <li>◦ fistula following tube removal</li> </ul>

<sup>a</sup>Percutaneously placed tubes avoid risks of surgery and general anesthesia; however, may require endoscopy, abdominal ultrasound, or radiologic procedure with contrast media. Endoscopy may be difficult in the presence of a tumor or stricture, altered anatomy, or severe obesity.

<sup>b</sup>Laparoscopically or operatively placed tubes require general anesthesia; however, patients may be able to return home on the same day after the procedure.

risk. Although nasojejunal (NJ) feedings are not required unless patients have gastric feeding intolerance, small bowel feedings have been associated with a significant reduction in ventilator-associated pneumonia in some but not all studies (ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009). Combined gastro-jejunal tubes are indicated when gastric decompression is needed, but jejunal feeding is possible, as occurs in patients who have impaired gastric motility but normal small-bowel motility and absorption (Metheny and Meert, 2004; ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009).

### **Tube Feeding Formula Selection**

Once an enteral route has been established for the initiation of tube feeding, an appropriate formula must be selected. There are numerous commercially available products, which fall into one of the following categories: standardized or polymeric, hydrolyzed, caloric dense, fiber-enriched, fat-modified, disease-specific, immune-modulated, and powdered formulas, to meet the various needs of most patients (Table 57.2). EN formulas vary in terms of caloric density, composition of macronutrients, macronutrient digestibility, viscosity, osmolarity, and cost. The polymeric formulas contain intact protein, complex carbohydrates, long- and medium-chain triglycerides, vitamins, minerals, and trace elements. All formulations are lactose- and gluten-free, and most are low residue as well as isotonic or slightly hypertonic, with a caloric content ranging from 1 to 2 kcal/mL.

Because of the variations between enteral formulas, a systematic comparison of the patient-specific variables and nutrient needs with the specific characteristics of the available formulas can be used to select an appropriate formula that will most approximate the individual's estimated requirements. Patient-specific variables include clinical status, nutritional status and requirements, metabolic abnormalities, digestive and absorptive capacity of the GI tract, disease state, expected outcomes, and possible routes available for administration. The simple correlation of a medical diagnosis with a specifically marketed formula can result in the administration of inappropriate nutrition support and an increased cost of nutrient provision.

Most hospital patients can be safely fed with standard, inexpensive, polymeric, enteral formulas (Table 57.2). The more calorically dense mixtures are useful for patients requiring fluid restriction. The addition of soluble fiber in enteral products is increasingly common in commercial

formulas and may prevent constipation or control diarrhea. Available research in the role of fiber-enriched formulas in the management of diarrhea, however, has not demonstrated consistent benefit, probably because a myriad of factors can cause diarrhea in hospital patients (e.g. antibiotics) (Yang *et al.*, 2005). The polymeric formulas are usually tolerated as well as, or better than, much more expensive hydrolyzed formulas (Ford *et al.*, 1992; Mowatt-Larssen *et al.*, 1992). Hydrolyzed formulas, which contain hydrolyzed casein or whey as the protein source (also known as oligomeric, semi-elemental, or peptide-based), are designed for patients with malabsorption and pancreatic insufficiency. Clinical data documenting the advantages of routine use of peptide-based formulas are limited; however, their use in patients with acute pancreatitis in one study showed a significantly shorter hospital length of stay when compared with polymeric formulas (Tiengou *et al.*, 2006).

Commercial enteral formulas have been developed for use in disease-specific conditions such as diabetes, renal failure, pulmonary disease, and infection. Diabetes-specific formulas are developed with lower amounts of carbohydrate and higher amounts of fat as energy sources to improve glycemic control; some studies show that their use in hospitalized diabetic patients resulted in improved blood glucose control and decreased insulin requirements (Leon-Sanz *et al.*, 2005; Pohl *et al.*, 2005; Alish *et al.*, 2010). Renal-specific products are available for patients with different degrees of renal failure (presence or absence of renal replacement therapy) (Table 57.2). Several RCTs suggest that formulas containing increased amounts of antioxidant nutrients (e.g. vitamins C and E) and anti-inflammatory lipids (e.g. eicosapentanoic acid, gamma-linolenic acid) result in improved clinical outcomes compared with standard EN formulations in patients with adult respiratory distress syndrome (ARDS) (Gadek *et al.*, 1999; Singer *et al.*, 2006), although results of a recent Phase II trial of omega-3 fatty acid enriched EN showed no benefit (Stapleton *et al.*, 2011). A variety of so-called "immune-modulating" EN formulations are commercially available and are supplemented with, typically, a combination of glutamine, arginine, omega-3 fatty acids, probiotics, and or/antioxidants (ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009). Routine use of these designer formulations remains controversial because of inconsistent results (especially in ICU patients) and lack of effects on mortality (Marik and Zaloga, 2008; Dupertuis *et al.*, 2009).

**TABLE 57.2** Examples of commercially available enteral nutrition formulas in the United States

Categories	Potential indications	kcal (per mL)	Protein (g/L)	Fat (g/L)	Carbohydrate (g/L)	% water	Osmolality (mOsm/kg H <sub>2</sub> O)
<i>Polymeric</i>							
Standard (e.g. Osmolite <sup>®</sup> ; Isocal <sup>®</sup> )	Most patients	1.0 1.2 1.5	44 56 63	35 39 49	144 158 204	84 82 76	300 360 525
Caloric dense (e.g. TwoCal HN <sup>®</sup> )	Fluid- restricted	2.0	84	90	218	70	725
Fiber-enriched (e.g. Jevity <sup>®</sup> ; Ultracal <sup>®</sup> )	Diarrhea	1.0 1.2 1.5	44 56 63	35 39 49	155 169 216	84 82 76	300 450 525
<i>Hydrolyzed</i>							
Semi-elemental/peptide-based (e.g. Crucial <sup>®</sup> ; Peptamen <sup>®</sup> )	Pancreatitis, malabsorption	1.0	40–51	28–39	127–138	83–85	300–585
<i>Disease-specific</i>							
Immune-modulating (e.g. Impact with Glutamine <sup>®</sup> ; Crucial <sup>®</sup> )	Immuno-suppressed, critical illness	1.3	78	43	150	81	630
Oxepa <sup>®</sup>	Adult respiratory distress syndrome	1.5	63	94	105	79	535
Nepro <sup>®</sup>	Renal failure, on dialysis	1.8	81	96	167	73	600
Suplena <sup>®</sup>	Renal failure, predialysis	1.8	45	96	202	73	600
Glucerna <sup>®</sup>	Diabetes	1.0 1.2 1.5	42 60 82	54 60 75	95.6 114.5 133.1	85 81 76	355 720 875
Promote <sup>®</sup>	Wound healing	1.0	62	26–28	130.0–138	84	340–380

This table does not constitute an all-inclusive list. Information provided by manufacturers.

However, meta-analyses in GI surgery patients suggest that use of these formulations results in lower rates of hospital total complications and infections and decreased length of hospital stay compared with standard EN products (Cerantola *et al.*, 2011).

### Methods of Tube Feeding Administration

In the initial administration stages of tube feeding, diluting enteral formulas is not necessary. The practice of diluting formulas is more likely to promote microbial growth than full-strength formulations, and increases the risk of intolerance due to diarrhea secondary to microbial contamination (ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009). There is limited data to form strong recommendations for the best starting rate for enteral feeding at initiation. Enteral feedings can be administered as a continuous bolus, or using intermittent techniques, or via a combination of these methods (Table 57.3).

Continuous feedings are delivered slowly over 24 hours via gravity drip or with the assistance of an enteral infusion device (electronic feeding pump). Utilizing a feeding pump is more advantageous than gravity drip because it can enhance safety and accuracy in delivery by sustaining

a constant infusion rate and making accidental bolus delivery unlikely to occur. Most commercially available formulas are well tolerated at full strength when delivered into the stomach or small intestine at 10 to 30 mL/hour. The infusion rate can generally be advanced in increments of 10 to 20 mL/hour every 8 to 12 hours as tolerated until goal rate is reached (ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009). Medically stable patients can tolerate a fairly rapid progression of infusion rate and achieve the established goal rate within 24 to 48 hours of initiation. There is also evidence to support starting EN at goal rates in stable adult patients (Rees *et al.*, 1985; Mentec *et al.*, 2001). Continuous administration is usually better tolerated, with lower incidence of GI intolerance and risk of aspiration than bolus tube feeds in hospital settings. Continuous infusion may be necessary for post-pyloric feedings because the small bowel cannot act as a reservoir for large feeding volumes over a short period of time. Hospitalized patients may initially benefit from a continuous infusion to establish tolerance and later transition to an intermittent or cyclic infusion schedule.

Bolus and intermittent feedings are the most physiological feeding techniques because they mimic normal

**TABLE 57.3** Methods of administration of enteral tube feeding

Method	Indications	Advantages	Disadvantages
Continuous	Initiation of feeding Critically ill patient Small bowel feeding Intermittent or bolus feeding intolerance	Pump-assisted Enhances tolerance Minimizes risk due to: ○ high gastric residual ○ aspiration ○ metabolic abnormalities	Restricts ambulation Increased cost due to equipment and supplies
Bolus – intermittent	Non-critically ill patient Home TF Rehabilitation patient Gastric feeding	Ease of administration No pump required) Short feeding time Most physiological	Highest aspiration risk Potential GI intolerance (nausea, vomiting, abdominal pain, diarrhea)
Cyclic – intermittent	Non-critically ill patient Home TF Rehabilitation patient Small bowel feeding	Physical and psychological freedom from pump Beneficial for transitioning TF to oral diet	Requires high infusion rate over short time (8–16 hours) May require formula with higher calorie and protein density to meet needs Potential GI intolerance

TF, tube feeding; GI, gastrointestinal.

dietary habits and allow bowel rest in between feedings (ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009; Table 57.3). These are the easiest to deliver and can be administered over a short period of time via syringe bolus or a feeding container by gravity drip with or without an enteral feeding pump (Lord and Harrington, 2005). Bolus feedings generally deliver the formula in less than 15 minutes, whereas intermittent feedings deliver it over 30–45 minutes. The feeding is initiated with full-strength formula three to eight times daily with increases of 60–120 mL every 8–12 hours as tolerated up to the goal volume of 250–500 mL per feeding, four to six times daily. Bolus and intermittent methods are primarily reserved for medically stable patients with gastric feeding tubes because the stomach can act as a reservoir to handle relatively large volumes within a short time. Feedings provided by this method may result in adverse GI effects due to the sudden delivery of a large, hyperosmolar formula (Lord and Harrington, 2005; ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009).

Cyclic feedings are defined as continuous infusion in an intermittent fashion, for which the formula is infused continuously over a set number of hours (i.e. 8–16 hours). Tube feedings can be cycled for patients with duodenal or jejunal feeding tubes, patients who are transitioning from tube to oral feeding (in which cycled feeding may stimulate appetite), or for those requiring eventual home EN. A cyclic feeding schedule allows bowel rest, free time off the pump, and flexibility to administer overnight and discontinue during the day to afford the patient greater mobility and an opportunity to eat oral food.

Regardless of the delivery technique, most patients on EN will require additional fluid to meet minimum fluid requirements (typically 30–40 mL/kg body weight). Supplemental fluid (i.e. sterile water or normal saline) is administered intermittently as flushes throughout the day (i.e. flush tube with at least 30 mL every 8 hours). To calculate additional fluid requirements, begin by determining the patient's total fluid needs. Then determine that amount of free water provided by the tube feeding formula by multiplying the percent free water content by the total volume of enteral formula to be administered daily (Table 57.2). Subtraction of the free water supplied by the formula from the calculated total free water requirement equals the remaining volume of free water required. The remaining volume is divided into three or four boluses per day.

### **Complications of Enteral Tube Feeding**

While the administration of EN may appear less complex compared with PN, it is not without potential complications. Serious harm and death can result due to potential adverse events occurring throughout the process of ordering, administering, and monitoring. Complications include GI intolerance, mechanical tube complications, bronchopulmonary aspiration, enteral access device misplacement and displacement, metabolic abnormalities, and drug–nutrient interactions (Malone *et al.*, 2007; Guenter *et al.*, 2008; ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009). The acceptable ranges for gastric residual volumes at which to decrease tube feeding rates have been re-evaluated in recent years, and higher amounts than were previously routine have been advocated based on available data (Hurt and McClave, 2010). Many clinicians feel that if the gastric residual volume is  $\geq 250$  mL after two consecutive gastric residual checks, a promotility agent should be considered in adult patients. However, no adequately powered studies have to date demonstrated that elevated gastric residual volumes are reliable markers for increased risk of aspiration pneumonia (Hurt and McClave, 2010). Gastric residuals should be checked more frequently (i.e. every 4–6 hours for the first 48 hours) when gastric feedings are first initiated. After desired gastric feeding rate is established, gastric residual monitoring may be decreased to every 6–12 hours in the non-critically ill patients (Hurt and McClave, 2010). Patient positioning, use of post-pyloric continuous feeding, and judicious use of prokinetic agents (e.g. metoclopramide or erythromycin) have been advocated as important to prevent pulmonary aspiration of tube feeding in patients demonstrating intolerance (e.g. emesis, gastric distention) (Torres *et al.*, 1992; McClave *et al.*, 2002; Metheny *et al.*, 2006). Patients should be monitored frequently for evidence of complications from enteral nutrition support. Table 57.4 lists common potential complications of tube feedings and suggested interventions.

Feeding tubes are prone to clogging for a variety of reasons, including use of small-bore feeding tubes, improper medication administration, and formula sediment accumulation in the lower segment of the tube, especially during slow administration rates of caloric-dense or fiber-enriched formulas (Lord, 2003). Most clogging can be prevented by use of a clean technique to minimize formula contamination, and adherence to protocols for proper flushing of tubes before and after each medication

**TABLE 57.4** Complications of tube feeding

Complications	Possible causes	Possible management
<i>Gastrointestinal</i>		
Diarrhea (>4 bowel movements per day or large loose stool)	Medications (e.g. antibiotics) Formula intolerance Bacterial overgrowth Osmotic overload Decreased bulk <i>C. difficile</i>	Medication modifications: <ul style="list-style-type: none"> <li>• Eliminate antibiotics, antacids, liquid formulations containing sorbitol.</li> <li>• Further dilute hypertonic medications.</li> <li>• Administer medications by intravenous route.</li> <li>• Administer bulking agents (e.g. psyllium).</li> <li>• Administer probiotics.</li> <li>• Administer antidiarrheal agents.<sup>a</sup></li> </ul> Stool culture for pathogens. Feeding modifications: <ul style="list-style-type: none"> <li>• Change to a low-fat, high-fiber, or isotonic formula.</li> <li>• Decrease concentration of formula or rate.</li> </ul>
Nausea or vomiting	Patient position Volume overload Delayed gastric emptying Nutrient intolerances GI tract obstruction Hyperglycemia	Elevate head of bed to 35–45 degrees. Position patient on right side to facilitate passage of gastric contents through pylorus. Medication modifications: <ul style="list-style-type: none"> <li>• Consider reducing narcotic use.</li> <li>• Administer prokinetic agents (i.e. metoclopramide).</li> <li>• Consider antiemetic.</li> </ul> Feeding modifications: <ul style="list-style-type: none"> <li>• Decrease total volume or delivery rate.</li> <li>• Advance delivery rate slowly over 12–24 hours.</li> <li>• Stop feeding for 2 hours and check residuals.</li> <li>• Change to lactose-free or low-fat formula.</li> </ul>
Constipation	Dehydration Decreased fiber GI obstruction	Change to fiber formula. Administer bulking agents. Tube flush with water. Stop feeding temporarily.
<i>Mechanical</i>		
Pulmonary aspiration	Supine position Impaired gag reflex Reflux Tube malposition or displacement Abnormal mental status	Elevate head of bed 30–45 degrees. Infuse feedings into duodenum or jejunum. Change to smaller bore tube. Radiographic confirmation for proper placement after insertion and after severe coughing, vomiting, or a seizure. Tape tube in place and mark with indelible ink at exit point for reference. Reconfirm placement prior to each feeding by checking residuals, ink mark.
Tube obstruction	Acid precipitation of formula Insufficient tube irrigation Medications	Flush tube before and after each medication, residual check, bolus feeding, and every 8 hours during continuous feeding, or whenever feeding is stopped. Infuse feedings into duodenum or jejunum. Do not mix medications with enteral formula. Adequately crush meds and mix powder with water. Use liquid meds where possible or administer via alternative route. Avoid administering bulk-forming agents via small bore tube.

<sup>a</sup>Begin antidiarrheal agent only when infectious and inflammatory etiologies and fecal impaction have been ruled out and causal medications have been changed or discontinued.

administration. Water is the preferred flush solution (e.g. every 4 hours during continuous feeding, before and after intermittent feedings, or after residual volume measurements in an adult patient [Lord, 2003; ASPEN Board of Directors and Enteral Nutrition Practice Recommendations Task Force, 2009]). Use sterile water for tube flushes in immunocompromised or critically ill patients, especially when the safety of tap water cannot be reasonably assumed (Lord, 2003). The recommended first-line method to unclog a tube is to instill warm water using slight manual pressure. Flushing with a combination of pancreatic lipase and sodium bicarbonate solution or with carbonated soda drink may dissolve the clog (Lord, 2003).

Metabolic complications of EN are similar to those that occur during PN, although the incidence and severity may be less (see below). As with PN, outlined below, prevention of refeeding syndrome and monitoring patient's tolerance of EN are essential for the safe delivery of EN (Stanga *et al.*, 2008). Monitoring metabolic parameters prior to the initiation of enteral feedings and periodically during enteral therapy should be based on protocols and the patient's underlying disease state and length of therapy. Patients at risk of developing refeeding syndrome should be identified, and severe electrolyte abnormalities should be corrected prior to the initiation of nutrition support.

## Parenteral Nutrition Support

As with enteral nutrition support, relatively few well-designed, adequately powered RCTs on PN efficacy in hospital settings have been published (Doig *et al.*, 2005, 2009; Koretz, 2008, 2009; Casaer *et al.*, 2011; Ziegler, 2011). Thus, current practices of PN use in hospital patients are largely based on guidelines from professional societies, which in turn are largely derived from observational studies, small clinical trials, and expert opinion (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; Heyland *et al.*, 2003; Mirtallo *et al.*, 2004; Koletzko *et al.*, 2005; Kreymann *et al.*, 2006; McClave *et al.*, 2009; Mehta *et al.*, 2009; Singer *et al.*, 2009). A caveat regarding efficacy of current PN modalities is that no rigorous RCT has featured an unfed or minimally fed control group. Such studies would be difficult to perform (and to recruit subjects for), particularly as the clinical effect of various durations of minimal or no feeding is essentially unknown in ICU and other hospital patients (Ziegler, 2011). Also, many of the earlier RCTs in nutrition support were conducted with excessive PN

caloric doses and liberal blood glucose control strategies compared with current practice. None the less, available data suggest that patients with moderate to severe generalized malnutrition benefit from PN in terms of overall morbidity and possibly mortality if EN is not possible (Ziegler, 2009).

### Indications for Parenteral Nutrition

Although not evidence-based, commonly accepted indications for PN in hospital patients in settings when the enteral route is unavailable for feeding or when EN is not tolerated (especially in already malnourished patients) are as follows: (1) following massive small bowel  $\pm$  colonic resection; (2) when there is a perforated small bowel or a proximal high-output fistula; (3) in other conditions associated with prolonged intolerance to EN (e.g. severe diarrhea or emesis, significant abdominal distention, partial or complete bowel obstruction, or acute gastrointestinal bleeding, severe hemodynamic instability) precluding adequate EN for >3–7 days (McClave *et al.*, 2009; Singer *et al.*, 2009; Ziegler, 2009). There are no data to support withholding of PN in patients with pre-existing protein-energy malnutrition who cannot tolerate EN. However, a recent large RCT from Belgium (4640 patients) explored the impact of timing of PN initiation in adult ICU patients receiving inadequate amounts of early enteral feeding (EN in all subjects began on day 2 of ICU admission) (Casaer *et al.*, 2011). In the early-initiation group, supplemental PN to meet the caloric goal of 25–30 kcal/kg/day was started on ICU day 2, according to 2009 European clinical practice guidelines (Singer *et al.*, 2009). In the late-initiation group, supplemental PN to meet the caloric goal of 25–30 kcal/kg/day was started on ICU day 7, according to 2009 American clinical practice guidelines (McClave *et al.*, 2009). The early initiation of PN was associated with modestly increased ICU and hospital length of stay, infectious complications, indices of organ dysfunction, and total hospital costs (Casaer *et al.*, 2011; Ziegler, 2011).

Contraindications for PN (largely not evidence-based) include: (1) when the GI tract is functional and access for enteral feeding is available; (2) if the patient cannot tolerate the intravenous fluid load required for PN, or has severe hyperglycemia or severe electrolyte abnormalities on the planned day of PN initiation; (3) when PN is unlikely to be required for >5–7 days; and (4) if new placement of an intravenous line solely for PN poses undue risks (McClave *et al.*, 2009; Singer *et al.*, 2009; Ziegler, 2009).

### Parenteral Nutrition Administration

PN can be delivered as complete solutions given by either peripheral or central vein. A comparison of typical fluid, macronutrient and micronutrient content, and characteristics of peripheral and central vein PN is shown in Table 57.5. Because of the risk of phlebitis, peripheral vein PN provides low amounts of dextrose (5%; dextrose = 3.4 kcal/g) and amino acids ( $\leq 3.5\%$ ; 4 kcal/g) and a large proportion of the caloric content is given as fat emulsion (50–60% of total calories) (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002). Fluid restriction due to cardiac, hepatic, and/or renal dysfunction may be a contraindication to the use of large fluid volumes for PN; thus, peripheral vein PN is generally not indicated in ICU patients as larger volumes are required to meet energy and amino acid goals. Central venous PN allows concentrated dextrose and amino acid delivery via the superior vena cava. Adequate energy and amino acid intake in the vast majority of adults can thus be achieved with central venous volumes of 1 to 1.5 L/day (Table 57.5). Depending on fluid status, non-PN hydration fluid rate should be proportionally decreased when PN is infused (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; McClave *et al.*, 2009).

**TABLE 57.5** Composition of typical parenteral nutrition formulations

Component	Peripheral vein PN	Central vein PN
Volume (L/day)	2–3	1–1.5
Dextrose (%)	5	10–25
Amino acids (%)	2.5–3.5	3–8
Lipid (%)	3.5–5.0	2.5–5.0
Sodium (meq/L)	50–150	50–150
Potassium (meq/L)	20–35	30–50
Phosphorus (mmol/L)	5–10	10–30
Magnesium (meq/L)	8–10	10–20
Calcium (meq/L)	2.5–5	2.5–5
Vitamins <sup>a</sup>		
Trace elements/minerals <sup>b</sup>		

<sup>a</sup>Vitamins typically added on a daily basis to peripheral vein and central vein PN are comprised of commercial mixtures of vitamins A, B<sub>1</sub> (thiamin), B<sub>2</sub> (riboflavin), B<sub>3</sub> (niacinamide), B<sub>6</sub> (pyridoxine), B<sub>12</sub>, C, D, and E, biotin, folate, and pantothenic acid. Vitamin K is added on an individual basis (e.g. in patients with cirrhosis). Specific vitamins can also be supplemented individually.

<sup>b</sup>Trace elements/minerals typically added on a daily basis to peripheral vein and central vein PN are comprised of commercial mixtures of chromium, copper, manganese, selenium, and zinc. Minerals can also be supplemented individually.

PN electrolytes are adjusted as indicated to maintain serially measured serum levels within the normal range. With elevated blood levels, lower doses (or elimination) of specific electrolytes, as compared with the typical ranges outlined in Table 57.5, may be indicated until blood levels are within the normal range. Higher dextrose concentrations in central vein PN may increase potassium, magnesium, and phosphorus requirements. The relative percentage of sodium and potassium salts as chloride is increased to correct metabolic alkalosis, and the percentage of these salts as acetate is increased to correct metabolic acidosis. Tighter blood glucose control in ICU and other hospital patients is now the standard of care (<180 mg/dL) (NICE–SUGAR Study Investigators *et al.*, 2009; Kavanagh and McCowen, 2010). To achieve these goals, regular insulin can be added to PN and/or the dextrose load can be reduced as needed (separate intravenous insulin infusions are commonly required with hyperglycemia in ICU settings) (Ziegler, 2009).

Conventional PN provides all essential nine amino acids and several non-essential amino acids, depending on the commercial amino acid formulation used (Yarandi *et al.*, 2011). Although controversial, European guidelines recommend routine addition of glutamine as a conditionally essential amino acid in ICU patients, given the evidence that this amino acid may become conditionally essential in certain catabolic patients (Singer *et al.*, 2009; Yarandi *et al.*, 2011). The dose of amino acids is adjusted downwards or upwards in relation to goal amounts as a function of the degree of azotemia or hyperbilirubinemia in patients with acute renal and hepatic failure, respectively. Complete PN provides intravenous lipid emulsions as a source of both energy and essential linoleic and linolenic fatty acids. In the United States, the only commercially available lipid emulsion is soybean oil based; in Europe and other countries, intravenous soybean oil/medium-chain triglyceride mixtures, fish oil, olive oil/soybean oil mixtures, and combinations of these oils are approved for use in PN. Lipid is typically mixed with dextrose and amino acids in the same PN infusion bag (“all-in-one” solution) and given with PN over 16–24 hours. Lipid emulsion may also be infused separately from the main PN bag over 10–12 hours. The maximal recommended dose of lipid emulsion infusion is 1.0–1.3 g/kg/day, with monitoring of blood triglyceride levels at baseline and then approximately weekly and as indicated to assess clearance of intravenous fat (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; Mirtallo *et al.*, 2004; Ziegler, 2009).

### BOX 57.3 Clinical and metabolic complications of overfeeding and refeeding syndromes in patients receiving central venous parenteral nutrition

- Intracellular shift of magnesium, phosphorus and/or potassium (excess dextrose infusion, refeeding hyperinsulinemia).
- Immune cell dysfunction and infection (hyperglycemia).
- Cardiac failure or arrhythmias (excess fluid, excess sodium and other electrolytes, refeeding-induced electrolyte shifts).
- Neuromuscular dysfunction (thiamin depletion, refeeding-induced electrolyte shifts).
- Azotemia (excess amino acid, inadequate energy provision in relation to amino acid dose).
- Fluid retention (excess fluid, sodium, refeeding hyperinsulinemia).
- Elevated liver function tests and/or hepatic steatosis (excess kilocalories, dextrose or fat).
- Increased blood ammonia levels (excess amino acids with liver failure).
- Hypercapnia (excess total kilocalories).
- Respiratory insufficiency (refeeding-induced hypophosphatemia, excess fluid, kilocalories, carbohydrate or fat).
- Hypertriglyceridemia (excess carbohydrate or fat).

Triglyceride levels should be maintained below 400–500 mg/dL by decreasing the amount of lipid infused to decrease risk of pancreatitis and diminished pulmonary diffusion capacity in patients with severe chronic obstructive lung disease (Box 57.3). In central venous PN, a reasonable initial guideline is to provide 60–70% of non-amino acid calories as dextrose and 30–40% of non-amino acid calories as fat emulsion (Mirtallo *et al.*, 2004; McClave *et al.*, 2009; Singer *et al.*, 2009; Ziegler, 2009).

Specific requirements for intravenous vitamins and minerals have not been rigorously defined in hospital patients (Mirtallo *et al.*, 2004; McClave *et al.*, 2009; Singer *et al.*, 2009; Ziegler, 2009, 2011). Therapy is therefore directed at meeting published recommended doses that maintain blood levels in the normal range in most stable patients using standardized intravenous preparations of combined vitamins and minerals (Table 57.5). However, several studies show that a significant proportion of ICU patients receiving conventional nutrition support variously exhibit low zinc, copper, selenium, vitamin C, vitamin E,

and vitamin D levels (Nathens *et al.*, 2002; Luo *et al.*, 2008). This may be due to pre-ICU depletion, increased ICU requirements (possibly secondary to oxidative stress), increased excretion, and/or tissue redistribution. Depletion of these essential nutrients may impair antioxidant capacity, immunity, wound healing and other important body functions. Thus, as with electrolytes, therapy is directed at maintaining normal blood levels, with serial measurements in blood as clinically and biochemically indicated.

PN formulations can be admixed under a sterile hood by trained pharmacists, but “premixed” off-the-shelf formulations are also available commercially. PN is administered by infusion pump to control delivery rates, and the infusion catheters incorporate an in-line filter to prevent microbial contamination.

### Clinical Monitoring of Parenteral Nutrition

Monitoring of PN therapy in the hospital setting requires daily assessment of the multiple factors outlined in Boxes 57.1 and 57.2. Blood glucose should be monitored several times daily, and blood electrolytes and renal function tests should generally be determined daily. Blood triglyceride levels should be measured at baseline and then weekly until stable. Although guidelines are few, some centers routinely monitor periodic blood levels of copper, selenium, zinc, thiamin, vitamin B<sub>6</sub>, vitamin C, and 25-hydroxyvitamin D (Ziegler, 2009). Liver function tests should be measured at least a few times weekly. pH should be monitored generally daily in ventilated patients when arterial blood gas pH measurements are available. Monitoring of blood glucose, electrolytes and organ function is routine in the ICU setting.

### Adverse Effects of Parenteral Nutrition

Metabolic, infectious and mechanical complications may occur with PN (Solomon and Kirby, 1990; Mirtallo *et al.*, 2004; Grau *et al.*, 2007; Fallon *et al.*, 2010; Walshe *et al.*, 2010; Byrnes and Stangenes, 2011; Zeki *et al.*, 2011). Mechanical complications, particularly with insertion and use of central venous catheters, include pneumothorax, hemothorax, thrombosis, and bleeding. Catheter-related bloodstream infections can occur in PN patients and are not uncommon in these individuals, who typically have other risk factors for infection. For example, in a recent study of 1325 patients receiving PN in a tertiary-care hospital over a 12-year period, the catheter-related bloodstream infection rate was 10 to 13 per 1000 central venous catheter days, depending on the criteria used (Walshe

*et al.*, 2010). Proper and safe administration of both peripheral and central vein PN requires strict catheter care and nursing care protocols, including use of dedicated catheter ports for PN administration and subclavian vein insertion sites for central venous PN (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; Mirtallo *et al.*, 2004; Ziegler, 2009).

Potential metabolic and clinical consequences of overfeeding and refeeding syndrome during central venous PN in critically ill patients are shown in Box 57.3. High caloric, dextrose, amino acid, and fat loads (“hyperalimentation”) are readily administered via a central vein. While not the standard of care per current guidelines, excess dextrose, fat, and overall calorie administration remains a common practice in some centers (ASPEN Board of Directors and the Clinical Guidelines Task Force, 2002; Mirtallo *et al.*, 2004). Risk factors for PN-associated hyperglycemia include: (1) use in obese, diabetic, and/or septic patients; (2) poorly controlled blood glucose at PN initiation; (3) initial use of high dextrose concentrations (>10%) or dextrose load (>150g/day); (4) insufficient insulin administration and/or inadequate monitoring of blood glucose; and (5) concomitant administration of corticosteroids and pressor agents (Mirtallo *et al.*, 2004; McClave *et al.*, 2009).

Electrolyte administration requires careful monitoring and general day-to-day adjustment in PN to maintain normal blood levels. Overfeeding can induce several metabolic complications of varying degrees of severity affecting several organ systems (Box 57.3). A recent large study found that PN use *per se*, overfeeding, and sepsis were the major risk factors for liver dysfunction in critically ill patients (Grau *et al.*, 2007). Elevated transaminases and eventual PN-induced liver dysfunction that may lead to hepatic failure occur with PN administration, especially in individuals receiving chronic PN therapy (Mirtallo *et al.*, 2004). The mechanisms for PN-induced liver dysfunction remain unclear, but are probably multifactorial (Mirtallo *et al.*, 2004). Of interest, recent studies suggest that switching from conventional soybean-oil-based lipid emulsion to fish-oil-based lipid emulsion is associated with decreased PN-associated liver failure in children receiving chronic PN, but mechanisms remain obscure (Fallon *et al.*, 2010). PN should be advanced carefully to goal rates and the composition adjusted as appropriate based on the results of close metabolic and clinical monitoring performed daily. The calories provided by dextrose present in non-PN intravenous fluids, the soybean oil lipid emulsion

carrier of propofol, a commonly used intravenous ICU sedative, and clevidipine, an intravenous calcium-channel blocker, as well as the nutrients provided in any administered EN, must be taken into account in the PN prescription to avoid overfeeding.

Refeeding syndrome is relatively common in at-risk patients (alcoholics, pre-existing malnutrition or electrolyte depletion, recent significant body weight loss, prolonged periods of intravenous hydration therapy alone, or administration of insulin or diuretics prior to refeeding) (Solomon and Kirby, 1990; Byrnes and Stangenes, 2011; Zeki *et al.*, 2011). In a recent study of at-risk hospital patients given EN, PN or both, 25% of 92 patients developed refeeding-induced hypophosphatemia (Zeki *et al.*, 2011). Refeeding syndrome is mediated by administration of excessive intravenous dextrose (>150–250 g or 1 L of PN with 15–25% dextrose). This markedly stimulates insulin release, which may rapidly decrease blood potassium, magnesium, and especially phosphorus concentrations due to intracellular shift and utilization in metabolic pathways (Solomon and Kirby, 1990; Byrnes and Stangenes, 2011; Zeki *et al.*, 2011). High doses of carbohydrate increase thiamin utilization and can precipitate symptoms of thiamin deficiency. Hyperinsulinemia may cause sodium and fluid retention by the kidney. This, together with decreased blood electrolytes (which can cause cardiac arrhythmias), can result in heart failure, especially in patients with pre-existing heart disease (Solomon and Kirby, 1990; Byrnes and Stangenes, 2011; Zeki *et al.*, 2011). Prevention of refeeding syndrome requires identification of at-risk patients, use of initially low PN dextrose (e.g. 1 L of PN with 10% dextrose), empiric provision of higher PN doses of potassium, magnesium, and phosphorus, based on blood levels and renal function, and supplemental PN thiamin (e.g. 100 mg/day for 3–5 days) (Stanga *et al.*, 2008; Ziegler, 2009; Zeki *et al.*, 2011).

Consultation with an experienced multidisciplinary nutrition support team for recommendations regarding the PN prescription is ideal when such personnel are available. Nutrition support team daily monitoring has been shown to reduce complications and costs, and to decrease inappropriate use of PN (Trujillo *et al.*, 1999; Kennedy and Nightingale, 2005).

## Future Directions

Numerous areas of uncertainty remain with regard to administration of specialized EN and PN, despite routine

use in hospitals and other settings (Ziegler, 2011). For example, the optimal timings for EN and PN initiation in hospital patients remain areas of uncertainty (Casaer *et al.*, 2011; Ziegler, 2011). Few prospective data are available on the clinical effects of minimal or no feeding over time (e.g. >7 days), and such data are unlikely to be forthcoming. Rigorous RCTs are needed to define optimal caloric and protein/amino acid dose regimens in subgroups of ICU and non-ICU patients (Ziegler, 2009, 2011). Some studies show that larger doses of standard soybean-oil-based intravenous fat emulsions induce pro-inflammatory and pro-oxidative effects and possibly immune suppression (Grau *et al.*, 2007). However, conflicting results of small RCTs comparing soybean-oil-based lipid emulsion with other types of lipid emulsion have not clarified optimal use (Waitzberg *et al.*, 2006). Available data suggest that glutamine may become a conditionally essential amino acid in ICU patients (Wischmeyer, 2008; Yarandi *et al.*, 2011). Glutamine serves as an important fuel for immune and gut mucosal cells, and has cytoprotective properties among other potentially beneficial functions. Several clinical trials have shown that glutamine-supplemented PN (0.2–0.5 g/kg/day as the L-amino acid or as glutamine dipeptides) has protein-anabolic effects, enhances indices of immunity, and decreases hospital infections (Wischmeyer, 2008; Yarandi *et al.*, 2011). Thus, some recent expert panels recommend that glutamine be routinely added to PN in ICU patients, if available (Heyland *et al.*, 2003; Singer *et al.*, 2009). Ongoing large, randomized controlled trials on glutamine-supplemented PN should provide the information that is needed. Phase III level, double-blind, intent-to-treat RCTs are needed in specific ICU patient subgroups to define clinically optimal caloric, protein/amino acid, and specific vitamin and mineral requirements, as well as to determine the efficacy of supplemental PN combined with EN to achieve caloric and protein/amino acid goals (McClave *et al.*, 2009; Singer *et al.*, 2009; Wischmeyer and Heyland, 2010; Cahill *et al.*, 2011). In addition, rigorous trials to verify proposed “pharmakonutrition” strategies (e.g. use of high doses of supplemental parenteral and enteral glutamine, vitamin C and other antioxidants, selenium, and/or zinc, etc.) are also needed (Wischmeyer and Heyland, 2010). Fortunately, numerous large, multicenter RCTs in this regard are in progress and will help to define optimal use of these important adjunctive nutritional therapies over the next several years.

## BODY COMPOSITION EVALUATION

KRISTA CASAZZA, PhD, RD AND TIM R. NAGY, PhD

*The University of Alabama at Birmingham, Birmingham, Alabama, USA*

### Summary

Body composition plays a critical role in the health of humans. This chapter focuses on a few of the more commonly used and/or available methodologies to determine body composition in human research, including anthropometry, bioelectrical impedance analysis (BIA), hydrodensitometry (HD), air displacement plethysmography (ADP), dual-energy X-ray absorptiometry (DXA), magnetic resonance imaging (MRI), and quantitative magnetic resonance (QMR). Because the emphasis of this chapter is to discuss research methods, we chose not to discuss any method that may pose harm to healthy research subjects, such as computed tomography with its associated radiation exposure.

### Introduction

The methods of *in vivo* body composition analysis are based upon centuries-old mathematical, conductivity, and membrane permeability principles. However, recent technology has greatly enhanced the capacity to assess body composition using fairly precise and accurate methods.

Anthropometric procedures are often the most practical; however, the information that can be obtained from such measurements is limited. As such, anthropometric variables are often considered to be indices *related to* body composition, relying on the ability to categorize individuals usually for comparison with a reference population. Estimation using bioelectrical impedance allows for the assessment of body composition using the two-component

model. This is because the water content of fat-free mass is relatively constant, and fat is an electrical resistor and, therefore, the lipid components of the membranes of the body cells behave as capacitors and reduce the flow of intracellular ions. Hydrodensitometry capitalizes on Archimedes' principle, where body volume of a subject immersed in water is equal to the loss in weight in water (weight in air minus weight in water) divided by the density of water. Similarly, air displacement plethysmography utilizes air pressure to determine volume, from which density and ultimately body composition can be determined. Dual-energy X-ray absorptiometry has rapidly become the method of choice for researchers conducting human studies that require information on body composition. Even with the potential pitfalls of DXA, it is clear

that this method for measuring body composition will continue to grow in popularity mainly due to its availability, ease of use with research subjects, and ability to quantify bone in addition to fat and lean tissue.

Some relatively newer methods have evolved in terms of body composition research. An important development in the field of body composition studies is the use of magnetic resonance imaging (MRI) to quantify adipose, lean, and bone tissue, as well as to provide information on the regional distribution, without exposure to ionizing radiation. Quantitative magnetic resonance (QMR) is a relatively new method for the determination of body composition. In this method, protons from different tissues are differentially affected by the instrument.

Ideally, a method for determining body composition in humans should be precise, accurate, readily accessible, inexpensive, rapid, non-invasive, and non-harmful; unfortunately, there are no such tests available. There are a vast number of variations (age sex, race, disease state) that influence body composition and must be considered. Which method one uses depends on the compartment of interest, availability of techniques, technical training of staff, condition of patient, and the location in which assessment will be done.

## Anthropometric Indices

Anthropometry, the measurement of the human individual for the purposes of understanding physical variation, is useful for monitoring growth as well as for estimating risk factors for chronic disease and for nutritional assessment. Anthropometric instruments are generally portable and relatively inexpensive, procedures are non-invasive, and minimal training is required. However, information that can be obtained from such measurements is limited. Most notably, anthropometric assessment does not provide metric values for aspects of body composition. Therefore, rather than being seen as direct measurements, anthropometric variables are considered to be indices *related to* body composition. The primary use of anthropometric indices relies on the ability to categorize individuals usually for comparison with a reference population.

Body mass index (BMI) is the most commonly used primary outcome in both research and clinical practice. BMI is a global index for nutritional status, used to classify people as under- or overweight, but its relation to body composition per se is controversial (Wells and Fewtrell, 2006); BMI serves only as an anthropometric surrogate of

adiposity, provides little information on fat-free components of weight, and has been shown to vary in its ability to predict body fat uniformly across all (heterogeneous) groups. Recent investigations indicate that current BMI categorization can identify a high prevalence of high adiposity in individuals with high BMI and a low prevalence of high adiposity in individuals with normal BMI, yet difficulties in the accurate assessment of adiposity among individuals with intermediate BMIs have been observed (Flegal *et al.*, 2010). Differences in BMI categorization and the relationship with adipose tissue mass between race/ethnic groups are an additional concern (Jackson *et al.*, 2009; Affuso *et al.*, 2010).

Body circumference at various sites is commonly used to provide information on body fat distribution and may be better able to predict adiposity relative to BMI. Waist circumference (WC, commonly measured at the level of the umbilicus or at the iliac crest) provides a simple measure of central fatness (Wells and Fewtrell, 2006) and has been used as a surrogate measure of abdominal adiposity, although there is no differentiation between intra-abdominal and subcutaneous adipose tissue compartments. A recent analysis of cross-sectional studies suggests that waist circumference or waist-hip ratio discriminate better in terms of adiposity and health outcomes as compared with BMI (Bosy-Westphal *et al.*, 2010; Qiao and Nyamdorj, 2010). In general, BMI, WC, and waist-hip ratio perform similarly as indicators of body fatness, and are more closely related to each other than to percentage body fat. Circumferences are often used for estimations of obesity, but they have also been proposed as measures of thinness, particularly low mid-upper arm circumference and low calf among older individuals (Wijnhoven *et al.*, 2010). Although there is support for use of circumference in addition to or in lieu of BMI, it should be recognized that the 95% confidence intervals for BMI and WC overlap in all comparison studies and the variations in observations among circumferences, as with BMI, are highly dependent upon age, gender, and race/ethnicity.

One of the simplest measurements for direct assessment of body fat is skinfold thickness, providing reasonable correlation with total percent body fat. Skinfold thickness is the double layer of skin and subcutaneous fat lifted as a fold and measured with standardized calipers and methodology at specific sites on the body. Understandably, because of the wide variation of subcutaneous fat across the body, multiple sites are required for sampling to provide accurate estimates. Values from various sites are

incorporated into predictive equations, selection of which is based on characteristics of the cohort to be measured. The most widely applied method for calculating total body fat from measured skinfold was developed by Durnin and Womersley in 1974 (Braulio *et al.*, 2010). This uses the sum of four skinfold measurements to provide an estimation of the fat mass; subtracting this from total body weight gives an estimation of fat-free mass. Subsequently a vast number of prediction equations have been developed, many of which rely on values obtained from the reference population of Durnin and Womersley. Recent investigations suggest that the original values cannot be applied to individuals living today, and modification is required (Kagawa *et al.*, 2010). Moreover, skinfold thickness measurements for the assessment of non-fat tissue are likely to be ineffective because the thickness of adipose tissue and of muscle in limbs is essentially independent.

### Bioelectrical Impedance Analysis

Bioelectrical impedance (BIA) capitalizes on the fact that each tissue of the body is characterized by a specific conductivity, which is directly related to the water and electrolyte content of the tissue. Within the tissue, the water is localized into two compartments, extracellular water (ECW) and intracellular water (ICW). BIA involves introduction of a small electric current to the body (Dehghan and Merchant, 2008). The impedance represents the whole resistivity of the tissues divided into resistive component (the opposition of the ECW component to the current) and the capacitive component, i.e. the current passes freely through the ECW, but penetration is reduced by the capacitance effect of cell membranes influencing passage through ICW. In terms of body composition estimation, the water content of fat-free mass is relatively constant: 0.732 L/kg (Leone *et al.*, 2000); thus in lean tissue, which is rich in water and electrolytes, the minimal impedance can be calculated from difference in conductivity. Conversely, fat is an electrical resistor and therefore the lipid components of the membranes of the body cells behave as capacitors and reduce the flow of intracellular ions, a fact not actually reflected by electrical data. The values of resistance and reactance depend on the frequency of the electric current. Mathematical modeling and theories on fluid resistivity are subsequently used to estimate the conductive path to ascertain total body water, fat-free mass (FFM), and body cell mass using

height, sex, age, and race. Total body percent fat mass can be defined as  $[(wt - FFM_{TBM})/Weight] \times 100$ .

BIA was initially designed using single-frequency impedance analyzers (usually 50 mHz). However, single-frequency BIA is limited in the ability to distinguish between fluid shifts and balance between ECW and ICW compartments. The overall effect in subjects who have a high ECW/ICW ratio and increased TBW would be an overestimation of FFM and underestimation of fat mass (FM) (Das *et al.*, 2003). Accordingly, multiple-frequency BIA (varying from 5 kHz to 1 MHz) has been developed. Mathematical modeling (e.g. Cole-Cole, Hanoi) produces estimates of theoretical resistance at zero frequency (reflecting purely ECW) and at an infinite frequency, reflecting passage through total body water space. This has not completely circumvented the issues associated with BIA, however. The human body is complex in shape, represented by not one but five heterogeneous cylinders with different resistivities, over which resistances are measured separately. Settle and colleagues (1980) observed that 85% of total body impedance was accounted for by the sum of the impedance of the arm and the leg although these segments only accounted for 35% of the total body volume. Thus, in an attempt to overcome the concerns with the assumption of the body as approximated by a single cylinder, a segmental approach was proposed in which the arm(s), leg(s), and trunk are determined separately and together with the length of these segments. Segmental BIA uses six electrodes instead of four (Mattsson and Thomas, 2006).

The accurate assessment of fluid status represents a major challenge. The determination of body fluid volumes by BIA is based on the assumption that electrical current at low frequencies cannot penetrate cell membranes and flows through the ECW only, whereas high-frequency current flows through ECW and ICW. Therefore the low and high frequencies are related to ECF, total body water, and BCM. However, the apparent resistivity is dependent upon the size of cells. For example, in overweight/obese states, greater lipid content would significantly change the path length around the cells, thereby limiting accuracy of measurement. Similarly, low hydration status or wasting would decrease the path.

### Hydrodensitometry

Hydrodensitometry (HD), commonly referred to as underwater weighing (UWW), is a method of determining

body composition based on the density of the body. Density is calculated as the ratio of the body's mass ( $M$ ) and volume ( $V$ ):

$$D_b = M/V$$

where body mass is estimated from the measurement of body weight and volume determined by underwater weighing. Using Archimedes' principle, body volume of a subject immersed in water is equal to the loss in weight in water (weight in air minus weight in water) divided by the density of water.

For human body composition measurements with HD, the body is considered a two-component model consisting of fat mass (FM) and FFM, and the density of the body is equal to the proportions and density of the two components (Going, 2005). The two most widely used models were developed by Siri (1956) and Brozek *et al.* (1963) more than 40 years ago. However, for these equations to accurately predict body composition, the densities of the components must be constant among individuals.

The density of fat mass is typically given as 0.9007 g/mL and seems to be fairly constant (Fidenza *et al.*, 1953; Brozek *et al.*, 1963). Fat-free mass consists of approximately 73.8% water (0.9937 g/mL), 19.4% protein (1.34 g/mL), and 6.8% mineral (3.038 g/mL), where the mineral is a combination of osseous (5.6%; 2.982 g/mL) and non-osseous (1.2%; 3.317 g/mL) (Brozek *et al.*, 1963). However, these proportions, and therefore the density of FFM, can vary with age, sex, training, and race. This has led to the development of three- and four-component models in which total body water (by dilution techniques), and osseous mineral content (by DXA) are included in the calculation of percentage fat (Lohman, 1986; Going, 2005).

Notwithstanding its limitations, HD has long been considered the "gold standard" of body composition methodologies for humans. It is often used to gauge new methods for accuracy of measurements, and forms the basis for most multicomponent models.

### Air-Displacement Plethysmography

Similar to HD, air-displacement plethysmography (ADP) calculates the density of the body, using mass and body volume to determine body composition. However, unlike UWW, volume is not determined by submersion in water.

Instead, ADP relies on the relationship between pressure and volume, that is, Boyle's law:

$$P_1/P_2 = V_2/V_1$$

where  $P_1$  and  $V_1$  are one condition and  $P_2$  and  $V_2$  are a second condition. Boyle's law is true only if temperature is kept constant within a closed system (i.e. isothermal conditions). However, under adiabatic conditions, the temperature of air does not remain constant and temperature changes with changes in volume. This situation is described as an isentropic process from:

$$P_1/P_2 = (V_2/V_1)^\gamma$$

where  $\gamma$  is the ratio of the specific heat capacity at constant pressure divided by the specific heat capacity at constant volume ( $C_p/C_v$ ) (Van Wylen and Sonntag, 1965).

The Bod Pod plethysmograph (Life Measurement Instruments, Inc., Concord, CA) is one such instrument that can be used to determine the volume of the human body (Figure 58.1). The instrument consists of two

**FIG. 58.1** An air-displacement plethysmograph located in the Department of Nutrition Sciences at the University of Alabama, Birmingham. Because the system measures pressure, it is important to house it in an area that does not experience rapid fluxes in air movement. This unit is housed in a room in which the room air circulation can be turned off during the measurement period, thereby decreasing measurement error.

chambers, a reference chamber that houses the electronics, and a test chamber for the subject. A diaphragm between the two chambers pulses to produce pressure changes within the chambers, thereby allowing for the determination of a change in volume in the test chamber. A complete review of the theory and mechanics can be found elsewhere (Fields *et al.*, 2002; Going, 2005).

A major advantage of ADP over UWW is ease of use, as the former does not require subjects to be immersed in water and to have the ability to hold their breath while underwater. This is particularly useful for studies involving children, the elderly, or disabled individuals. Our own personal experience from conducting ADP and UWW studies is that even normal healthy individuals are more relaxed and more likely to come back for repeat measurement when ADP rather than UWW is used. In addition, the technique is fairly rapid (8–12 minutes), and requires minimal compliance and a low degree of technical skill (Fields *et al.*, 2005).

Numerous studies have investigated the precision and accuracy of ADP (Fields *et al.*, 2002, 2005). Within-day variations (coefficients of variation; CVs) range between 1.7–4.5% and 2–2.3% between days and compare well with published reports from UWW (Fields *et al.*, 2002). Body fat determined from ADP has been shown to be within 1% and 2% compared with that measured by UWW and DXA respectively (Fields *et al.*, 2005).

Similar to UWW, ADP relies on the consistency of body density to predict fat mass and therefore has the same issues that FFM can vary with age, sex, training status, and race. However, the ease of use makes ADP attractive for the determination of body composition in infants, children, and adults.

## Dual-Energy X-Ray Absorptiometry

Dual-energy X-ray absorptiometry (DXA) allows for the determination of total and regional bone mineral (BM, g), total and regional bone mineral density (BMD, g/cm<sup>2</sup>), fat mass (FM, g), bone mineral free lean tissue mass (LTM, g), and soft-tissue mass (STM, g; STM = FM + LTM) (Pietrobelli *et al.*, 1996; Nagy, 2001; Lohman and Chen, 2005). Even though DXA utilizes X-rays, the method is considered relatively safe since the radiation exposure is less than a person would receive on a transcontinental flight across the United States (4–6 mrem) (Lohman and Chen, 2005). However, some governing bodies do not approve of DXA use during pregnancy, thus necessitating

pregnancy testing in women of childbearing years. Repeated measurement of individuals and the testing of children have been questioned as well. However, where there is justification for their use, these procedures are typically approved.

The theory behind DXA has been reviewed in detail numerous times (Cullum *et al.*, 1989; Mazess *et al.*, 1990; Pietrobelli *et al.*, 1996), and will not be discussed here.

DXA has rapidly become the method of choice for researchers conducting human studies that require information on body composition. Numerous studies have validated the use of DXA by either analyzing large animals and comparing the DXA-derived values with chemical carcass analysis, or by measuring humans and comparing the results with those of other established techniques (underwater weighing or four-compartment model) (Brunton *et al.*, 1993; Ellis *et al.*, 1994; Pintauro *et al.*, 1996). Pintauro and colleagues (1996) utilized pigs within the pediatric weight range (15–37 kg) to validate the use of DXA in children. All pigs were scanned in duplicate to determine precision and then killed, and chemical carcass analysis was performed. The coefficients of variation ranged from a low of 0.9% for lean tissue to a high of 4.1% for fat mass. The relationship between fat and lean derived from carcass analysis and DXA was strong with  $r^2 > 0.98$ . However, there was a significant difference in the absolute values between the two techniques. The authors then derived equations to correct the DXA-derived data to match that from chemical carcass analysis.

Wong *et al.* (2002) compared DXA measured values of body fat with values obtained from the four-compartment model in a group of girls and female adolescents. The four-compartment model utilizes data obtained from body density (obtained from underwater weighing or air-displacement plethysmography), body water (obtained from isotope dilution), and bone mineral content (obtained from DXA). By utilizing information from the various techniques, the models are typically able to account for more biological variability and are likely the most accurate methods for determining body composition (Wang *et al.*, 2005). Data from DXA was highly correlated with the four-compartment model ( $r = 0.90$ ), however, an individual value for percentage fat mass could be over- or underestimated by 6.7% using DXA. Although the authors suggested that DXA was an appropriate method for determining body composition, it was not considered optimal.

In addition to questions concerning accuracy of the method, there are well-documented studies showing dif-

ferences between instruments and well as among software versions on the same instrument (Huffman *et al.*, 2005; Lohman and Chen, 2005; Shypailo *et al.*, 2008). Huffman and co-workers (2005) assessed body composition on 106 apparently healthy subjects (34 males, 72 females; ages 8–72) using the Lunar DPX-L and Lunar Prodigy DXA. The results showed that, relative to the DPX-L, the Prodigy significantly overestimated body mass (percentage difference = 1.1%), total body bone mineral density (2.2%), total body bone mineral content (2.9%), fat mass (3.5%), and percentage fat (2.8%), but not lean tissue mass (−0.2%;  $p = 0.35$ ). However, the two measures were well related and therefore correction equations were published that allow comparison of the data between instruments.

More recently, Shypailo *et al.* (2008) evaluated 1384 pediatric scans (1.7 to 17.2 years of age) using two software versions (Hologic software V11.2 vs. V12.1). Their study showed that DXA-derived body composition values were not affected by subjects who weighed >40 kg. However, in subjects weighing <40 kg, body fat was greater and lean mass less on the latter software version, which had the effect of increasing the percentage body fat. The change was sufficiently different that 14% of girls and 10% of boys were reclassified from normal body fat to “at risk for obesity”, and 7% and 5% were reclassified as obese. These studies suggest that data obtained from different software and/or instruments cannot necessarily be compared, and that users should be aware of software being utilized for their studies.

An important limitation of lean tissue measured by DXA is that it does include ECW as well as ICW, and so changes in hydration will be interpreted as change in lean tissue (Pietrobelli *et al.*, 1998).

Even with the potential pitfalls of DXA, it is clear that this method for measuring body composition will continue to grow in popularity mainly due to its availability, ease of use with research subjects, and ability to quantify bone in addition to fat and lean tissue. Figure 58.2 shows a typical bone and tissue image obtained from a DXA scan.

## Magnetic Resonance Imaging

An important development in the field of body composition studies was the use of magnetic resonance imaging (MRI) to quantify body composition adipose, lean, and bone tissue as well as to provide information on the regional distribution without exposure to ionizing radia-

tion. By exploiting the particular characteristics of hydrogen protons, MRI can provide contrast between soft tissues (Bley *et al.*, 2009). MRI estimates the volume rather than the mass of tissue compartments.

Estimation of tissue volume by MRI is based upon the interaction between hydrogen protons abundant in all tissues and the magnetic fields generated by the MRI instrumentation. That is, when a strong magnetic field is applied to body tissues, the magnetic moments present in the nuclei of cells will align with the magnetic field. Although only a small number of protons become aligned, the number is sufficient to enable detection of a change when the field is removed or altered. Accordingly, the hydrogen protons absorb energy, which is released when the pulse is turned off. The time it takes for the nuclei to release and return to random orientation differs between fat and water (Ellis, 2000). This energy is integrated into cross-sectional imaging slices based on spatial variation in the phase and frequency of the energy absorbed and emitted, which can be summed to calculate regional tissue volumes (Wells and Fewtrell, 2006).

The classical approach of tissue density determination by MRI utilized chemical-shift-based water–fat separation, commonly known as Dixon water–fat separation. Dixon methods rely on the phase shifts created by fat–water resonance frequency between water and fat. Phase information is encoded by acquiring images at slightly different echo times. Dixon methods provide a fat-suppressed water-only image and a water-suppressed fat-only image. The two images are acquired at different echo times (TE) such that water and fat are in phase or out of phase. By adding and subtracting  $S_{in}$  and  $S_{out}$ , water and fat are easily separated.

Alternatives to the Dixon two-point method have been introduced in an effort to reduce inhomogeneities that resulted in water and fat swapping in the image (Costa *et al.*, 2008; Bley *et al.*, 2009). The Dixon method has evolved over the past 25 years, generating various modifications resulting in the three-point method and ultimately in IDEAL, the iterative decomposition of water and fat with echo asymmetry and least-squares estimation technique. Instead of collecting just two images, the IDEAL technique requires careful selection of echo times so that the reconstructed fat-only and water-only images have the maximum signal-to-noise ratio. IDEAL imaging provides uniform and reliable fat suppression throughout the body, with the potential to simplify MRI protocols (Hu *et al.*, 2010).

**FIG. 58.2** Bone and tissue images of a research subject. The scans were obtained from a Lunar iDXA system. Segmentation lines are used to divide the body into regions of interest to provide data on specific areas.

Compartmental tissue measurements using MRI have shown excellent precision (Browning *et al.*, 2010; Thamer *et al.*, 2010). Comparisons of various body measures with MRI indicate that although, generally, there were significant correlations of all modalities with body fat content and mainly with subcutaneous fat, correlations with intra-abdominal fat were much weaker. If it is important to

investigate fat distribution and especially the intra-abdominal adipose tissue, MRI cannot be substituted by simpler methods (Ludescher *et al.*, 2009). MRI has also broadened the scope of investigations into additional tissue depots. For example, brown adipose tissue, with its multilocular fat distribution and extensive mitochondrial, cytoplasm, and vascular supply, has a significantly lower

fat signal, making its quantification difficult. However, the fat fraction metric from IDEAL-MRI has recently been demonstrated to be a sensitive and quantitative approach for noninvasively characterizing brown adipose tissue (Hu *et al.*, 2010). Further, quantification of bone-marrow adipose tissue and its relation to loss of bone mineral content has led to investigations of the reciprocal relationship between fat and bone tissue compartments (Shen *et al.*, 2007). Although there are obvious limitations in terms of finances, population and space requirements associated with MRI, techniques are likely to be of use in a variety of medical investigations (Muller *et al.*, 2002).

## Quantitative Magnetic Resonance

Quantitative magnetic resonance (QMR) is a relatively new method for the determination of body composition. Similar to MRI, QMR utilizes the measurement of hydrogen to determine fat and lean tissue, and total body water. Protons from different tissues are differentially affected by the instrument. Fat tissue produces a greater peak amplitude and has a greater rate of relaxation than lean because of a greater hydrogen density (40% more hydrogen per unit) (Taicher *et al.*, 2003). A number of QMR instruments have now been validated, and used to determine body composition in mice, rats, pigs, and humans (Tinsley *et al.*, 2004; Napolitano *et al.*, 2008a; Johnson *et al.*, 2009; Jones *et al.*, 2009; Gallagher *et al.*, 2010; Swe Myint *et al.*, 2010).

The precision of QMR has been shown to be excellent. Gallagher *et al.* (2010) determined the coefficient of variation for fat to be 0.437% based on a standard deviation of 0.131 kg and an average fat value of 30.057 kg. Their results suggested that it may be possible to determine changes in fat mass of as little as 250 g, which is quite good compared with most methods. Similarly, Swe Myint and colleagues (2010) showed that QMR provides a benefit over other methods when the studies have a small standard deviation (0.5–1 kg) and a moderate difference among groups (1–2 kg). In this case, sample size can be reduced by up to 40% over conventional methods (DXA and/or the four-compartment method).

Although the precision of QMR is excellent, there are issues related to accuracy. Studies have demonstrated that QMR-measured fat, lean, and total body water in mice, rats, pigs, and humans differed significantly from other more established measures such as chemical carcass analysis and the four-compartment model (Napolitano *et al.*,

2008b; Johnson *et al.*, 2009; Jones *et al.*, 2009; Andres *et al.*, 2010; Gallagher *et al.*, 2010; Mitchell, 2010; Swe Myint *et al.*, 2010). It is not clear at this time why the measures differ, but care should be taken when using QMR to determine absolute quantities of fat, lean or total body water. However, given QMR's excellent precision, it is extremely useful for measuring differences between groups, or within groups over time.

One of the major benefits of QMR is its non-invasive nature. Not only does the instrument not expose the subject to ionizing radiation; the method does not even require the subject to remain completely still, since it is not capturing an image per se. Clearly this is beneficial when studying a pediatric population or a potentially health-impaired population where involuntary movement cannot be helped. In addition, measurement times are on the order of minutes, which facilitates subject compliance and the ability to measure numerous subjects per unit time.

## Assessment of Body Composition in Disease States

An important area of use of body composition techniques is in disease states. Due to the reliance on constant hydration of fat-free mass, which is not always the case in pathological processes, progressive involuntary weight loss or wasting presents a challenge in the accuracy of body composition assessment. Numerous studies have reported altered validity of BIA- and DXA-derived estimates with hydration status (Lohman *et al.*, 2000; Testolin *et al.*, 2000; Bredella *et al.*, 2010). Accordingly, the clinical evaluation and monitoring of body composition across disease states is a concern. Assessments of body composition in individuals with body habitus varying from anorexia nervosa (Bredella *et al.*, 2010) to those undergoing gastric bypass (Savastano *et al.*, 2010) present added complexity. Further, disease states in which wasting is often a symptom (e.g. cancer, HIV) also impart validity issues. Inconsistencies have been reported in DXA, BIA, and MRI measurements in patients with HIV (Esposito *et al.*, 2006; Scherzer *et al.*, 2008), celiac disease (De Lorenzo *et al.*, 1999), and short bowel disease (Carlsson *et al.*, 2004). The limited agreement between methods prevents generalizability, particularly in comparisons across varying weight and disease states. It is important to recognize that, beyond the limitations of each assessment device, additional factors such as hydration may also influence validity.

**TABLE 58.1** Major attributes of body composition methods

Method	Cost	Average test time	Accuracy <sup>a</sup>	Accessibility	Ease of use	Additional concerns
BMI	Low	<2 minutes	Low	High	Some training	Population-based differences
Body circumference	Low	<3 minutes	Low	High	Some training	Population-based differences
Skinfold	Low	5–10 minutes	Moderate	High	Some training	Population-based differences
BIA	Moderate	5–10 minutes	Moderate	Moderate	Some training	Hydration status
DXA	High	6–15 minutes	High	Low	Technician required	Radiation exposure
UWW	High	40–60 minutes		Low	Technician required	Breath hold
Air displacement plethysmography	High	8–12 minutes	Moderate	Moderate	Technician required	Air trapping/confinement
MRI	High	15–30 minutes	High	Low	Technician required	Space confinement
QMR	High	2–3 minutes	High	Low	Technician required	Space confinement

<sup>a</sup>As a measure of total adiposity, compared with UWW.

## Future Directions

Ideally, a method for determining body composition in humans should be rapid, non-invasive and non-harmful, rapid, precise, accurate, readily accessible, and inexpensive. Unfortunately, there are no such tests available. Instead, those methods that are low cost and rapid have lower precision and accuracy and therefore are better suited for population-based studies (Table 58.1). Methods that have high precision and accuracy require expensive equipment with trained technicians, are not portable, and are costly, making them better suited for smaller studies. Practical considerations must be taken into account when choosing body composition methods.

Knowledge of the limitations of each method is critical for appropriate experimental design. For example, the use of UWW would not be ideal if the subject population to be studied varied dramatically in age, gender, training status, and race, because of differences in the density of FFM. Knowing the assumptions inherent in methods allows the researcher to choose the appropriate method or component model to minimize bias in the results.

There is still much to be done in the area of body composition methodology. Although many of the methods

introduced in the chapter have been validated, many have not been validated in diverse groups. There is a critical need to increase the diversity of subject populations in validation studies so that future research is not hindered by the lack of adequate prediction equations.

### Summary

In this chapter we describe the different dietary assessment methods, their strengths and weaknesses, and the importance of examining sources of error and variation. There is no best method for all purposes, and therefore the investigator has to select the method appropriate for the purpose and target group of the survey. In selecting a dietary assessment method, it is important to answer several basic questions, as follows. *Who*: Who are the subjects and is group-based or individual information wanted? *What*: What information is wanted on which foods, nutrients, or other food compounds? *When*: Is the focus usual or current diet? Are special times of the day, days of the week, or season of the year of interest? *Where*: Where food is consumed may sometimes be important—for example, whether the food was consumed at home or outside the home. *Why*: The aim of the study determines the type of information of interest, such as mean intakes of groups and distribution and characterization of individuals. It also determines how accurate data have to be to adequately answer the research question. This information plus consideration of practical issues such as available time, trained staff, computer facilities, and funding will direct a researcher to the most efficient method for answering specific research questions.

### Introduction

Estimations of dietary intake always focus on food consumption of individuals or groups, but the underlying purpose may vary. For instance, metabolic studies are focused on the fate of nutrients in the body, and public health studies examine the adequacy of the diet and the relation between food consumption and health.

Various study designs exist for each objective, and the approaches are possible at different levels: national accounts of annual food availability per head of the population

(food balance sheets), family budget and household consumption surveys, and individual food intake or dietary surveys. In the context of this book, we will concentrate on dietary methods. Several dietary assessment tools directed at the individual are available. They differ in the time frame used, the method of administration, assessment of the foods eaten, and conversion into food components. Moreover, the immediate goals (information on meals, food groups, and specific nutrients or compounds), underlying assumptions, and cognitive approaches to acquiring dietary intake information vary between dietary

assessment methods (Table 59.1) (Cameron and van Staveren, 1988; Thompson *et al.*, 2010).

This chapter describes the main dietary assessment methods and the strengths and weaknesses of each. The concept of these methods has not changed much since the first edition of this book, but a wider range of suitable equipment and related resources for field use is available. More use is made of epidemiological studies, and the development and use of biomarkers have led to more information on sources of variation and errors inherent to these methods (Beaton *et al.*, 1994). These sources have to be taken into account in study design, data collection and treatment, and interpretation of results. Because the main causes of death are nutrition-related diseases (World Health Organization, 2003), obtaining more valid knowledge on dietary patterns is of the utmost importance.

## Dietary Assessment Methods

In general, methods can be divided into two basic categories: those that record data at the time of eating (prospective methods consisting of weighed and estimated records) and those that collect data about diet eaten in the recent past or over a longer period of time (retrospective methods

consisting of 24-hour recalls, dietary history, and food frequency method).

Prospective methods may include several days of recording, sometimes accompanied by collecting duplicate samples for chemical analysis or performed by proxies, e.g. by observation. Retrospective methods may refer to recent diet (24-hour food recalls) or habitual diet (dietary history and food frequency method). The three methods differ in many aspects, but if they are performed as an interview some practical aspects are similar for all. Interviewers should have a thorough knowledge about the purpose of the method; dietary components of interest; nutrient database to be used; details of the standardized protocol, including a quality control system to minimize errors; and foods available in the marketplace (including prevalent ethnic foods) and preparation practices. The location and mode (written questionnaire, face-to-face or telephone interview, web-based application) of the assessment may affect respondents' willingness and ability to report their diet.

Also, in using face-to-face interviews, cognitive aspects should be taken into account, especially those that govern the interview process. Most important are the aspect of "relation," which makes the contribution relevant to the perceived aims of the conversation; the aspect of "quantity," which makes the interview informative but not overly elaborate; the aspect of "manner," which makes the interview clear rather than obscure; and finally the aspect of "quality," which holds the speakers not to say anything deemed false or that has insufficient basis (Greenfield and Kerr, 2008).

The success of the interview relies on the respondents' ability to remember and adequately describe their diet. Because memory of past events is based on a variety of cognitive processes, it is important to take advantage of what is known about how respondents interpret questions about their food consumption and how they remember dietary information, and how that information is retrieved, judged, and reported to the interviewer. Probing is useful, but the questions asked in an interview should be as neutral as possible.

In collaborative research all interviewers must have had the same training and must be visited regularly during fieldwork. Checks should be made to detect systematic differences among interviewers in data collecting and coding. Several aspects of the application of dietary assessment methodology may be facilitated by technology to help standardization of interviewers and to reduce costs of data collection and processing.

## **Dietary Records**

### **Principles**

In the weighed record technique, the subject is taught to weigh and record the food and its weight immediately before eating and to weigh any leftovers. In most surveys not all items are weighed. Where weighing would interfere with normal eating habits, describing the quantity of foods consumed is acceptable. For example, for meals eaten in a restaurant, the investigator will estimate weights from the description. The weighed method differs from the estimated record where subjects do not use a scale but keep records, in portion sizes, of all the foods they eat on one or more days. The portion sizes are described in natural units (household measures) by using the utensils commonly found in homes.

### **Practical Aspects**

The number of days needed to record food intake depends on the aim of the survey and the expected between- and within-individual variation in intakes of the nutrients of interest. However, in practice no more than three or four consecutive days are included because of respondent fatigue. The form used to record intake is kept in a record book and may be closed or open (Nydahl *et al.*, 2009). A closed form is a precoded list of all of the commonly eaten foods in units of specified portion size. This list allows for rapid coding but could be less adequate because defined units may be unfamiliar to the subjects. A semi-open form may be meal-based and preconstructed with many foods and amount options listed, but including sufficient space for other foods. In general an open form is used more often. An optically readable food record has been tested, but a computerized record seems easier to handle.

If habitual diet is being assessed, it must be stressed that the subject must not use the opportunity to change intake. To avoid bias in response, it is advantageous not to disclose the nutrient being studied. Dietary records may be completed by someone other than the subject. For example, children <10 years old will not supply adequate records and the carer should help.

Respondents must be trained to record the level of detail needed to describe adequately the foods and amounts consumed, including the name of the food, preparation methods, and recipes. At the end of the recording period, the record should be checked in detail. The records should be coded for computer calculation as soon as possible so that the subject can be contacted again if necessary.

### **Strengths and Uses**

Strengths include that two or more days of recording provide data on within- and between-individual variation in dietary intakes, which allows estimation of the population distribution of usual intake; multiple days of recording may allow individuals to be classified according to their usual intakes; and 2-day records kept intermittently over the year may provide an estimate of usual intake by an individual. Open-form records may provide data on less frequently eaten foods in a defined time period. Portions can be assessed or weighed to increase accuracy (Bingham *et al.*, 1995).

### **Weaknesses**

In general, respondents must be literate and highly cooperative. This requirement may lead to response bias as a result of over-representation of more highly educated individuals who are interested in diet and health. Also, food consumed away from home may be less accurately reported, and the usual eating pattern may be influenced or changed by the recording process. In addition, since record keeping increases respondent burden, accuracy of records may decrease when the number of days increases. Finally, substantial under-reporting is suspected in specific subpopulations (e.g. obese persons) (Pietiläinen *et al.*, 2010).

Mobile telephones with an integrated camera to record food intake are new dietary record devices. It appears that adolescents readily adopt such technology, but, for valid assessment of food intake, improvements in the food-record design, the images, and the training of participants are required.

## **Twenty-Four-Hour Food Recall**

### **Principles**

An individual recalls actual food and beverage intake for the immediate past 24 or 48 hours or for the preceding days. The 24-hour food recall is the most common recall used. Food quantities are usually assessed by use of household measures, food models, or photographs.

### **Practical Aspects**

The diet recall was traditionally conducted by a personal interview with open forms, precoded questionnaires or tape recorders, but computer-assisted interviews have become common (Slimani *et al.*, 1999; Conway *et al.*, 2003). More recently, self-administered computerized 24-hour diet recalls have been developed (Zimmerman *et al.*, 2009). In the case of interviews, training of the interview-

ers is crucial because diet is recalled by asking probing questions. Most commonly the recalled day is defined as from when the respondent gets up until the respondent gets up the next day. The 24-hour recall is often structured with specific probes to help the respondent to remember all foods consumed throughout the day. Sometimes at the end of the interview there is a checklist with foods or snacks that might be easily forgotten. For children (Baxter, 2009) and elderly people (Kumanyika *et al.*, 1997), specific adaptations to their cognitive processes can improve the recall process. For this purpose, computer-assisted 24-hour recalls usually consist of multiple steps (Conway *et al.*, 2003).

Because the recall method depends on subjects' ability to remember and adequately describe their diet, this method is not suitable for children younger than  $\approx 7$  years and many adults  $\geq 75$  years. The 24-hour recall method is appropriate for describing the mean intakes of groups of individuals. Days of the week must be equally represented. Two or more non-consecutive repeated 24-hour recalls in combination with statistical modeling allow estimation of the usual intake distribution of individuals. It is advised that no prior notification be given to the subjects about whether or when they will be interviewed about their food intake. Although notification could help the memory of some subjects, others might change their usual diet for the occasion (Cameron and van Staveren, 1988).

### Strengths and Uses

The design of the method is appropriate for describing the mean intake of a group (Beaton *et al.*, 1979). Two or more days provide data on within- and between-individual variation, which allows for the estimation of the distribution of usual intake; open interviews provide data on less frequently eaten foods and are not culture specific, administration time can be short, the time period is well defined, and, in the event of interviewer administration, literacy is not required. Response rates are usually rather high for recalls. Administration by a dietician allows probing for incomplete information and requires fewer callbacks.

### Weaknesses

Weaknesses are that respondents' recall depends on short-term memory and it is known that omission and intrusions occur; portion size is difficult to remember and might be misestimated; and intakes tend to be under-reported. A 1-day intake does not reflect usual dietary intake of an individual and does not provide information

on within-individual variation. The method is vulnerable to variability between interviewers, and requires substantial staff time for interviewing, processing, and quality control. This is also the case for interviewer-administered computerized 24-hour recalls.

## Dietary History

### Principles

The dietary history assesses an individual's total daily food intake and usual meal pattern over varied periods of time. In practice the history usually covers the past month, 6 months, or 1 year. Originally, Burke (1947) developed the dietary history technique in three parts, including (1) an interview about the subject's usual daily pattern of food intake with quantities specified in household measures; (2) a cross-check using a detailed list of foods; and (3) a food diary in which the subject recorded food intake for 3 days. Today the diet history is applied in many ways. The meal pattern and the checklist of foods are considered as essential for the method, but the 3-day record is often omitted.

### Practical Aspects

In an open interview the subject is questioned about a typical day's eating pattern or, alternatively, the interview may start with a 24-hour recall. The purpose of the study must be so well known to the interviewer that it is easy for him or her to judge how much detailed information should be collected for each food group. Usual portion sizes are estimated with standard household measures and may be checked by weighing.

Because a dietary history aims to record a food pattern, it is a more complex interview than the 24-hour recall which records only the food consumption of the day before the actual interview. This makes a diet history too difficult to administer for a non-nutritionist. Exceptions may be diet histories guided and controlled by a precoded interview form or computer software, especially if they are developed for self-administration.

The diet history is also more demanding for the subject. It is not appropriate for individuals with a large day-to-day variation in their diet, because the method asks for a habitual dietary pattern. A satisfactory history is not always obtained from young children (Waling and Larsson, 2009), people preoccupied with weight problems, and mentally retarded people.

A short version of this method with a limited checklist of foods is often used in the clinical setting for diagnosis and as a basis for therapeutic dietary guidelines.

**Strengths and Uses**

The dietary history is used for assessment of usual meal patterns and details of food intake. The data can be applied to classify in categories (e.g. quantiles) of intake and to assess the relative average intakes of groups of people and the distribution of intakes within these groups. Respondent literacy is not required for an interviewer-administered dietary history (Thompson and Subar, 2008)

**Weaknesses**

Respondents are asked to make many judgments about the usual food intake and the amounts of those foods, and the recall period is difficult to conceptualize accurately. Reports covering a longer period may be influenced by present consumption and reveal higher estimates. Respondents need to have a regular dietary pattern and a good memory, which may hamper getting a representative sample of the population. It may become even more difficult in future, because an increasing number of people snack throughout the day. Highly trained nutritionists with well-developed social skills are required to conduct the interview, and the interview is very liable to evoke socially desirable answers. Finally, because there is no standardized technique for conducting a diet history, the performance differs between studies.

**Food Frequency Method****Principles**

The first food frequency questionnaires were developed for large epidemiological studies, for instance on the relation between diet and chronic disease. In such studies the diet history puts too heavy a burden on subject and investigator.

The questionnaire is a pre-printed list of foods on which subjects are asked to estimate the frequency and very often also the amount of habitual consumption during a specified period. The types of foods vary between questionnaires depending on whether the researcher is interested in specific nutrients or the total diet. The list of foods on a food frequency questionnaire may be developed in several ways (Willett, 1998; Molag *et al.*, 2010). For epidemiological studies the best way is to select foods contributing most to the variance of intake from a recent food-consumption database of a similar population as the target population. A nutrient value must be assigned for each food item listed. The value is based most often on weight-

ing each food in an item by usage. The first questionnaires did not include quantitative estimates other than servings or portions per day, week, or month. The data from these questionnaires are based on the assumption that total intake is more determined by variation in consumption frequency than by variation in portion size, and that consumption frequency is unrelated to consumed quantities. Nevertheless, some investigators have built a quantitative aspect into the technique and called their method a semi-quantitative food frequency method. Not all investigators advocate inclusion of portion sizes, because errors made by the estimation may outweigh the variance in intake of most foods.

**Practical Aspects**

Food frequency questionnaires vary in the foods listed, the length of the reference period, response intervals for specifying frequency of use, procedure for estimating portion size, and manner of administration. Often there is a tension between the length of the questionnaire and the required detail of information. The longer the food list, the more detailed the information; however, the respondent may become tired and subsequently less precise in answering the questions. From a review by Molag *et al.* (2007) that investigated the characteristics of FFQs, it became clear that more accurate results were obtained with longer FFQs (200 vs. 100 items). However, longer FFQs have the risk that respondents do not complete the FFQ. The development of the food list is crucial to success and takes a lot of time, especially since a validation study has to be part of the development.

If the food frequency method is administered by an interviewer, all requirements mentioned for the diet history and 24-hour recall have to be taken into account but nutritionists are not necessarily required for the interview. The advantage of a food frequency method is that the food list can be completely standardized, which reduces between-interviewer variation. For the respondents it may be cognitively difficult to combine the intake of similar foods or mixed dishes over a longer period of time and to report about them in one question. Therefore separate questions might be introduced. A disadvantage is that these questions may lead to double counting. It is important to address the best time frame for the study objective, although it is questionable whether respondents can accurately report over a period longer than 2 months. Because the questionnaire is usually self-administered, the accompanying instructions are important. Web-based question-

naires have the advantage that they can easily give cognitive support and prevent respondents skipping questions.

### Strengths and Uses

The food frequency method estimates the usual food (group) intake of an individual. When portion sizes are included or when certain assumptions are made, individuals can be ranked according to nutrient intake. A self-administered questionnaire may require little time to complete and to code; the response burden is generally low, and response rates, therefore, are high. The method can be automated easily and is not very costly.

### Weaknesses

Weaknesses of this method include that memory of food use in the past is required and that the respondents' burden is governed by number and complexity of foods listed and quantification procedure. The listing of foods may be incomplete or missing details. The quantification of portion sizes might be less accurate than in records or recalls. Also, the development and testing of the food list will take much time; no information on day-to-day variation is provided; and the suitability is questionable for sub-populations who consume culture-specific foods not on the list. Longer food lists and longer reference periods often lead to overestimation of intake, and the cognitive process for answering questions about food frequency may be more complex than those about a daily food pattern. Because of these problems, relationships in epidemiological studies are attenuated and thus may obscure existing relationships.

### Other Methods

Several brief dietary assessment methods have been developed. These instruments may be useful in clinical settings or for health promotion if only information of a part of the diet or qualitative information of the total intake is required. For example, a fat screener might be useful to increase awareness about unhealthy eating habits and in this way activate interest to alter consumption (Thompson and Subar, 2008). In addition, new technologies might allow so-called snapshot techniques, which collect detailed information on dietary practice at a specific point in time such as single meals or purchases rather than intake of a complete day (Illner *et al.*, 2010).

### Combined Methods

Sometimes a combination of two or more methods provides greater accuracy. A combination might balance the shortcomings and strengths, as summarized in Table 59.2, of one method with those of another. For example, a 2-day record or 24-hour recalls combined with a food frequency list may provide valid absolute mean intakes of groups, including within- and between-individual variation as well as a classification of high-risk groups for low (e.g. iron) or high (e.g. cholesterol) intakes. The information from the records or recalls provides details about the type and amount of foods consumed and the FFQ provides information on the propensity of a person to consume the food, which is especially helpful if foods are consumed infrequently (Tucker, 2007). A combination of methods might be too expensive for small-scale studies but is often done in large multicenter studies (Kaaks *et al.*, 1994) or

**TABLE 59.2** Sources of error in techniques for estimating food consumption

Sources of error	Weighed record	24-hour recall	Diet history	Food frequency
Variation with time	+	+	–	–
Response errors:				
omitting foods	+	+	+	
including foods	–	+	+	+
estimation of weight of foods	–	+	+	+
estimation of frequency of consumption of foods	n.a.	n.a.	+	+
changes in real diet	+	+/-	–	–
Errors in conversion into nutrient:				
FC tables	+	+	+	+
coding	+	+	+	–

+, error is likely; –, error is unlikely; n.a., not applicable.

**TABLE 59.3** Estimation of time to be spent by the fieldworker for one interview on administration, coding, and checking

Method	Administration explanation (minutes)	Check completeness of interview (minutes)	Coding (minutes)
Weighted record 3 days <i>face-to-face</i> interview excluding travel time	30	30	60
24-hour recall	30	5–30	30
Diet history	45–90	–	60
Scannable FFQ	30–60	5	5–10 (scan)

nationwide surveys (Beaton *et al.*, 1997), often facilitated with automated methods. Another example is the 24-hour recall assisted by a food record. Lytle *et al.* (1993) concluded that this was a valid method for assessing the dietary intake of children. During interviews by trained staff the children used diaries to record their food intake and recalled their 24-hour food intakes using the diary as a memory prompt. Combined methods are more time consuming for respondents and fieldworkers, although computers have facilitated the blending of methods. Table 59.3 gives an estimation of the time required for fieldworkers for interviewing, checking, and coding.

## Assessment of Specific Food Components and Dietary Supplements

### ***Micronutrients and Bioactive Components***

Knowledge of the validity of micronutrient status parameters as well as validity of intake measures is still limited, and further improvements in methods to assess micronutrient status are needed (Allen, 2009). The European Commission's EUROpean micronutrient RECommendations Aligned Network of Excellence (EURRECA) reviewed the validity of dietary assessment methods for use in epidemiologic studies with a special focus on micronutrients (Serra Majem, 2009). Their findings support the value of current methods, when applied according the current rules. For many diseases, research interest has also shifted to the bioactive components of foods, such as flavonoids, glucosinolates, allyl compounds, and phytoestrogens. Dietary measurement tools often need to be adapted specifically to the bioactive component of interest. Moreover, assessment of these components requires good data about the content of the bioactive components in foods, which are often not available in food composition

tables, necessitating chemical analyses in individual foods or replicate portions.

### ***Dietary Supplements, Fortified Foods, and Functional Foods***

Terms for dietary supplements, such as multivitamins or multiminerals, are widely used, but they have no standard scientific regulatory or marketplace definitions. Thus the composition and characteristics of these products vary. Also systematic information on the bioavailability and bioequivalence of vitamins and minerals in foods and other marketed products and on potential drug interactions is scarce. Collection of valid data on (components of) supplement use is therefore difficult (Yetley, 2007). This is problematic because, in Northern American and Western European populations, the use of dietary supplements, fortified foods, and functional foods is substantial. These products can contribute >50% of micronutrient intake for an individual. Failure to include such important sources of nutrient intake can result in estimates of intake that bear little relation to biochemical status, which is often the ultimate parameter of interest. Supplement users may take supplements irregularly. Therefore, to take a measure of supplement use on one or a few days as a proxy for long-term intake incorporates measurement error that attenuates measures of association with status parameters (Patterson *et al.*, 1998). The same conclusions will probably hold for fortified and functional foods.

In large-scale studies focusing on diet–disease relations, the frequency and number of supplements taken seem to be much more important than precision about content. Distinction between single and multiple vitamin supplements is essential; distinction between one-a-day and high-dose types is desirable. Within each of these subtypes the exact brand name or exact content does not seem to

be necessary because assumptions about the amount will be approximately correct. For assessment of actual intake – in contrast to usual intake – and for quantitative assessment of the distribution of intake for a population, brand name and dose information are relevant.

An approach similar to that used for dietary supplements will probably work for foods marketed in a fortified or functional version as well as the ordinary version. Examples of such foods are milk products when calcium is the component of interest: consumers will probably know whether they buy the fortified version, and amounts of added calcium will not vary substantially. Usual intake of milk can then be questioned separately for calcium-fortified milk as a generic term. However, for many other types of functional foods, information at the brand-name level and subtype will be required. This may be the case because the consumer is unaware of consuming a fortified or functional product, the consumer does not know the specific content of the product, or the amounts of added components in some products vary enormously.

### **Alcohol**

The assessment of alcohol intake should also be conducted carefully, because alcohol is not always considered a normal food substance. On a population level, alcohol intake might be assessed by using official data such as food balance sheets collected by the Food and Agriculture Organization of the United Nations or by using sales statistics. The advantage of such statistics is that the population is not aware of the registration, and socially desirable answers – a big problem in individual-based approaches – are thus avoided. However, these statistics do not provide data on manner and amount of alcohol consumption of specific groups or individuals, and are not very useful for epidemiological purposes. Most individual-based dietary assessment methods described here will include questions on alcohol intake. In addition, specific frequency questionnaires were developed to assess alcohol intake. Altogether, according to the literature, there are five main approaches (Feunekes *et al.*, 1999): the quantity frequency method (includes simple questions on intake of glasses of alcoholic drinks in a specific period), the extended quantity frequency (includes questions on specific drinks – wine, beer, liquor – and variability during the week and at week-ends), prospective and retrospective diaries, and repeated 24-hour recall.

The mean level of alcohol intake may differ by 20% by applying various methods. Intake data yielded higher esti-

mates for beer, wine, and liquor consumption than did sales information. Nevertheless, underestimation is common to all methods, and heavy drinkers will seldom participate in a survey on alcohol intake, which leads to selection bias. Ranking participants according to alcohol intake may distinguish those who consume small and large quantities sufficiently for epidemiological purposes.

There has been some discussion about including alcohol intake in research on estimating daily energy intake. On the one hand, if energy from alcohol is not included, the proportions of macronutrients contributing to the daily energy supply are incorrect. On the other hand, high alcohol intake may mask a relatively high fat intake contributing to the daily energy supply (Greenfield and Kerr, 2008).

### **Variation and Error**

The choice of the most appropriate assessment tool depends on purpose and design, type of information required (such as means, medians, distribution), and practical issues (e.g. availability of funding, time, and skilled staff; characteristics of the subjects). In order to select the most appropriate dietary method to answer a research question, it is important to understand the potential sources of variation and error for each method and their effects on the results of the study.

#### **Sources of Variation**

At the level of the individual, dietary intake is characterized by daily variation superimposed on an underlying consistent pattern (Willett, 1998). Factors such as day of the week or season often contribute to daily variation in a systematic way whereas other aspects of dietary intake are random. Dietary data collected on multiple days incorporate these kinds of variation. In food frequency questionnaires and the dietary history method, participants are asked to filter out the underlying consistent dietary pattern themselves. It can easily be imagined that this is more difficult in the absence of a regular dietary pattern. All dietary data include variation that is due to measurement error, but measurement error can also result in the loss of some of the real variance. Measurement error usually consists of a random and a systematic component.

The degree of random and systematic variation in dietary data differs across nutrients. For example, total energy and macronutrient intake have relatively little random variation whereas intake of some nutrients such

**TABLE 59.4** Within-subject ( $CV_w$ , %) and between-subject ( $CV_b$ , %) coefficients of variation in nutrient data collected by repeated 24-hour dietary recalls and food frequency questionnaires

Nutrient	24-hour dietary recalls				Food frequency questionnaires			
	Men		Women		Men		Women	
	$CV_w$	$CV_b$	$CV_w$	$CV_b$	$CV_w$	$CV_b$	$CV_w$	$CV_b$
Energy	26	18	24	18	12	23	11	20
Protein	27	16	26	17	13	20	12	18
Fat	38	26	37	24	16	28	14	25
Carbohydrates	26	24	22	22	14	27	12	25
Cholesterol	56	29	52	23	17	29	15	24
Retinol	259	35	155	44	32	41	41	50
Vitamin C	65	33	68	36	26	37	32	33
Calcium	40	29	32	31	24	32	18	31

Data are based on twelve 24-hour recalls and three food frequency questionnaires in 63 Dutch men and 59 Dutch women. Reproduced with permission from Ocké *et al.* (1997).

as retinol and marine fatty acids is characterized by large random variation resulting from the large variation in their daily intake. Within- and between-subject variation in nutrient intake is illustrated in Table 59.4 with data from a Dutch validation study for 24-hour recalls repeated 12 times and from food frequency questionnaires repeated three times (Ocké *et al.*, 1997). The findings are, however, culturally determined because they depend on dietary pattern.

### Measurement Error

From a methodological point of view, four types of measurement error exist: random within-person error, systematic within-person error, random between-person error, and systematic between-person error (Willett, 1998). Systematic error is also called bias. The types and size of error vary with the particular dietary assessment method and probably also with the population in which it is applied. (See also Table 59.2.)

Random within-person error may be due to day-to-day variation in an individual's daily intake when habitual intake is estimated. Thus, error in this methodological sense is not a mistake in the data collection but rather a mismatch in time frame. Random within-person error also includes errors in the measurement of intake on any occasion that are not systematic. Examples of this type of error are foods that are omitted or included falsely in dietary records or recalls, portion sizes that are estimated inaccurately, and coding mistakes. When random within-person

error is the only type of error present, the precision of the estimated mean value for an individual depends on the within-subject variation and the number of replicate measurements, as shown in equation 1. This equation can also be rearranged to calculate the number of days required to estimate mean intake for an individual given the size of the random variation and the precision that is needed (Beaton *et al.*, 1979):

$$D_0 = Z_\alpha \frac{CV_w}{\sqrt{n}} \quad (1)$$

where  $D_0$  is the greatest deviation from the mean (as a percentage of long-term true intake),  $Z_\alpha$  is the normal deviate for the percentage of times the measured value should be within a specified limit (1.96 for 95% confidence),  $CV_w$  is the within-subject coefficient of variation, and  $n$  is the number of days for the person.

Systematic within-person error may be caused when a person consciously or unconsciously underestimates or exaggerates his food intake. An important food for an individual that is not included in a questionnaire or a question that is systematically misunderstood by an individual will also lead to systematic within-person error. If the dietary assessment method is repeatedly administered, the error will occur again. Consequently, the estimation of mean intake for an individual is not improved by repeated measurements and remains biased. Increasing evidence suggests that most dietary assessment methods, including

those for recalls and records, are likely to be flawed with systematic person-specific biases (Kipnis *et al.*, 2003).

Random between-person errors may be due to random and systematic within-person errors if they are distributed randomly across individuals; an overestimation by some individuals is counterbalanced by an underestimation by others. The estimated mean intake is consequently not biased but the precision is affected and the distribution of measured intake is artificially widened. Estimates for the percentage of subjects below or above a certain cut-off level (e.g. estimated average requirement, EAR) are therefore not valid. Also, the validity of measures of associations with health parameters is hampered and for univariate association is attenuated. In equation 2 it is shown that the precision of the estimate of the mean group intake can be improved by increasing the number of subjects or the number of replicate measurements (Beaton *et al.*, 1979):

$$D_t = Z_\alpha \sqrt{\frac{CV_b^2}{g} + \frac{CV_w^2}{gn}} \quad (2)$$

where  $D_t$  is the greatest deviation from the mean (as a percentage of long-term true intake),  $Z_\alpha$  is the normal deviate for the percentage of times the measured value should be within a specified limit (1.96 for 95% confidence),  $CV_b$  is the between-subject coefficient of variation,  $CV_w$  is the within-subject coefficient of variation,  $g$  is the number of persons, and  $n$  is the number of days per person.

Systematic between-person error is caused by systematic within-person error that is not randomly distributed across individuals. The use of questionnaires that fail to include important foods for a population, or of incorrect standard portion sizes; people giving socially desirable answers; and recalls or records that do not include weekend days, will all result in systematic between-person error. As a result the mean intake is not estimated correctly, nor is the percentage of persons above or below a certain cut-off level. Testing whether an association with a health parameter exists is not affected by systematic between-person error that applies equally to all subjects. However, this error may be associated with a variable for which the relation to dietary intake is the topic of study, and a misleading conclusion might be drawn. An example is body mass index: subjects with a higher body mass index underreport their energy intake more than those with lower body mass index.

**TABLE 59.5** The effects of random and systematic between-person error in dietary intake on parameters to be estimated

Parameter to be estimated	Type of between-person error	
	Random	Systematic
Mean intake	Precision ↓	Validity ↓
Distribution of intake	Validity ↓	No effect
% of subjects below RDA	Validity ↓	Validity ↓
Association with health outcome	Validity ↓	No effect

Prepared by Jan Burema.

The effects of random and systematic between-person measurement error on various parameters to be estimated are summarized in Table 59.5. Formulas and statistical models that correct for the effects of random measurement error are now available for many outcome measures such as the distribution of intake and measures of associations with other variables such as correlation coefficients, regression coefficients, and relative risks (Willett, 1998; Carroll *et al.*, 2006). Information on the size of random measurement error can be obtained from dietary reproducibility and validity studies. The former only gives information on part of the total random between-person error (i.e. not that based on systematic within-person error). In theory, validity studies supply information on the total error. However, in practice this is limited by the lack of a true gold standard, that is, dietary assessment methods without errors or with completely independent errors. The OPEN study (Kipnis *et al.*, 2003) is an example of a study that gives insight in the error matrix for 24-hour diet recalls and food frequency questionnaires.

Quality control checks can indicate systematic measurement error. An often-used check for underestimation is the ratio of energy intake to estimated basal metabolic rate. If this ratio is below a certain cut-off value, energy intake is very likely underreported (Willett, 1998; Livingstone and Black, 2003; Abbot *et al.*, 2008). Techniques for adjustments are not well developed for systematic measurement error associated with parameters of interest.

## Assessment in Specific Situations

### Clinical Settings

Diet might be assessed in a clinical setting for diagnostic purposes, as a screening tool for probable dietary risk, or

as a basis for dietary advice. The required accuracy of the collected information depends on the purpose of the data collection. However, because dietary treatments should be evidence based rather than experience based, a reproducible estimate – standardized for specific purposes of the assessment – is required so that the results of treatment can be evaluated and compared. When current diet is the information of interest, structured questionnaires based on the meal pattern of the clinic may be efficient. This type of questionnaire can be computerized.

### **Geographic and Ethnic Differences**

In remote areas food policy is more concerned than it is in the industrialized world with how people produce or otherwise obtain their food and how they deal with it. A method for collecting these data is food ethnography. This method is introduced by anthropologists with the aim of getting more insight into responses of populations to natural, social, cultural, and economic pressures. Food ethnography provides a descriptive analysis of the food system and food habits; it includes the ways in which individuals or groups choose, prepare, consume, and make use of available foods. The main deterrents to surveying remote areas are the cost and time involved in fielding survey teams. Mail, telephone, and internet services can be inexpensive alternatives to face-to-face interviewing. Special sampling techniques and procedures can be used to limit the geographical scatter of the sample selected from remote areas. Cluster sampling, for example, can reduce the number of such locations selected without affecting the representativeness of the sample, substantially reducing the logistic demands and operating costs of the survey (Cameron and van Staveren, 1988; Den Hartog *et al.*, 2006).

Otherwise, for a quick insight in the adequacy of the diet, a food diversity score can give insight. It is well known that, in remote societies, diversity of available food can be very narrow. It is possible to survive and maintain health with narrow food diversity, if the foods are sufficiently nutrient dense and different in composition. Wahlqvist and Lee among others developed a food diversity score, which can be used as a kind of screening for the adequacy of food intake (Wahlqvist *et al.*, 2009).

When an in-depth dietary assessment is required in minority groups with a strong ethnic identity, note that structured questionnaires or records need to be adapted. Employing interviewers with the same background if possible is a great help. Food composition databases should

be checked for completeness regarding ethnic foods and recipes. Photo books are often necessary for identifying foods (Den Hartog *et al.*, 2006).

## **Assessment in Specific Populations**

### **Individuals with Disabilities**

Disabilities affecting sight, hearing, speech, memory, or the ability to write are particular problems in the collection of all kinds of data, including dietary intake data from affected individuals. If only one faculty is affected, survey methods relying on other faculties will provide the solution needed. For example, carefully prepared, self-explanatory, written instructions and questionnaires are required when the subject of a study is deaf. The process can be helped by using printed instructions, questionnaires, and probing techniques or a sign-language interpreter. Replica models or pictures can help the identification of the foods and the quantity consumed. If speech is impaired, provision should be made for written responses.

When respondents are unable to answer, surrogate responders may be used. Individuals who are closest to the subject (e.g. carers) are assumed to be the best surrogate responders not only because they know the most about a subject's lifestyle but also because their commitment is probably greater (Den Hartog *et al.*, 2006; Emmett, 2009). In institutionalized persons, e.g. care-dependent elderly, proxies may use an observation method, although it is not possible to apply such an intensive method to large numbers of residents (de Vries *et al.*, 2009). Mean frequencies of food-group use reported by subjects and surrogates are more or less similar, depending on the type of food (e.g. frequencies are better for drinks than for other foods). Furthermore, although subjects reporting themselves at the extremes of the distribution seldom are reported by their surrogate to be at the other extreme, many are reported to be in the middle of the distribution. This limits the usefulness of surrogate information for analyses that rely on proper ranking of people. When surrogates are included in a study, analyses should also be conducted after the surrogates are excluded in order to examine the sensitivity of reported associations to possible biases in the surrogates' reports.

Another possibility is observation by interviewers. To adequately observe food habits, however, the interviewer needs to stay for one or more days in the home. The presence of an outsider may interfere with daily life. People may refrain from eating low-esteemed foods for reasons of

dignity or vice versa, making the diet less varied and healthier. After some time subject and interviewer become used to one another, but this may take a lot of time.

### **Young Children**

Young children up to the age of 7 years have insufficient ability to cooperate in dietary assessment procedures. Therefore parents or other carers have often functioned as surrogate respondents. Studies comparing direct observations with recalls by parents suggest that the latter are reliable reporters of food intake at home but not of consumption outside the home.

From the age of 8 years onwards there is a rapid increase in the ability to self-report food intake. Issues to take into account are limitations of memory, concept of time, attention span, and knowledge of foods and food preparation. Food preference and rapidly changing food habits affect the reliability of recall of food consumption. Of key importance in designing questionnaires is to understand how food-related information is organized in memory and subsequently retrieved in dietary recall. Domel *et al.* (1994) developed a model that showed that the most usual retrieval mechanism categories employed by children were: visual imagery (the color of foods and their shape); usual practice (familiarity with eating the food previously); behavior chaining (linking foods to other food items or activities during the meal) and food preference. In order to improve recall accuracy, the retention interval between intake and report must be minimized. For example, for a 24-hour recall interview it is preferable that no meals be consumed between the last meal to be reported and the start of the interview. Using photographs and technology, children were found to estimate food portion size with an accuracy approaching that of adults (Domel *et al.*, 1994). By adolescence, cognitive abilities should be fully developed; limiting problems in that age are issues of motivation and body image. Techniques including attractive technologies may improve reports because they may increase motivation, cooperation, and recognition of types of foods and portion sizes (Baxter, 2009).

### **The Elderly**

When people become older the risk of disabilities increases. Ability of older adults to participate in dietary assessment studies requires careful consideration. Up to the age of 70 years, ability to participate will not differ seriously from that of younger adults. Accurate reporting by elderly people up to their 80s is regularly found, but older people

may tend to report food habits from earlier in life. For these higher age groups, some techniques as reported above may help them to report reliably on their food intake. Because memory fades with age, surveying the elderly requires particular care. Adaptations of recording methods and diet histories have resulted in valid reports for older adults. As in adolescents a picture-sort technique including a cognitive processing approach helps elderly people to remember what they usually eat (Kumanyika *et al.*, 1997). With regard to 24-hour recalls and food frequency questionnaires, the possibility of cognitive decline needs to be borne in mind. For food frequency questionnaires, reviewing these with participants remains important in this group, especially in order to check that no answers to questions have been omitted. Therefore, testing the method of data collection is particularly important in this age group to ensure valid results. It may also be helpful to use a combination of different techniques, for example, a food record combined with dietary recall (de Vries *et al.*, 2009).

## **Equipment for Dietary Surveys**

### **Mode of Administration and Survey Forms**

Interviews may be conducted either face to face at home or in special settings, or by telephone. Also questions can be mailed, or computerized and asked via special websites. Each mode has advantages and disadvantages. For example, mailed and telephone interviews have lower costs, because no costs and time for traveling have to be included. However, the response rates are in general lower with these types of interview. Instructions with mailed questionnaires must be clear. Portion sizes, as in telephone interviews, may be difficult to assess (Cameron and van Staveren, 1988). Computerized interviews are highly standardized, and errors in coding are minimized, but the development is costly and takes time. Face-to-face interviews require highly skilled and trained interviewers. Survey forms should be clear, logical and easy to complete.

Several new technologies in the field of dietary assessment have become available in recent years or are under development. They address several aspects of the dietary methodology, including facilitation of interviews, estimation of portion sizes, and data processing. Examples of new technologies include mobile phones with cameras to identify the types and amounts of foods consumed, allowing real-time processing of dietary data (Weiss *et al.*, 2010); in addition automated 24-hour recalls have been developed

that are self-administered and make use of photographs of portion sizes (Subar, 2010). Expected advantages of these innovative technologies are greater accuracy and cost reductions. Validation is, however, always necessary.

### **Scales and Models**

The quantities consumed can be assessed in various ways although, as explained earlier, not all approaches are suitable for all purposes. Equipment for quantifying portion sizes is not always necessary because foods can be expressed in household measures, natural or commercial units, or typical serving sizes. Examples of this approach are the amount of coffee expressed as the number of cups of coffee, the quantity of egg by the number of eggs used, and the amount of green salad in the number of cups of standard salad. This approach is cognitively easier and preferable over estimation of rates; however, it is suitable for many but not all foods. It is, for example, less accurate for vegetables and meats. Information on the weight of the reported units and serving sizes and the volume of typical household measures is required for portions to be converted to weight.

### **Scales**

If calibrated weighing scales of good quality are used, this method is most accurate for obtaining the quantity of a food. However, the weighed quantity does not necessarily represent the quantity that would have been eaten if the weighing process were not necessary. When scales are used, they should be robust, be accurate to at least 5 g, and weigh up to 1.5 kg so that a normal plate can be used when weighing the food to be eaten. The weights of foods need not be recorded by hand, but can be done verbally, for example by using a scale with an audiocassette or a scale that is directly connected to a computer.

### **Food Photographs**

During the past decade food photographs have been used increasingly for estimating portion sizes. In most cases a series of photographs representing different quantities are offered to the subject, who is asked to identify the photograph that most resembles the quantity consumed. Sometimes only one photograph is available for each food, and the quantity is indicated as a fraction or multiple of the amount shown. This latter approach gives rise to larger systematic error than does a series of food photographs. Several studies have examined the validity of this type of portion size estimation or the added value of food photo-

graphs versus standard amounts. The angle at which the photographs are taken as well as the number and range of depicted quantities are important for the perception of the quantities shown.

### **Food Models**

Food replicas are three-dimensional models representing specific foods. They are lifelike in size and color and are often made of plastic. Portion-size models are more abstract and represent sizes of portions (mounds, cubes, balls, etc.) rather than specific foods. Drawings are alternative ways to help in estimating amounts of foods. The validity of the various food models seems highly dependent on the specific model and the culture of the subject. It is important to check standard portion sizes regularly, because industry tends to increase the portion sizes of the foods they produce. More foods are now prepacked, and information about portion sizes from the manufacturer is often available. Technologies such as digital photography and more sophisticated approaches have the potential to improve the estimation of portion size in dietary assessment. Young people in particular are likely to respond positively to such technologies.

### **Computer Software**

Today software is available for almost all dietary assessment methodologies. Many computer packages for developing food frequency questionnaires, data collecting and processing, and also for converting foods to nutrients, include a nutrient database as well as software to convert subjects' food consumption into intake of energy, nutrients, and other bioactive compounds. The quality of the databases, including nutrition survey data for selecting foods, food lists and food composition data, is critically important; the quality of the data for nutrients and other food components important for answering the research questions of the survey should therefore be checked and if necessary updated. Software should be chosen on the basis of the research needs and user-friendliness. Automation has been incorporated into dietary surveys to varying degrees, and changes quickly (Thompson *et al.*, 2010).

### **Future Directions**

What are the trends in dietary assessment methods and where are we going? The international conferences on dietary assessment methods have tried to answer this question every four years since 1992. Main conclusions are:

- There is not and never will be a method that can estimate dietary intake without error.
- Different types of error have different effects in analyses and in interpretation of data.
- The challenge is to develop methods for error structure of data sets and statistical approaches that take that error structure better into account.
- With the increasing number of foods marketed – including enriched products and supplements – the food list and consequently the interviews become very long and boring. Especially when more than one method has to be applied, this might affect the quality of the data collections.

Future developments in this respect may include improvements such as will enable:

- work with attractive computerized questionnaires, including pictures of foods and portion sizes;
- application of a cognitive approach in these questionnaires;
- researchers to make use of an internet approach and to use strip-codes on foods.

## TASTE AND FOOD CHOICES

ADAM DREWNOWSKI<sup>1</sup>, PhD AND PABLO MONSIVAIS<sup>2</sup>, PhD, MPH

### Summary

The concept of “food taste” includes the sensations of taste, aroma, and texture, as well as the pleasure response to foods. Although taste is an important factor, food choices are complex decisions that are also guided by cost, convenience, and concerns about nutrition. While gustatory senses and olfaction mediate the perception of food attributes, the central nervous system determines the reward value associated with food consumption. Recent research has identified specific regions of the brain and pharmacological pathways that are involved in the hedonic response to foods. Taste preferences vary with age and gender, and can be modulated by anticipation as well as by nutritional and/or physical status. The notion that taste sensitivities and preferences alone determine dietary choices and therefore health outcomes is overly narrow and ignores the many intermediate steps between taste functioning, dietary choices, and health. Public health programs to improve population diets ought to consider age-specific food preferences and social norms of food consumption as well as a wide range of demographic and socioeconomic variables that mediate the link between taste preferences and food consumption.

### Introduction

Taste is said to be the most important factor influencing food purchases (Glanz *et al.*, 1998), well ahead of cost, convenience, or consumer concerns with health, weight or dietary variety (Logue, 2004). The popular concept of “taste” is based on the physiologic sensations of taste, aroma, and texture (Drewnowski, 1997a) and on the sensory pleasure response to foods (Drewnowski, 1997a, 1998). This chapter will focus primarily on taste or gusta-

tion, with the aim of understanding how taste sensations contribute to food liking and the patterns of food consumption.

Taste sensations are conventionally divided into five primary tastes: sweet, sour, salty and bitter, and the savory taste of umami. The mechanisms that underlie these five taste sensitivities can be broadly grouped into those that function as ion channels (salty and sour) and those that function via G-protein-coupled pathways (sweet, bitter, and umami). Tastants such as sucrose (sweet),

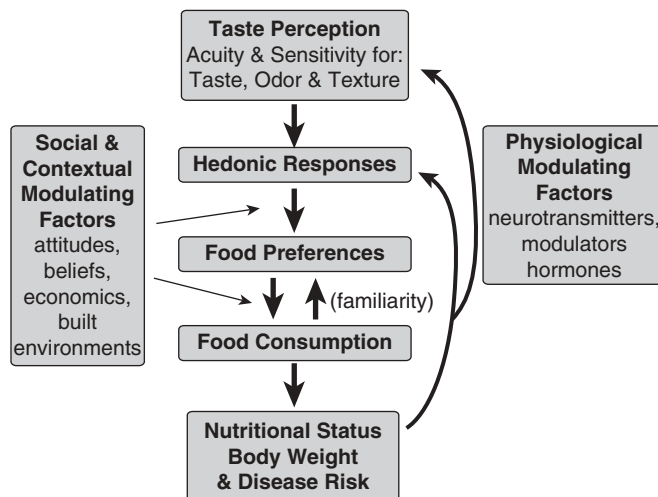

hydrochloric acid (sour), sodium chloride (salty), and quinine (bitter) need to be dissolved in water to stimulate the taste response. Two unique compounds, propylthiocarbamide (PTC) and 6-*n*-propylthiouracil, taste bitter to some people but are completely tasteless to others. Those compounds have long served as genetic markers for the perception of bitter taste.

Taste sensations can be measured using detection thresholds (lowest detectable amounts) or by scaling the perceived taste intensity of more concentrated taste solutions. Neither detection thresholds nor taste scaling can predict individual likes or dislikes for the tasted substance. In general, humans like sweet and dislike sour, salty, and bitter tastes; however, a great deal of individual variability in taste acuity or in hedonic response is observed.

Several lines of research have sought to link individual differences in taste response to food consumption patterns and chronic disease risk. The underlying assumption was that taste responses drove food-seeking behaviors, determined energy and nutrient intakes, and so affected chronic disease risk. In reality, food choices are influenced by a myriad of cultural, social, and economic variables in addition to taste.

In reality, there are multiple steps between an individual's gustatory profile and his or her food choices (Drewnowski, 1997a, 1998) and chronic disease risk. First, very few studies have examined taste responses, food preferences, and nutrient intakes in the same subject population. No direct association between taste function and health outcomes can be made, and in the absence of longitudinal data no causal pathways can be drawn. Secondly, population eating habits are influenced by age, gender, and energy needs, as well as by demographic and socioeconomic factors, making it difficult to link taste-related variables with particular health outcomes. Thirdly, there is new appreciation that taste responses are not static but can be modulated over the course of days and even hours, partly as a result of changes in nutritional status and partly as a result of activity in particular neuroendocrine systems.

The factors that influence taste and food preferences operate at multiple levels and can range from molecular biology to economics (Figure 60.1). Whereas the individual responsiveness to sugars or fat texture may depend on physiologic variables (Mattes, 2005), there is little doubt that the relatively low cost and accessibility of these nutrients in the modern food supply promotes their consumption (Drewnowski, 1998). Examining some of these

**FIG. 60.1** Hypothesized chain of events between sensory perception and food consumption and nutritional status. At least three steps lie between sensitivity to taste stimuli and nutritional status, body weight, and disease risk. The strength of some links is modulated by various factors. Note that taste perception, hedonic responses, and food preferences receive feedback from a number of sources.

causal pathways linking taste with food selection is the topic of this review.

## Measuring Taste Responses

Assessments of taste responsiveness measure taste perception as well as taste preferences. Taste perception includes taste acuity, determined using detection and recognition thresholds, and taste sensitivity, based on intensity scaling of more concentrated taste stimuli (Drewnowski, 2003). Most research in nutrition and taste psychophysics has focused on the detection and perception of four basic tastes: sweet, sour, salty and bitter. The typical stimuli were aqueous solutions of different simple sugars (sweet), sodium chloride (salty), citric or hydrochloric acid (sour), and either caffeine or quinine (bitter). The umami taste of glutamate was once considered to be a taste enhancer, but is now considered to be a distinct fifth taste (Beauchamp, 2009).

With the exception of bitter taste, the ability to detect extremely low concentrations of a given tastant does not predict preferences for that taste at above-threshold levels.

As a result, studies on taste and food choice have focused on intensity scaling of supra-threshold solutions (Bartoshuk, 1993) and on hedonic response profiles. Among the methods used for intensity scaling were 9-point category scales, visual analog scales (VAS), the labeled magnitude estimation scale (LMS), magnitude estimation, and other ratio scales (Mattes *et al.*, 2005). Intensity ratings recorded in taste psychophysics are on a logarithmic scale since taste, like other sensory systems, has sensitivity to stimulus concentrations that spans several orders of magnitude.

Measures of taste sensitivities are distinct from the hedonic response, a measure of the acceptability or pleasantness of a given taste stimulus. Intensity and hedonic ratings for the same taste stimuli follow different psychophysical curves. Laboratory studies have generally tested hedonic ratings for simple foods and beverages such as sugar solutions, sweetened lemonade, salted soups or tomato juice, or mixtures of milk, cream and sugar. Industry studies on the taste acceptability of more complex foods, conducted in commercial sensory evaluation laboratories, generally asked respondents to rate the acceptability of flavor, color, and texture, as well as the overall acceptability of the food product (Clydesdale, 1993). The key measure of liking has been the 9-point hedonic scale, commonly known as the hedonic preference scale (Drewnowski, 1997a).

## The Taste Sensations

Taste responses, as measured by response thresholds, recognition thresholds, and hedonic responses, are both innate and acquired. Whereas much of the population's variation in response to sweetness is genetic (Keskitalo *et al.*, 2007), taste responses also evolve over the life course and can be altered by our dietary habits.

Growing children equate palatability with sweetness and selectively consume the sweetest and the most energy-dense foods (Birch, 1999). Sweetness signals food energy, and, at least for naturally sweet foods such as ripe fruits, also signals the presence of nutrients. Bitterness signals dietary danger (Drewnowski, 2001a), which is why bitter-tasting vegetables and fruits are often rejected by children and by pregnant women. Other tastes may signal other nutritional qualities. For instance, the savory umami taste, which is elicited by salts of the amino acid glutamate, may signal the protein content of foods.

## Sweet Taste

Sweet foods and beverages are universally liked across all cultures and by all age groups (Drewnowski, 1997a, 1998). Hedonic response profiles for increasing concentrations of sugars are highly diverse and are strongly associated with age. While children typically show a monotonic rise in hedonic ratings with increasing sweetness, adults tend to show a non-monotonic pattern, where the degree of decline at highest sweetness levels is associated with age. For most adults, 10% of sugar in water is the ideal or optimal sweetness level. By contrast, young children aged 3–5 years did not show the characteristic hedonic optimum for sucrose, and selected the most intensely sweet solutions in the 20% range. The sweetness optimum declined during adolescence, and sweet taste preferences diminished further with age. Although taste functioning is still robust, sugar consumption among adults is less than half of what it is among younger age groups.

For children, sweetness is one of the most salient attributes of a food or beverage. Indeed young children categorized foods according to whether they were familiar or sweet (Birch, 1999). Children's preferences for intensely sweet foods and beverages have been attributed to the high energy needs of children, which increase the perceived reward value of consuming foods. This notion is rooted in a broader concept that the body's energy and nutrient requirements are dynamically manifested in taste sensitivities and preferences. Testing this concept, a number of influential studies attempted to link the taste preferences for sweetness with energy balance and body weight.

Despite many attempts, taste response profiles to increasing concentrations of sweet taste have never been linked to body weight or to body mass index ( $BMI = kg/m^2$ ). Similarly, taste responses to sweetness have never been linked to dietary restraint, a measure of concern with dieting that was at one point said to measure the distance from the physiological set-point of body weight.

The suppression of taste preferences for sweetness following exposure to sweet solutions has been used as a measure of appetite control. Studies showing that obese persons did not reduce their preferences for sweet taste even after drinking 200 ml of sweet glucose solution (Cabanac and Duclaux, 1970) were used to support the argument that obese persons were hyper-responsive to sweet taste and incapable of judging whether they were hungry or not. However, the notion that obese persons failed to perceive or to respond to sweetness was abandoned

as sensory studies demonstrated that taste sensitivity to sweetness of obese and lean persons was approximately the same (Thompson *et al.*, 1976). Studies using sucrose solutions, sweetened soft drinks, or chocolate milkshakes found no connection between preferences for sweetness and body weight. These studies, mostly conducted in the 1970s and 1980s, failed to make the case that a “sweet tooth” was the principal cause of human obesity.

More recent studies have shown that sweet taste can be modulated by hormones and other signaling molecules. Sweet taste receptors were found to have CB-1 cannabinoid receptors, and activation of CB-1 receptors by anandamide, an endocannabinoid, has been shown to increase the physiological response to sweetness (Yoshida *et al.*, 2010). Sweet taste threshold is also lowered by serotonin (Heath *et al.*, 2006). Countering this effect, sweet taste receptors also are responsive to leptin, a circulating peptide hormone produced by adipocytes. Leptin was found to reduce the response to sweetness by sweet taste receptors (Jyotaki *et al.*, 2010).

### **Bitter Taste**

From birth, humans dislike and reject bitter tastes (Drewnowski, 1985, 2001a; Birch, 1999), which are a universal signal for potential dietary danger. The sensitivity to bitter taste is highest in infants, young children, and pregnant women, who would be the groups most vulnerable to bitter-tasting dietary toxins. The more intensely tasting bitter stimuli are most likely to be rejected (Drewnowski, 2001a). The acceptance of bitter taste, when present, has to be learned over time. Recent studies show that the newborn infant’s rejection of sour and bitter solutions has changed to partial acceptance after the first year of life (Schwartz *et al.*, 2009). Even so, young children dislike bitter chocolate, preferring instead white chocolate, from which all bitter-tasting compounds have been removed. Adults learn to tolerate bitter taste later in life, especially when the bitter taste is accompanied by fat (chocolate), caffeine (coffee), or alcohol (beer) (Drewnowski, 2001a).

Genetic sensitivity to bitter tastes has been systematically explored using two bitter compounds: phenylthiocarbamide and 6-*n*-propylthiouracil (PROP). Individual taste sensitivity to these compounds is an inherited trait with an identified genetic basis (Kim *et al.*, 2003). The ability to taste phenylthiocarbamide/PROP has been associated with higher sensitivity to selected bitter compounds and with aversions to some bitter foods (Tepper, 2008).

Whether genetic PROP sensitivity, by affecting bitter taste, predicts food choices and dietary habits has been a topic of some debate (Duffy and Bartoshuk, 2000; Duffy, 2004; Drewnowski *et al.*, 2007; Tepper *et al.*, 2009).

Although plant-based diets, rich in cruciferous and other vegetables, may be protective against cancer, the active phytochemicals are almost always bitter, acrid, or astringent (Barratt-Fornell and Drewnowski, 2002; Drewnowski and Gomez-Carneros, 2002). Chemopreventive phenols, tannins, lignans, flavonoids, isoflavones, and glucosinolates impart a perceptible bitter taste to many vegetables and fruit (Drewnowski and Gomez-Carneros, 2002). Drewnowski and Rock (1995) first suggested that genetic taste markers might have an influence on the ability of cancer patients’ compliance with therapeutic diets that were phytonutrient-rich, namely bitter-tasting vegetables and fruit. Based on previous research (Fischer *et al.*, 1963; Glanville and Kaplan, 1965), bitter brassica vegetables such as Brussels sprouts, cabbage, spinach, and kale are often disliked the most (Drewnowski and Gomez-Carneros, 2002).

While studies have been able to link PROP taster status taste responses to some bitter foods and some food preferences, no links were found to food consumption patterns or to disease risk. The argument that “supertasters” of PROP were at lower risk for heart disease because of their alleged dislike of the texture of dairy fat (Duffy, 2004) has not been supported by observational data on fat consumption in epidemiologic studies. A recent study of women found that, relative to PROP tasters, non-tasters did not consume more fat but did consume more calories overall at a buffet meal (Tepper *et al.*, 2011). However, another study of dietary patterns, biomarkers, and BMI of over 350 women found no link between PROP taster status and nutrition and health outcomes (Drewnowski *et al.*, 2007). The lack of consistent associations between PROP sensitivity and dietary habits suggests that many moderating and mediating factors are interposed between the taste acuity measures and food-seeking behavior (Tepper *et al.*, 2009). Moreover, being highly sensitive to PROP might also reflect heightened sensitivity to other taste and texture stimuli (Lim *et al.*, 2008; Reed, 2008).

### **Salt Taste**

Sodium is essential for normal functioning of physiological processes. The taste for salty foods is partly a reflection of homeostatic requirements for sodium, which is continuously excreted into the environment. Taste responses

to sodium chloride can be modified when dietary sodium intake is restricted. Research has shown that sodium depletion, achieved by medication or diet, can shift liking for salty stimuli to levels that would be aversive under normal, non-depleted conditions (Johnson, 2007). Depletion induced by drugs or exercise can also induce liking for salty foods (Beauchamp *et al.*, 1990) and can promote the development of novel flavor preferences that are linked to saltier tastes (Wald and Leshem, 2003). The liking for salty taste thus appears to be dynamic, in response to physiological demands.

In longer term experimental studies, limiting dietary sodium to 1600 mg/day led to an increase in the hedonic value of unsalted food and a decrease in the hedonic value of salted soups (Blais *et al.*, 1986). The same study showed that sodium restriction also led to a progressive reduction in the amount of table salt added to soup by the study participants. Such shifts in liking for salty taste can occur without changes in detection or recognition thresholds for salt stimuli (Blais *et al.*, 1986; Mattes, 1997; Lucas *et al.*, 2011).

A person's sensitivity and hedonic response to salty stimuli has implications for health. For instance, higher sodium recognition thresholds have been associated with hypertension and history of type-2 diabetes (Isezuo *et al.*, 2008; Michikawa *et al.*, 2009). However, sodium recognition thresholds are not consistently associated either with liking for salty taste or with the amounts of sodium consumed (Lucas *et al.*, 2011). Other studies have failed to support the claim that higher liking for salty taste was causally linked with a higher risk of hypertension (Mattes, 1997).

Observations that the liking for salty taste was flexible and could be modified by the levels of dietary sodium has led the 2010 Dietary Guidelines to suggest that a systematic and gradual reduction to the sodium content of processed foods was the best population-based approach to lowering sodium intake. Such a reduction would be part of a comprehensive population health program to control and prevent hypertension and other chronic diseases (Cook *et al.*, 2007; Dötsch *et al.*, 2009). The current 2010 Dietary Guidelines call for a reduction in sodium intakes down to 1500 mg per person per day. The Guidelines are to be implemented gradually over time, both to give the food industry time to formulate lower sodium foods and to allow the American public to adjust taste preferences to the lower level of sodium in the food supply.

### **Umami Taste**

Together with salt taste, umami contributes to the savoriness of foods. For over 100 years, glutamate salts, including monosodium glutamate (MSG), have been used to evoke the umami taste, enhancing the sensory quality of certain savory foods (Bellisle, 1999). Only in the last 10 years was a g-protein-coupled receptor identified for this taste (Nelson *et al.*, 2002), establishing the umami sensation as a distinct taste pathway. Laboratory-based sensory studies have shown that MSG can potentiate the perceived savoriness of foods and improve hedonic response overall (Bellisle *et al.*, 1991; Roininen *et al.*, 1996; Okiyama and Beauchamp, 1998; Schiffman, 2000; Ball *et al.*, 2002; Carter *et al.*, 2011a).

The umami taste may be important for signaling nutritional characteristics of foods. Glutamate salts are related to glutamic acid, an amino acid integral to food proteins, but glutamic acid in protein does not have the umami taste. However, protein hydrolysis that occurs during fermentation and aging can release free glutamate. For example, free glutamate is found in abundance in soy sauces, aged cheeses, and even some fresh foods such as tomatoes and shellfish. Foods that are higher in protein or higher in free glutamate may be preferred by persons with greater sensitivity to MSG (Luscombe-Marsh *et al.*, 2008).

The flavor-enhancing effects of MSG and other glutamate salts could promote food consumption, but evidence that MSG is associated with excess energy intake is mixed. In short-term experimental studies, no significant differences in hunger ratings or differences in subsequent energy intake were observed following MSG supplementation (Rogers and Blundell, 1990). In other studies, adding MSG to foods led to a selective increase in the consumption of those foods but did not increase the total food energy consumed (Bellisle, 2008). In still other studies, the addition of MSG led to higher energy intakes at the next meal (Luscombe-Marsh *et al.*, 2009) or had no effect (Carter *et al.*, 2011b). More studies on MSG and body weight are clearly required. Whereas some have found a negative relation between MSG consumption and body weight (Essed *et al.*, 2007; Kondoh and Torii, 2008; Shi *et al.*, 2010), others have pointed to a link between MSG consumption and weight gain (Hirata *et al.*, 1997; Hermanussen *et al.*, 2006; He *et al.*, 2008).

### **Sour Taste**

Sour stimuli and sour-tasting foods are, like bitterness, instinctively aversive (Desor *et al.*, 1975) and the ability

to detect sourness has a strong genetic component (Wise *et al.*, 2007). Sourness in foods is associated with acid content, which can be higher in foods that have spoiled. An aversion to sourness can therefore be viewed as a protective trait. However, fresh foods that are rich in essential nutrients can also be sour. Studies have linked greater sour preference in children to the consumption of fresh fruit (Liem *et al.*, 2006). With obvious health benefits associated with greater acceptance of sour taste, researchers have explored means of increasing sour taste preference. While repeated exposure over a period of 8 days does not appear to increase the liking for sour beverages (Liem and de Graaf, 2004), adding sugar to sour solutions does appear to decrease the dislike toward sourness (Capaldi and Privitera, 2008). Other research indicates that, at least for children, a liking for very sour tastes may be part of a broader acceptance toward novel and intense stimuli (Liem *et al.*, 2004).

### Sensory Response to Fats

Fats endow foods with their characteristic taste and texture, and contribute to the overall palatability of the diet. The first sensory response to fat involves perception through the nose or mouth of fat-soluble volatile flavor molecules. Oral perception of fat content has been described as sensitivity to food texture as sensed by the oral cavity during chewing or swallowing. This form of fat perception is akin to somatosensation, mediated by nerve endings responsive to pressure or pain (Mattes *et al.*, 2009). Other mechanisms of chemosensation have been implicated, involving G-protein-coupled receptors, lipid transporters and potassium channels inhibited by free polyunsaturated fatty acids (Gilbertson *et al.*, 2005; Kahn and Besnard, 2009).

The orosensory experience evoked by fat depends on the food product. In dairy products, fat takes the form of emulsified globules that are perceived as smooth and creamy. Water binding qualities of fat account for the tenderness and juiciness of steaks and the moistness of cakes and other baked goods. Heat transfer at high temperature gives rise to food textures that are crisp, crunchy and brittle. Among textural qualities that depend on the fat content of foods are hard, soft, juicy, chewy, greasy, viscous, smooth, creamy, crunchy, crisp, and brittle. Generally, high fat content of foods has been a desirable sensory feature, and one that is often linked with higher product quality. As with salt preferences, self-reported preferences for fat in foods may be influenced to some

extent by the amount of fat in the habitual diet (Cooling and Blundell, 1998).

### Interactions between Fats and Sweetness

Fat potentiates the hedonic response to sweetness. A study using 20 different mixtures of dairy products of different fat content and sweetened with different amounts of sugar found evidence for hedonic synergy. Peak hedonic ratings were obtained for stimuli containing 20% fat wt/wt and 8% sucrose wt/wt, corresponding to whipping cream with sugar (Drewnowski and Greenwood, 1983). These studies made use of response surface methodology and three-dimensional projections of the hedonic response surface. These findings of a hedonic synergy for sugar and fat mixtures were later extended to sweetened cream cheese, the French creamy white cheese fromage blanc, cake frostings, and ice cream.

Perceptual interactions between sugar and fat depend on sensory phenotypes. The perceived sweetness of sugared solutions is positively tied to the level of added sugar but also to the amount of fat. At a constant sugar concentration, increasing the percentage of fat by shifting the base solution from water to milk and to heavy cream increased sweetness ratings, and the effect was greatest for those who rated PROP as most bitter (Hayes and Duffy, 2007). More recently, the optimal combination of sugar–fat mixtures for liking was associated with oral and sensory phenotypes. While sweet, high-fat combinations of dairy and sugar are generally liked across all groups, persons who were most sensitive to the bitter taste of PROP and quinine tended to report greater creaminess of fat-containing stimuli and to have hedonic optima at lower levels of fat and sugar than the other groups (Hayes and Duffy, 2008).

### Taste Preferences and Food Choices

Preferences for sweet taste, typically measured in the laboratory using sugar solutions, are thought to predict the liking and consumption of sweet foods and beverages in real life. However, studies have shown that taste preferences for sweet and salty tastes in aqueous solution were not a good predictor of self-reported liking for sweet or salty foods (Mattes *et al.*, 2005). Of course, many studies of food likes and dislikes employed not actual foods but printed lists of food names. Such tools merely capture respondents' attitudes toward a verbal concept of a given food, since the food itself is never presented to the subject and is not available for consumption. Best correspondence

between the two sets of ratings is obtained when the taste stimulus closely resembles the food product. For example, preferences for sugar solutions in water may predict the same subjects' preferences for cola or fruit juice. However, preferences for sugar solutions in water may not predict preferences for such foods as doughnuts or candy.

Taste preferences and food choices differ over the life course and in relation to our physical conditions. Preferences and aversions are modifiable by growth, maturation, and hormonal status. Both taste preferences and food choices are further shaped by prior experience and associative learning. Preferences for aversive tastes including bitter (caffeine), alcohol, and hot spices are all said to be the result of associating the often unpleasant taste with the desirable post-ingestive consequences (Logue, 2004). A previously neutral or even unpleasant taste can become preferred, provided it is linked with a suitable mechanism of reward.

### **Taste and Food Choices in Childhood**

Studies of preschool children have shown that food preferences in early life are determined by two factors: familiarity and sweetness (Birch, 1999). Preferences for fat may be acquired early in life, as children learn to prefer those flavors that are associated with high energy density and fat content. Fat and sugar are the chief components of peanut butter and jelly sandwiches, chocolate candy, cookies, and ice cream.

Both sweet taste preference and sugar consumption decline between adolescence and adult life (Bowman, 1999). Whereas children's food preferences are often guided by taste alone (Birch, 1999), food choices of adults also tend to be influenced by nutritional beliefs and attitudes toward weight and dieting (Logue, 2004). However, all evidence is indirect, since no study examined taste preferences, diet-related attitudes, and food intakes in the same subject group. Other studies have shown that children's preferences for high-fat foods have a familial component. Studies on children aged 3–5 years later reported that both preferences for and the consumption of fats by children were linked to body mass indices of parents (Fisher and Birch, 1995; Wardle *et al.*, 2001).

Children also show an aversion to bitter foods (Drewnowski, 2001a; Logue, 2004). Typical food dislikes are based on taste (bitter), aversive trigeminal stimulation (sharp), and a variety of unpleasant food textures. Acquired preferences for coffee, beer, alcohol, and hot peppers are commonly cited as evidence that food preferences can be learned and modified with age.

### **Taste and Food Choices in Aging**

Age-related deficits in taste and smell are reputed to decrease the enjoyment of food and reduce food consumption leading eventually to malnutrition and ill health (Morley, 2001; Hays and Roberts, 2006). However, the evidence supporting this view is mixed. While many elderly people suffer from an olfactory deficit and some suffer from taste deficits (Murphy, 2008), their impact on food choices, nutrition and health is not always clear. Older adults can also have a decline in sensory specific satiety (Rolls, 1999), which in theory would promote more homogeneous dietary habits. However, older adults often have diets that are as varied or even more varied than younger adults (Rolls, 1999).

Most studies on taste and aging have focused on taste acuity and sensitivity rather than on enjoyment, quantified through hedonic ratings. Early studies were guided by the hypothesis that elderly subjects suffering from taste losses would prefer sweeter and saltier stimuli and so consume more sugar and salt. Though some studies reported that hedonic ratings for solutions of sucrose, sodium chloride, and citric acid increased with age, other studies failed to confirm a broad age-related shift in hedonic response. Taste function is relatively robust, and whole-mouth tasting can be normal even into advanced old age. In at least one study, older adults showed no impairments in taste sensitivity and hedonic response profiles for sucrose and sodium chloride solutions (Drewnowski *et al.*, 1996). The same study showed that preference for salty stimuli had no impact on sodium consumption.

To promote food intake by the elderly, some have suggested flavor amplification (Rolls, 1999). Intervention studies using flavor enhancers in the foods consumed by elderly participants have shown both positive (Mathey *et al.*, 2001) and negative (Essed *et al.*, 2007) results. The diets of older persons can lack variety (Marshall *et al.*, 2001), but it is difficult to attribute these patterns to sensory limitations. Other factors such as poor dentition (Marshall *et al.*, 2002; Sahyoun *et al.*, 2003) and a host of psychosocial variables, including depression, loneliness, bereavement, and social support, all have a major impact on diet habits (Ahmed and Haboubi, 2010).

### **Taste and Food Choices in Obesity**

Much research attention has focused on those taste responses in obesity that might contribute to unhealthful eating patterns and to weight gain. Perceptual and hedonic responses to sweet and fat tastes have received the greatest

attention, in part because diets of obese persons tend to be energy dense and are relatively high in refined grains, added sugars, and fats (Miller *et al.*, 1990; Bolton-Smith and Woodward, 1994). Whereas the sources of sugar and fat can vary by continent and culture, the liking for good-tasting energy-dense foods is a universal human trait.

One line of research has examined taste acuity for sweetness and fat in obese children and adolescents (Pasquet *et al.*, 2007). While detection thresholds for sweetness were the same in lean and obese adults (Malcolm *et al.*, 1980), the linking for sugar and fat mixtures did differ.

Obese women selected fat-rich taste stimuli in sensory studies, and listed high-fat foods as their favorites on food preference checklists, including doughnuts, cake, cookies, ice cream, chocolate, pies, and other desserts. Conversely, anorectic women below normal body weight had lower preference ratings overall, tending to select stimuli that were relatively sweet but virtually fat-free (Drewnowski, 1989). Obese women and women who had recently lost weight gave the highest hedonic ratings to the energy-dense mixtures of sugar and fat (Drewnowski *et al.*, 1985). Those formerly obese patients were struggling at the time against weight regain. These findings are consistent with more recent studies showing that BMI was positively associated with dietary fat intake (Ahluwalia *et al.*, 2009).

Less is known regarding weight-related differences in perception or preference for savory or salty foods. Thresholds for salt were lower in obese adolescents (Pasquet *et al.*, 2007), and BMI of adults was positively associated with preference for salty and fatty foods (Keskitalo *et al.*, 2008). Obese women were less sensitive to the taste of MSG and preferred significantly higher levels in soup than normal-weight women (Pepino *et al.*, 2010). Obese men reported preferences for steaks, roasts, hamburgers, French fried potatoes, and pizza (Drewnowski, 1997a,b). These findings were consistent with intake data from studies showing that obese adults tend to over-consume energy-dense, salty foods (Cox *et al.*, 1999).

In some studies, taste preference profiles were linked to increased risk of weight gain. For example, a more favorable rating of sweetened, high-fat, dairy beverages was associated with weight gain in Pima Indians (Salbe *et al.*, 2004). Japanese adults who reported preferring rich and heavy foods (fat) and sweet foods also gained more weight than those who did not report such preferences (Matsushita *et al.*, 2009). Reducing body weight through surgery appears to lead to changes in taste perception and preferences. Obese patients who underwent bariatric surgery

showed increased sensitivity to sweet taste (Miras and le Roux, 2010). The surgery has also been shown to reduce obese adults' motivation to eat highly palatable foods (Schultes *et al.*, 2010).

## Neurobiology of Taste and Appetite

Human beings eat for survival, maintaining energy balance and fulfilling their nutrient needs. The impulse to eat in response to an energy deficit is a powerful motivational drive that is controlled by several regions of the hypothalamus and pharmacological pathways of the brain (Kalra and Kalra, 2004; Wurst *et al.*, 2007). But eating is also one of life's greatest pleasures, and the taste senses mediate the enjoyment of food independent of hunger (Lowe and Butryn, 2007). The hedonic motivations to eat involve anticipation (wanting/craving) and reward (liking) associated with consuming palatable foods and beverages (Berridge, 1996; Barbano and Cador, 2007a), which can override homeostatic signals to promote excess energy intake and the development of obesity. While the neurobiological substrates and pharmacological pathways controlling hedonic motivations are to some extent shared with those involved in homeostatic regulation of appetite, some differences are apparent (Barbano and Cador, 2007b; Kenny, 2011).

### Craving and Wanting

Studies of food cravings have implicated the serotonergic system, endogenous opiate peptides, and endocannabinoids. Serotonergic pathways were first linked to food cravings and intake from studies of clinically depressed individuals (Pelchat, 2002; Pelchat, 2009). Serotonin is primarily associated with cravings for carbohydrates in what is thought to be a homeostatic regulatory process: Low serotonin levels stimulate the ingestion of carbohydrates, which can increase levels of L-tryptophan, the metabolic precursor of serotonin (Pelchat, 2002; Yanovski, 2003).

Endogenous opiates or endorphins are implicated in food cravings for fats and sweets (Drewnowski *et al.*, 1995). Opiates act via the mu-type opioid receptor (Kelley *et al.*, 2002) to increase the response to sweet taste by humans and the intake of sweet solutions by rats (Pecina and Berridge, 2005). Fat consumption in rats was likewise increased by the opiate agonists morphine and butorphanol. Endogenous opiates also mediate the hedonic response

to preferred foods (Levine *et al.*, 2003). Opiate antagonists such as naloxone, naltrexone or nalmefene appear to reduce food intakes by lowering preferences for selected foods. Whereas the consumption of non-preferred foods remained stable after naltrexone, rated pleasantness of a sweet solution declined (Hetherington, 2001). Similar results were obtained with another opiate antagonist, nalmefene (Yeomans and Wright, 1991).

Plant-derived or synthetic cannabinoids have long been used for alleviating nausea and promoting food intake in cancer and AIDS patients. The discovery of endocannabinoids in the 1990s fostered research on the natural function of these fatty acid-derived neurotransmitters. The orexigenic effect of endocannabinoids is thought to be localized to endocannabinoid receptors in the hypothalamus and limbic forebrain. Endocannabinoid levels are elevated with fasting. As mentioned in a previous section of this chapter, endocannabinoids also have a peripheral target that could also explain their orexigenic effects. Sweet taste receptors express CB-1 receptors, which, when activated, enhance the response to sweet stimuli (Jyotaki *et al.*, 2010; Yoshida *et al.*, 2010). Unlike opiate receptor blockade, pharmacological block of CB-1, an endocannabinoid receptor, reduces intake of all food, both preferred and non-preferred (Di Marzo and Matias, 2005). Such an intervention can lead to weight loss, which arises partly through a reduction in energy intake and partly through an increase in energy expenditure and fat oxidation (Addy *et al.*, 2008).

### **Food Liking and Reward**

Eating is driven by brain circuitry that is linked to reward centers in the striatum (Stricker and Woods, 2004), where feeding is thought to be reinforced by dopaminergic projections from the midbrain (Wang *et al.*, 2001, 2004; Epstein and LeDey, 2006). Unlike opiates and endocannabinoids, dopamine's release is not tied to the reported hedonics of a food stimulus (Volkow *et al.*, 2002). Abnormalities in reward circuitry have been linked to obesity. Human brain imaging has shown an inverse relationship between levels of the D2-type dopamine receptor in the striatum and subjects' BMI (Wang *et al.*, 2001; Volkow *et al.*, 2008). More recent work using functional magnetic resonance brain imaging found that women who gained weight over a 6-month period showed a weaker pattern of activity in the striatum relative to weight-stable women (Stice *et al.*, 2010). The result led to the suggestion

that low sensitivity of the reward pathway could promote overconsumption of food, which in turn could weaken the responsiveness of the reward system further.

Recent research has found that food reward centers can be modulated by the pharmacological pathways involved in energy homeostasis. Animal studies indicate that two hormones involved in energy homeostasis, insulin and leptin, can influence the function of dopaminergic and opioid signaling in the midbrain (Figuelewicz and Benoit, 2009). These experiments also show that insulin and leptin reduce food reward behaviors. Other studies have suggested that two gut peptides also involved in energy balance modulate brain areas involved in food reward (Fulton, 2010). Ghrelin receptors are found throughout the dopaminergic pathways of the brain, including ventral tegmental area (VTA) neurons of the midbrain (Guan *et al.*, 1997), where ghrelin can enhance the activity of dopaminergic neurons (Abizaid *et al.*, 2006). Imaging studies have shown that ghrelin enhances the response to visual food cues detected in the striatum and VTA of the midbrain (Malik *et al.*, 2008). Similarly, Peptide YY (PYY) administration appears to activate the VTA and ventral striatum, and when PYY levels are high (as after a meal), food intake appears to be correlated with activity in the orbitofrontal cortex (part of the circuitry involved in hedonic drive) rather than by hypothalamic centers involved in homeostatic eating (Batterham *et al.*, 2007).

### **Binge Eating and Food Addiction**

Pathology of the neural circuits and pharmacological pathways described earlier in this chapter are thought to underlie binge eating, a phenomenon of disordered eating in humans characterized by bouts of excess food intake, particularly of palatable foods, that are not compensated by either purging (as with bulimia nervosa) or anorexia (Spitzer *et al.*, 1992). The concept has been invoked to explain unhealthy patterns of food consumption that may reflect disordered craving and reward (Pelchat, 2009). Parallels have been drawn between binge eating and drug addiction, since both behavioral syndromes involve cravings and loss of control. The drawing of this parallel has sparked debate as to whether binge eaters suffer from an "addiction to food" (Pelchat, 2009).

Pharmacologically, the parallel between drug and alcohol addiction and binge eating is consistent. Endogenous opiate peptides are thought to mediate alcohol cravings, and naltrexone, a long-lasting opiate

antagonist, has been used to curb these cravings in alcoholics. Addictions to opiates such as morphine and methadone have been associated with an enhanced appetite for sweets, and opiate withdrawal is eased by ice cream and chocolate (Drewnowski *et al.*, 1995). These effects are consistent with other studies showing that opioid antagonists reduce the hedonic response to palatable foods (Nathan and Bullmore, 2009).

Binge eating has implications for the dopaminergic pathways of the mesolimbic system. Animal studies indicate that binges of fat or sugar (both nutrients that are typically contained in palatable foods) can lead to excessive release of dopamine (Avena *et al.*, 2009), which may lead to compensatory changes in dopamine receptors. Functional imaging studies have found a paucity of available D2-type dopamine receptors in both obese and drug-addicted subjects (Wang *et al.*, 2004). Together, these findings suggest that these pathways provide a common anatomical substrate for behavioral responses to both food and drugs of abuse.

## Palatability and Satiety

Satiety is one among many mechanisms regulating energy balance. Palatability and satiety have opposite effects on food intakes. While palatability increases appetite and therefore food consumption, satiety limits consumption by reducing meal size or by delaying the onset of the next meal. As such, both palatability and satiety help to adjust energy intakes to energy needs. However, in experimental studies, both palatability and satiety tend to be measured in terms of the amounts of food consumed. As a result, the foods that are overeaten are by definition the most palatable and the least satiating.

Standard measures of palatability include the perceived pleasantness of a given food, intent to eat, or the amount of food consumed. Among standard measures of satiety are reduced hunger, fullness, reduced intent to consume a meal or a snack, or the amount of food consumed. Some investigators have made a distinction between satiety and satiation (Mattes *et al.*, 2005). Whereas satiation is responsible for the termination of a given meal and reduced meal size, satiety, defined as a state of internal repletion, delays the onset or reduces the size of the next meal. Increased satiety has also been measured in terms of reduced palatability. Sensory-specific satiety was specifically defined as reduced palatability of the just-consumed food relative to other foods.

The low satiating power of energy-dense, sweet and fat-rich foods has been singled out for special scrutiny (Holt *et al.*, 1995; Erlanson-Albertsson, 2005). Some researchers have argued that the palatability of sugar overrode normal satiety signals, leading to overeating and overweight (Green *et al.*, 1994). Others have noted that fat had low satiating power, judging by the “passive overeating” of fat-rich foods (Blundell *et al.*, 1993). One question is whether palatable fat-rich foods are overeaten because of their high energy density or because of their fat content (Blundell *et al.*, 1993). If satiety is macronutrient driven, fat may be overeaten because it affects satiety less than a corresponding amount (in kilocalories) of carbohydrate or protein. The creation of palatable and yet highly satiating foods, the avowed goal of the weight-loss industry, may represent a contradiction in terms.

## Food Preferences and Habitual Food Intake

Food preferences are said to predict food consumption. However, people may have positive attitudes toward the foods they already eat so that food preferences may merely be a reflection of existing eating habits. For instance, a study of school children found that higher liking for vegetables and fruit was associated with higher consumption (Brug *et al.*, 2008). It may be that higher consumption led to the reports of higher liking (Aldridge *et al.*, 2009).

The association between food liking and food use has implications for dietary intake assessment. Food frequency questionnaires (FFQs), used to assess dietary intakes in large-scale survey studies, consist of a list of about 100 or more names of foods and food groups (Willett, 1998). Respondents are asked to report the usual frequency of consumption of each food using anchored 9-point category scales where the categories can range from “never or less than once per month” to “5+ per day” (Willett, 1998). The self-reported frequency of food use is thought to be a measure of past dietary behavior, based on a combination of memory and retrieval processes (Willett, 1998). Past efforts at improving FFQ instruments have focused on aided recall, cognitive interviewing and other ways to help the respondents’ memory of past food use (Subar *et al.*, 1995; Willett, 1998).

Yet the frequency of food use may be no more than a general attitude, positive or negative, toward a mental image of a given food. Food preference checklists are long lists of food names, with respondents asked to indicate the

degree of liking using anchored 9-point category scales ranging from “1 = dislike extremely” to “9 = like extremely”. Correlations between self-reported food preferences and frequencies of use have shown that dislikes were strongly associated with non-use (Drewnowski *et al.*, 2000). FFQ instruments performed no better than food preference checklists in assessing the fat content of a typical diet (Drewnowski, 2001b; Kristal *et al.*, 2005).

## Economics of Food Choice Behavior

Consumer food choices are economic decisions made in response to taste, reward value, incomes, time constraints, and the perceived nutritional value of foods. Taste response or the liking for foods alone do not always predict purchase intent, or actual consumer behavior. Consumption patterns are also influenced by price, convenience, safety and nutritional concerns (Glanz *et al.*, 1998; Sobal and Bisogni, 2009). Other demographic, cultural and socioeconomic factors also modulate the connection between taste responsiveness and food choice.

Besides taste, the monetary cost of food is a dominant factor guiding food selection and is a major constraint on the diet quality of individuals, particularly those of lower socioeconomic position (Beydoun and Wang, 2008). Several economic studies have made the association between the declining monetary and time cost of food and rising obesity rates (Philipson, 2001; Lakdawalla and Philipson, 2009). Those studies pointed to the widespread availability of palatable energy-dense fast foods, the entry of women into the labor force, and lower physical activity associated with work (Philipson, 2001; Cutler *et al.*, 2003).

However, not all foods have become less expensive. There is a growing price disparity between the lower-cost, energy-dense foods based on refined grains, added sugars, and added fats and the more expensive nutrient-dense foods including lean meats, dairy products, whole grains, and fresh vegetables and fruit (Monsivais and Drewnowski, 2007; Monsivais *et al.*, 2010). Furthermore, healthier foods are not always available in economically disadvantaged areas (Jetter and Cassady, 2006; Larson *et al.*, 2009). Disparities in access to healthy foods, together with decreasing time devoted to food preparation and consumption, may help explain some of the observed disparities in health (Wiig and Smith, 2009; Davis and You, 2010).

The nature of the relation between diet quality and diet cost, at different socioeconomic levels, has important

implications for the study of diets and disease risk. Whereas spending more money does not guarantee a healthier diet, reducing food costs below a certain limit virtually guarantees that the resulting diet will be nutrient-poor (Darmon *et al.*, 2002). One key question is whether palatable, low-cost, energy-dense diets are associated with higher energy consumption overall. In other words, can BMI values be linked directly to food prices and to diet costs, after adjusting for covariates? Although some studies have demonstrated this association (Powell and Bao, 2009; Sturm and Datar, 2008), the answers to all these questions are far from clear.

## Future Directions

Public health and nutrition campaigns have focused on persuading consumers to replace palatable energy-dense foods with less palatable but arguably healthier options (Ashfield-Watt *et al.*, 2007). Nutritional education strategies aimed at improving diet quality have focused almost exclusively on the nutritional quality of foods, and not on taste or the pleasure response. Yet humans have an innate preference for good-tasting, energy-dense foods, which are available in an ever-expanding variety of attractive, palatable, convenient, and inexpensive forms. Taste preferences are also associated with a range of demographic, economic, social, and cultural variables. How these variables interact to produce individual and population-level patterns in food consumption is an important emerging area of research. The results of this research will be critical for informing the development of nutrition guidance and interventions that directly account for the role of taste in food choice.

## ENERGY INTAKE, OBESITY, AND EATING BEHAVIOR

ALEXANDRA M. JOHNSTONE, PhD

*Rowett Institute of Nutrition and Health, Aberdeen, UK*

### Summary

In the context of the rising obesity epidemic, understanding the role of eating patterns and diet composition in calorie intake and body weight is clearly important for the development of dietary strategies that encourage body weight control in adults. It is now accepted that there are many nutritional and non-nutritional factors that will influence energy intake (EI) and eating behavior. Non-nutritional factors include palatability of food, portion size, sensory variety, and meal patterns (e.g. snacking). It is accepted that these factors can contribute to passive overconsumption of calories, at least in the short term, and that these attributes make a major contribution to the reward value of food. The main nutritional factors are macronutrient composition and energy density (ED). People do not always eat in response to a physiological hunger cue, so common psychological influences on eating behavior are discussed. Future perspectives for developing our understanding of control of eating and energy intake within a multidisciplinary obesity team are discussed.

### Introduction

With obesity growing as a major public-health concern, our eating environment is ever more in focus as a contributing factor to weight gain. We live in an “obesogenic environment” where lifestyle choices associated with eating behavior and physical activity contribute to the development of obesity. Definition and classification of obesity have been outlined in Chapter 45, “Obesity as a Health Risk.” Reversing the effects of obesity is a huge challenge, and understanding the role of food, energy, and nutrients on eating behavior(s) is essential in order to develop dietary strategies for both the prevention and treatment of obesity.

This is complicated by the fact that eating and food choice are a social experience and the pleasure or reward value of feeding behavior(s) can override the physiological processes that control metabolism and body weight, at least in the short term.

The content of this chapter refers to work on adults, with some reference to work on children’s eating preferences mentioned in Chapter 60, “Taste and Food Choices.” Little directly comparable research has been conducted across the lifespan to include interventions in children, young people, adults, and the elderly, and this is an area for future research. Furthermore, energy intake is only one side of the energy balance equation and needs to be

considered in that context. The role of exercise in appetite control and body weight has recently been reviewed by Hopkins *et al.* (2010), who highlight the benefits of exercise but also the variable nature and diversity in weight-loss response.

## Nutritional Influences on Energy Intake, Obesity and Eating Behavior

It is now accepted that both nutritional and non-nutritional factors influence food intake. The main nutritional factors are macronutrient composition and energy density (ED). How these influence eating behavior and calorie intake in the short and medium term are discussed.

### **Appetite Control Definitions**

As much of the work within this chapter refers to appetite, commonly used terms relating to appetite are defined below. Appetite control and methodological aspects have recently been reviewed by Blundell *et al.* (2010) within the context of the evaluation of foods for health claims. A major mechanism by which feeding behavior is coupled to physiological (and other) events is the process of learning. To understand feeding behavior, hunger and satiety processes, the mechanism by which learning links feeding behavior to physiological, sensory, nutritional, situational, and other learning cues must be appreciated. A major form of learning in this regard is termed associative conditioning of preferences, appetites, and satieties (Blundell *et al.*, 2010).

Hunger is a motivational construct that describes the drive to eat, which is not directly measurable, and is, rather, inferred from objective conditions and conscious sensations reflecting the mental urge to eat. In simple terms, this is a cue that we learn to recognize as telling us to go to search for food and to eat. The hunger cue does not tell us what to eat, or how much, but simply to initiate eating. It is influenced by a number of internal physiological factors (e.g. declining blood glucose, hunger pangs in the stomach) and external non-physiological factors (e.g. time of day, social conditioning). Hunger has a large, learned, anticipatory component rather than being the direct consequence of unconditioned physiological signals *per se*.

Appetite is defined as “the disposition or desire to eat a specific food.” This term is used in everyday language to express an appetite for “something sweet” or “something savoury.” It has been argued that appetite is enhanced by

sensory factors that influence palatability of food, such as taste, texture, or temperature. Appetite is *sensory specific* and has a large learned component. Appetite is not rigidly determined by physiological signals *per se*, although they may exert a considerable influence.

Blundell proposed the satiety cascade 20 years ago (Blundell, 1991), to provide a conceptual framework for examining the impacts of foods on satiation (processes that bring an eating episode to an end) and satiety (processes that inhibit further eating in the postprandial period). This is shown in Figure 61.1 (adapted from Blundell *et al.*, 2010).

Satiety is another motivational construct and typically used to refer to “a state of inhibition of eating.” Simply, this can be considered as the inter-meal interval. This is mainly influenced by physiological postprandial and central nervous system effects. For example, early postingestive events include gastric distension and emptying and release of hormones, followed by postabsorptive events, including mechanisms arising from the action of glucose, fats and amino acids after absorption across the intestine into the bloodstream and interactions with the CNS. After a meal, we do not eat for a period of time and this reflects satiety.

Satiation is defined as “the process leading to the termination of an episode of eating.” This describes the process of meal termination or stopping eating, and may be expressed as a feeling of fullness. Meal termination is affected by psychological events and behavior, as well as an early cephalic phase response. These are the sensory perceptions generated by smell, taste, temperature, and texture that inhibit eating in the short term. Cognitive beliefs that we hold about food may inhibit eating in the short term.

### **The Role of Diet Composition**

Although there is a strong genetic component to obesity (Vimaleswaran and Loos, 2010), the fact that the incidence of this disease has dramatically increased over the past 20 years implicates an environmental and behavioral basis. Some workers have emphasized the increase in energy intake (Hill, 2006), whereas others attribute increasing weight gain to decreased energy expenditure because of an increasingly sedentary lifestyle (Levine, 2003). The mechanisms linking energy intake and expenditure are unclear, but it seems reasonable to believe that appetite (sensations that promote food ingestion or rejection) is central to the maintenance of energy balance and

FIG. 61.1 Example of the “Satiety Cascade”. Adapted from Blundell *et al.* (2010).

body weight. The role of micronutrients (vitamins, minerals and trace elements) and phytochemicals in appetite and food intake is an evolving field, but is not covered in this review.

The dietary macronutrients are those that provide energy, and are protein, fat, carbohydrate, and alcohol. It is generally accepted that diet composition strongly affects ad libitum energy intake under laboratory (Poppitt *et al.*, 1998) and free-living (de Castro, 2006) conditions, with protein highlighted as the most satiating macronutrient (Halton and Hu, 2004). Even when ingested at the same level of energy density, protein is the most satiating macronutrient (Johnstone *et al.*, 1996; Stubbs *et al.*, 1996). Under these conditions differences between carbohydrate and fat are less clear-cut.

Recent findings suggest that an elevated protein intake seems to play such a key role in body-weight management, through (1) increased satiety related to increased diet-induced thermogenesis, (2) its effect on thermogenesis, (3) body composition, and (4) decreased energy efficiency (Westertep-Plantenga and Lejeune, 2005). Supported by these mechanisms, a relatively larger weight loss and

stronger body-weight maintenance thereafter have been observed with protein-enriched diets. The safety and efficacy of high-protein diets for weight loss has been questioned, with Eisenstein *et al.* (2002) summarizing the experimental and epidemiological data. Protein-induced satiety has been shown acutely (within single meals that contain between 25% and 81% of energy from protein), with reductions in subsequent energy intake. It has been shown with high-protein ad libitum diets lasting from 14 days (Johnstone *et al.*, 2008) up to 6 months (Skov *et al.*, 1999).

Carbohydrate tends to exert a more acute effect on satiety than fat (Raben *et al.*, 1996). The role of carbohydrate in regulation of appetite and energy balance has attracted attention as a mediator of short-term appetite (Stubbs *et al.*, 2001), and has been reviewed by Mattes *et al.* (2005). Both the type and amount of carbohydrate consumed influence many ingestive processes. Hypotheses based on the glycemic index value of carbohydrate-containing foods suggest that both low and high insulin responses to foods promote hunger and energy intake (Flint *et al.*, 2007). The role of fuel oxidation in appetite

control is discussed by Stubbs (1995), and suggests that the hierarchy in the oxidation of nutrients is linked to the potency of effect on appetite control, such that protein is more satiating than carbohydrate than fat.

Fat intake's association with energy balance has been reviewed by Westerterp-Plantenga (2004). A paradox becomes apparent when considering fat intake and satiety (Blundell *et al.*, 1995). Although the body appears to generate potent physiological responses that are triggered by fat ingestion, many studies have demonstrated that people who consume high-fat foods (either through personal choice or in experimental situations) tend to overconsume energy, a process termed passive overconsumption. Rodent studies suggest that fat delivered to the intestine (duodenum or jejunum) generates potent satiety signals. On the other hand, exposure to high-fat foods leads to a form of passive overconsumption that suggests that fat has a weak effect on satiety (poor fullness feedback). When human subjects are given a range of high-fat foods, they increase their EI and gain weight compared with subjects eating a medium- or low-fat diet (Blundell and Stubbs, 1999). This may be explained by the fact that fat consumed orally takes some time to reach the intestine, and its negative feedback action is likely to be diluted by other nutrients. Fat produces potent oral stimulation (positive feedback) that facilitates intake; high-fat foods normally have a high-energy density, which means that a large amount of fat energy can be consumed before fat-induced satiety signals become operative. The signals are apparently too delayed to prevent the intake of large amounts of this food (Blundell and Macdiarmid, 2006).

Alcohol is exceptional in that its ingestion can stimulate EI, and thereby induce counter-compensatory feeding behavior (Yeomans, 2010). Given that alcohol is also a drug with depressant effects on the central nervous system (CNS), this is not surprising. Whether there is an association between alcohol intake and obesity is controversial (Suter, 2005) although, in terms of overall energy contribution, significant consumption of alcohol-based beverages has the propensity to increase total EI and hence contribute to obesity. Alcohol may also promote increased snacking and EI, which is not compensated for.

### **The Role of Energy Density**

Energy density (ED) is the amount of energy in a particular weight of food (kJ/g). Dietary ED tends to act as a constraint on feeding behavior (Rolls, 2009), influencing satiety or the feeling of fullness after eating. It is influenced

by the moisture content of food (adding weight with no calories), fiber content (adding volume with limited calories), and macronutrient composition, mainly from fat content, because of its high energy content per gram. One classic experiment on how ED affects satiety and food intake is the provision of a soup-based preload before eating, which reduces EI at the next meal (Himaya and Louis-Sylvestre, 1998); interestingly, provision of a glass of water does not have the same effect on satiety as incorporating it into food to lower ED (Rolls *et al.*, 1999), which suggests a role for viscosity on gut responsiveness.

A diet that is low in ED will induce an energy deficit, determined by the rate (volume over time) at which low ED foods can be digested and absorbed. This might be a useful strategy to achieve weight loss. One dietary strategy to decrease ED is to increase the intake of water-rich foods such as fruit and vegetables, allowing a satisfying portion size whilst decreasing EI. Data from clinical trials suggest that substantial weight loss can be achieved with this approach (Yao and Roberts, 2001). Conversely, if a diet is too high in ED, overconsumption will tend to occur because the amount of food people eat tends to be conditioned and there is relatively weak defense against excess EI (Rolls, 2010). Consumption of foods with a high ED may increase the risk of passive overconsumption and weight gain. As a general rule, then, decreasing the fat content either of individual foods or the diet as a whole should decrease the ED of the diet. Studies performed in subjects who were fed a diet where the ED was varied while maintaining the macronutrient composition found that subjects ate a similar weight of food regardless of macronutrient composition, thus promoting energy overconsumption on diets with a high ED (Stubbs *et al.*, 1998a,b). Conversely, several studies have shown that, if the amount of fat in the diet was varied while keeping the ED constant, subjects consumed a similar weight of food and hence EI remained unchanged (Stubbs, 1995; Bell *et al.*, 1998). These studies, however, involved diets that were highly constructed in terms of macronutrient composition and ED in order to create dissociations, and hence do not reflect typical population diets. What the studies suggest is that the overall ED of the diet is strongly influenced by fat content, and is probably a major contributor to total EI.

While many previous studies have focused on the link between ED and foods, beverages can also make a significant contribution to the total EI of an individual. In Australia, beverages contribute 16.3% of the total daily EI

for all persons (McLennan and Podger, 1998); in the USA soft-drink consumption has increased by more than 60% between 1977 and 1998 (Economics Research Service, 1999). Of recent interest is the role of liquid carbohydrate intake as a contributing factor to the rise in obesity. Energy-containing drinks (fizzy, alcohol, milk, or juice) appear to increase daily intake in free-living adults aged 18–75 years in comparison with days when they are not consumed, suggesting these extra calories are not compensated for in subsequent eating (de Castro, 1993). This concurs with laboratory studies of Mattes and Campbell (2009), suggesting energy-containing beverages are less compensated for in the next eating episode compared with solid food. It has also been suggested that fructose, a major ingredient in sweetened beverages (often as high-fructose corn syrup), may promote appetite and food intake (Bray *et al.*, 2004); this is thought to be associated with insufficient secretion of insulin and leptin and suppression of ghrelin (Melanson *et al.*, 2008).

### **The Role of Dietary Fiber**

There is much evidence that dietary fiber is a key component in the diet for prevention of chronic diseases such as cardiovascular disease (CVD), as shown by considerable research on glycemic index (GI) and glycemic load (GL), especially in subjects with impaired metabolic control (hyperlipidemia or diabetes). This can be achieved by altering the amount of available carbohydrate or type of carbohydrate. CVD risk profile may also be independently improved with whole-grain consumption, such as oats as it is suggested that they may have positive anti-inflammatory effects, possibly relating to beta-glucan content (Kallio *et al.*, 2008). Fiber may be useful in the treatment of obesity by facilitating compliance to low EI (Rigaud *et al.*, 1987; Astrup *et al.*, 1990). It can impact on satiety in several ways: it increases food volume; decreases ED; increases gastric volume; retards gastric emptying, which maximizes early satiety signals; and influences satiety hormones in the gut. Increasing fiber intake during weight maintenance, however, has limited impact on body weight control (Aston *et al.*, 2008).

Different types of fiber have been examined for their impact on satiety. Specifically, soluble fibers, which provide viscosity to a food, can increase its satiating effects (Dikeman and Fahey, 2006), with highly viscous fiber reducing subsequent food intake more than medium- or low-viscosity fiber (Vuksan *et al.*, 2009) by forming a viscous gel matrix in the gut, believed to slow gastric emp-

tying and to lead to a greater feeling of fullness (Howarth *et al.*, 2001; Hoad *et al.*, 2004). Viscous fibers can slow absorption of glucose in the small intestine and lead to lower postprandial glycaemic and insulinemic responses (Behall *et al.*, 2006; Casiraghi *et al.*, 2006). Both of these mechanisms are postulated to increase satiety. Insoluble fiber has limited effects on gastric emptying and absorption in the small intestine, but it may be partially fermented in the large intestine. Research on resistant starch (RS) and satiety is inconsistent (Raben *et al.*, 1994; de Roos *et al.*, 1995; Nilsson *et al.*, 2008). It is possible that certain types or amounts of RS could improve satiety by increasing levels of the gut hormones glucagon-like peptide-1 (GLP1) or peptide YY (PYY). One study has reported that RS may mediate satiety by altering colonic fermentation and gastric emptying rate (Nilsson *et al.*, 2008), with colonic fermentation (as measured by breath hydrogen) positively correlated with satiety and inversely correlated with gastric emptying.

### **Non-Nutritional Influences on Energy Intake, Obesity, and Eating Behavior**

Examining the non-nutritional influences on eating behavior tends to focus on what we eat (food choice), whereas the physiological or metabolic aspects focus on how much we eat (calorie content or weight of food intake). The sensory (odor, texture, taste, appearance) aspects of a food or meal can significantly alter our choice, at least in the short term. These sensory or hedonic parameters influence the reward aspects of eating behavior, and much research focuses on assessing responses to changing single parameters. It is worth noting that Finlayson and co-workers have recently developed assessment techniques for quantifying “liking” and “wanting” foods. Liking is the hedonic evaluation (pleasantness, appreciation) of tasting a particular food, whereas wanting refers to the desire to actually ingest a particular food. Wanting has a much more direct effect on food intake than liking (Finlayson *et al.*, 2007).

### **The Role of Palatability**

The palatability of a food can be thought of as its sensory capacity to stimulate ingestion of that food (Mela and Rogers, 1998). This definition takes account of the fact that the palatability of the food is jointly determined by the nature of the food (odor, taste, texture, and state), the sensory capabilities and metabolic state of the subject, and the environment in which the food and subject interact.

Palatability is therefore not stable; indeed, the palatability of a food typically declines as its own ingestion proceeds, as described below. This has been called sensory-specific satiety (Le Magnen, 1971; Rolls *et al.*, 1981a). Satiety is said to be sensory specific in relation to foods because the palatability of a food declines as its ingestion proceeds whereas unsampled foods do not change in perceived pleasantness (O'Doherty and Rolls, 2000). This suggests that, once a given amount of a certain food has been ingested, its palatability will decline to a point where it is deemed less palatable than other foods. This in turn should promote subsequent selection of those other foods and so maintain a variety of foods ingested in a meal. In this context, it is important to ascertain exactly why the pleasantness of a specific food declines as its ingestion proceeds. The texture of foods can influence palatability and calorie intake. Both people and rodents can consume more ad libitum from liquid foods than they can consume in solid foods. This is related to rate of eating, which is higher for liquids when compared with semi-solids. For example, eating 500 g of apples takes about 17 minutes, whereas drinking the equivalent amount of apple juice can be done in 1.5 minutes (Flood-Obbagy and Rolls, 2009). However, it should be noted that slower eating does not necessarily lead to lower food intake.

Commercially available foods are largely designed to maximize both the sensory and dietary parameters, which make foods appealing to enhance consumer demand and repeat sales. These foods are likely to promote weight gain. However, the food industry produces the types of food that consumers demand. Further knowledge about the importance of palatability and food intake in the long term and how to alter food processing to maximize palatability of food during weight loss is likely to be a future research area.

### **The Role of Sensory Variety**

In summary, short-term studies (within-day) have indicated that increasing sensory variety leads to an increase in food intake (Rolls *et al.*, 1981a,b). It has been shown that increased variety of foods made available either sequentially or simultaneously increases very short-term food intake (i.e. within a meal) (Bellisle and Le Magnen, 1981; Rolls *et al.*, 1981b; Rolls, 1985; Spiegel and Stellar, 1990). Changes in the variety of similar foods offered at a meal elevate EI, compared with one food offered throughout (Bellisle and Le Magnen, 1981; Rolls *et al.*, 1981b, Rolls, 1985). Spiegel and Stellar (1990) have shown this

to be the case in both lean and overweight women. They also found that simultaneous increases in the variety of foods offered elevates intake as compared with sequential increases in the variety of foods offered in a single meal. Rolls has reported that the greater the dissimilarity between different foods, the greater the variety-stimulating effect on the short-term intake of foods (Rolls, 1985). This is explained by the phenomenon of “sensory-specific satiety”. This refers to the decline in reward value during consumption of a food because of repeated exposure to a particular sensory signal. This can be simply described as increased boredom with the taste of a particular product.

It has also been shown by Blundell's group that combinations of sensory attributes associated with mixtures of fat and sugar can have a large effect on EI at a specific feeding episode (Green and Blundell, 1996). This suggests that increases in EI will be promoted by the combination of sensory attributes of foods. More food is often consumed in the presence of other people, a phenomenon known as “social facilitation of energy intake” (de Castro, 1997), a feature of social eating.

One longer term study conducted over a week (Stubbs *et al.*, 2001b) assessed the effects of increasing the variety of nutritionally very similar but sensorially distinct foods available ad libitum in lean and overweight men. Offering 5, 10 or 15 food items per day led to a significant increase in food and EI in the lean men. These data indicate that increasing the variety of sensorially distinct but nutritionally similar foods increased food intake. This had a potent effect on EI and energy balance because subjects actively increased the amount of food they ingested in response to the variety offered. It is not clear if this effect would be maintained over a more prolonged period of time (weeks or months).

### **The Role of Eating Patterns – Snacking and Frequency of Eating**

There is no strong relationship between eating frequency and obesity; obese people ingest more energy than non-obese people, therefore it might be reasonable to assume that meal size is a key factor in overconsumption in obesity. However, the combined contribution of meals and snacks to overeating is still debated within the research arena. There are two alternative hypotheses about how snacking may influence EI and body weight (Johnstone *et al.*, 2000): (1) snacking helps “fine tune” meal-time EIs to match intake with requirements; (2) habitual consumption of calorific drinks and snacks between meals is a major factor

driving EI up and predisposing people to weight gain (Booth, 1988). For example, snackers report consuming more energy than non-snackers do (McCroory *et al.*, 2002), but these people may be more physically active and use snacking to modify EI. This is further complicated by the lack of a universal definition of a “snack”, either by time of day (e.g. intermeal interval) or size (“small meal”) or nutrient profile (food group) or structure (e.g. solid/liquid). The evidence in relation to meal patterns, appetite, EI, and body weight is indirect and fragmentary. Cross-sectional studies tend to support no or a negative relationship between meal frequency and body mass index (BMI) (Fábry *et al.*, 1964; Fábry and Tepperman, 1970). In contrast, increased snacking is associated with television viewing and the latter is associated with increased adiposity (Jackson *et al.*, 2009). Bellisle *et al.* (1997) argue that examinations of the relationship between snacking and energy balance in free-living subjects are extensively flawed by misreporting and misclassification of meals and snacks.

Snacking and commercially available snack foods are often believed to elevate EI (Drummond *et al.*, 1996; Gatenby, 1997; Grogan *et al.*, 1997). This does not mean that ingestion of commercially available foods (commonly termed snack foods) may not influence appetite and EI. Snack foods can differ from other foods in ED, orosensory characteristics which may influence the hedonics of eating, and macronutrient composition. There is some evidence that people who snack frequently exhibit a greater capacity to compensate for changes in the energy content of specific meals, relative to subjects who derive most of their EI from fewer, larger meals (Westerterp-Plantenga *et al.*, 1994). Few controlled laboratory studies have examined whether simply altering the number of small, intermeal “snack” events affects total daily food and EI, although less controlled interventions have been conducted (Fábry *et al.*, 1964). Whereas the inclusion of snack foods in short-term protocols may elevate EI at a given eating episode (Green and Blundell, 1996), data from a more real-life context (Lawton *et al.*, 1998) suggest that, over periods of several days, altering meal patterns *per se* does not drastically alter EI in lean young adults. These data suggest that altering the temporal distribution of EI in itself is not likely to lead to weight gain. However, different subjects may respond differently. Westerterp-Plantenga *et al.* (1994) have shown that habitual meal feeders do not compensate well for alterations in the ED of specific meals and habitual snackers compensate more accurately. It is probable that, just as diet composition and sensory characteristics can interact

to affect EI, so can diet composition and ED, especially in certain groups of subjects.

Habitually skipping breakfast is associated with a higher BMI in observational studies in adults (Keski-Rahkonen *et al.*, 2003) and consuming breakfast is associated with achieving and maintaining weight loss (Wing and Phelan, 2005). However, targeting the importance of a single eating episode for intervention has proved largely unsuccessful for weight control (Giovannini *et al.*, 2010). Controlled laboratory studies have examined frequency of eating, using small-portion feeding regimes (“nibbling”) with isocaloric, larger-portion feeding regimes (“gorging”), to assess eating frequency and regularity on energy and nutrient metabolism (e.g. Verboeket-van de Venne and Westerterp, 1993), and have reported no metabolic advantage of either regime.

### **The Role of Portion Size**

Since the 1970s, the portion size of commercially available foods and beverages has increased, a trend observed in a variety of settings including restaurants, supermarkets, and also in the home environment (Rolls, 2010). Laboratory-based studies examining single-meal eating episodes have suggested increased portion size promotes increased EI. There is a clear relationship between amount served and amount consumed, even when participants serve themselves. The “bottomless soup bowl experiment”, where subjects received tomato soup with a hidden self-filling tube, consumed 73% more soup (113 kcal), compared with when the bowl was refilled by a server (Wansink *et al.*, 2005). Other studies suggest this effect persists for up to 4 days (Kelly *et al.*, 2009), but this would have to be sustained over an extended period of time to contribute to weight gain. Studies in a more natural environment, such as a cafeteria-style restaurant or workplace, have also indicated that increasing the size of a meal portion by 50% increased intake with no apparent compensatory reduction, even when studied for a month (Diliberti *et al.*, 2004). Self-reports of food intake also suggest poor regulation with increased portion size (Bray *et al.*, 2004). One study reports men and women eating 19.4 MJ extra (a 16% increase in EI) over an 11-day period when provided with larger portions, which would equate to a 0.5-kg weight gain (Rolls *et al.*, 2007). This feature of modern eating behavior has, in particular, been the focus of media attention, with “supersize” portions being blamed for the rise in obesity in children and adults. Roughly 41% of Americans report consuming three or more commercially

prepared meals a week in 1999–2000 (Kant and Graubard, 2003). The ready availability and low cost of large portions of energy-dense foods can contribute to a positive energy balance over a prolonged period. However, the data do not prove that portion size plays a role in the etiology of obesity, and there is little evidence that decreasing portion size is acceptable or effective for weight control. Reducing portion sizes or marketing of foods for dieting is not straightforward, since consumers equate large portions with good value and small portions with feeling deprived. Improving consumer awareness about nutritional information at point of sale and incentives for the food industry to offer a variety of portions are measures likely in the future to be considered by policy makers to control food provision within the “obesogenic” eating environment.

### Psychological Influences on Energy Intake, Obesity, and Eating Behavior

There is a growing body of evidence that suggests that subjects behave differently in relation to various nutritional challenges. These are often termed “responders” and “non-responders” to interventions. The reasons for disparity in response may be physiological (e.g. body size or age), genetic (e.g. leptin resistance), phenotypic (gene–nutrient interaction), or psychological influences. There are a number of common categories of psychological influences on eating behavior, discussed below.

#### Restrained Eating Behavior

Dietary restraint refers to the tendency to restrict food intake in order to control body weight. Investigators commonly use a questionnaire such as the Dutch Eating Behavior Questionnaire (DEBQ, van Strien *et al.*, 1986) or the three-factor eating inventory (TFEI, Stunkard and Messick, 1985) to classify subjects as restrained eaters. Dietary restraint can also be associated with “disinhibition,” loss of control over eating resulting in binge eating. Examples from the literature in which dietary restraint can influence study results include two studies conducted by Westerberp-Plantenga *et al.* (1997, 1998) where restrained women responded to covert manipulations of meals by failing to compensate for dietary inclusion of the fat mimetic (Olestra) as an energy deficit whereas non-restrained lean women compensated EI by 44%. An additional difference in response was that the EIs of restrained women were actually (or were self-reported as) lower than those of their unrestrained counterparts.

#### Emotional and External Eating Behavior

The DEBQ and EI questionnaires can also identify the extent to which external environment and internal emotional aspects influence food intake. The *externality theory* of human obesity was developed by Schachter and co-workers in the 1960s (Schachter *et al.*, 1968). They proposed that obese subjects are more reactive to external food-related cues and less sensitive to internal hunger and satiation cues than lean individuals. This relates to a scenario such as walking past a baker’s shop and buying a nice cake or pastry to eat, with no prior plan to have a snack. Inter-individual differences in susceptibility to weight gain may be due, in part, to variability in responsiveness to environmental (external) triggers, particularly in an obesogenic environment. The phenomenon of food craving (“an irresistible urge to consume a specific food”), in particular for high-fat foods (Waters *et al.*, 2001), has been implicated as an important factor influencing appetite control. Burton *et al.* (2007) identified an association between food craving and external eating scores among a mixed-age sample of both males and females. More specifically this was in relation to total food cravings and cravings for high-fat foods, with food craving accounting for approximately 8–20% of the variance in BMI. This area merits further investigation, since the link between eating behavior(s), externality, and food craving as a risk factor for obesity is not well understood.

#### Emotionality Theory

Food intake can have a remarkable effect on mood, and most individuals will have their own food-associated, mood-related habits, e.g. a cup of coffee to get going in the morning or eating sweet foods to reduce anxiety. Emotional states can have major effects on eating behavior, and result in either overeating or undereating. There have been several reviews of studies concerning emotional eating in relation to body weight (e.g. Allison and Heshka, 1993). These studies have almost always dealt with negative emotions such as depression or fear, comparing obese and normal-weight subjects, with results indicating relative overeating in obese individuals during negative emotional states. A psychosomatic interpretation has been that eating by obese individuals in response to negative emotions is a learned behavior to reduce the negative state (Kaplan and Kaplan, 1957). Geliebter and Aversa (2003) conducted a questionnaire study of underweight, normal-weight, and obese subjects and also similarly reported that the overweight group ate more than the other weight

groups when experiencing negative emotions and situations, whereas underweight individuals reported eating more when experiencing positive emotions and situations. Most striking was the undereating by underweight individuals during negative emotions and situations, which may contribute to their being underweight. The relationship between mood and food will continue to be hotly debated at an individual and population level.

### **Stress and Eating Behavior**

Stress is a fact of modern everyday life and the interaction between stress and eating is complex, with subgroups of the general population either increasing or decreasing their food intake during or after stress, depending on eating behavior profile and personality phenotype. There is a relationship between reported stress/daily hassles and increased consumption of high-fat and high-sugar foods between meals (snacking) (Wallis and Hetherington, 2009). The impact of stress on eating behavior varies with both the types of stress experienced and the personality and eating phenotype. For example, O'Connor *et al.* (2008) have reported that work-related, ego-threatening and interpersonal stresses were associated with increased snacking, whereas physical stressors were associated with decreased snacking. Accordingly, chronic stress may contribute to the obesity epidemic. Also, restrained or disinhibited eating will alter response to stress in terms of increasing and decreasing food intake (Haynes *et al.*, 2003). The relationship between food intake and stress varies with gender, obesity, and eating behavior(s) (e.g. emotional eating, dietary restraint) (Wardle *et al.*, 2000).

### **Physiological Influences on Energy Intake, Obesity, and Eating Behavior**

When food is ingested, physiological and psychological responses are induced that depend on its energy and macronutrient content and structure. The macronutrient composition determines the caloric content, digestibility, and rate of passage of a meal through the gastrointestinal tract (the gut) and strongly influences the secretion of peptide hormones from the gut. These hormones in turn feedback to brain centers that control eating behavior, metabolism, and energy utilization. During meal processing, the gut secretes a number of newly identified hormones that signal to the brain to suppress future food intake. Physiological changes, such as gut peptide concentrations, are related to appetitive ratings or food intake,

and can be used as biomarkers of appetite. The regulation of appetite is, however, complex and it is not surprising that multiple control systems exist. A review of satiety and satiation bio-markers is detailed in de Graaf *et al.* (2004), with a summary of common plasma markers below.

*Glucose* has been central to many short-term appetite-regulation theories since the proposal of the glucostatic theory of eating in the 1950s (Mayer, 1995). This theory suggests, in part, that a spontaneous meal request is frequently preceded by a transient decline in blood glucose utilization (see Van Itallie, 1990, for a review). Thus, it has been proposed as an appetitive biomarker candidate. However, this may not be the case because glucose is not a robust measure of meal initiation since feeding occurs in the absence of transient declines in blood glucose. Indeed, changes in insulin concentration have also been identified as appetite markers in normal-weight subjects (Flint *et al.*, 2007).

A more recently identified potential biomarker of meal initiation is the gut peptide, ghrelin. Data have suggested ghrelin to be a potent stimulator of ad libitum food intake when administered intravenously, with changes in concentration mirroring subjective ratings of hunger (Wren *et al.*, 2001) in lean and obese subjects (Druce *et al.*, 2005).

*Cholecystokinin* (CCK) has been the most extensively studied gut peptide associated with satiation, and is particularly linked to fat ingestion (see Moran, 2000, for a review). CCK is released from the gastrointestinal tract by the local action of digested food, and exerts various functions: stimulation of gall bladder contraction and exocrine pancreatic secretion, inhibition of gastric emptying, and inhibition of appetite. CCK acts as a positive feedback signal to stimulate digestive processes and as a negative feedback signal to limit the amount of food consumed during an individual meal (Beglinger and Degen, 2004).

Drugs that can be considered suitable candidates for appetite suppressants are agents that peripherally enhance satiety peptide systems include GLP-1 (Halford *et al.*, 2010). *Glucagon-like peptide 1* (GLP-1) is released predominantly in the ileum and influences gastrointestinal motility and, through this mechanism, may moderate appetite (Holst, 2007). Because of these actions, GLP-1 or GLP-1 receptor agonists are being evaluated for the therapy of type 2 diabetes.

*Peptide YY* (PYY) is released primarily in the colon and acts as an agonist on a receptor in the hypothalamus. The studies of Batterham *et al.* (2002) suggest a differential expression in lean and obese subjects to suppress

short-term food intake. Further work on different diet compositions and energy load are required to establish it as a novel biomarker.

*Insulin* is unlikely to be a biomarker of satiety since it is involved in long-term energy balance. In healthy subjects it stabilizes blood glucose by stimulating the uptake of glucose by peripheral tissues and by suppressing hepatic glucose production (de Graaf *et al.*, 2004). The role of insulin in metabolic health is discussed in more detail in Chapter 45, “Obesity as a Health Risk.”

*Leptin* is a product of the *ob* gene, and is synthesized mainly by adipose tissue, providing information on the availability of fat stores to the hypothalamus. Thus, the effects of leptin as a biomarker are most potent when humans are not in energy balance, particularly when energy restricted. Leptin is not a sensitive marker of short-term satiety. The role of adipose tissue and expression of inflammatory markers is not covered by this chapter but is discussed elsewhere, for example, Chapter 45, “Obesity as a Health Risk.”

*Glucose-dependent insulinotropic polypeptide* (GIP) is released in response to glucose and fat ingestion. Short-term (within-day) intervention studies in lean and obese subjects suggest that it has a poor relationship with appetite ratings and is therefore not a major biomarker of appetite.

## Future Directions

Developing our understanding of control of eating, energy intake, and the development of obesity is likely to be best achieved by multidisciplinary groups of researchers working on large projects. The following are some that have attracted European Union funding streams that will provide novel data over the next 5 years:

### **Obesity and the Workplace**

Since many adults spend a substantial amount of their time at work and consume at least one meal at work each day, a healthy workplace environment is important, particularly as jobs become more sedentary. An increased prevalence of obesity among employees can have indirect economic consequences for employers in terms of lost productivity through illness and absenteeism of employees. This will become an area of focus for policy makers, particularly in order to increase our understanding of stress-induced eating and its potential impact on body-weight regulation. There are currently limited initiatives

to reduce stress, particularly in the workplace. Shaping the work environment to reduce the incidence of disadvantageous eating patterns and promote healthier physical activity patterns in order to control calorie intake and body weight requires evidence-based research. In particular, research may focus on elucidating how typical stress situations in modern life trigger disadvantageous eating patterns and preferences for certain foods.

### **Food Addiction?**

A key attribute of our modern environment is a plentiful supply of safe, energy-dense food. The shared giving and receiving of food is important in a social context, and the consumption of highly palatable food can be intensely rewarding. Public health strategies that fail to preserve this are doomed to failure through population non-compliance. The neuropsychology of food reward and food choice and the links between the appetite regulatory network, eating behavior, and food preference are not understood. Future research will likely focus on brain neuroanatomy and interactions with food to challenge whether food is indeed “addictive” and to investigate the pathways involved in the “rewarding” aspects of food and whether this experience can be replicated in healthier food-product alternatives so as to control body weight.

### **Gut–Brain Control of Energy Balance across the Lifespan**

Hunger involves a complex interaction of psychological and physiological systems that link the gut (the gastrointestinal tract) and brain (Badman and Flier, 2005). There are three important elements to the regulation of EI: food – its nutrient, energy and physical composition; the gut – the origin of multiple feedback signals; and the brain. Together, these form the food–gut–brain axis, which is important in the common scenario of overconsumption. During early neonatal life, the developing hypothalamic projections are sensitive to peripheral hormonal signals, which may include the gut hormones, and this developmental programming may influence susceptibility to obesity and chronic disease in adult life. It is important to understand exactly how early life nutrition may affect subsequent eating behavior to inform appropriate recommendations and design foods targeted at the young. Towards the end of life, different problems arise: dysfunction of neural and neuroendocrine processes can result in loss of appetite, and consequent wasting adds to morbidity and impairs quality of life in the elderly. Here, the greater need

may be to develop foods that stimulate appetite effectively in this population.

### **Understanding Mechanisms of Dietary-Induced Satiety for Weight Control**

Dietary interventions based on caloric restriction or macronutrient manipulation can promote weight loss, as can exercise-induced energy deficit. In theory, weight loss is easy, whereby calorie intake is less than expenditure. However, in practice this is often difficult to achieve in the medium to long term by obese subjects. One of the main reasons for failure to adhere to a diet is feeling hungry. We do not understand the variability in psychological and behavioral parameters of hunger/satiety and food preference during energy deficit (exercise or diet induced) across the life course, and how these manipulations relate to gut hormones, neural activation, and energy metabolism. The psychological, behavioral, and endocrine/neurological bases of these effects and their applicability across age, gender, and phenotype remain to be determined.

### Summary

This chapter focuses on behavioral approaches for changing eating and exercise behaviors, with specific application to weight control. After reviewing the history of behavioral approaches and the core strategies that are taught in these programs, the chapter highlights research on the most effective ways to change dietary intake and physical activity, such as the recommended level of caloric intake and activity and strategies to promote adherence to these recommendations. The chapter also addresses newer directions in the field, focusing on strategies to promote social support, the use of media to cost-effectively disseminate programs, and the critical question of how best to maintain behavior changes long term.

### Introduction

The leading causes of disease and death in the United States – coronary heart disease and cancer – are related to lifestyle factors. By changing eating and exercise habits and eliminating smoking, the prevalence of these diseases could be markedly reduced. The goal of this chapter is to provide readers with an overview of behavioral strategies that can be used to modify lifestyle behaviors. Although the behavioral principles are applicable to changing any

type of health habit, this chapter will focus primarily on obesity, and will review strategies that may help in both the treatment and prevention of this disease.

### History of Behavioral Weight Loss Programs

The underlying premise of a behavioral approach is the functional analysis of behavior, also known as the “A-B-C” model. A functional analysis involves identifying the

behaviors to be changed, which in the case of obesity would be eating and exercise behaviors, and the antecedent cues in the environment and the consequences or reinforcers that influence the behaviors. Behaviorists propose that, by changing the antecedents and consequences, it is possible to change the behavior.

Antecedent → Behavior ← Consequences  
(Cues) (Reinforcers)

The earliest application of behavioral principles to the problem of obesity occurred in the 1960s–1970s. With the notable exception of Stuart’s initial study of eight overweight women (1967), these early behavioral weight-loss programs were typically conducted in groups with mildly overweight patients, and lasted about 10 weeks. The primary “behavior” that was targeted was a change in eating patterns (when and where food was eaten) rather than total calories. Similarly, participants were encouraged to change activity patterns by strategies such as using stairs instead of elevators, but no specific calorie goals for physical activity were prescribed. These early studies produced weight losses of 3.8 kg over an 8- to 10-week treatment program and were shown to be more effective than alternative approaches, such as nutrition education or psychotherapy.

The next generation of behavioral programs, conducted in the 1980s and 1990s, placed increasing emphasis on caloric intake and expenditure. Although moderate goals were initially prescribed for these behaviors, over time stricter dietary regimens and higher doses of activity were recommended. There was also increased attention given to changing cognitions, with introduction of concepts such as relapse prevention, and a gradual lengthening of treatment programs. By the end of the 1990s, average weight losses of 8.5–10 kg over approximately 24 weeks had become typical (Wing, 2008).

With these improvements in initial weight loss outcomes, attention shifted toward improving maintenance of the outcomes. As will be discussed later in the chapter, it quickly became apparent that, in order to reduce weight regain, a chronic disease model of obesity treatment was needed, and some type of ongoing therapy had to be provided. Programs were lengthened and various forms of ongoing treatment contact were provided. Thus, gradually, standard behavioral programs became longer, more intensive, and more effective. Figure 62.1 presents the weight losses achieved in behavioral treatment programs from

**FIG. 62.1** Weight-loss outcomes in behavioral treatments from 1990 to 2000. Reproduced with permission from Wing, (2008).

1990 to 2000; weight losses in these trials averaged 10.37 kg at 6 months (12 studies), 10.35 kg at 12 months (eight studies), 8.2 kg at 18 months (seven studies), and 7.1 kg at 24 months (two studies).

Given the improvements in initial weight losses and longer-term maintenance, it also became possible to examine the role of weight loss in promoting health improvements. Several trials demonstrated that lifestyle interventions could successfully reduce the risk of developing hypertension and could also improve treatment outcomes for those with hypertension (Trials of Hypertension Prevention Collaborative Research Group, 1997; Whelton *et al.*, 1998). In 2002, the Diabetes Prevention Program showed that lifestyle intervention could reduce the risk of developing diabetes by over 58% compared with placebo, and was twice as effective as metformin in preventing this disease (Knowler *et al.*, 2002). More recently, behavioral weight loss interventions have been shown to reduce urinary incontinence in overweight/obese women (Subak *et al.*, 2009), to improve non-alcoholic steatohepatitis (Promrat *et al.*, 2010) and osteoarthritis (Christensen *et al.*, 2007), and to improve glycemic control and cardiovascular risk factors in individuals with type 2 diabetes (Look AHEAD Research Group, 2007). Marked improvements in mood and quality of life also occur with these programs (Williamson *et al.*, 2009).

## Behavioral Strategies

This section provides a brief description of the key behavioral strategies used in weight-loss programs. These same

basic strategies would be applicable to changing any type of nutrition behavior.

### **Identifying the Behaviors to Be Changed**

The first step of a behavioral intervention is to clearly identify the specific behaviors to be modified. For example, for weight loss, the key behaviors that are targeted are those related to energy balance (calories consumed and calories expended). In applying behavioral principles to reduction of cholesterol levels, the key behaviors would include reductions in intakes of saturated fat and cholesterol. Similarly, in an intervention to reduce blood-pressure levels, reducing sodium intake would be an additional behavioral focus.

### **Setting Goals**

In changing behaviors, it is helpful to set specific goals that can be achieved by the participant. Often both behavioral goals and physiological (outcome) goals are identified. For example, participants in weight-loss programs may aim to consume no more than 1200 kcal/day (5023 kJ/day), or to expend at least 1000 kcal/week (4186 kJ/week) in exercise; a weight-loss goal of 2 lb or 1 kg per week is often used. Short-term goals have been shown to be more effective than long-term goals in promoting behavior change (Bandura and Simon, 1977). Often behaviors are “shaped” by setting easier goals initially and then increasing the goal as the participant progresses. An example of shaping is seen in physical activity, where participants are first helped to increase their activity to 250 kcal/week (1046 kJ/week) or 500 kcal/week (2093 kJ/week) before attempting the 1000 kcal/week (4186 kJ/week) goal.

### **Self-Monitoring**

A key strategy in the behavioral treatment of obesity is teaching participants to observe and record their own eating- and activity-related behavior, a technique known as self-monitoring. A variety of information can be recorded through self-monitoring, including the type and amount of food eaten, the number of calories in each food, the number of fat grams, and other eating-related items such as eating situation and pre-meal mood. Similarly, types and amounts of physical activity can be recorded in minutes or calories. Participants are instructed to record their intake daily and bring their self-monitoring books to group meetings, providing an opportunity for feedback from group leaders and other participants. Self-monitoring is usually done on a daily basis for the initial 6 months of

treatment and then periodically during maintenance. Several studies support the utility of self-monitoring, suggesting a strong association between the completeness and consistency of self-monitoring and weight loss (Burke *et al.*, 2008).

Technologies including internet and mobile devices (PDAs, smartphones, etc.) as well as objective activity monitors (accelerometers, pedometers, etc.) offer alternatives to the traditional paper-based diary and calorie books. Internet-based diaries allow the user to look up calories in a database and save those foods to an online record that is accessible from any internet-connected location. PDA and smartphone applications work in a similar fashion but offer the convenience of being portable so that monitoring can occur at the time a food is eaten. Recent studies show that self-monitoring intake using a Personal Digital Assistant (PDA) improves adherence to self-monitoring (Burke *et al.*, 2008). For monitoring of physical activity, newer objective monitors are available that record acceleration or steps, and allow the user to upload the data to an internet site.

### **Stimulus Control**

A central tenet of behavior modification is that an individual's behavior is influenced by his or her environment. Thus, by manipulating their surroundings, participants can change the likelihood of behavioral outcomes. Participants in behavioral treatment programs are taught to restructure their environment to decrease cues for inappropriate food consumption and increase cues for appropriate diet and exercise (Stuart, 1967). For example, participants are instructed to limit their purchases of high-fat foods and, if purchased, to store these foods out of sight. Conversely, participants are encouraged to purchase more fruits and vegetables and to increase the visibility of these items by storing them in prominent locations. To prompt physical activity, participants are encouraged to put items related to exercise in places where they will be seen on a frequent basis. Other stimulus-control strategies such as restricting eating to a designated place and eliminating the pairing of eating with other activities (e.g. watching television, reading) may also be effective means for altering antecedents that influence eating behavior. Stimulus-control techniques could be used to change other types of dietary behaviors; for example, individuals attempting to reduce their blood pressure might be instructed to remove the salt shakers from the table.

### **Problem Solving**

When attempting to make permanent lifestyle changes, participants face many hurdles and obstacles. To help participants successfully navigate this process, training in problem-solving skills is included in behavioral treatment programs. Participants are taught to: (1) identify a specific problem that is hindering their weight-loss effort; (2) generate as many solutions as possible to the problem; (3) evaluate the possible solutions and select one; (4) implement the solution; and (5) evaluate the outcome and repeat the problem-solving process if necessary. Problem-solving techniques are used for individually identified problems; for example, one participant may have difficulty with overeating while preparing dinner while another may focus on the difficulty of eating out in restaurants. Perri and colleagues (2001) have demonstrated the importance of teaching problem solving during the maintenance phase of a behavioral weight-loss program.

### **Cognitive Restructuring**

A more recent addition to behavioral weight-loss treatment is cognitive restructuring. Cognitive restructuring involves identifying and modifying maladaptive thoughts contributing to overeating and physical inactivity. These thoughts can take several forms such as dichotomous thinking (e.g. “If I can’t exercise for 30 minutes, I might as well not do it all”) and rationalization (e.g. “I’ve had a stressful day so I deserve a piece of cake”). Participants are often unaware of the impact thoughts have on behavior. Cognitive restructuring serves to highlight this process by having participants identify and challenge maladaptive thoughts and develop more positive self-statements to assist in behavior change.

### **Relapse Prevention**

Helping participants prepare and plan for lapses in the weight-loss process is also included in behaviorally based programs. An extension of Marlatt and Gordon’s work with addictions (1985), relapse prevention in behavioral weight-control programs involves teaching participants to anticipate problematic situations that might result in overeating and develop specific strategies for overcoming these lapses. Participants are encouraged to have a plan in place so that one overeating slip or lapse does not develop into a full-blown relapse.

Focusing on relapse prevention during the maintenance program has improved long-term outcomes in some

behavioral programs (Perri *et al.*, 1984) but not in others (Perri *et al.*, 2001).

## **Changing Eating Behavior**

As noted above, the behaviors that must be targeted to produce weight loss are the behaviors related to energy balance. However, the best way to accomplish these changes remains unclear. In fact, there is little information about very basic aspects of these behaviors, e.g. the level of caloric intake that is best to prescribe, or the types of macronutrient composition in the diet that should be recommended. In the following sections, we will describe some of the behavioral research that has addressed these issues. Readers interested in more information about behavior changes to reduce intake of saturated fat or sodium or to increase intake of fiber, fruits, and vegetables are referred to the excellent review by Kumanyika *et al.* (2000).

### **Calorie Intake**

Behavioral weight-loss programs typically utilize low-calorie diets of approximately 1200–1500 kcal/day (5023–6278 kJ/day) that are designed to produce weight losses of approximately 1–2 lb (0.5–1.0 g) per week. These regimens have been developed based on empirical studies comparing diets of different caloric levels. For example, in the 1980s and early 1990s, there was a great deal of interest in the use of very low calorie diets (VLCDs) during the initial phase of a behavioral program (Wadden and Stunkard, 1986; National Task Force on the Prevention and Treatment of Obesity, 1993). VLCDs are diets of 400–800 kcal/day (1674–3348 kJ/day), typically given as liquid formula or as lean meat, fish, and fowl. These regimens were found to produce large initial weight losses, averaging 20 kg over 12 weeks. However, since weight regain occurred when these diets were stopped, researchers suggested that it might be helpful to utilize VLCDs to increase initial weight loss, but to combine these diets with behavioral techniques to help maintain the weight loss long term. Several studies evaluated this combination (Wing *et al.*, 1991, 1994; Wadden *et al.*, 1994). Unfortunately the results consistently showed that participants rapidly regained their weight after completing the VLCDs, even if they had been taught behavioral strategies. Thus in the longer term, there was no advantage of these stricter calorie levels compared with the more modest degrees of calorie restriction, and conse-

quently the field returned to the use of the 1200–2000 daily calorie level recommendations.

### **Macronutrient Composition**

A second issue relates to the macronutrient composition of the diet. In the past, behavioral researchers focused primarily on calories and paid less attention to the types of foods consumed. However, based on epidemiological and metabolic studies showing an association between dietary fat intake and body weight (Tucker and Kano, 1992), researchers began to examine whether restricting fat intake would improve long-term weight-loss outcome. Behavioral weight-loss programs that taught patients to decrease calories and fat intake were found to be more effective than programs that focused on only calories or only fat, and thus the field began to adopt this approach (Schlundt *et al.*, 1993; Jeffery *et al.*, 1995; Pascale *et al.*, 1995).

More recently there has been interest in low-carbohydrate diets (e.g. the Atkins or South Beach diets), some of which allow unlimited intake of protein and fat but drastically reduce carbohydrate intake. In the short term, these regimens appear to improve weight loss, but longer-term results have not been as supportive. For example, Dansinger and colleagues (2005) randomly assigned 160 overweight/obese participants to one of four dietary regimens: Atkins (low-carbohydrate diet), Zone (balanced diet), Weight Watchers (point-system diet that is low in fat), or Ornish (very low fat diet). There were no differences in weight loss at one year between the four groups (all groups lost 2.1–3.2 kg at 1 year). However, those who adhered best to whichever diet they had been prescribed had the best weight losses. This finding, stressing the importance of adherence rather than the actual macronutrient composition of the diet, has been confirmed in several other recent trials (Alhassan *et al.*, 2008; Sacks *et al.*, 2009).

### **Food Provision and Structured Meal Plans**

Behaviorists have long recognized the importance of modifying the home environment as a means of influencing eating behaviors, and emphasized stimulus-control techniques to rearrange the home environment. Recently, behavioral researchers suggested that it might be possible to make even greater changes in the home environment by actually providing patients with the food they should eat in appropriate portion sizes. In a programmatic series of studies, Jeffery and Wing showed that participants who were actually provided with the foods they should eat had

better dietary adherence and greater weight losses than participants given the same calorie goals but left on their own to develop their meal plans (Jeffery *et al.*, 1993; Wing *et al.*, 1996). Positive results have also been obtained in several other studies where participants were given prepared meals (Pi-Sunyer *et al.*, 1999) or where Slim-Fast™ (Ditschuneit *et al.*, 1999) was used for one or two meals per day along with a healthy low-fat dinner meal. These studies suggest that simplifying eating, by providing individuals with structure and models of appropriate meals, may promote adherence to weight-loss regimens. Since, as described above, the most important factor in the dietary prescription is the level of adherence to the dietary prescription, techniques such as food provision may be critical in improving weight-loss outcomes.

### **Changing Exercise**

The single best predictor of long-term maintenance of weight loss is physical activity (Pronk and Wing, 1994). Individuals who continue to exercise long term are the ones who are most successful at maintaining their weight loss. The challenge for behavioral researchers is to get overweight individuals to adopt and maintain an exercise program. Typically, behavioral weight-loss programs stress brisk walking or other similar moderate-intensity activities as the primary form of physical activity. Gradually increasing physical activity until reaching a goal of 200 minutes per week (40 minutes on 5 days per week) is encouraged.

### **Home Based versus Supervised**

Having patients exercise under supervised condition allows researchers to better quantify the activity, to adjust the intensity or dose of activity over time, and to teach participants about warming up, cooling down, etc. However, traveling to a supervised site adds an extra burden for the participant and may discourage continued adherence. Several researchers have compared long-term participation and weight losses (Perri *et al.*, 1997; Andersen *et al.*, 1998) in supervised activity vs. home-based lifestyle activity programs. Andersen *et al.* (1998) compared a supervised exercise group that attended three aerobic dance classes per week with a lifestyle group whose members exercised on their own. Initial weight losses were comparable; there was, however, a trend for the lifestyle group to regain less weight during follow-up. Perri *et al.* (1997) also found similar initial weight losses between lifestyle vs. supervised

exercise groups, but at month 15 the home-based program had an average weight loss of 11.65 kg whereas the supervised group had a mean weight loss of 7.01 kg, suggesting that home-based exercise may be more effective than supervised exercise for long-term weight-loss maintenance.

### **Short Bouts Versus Long Bouts**

The supervised versus lifestyle programs described above may have differed not only in location but also in the way in which the activity occurred. In the studies cited above, participants in the supervised exercise conditions completed their activity in one bout on each of 3–5 days/week. The lifestyle conditions were told to “accumulate” 30 minutes of exercise each day. These participants may likewise have done this exercise in one bout, or alternatively completed several short bouts each day. Since lack of time is considered the greatest barrier to exercise, it may be easier for participants to exercise in multiple short bouts (four 10-minute bouts), rather than one 40-minute bout. To test this hypothesis, Jakicic and co-workers completed two weight-loss studies (1995, 1999) comparing programs which prescribed the same amount of lifestyle exercise in either one 40-minute bout or four 10-minute bouts 5 days per week. The first study found better exercise adherence over 6 months and somewhat greater weight losses in the short-bout condition (Jakicic *et al.*, 1995). The second study (Jakicic *et al.*, 1999) again found greater exercise participation in the short-bout group for the first several weeks of the study; however, from 6 to 18 months of the program, no differences between the short-bout and long-bout groups were observed. These two groups had comparable exercise participation, initial and long-term weight loss (–3.7 kg and –5.8 kg) and long-term improvements in fitness. Thus short-bout prescriptions of exercise may be particularly helpful during the initial phase of a weight-loss program; for long-term changes these two different types of exercise format appear to provide alternative, equally effective approaches to physical activity.

### **Providing Home Exercise Equipment**

Another approach to promoting adherence to exercise is to provide patients with home exercise equipment. Although it is often noted anecdotally that such equipment receives little use over time, there has been little

empirical investigation of this strategy. Jakicic *et al.* (1997) observed a correlation between the number of pieces of activity equipment in the home and the activity level. Conceptually it would appear that providing exercise equipment to participants (like providing food) would help cue the appropriate behavior and reduce barriers related to access, cost, etc. Jakicic *et al.* (1999) examined this strategy in a study of overweight women participating in a behavioral weight-loss program, where one group was asked to complete their exercise in short bouts and another group was given the same exercise prescription and provided with a home treadmill. The group given the exercise equipment maintained a higher activity level from months 13–18 of the program and had significantly better weight loss over the 18-month study (–7.4 vs. –3.7 kg). Thus, this study supports the use of this strategy for improving long-term exercise adherence and weight loss.

### **Decreasing Sedentary Activities**

Several studies have attempted to decrease sedentary activity, rather than increase exercise, as a way to influence overall activity level and either treat or prevent obesity. To date, this approach has been used primarily with children. Epstein and colleagues have studied various approaches to the treatment of obesity in children aged 8–12, and recently compared the effects of decreasing sedentary activities (TV, video games), increasing physical activity, versus the combination (Epstein *et al.*, 1995). The group that focused on decreasing sedentary activities had the greatest decreases in percent overweight at 4 months and at 1 year (–18.7% in sedentary; –10.3% in combined, and –8.7% in the increased physical activity group). The group that was instructed to decrease sedentary activity also reported the greatest increases in their liking for vigorous activity. All groups showed comparable improvements in fitness level.

Reducing television viewing as a means to prevent obesity was also examined in a school-based study (Robinson, 1999) with 192 children (mean age 9 years). One school was randomly assigned to an 18-lesson, 6-month curriculum designed to decrease TV viewing. The children in that school self-monitored their television, video game, and videotape use and attempted a 10-day “turnoff” during which they watched no TV or video games. Subsequently, they attempted to decrease these sedentary activities to 7 hours per week. Electronic devices

were attached to home television sets to monitor and budget viewing time. The control school received no intervention.

Children in the intervention school had statistically significant decreases in television viewing and meals eaten in front of the TV. The intervention children also had smaller increases in BMI (18.38 to 18.67) than the control children (18.10 to 18.81) over the 7-month study.

While reducing sedentary activity has demonstrated empirical support among children, only one small randomized controlled trial (RCT) has tested this approach among adults. Otten and colleagues (2009) recruited 36 adults who viewed 3 hours of TV per day or more, and randomized them to an intervention group with a goal of reducing TV viewing by 50% or to a control group. After 3 weeks, the TV reduction group showed significantly greater positive changes in energy expenditure per day (119 kcal/day vs. -95 kcal/day;  $p < 0.05$ ) and a trend toward improvements in energy intake relative to controls ( $P = 0.07$ ), suggesting that this might also be a promising strategy for adults.

### **Amount of Physical Activity**

Behavioral weight-loss programs have traditionally encouraged participants to gradually increase their physical activity until they achieve a 1000-kcal/week (4186 kJ/week) goal. (A 150-lb (68-kg) individual could achieve this caloric expenditure by walking 10 miles (16 km) per week or 2 miles (3.2 km) on each of 5 days in the week.) However, it was unclear whether this amount of activity was sufficient for weight loss and maintenance. The notion that higher levels of activity may be associated with better long-term weight-loss maintenance was first suggested by data collected in the National Weight Control Registry (Klem *et al.*, 1997). This registry is a database of over 6000 individuals who have lost at least 30 lb (13 kg; mean = 66 lb, 30 kg) and kept it off at least 1 year (mean = 6 years). Data from the first 784 subjects in the registry (629 women; 155 men) indicated that on average these individuals were expending 2829 kcal/week (11 841 kJ/week) in physical activity (Klem *et al.*, 1997). More recently this high level of physical activity in successful weight-loss maintainers was confirmed using accelerometers to provide an objective measure of physical activity (Phelan *et al.*, 2007).

Further evidence supporting the need for high levels of exercise for weight-loss maintenance emerged in post-hoc

analyses from a study of physical activity and weight loss (Jakicic *et al.*, 2008). Subjects ( $n = 170$ ) were divided into categories according to their self-reported activity level. There was a strong association between physical activity and weight loss. Those participants who reported greater than 2000 kcal/week of activity had the best weight loss and maintenance.

Based on these data, Jeffery and colleagues conducted a randomized clinical trial comparing the weight-loss effects of a standard behavioral weight-loss program with a 1000-kcal/week (4186 kJ/week) exercise prescription, with a group prescribed a 2500 kcal/week (10 464 kJ/week) level of activity (Jeffery *et al.*, 2003). After 12–18 months, the group prescribed the higher dose of activity lost on average 3–4 kg more weight than the lower dose group. By follow-up at 30 months, most participants were no longer maintaining high levels of physical activity; thus, weight loss at 30 months did not differ between the randomized groups (Tate *et al.*, 2007). However, those who maintained their physical activity at the 2500 kcal/week level or greater showed greater weight losses than those who did less activity (12 kg vs. 0.8 kg).

Jakicic and colleagues (2008) recently examined a related and important question: what is the optimal amount and intensity of physical activity for weight loss and maintenance? In a 24-month randomized controlled trial, participants were assigned to one of four groups, with either a lower dose (1000 kcal/week) or a high dose (2000 kcal/week) of exercise, at either a moderate (50–65% maximal heart rate,  $HR_{max}$ ) or vigorous (70–85%  $HR_{max}$ ) intensity; all groups included standard energy restriction and a face-to-face behavioral weight-loss program. After 12 months there appeared to be no effect of either intensity level or dose. Similarly, at 24 months, all groups had regained weight, and the net weight losses were not different. Since the exercise was unsupervised, the authors speculate that participants did not adhere to the intensity prescription and over time the doses may have converged. However, as noted above, those who reported  $\geq 2000$  kcal/week of activity had the best weight loss and maintenance.

### **Support for Healthy Eating and Exercise Behavior**

When changing eating and exercise habits, people are often influenced by the actions and words of those around

them. Recent evidence suggests that both obesity and weight loss can spread in social networks (Christakis and Fowler, 2007; Gorin *et al.*, 2008). Several studies have evaluated the effects of including spouses, other family members, and friends in the treatment process with mixed results. A meta-analysis of this literature (Black *et al.*, 1990) suggested a small positive effect for spouse involvement, and a more recent review (McLean *et al.*, 2003) indicated that family involvement was modestly effective for both children and adults but less so for adolescents.

In a cleverly designed study, Wing and Jeffery (1999) evaluated two different approaches to social support. These investigators recruited participants for a weight-loss program and asked them to identify three overweight friends who would also like to be in the program and work with them as a team to lose weight. Individuals who identified three friends were compared with individuals who were unable or unwilling to identify three friends or were not asked to recruit others (i.e. this aspect of the study was not randomized). This natural social-support intervention was crossed with an experimental manipulation of social support in a  $2 \times 2$  research design. The experimental manipulation of social support included intra-group cohesiveness activities and inter-group competitions in which participants competed for money that was returned contingent on maintenance of weight loss. Those participants who were recruited with friends and given the social-support manipulation had the best outcome. Whereas 95% of these individuals completed the 10-month study, only 76% of the standard behavioral group (those recruited alone and not given the social support intervention) completed the study. Moreover, 66% of participants recruited with others and given the social-support intervention maintained their weight loss in full from month 4 of the program to month 10; only 24% of the standard behavioral group maintained their weight loss in full over the same time frame.

Kumanyika and colleagues (2009) recently reported the results of the SHARE trial, a culturally specific intervention for African-American adults that utilized the same  $2 \times 2$  research design as Wing and Jeffery's earlier work. No differences in weight loss were seen between the social support conditions. Post hoc analyses revealed that participating in weight-loss treatment with family members or friends was beneficial only if the support partners themselves were more engaged in treatment activities and lost weight. More research is needed to better understand how

to harness the power of social networks to influence healthy behavior change.

## Media-Based Interventions for Weight Loss

Traditionally, behavioral weight-loss programs have been offered in face-to-face meetings with health professionals. However, because obesity is such a pervasive problem, research has focused on developing treatment approaches that involve little or no face-to-face contact and thus can be more easily disseminated.

Telephone calls have been used as part of traditional clinic-based programs. Phone calls enable therapists to maintain contact with participants but also gradually reduce the number of in-person contacts. Self-directed materials supplemented with telephone counseling were found to be superior to delayed controls (VanWormer *et al.*, 2009) and when delivered with weekly and then bi-weekly frequency can be similar to face-to-face interventions delivered with the same frequency and superior to lower frequency telephone calls (Digenio *et al.*, 2009).

Internet-based interventions have proliferated over the past decade and are now recognized as an alternative to deliver all or some of the components of face-to-face behavioral programs. The great potential of the internet is low-cost delivery of printed materials and the interactive nature of the communication. Early research showed that including behavioral components (self-monitoring, structured weekly guidance, feedback, etc.) with access to informational websites produces significantly better weight losses compared with informational websites alone (Tate *et al.*, 2001) and subsequent studies have shown that providing ongoing feedback and counseling support via e-mail or chat groups can enhance weight losses of internet programs (Tate *et al.*, 2003; Harvey-Berino *et al.*, 2004).

Tate and colleagues (2006) found that initial weight losses could be improved even by using computer-automated feedback. Participants were randomized to a self-directed internet program, an internet program supplemented with weekly computer-automated feedback about self-monitoring and weight-loss progress (automated e-counseling), or an internet program supplemented with weekly e-mail counseling advice provided by a human weight-loss counselor. After 3 months, the auto-

mated counseling group and the human e-counseling groups had achieved weight losses that were similar to each other and both were significantly better than the self-directed internet group. At 6 months, the human counseling group achieved the largest weight losses, but the automated counseling group produced average weight losses of about 5% of initial body weight, suggesting the approach may be an inexpensive way to provide ongoing feedback.

Though internet weight-control studies can produce weight losses of a magnitude that would achieve health benefits, the outcomes have been regarded as less than what can be produced using face-to-face counseling methods. Recently, a large RCT confirmed these speculations. Harvey-Berino and colleagues (2010) randomized 481 overweight adults to an internet-only program, an in-person program, or a hybrid program including the internet program plus monthly in-person meetings. Weight losses were significantly greater in the in-person condition compared with the other two internet groups. Interestingly, the hybrid condition that included periodic in-person visits did not improve weight losses compared with the internet-only condition. This finding replicates a prior study showing no additional benefit to adding monthly in-person visits to a comprehensive internet behavioral weight-loss program (Micco *et al.*, 2007).

With the surge in adoption of cell-phone and mobile web-enabled devices, internet access no longer requires a laptop or large computer, allowing weight-loss programs and tools to be more portable. Though the body of research is still quite small, a few studies suggest the potential of delivering weight-loss programs via mobile technologies. A program consisting of an initial binder of print materials, daily tailored text messages (delivered two to five times per day) and a monthly phone call from a counselor showed a 3% average weight loss after 4 months compared with a 1% average weight loss among control participants who received monthly print materials (Patrick *et al.*, 2009). Turner-McGrievy and colleagues (2009) conducted a randomized trial comparing available weight-control audio podcasts delivered twice each week to podcasts that were matched in frequency and duration but were designed using key concepts from social cognitive theory. The theoretically based podcasts produced about a 3% weight loss after 12 weeks compared with no weight loss with the other podcasts. Thus, as with internet-delivered programs, mobile programs that provide structure or tailored feedback, or are based on sound theoretical behavior-change

principles, appear superior to self-directed educational programs.

## Maintenance of Initial Weight Loss

Despite the initial success of behavioral weight-loss programs, weight regain is common. It is often reported that 95% of individuals who lose weight will regain it within 3–5 years, raising doubts about whether successful weight-loss maintenance is possible and leading some to question whether weight loss is a futile treatment goal. The National Weight Control Registry, a database of over 6000 individuals who have lost at least 30 lb (13.6 kg) and kept it off for at least a year, provides evidence that weight loss can be maintained over the long run. On average, Registry members have maintained a weight loss of 72.8 lb (33 kg) for almost 6 years (Wing and Phelan, 2005). Key behavioral strategies used by Registry members are described in Box 62.1 (Klem *et al.*, 1997; Wyatt *et al.*, 2002; Gorin *et al.*, 2004; Raynor *et al.*, 2004, 2006; Phelan *et al.*, 2006, 2007, 2009; Butryn *et al.*, 2007). To maintain their weight losses, these individuals report continuing to consume a low-calorie, low-fat diet (Klem *et al.*, 1997; Phelan *et al.*, 2006). Most report eating breakfast every day (Wyatt *et al.*, 2002), and they maintain a consistent diet (with low levels of dietary variety) across weekdays and weekends (Gorin *et al.*, 2004). Registry members also report high levels of physical activity (Klem *et al.*, 1997; Phelan *et al.*, 2007; Catenacci *et al.*, 2008). A key characteristic of these successful weight-loss maintainers is their ongoing vigilance about their diet, exercise, and body weight (Butryn *et al.*, 2007). For example, 44%

### BOX 62.1 Behaviors reported by National Weight Control Registry members

- Consume a low-calorie, low-fat diet
- Engage in high levels of physical activity
- Limit TV viewing
- Daily self-weighing
- Maintain diet consistency across weekdays/weekends
- Limit dietary variety
- Eat breakfast daily
- Limit fast-food intake
- Use of fat and sugar modifiers in foods

report weighing themselves daily, and another 31% report weighing at least once weekly. Even within this highly successful group, however, small weight gains of just a few pounds are difficult to recover from (Phelan *et al.*, 2003), arguing for the need to adopt a chronic care model of obesity management and to provide continued support to facilitate weight control.

Interventions designed specifically for maintenance, not just extensions of the initial weight-loss phase, have recently been developed. In the STOP Regain trial (Wing *et al.*, 2006), participants were recruited after they had lost significant amounts of weight through any type of program on their own. To maintain this weight loss, participants were taught a self-regulation approach that involved daily weighing, comparison of their current weight with a goal weight (weight at the start of the maintenance program), and, depending on the discrepancy or correspondence between the two weights, making adjustments in eating and exercise behaviors or providing self-reinforcement. Weight, calories, and minutes of exercise were reported weekly via a telephone call-in or email, and, if successful at weight maintenance, participants were provided with a small monthly gift to reinforce their progress. The intervention was tested in two different delivery formats – via the internet or face to face – and compared with a newsletter control group. Over an 18-month period, only 46% and 52% of participants in the face-to-face and internet groups, respectively, regained 5 lb (2.3 kg) or more compared with 72% of control-group participants. The face-to-face group also reduced the magnitude of weight regain by almost 50% compared with the control group. In the active intervention groups, participants who weighed themselves daily had the most weight-loss maintenance success and were over 80% less likely to regain weight compared with those who weighed themselves less often.

A maintenance-specific treatment group that involved some face-to-face meetings was also successful in preventing weight regain in the Weight Loss Maintenance Trial (Svetkey *et al.*, 2008). Following an initial 6-month weight-loss induction phase, adults who had lost at least 4 kg were randomly assigned to a self-directed, minimal-contact control group, an interactive technology-based condition, or a personal-contact intervention. Contact for the technology-based group occurred via the internet, and participants were encouraged to log in to the study website once a week, enter their weight, and utilize interactive features including goal-setting and problem-solving

modules. The personal-contact group consisted of monthly telephone contacts with a case manager, with in-person visits every 4 months. At 30 months, the personal-contact group was superior, regaining 1.5 kg and 1.2 kg less than the self-directed and interactive technology-based groups, respectively. Taken together with findings from STOP Regain, it appears that some face-to-face contact over an extended period may facilitate weight-loss maintenance.

What the content of this extended contact should be remains unclear. In the recently published PRIDE study (West *et al.*, 2011), two different face-to-face maintenance interventions were compared: a standard skills-based group that focused on reviewing and refining behavioral skills, and a motivation-focused group that aimed to increase motivation to engage in healthy behaviors by strengthening satisfaction with progress, cultivating participants' identities as successful weight losers, eliciting personal motivations for engaging in long-term behavior change efforts and supporting autonomous self regulation, and increasing motivation to engage in non-food-related activities. Compared with an education control group, both active-treatment groups achieved comparable 18-month weight losses (–5.48% for motivation-focused vs. –5.55% in skill-based,  $P = 0.98$ ), and both groups lost significantly more than controls (–1.51%;  $P = 0.0012$  in motivation-focused and 0.0021 in skill-based). As the field moves forward, theoretical models that recognize the unique process of behavior-change maintenance, and not just initiation, will likely inform the development of more effective weight-loss maintenance approaches (Rothman, 2000).

## Future Directions

Behavioral treatments have been shown to be effective in producing significant initial weight losses and improving health. Currently attention is focused on developing more effective weight-loss-maintenance interventions. While we know that changing both eating and exercise behaviors is critical for long-term weight control, we lack basic information regarding how to promote long-term adherence to these healthier behaviors. Given the epidemic of obesity, there is also a need to explore more cost-effective ways to deliver intervention. Finally, research related to the prevention of obesity is a high priority; such research will need to examine how eating and exercise behaviors are devel-

oped in young children, and the role of both the home and the outside environment in supporting these behaviors. A better understanding of the development and maintenance of healthy eating and exercise behaviors is critical, not only for combating the obesity epidemic but also for the treatment and prevention of hypertension, hyperlipidemia, and some forms of cancer.

## Acknowledgment

Preparation of this chapter was supported in part by NIH grants DK056992 and HL090864 awarded to Dr Rena Wing.

## EPIDEMIOLOGIC APPROACHES TO EVALUATION OF NUTRITION AND HEALTH

SUSAN E. STECK, PhD, MPH, RD

*University of South Carolina, Columbia, South Carolina, USA*

### Summary

Nutritional epidemiology encompasses a variety of endeavors, including monitoring the dietary intake and nutritional status of populations, contributing to the evidence for or against hypotheses related to nutrition and health outcomes, and designing interventions to promote healthy eating habits. When examining nutrition and health relationships with epidemiologic methods, there are a number of issues that must be considered because of unique features of dietary intake as a determinant of health. For example, diet is a complex exposure and populations often consume dietary factors within a narrow range of intake, creating challenges in our ability to observe associations owing to the limited contrasts available. The types of epidemiologic study designs used to examine nutrition and health, along with examples from the literature, are discussed in this chapter. Focus is given to the challenges and strengths of each study design, as well as to issues inherent in epidemiology such as bias, confounding, and external validity in interpretation of study results. One specific diet–disease relationship that has been studied with both observational studies and clinical trials will be discussed to illustrate some of the concepts presented in the chapter. Finally, suggestions for future directions for enhancing epidemiologic studies of nutrition and health are proffered.

### Introduction

Epidemiology is defined as “the study of the occurrence and distribution of health-related states or events in a specified population, including the study of the determinants influencing such states, and the application of this knowledge to control the health problem” (Porta, 2008).

When applied to nutrition and health, there are a number of issues that must be considered in view of the unique features of dietary intake as a determinant of health. For example, diet is a complex exposure and one that is ubiquitous. For the majority of dietary factors of interest, most individuals are consuming some amount, and thus it is often impossible to compare absent exposure from present

exposure as is possible with other lifestyle factors such as cigarette smoking or use of non-steroidal anti-inflammatory drugs. Many dietary factors are correlated with one another, creating challenges in trying to determine the independent effects of a specific dietary factor. In addition, populations often consume dietary factors within a narrow range of intake, creating challenges in our ability to observe associations within a population being studied due to the limited contrasts available. Usually, relative risks of dietary factors determined from epidemiologic studies are modest (around 0.5 to 2.0), but, given the high prevalence of exposure, these can be quite meaningful from a public health point of view.

Nutritional epidemiology includes several activities, such as monitoring the dietary intake and nutritional status of populations, contributing to the evidence for or against hypotheses related to nutrition and health outcomes, and designing interventions to promote healthy eating habits. This chapter will focus on the study designs and methodologic considerations when evaluating nutrition and health outcomes using epidemiologic approaches. Because of inherent limitations in epidemiologic study designs and the possibility of biases, no one epidemiologic study alone can provide definitive evidence that a dietary factor causes or prevents a health outcome. The epidemiologic literature must be evaluated and taken in context with other epidemiologic studies, as well as with other lines of evidence, such as *in vitro* and animal model experimental studies, when determining the merit of a given exposure–disease relationship. There are various methods for dietary assessment in humans and these are an important component of nutritional epidemiologic studies but will be covered in more detail in another chapter of this book and not discussed here.

Diet can be investigated in epidemiologic studies at several different levels, anywhere from very broadly as dietary patterns to food group or individual food intake to more specifically as individual nutrient or phytochemical intake. For the estimation of nutrient or phytochemical intake, a food composition database is required to convert the reported food consumed into nutrients and phytochemicals. Thus, this adds an additional layer of potential measurement error given that the nutrient value for a given food in a food composition database may be very different from what was actually consumed by the study participant. Analyzing whole food intake or dietary patterns has the benefit of not having to rely on food composition databases, and thus eliminates that additional source of error.

There is ongoing debate comparing the attributes of the holistic approach (dietary patterns and food groups) with that of the reductionist approach (individual nutrients or phytochemicals) for studies of nutrition and health. The study of individual nutrients or phytochemicals lends itself better to understanding biologic mechanisms because associations that are observed in epidemiologic studies can be tested in the laboratory and in experimental models to identify the active agents in foods and their biologic properties. On the other hand, the study of food groups or dietary patterns has more potential for public health applicability given that the combination of individual nutrients and phytochemicals found in whole foods is likely to be most beneficial, and dietary patterns can be more easily translated into public health recommendations. Certainly, there is a need for multiple levels of analyses in improving our understanding of the role of nutrition in health.

## Epidemiologic Study Designs

There are two broad types of epidemiology: (1) descriptive epidemiology, which describes distributions of disease by place, time or person and includes ecological and migrant studies, and (2) analytical epidemiology which tests specific hypotheses about exposure–disease relationships and includes case-control studies, cohort studies, clinical trials, and meta-analyses. The following sections will describe these major study designs, discuss strengths and weaknesses of each, and provide examples of their application to the investigation of nutrition and health.

### ***Ecological or International Correlation Studies***

Ecological studies are investigations into the relationship between an exposure and a disease outcome at the population level, rather than the individual level. In studies of nutrition and health, per capita intake of a given food can be estimated from national aggregate data and correlated with disease rates across various countries (or across regions within a country if differences in eating habits exist within the different subpopulations in the country). Several important hypotheses have been generated by studies that compare international rates of disease with country-specific dietary intake, for example the association between dietary fat and breast cancer and the association between meat intake and colorectal cancer (Willett, 1998).

One benefit of the ecological approach is that, because of the heterogeneity in diets across different countries and cultures, much larger contrasts in dietary intake can be

examined than can be obtained in observational studies of a more homogeneous population. For example, intake of soy is high among Asian populations but not among the US population. Thus, studies of the association between soy intake and a given health outcome within the United States would be limited by the narrow range of intake within this population. In fact, if a higher level of intake is required before an effect can be observed, studies in the United States are likely to find null associations, as has been discussed for the relationship between soy intake and breast cancer risk (Gammon *et al.*, 2008). Another example where the narrow range in intake limits the ability to observe associations is that of fat and breast cancer (Hebert and Wynder, 1987), where ecological studies support a linear association, but the majority of observational studies within specific populations have found null associations. Narrow ranges in intake in studies of individuals' diets as well as different effects for different types of fat may partly explain these conflicting results.

Another advantage of ecological studies is that they can be performed relatively quickly and inexpensively compared with other types of epidemiologic studies. However, a major limitation of ecological studies is the lack of information on other variables that could confound the relationship between the dietary factor and the health outcome (for example, smoking, physical activity, and socioeconomic status which can be related to both dietary intake and disease outcomes, meeting the definition of a confounder). Without appropriate measurement and control for these potential confounders, a causal association may be erroneously attributed to the dietary factor when, in fact, the causal agent may be a different factor that is related to both the dietary factor and the disease outcome. For this reason, causality should not be inferred from ecological studies. Also, because ecological studies use national aggregate data, the findings are impossible to reproduce in other studies. Replication and consistency of findings in epidemiologic studies are important components of establishing a causal link between an exposure and outcome. Thus, cross-national or cross-cultural comparisons can still play a role in advancing the science of nutrition and health, but the role is limited to that of hypothesis-generating and not inferring causality.

### **Migrant Studies**

Migrant studies provide some of the most compelling evidence for a major role of diet and other environmental or lifestyle factors in disease etiology. For example, numer-

ous studies have observed that, when populations migrate to a new country, very soon (within one or two generations) they will develop the cancer rates of the new host country. These relationships are striking, particularly when the disease rates of the host country and the country of origin are in sharp contrast with one another, for example stomach cancer rates have historically been much higher in Japan than in the United States. Japanese Americans who were born in Japan have similar stomach cancer rates to those from their host country, while second-generation Japanese Americans have stomach cancer rates similar to those of the US population (Tominaga, 1985; Kamineni *et al.*, 1999). These types of studies provide evidence that it is not only genetics or inherited susceptibility that is responsible for disease; lifestyle and environment are also very important. Thus, while migrant studies do not identify the specific dietary habits or biologic mechanisms involved, these studies contribute greatly to our knowledge about the relative importance of diet and other environmental factors in health outcomes.

### **Case-Control Studies**

A case-control study is one type of observational study in epidemiology that collects data at the individual level and estimates risk of a disease or health outcome. In these studies, investigators recruit cases (individuals with the disease or health outcome) and controls (individuals without the disease or health outcome of interest from within the same population in which the cases arose), and make comparisons regarding exposures that may be associated with disease risk. For example, in a study of the association between cruciferous vegetable intake and breast cancer, investigators would identify women diagnosed with breast cancer (cases) and women without breast cancer (controls) and then ask them to recall their dietary intake over a certain period of time to assess intake of cruciferous vegetables. Using statistical methods, the investigators could then examine whether increased intake of cruciferous vegetables was associated with reduced risk of breast cancer within this population. Other factors that may be related to both cruciferous vegetable intake and breast cancer risk (i.e. potential confounders) would also be assessed and controlled for, either by matching the cases and controls on that factor (for example, matching on age is often performed in case-control studies), or by adjusting for those factors in the statistical models.

Case-control studies tend to dominate the epidemiologic literature because they are usually less expensive and

time-consuming than other types of individual-level epidemiologic studies (e.g. cohort studies or clinical trials discussed below). Case-control studies also have the advantages of being able to study rare diseases more easily and being able to assess a number of different risk factors in a given study. As with cohort studies, data can be collected on potential confounding variables and these can be controlled for in the design of the study by matching or in the statistical analyses by using multivariate methods.

However, there are several potential biases associated with case-control studies that need to be considered in the interpretation of the results. These include selection bias and information bias. Selection bias refers to the act of choosing subjects in a way that alters the observed association between the exposure and disease of interest. There are several ways in which selection bias can enter a study. A classic example is the use of hospital controls, where control subjects are selected from the hospital from which cases were treated. If the exposure of interest is more likely to be present or absent in the hospital-based controls than in the general population (e.g. because it is also associated with their reason for hospitalization), then this can lead to distorted results.

Even when controls are selected from the general population, rather than from a hospital, selection bias is possible if controls are recruited using methods that would exclude certain participants with different socioeconomic status or health status. For example, recruiting controls via random-digit-dialing would exclude participants without telephones, which tends to be an indicator of low socioeconomic status (Langseth, 1996), or recruiting controls with drivers' licenses from the Department of Motor Vehicles would exclude individuals who do not drive, perhaps an indicator of low literacy or poor health. In addition, controls who volunteer for studies tend to be more health conscious than the general population, so, especially when participation rates among the control population are low, this could result in the diets of the control population being much healthier than the general population, causing erroneous findings. Thus, exclusion of certain groups in the control population may bias study results, pointing to the importance of trying to minimize these potential sources of bias when determining recruitment strategies and selection criteria for a given study.

Information bias is another potential limitation in case-control studies. Information bias occurs when data are collected differently in cases than in controls such that results may be misleading. One form of information bias

that is especially problematic in case-control studies of diet and disease is recall bias. Since cases are recruited after diagnosis, they are asked to recall their dietary intake prior to disease diagnosis. If the diagnosis of disease distorts their recall in a systematic way, then spurious associations may appear when in fact there is no causal association. Examples of this could be that women diagnosed with colon cancer recall consuming more red meat than they actually consumed because they think red meat is to blame for their disease status, or individuals diagnosed with diabetes change their diet soon after diagnosis and report their diet after diagnosis rather than prior to diagnosis, or perhaps symptoms of the disease itself force the individual to change their dietary habits in the months leading up to diagnosis, as could be the case in oral cancers, and the cases recall their more recent diet instead of that consumed prior to the onset of symptoms. Regardless of the reason, if cases recall their diet in a systematic way differently from controls, then recall bias can occur and cause misleading results.

Another type of information bias is interviewer bias, which can occur if the interviewer knows the disease status of the participant and conducts the interview differently because of that knowledge. Finally, even the use of objective biomarkers of nutrients as the exposure measurement can lead to information bias if the biomarker is affected by the disease process. Given the likelihood that relative risks for a given diet–disease relationship are relatively small, even minor measurement error caused by bias could affect results of case-control studies, and it is difficult to completely eliminate these potential sources of bias in each study (Willett, 1998). Because of these limitations, case-control studies of a given dietary factor and disease outcome can produce inconsistent results, and are at times in contrast to those obtained with cohort studies.

### **Cohort Studies**

In a prospective cohort study, participants from a defined study population are recruited prior to the onset of disease and followed for a period of time to determine who is diagnosed with the disease of interest. Dietary intake assessment occurs at baseline, and in the majority of studies this is repeated at intervals during the follow-up period. In this way, the role of nutrition in the prevention or causation of disease can be determined prior to disease diagnosis by comparing the frequency of disease in individuals exposed to the frequency of disease in the non-exposed (or less exposed) individuals. Thus, many of the

biases associated with case-control studies that are a consequence of the timing of exposure assessment occurring after disease diagnosis are eliminated or reduced in cohort studies, such as recall bias and interviewer bias. Another advantage is that cohort studies allow for measurement of diet over time, so that changes in diet can be assessed and examined in relation to disease etiology. In addition, cohort studies can examine a variety of disease outcomes in one study.

There are some disadvantages to cohort studies, however. Because some chronic diseases are rare, such as cancers of certain organ sites, a large number of participants (usually tens of thousands) have to be enrolled and followed for a long period of time in order to obtain enough disease outcomes to study the hypotheses of interest. Loss to follow-up can be a concern if participants who drop out of the study are different in important ways from those who stay in the study, and can lead to distorted associations. Thus, cohort studies require extensive retention efforts to maintain participation in the study. For these reasons, cohort studies are typically much more expensive and time-consuming than case-control studies.

Another concern in cohort studies is external validity. External validity refers to the ability to generalize the results of a given study to different populations or groups that did not take part in the study. Because cohort studies tend to recruit participants based on an exposure of interest (e.g. farmers exposed to pesticides) or by a defined study region, demographic or occupation (e.g. European Investigation in Nutrition and Cancer [Riboli and Kaaks, 1997], Women's Health Initiative [1998], or Nurses' Health Study [Colditz *et al.*, 1997]), rather than a disease of interest as in a case-control study, the generalizability of the results may be limited to a specific group of people. This can also limit the ability of the study to observe an association if the study population is very homogeneous with insufficient variation in dietary intake.

A special kind of case-control study called a nested case-control study can be performed within a cohort study, which is less costly and time-consuming than starting a brand new cohort, and can minimize bias as compared with a traditional case-control study. In a nested case-control study, investigators choose a subset of the entire cohort to examine a hypothesis of interest. As in a case-control study, individuals diagnosed with a given disease are chosen, and a subset of controls without the disease are chosen from the cohort for comparison. Frequencies of exposures (measured in the past prior to disease onset)

are then compared between cases and controls. This is especially advantageous for biomarker-based studies where it is less costly to conduct the laboratory measurements on a subset of the cohort rather than the entire cohort, and it minimizes information bias because the biologic specimens were collected prior to disease diagnosis. Thus, nested case-control studies can incorporate the advantages of both case-control and cohort studies while minimizing the disadvantages, thus improving efficiency of design.

### **Clinical Trials**

Randomized controlled trials or interventions are often considered the gold standard of epidemiologic study designs because of their ability to control the exposure of interest rather than relying on dietary recall or laboratory measurement of exposures. In a randomized controlled trial, participants are randomly assigned to either a placebo (control) group or a treatment (intervention) group and are followed for a period of time to examine whether the intervention group has fewer disease outcomes than the control group. These can be double-blinded, in which neither the investigators nor the participants are aware of their study assignment, or single-blinded, where the participants are aware of their assignment but the study investigators are not. Clinical trials involving a single agent can often be double-blinded because the dietary factor can be put in a capsule form that can be made to look, smell, and taste exactly like a placebo capsule. However, for obvious logistical reasons, whole diet interventions cannot be double-blinded owing to the inability to blind the participants to a change in the foods they are consuming. While dietary supplements in capsule form are easy to administer, and allow for creating large contrasts between the intervention and control groups, they are at times not appropriate because the real interest is on whole foods or dietary patterns.

A major advantage of randomized controlled clinical trials is the ability to reduce confounding by other factors. Randomization, if done correctly, reduces the potential confounding effects of factors that may be related to diet and disease because the presence of these other factors is randomly distributed between intervention and control groups. Clinical trials are generally thought to be able to directly examine cause and effect for a given exposure and disease or health outcome. This study design is useful for studying rare exposures, and, in the case of a single agent supplement, can create larger contrasts between groups than might be available in observational studies.

However, particularly when diet is being studied, there are some disadvantages to randomized controlled trials that can restrict our ability to address hypotheses of interest with this study design because of ethical or logistical concerns. Clearly, only dietary factors that are thought to prevent rather than cause disease can be examined in an intervention as it would be unethical to randomize individuals to an exposure that is thought to increase risk of disease. In addition, the evidence that the intervention will work must be considerable enough to warrant the expense and effort of conducting the study, while at the same time not so substantial that it would be unethical to withhold the intervention from the control group.

For studies employing whole diet interventions (such as a low-fat diet or high fruit and vegetable diet intervention), it is often difficult to create large enough contrasts between the study arms to observe an effect on the disease of interest, and contamination of the control group is often a possibility especially when the dietary factor or dietary pattern being studied receives substantial media attention. Compliance with the intervention and control diets needs to be monitored carefully. Additionally, clinical trials are limited in that the effects of only one or a few dietary factors can be assessed in a given trial.

Many chronic diseases have long latency periods, so interventions must be administered for long periods of time. To try to minimize the length of the study, large trials of dietary factors have often enrolled high-risk subjects where the time to disease diagnosis would be much shorter, for example, smokers and asbestos workers in trials of  $\beta$ -carotene and lung cancer (Alpha-Tocopherol Beta Carotene Cancer Prevention Study Group, 1994; Omenn *et al.*, 1996), or have employed intermediate endpoints such as enrolling individuals with a previous polyp removed in studies of diet and polyp recurrence (Schatzkin *et al.*, 2000). These studies have frequently resulted in unexpected findings, i.e. either (most commonly) no effect or (more rarely) unexpected increased risk of the intervention on cancer incidence or mortality as in the case of the  $\beta$ -carotene lung cancer trials (reviewed in Lippman *et al.*, 1998; Byers, 1999; Davies *et al.*, 2006; Bjelakovic *et al.*, 2007). Many reasons for these unexpected results have been discussed (Forman *et al.*, 2004; Meyskens and Szabo, 2005; Prentice, 2007; Rock, 2007). Incorporating these lessons learned into new, innovative study designs is essential if we are to advance public health through diet. In many of the studies, most notably the  $\beta$ -carotene lung cancer trials, large doses of single agents as supplements

were used as the intervention, despite the fact that the epidemiologic evidence was in support of food-based sources of nutrients often at lower levels of intake than found in supplements (Mayne, 1996). More recently, large dietary intervention trials have shown no effect of increasing fruit and vegetable intakes, or reducing fat and increasing fiber intakes (or some combination of these) on cancer incidence, survival, or recurrence of precancerous lesions (Schatzkin *et al.*, 2000; Prentice *et al.*, 2006; Pierce *et al.*, 2007). Possible reasons for null effects of dietary interventions are discussed in detail in the Future Directions section.

### **Meta-Analyses and Pooling Studies**

Given the challenges associated with each epidemiologic study design and the limitations previously noted regarding drawing conclusions from only one study or from only one population, the use of meta-analyses and pooling projects has increased in recent years (Smith-Warner *et al.*, 2006). Meta-analyses and pooling studies represent methods for combining data from multiple studies and multiple populations to summarize the effect of a dietary factor on a particular health outcome. A meta-analysis is a systematic review of the literature which combines the results from previous studies and determines a summary estimate of effect, in contrast to pooled studies where the actual study data from multiple studies are obtained and re-analyzed with the larger sample size (and presumably larger variation in dietary intake).

Meta-analyses provide a systematic way of reviewing and summarizing the literature, but are faced with challenges when it comes to nutrition data. Intake of a given dietary factor is often categorized into quantiles in epidemiologic studies, and the number of quantiles used (whether it be tertiles, quartiles, quintiles, etc.) varies from study to study, as do the cutpoints used to create those quantiles (and these cutpoints unfortunately are not always reported), and the confounding variables included in the models. Thus, the dose of the dietary factor that is associated with an effect is not readily apparent, and determining how to summarize the data is no trivial matter. Pooling projects, on the other hand, obtain the original data from multiple studies and can thus create new quantiles using all of the data and can standardize the covariates, outcome variables, and types of analyses. As with meta-analyses, pooling projects must deal with the fact that different studies use different dietary assessment methods and different food composition databases, resulting potentially in

various units of intake that must be converted to a common unit, and varying accuracy in intake estimates for a given nutrient or dietary factor. Thus, while these types of studies have strength in numbers (number of studies or sample size of the population) and minimize some of the aforementioned issues related to narrow ranges in intake, external validity, and low power for uncommon exposures or rare diseases, the accuracy of results is still dependent on the quality of the data collection methods used in the studies that they are summarizing. An example of a large pooling project is the ongoing Pooling Project of Prospective Studies of Diet and Cancer, which began in 1991 and combines data from 16 prospective cohort studies (Smith-Warner *et al.*, 2006). Multiple papers have been published using these data, and, in particular, the project has enabled the examination of associations between dietary factors and rare diseases such as pancreatic cancer, renal cell cancer, and ovarian cancer with more power than previous studies given the larger sample size (Koushik *et al.*, 2005; Genkinger *et al.*, 2009; Lee *et al.*, 2009).

## Example of Diet and Disease Relationship Studied with Multiple Epidemiologic Study Designs

### *Folate and Colorectal Cancer*

There is no doubt that a true success story in nutritional epidemiology is the identification through numerous types of study designs that folic acid supplementation can reduce the incidence of neural tube defects (Wolff *et al.*, 2009) (also, see Chapter 21). This conclusion led to the implementation of mandatory folic acid fortification in the United States and Canada in 1998, with many other countries following suit later, and a concomitant reduction in rates of neural tube defects has been reported in several countries (Honein *et al.*, 2001; Ray *et al.*, 2002; Chen and Rivera, 2004; Hertrampf and Cortes, 2004; De Wals *et al.*, 2007). However, the effect of folic acid on colorectal cancer is not as clear (Ulrich and Potter, 2006; Kim, 2008).

In multiple observational studies, high folate intake is associated with reduced risk of colorectal cancer. Both case-control and cohort studies have supported this association (Giovannucci, 2002; Kim, 2008; Kim *et al.*, 2010; Lee *et al.*, 2011), with measurement of folate in the diet or as a biomarker measured in red blood cells, and a few small clinical trials have provided evidence that folic acid

supplementation reduces recurrence of adenomatous polyps (precursors to colorectal cancer) (Paspatis and Karamanolis, 1994; Jaszewski *et al.*, 2008), while other trials have found no significant effect, either protective or adverse, on recurrent adenomas (Logan *et al.*, 2008; Wu *et al.*, 2009). However, an ecological study examining time trends in the United States and Canada found increased incidence of colorectal cancer in these countries following the initiation of mandatory fortification (Mason *et al.*, 2007). While this does not prove causality due to the possibility of ecologic fallacy, one clinical trial has observed increased risk of advanced adenomas in individuals supplemented with folic acid compared with placebo (Cole *et al.*, 2007). A possible explanation for this lies in our knowledge about the biologic mechanisms for folate's anti-cancer effects. Folate is involved in DNA synthesis and DNA methylation, and may have a protective role in preventing carcinogenesis but a potentiating role for pre-neoplastic lesions by supporting the proliferation of neoplastic cells. Thus, the evidence for health benefits of even a single dietary factor can be quite complex, and dietary factors that may be beneficial for one health outcome may turn out to be detrimental for another health outcome.

Future work in genetics and epigenetics may help to identify the most beneficial application of folic acid to the promotion of overall health. As an example, the gene that encodes an enzyme involved in folate metabolism, 5,10-methylenetetrahydrofolate reductase (MTHFR), is polymorphic, and a single nucleotide polymorphism (SNP) in *MTHFR* (C677T) results in a functional change to the enzyme (TT and CT genotype carriers have lower enzyme activity than CC genotype carriers) and has been consistently shown to be associated with colorectal cancer risk in meta-analyses of epidemiologic studies (Huang *et al.*, 2007; Hubner and Houlston, 2007; Taioli *et al.*, 2009). The association of candidate gene SNPs involved in nutrient metabolism with a human disease outcome can provide further evidence for a causal association between the nutrient and the disease.

In addition, the examination of gene-diet interactions can help to explain the inconsistent associations observed in epidemiologic studies of diet alone or of genes alone (Nowell *et al.*, 2004; Hunter, 2005). Associations between specific dietary factors and disease may only become apparent in those individuals with certain genetic variants related to the disease process or related to the activity or metabolism of the dietary factor, thus providing some

explanation for null associations observed in epidemiologic studies that do not take genetics into account, even in the presence of solid experimental data of a biologic effect for a given dietary factor. For the folate-*MTHFR* example, the effect of the *MTHFR TT* genotype appears to be modified by folate status, such that the beneficial effect disappears under low folate conditions (Bailey, 2003). Other genes and environmental factors are likely to influence these associations (e.g. alcohol can also modify the effect of folate on colorectal cancer risk and there are multiple other SNPs within *MTHFR* and other genes involved in one-carbon metabolism that may play a role [Bailey, 2003; Steck *et al.*, 2008]), so the ability to analyze large complex sets of data with multiple interactions (and the subsequent need for large sample sizes) is an ongoing challenge in the field of gene–diet interactions. Data from genome-wide association studies are now being combined with environmental exposure data to examine gene–environment interactions on an even larger scale. Beyond sequence changes to DNA, other heritable factors such as DNA methylation (in which folate is directly involved) and histone modification (i.e. epigenetic factors) are known to be important in disease etiology, are influenced by nutrition, and are beginning to be incorporated into epidemiologic studies of nutrition and health (Waterland and Michels, 2007; Ulrich and Grady, 2010).

## Future Directions

As discussed here, clinical trials are often not feasible or ethical for examining diet and health relationships. In fact, several reasons may explain the absence of a dietary intervention effect when, in fact, an association between diet and the health outcome exists (Hebert and Miller, 1988; Jeffery and Keck, 2008). These include: (1) the distinction between the diets of the intervention and control groups in the trial was not great enough to observe a difference in disease incidence between the groups due either to (a) targeting the wrong foods or dietary patterns for the intervention, or (b) the fact that the control group was eating a diet too similar to the intervention group because of self-selection of health-conscious individuals into the trial, non-compliance by the intervention group, or compensatory change in the control group; (2) genetic heterogeneity, such that a true effect in susceptible subpopulations is masked when all individuals are grouped together in analyses; (3) the targeted timepoint for the intervention was not

relevant to, or appropriate for, the disease process under study (e.g. the study population involved older adults when earlier-life interventions were needed, or the intervention period was too short to produce an effect); or (4) the intervention may work only in those individuals whose diets are deficient or insufficient to begin with, and these are not the typically health-conscious people who enroll in clinical trials. Given these limitations of clinical trials, observational studies will continue to be essential in providing evidence for or against diet–disease hypotheses, and finding ways to strengthen these studies is a critical future direction.

Enhancing dietary measurement is one such way to improve epidemiologic studies of nutrition and health. Developing technology for dietary assessment such as administration via the internet, PDAs or cell phones is underway and recognized as an important current need in nutritional epidemiology (Guillén *et al.*, 2009; Ngo *et al.*, 2009; Arab *et al.*, 2010; Six *et al.*, 2010; Subar *et al.*, 2010; Thompson *et al.*, 2010). In addition, as discussed above, insufficient variation in the diets of populations has been a limiting factor for many diet–disease relationships studied with epidemiologic methods. This is being addressed by pooling large cohort studies to obtain greater variation in diet and greater numbers of disease outcomes to investigate those hypotheses that have conflicting results in previous studies as discussed above (Smith-Warner *et al.*, 2001; Cho *et al.*, 2004; Smith-Warner *et al.*, 2006).

Additionally, timing of dietary exposure is recognized as crucial, particularly in diseases with long latencies such as cancer (Michels, 2003a; Steck *et al.*, 2007; Gammon *et al.*, 2008). Thus, finding ways to incorporate early life exposures or exposure assessment across the lifecourse in epidemiologic studies will contribute greatly to our understanding of diet–disease relationships (Michels, 2003b). Furthermore, new analytic methods for handling time-varying data, such as marginal structure models, are being employed in epidemiologic studies of diet and health (Robins *et al.*, 2000; Bodnar *et al.*, 2004). Marginal structure models allow for adjustment of time-dependent confounding, as in the case when a confounder is associated with outcome and with subsequent exposure, and when past exposure is associated with the level of the confounder. An example of this is the association between prenatal iron supplementation and anemia at delivery where dose of iron supplementation can change over time based on the time-dependent covariates of a subject's side-effects or

biomarkers of iron status (Bodnar *et al.*, 2004). Depending on the analyses, the direction of the effect of iron supplementation on anemia can be reversed, from an adverse effect when using an ordinary logistic regression model, to an inverse association when using a marginal structure model, which highlights the importance of employing appropriate analytic methodology to obtain fitting interpretations of epidemiologic studies of diet and health.

Some of the limitations of clinical trials are logistically impossible to overcome in human studies, such as those related to the long latency period of chronic disease development, e.g. intervening early and following individuals to a bona fide health outcome is usually infeasible. Others, however, such as the idea that genetic susceptibility may be modifying effects of dietary factors, may be better understood by designing smaller, shorter-term intervention studies that utilize our increasing knowledge about biologic mechanisms of disease (Lampe, 2004; Prentice *et al.*, 2004). Applying what we know about the human genome and emerging “-omics” technologies (e.g. nutrigenomics, epigenomics, proteomics, metabonomics) in the field of nutrition (Stover, 2004; Zeisel *et al.*, 2005; Jenab *et al.*, 2009) should lead to innovative areas of research that will deepen our understanding of the biologic processes involved in diet and disease, and reconcile trial data with a preponderance of ecological, observational, and laboratory evidence that implicates certain foods in disease etiology. Such understanding has very practical implications for translating findings to individuals and communities in which the dietary factors will have a beneficial and substantial effect.

## NUTRITION MONITORING IN THE UNITED STATES

RONETTE R. BRIEFEL<sup>1</sup>, DrPH, RD AND MARGARET A. MCDOWELL<sup>2</sup>, PhD, MPH, RD

<sup>1</sup>*Mathematica Policy Research, Washington, DC, USA*

<sup>2</sup>*National Institute of Health, Bethesda, Maryland, USA*

### Summary

The US nutrition monitoring program is comprised of national and state surveys of individuals and households, health record systems, and specialized databases on food and dietary supplement composition, environmental contaminants, and food availability. Although the continuous National Health and Nutrition Examination Survey (NHANES) still collects the most comprehensive health and nutrition data on the US population, a growing number of other federal and state surveys and databases also contribute information on diet and health knowledge, attitudes and behaviors, food consumption, nutrition, and health for the general population and subgroups at nutritional risk.

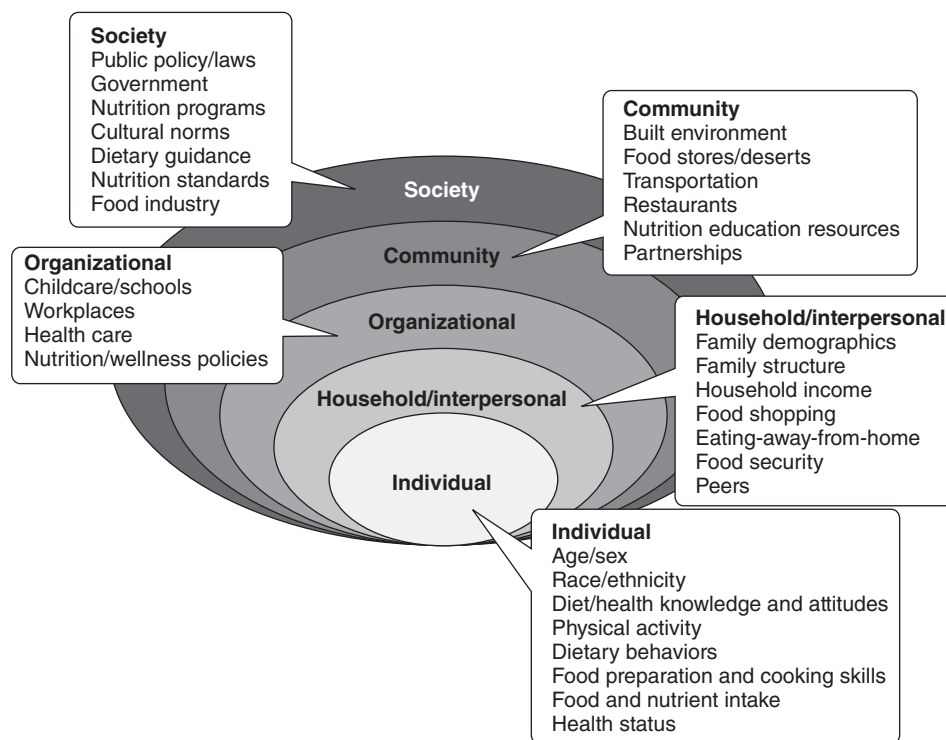

Since 2000 a growing array of data resources have come into use to monitor US trends in dietary intake, nutritional status, and nutrition-related health conditions (e.g. obesity, hypertension, diabetes, osteoporosis, and dental caries); to evaluate nutrition assistance programs, food fortification and food labeling policies, and food safety; and to conduct research on nutrition standards and diet and health relationships. Greater recognition of the role of the food environment (e.g. store proximity, food price structure, and community characteristics) in food choices and diet quality is evident today.

### Introduction

Nutrition monitoring has been defined as “an on-going description of nutrition conditions in the population, with particular attention to subgroups defined in socioeconomic terms, for purposes of planning, analyzing the effects of policies and programs on nutrition problems, and predicting future trends” (Mason *et al.*, 1984). This

chapter provides a brief history of the National Nutrition Monitoring and Related Research Program (NNMRRP) in the United States, uses of nutrition monitoring data, monitoring activities since 2000, and nutrition monitoring research to meet challenges in the future.

The NNMRRP is composed of interconnected federal and state activities that provide information about the dietary and nutritional status of the US population, condi-

**FIG. 64.1** Socio-ecologic model for nutrition and health monitoring. Individuals’ nutrition and health status are influenced by interpersonal, organizational, community, and societal factors; a comprehensive nutrition monitoring program should assess the factors and levels shown in the socio-ecologic model for nutrition and health monitoring. Adapted from Centers for Disease Control and Prevention (2010).

tions existing in the US that affect the dietary and nutritional status of individuals, and relationships between diet and health (Briefel, 2006; Briefel and Bialostosky, 2008). Nutrition is one component of a broader socio-ecologic framework (Figure 64.1) in which individuals are influenced by their families, communities, and programs and policies at the federal, state, and local levels (Glanz *et al.*, 2005). A general conceptual model representing the relationship between food and health is presented in Figure 64.2. This figure aligns with the five NNMRRP measurement component areas described in past reports: (1) food supply determinations; (2) food and nutrient consumption; (3) food composition and nutrient databases; (4) knowledge, attitudes, and behavior assessments; and (5) nutrition and related health measurements (US Department of Health and Human Services (HHS) and US Department of Agriculture (USDA), 1993; Life Sciences Research Office (LSRO), 1995; Briefel, 2006). For this chapter update, a sixth measurement area on environmental factors was added to incorporate food access and the built environment (Brownson *et al.*, 2009).

The US nutrition monitoring program is a model for integrating national and state data from many sources to understand the relationship between food and health and to improve nutrition in the population.

### History and Recent Accomplishments/Activities

A nutrition monitoring system was first established with the passage of the Food and Agriculture Act (Pub. L. 95–113) in 1977. Major legislative efforts to increase federal efforts to coordinate nutrition surveys occurred in the late 1970s and 1980s and culminated in the passage of the National Nutrition Monitoring and Related Research Act 1990 (Pub. L. 101–445) in 1990 (US Congress, 1990). The Act established several mechanisms to ensure the collaboration and coordination of federal agencies as well as state and local governments involved in nutrition monitoring. These included the formation of an

**FIG. 64.2** Relationship of food to health. A comprehensive nutrition monitoring program should assess the characteristics of, and interactions between, the food environment; food supply; food and dietary supplement composition; and individuals' food consumption, nutrient intake, knowledge/attitudes/behaviors, and nutrition/health status. These components reflect the relationship of food to health. Adapted from Life Sciences Research Office (1995).

interagency board to coordinate annual budget reports, biennial reports on progress and policy implications of scientific findings, and periodic scientific reports to describe the nutritional and related health status of the US population. A National Nutrition Monitoring Advisory Council provided scientific and technical guidance to the board and made important contributions to improving information dissemination and focusing attention on issues such as the coverage of high-risk population subgroups, assessment of the needs of data users, and integration of federal, state, and private data needs.

The *Ten-Year Comprehensive Plan* guided federal actions for nutrition monitoring during the period 1992 to 2002 (US Department of Health and Human Services (HHS) and US Department of Agriculture, 1993). The plan identified three national objectives critical to the success of the overall goal of a coordinated, comprehensive nutrition-

monitoring program: (1) provide for a comprehensive program through continuous and coordinated data collection; (2) improve the comparability and quality of data across the program; and (3) improve the research base for nutrition monitoring. During the period 1992–1997, federal efforts were focused on improving survey coordination and survey methods, conducting research, and increasing nutrition information dissemination (Dwyer *et al.*, 2003a; Briefel, 2006). To meet one of the research objectives, an 18-item food security measure was developed to track the prevalence of hunger and food insecurity in the population and high-risk subgroups (Hamilton *et al.*, 1997). This measure is used in national surveys, evaluation studies of nutrition assistance programs, and other research studies on low-income groups.

Since 2000 the major activities and accomplishments were related to the integration of the two national nutri-

tion surveys, the US Department of Health and Human Services' National Health and Nutrition Examination Survey (NHANES), and the US Department of Agriculture's Continuing Survey of Food Intakes by Individuals (CSFII) (Murphy, 2003; Woteki, 2003). An expanded array of diet and health information resources including specialized food and dietary supplement composition, food environment, food safety, and food supply databases were developed to support monitoring and research activities. Nutrition monitoring data were also used to support health-care-reform legislation, to expand child and adult feeding programs, and to improve school nutrition standards.

Nutrition monitoring has also been the focus of scientific and professional organizations. In 1999 the US National Academy of Sciences (NAS) sponsored a symposium on the future of nutrition monitoring in view of the fact that the 1990 legislation was up for reauthorization in 2002. The purpose of the meeting was to draw attention to the federal, research, industry, media, and consumer uses of NNMRRP data, and to discuss the future challenges for the program. Despite the NAS symposium, a report by the American Societies for Nutritional Sciences Working Group (Woteki *et al.*, 2002), and other efforts to gain support for reauthorization, the nutrition monitoring legislation was not renewed in 2002. Monitoring activities are continuing, but without the formal, coordinated guidance of an interagency board or legislative mandate. In 2002 a workshop was held with nutrition monitoring stakeholders to develop recommendations on how best to meet data needs for policy and research with the integrated survey (Dwyer *et al.*, 2003a,b,c,d). In 2004 a US National Research Council panel published a review of the infrastructure to support food and nutrition programs, research and decision making, and, in 2005, a report on recommendations to improve the data for such purposes (National Research Council (NRC), 2004, 2005). The 2005 report provides the most recent information on nutrition monitoring activities, but does not cover the entire program to the extent of the 2000 *Directory* more than a decade ago (Interagency Board for Nutrition Monitoring and Related Research (IBNMRR), 2000).

Since 2005 the major sources of nutrition monitoring data are individual federal and state government reports, journal articles, and special reports commissioned by the federal government to address specific topics and research needs. For example, a report by Logan *et al.* (2002) summarizes the types of data available from national surveys

and surveillance systems that can be used to assess the relationship between food assistance program participation and nutrition and health outcomes. The coordinated interagency reporting and data syntheses that occurred between 1984 and 2000 have been discontinued (LSRO, 1995; IBNMRR, 2000; Woteki *et al.*, 2002; Briefel, 2006). While these joint efforts served to improve coordination by increasing communication and standardization and reducing duplication of effort, they also require staff and other resources that can be labor intensive and political. In their place a broader range of research and reporting initiatives led by individual agencies have been undertaken. For example, the National Cancer Institute maintains a website that provides information on dietary methods, surveillance, and analysis approaches for assessing the diet, nutritional status, and physical activity of populations (<http://riskfactor.cancer.gov/>). There is a continued need for Congressional support to ensure that there is a sound NNMRRP in the future with steady financial resources for national nutrition monitoring (Woteki *et al.*, 2002; NRC, 2005).

## Purposes and Uses of Nutrition Monitoring Data Today

Nutrition monitoring serves a vital role in health policy making and research (US Congress, 1990; LSRO, 1995; Office of Science and Technology Policy, 1996). Monitoring provides information and a database for establishing public policy and identifying research priorities. Nutrition research provides data for policy making and for identifying nutrition monitoring needs for data. Box 64.1 provides examples of uses of nutrition monitoring data for public policy and scientific research purposes. Monitoring provides information for public policy decisions related to nutrition education programs such as the *Dietary Guidelines for Americans* (USDA and HHS, 2010), MyPyramid (now called MyPlate) (USDA, 2011), and 5 A Day (CDC, 2008); public health programs such as the National Cholesterol Education Program (NCEP) (NCEP Expert Panel, 2002) and the National High Blood Pressure Education Program (National Heart, Lung, and Blood Institute, 2004); federally supported nutrition assistance programs such as school meals and the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) (Logan *et al.*, 2002; Woteki *et al.*, 2002; Fox *et al.*, 2004); the USDA Food Plans (Carlson *et al.*, 2007a,b);

**BOX 64.1 Uses of nutrition monitoring data****Public Policy****Monitoring and surveillance**

- Identify high-risk groups and geographical areas with nutrition-related problems to facilitate implementation of public health intervention programs and food assistance programs.
- Evaluate changes in agricultural policy that may affect the nutritional quality and healthfulness of the US food supply.
- Track trends in dietary behavior, nutritional status, and health to assess progress toward achieving the nutrition and health objectives in *Healthy People 2010* and the *Dietary Guidelines for Americans*.
- Recommend guidelines for prevention, detection, and management of nutrition and health conditions.
- Develop reference standards for nutritional status.
- Assess environmental exposures from food consumption.
- Monitor food production and marketing.

**Regulatory**

- Develop food labeling policies.
- Document the need for, and monitor, food fortification policies.
- Establish food safety guidelines.

**Nutrition-related programs**

- Develop nutrition education and dietary guidance (e.g. *Dietary Guidelines for Americans* and MyPlate).
- Plan and evaluate food assistance programs.
- Plan and assess nutrition intervention programs and public health programs.

**Scientific Research**

- Establish nutrient requirements through the lifecycle (e.g. *Dietary Reference Intakes*) and assess nutrient adequacy and excess.
- Study diet–health relationships and the relationship of knowledge and attitudes to diet and health behavior.
- Develop biomarkers of diet and health behaviors and nutritional status.
- Foster and conduct nutrition monitoring research – national and international.
- Conduct food composition analysis.
- Study the economic aspects of food consumption.
- Assess the contribution of dietary supplements to usual nutrient intake.

and food production and marketing such as the development of reduced-fat or reduced-calorie food products.

Monitoring data are used to evaluate progress towards achievement of long-term health objectives including the 2010 and 2020 Health Objectives for the Nation (US Department of Health and Human Services, 2000). The Healthy People findings are used to inform policy development, identify areas of future nutrition research, and evaluate diet and health guidance for the US population. NHANES data on heights and weights were used to develop growth charts to assess children's growth and weights status (Kuczmarski *et al.*, 2000).

Specific uses of the dietary intake and biomarker data collected during the NHANES include assessments of the population's dietary intakes and serum nutrient

levels to determine and evaluate the Dietary Reference Intakes recommended by expert groups convened by the Institute of Medicine (Institute of Medicine (IOM) 2000, 2010a,b); evaluations of fortification policies by the Food and Drug Administration (FDA) (Lewis *et al.*, 1999; Centers for Disease Control and Prevention (CDC), 2000; Woteki, 2003; Bailey *et al.*, 2010); use of dietary supplements by the US population (Heimbach, 2001); and dietary exposure estimation for nutrient and non-nutrient food components by the Environmental Protection Agency (EPA) (1997). The data have been used to establish reference ranges for dietary exposures in children and adults and to evaluate public health initiatives to the human health effects of environmental exposures (CDC, 2009).

Numerous private industries use nutrition monitoring data for marketing purposes and research. Food industry has used national food consumption data to assess brand-name loyalty, to target marketing practices, and to study the relationship of a particular food commodity such as soup or iron-fortified cereals to overall intake and nutritional status. Pharmaceutical companies have used NHANES data to estimate the proportion of the population taking a particular drug, to estimate treatment of various health conditions with drugs (Dodd *et al.*, 2009), and to conduct cost–benefit analysis of the use of cholesterol-lowering drugs and cardiovascular risk. National survey data on the population’s use of dietary supplements have been used by trade associations to study the characteristics of users and the nutritional effects of supplements. Consumers and practitioners also use national nutrition data to learn about diet and health, the effects of supplements on diet, nutrition, and health, and the effectiveness of weight-loss practices.

Nutrition monitoring data have also been used to identify food and nutrition research priorities of significance to public health. The Institute of Medicine used NHANES dietary and biochemical data in its review of the Dietary Reference Intakes for calcium and vitamin D, and NHANES 2003–2006 hypertension and dietary data to recommend strategies to reduce sodium intake in the United States (Institute of Medicine, 2010a,b). Trends in energy and food and nutrient intake based on national dietary data have been used to understand the relationship between changes in dietary intake and the population’s increase in overweight and health status (Logan *et al.*, 2002; Briefel and Johnson, 2004; Fox *et al.*, 2004; Briefel, 2007). State-level data have been used to plan health and nutrition education programs. For example, New York used Behavioral Risk Factor Surveillance System (BRFSS) data on the consumption of whole milk to plan a state campaign to encourage people to drink low-fat milk, and Arkansas used BRFSS data on physical activity and hypertension to design interventions and education programs to target African-American women.

## Nutrition Monitoring Components in the United States

### Background

The first national dietary surveys were carried out in the 1930s. Since then, more than 35 surveys, surveillance systems, and databases have been developed and evolved to meet the information needs of federal agencies, research-

ers, and data users. Chronological listings of past nutrition monitoring surveys and activities have been published (US Department of Health and Human Services and US Department of Agriculture, 1993; LSRO, 1995; NRC, 2005; Briefel, 2006). This section of the chapter describes ongoing nutrition monitoring activities by the components shown in the food-to-health framework in Figure 64.2. Additionally, a new section on environmental data sources has been added to reflect growing interest in ecological factors that are related to food consumption patterns (French *et al.*, 2001; McKinnon *et al.*, 2009). Table 64.1 summarizes information on the federally sponsored surveys of households, individuals, and nutrition assistance program participants, and surveillance activities since 2000. Table 64.2 summarizes information on food supply and availability, environmental databases and the technical databases used in national nutrition monitoring. Website information links for each data source are included in Tables 64.1 and 64.2 and listed at the end of the chapter.

### Food Supply and Food Availability (Per Capita) Data Systems

Annual per capita nutrient availability or national food supply estimates have been produced by the USDA Economic Research Service (ERS) since 1909 (Table 64.2). Food supply data reflect the amounts of foods and nutrients available for consumption and thus trends in food available for consumption rather than actual food intakes by individuals and households. Food supply data are often used to: (1) assess the potential of the US food supply to meet the nutritional needs of the population; (2) evaluate the effects of technological alterations and marketing changes on the food supply; (3) indicate the relationships between food and nutrient availability and nutrient–disease associations; and (4) facilitate management of federal marketing, food assistance, nutrition education, food enrichment and fortification policy. The Food Availability Data System has been expanded since the last edition of this chapter to include per capita loss-adjusted food availability (LAFA) information and nutrient availability information. The LAFA information adjusts the per capita food availability data for food spoilage and other losses to more closely approximate actual per capita intake, resulting in per capita estimates for each food commodity group: the number of calories per day and the number of MyPyramid equivalents per day (now called MyPlate) (USDA, 2011). Nutrient availability information provides estimates of the amounts per capita per day of food energy and 27 nutrients and dietary components (for example,

**TABLE 64.1** Major federally sponsored nutrition monitoring surveys, surveillance systems, and activities (2000–2011)

Survey name	Federal department (agency)	Schedule (initial year)	Sample design (estimates)	US target group	Sample (size)	Survey content, measures, and link for further information
<i>Individual-Level Data Collection and Reports</i>						
National Health and Nutrition Examination Survey (NHANES)	HHS (CDC/NCHS) "What We Eat in America" funded by USDA/ARS	Periodic 1971–1974, 1976–1980, 1982–1984, 1988–1994 Continuous, annual: 1999– present	Cross-sectional (national)	Civilian, household population; all ages since 1999	Annual sample: ~5000 persons interviewed and examined annually	Household interview, physical exam, and post-exam components. Dietary information: two dietary recalls per person since 2002; food security, supplement use, diet behavior, and health questionnaires. Exam includes measured height and weight; biomarker assessments; clinical tests (vary by survey) NHANES link: <a href="http://www.cdc.gov/nchs/nhanes.htm">http://www.cdc.gov/nchs/nhanes.htm</a> USDA: "What We Eat in America (WWEIA)" tables: <a href="http://www.ars.usda.gov/Services/docs.htm?docid=13793">http://www.ars.usda.gov/Services/docs.htm?docid=13793</a>
Flexible Consumer Behavior Survey (component of NHANES)	HHS (CDC/NCHS) Funded by USDA/ERS	Special module (2005–2010)	Cross-sectional (national)	NHANES subsample 1+ years	In-person and telephone interview methods	Core questions asked in the NHANES household interview; post-exam phone interview. Family and individual level data Link: <a href="http://www.ers.usda.gov/Briefing/DietQuality/flexible.htm">http://www.ers.usda.gov/Briefing/DietQuality/flexible.htm</a>
National Health Interview Survey (NHIS)	HHS (CDC/NCHS)	Annual (1957)	Cross-sectional (national, selected state estimates with combined years combined)	Civilian, household population, all ages	All ages (sample sizes have varied) 2010 sample: 34 329 households yielded 89 976 individuals	In-person household interview. Content includes core questionnaire on basic health and demographic items and special modules on current health topics (content and topics vary) Link: <a href="http://www.cdc.gov/nchs/nhis/about_nhis.htm">http://www.cdc.gov/nchs/nhis/about_nhis.htm</a>
Health and Diet Survey (HDS)	HHS (FDA/CFSAN)	Periodic since 1982	Cross-sectional	Random-digit-dialing (RDD) telephone survey	2008 sample: 2584 adults 18 years and over	Tracks consumer knowledge, attitudes, and practices related to foods and dietary supplements Link: <a href="http://www.fda.gov/ForConsumers/ConsumerUpdates/ucm202611.htm">http://www.fda.gov/ForConsumers/ConsumerUpdates/ucm202611.htm</a>

Behavioral Risk Factor Surveillance System (BRFSS)	HHS (CDC/ NCCDPHP)	Annual (1984)	Cross-sectional (national and state)	Civilian, households with telephones; age 18+ years. Sampling frame: 50 states, DC, Puerto Rico, Virgin Islands, and Guam Youth in school grades 9–12; ages 12–21 years	In 2010, 451 075 adults participated in BRFSS	Telephone interviews. Core questions and state-specific questions asked Field operations are managed by state health departments that follow guidelines provided by the CDC Link: <a href="http://www.cdc.gov/brfss/technical_infodata/surveydata/2010.htm">http://www.cdc.gov/brfss/technical_infodata/surveydata/2010.htm</a>
Youth Risk Behavior Surveillance System (YRBSS)	HHS (CDC/ NCCDPHP)	Biennial (1991)	Cross-sectional (national and state)	Youth in school grades 9–12; ages 12–21 years	National school-based survey samples; 2009 data on 16 410 persons 12–21 years based on 47 states, DC, and 20 local regions	Monitors priority health-risk behaviors and the prevalence of obesity and asthma among youth and young adults Link: <a href="http://www.cdc.gov/HealthyYouth/yrbss/index.htm">http://www.cdc.gov/HealthyYouth/yrbss/index.htm</a>
National Immunization Survey (NIS)	HHS (CDC/ NCIRD and CDC/NCHS)	Annual and periodic surveys (1994)	Cross-sectional (national and state)	Annual surveys of children 19–35 months; add-on survey of teens 13–17 years since 2006 (NIS-Teen); adult survey conducted 2007	2010 NIS included 25 948 children 19–35 months. 2008 NIS-Teen: surveyed 19 257 teens	RDD telephone survey followed by mail survey to providers. Breastfeeding questions since 2001 Link: <a href="http://www.cdc.gov/breastfeeding/data/NIS_data/index.htm">http://www.cdc.gov/breastfeeding/data/NIS_data/index.htm</a>
State and Local Area Integrated Telephone Survey (SLAITS)	HHS (CDC/ NCHS) with government agency and nonprofit organization support	Periodic (1997)	Cross-sectional (national and state)	RDD design; uses NIS sampling frame; children and adults have participated	Sample size varies. The 2007 National Survey of Children's Health (with HRSA) collected information on 91 642 children birth–17 years	Health data on varied topics at the national, state, and local levels The 2011 survey expects to collect information on 91 800 children birth–17 years Link: <a href="http://www.cdc.gov/nchs/slait.htm">http://www.cdc.gov/nchs/slait.htm</a>

TABLE 64.1 (Continued)

Survey name	Federal department (agency)	Schedule (initial year)	Sample design (estimates)	US target group	Sample (size)	Survey content, measures, and link for further information
National Survey of Family Growth (NSFG)	HHS (CDC/NCHS)	Periodic cycles (1973–2002) Continuous, annual surveys since 2006	Cross-sectional (national)	National samples of US household population	Target age: 15–44 years; ~4400 interviews/year	Information on family life, marriage and divorce, pregnancy, infertility, use of contraception, breastfeeding, and men's and women's health Link: <a href="http://www.cdc.gov/nchs/nsfg.htm">http://www.cdc.gov/nchs/nsfg.htm</a>
Pregnancy Risk Assessment Monitoring System (PRAMS)	HHS (CDC/NCCDPHP)	Annual (1987)	Cross-sectional (state)	Women with recent live birth	Randomly sampled from birth certificates; 1300–1400 mothers from each participating state	Mixed mode (mail; phone if needed). Data used to monitor changes in maternal and child health indicators Link: <a href="http://www.cdc.gov/prams/">http://www.cdc.gov/prams/</a>
Infant Feeding Practices Survey (IFPS)	HHS (FDA/CFSAN) with several federal partners	Periodic IFPS I: 1992–1993 IFPS II: 2005–2007	Longitudinal (nationally distributed)	Pregnant women and their infants; sampled from a large national consumer opinion panel	Pregnant women followed up to 12 months postpartum. ~4000 pregnant women identified and ~2000 mothers completed IFPS II ECLS–Birth: 14,000 children born in 2001 ECLS–Kindergarten class 1998–1999 Kindergarten class through 8th grade ECLS–Kindergarten class 2010–2011: Following through grade 5 (in progress)	Brief phone interview and series of mail questionnaires on pre- and postnatal diet and health, infant feeding and health, child care, and WIC Link: <a href="http://www.cdc.gov/ifps/">http://www.cdc.gov/ifps/</a>
Early Childhood Longitudinal Study Program (ECLS)	DoEd (NCES)	3 cohorts	Longitudinal	Children from birth through age 8 years		Child development, school readiness, and early school experiences assessed; measured height and weight; food consumption questionnaire ascertained food consumption frequency (home and school) General Link: <a href="http://nces.ed.gov/ecls/">http://nces.ed.gov/ecls/</a> ECLS–K links: <a href="http://nces.ed.gov/ecls/kinderdataprocure.asp">http://nces.ed.gov/ecls/kinderdataprocure.asp</a> Codebook: <a href="http://sodapop.pop.psu.edu/codebooks/ecls/k5userpart1.pdf">http://sodapop.pop.psu.edu/codebooks/ecls/k5userpart1.pdf</a>

Current Population Survey (CPS) Food Security Supplement (FSS)	DOL (BLS) Conducted by the Census Bureau	Food Security Supplement (FSS) data collected since 1995	Cross-sectional (national)	Supplement to the monthly CPS FSS sample: ~44,000 households surveyed in 2008	FSS ascertains food security, food expenditures, and use of food and nutrition assistance programs	CPS-FSS is the source of USDA's annual reports on household food security and state-level statistics on food insecurity Link: <a href="http://www.ers.usda.gov/Data/foodsecurity/cps/">http://www.ers.usda.gov/Data/foodsecurity/cps/</a>
American Time Use Survey (ATUS)-Eating and Health (EH) Module of the CPS	DOL (BLS) conducts CPS Bureau of the Census administers CPS EH module sponsored by USDA/ERS and NIH/NCI	3 EH modules released (2006-2008)	Cross-sectional (national)	National sample of individuals in households	Individuals 15+ years sampled from CPS households	Data uses: relationships among time use patterns and eating patterns, nutrition, and obesity; food and nutrition assistance programs; grocery shopping and meal preparation Links: <a href="http://www.bls.gov/tus/ehdatafiles_2008.htm">http://www.bls.gov/tus/ehdatafiles_2008.htm</a> and <a href="http://www.bls.gov/tus/ehquestionnaire.pdf">http://www.bls.gov/tus/ehquestionnaire.pdf</a>
Food Safety Survey	HHS (FDA) and USDA (FSIS)	Periodic 2006 (1988)	Cross-sectional (national)	Individuals sampled from households with telephones in 50 states and DC	RDD sample of 2275 individuals ages 18+ years	Food handling, food allergies, food-borne illnesses, consumption of potentially unsafe foods Link: <a href="http://www.fda.gov/Food/ScienceResearch/ResearchAreas/ConsumerResearch/ucm080374.htm">http://www.fda.gov/Food/ScienceResearch/ResearchAreas/ConsumerResearch/ucm080374.htm</a>
Surveys of Nutrition Assistance Programs and Program Participants	USDA (FNS)	Biennial since 1992 (multiple studies)	Cross-sectional	Participants in WIC	Varies by survey	Breastfeeding, food consumption, infant feeding practices, program practices, WIC food package Link: <a href="http://www.fns.usda.gov/ora/menu/Published/WIC/WIC.htm">http://www.fns.usda.gov/ora/menu/Published/WIC/WIC.htm</a>
Special Supplemental Nutrition Program for Women Infants and Children (WIC) participants	USDA (FNS)	Child Care Food Program began in 1968; name changed in 1990	Day-care programs with CACFP	Children and adults receiving day-care services in CACFP	Children to age 18 years and adults	CACFP provides reimbursement to qualified caregivers for meals and supplements (snacks) served to participants Link: <a href="http://www.fns.usda.gov/cnd/care/default.htm">http://www.fns.usda.gov/cnd/care/default.htm</a>

**TABLE 64.2** Food supply measures and technical databases that support national nutrition monitoring

Database name	Department (agency)	Data release (year)	Description
<i>Food Supply and Food Environment Databases</i>			
Food Supply and Availability and Nutrient Availability (per capita) in the US	USDA (ERS)	Food availability tracked since 1909; tabulated through 2008 Loss-adjusted results available since 1970 Annual since 1910	Three distinct but related data series: Food supply per capita by commodity groupings; raw and loss-adjusted results; and nutrient availability per capita. The data serve as proxies for actual/individual consumption Link: <a href="http://www.ers.usda.gov/Data/FoodConsumption/">http://www.ers.usda.gov/Data/FoodConsumption/</a> Records data on domestic and imported fish and shellfish adjusted for exports; edible weight (lb) reported. 2009 Annual Report: Fisheries of the United States includes per capita consumption data Link: <a href="http://www.st.nmfs.noaa.gov/st1/fus/fus09/index.html">http://www.st.nmfs.noaa.gov/st1/fus/fus09/index.html</a> Provides a spatial overview of access to healthy foods in communities. Statistics on food environment indicators linked to food choices and diet quality such as store and restaurant proximity, food prices, food and nutrition assistance programs, and community characteristics Link: <a href="http://www.ers.usda.gov/foodatlas/">http://www.ers.usda.gov/foodatlas/</a>
Fisheries Disappearance Data	DOC (NMFS)		
Food Environment Atlas	USDA (ERS)	Released 2010	
<i>Food Composition</i>			
National Nutrient Database for Standard Reference (NNDSR)	USDA (ARS/NDL)	Release 22 (SR22) released 9/2009; data on 7538 food items and up to 143 nutrients and food components	NNDSR consists of several relational database files. Food composition values are the basis for FNDDS files and numerous other US food composition databases and tables. Data are updated regularly Link: <a href="http://www.ars.usda.gov/Services/docs.htm?docid=8964">http://www.ars.usda.gov/Services/docs.htm?docid=8964</a> Series of data files including nutrient values for foods and gram weights for typical food portions. The NNDSR files are used to process and report dietary interview data from NHANES/ WWEIA. The base nutrient values are from the NNDSR Link <a href="http://www.ars.usda.gov/Services/docs.htm?docid=12089">http://www.ars.usda.gov/Services/docs.htm?docid=12089</a> Contains ounce and cup equivalents data for foods included in the USDA food coding databases to allow linkages to dietary intake data and estimates of MyPyramid equivalents. MPED 2.0 includes the number of MyPyramid equivalents of each of the 32 major groups and subgroups that are present in 100g of foods in the FNDDS 2.0 and for all foods and food modifications reported eaten in WVEIA, NHANES 2003–2004 Links: <a href="http://www.ars.usda.gov/Services/docs.htm?docid=8498">http://www.ars.usda.gov/Services/docs.htm?docid=8498</a> and <a href="http://www.ars.usda.gov/Services/docs.htm?docid=17558">http://www.ars.usda.gov/Services/docs.htm?docid=17558</a> (Continued)
Food and Nutrient Database System for Dietary Studies (FNDDS)	USDA (ARS/FSRG)	FNDDS v.4.1 applied to NHANES 2007–2008 data	
MyPyramid Equivalents Database (MPED)	USDA (ARS/FSRG)	2008 MPED version 2 applied to NHANES 2003–2004 (2006 MPED version 1 applied to 1994–2002 USDA survey food codes)	

TABLE 64.2 (Continued)

Database name	Department (agency)	Data release (year)	Description
Total Diet Study	HHS (FDA)	Ongoing since 1961	Market basket study: ~280 foods are sampled from around the US, prepared for consumption, and chemically analyzed; levels of radioactive contaminants, pesticide residues, industrial chemicals, and toxic and nutrient elements are measured Link: <a href="http://www.fda.gov/Food/FoodSafety/FoodContaminantsAdulteration/TotalDietStudy/default.htm">http://www.fda.gov/Food/FoodSafety/FoodContaminantsAdulteration/TotalDietStudy/default.htm</a>
Food Label and Package Survey	HHS (FDA)	2006–2007 (periodic since 1976–1978)	Representative sample of 1227 processed, packaged food products (labels) from the retail food supply drawn from 2005 Nielsen database of US food stores. Data are combined with Nielsen sales data to estimate products with nutrition labeling, health claims, and food safety statements Link: <a href="http://www.fda.gov/Food/LabelingNutrition/ConsumerInformation/ucm122084.htm">http://www.fda.gov/Food/LabelingNutrition/ConsumerInformation/ucm122084.htm</a>
<i>Dietary Supplement Products</i>			
Dietary Supplements Ingredient Database (DSID)	USDA (ARS/NL)	Release 1 (2009)	Estimated levels of 18 vitamin and mineral ingredients derived from analytical data for 115 representative unspecified adult multivitamin and multimineral supplement (MVM) products Link: <a href="http://dietarysupplementdatabase.usda.nih.gov/">http://dietarysupplementdatabase.usda.nih.gov/</a>
Dietary Supplement Labels Database	HHS (NIH/NLM)	Data reflect 2005–2009 label information compiled for the Dietary Supplements On-Line Database (DSOL) ©2005–2009 by DeLima Associates)	Label ingredient information on more than 4000 brands of dietary supplements Link: <a href="http://dietarysupplements.nlm.nih.gov/dietary/">http://dietarysupplements.nlm.nih.gov/dietary/</a>
<i>Food Safety</i>			
FoodNet	HHS (CDC, FDA), USDA, and 10 Emerging Infections Program sites around the US participate	Website lists products by year	Principal foodborne disease component of CDC's Emerging Infections Program (EIP). FoodNet is a collaborative project of the CDC, ten EIP sites, USDA, and FDA. Annual reports, MIMWR articles, and tables produced Link: <a href="http://www.cdc.gov/foodnet/">http://www.cdc.gov/foodnet/</a>
OutbreakNet	HHS (CDC)	1998–2007 posted online	Most of the data consists of outbreaks reported to the National Outbreak Reporting System (NORS) by the state, local, territorial, or tribal health department that conducted the outbreak investigation Link: <a href="http://wwwwn.cdc.gov/foodborneoutbreaks/">http://wwwwn.cdc.gov/foodborneoutbreaks/</a>

ARS, Agricultural Research Service; CDC, Centers for Disease Control and Prevention; DOC, Department of Commerce; ERS, Economic Research Service; FDA, Food and Drug Administration; FSRG, Food Surveys Research Group; HHS, Department of Health and Human Services; MMWR, Morbidity and Mortality Weekly Report; NDL, National Data Laboratory; NIH, National Institutes of Health; NLM, National Library of Medicine; NMFS, National Marine Fisheries Service; USDA, US Department of Agriculture.

protein, carbohydrates, fats, vitamins, and minerals) in the US food supply. Other sources of annual US per capita food availability information include fish availability data reported by the National Marine Fisheries Service (since 1910), consisting of annual estimates of per capita consumption of fish and shellfish based on “disappearance” in the food distribution system.

### **Environmental Factors: Macro Level Information on the Distribution and Determinants of Food Choices and Diet Quality**

A number of environmental factors affect the distribution and availability of foods in the neighborhoods where people live. Persons living in lower-income communities may experience food deserts, or areas that lack access to affordable and healthy foods such as fresh fruits and vegetables or low-fat milk (Beaulac *et al.*, 2009). The National Household Food Acquisition and Purchase Survey (FoodAPS) is a new 2012 data collection funded by USDA’s Economic Research Service to assess households’ food acquisition and expenditures, and diet quality among low-income and higher-income households (Table 64.1). Data collection will include 7-day food diaries of foods purchased, home scanners of foods purchased from retailers, and interviews about shopping behaviors, household income, and participation in nutrition assistance programs.

Previous research on food expenditures and food shopping have relied on the Consumer Expenditure Survey (CES) and the availability of proprietary databases. Monthly and annual proprietary sales data purchased from A.C. Nielsen Company (since 1985) measure grocery-store sales of all scannable packaged food products (NRC, 2005). Nielsen supermarket scanner data (SCANTRACK) do not reflect fruits and vegetables or prepared foods from supermarkets, restaurants, or other food outlets. Another source of household purchase information is Nielsen’s Homescan Consumer Panel data. Consumers transmit data on scanned purchases, including fresh foods, weekly through a telephone line. A number of other proprietary databases include scanner data, food prices, and household purchases, but are limited in that they include only foods purchased at retail stores, and not foods purchased at restaurants (NRC, 2004, 2005). The FoodAPS is intended to address these limitations by collecting scanner data for foods purchased at retail stores and recording all foods

obtained and purchased from all sources, including school meals and restaurants.

### **Food Security**

Since 1995 a special yearly supplement to the Current Population Survey (CPS) conducted by the United States Census Bureau has been devoted to measuring the extent of food insecurity and hunger among people living in low-income households (Hamilton *et al.*, 1997). The 18-item food security measure has been included in NHANES, the CPS, and the School Nutrition Dietary Assessment (SNDA) studies. In 2005 a National Research Council panel recommended additional research to address measurement issues related to item nonresponse and food insecurity labels used to assess households and individuals (NRC, 2006; Nord and Hopwood, 2007).

### **Estimating Food and Nutrient Consumption of Individuals**

NHANES is the only nationally representative survey that collects dietary recall and dietary supplement intake information on children and adults. Dietary data collection was expanded in 2002 when the NHANES and USDA CSFII survey programs were integrated. Two dietary recalls are collected on all NHANES survey participants using in-person (Day 1) and telephone-interview (Day 2) modes (Murphy, 2003; Raper *et al.*, 2004). The USDA automated multiple-pass method (AMPM) and dietary interview system and USDA Survey Nutrient Databases used to collect and process NHANES dietary recall data were integrated into the 2002 NHANES (Dwyer *et al.*, 2003a,b; Moshfegh *et al.*, 2008). The NHANES diet and supplement intakes are related to health status in the same individuals, with emphasis on ethnic/racial determinants of health (Briefel, 2007).

Evaluations of USDA’s nutrition and food assistance programs are also routinely conducted and provide information on the dietary intakes and nutrition and health behaviors of program participants, often low-income and/or disadvantaged populations (Logan *et al.*, 2002; Fox *et al.*, 2004) (Table 64.1). A series of studies have been conducted to evaluate the nutrition and health effects of participating in WIC and to provide current participant and program characteristics of the WIC program. The SNDA first assessed the diets of American schoolchildren and the contribution of the National School Lunch

Program to overall nutrient intake in 1992. The third study in 2005 measured schoolchildren's heights and weights, usual nutrient intake, and mean food intake, and collected information on school food service operations, the quality of meals offered, and foods and beverages available in vending machines, school stores and à la carte lines. Data from the SNDA studies have been instrumental in addressing changes to school meal regulations to increase dietary quality and reduce excess calories in light of childhood obesity (Institute of Medicine, 2005).

In addition to the national survey programs, periodic assessments of food and nutrient consumption of specific subgroups of the population not adequately covered in national surveys have been conducted for military populations, American Indians, children, low-income populations, and pregnant and lactating women. FDA's Infant Feeding Practices Survey II assesses the diets of pregnant women and new mothers and their infant feeding practices (Table 64.1).

### **Food Intake and Nutrients from Foods and Dietary Supplements**

USDA/ARS, CDC/NCHS and many other groups report trends in mean and usual intakes of nutrients from foods, and total intakes from foods and dietary supplements (Dwyer *et al.*, 2003a,b; Murphy, 2003; Woteki, 2003; Briefel and Johnson, 2004; Bailey *et al.*, 2010). Results are used to examine the food and nutrient intakes of the non-breastfeeding general population and subgroups of the population as it relates to various socioeconomic factors (Logan *et al.*, 2002; Woteki, 2003). Improved statistical-analysis methodologies to estimate total usual food and nutrient intakes are readily accessible to NHANES data users, thus improving the quality and completeness of nutrient intake estimates (Carrquiry, 2003; Tooze *et al.*, 2006).

NHANES dietary results are also linked to other federal food and nutrition surveillance and reporting systems including the Food and Drug Administration's (FDA's) Total Diet Study, the Environmental Protection Agency's pesticides and environmental toxicants databases, and USDA's commodity databases (Table 64.2). Survey data linkages such as these illustrate the vital role that health and nutrition data play in health monitoring and surveillance. For example, national dietary data were used to estimate food exposure to pesticides and mercury (EPA, 1997; CDC, 2009).

### **Food Composition Databases Used to Estimate Nutrient Intakes from Foods**

Since 1892, USDA has operated the National Nutrient Database for Standard Reference (NNDsr) for the purpose of deriving representative nutrient values for more than 6000 foods and up to 80 components consumed in the United States (Table 64.2). Data are obtained from the food industry, from USDA-initiated analytical contracts, and from the scientific literature, and are updated to reflect changes in the food supply as well as changes in analytical methodology (Dwyer *et al.*, 2003c). These values are used as the core of most nutrient databases developed in the United States for special purposes, such as those employed in the commercially available dietary analysis programs. USDA produces the Food and Nutrient Database for Dietary Studies, which contains data for energy and 60 nutrients/components for each food item for analysis of NHANES – What We Eat in America. A system is in place at USDA to periodically update this database with the most current information available from the National Nutrient Database (NNDb) and to retroactively apply revised or new food composition data to earlier food composition databases for tracking nutrient consumption patterns (Anderson *et al.*, 2001; Ahuja *et al.*, 2006). USDA also releases special interest databases (e.g. fluoride and choline).

FDA's Total Diet Study provides annual food composition analysis based on the foods consumed most frequently in NHANES. Representative foods are collected from retail markets, prepared for consumption, and analyzed individually for nutrients and other food components at the Total Diet Laboratory to estimate consumption of selected nutrients (e.g. folate) and organic and elemental contaminants such as pesticide residues. The Food Label and Package Survey is conducted to monitor labeling practices of US food manufacturers. The survey also includes a surveillance program to identify levels of accuracy of selected nutrient declarations compared with values obtained from nutrient analyses of products.

### **Dietary Supplement Composition Databases (Label and Analytical)**

The National Institutes of Health Office of Dietary Supplements, USDA, and NCHS collaborate to support the development and maintenance of a dietary supplements food composition database (Dwyer *et al.*, 2003c). The Dietary Supplements Labels Database of the National

Library of Medicine is based on the Dietary Supplements On-Line Database ©2005–2009 by DeLima Associates. The database contains information on the ingredients of over 4000 products of dietary supplements sold in the United States; information in the database obtained from publicly available sources including product-specific labels and information from manufacturers' websites.

The USDA/ARS Nutrient Data Laboratory (NDL) worked with the HHS/NIH, Office of Dietary Supplements and other federal agencies to develop the Dietary Supplement Ingredient Databases (DSID) (see Chapter 73). DSID-1 provides information on analyzed levels of nutrients in adult multivitamin/minerals (MVMs). The DSID is intended primarily for research applications. Product data are grouped by nutrient levels rather than by product names. Statistical regression methods were used to estimate mean percent differences from label values and variability at specific nutrient levels for each of the eight vitamins and ten minerals analyzed. DSID data are appropriate for conducting population studies of nutrient intake, rather than for assessing individual products.

### **Assessing Nutrition and Diet Knowledge, Attitudes, and Behavior**

National and state surveys that measure knowledge, attitudes, and behavior about diet and nutrition and how these relate to health were added to the nutrition monitoring program in the early 1980s and have expanded in scope and number over time. Surveys have addressed specific topics such as shopping behaviors, weight-loss practices, diet and health knowledge, infant feeding practices, food handling practices, and progress toward achieving nutrition-related national health objectives.

### **Consumer Behaviors**

New surveys of consumer knowledge and behaviors conducted and/or funded by the USDA include the 2005–2010 Flexible Consumer Behavior Survey as an NHANES component and the FoodAPS (Table 64.1). The Flexible Consumer Behavior Survey collects information on household economics (e.g. income, nutrition program participation), the types of foods available at home, the frequency of eating away from home, and behaviors (e.g. food-label reading, grocery shopping practices). The FoodAPS study will collect information on consumers' shopping behaviors and eating away from home.

### **Adult Behaviors**

The NHANES collects information on adults' health and nutrition behaviors including dietary supplement use, weight-loss practices, physical activity, breastfeeding, and smoking. Accelerometers were introduced to measure physical activity in the 2003–2004 NHANES (Tudor-Locke *et al.*, 2010). The focus of the BRFSS, initiated in 1984 as a telephone survey of adults, is on personal health practices such as intake, physical activity, weight control practices, and health screening practices (Table 64.1). BRFSS data have been used by state health departments to plan, initiate, and guide health promotion and disease prevention programs, and to monitor their progress over time. BRFSS collects self-reported height and weight for estimates of overweight and obesity and includes optional modules on dietary habits that states can collect periodically. Topics include the consumption of fruits and vegetables and high fat and cholesterol foods, binge drinking, physical activity, and the use of supplements, particularly folic acid. In 2002, BRFSS data began to be used for prevalence estimates for metropolitan and micropolitan statistical areas, allowing CDC to make estimates for counties to assist local public health planners and program evaluators. In general, the focus of FDA's Health and Diet Survey is on people's awareness of relationships between diet and risk for chronic disease and on health-related knowledge and attitudes. The survey has studied consumer use of food labels, weight-loss practices, and the effectiveness of the National Cholesterol Education Program.

### **Youth Behaviors**

The NHANES collects information on children's breastfeeding, infant-feeding practices, dietary intake, supplement use, weight-loss practices, physical activity, and smoking (Woteki, 2003; Briefel, 2007). In addition to answering survey questions about physical activity levels, respondents wore physical activity monitors in NHANES in 2003–2006. These monitors improved physical activity measurement, which has relied in the past on self-report or parental reports for children. The Youth Risk Behavior Surveillance System (YRBSS) includes national school-based surveys of high-school students as well as state, territorial and local school-based surveys conducted by health and education agencies. Information is collected on students' health risk behaviors that include smoking, dietary intake, weight-loss practices, and physical activity. Every two years, CDC conducts a national survey to produce

data representative of students in grades 9–12 in the 50 states and the District of Columbia.

### Maternal and Infant Health

CDC's Pregnancy Risk Assessment Monitoring System is used by 29 states to monitor selected maternal attitudes, behaviors, and experiences related to adverse maternal and infant outcomes. The second Infant Feeding Practices Survey assessed the diets of pregnant and new mothers and tracked breastfeeding and other infant-feeding practices. Information on breastfeeding is collected in several other studies, including the NHANES, the National Survey of Family Growth (NSFG), the National Immunization Survey (NIS), and state surveillance systems, the Pregnancy Nutrition Surveillance System and the Pediatric Nutrition Surveillance System (Table 64.1).

### Food Safety

The FDA conducted a study to assess consumer food handling practices and awareness of microbiological hazards, and several studies to evaluate the Nutrition Facts Label features and usability by consumers (Table 64.1). The Food Safety Survey tracks consumers' knowledge, behaviors, and perceptions about food safety and consumption of potentially risky foods. FoodNet is a cooperative surveillance effort between CDC's Emerging Infections Program, FDA, and the Food Safety and Inspection Service, USDA, to monitor food-borne illness and to conduct epidemiologic research on illnesses attributable to food-borne pathogens (Table 64.2). FoodNet includes laboratory analysis and surveys of physicians and the population. Twelve-month cycles of the population survey are conducted to assess diarrheal disease and exposure.

### Assessing the Nutritional Status and Health of the US Population

Nutrition and related health data support a wide variety of policy, research, health and nutrition education, and health care utilization and evaluation activities. Population and records-based surveys conducted by the CDC are used to assess population trends and to assess the health and nutritional status of individuals and population groups (Table 64.1). In addition to providing national population reference data obtained using health interview and examination methods, NHANES results are used to monitor national prevalence rates of diseases and risk factors, and trends in nutritional and health status over time. NHANES follow-up studies have explored the relationships of nutri-

tion and health to risk of death and disability. The continuous NHANES, which began in 1999, has a continuous, annual sample design. The design includes oversampling of Hispanics, African-Americans, older adults, and low-income white persons. Beginning in 2011, Asians are oversampled to produce reliable estimates for this growing population subgroup and for comparisons of health status and risk factors between race/ethnicity groups.

The National Health Interview Survey provides information about self-reported height, weight, and health conditions annually and about special nutrition and health topics periodically, such as vitamin/mineral supplement usage, youth risk behavior, aging, food program participation, diet and nutrition knowledge, cancer, and disability and food preparation (Table 64.1). Other special supplements relate to tracking progress in meeting national health objectives. Large sample sizes enable data to be reported for the major racial/ethnic subgroups in the US population in addition to age group, gender, and income level.

The State and Local Area Integrated Telephone Survey (SLAITS) was developed to supplement national data with state and regional data. SLAITS uses a telephone methodology and draws its sample from the same frame as the NIS. Previous topics included a national study on early childhood health in 2007 (Blumberg *et al.*, 2009).

A number of surveillance systems, primarily conducted by CDC, also contribute nutrition-related health information (height, weight, hemoglobin, and hematocrit), particularly for low-income pregnant women, infants, and children who participate in publicly funded health, nutrition, and food-assistance programs in participating states (Table 64.1). The Pregnancy Nutrition Surveillance System monitored nutrition-related problems and behavioral risk factors associated with low birth weight in high-risk prenatal populations, primarily drawn from the WIC program. The Pediatric Nutrition Surveillance System monitored key indicators of nutritional status in low-income infants and children. Information on anemia, weight status, birth weight, breastfeeding, and TV/video watching are collected primarily on children in the WIC program.

The National Center for Health Statistics conducts a number of records surveys, including tracking deaths due to nutrition-related conditions (Table 64.1). The National Survey of Family Growth collects information on subjects relating to maternal and child health such as breastfeeding and prenatal care. The surveys and surveillance systems that continuously collect nutrition and health measure-

ments are important for monitoring trends over time, for tracking progress toward achieving national health objectives, and for generating reference distributions.

### **Data Availability**

NNMRRP data are available in several formats. Many survey datasets and technical databases are posted on federal agency websites. Additionally, detailed survey documentation, brief reports and data tabulations, statistical guidelines, data analysis tutorials and guidelines, and questionnaires are also available online. Data users can subscribe to agency listservs to receive updates pertaining to data releases, stakeholder meetings, and data users' conferences. Articles published in the peer-reviewed literature are often cited in PubMed and can be located using search terms that identify the data source(s) of interest. The websites for the major surveys and surveillance systems have been included as references in this publication. A catalogue of existing surveillance systems that provide data relevant to childhood obesity research was established in 2001 by a collaborative led by the Robert Wood Johnson Foundation with CDC, the National Institutes of Health, and USDA (National Collaborative on Childhood Obesity Research, 2011).

### **Statistical Analysis Tools for Researchers**

The internet postings for many survey programs include working papers on survey design and methodology, statistical guidelines and software recommendations for data analysis, and sample programs and tutorials to assist data users with data analysis planning, data file access, statistical analysis program data review and recoding, and more. A comprehensive web-based tutorial for NHANES surveys, including a separate dietary data analysis tutorial developed jointly by the National Cancer Institute (NCI), NCHS, and the USDA's, Agricultural Research Service, is available at CDC's website (<http://www.cdc.gov/nchs/tutorials/Nhanes/>). Additional information on dietary intake and physical activity measurement can be found on NCI's website (<http://riskfactor.cancer.gov/studies/nhanes/>).

### **Future Directions**

A focused, comprehensive, nutrition-monitoring program includes improving methodologies for the collection and interpretation of data, timely processing and release of data, expanding coverage of population subgroups, and

conducting research to address current nutrition and public health issues. In the early 1990s the US President's Science Advisor identified the need for human nutrition research "that is ultimately aimed at promoting health, preventing disease, and reducing health care costs" (Office of Science Technology and Policy, 1996). To meet the expanding needs of the monitoring program, current nutrition monitoring research is aimed at (1) improving data collection, including population coverage and the use of technology; (2) the assessment of nutritional status using anthropometric, dietary, and laboratory approaches and biomarkers of diet and nutritional status; (3) understanding the behavioral and economic aspects of diet and health; and (4) conducting food composition analysis. Future directions are summarized below.

### **Population Subgroup Coverage**

Many surveys of NNMRRP are designed to collect data on various subgroups of the population, such as low-income persons and minorities; however, data are still limited for select subgroups of the population such as the homeless and Native Americans. Special subnational studies are the most economical way to cover these and other minority groups. Research is also needed on appropriate methods (such as questionnaires, interviewing procedures, physical measures, and biological indicators) for subgroups at increased nutritional risk.

### **State and Local Monitoring**

In addition to expanded coverage of population subgroups, improved geographic coverage is needed to provide nutrition data at state and local levels. National surveys provide data representative of the United States and major geographic regions, but cannot also provide data representative of states, counties, and cities. The CDC surveillance systems provide data for participating states that are complementary to national data, but there is increasing interest in collecting state and local data to address local health and welfare concerns. In 2004, the New York City Department of Health and Mental Hygiene conducted the New York City HANES with technical assistance from CDC (New York City Department of Health and Mental Hygiene, n.d.). National methods were adapted for use in a smaller scale examination. About 2000 New Yorkers were sampled to receive a health examination to estimate the prevalence of overweight, diabetes, high blood pressure, and high serum cholesterol; and exposure to tobacco,

pesticides, and heavy metals; they were also interviewed to assess depression and risky behaviors. Statistics are accessible on the NYC HANES website.

### **Use of Technology**

Researchers have been investigating the use of alternative data collection methods to augment in-person and telephone interviews. For example, an automated self-administered 24-hour dietary recall (ASA24™), adapted from the AMPM method used to collect dietary recalls in NHANES, was developed by the National Cancer Institute and made available to researchers and clinicians for public use (Subar *et al.*, 2007, 2010). Surveys such as NHANES have incorporated the use of self-administered computerized instruments for sensitive topics and adolescents. Research efforts should focus on the identification and development of methods and the utilization of computer technology that will enhance the monitoring of the nutritional status of the US population and support the timely interpretation and release of information to users. Improvements in standardizing data collection and analysis techniques to estimate total nutrient intake and usual food consumption have led to the NHANES tutorials and publications to inform researchers about issues in measuring diet at the population level (Carriquiry, 2003; Toozé *et al.*, 2006) and the use of available databases, e.g. MyPyramid equivalents database (see Table 64.2).

State and local monitoring systems should also take advantage of new technology for electronic data transfer. BRFSS is exploring the possibility of using web-based data collection in future surveys that would take advantage of technology and access to the Intranet. However, accommodations will still be needed to assess at-risk groups with no telephone or Intranet access.

### **Biomarkers**

The development and applied use of biomarkers in surveys such as NHANES that collect biological samples (i.e. blood, urine, saliva, and hair) are an important research area for nutrition monitoring. Biomarkers are substances within individuals or tissue samples that can be related to exposure, susceptibility to disease, or health outcomes (NRC, 2008). Biochemical measures of long-term exposure or nutritional status are not subject to the same inaccuracies or bias as the reporting of long-term dietary intake, but the sensitivity and specificity of biomarkers need to be evaluated for their role in assessing exposure to foods and nutrients, and for identifying high-risk popula-

tion groups. For example, following the recommendations of an IOM panel on strategies to reduce sodium intake in the US, plans are underway to incorporate urinary sodium measures in future NHANES (Institute of Medicine, 2010a). Further research to develop better biological indicators of nutritional status and dietary intake as a means of studying nutrition and health is needed to maximize the usefulness of NNMRRP data for nutrition policy making. The ongoing evaluation of standards and laboratory methods is also important to interpret time trends (Yetley *et al.*, 2011).

### **Behavioral and Economic Aspects of Diet and Health**

Research to develop and standardize questionnaires for valid and reliable estimators of knowledge, attitudes, and behavior will aid in the development of public health strategies at federal, state, and local levels to improve dietary status, promote health, and prevent nutrition-related disease. Adding questions on dietary or health behaviors to surveys designed to link socioeconomic factors can augment information on diet and health relationships. For example, the American Time Use Survey draws its sample from the CPS: respondents complete a time diary and report their height and weight. A food and eating module includes information on time spent snacking, TV watching, food shopping, and preparing food.

### **Nutrition Monitoring in Other Countries**

Nutrition surveillance activities in developing and developed countries include the use of food balance sheets, household budget surveys, individual surveys of dietary intake, consumer expenditure surveys, and periodic assessments of the nutrition and health status of individuals in the population (World Health Organization, 2011b). Food balance sheets are commonly used for surveillance in developing countries since they are more available and less costly than other surveillance methods. In developed countries monitoring often includes nutritional status measures and biomonitoring of environmental chemicals and toxicants such as blood lead (Board on Environmental Studies and Toxicology, 2006). In addition to NHANES in the United States, biomedical samples have been included in nutrition and health surveys conducted in Australia, Canada, the United Kingdom, and New Zealand (Department of Health and Ageing, 2011). For example,

the United Kingdom has collected weighed food records for dietary intake estimates, and blood and urine specimens, blood pressure, and anthropometric measures for the assessment of nutritional and health status. In 2001, the UK Expenditure and Food Survey was initiated in order to improve estimates of food eaten away from home, and improved the method used for dietary exposure in the National Food Survey (Rimmer, 2001). School nutrition policies have also been studied using similar methods to those used in the SNDA studies in the United States (Nelson *et al.*, 2004).

Comparisons of data across countries have been facilitated by standardizing definitions of nutrition indicators and outcomes. Examples of worldwide monitoring of nutrition outcomes include the World Health Organization (WHO) body mass index database (WHO, 2011a), and the Food and Agriculture Organization (FAO) of the United Nations' assessment of food insecurity as a follow-up activity to the World Food Summit in 1996 (FAO, 2004).

Nutrition topics of international concern include micronutrient deficiencies (most notably iodine, vitamin A, folic acid, and iron), child growth and malnutrition, breastfeeding, and obesity and chronic disease prevention. The WHO provides technical and financial support to member states for developing, strengthening, and implementing their national nutrition plans of action (WHO, 2011a,b). Federal agencies in the US also provide technical consultation on nutrition survey data collection methodologies and interpretation of data to assist other countries' nutrition monitoring and surveillance efforts. For example, CDC provides support for preventing micronutrient deficiencies worldwide (CDC, 2011), and ARS/USDA has shared the dietary intake data collection method with Canada for use in the Community Health Survey. The NHANES staff have provided expert consultation on health and nutrition measures to health officials in New Zealand, Australia, Korea, Canada, and the European Union (CDC, 2009). These collaborations foster the standardization of data across countries and serve as an important avenue for the exchange of data and ideas internationally.

## Public Health Implications

The primary goal of the *Ten-Year Comprehensive Plan* put forth in the early 1990s – to establish a comprehensive nutrition monitoring and related research program by col-

lecting quality data that are continuous, coordinated, timely, and reliable, using comparable methods for data collection and reporting of results; conducting relevant research; and efficiently and effectively disseminating and exchanging information with data users – is still pertinent more than 20 years later. Given competing demands for limited national resources and resulting budget limitations, the goals for the NNMRRP will continue to be evaluated against other competing national needs at specific points in time. Efforts and resources are critical in order to continue progress and research to expand and strengthen the nutrition monitoring program in the United States in an efficient manner.

Nutrition monitoring data are needed to track progress in meeting the prevention agenda for the nation and addressing the obesity epidemic (Institute of Medicine, 2005). The nutrition monitoring program must be positioned to answer the major research and policy questions that are relevant in the 21st century: the relationship of diet and health habits (including physical activity) to the increasing prevalence of overweight and obesity; the chronic disease burden and disparities of health across racial–ethnic and socioeconomic groups; food security during an economic recession; consumer behavior; food safety especially for vulnerable groups (children, aging, and immune-compromised persons); nutrient–gene interactions; and biomarkers of nutrition and health status. The ability to meet the policy needs of the future will depend on research and the availability of reliable, current, national nutrition data.

## DIETARY STANDARDS AND GUIDELINES: SIMILARITIES AND DIFFERENCES AMONG COUNTRIES

JOHANNA T. DWYER, DSc, RD

*Tufts University, Boston, Massachusetts, and National Institutes of Health,  
Bethesda Massachusetts, USA*

### Summary

Nutrient reference values and dietary guidelines are two key dietary standards necessary for nutrition science and policy making. Nutrient reference values are dietary standards for nutrient requirements that all humans share, and that are usually quite similar from country to country. Dietary guidelines are evidence-based, country-specific recommendations for food patterns that promote healthy weights and good health while helping to prevent and reduce diet-related disease. They differ from country to country. Nutrient reference values should be and are gradually converging and being harmonized between countries. In contrast, dietary guidelines remain unique to each country because of differences in foodways, cuisines, customs, economics, and food production capacity. The reasons for the similarities and differences between these two standards across several countries are described, and likely future directions are suggested. The focus is on standards published in English that are used by governments of highly industrialized countries with Western eating patterns. Possible useful future directions for dietary reference values and dietary guidelines are summarized as the chapter concludes.

### Introduction

Dietary reference intake values and dietary guidelines are two dietary standards that are essential nutrition policy tools. Their characteristics and purposes are quite different between countries. Therefore, in this increasingly global nutrition world, scientists and policy makers need to understand what they are, how they vary, and their proper use. Clarifications of the various meanings of the requirement estimates used in Western countries and provided in

this chapter may be helpful in sorting out true differences between reference standards and expert groups, and differences arising simply as a result of semantics.

### Dietary Reference Intakes

#### **Definition**

Dietary nutrient reference intake values describe and quantify universal human requirements for essential nutrients. The reason for developing dietary reference values is

to provide uniform, evidence-based, quantitative data on human nutrient needs. This information can be used for many purposes, including diagnosis or assessment of individual intakes, and in the examination and interpretation of nutrition surveys to provide an assessment of probable nutrient intake adequacy of populations. The reference standards are also used for planning of individual diets, food labeling, formulating criteria for food programs, institutional feeding, and other nutritional interventions. When reference values are used appropriately, they help to harmonize nutrient-based dietary assessment and planning, both within and between countries.

### ***Nutrient Reference Values and Their Meanings***

Table 65.1 presents a summary of the terms used in various countries for their nutrient reference standards. The reference values for nutrients used have various names in different countries, but generally the terms refer to similar concepts and use a similar framework for establishing them. Table 65.2 compares the terminology used by expert groups in different Western countries. In the future it is hoped that nutrient intake values can be better harmonized to improve the objectivity and transparency of values of recommendations and to smoothe the consideration of differences among them (King and Garza, 2007).

### ***Similarities Across Countries***

Today, methods for ascertaining nutrient requirements are becoming more widely accepted and harmonized between countries, with the result that values are converging more than ever before. The data on which dietary standards are based are generally similar from one country to another. They include relevant human clinical and experimental data (such as depletion–repletion studies, dose–response studies, and balance studies), epidemiological studies, and relevant animal studies. The methods used in formulating dietary standards generally involve a review of the literature and recommendations by expert scientists on the nutrient in question.

Most groups setting recommendations now provide values for classical nutrient requirements and newer sections on dietary factors that are relevant to the reduction in risk of diet-related diseases. These chronic disease risk reduction values are challenging since the causes of the diseases are multifactorial, including but not limited to one or more dietary constituents. When experimental studies are possible for studying chronic diseases, they are

usually of short duration with high doses and surrogate markers from which lower intakes over many years and chronic disease endpoints are inferred. Risk reduction values are therefore not usually determined experimentally; rather, they are based largely on observational epidemiology, with all the difficulties residual confounding creates for establishing causal inference.

There is variability in nutrient requirements even among individuals who are similar in age, sex, and life stage, and therefore statistical concepts are essential in the derivation and interpretation of nutrient requirement estimates. The use of probability models and statistical techniques is vital in the formulation of human nutrition requirements since human nutrient needs all have a probability distribution that must be dealt with by a probability approach (Rand, 1990). For individuals, the values are stated in probabilistic terms since an individual's nutrient requirements are never known with certainty.

Virtually all of the groups setting nutrient reference standards now use similar statistical approaches for determining the midpoint of the distribution of requirements for a given function for each nutrient, and for deriving an estimate of the standard deviation of the requirements. The standard setting groups also use probability theory to state a level that ensures health for most individuals at some point above the mean requirement, such as 2 standard deviations. Although data are often lacking at present, a second set of distributions of risk of excessive intakes is used as the basis for establishing the tolerable upper intake levels (ULs) of nutrients.

Most groups setting nutrient requirements base them on criteria that reflect a meaningful biomarker of a nutrient-related function (Yates, 2007). This is critical since the choice of the indicator or function chosen will determine the amount of the nutrient that is needed. Desirable criteria exhibit a dose–response function, are responsive to inadequacy or excess of a single nutrient, resist rapid day-to-day changes in response to inadequate, adequate, or excessive intakes, are easily measurable or assessable with non-invasive methods, and are unresponsive to environmental changes other than nutrient intakes (King and Garza, 2007). Although functional criteria that reflect chronic disease endpoints are often the most relevant, the data for using them are often not available (Trumbo, 2008).

Methods for using nutrient reference values in dietary assessment and planning are also becoming increasingly popular and uniform. One such use is in developing

**TABLE 65.1** Glossary of terms used for describing nutrient reference values by various expert bodies

Term	Abbreviation	Description	Comments
Adequate intake	AI	Value estimated when an RDA or PRI cannot be established or determined	Term used by Institute of Medicine/Health Canada. EFSA defines the AI as the average observed daily level of intake by a population group that is assumed to be adequate
Acceptable macronutrient distribution range	AMDR		Term used by Institute of Medicine/Health Canada
Average nutrient requirement	ANR	Mean intake to meet the average physiological requirement	Term similar to Institute of Medicine/Health Canada EAR
Average requirement	AR		Term similar to Institute of Medicine/Health Canada EAR
Dietary reference intake	DRI		Term used by Institute of Medicine/Health Canada
Dietary reference value	DRV		Term used in UK
Estimated average requirement	EAR		Term used by Institute of Medicine/Health Canada
Estimated values		An experimentally supported value that provides appropriate information for adequate and safe intakes when human requirements for a nutrient cannot yet be determined with desirable accuracy	Used in the DACH countries in Europe
Guiding values		Aids for orientation if some regulation of intake is needed (e.g. a lower limit for intake of water, fluoride, dietary fiber, or an upper limit for fat, cholesterol, alcohol, and table salt) for health reasons	Used in the DACH countries in Europe
Individual nutrient level, x = percentile chosen	INL x		Term used by UNU/WHO/FAO
Lower reference nutrient intake	LRNL		Term used by UNU/WHO/FAO

**TABLE 65.1** (Continued)

Term	Abbreviation	Description	Comments
Lower threshold intake	LTL	Intake below which nearly all individuals in the population or group will be unable to maintain metabolic integrity according to the criterion chosen (e.g. the 2.55th percentile; mean -2 SD)	Term suggested by the Scientific Committee on Food of the EU and EFSA
Nutrient intake value	NIV		
Population reference intake level	PRL	Intake that will meet the needs of nearly all healthy people in the population or group (the 97.5th percentile)	Term used by the Scientific Committee on Food of the EU
Recommended dietary allowance	RDA		Term used by Institute of Medicine/Health Canada
Recommendation		Average requirement increased by 2 SD, or lacking a normal distribution of values, the average requirement increased by 20–30% (assuming a coefficient of variation of 10–15%)	Term used in the DACH countries in Europe
Recommended intake		Intake of a nutrient representing the average requirement for a defined group of individuals (similar to the EAR)	Used in Nordic recommendation
Reference intake range for macronutrients	RI	The intake range for macronutrients, expressed as intakes that are adequate for maintaining health and associated with a low risk of selected chronic diseases	EFSA and EU definition
Reference nutrient intake	RNL		
Upper tolerable nutrient intake level	UL	ESA refers to this as the level of chronic daily intake of a nutrient from all sources judged to be unlikely to pose a risk of adverse effects	
Upper nutrient level	UNL		

dietary guidelines, which will be discussed later in the chapter.

### **Differences**

In spite of the similarities noted above, there are still many differences between countries in the processes they use to

set recommendations and in their estimates of nutrient requirements.

Although nutrient requirements are defined the same by most expert groups, there are still inconsistencies in the conceptual frameworks they use, which may lead the unwary to assume that differences in expert reports are

**TABLE 65.2** Comparison of terminology used for describing dietary standard nutrient values by various groups

Terms used	UN University	USA/ Canada	UK	EU/EFSA	WHO/FAO	Australia/ NZ
Dietary reference intake	NIV	DRI	DRV			
Average requirement	ANR	EAR	EAR	AR		EAR
Recommended intake level for individuals	INL x	RDA	RNI	PRI	RNI	RDI
Lower reference nutrient intake			LRNI	LTI		
Safe intake		AI	Lower end of safe intake range	Lower end of safe intake range		AI
Upper level of safe intake	UNL	UL	Upper end of safe intake range	Upper end of safe intake range	UL	UL
Acceptable macronutrient distribution range		AMDR		RI minimum and maximum population ranges	Population mean intake goals	

AI, adequate intake; AMDR, acceptable macronutrient distribution range; ANR, average nutrient requirement; AR, average requirement; DRI, dietary reference intake; DRV, dietary reference value; EAR, estimated average requirement; INLx, individual nutrient level, x = percentile chosen; LRNI, lower reference nutrient intake; LTI, lower threshold intake; NIV, nutrient intake value; PRI, population reference intake; RDA, recommended dietary allowance; RDI, reference daily intake/recommended daily intake; RNI, reference nutrient intake; UL, tolerable upper intake level.

Modified with additions and adapted from King *et al.* (2007).

much greater than they actually are. The reasons for the differences in estimates of nutrient requirements include the relative emphasis given to different types of evidence (human epidemiological or experimental studies, and that from other species), and the functional criteria chosen; the literature available when the reviews were done also contributes to differences. Differences also exist as a result of variations in dietary composition (which affect nutrient absorption and bioavailability), in the anthropometric reference standards used (e.g. height, weight, body mass or growth rates of reference individuals), definitions of reference groups (by age, health status, occupation, income),

groups at risk (e.g. premature infants, the very old, smokers, etc.), and assumptions about the climate, altitude, and temperature. Reference values also vary according to the functional criteria chosen, underlying assumptions about nutrient bioavailability, and how values are extrapolated if evidence is unavailable for certain life-stage groups.

Countries also differ in the extent to which the standard setting process is reproducible and objective. In some countries systematic evidence-based reviews are used to support the development of their reference values in order to promote a transparent and rigorous process for reviewing the relevant data and that facilitates the update of reference

**FIG. 65.1** Relationship between dietary standards, dietary guidelines, and associated interventions and health.

values as new evidence becomes available (Russell, 2008). Systematic reviews lend transparency to the process of developing dietary reference values, and clarify the process (Thuraisingam *et al.*, 2009). However, they require some modifications for this purpose (Lichtenstein *et al.*, 2008; Russell *et al.*, 2009). Challenges in applying systematic reviews for the development of dietary reference intakes include defining and prioritizing the key research questions, the quality of studies, and finding biomarkers or intermediate (surrogate) outcomes that can be used when there is a dearth of studies directly linking nutrient intakes to clinical or functional outcomes. Nevertheless, using vitamin A as an example, the process was judged to promise a greater degree of transparency and objectivity in setting nutrient reference values than not using it (Russell *et al.*, 2009). The US Institute of Medicine/Health Canada efforts on vitamin D and calcium incorporated a systematic evidence-based review in the process of updating nutrient reference values (Chung *et al.*, 2009, 2010). An independent panel of technical experts helped informatics experts to prioritize and select key questions and outcomes of interest; methods for using existing systematic reviews were refined for determining requirement-related questions; and quality assessment tools and methods for translating results from studies not designed to address the issues of interest were developed and applied (Chung *et al.*, 2010).

Methods for using nutrient requirements for planning and assessing nutrient intakes vary from one expert group to another. Since there is considerable variability in the intakes of similar individuals under similar circumstances that must be taken into account in dietary assessment and in planning, these procedures also require the application of statistics to adjust food consumption surveys for usual intakes. These methods are briefly described in a recent paper (Murphy and Vorster, 2007) and more extensively in volumes devoted to dietary assessment and planning (Institute of Medicine, 2000, 2003) (Figure 65.1).

## Examples of Dietary Reference Intakes for Nutrients from Various Countries

### *Dietary Reference Intakes (DRIs) of the United States and Canada*

The DRIs used in the United States and Canada are described in detail elsewhere and briefly below (Murphy, 2005; Barr, 2006b; Institute of Medicine, 2008). The key DRIs are defined as follows.

#### **Estimated Average Requirement (EAR)**

The EAR is the amount of a nutrient that meets the requirement for a specific criterion of adequacy for half of the individuals in the population of a given age, sex, and life stage or physiological condition (such as pregnancy or

lactation). This is an average or median value since the amount of the nutrient needed to achieve adequacy varies from one individual to the next. Because nutrient requirements are usually distributed normally or can be transformed mathematically to achieve a normal distribution, this is a useful summary number. For most nutrients there are many different functional criteria that might be chosen for setting the requirement, and therefore it is important to justify the choice of a given criterion. Because the EAR is a mean requirement for a group, and because the variation around the mean is considerable, the EAR is not useful for estimating the nutrient adequacy of an individual's intake. At the EAR, half of the individuals in a group are below their requirement and half are above it. An individual whose usual intake is below the EAR has a risk of inadequacy between 50% and 100%. Dietary advice to the general public should attempt to promote distributions of intakes by individuals in which as many individuals as possible have usual intakes that are above the EAR and below the UL.

### **Recommended Dietary Allowance (RDA)**

The RDA is the average daily dietary intake level that meets the nutrient requirements of nearly all (e.g. 97–98%) healthy persons of a specific sex, age, and life stage. It is the nutrient intake goal for planning the diets of individuals. In order to calculate the RDA, it is assumed that the requirement distribution is normal, and that the amount of the nutrient needed to cover virtually everyone in the population (defined statistically as 2 standard deviations about the EAR) is calculated. When no standard deviation is available, the coefficient of variation is used. It is usually assumed to be 10% (1.2 times the EAR) or 15% (1.3 times the EAR) on the basis of existing nutrient data. If an individual has an intake that is less than the RDA but more than the EAR, his risk of inadequacy would be between 2–3 % and 50%. As intakes fall further below the RDA, the risk but not the certainty of inadequacy rises. The RDA is an appropriate target to aim for in planning diets of individuals. However, it is not appropriate for assessing the diet of an individual since there are many whose intakes are below the RDA who may still be getting enough of the nutrient to be above their nutrient requirement levels. Because the RDA exceeds the actual needs of all but about 2–3% of the population, it is also overly generous as a standard for evaluating group intakes and should not be used for that purpose. An online interactive tool to help individuals find recommended intakes

of nutrients and safe levels of nutrients is now available at [http://ods.od.nih.gov/health\\_information/dietary\\_reference\\_intakes.aspx](http://ods.od.nih.gov/health_information/dietary_reference_intakes.aspx).

### **Adequate Intake (AI)**

The EARs for some nutrients are not known for the particular functional criterion that is most relevant, and in this case it is not possible to apply statistical theory and derive an RDA. However, often there is enough information to make some quantitative recommendations about adequate and healthful nutrient intake levels. Under such circumstances an AI is set as a tentative goal or target for the nutrient intake of individuals until more information is available. Because knowledge is limited, it tends to be generous. The definitions vary somewhat, but it is often the average or median intake of a group of healthy people, all of whom are assumed to be meeting their nutrient needs. Therefore falling short of it does not signify deficiency since the AI is not a requirement. The most common use of AI is for young infants where it is based on the mean intakes of groups of healthy infants.

### **Acceptable Macronutrient Distribution Range (AMDR)**

The AMDR is a range of acceptable macronutrient distributions for individuals, usually presented as a proportion of total dietary intake. Ranges are provided for protein, fat (omega-3 and omega-6 fatty acids), and carbohydrates. The values are estimates that are thought to minimize the potential for chronic disease over the long term, and that at the same time permit essential nutrients and energy to be consumed at adequate levels. For dietary cholesterol, *trans* fatty acids, and saturated fatty acid levels as low as possible while consuming a nutritionally adequate diet are recommended. For added sugars, the recommendation is to limit them to no more than 25% of energy intake. However, such a limit is likely to be appropriate only for very active individuals. For most Americans who are much more sedentary, their energy needs are so low that, after following the dietary patterns recommended by the 2005 and 2010 Dietary Guidelines for Americans and meeting their other nutrient needs, the percent of calories from added sugars would have to be far lower than 25% to stay in energy balance. Also, the American Heart Association has urged stricter upper limits based on their reviews of the evidence associating dietary sugars and cardiovascular health, and suggested a limit of closer to 13% of calories from added sugars (Johnson *et al.*, 2009).

### Upper Intake Levels (UL)

A relatively recent innovation in dietary reference values for nutrients is the tolerable or safe upper intake level for a nutrient. Intakes far in excess of the RDA may also give rise to health problems. The UL is the highest level of chronic, usually daily, nutrient intakes that is likely to pose no risk of adverse effects on health to almost everyone in the population. As intake levels rise above the UL, adverse effects are increasingly likely. Usually the functional criterion used for setting the UL is that which is likely to harm health and for which sufficient data are available. Unfortunately, for many nutrients, so few data are available at present that ULs cannot be set. However, lack of a UL does not mean that the risk of adverse effects does not exist.

### Estimated Energy Requirement (EER)

Small excesses in energy intake can, over time, result in weight gain. Also enough is known about energy output to permit quite exact calculations of energy output and intakes. The EAR and RDA do not apply for energy. Instead, energy needs are stated as minimal average requirements for individuals. The EER is derived from equations derived from experimental data on the energy need of individuals of normal weight with a healthy body mass index of between 18.5 and 25 for adults of a given sex, age, height, weight, and physical activity level. A calculator is available based on these data for EER and for the estimated energy requirement for those who want to lose weight at <http://www.mypyramid.gov>.

### Total Energy Expenditure (TEE)

The TEE is an estimate of the total energy expenditure needed to maintain current body weight and activity levels.

### Water Intake

Standard values for water are also provided, based on what is known about nutrient needs for water.

### Reference Daily Intake or Recommended Daily Intake (RDI) and Daily Value (DV)

In addition to the dietary standards described above, in many countries additional standard values have been developed to facilitate various uses, such as food labeling. A few of these terms that are common in the United States and Canada are listed below. These terms are not DRIs but are related reference values. The RDI is the daily

dietary intake level of a nutrient which was considered at the time they were defined to suffice to meet the requirements of nearly all (97–98%) of healthy individuals in each life stage and sex group. It is used to determine the Daily Value (DV), which is displayed on food labels in the United States, Canada, and Australia. Although newer DRIs are now available, some of these DVs are based on older RDAs of the United States dating from 1968. There is debate about whether the RDA or the EAR should be used in food labeling, but at present the RDA seems to be the better alternative (Murphy *et al.*, 2006a). There is also much agitation about whether and what nutrition information should be placed on the front of food packages, and whether, if such information is made available, it influences consumer purchasing decisions (Wartella *et al.*, 2010).

### World Health Organization/Food and Agricultural Organization/United Nations University (WHO-FAO-UNU)

Dietary standards have been promulgated jointly by three United Nations organizations to provide energy and nutrient requirement values that can be used, with appropriate adjustments, in virtually all countries (Taylor *et al.*, 2005). Expert groups are convened to make recommendations on specific nutrient requirements and nutrient intakes. The quantitative estimates of nutrient requirements are usually published as individual monographs clustering similar nutrients together rather than in a single volume with all nutrients.

In 2007 the UN University proposed a uniform terminology and a generic framework for establishing recommended nutrient intake values, or NIVs (King and Garza, 2007; King *et al.*, 2007). These include the *average nutrient requirement* (ANR) that reflects the median requirement for a nutrient in a specific population. The *individual nutrient level* (INL) is the recommended level of nutrient intake for all healthy people in the population. It is set at a certain level above the mean requirement, such as 2 standard deviations above the mean requirements, thus covering the needs of 98% of the population and referred to as INL98. However, it could also be set at levels other than 2 standard deviations above the mean requirement if the decision was made to cover less than virtually the entire population's needs. Finally there is the *upper nutrient level* (UNL), which consists of the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects for almost all individuals in a specific life-stage group.

Micronutrients reviewed by WHO/FAO focus on those most likely to present problems in human nutrition. Over the years they have included calcium, ascorbic acid, vitamin D, vitamin B<sub>12</sub>, folate, iron, and the trace elements. In addressing requirements for vitamins A, iron, vitamin B<sub>12</sub> and folate, and for trace elements, the expert groups initially used the term *basal requirements* as those sufficient to maintain all demonstrable functions of the nutrient. *Normative requirements* were defined as higher levels sufficient to maintain tissue stores or adaptive capacities that were judged to be desirable. The newer UNU recommended terminology is now gradually being adopted instead.

In the WHO/FAO system, energy requirements are based on energy expenditure, except in children. Energy needs are presented as average needs (so that half of a homogeneous population would have higher and half lower requirements).

There is universal agreement that the first goal of population nutrient intake goals is to ensure that all inhabitants of a country have access to affordable and available food that meets their nutritional needs. In the past decade, a WHO study group developed population nutrient intake goals that it judged to be both consistent with the maintenance of health and to include a low prevalence of diet-related disease in the population. The recommendations were designed to decrease risk factors for non-communicable diseases stemming from diet and physical activity, and to increase awareness of the influence of these factors on health. Nutrient intake goals for populations vary from country to country depending on the food supply and many other factors, and so they are generally best stated as ranges. The range of population nutrient intake goals recommended by WHO/FAO and other authoritative bodies is presented in Table 65.3. Since these ranges were published, several additional expert groups have met to further refine them.

Requirements for protein and macronutrients are presented as near the top end of the normal distribution of intakes or needs: a level termed “safe level of intake”. Fats, oils and carbohydrates have also been reviewed. Nutrient requirements for essential fatty acids have been stated, but since there are also increased risks of chronic non-communicable diseases from fats, recommendations for ranges of population mean intakes that are thought to be consistent with good health have also been stated. The terms used are *estimated average requirement* (EAR), the *acceptable macronutrient distribution range* (AMDR) with

*lower* (L-AMDR) and *upper* (U-AMDR) levels of the acceptable macronutrient distribution range that correspond to upper and lower bounds of confidence intervals. Finally there is the *upper level* (UL). For fatty acids the UL was used only with *trans* fatty acids. The UL is used to describe instances where biochemical indicators were needed to confirm adverse effects, measurable with a probability of occurrence. The latest recommendations include type and amount of fat, total carbohydrate, complex carbohydrates and free sugars, protein, dietary fiber, salt, and fruits and vegetables (which are viewed as sources of bioactive constituents that are seen as beneficial) (World Health Organization, 2003a).

Among the other more recent WHO/FAO/UNU technical reports are monographs reporting expert consultations on human energy requirements (Report of the Joint FAO/WHO/UNU Expert Consultation, 2004); diet in the prevention of chronic diseases (World Health Organization, 2003b); vitamin and mineral requirements (Joint FAO/WHO Expert Consultation on Human Vitamin and Mineral Requirements, 2004); protein and amino acid requirements (Joint WHO/FAO/UNU Expert Consultation, 2007); scientific updates on fat and fatty acid requirements for adults (Elmadfa and Komsteiner, 2009) and children (Uuay and Dangour, 2009; Uuay *et al.*, 2009); criteria for applying estimates for fat in dietary guidelines (Smit, 2009); the health effects of *trans* fatty acids (Koletzko, 2008; Uuay *et al.*, 2009); and an interim summary of conclusions and dietary recommendations on total fat and fatty acids from a Joint FAO/WHO Expert Consultation on Fats and Fatty Acids in Human Nutrition and carbohydrates (Mann *et al.*, 2007; Nishida and Martinez Nocito, 2007). The UN University has also issued documents to assist in applying dietary reference values, including one on establishing upper levels of nutrient intakes (Joint FAO/WHO Technical Workshop on Nutrient Risk Assessment, 2006).

### United Kingdom

*Dietary reference values* (DRV) are terms used in the UK to refer to recommended intakes which are set for energy and 33 nutrients by the Committee on Medical Aspects of Food Policy (COMA) (Panel on Dietary Reference Values of the Committee on Medical Aspects of Food Policy, 1991, 2006). The DRVs are provided as four values, all for population groups, not for individuals. *Estimated average requirement* (EAR) is the level at which 50% of the population's requirements are met. It is the average

**TABLE 65.3** Selected recommended ranges of population nutrient intake goals as percent of calories unless otherwise stated from various authoritative bodies

Nutrient or dietary factor	WHO 2003 goals	EFSA 2010	USA/Canada 2002 (acceptable macronutrient distribution range)
Total fat	15–30%	20–35%	20–35%
Saturated fatty acids	<10%	As low as possible	As low as possible
Polyunsaturated fatty acids (PUFAs)	6–10%	Not stated	–
n-6 PUFAS	5–8%	4% linolenic and 0.5% $\alpha$ -linolenic	5–10% linoleic
n-3 PUFAs	1–2%	250 mg EPA+DHA	0.6–1.2%
<i>Trans</i> fatty acids	1%	As low as possible	As low as possible
Monounsaturated fatty acids (MUFAs)	By difference from others	Not stated	–
Total carbohydrate	55–75%	45–60%	45–65%
Free sugars (all mono- and disaccharides added to foods plus sugars naturally present in honey, syrups and fruit juices)	<10%	Not stated	<25%
Protein	10–15% of calories		10–35%
Cholesterol	<300 mg/day	Not stated	As low as possible
Sodium chloride (sodium)	<5 g/day (<2 g/day)	Not discussed	
Fruits and vegetables	>400 g/day	Not discussed	
Total dietary fiber	From foods	25 g	25–38 g (14 g/1000 kcal)
Non-starch polysaccharide (NSP)	From foods (fruits, vegetables, whole grains, etc)		
Sodium chloride (sodium) g/day	<5 (2)		

EFSA, European Food Safety Authority; WHO, World Health Organization. Reproduced with permission from Taylor (2005).

requirement for a particular nutrient or for energy. This is similar to the EAR value in the US/Canadian DRI. The *Reference nutrient intake* (RNI) is the amount of a nutrient that is sufficient for almost all individuals (97.5% of the population). The RNI is equivalent to the UK's previous

recommended daily amount (RDA) value. It is similar to the recommended dietary allowance (RDA) of the US/Canadian standards. RNIs have been set for adults and children over the age of 5 years for vitamins A, B<sub>1</sub> (thiamin), B<sub>2</sub> (riboflavin), B<sub>3</sub> (niacin), C, D, folate, calcium, iron,

phosphorus, magnesium, potassium, and zinc. The *lower reference nutrient intake* (LRNI) is the amount of a nutrient that is sufficient for only a few individuals (2.5% of the population's needs are met). Therefore most people need more than this. The *Safe Intake* is a range of intakes that is sufficient for almost all individuals' needs but not so high as to cause harmful effects. This level is given for nutrients for which there is insufficient information to set more precise levels. This value is somewhat like the AI in the DRIs. The DRVs in the United Kingdom also include a *High Intake* which is the upper level of intake for a nutrient above which there is no further benefit and effects may be harmful. This is similar to the UL in the DRI. DRVs for total fat, fatty acids, starch, sugars, and fiber (as non-starch polysaccharides, or NSP) have been set as a percentage of daily energy intake in addition to those for energy and some vitamins and minerals. Desirable intakes of total fat, saturated fats, sugars, and starches are expressed as a percentage of the EAR for energy. Energy estimates are based on resting energy expenditure during sleep or rest, plus the energy expended in physical activity. Separate energy requirements for pregnant and lactating mothers are also given in the report.

Other dietary standards exist in the UK for purposes other than defining requirements. The *Guideline Daily Amounts* (GDAs) are not DRVs, but the amounts of fat, saturated fat, and other nutrients as target values used in nutrient labels in the United Kingdom to help consumers make sense out of nutrient labeling and achieve nutrient goals for the population. The GDAs are set based on various dietary reference values used in the United Kingdom or other countries that use the term.

### European Union (EU)

**Early Efforts.** Until recently, many of the countries in the EU set their own dietary standards, making assessments of dietary adequacy and planning between countries confusing and difficult. The various European reference values for children and their similarities and differences have recently been discussed (Prentice *et al.*, 2004). In 1993, the Scientific Committee on Food of the EU defined three reference levels. The five Scandinavian countries (Denmark, Finland, Iceland, Norway, and Sweden) have published Nordic Nutrition Recommendations jointly for many years (Becker *et al.*, 2004). The DACH consortium of the German-speaking countries of Europe, Austria, Germany, and Switzerland jointly published its recommendations (German Nutrition Society, 2000). The DACH has now

expanded to include Hungary, Slovenia, and Czechoslovakia as well. In the DACH the term *recommendation* is used to refer to what the Institute of Medicine/Health Canada refer to as the RDI, and the *estimated value* for the AI in that system and *Guiding Values* correspond to the AMDR for macronutrients and alcohol. The RDA and EAR are used for fluoride, water, and dietary fiber.

**EURECCA.** Starting in 2006, nutrition scientists in the countries of the EU came together in a European Commission effort at better coordinating the setting and assessing of nutrient requirements in the Union (Pijls *et al.*, 2009). Harmonization had proven difficult because existing recommendations use different terminology and different age groups – particularly in childhood and adolescence, and there are differences in target values for assessing requirements for nutrients and in some cases local variations in dietary requirements (Pavlovic *et al.*, 2007). Although the concepts, definitions, and defined population groups were quite similar, differences between countries were evident in criteria for adequacy, assumptions made, and types of evidence used to establish micronutrient recommendations.

The differences between countries were summarized in a recent report from the EURECCA consortium (Doets *et al.*, 2008). For example, recommendations for vitamin D in 50-year-olds varied greatly; the median was 5 µg/day but the inter-quartile range was from 5 to 8 µg/day, with one country having no recommendations. For 70-year-olds, although the median was 10 µg/day, again the variability was great, ranging from 5 to 10 µg/day. Similarly for vitamin A, the median was 900 µg/day of retinol equivalents with an inter-quartile range of 700–1000 µg/day at both 50 and 70 years of age (Doets *et al.*, 2008). European experts also performed a systematic review of micronutrient intakes that showed that across Europe different methods were applied to estimate the adequacy of micronutrient intakes, leading to different prevalence estimates of micronutrient inadequacy (Tabacchi *et al.*, 2009). Few of the countries used the recommended average requirement cut-point method or the probability approach to estimating the prevalence of inadequacy. The resulting prevalence of folate inadequacy thus revealed about 25% of the adult females surveyed had inadequate intakes when judged against these various criteria, but, when compared against the estimated average requirement cut-point value of 320 µg/day, nearly 75% of the women would have inadequate intakes. Although

the work of harmonization in Europe is still in progress, these results on adequacy of folic acid levels in the various European countries illustrate the need for uniform methods for setting requirements and estimating adequacy. In their absence, comparisons across countries are impossible. The European Food Safety Authority (EFSA) is the body in the European Union that sets dietary reference values. It recently published recommendations for carbohydrates, dietary fiber, fats, and water, and it is now addressing vitamins and minerals (European Food Safety Authority, 2008, 2010a,b; EFSA Panel on Dietetic Products, 2010b,c). Some examples of 2010 EFSA recommendations were provided in Table 65.3 (EFSA Panel on Dietetic Products, 2010a,b,c).

### **Australia and New Zealand**

Australia and New Zealand jointly publish nutrient reference values which are derived in a manner similar to that used by the Institute of Medicine/Health Canada and the UK Ministry of Health (Australian National Health and Medical Research Council and New Zealand Ministry of Health, 2006). Because the populations and food ways (e.g. cultural, social, and economic practices relating to the production and consumption of food) are similar to those in English-speaking North America, their recommendations are particularly germane to users in these countries. An interesting feature of the Australia/New Zealand guidelines is the presentation of a summary of recommendations to reduce chronic disease risk based on these experts' reviews of the evidence. Suggested dietary targets are provided for vitamins A, C, E, folate, sodium, potassium, dietary fiber, and long-chain omega-3 fatty acids. Acceptable macronutrient distribution ranges are also provided that are designed to reduce chronic disease risk and ensure adequate micronutrient levels for protein, fat, linoleic acid,  $\alpha$ -linolenic acid, and carbohydrate

### **Other Countries**

Many countries in the developing world use WHO/FAO dietary standards or adopt the standards of nearby neighbors that have similar populations and circumstances. Affluent countries such as Japan, Korea, and Singapore have established their own values, based in part on data from their countries and in part on data from one or more of the countries discussed above. There are also efforts to harmonize values in regions such as Southeast Asia (Barba and Cabrera, 2008).

## **Dietary Guidelines**

### **Definition**

Dietary guidelines are evidence-based recommendations of foods and food patterns that will meet nutrient needs, promote healthy weight and good health, and assist in reducing risk of diet-related diseases. They are designed to assist policymakers and consumers within specific countries to implement this advice. They also form the basis for government nutrition initiatives and nutrition education and consumer outreach by industry and health professionals.

Dietary guidelines are needed because consumers think of eating in terms of food and dietary patterns, not of nutrients. Since people eat foods and not nutrients, recommendations about healthful levels of nutrients need to be translated into foods.

### **Nutrient Reference Values versus Dietary Guidelines**

Nutrient reference standards differ from dietary guidelines in several ways. Nutrient standards are based on requirement estimates for specific nutrients but there are no human requirements for specific foods. Requirement levels are often lower than levels specified in dietary guidelines, which describe desirable and culturally acceptable dietary practices, which are often different from requirements (Hegsted, 1975). In addition to recommendations that cover or exceed nutrient requirements, and recommendations for ranges of population mean intakes of macronutrients thought to be consistent with good health and prevention of chronic disease, dietary guidelines have also included recommendations for type and amount of protein, fat, carbohydrate, salt, dietary fiber, types of fruits and vegetables, dairy products, protein-rich foods, and grains. Epidemiological evidence is used to a much greater extent in setting dietary guidelines than in setting nutrient requirements. Also, while nutrient requirements are generally the same for virtually all human beings, dietary guidelines are culture specific. Finally, national authorities are in a better position to establish dietary guidelines for their populations than are international groups. Certainly some aspects of dietary guidelines that reflect universal nutrient needs are similar across countries (Smitasiri and Uauy, 2007). However, country-specific dietary guidelines are probably more feasible and practical because countries differ so much in environmental circumstances, including the types of foods that are available, their nutritional

content, and accessibility. In addition there are vast differences in food cultures, lifestyles, public health priorities, economics and challenges of a cultural, social, political, and communications nature between countries. Translating dietary and nutrient standards into food-based dietary guidelines is therefore primarily a local endeavor because food and food patterns are so deeply rooted in culture, and because social and cultural sensibilities are so important.

### **Development of Dietary Guidelines**

The WHO and FAO led a worldwide effort in the 1990s to transform quantitative recommendations for nutrient intakes into general advice about dietary choices at the country level through the development of food-based dietary guidelines (Taylor, 2005). Thanks to that effort, many countries have updated and refined their country-specific food-based dietary guidelines. The process of food-based dietary guidelines development uses a stepwise approach which is summarized in Box 65.1 and described elsewhere in greater detail (World Health Organization, 2003a; Ashwell *et al.*, 2008). Guidelines that work well generally are well integrated with other nutrition information and education tools. For example, they consider not only eating and energy inputs, but also energy output and physical activity. Model dietary patterns and nutrient profiles are easy for nutritionists to create, but they are not easy to meet with common foods. Successful dietary guidelines take into account the fact that changes in food composition and availability may be needed. Without such changes many people will find the guidelines too difficult to follow.

### **Similarities of Dietary Guidelines Among Countries**

Some characteristics of food-based dietary guidelines are common in most countries. These include maintenance of a healthy weight, promotion of consumption of a variety of foods, and increased consumption of fruits and vegetables. Most guidelines also encourage physical activity and lowering consumption of salt and sugar. In addition, depending on the country, some specify consumption of certain types of fats (monounsaturates and polyunsaturates) and discourage consumption of others (saturated/*trans* fats and cholesterol); specify types of carbohydrates (“complex” vs. total or “added” sugars), protein sources

### **BOX 65.1 Main steps in the process of developing dietary guidelines**

#### *Identify:*

- *Diet–health relationships* – Evidence on diet – health relationships is available from reviews that are carried out regularly by national and international agencies.
- *Country-specific diet-related problems* – Specific diet-related health patterns, disease and mortality rates should be reviewed to identify and prioritize nutrition problems of public health significance.
- *Nutrients of public-health importance* – Nutrient imbalances in the population (groups) should be identified by comparing habitual intake from dietary surveys with dietary reference values, and by using anthropometric and available biochemical indicators of nutritional status.
- *Foods relevant for food-based dietary guidelines (FBDG)* – Food groups that are sources of nutrients of public health importance and foods for which intakes explain differences between groups who do and do not achieve target nutrient recommendations should be identified from observed patterns of dietary intake. Intake of food groups with established relationships to health (e.g. fruit and vegetables) should also be estimated.
- *Food consumption patterns* – Food consumption patterns in the population that are consistent with achievement of recommended intakes of nutrients should be identified. In addition it is important to identify population characteristics for each pattern. Recommendations for FBDG should be made, taking into account specific needs of population groups.

(plant vs. animal origin), and grains (processed vs. whole grains), and give guidelines for water and alcohol consumption. Some also mention specific nutrients, or deal with specific problems such as inadequate intakes of iron, vitamin A, or iodine. Others mention food safety. Recommendations sometimes include statements to encourage positive behaviors that have an indirect effect on nutrition and health, such as considering meals as social occasions, enjoying food, emphasizing the role of family life and well-being, and stressing consumption of traditional or local foods (Taylor, 2005). However, only a few guidelines mention these latter recommendations.

### **Differences in Dietary Guidelines Among Countries**

The FAO has developed an excellent website that provides detailed information on dietary guidelines from the various countries in the world. It is accessible at: [http://www.fao.org/ag/agn/nutrition/education\\_guidelines\\_country\\_en.stm](http://www.fao.org/ag/agn/nutrition/education_guidelines_country_en.stm). Note that at the very time that dietary standards are increasingly being harmonized across countries, dietary guidelines are becoming more country-specific. The reasons for this relate to the more extensive use of population-based surveys of dietary intakes and health status within countries, permitting better recognition of specific nutritional problems. Also governments are increasingly aware that the cultural and economic context in which dietary recommendations are made is very country-specific.

### **Examples of Dietary Guidelines Dietary Guidelines for Americans**

The Dietary Guidelines for Americans are part of the core of federal dietary guidance and nutrition-related public health efforts in the United States (Dietary Guidelines Advisory Committee, 2005; Murphy, 2005; US Department of Health and Human Services and US Department of Agriculture, 2005; Dietary Guidelines Advisory Committee on the Dietary Guidelines for Americans, 2011). The policy document that incorporates them serves as a cornerstone upon which all Federal nutrition policy, education and food-assistance programs are based. In addition, all Federal dietary guidance for the public is required to be consistent with the evidence-based Dietary Guidelines so that the government speaks in a consistent and uniform manner. Consumer-focused outreach and educational materials based on the Dietary Guidelines are now widely available at <http://www.healthierus.gov/dietaryguidelines>.

The advisory committee for the 2010 version of the Dietary Guidelines for Americans used the USDA's new Nutrition Evidence Library for a systematic review process to review, synthesize, and analyze the latest science relevant to questions arising during guidelines development. The systematic reviews were used more extensively than was possible in earlier editions of the guidelines. The 2010 Dietary Guidelines Advisory Committee Report's overall theme was the challenge of the obesity epidemic in the United States, particularly that among children, since the prevalence of obesity has tripled in the past 30 years. It recommended four major priorities for action which are summarized below (Dietary Guidelines Advisory

Committee on the Dietary Guidelines for Americans, 2011):

1. Reduce overweight and obesity by reducing overall calorie intake and increasing physical activity.
2. Shift food intake patterns to a more plant-based diet that emphasizes vegetables, cooked dry beans and peas, fruits, whole grains, nuts, and seeds. In addition increase the intake of seafood and fat-free and low-fat milk and milk products while consuming only moderate amounts of lean meats, poultry, and eggs.
3. Significantly reduce intake of foods containing added sugars and solid fats because these dietary components contribute excess calories and few, if any, nutrients. Reduce sodium. Eat fewer refined grains, especially those in foods with added sugar, solid fat, and sodium.
4. Meet the 2008 Physical Activity Guidelines for Americans (Office of Disease Prevention and Health Promotion, 2008).

### **MyPyramid**

This is the latest version of an icon to educate consumers about diet and lifestyle that is consistent with the Dietary Guidelines for Americans. It replaces the previous food-group pyramid with a new icon that stresses physical activity, moderation, and the proper balance between food groups in the diet. Its development has been described (Britten *et al.*, 2006), and details of its construction have been outlined (Murphy, 2005). The pyramid contains six food groups, a variety of which are needed each day for health. The food groups are: vegetables, emphasizing dark green and orange vegetables, and dry beans and peas; fruits, emphasizing variety and de-emphasizing fruit juices; milk and milk-based products; meat and beans, emphasizing low-fat and lean meats such as fish as well as more beans, peas, nuts, and seeds; grains (of which at least half should be whole grains); and oils, with an emphasis on vegetable, nut, and fish sources. In addition, the top of the pyramid includes discretionary calories, including items such as candy, alcohol, and additional foods from any other group. The widths of the bands in the pyramid food group suggest proportionality and how much of the food group a person should choose. The narrowing of the food-group band from the bottom to the top represents moderation. The base of the pyramid where the band is wider stands for foods with little or no solid fats, added sugars or other caloric sweeteners, suggesting that these should be selected more often since they are the most

nutrient dense. The current pyramid has 12 sets of possible patterns based on energy needs, with the appropriate guide for each individual based on sex, age group, and physical activity level. The current pyramid version and many other tools are available in personalized versions at <http://www.MyPyramid.gov>.

### **DASH**

An alternative eating pattern suggested as appropriate in the Dietary Guidelines for Americans is the Dietary Approaches to Stop Hypertension (DASH) diet, which is reduced in sodium. This eating plan is also rich in fruits, vegetables, whole grains, and low-fat dairy foods, including meat, fish, poultry, nuts, and beans, and is limited in sugar-sweetened foods and beverages, red meat, and added fats. The DASH diet is based on clinical studies that show that it reduces both systolic and diastolic blood pressure (Appel *et al.*, 1997; Sacks *et al.*, 2001).

### **Disease-Specific Guidelines of Professional Associations in the USA**

In North America and elsewhere in the world over the past several decades, many different disease-oriented associations have published guidelines devoted to preventing or curing various chronic diseases. The disease-specific guidelines are similar in most respects to the recommendations embodied in MyPyramid (Krebs-Smith and Kris-Etherton, 2007). Although the guidelines have no direct influence on government programs, they may influence both individuals and the policies of professional associations. Usually a group of experts on the disease in question chosen by the convening group is gathered to review the literature and provide their expert opinion. The objectivity of the group varies, as does the thoroughness of the reviews, which can vary from extremely extensive to quite cursory. The more extensive reviews include systematic evidence-based literature reviews to help ensure that all relevant information is obtained and that all of the relevant data are presented. Consortia such as the Cochrane Collaborative, the Agency for Health Research and Quality of the US Department of Health and Human Services have websites which summarize recent reviews that may be useful. The degree of specificity of topics chosen also varies greatly. For example, the American Institute of Cancer Research (AICR)/World Cancer Research Foundation conducted extensive evidence-based systematic reviews on various cancer sites before promulgating its guidelines (World

Cancer Research Foundation and American Institute for Cancer Research, 2009). Other expert groups limit their work to reviews based on more cursory analysis of the literature and expert opinion (American Heart Association Nutrition Committee *et al.*, 2006; Gidding *et al.*, 2006, 2009; Kushi *et al.*, 2006; Johnson *et al.*, 2009). The disease guidelines are largely focused on reducing risks of a specific disease and contain specific recommendations that are thought to reduce risk of the specific disease in question. Among the other organizations producing such guidelines are the American Diabetes Association (American Diabetes Association, 2008, 2010), the American Cancer Society (Kushi *et al.*, 2006), and the American Heart Association (American Heart Association Nutrition Committee *et al.*, 2006; Gidding *et al.*, 2006, 2009; Johnson *et al.*, 2009). At present there are no data that show that adhering to these guidelines actually does reduce the risk of chronic degenerative diseases any more than would adherence to the more general guidelines

### **Canada's Food Guide**

Canada's Guidelines for Healthy Eating are clear, simple messages intended to promote healthy eating (Katamay *et al.*, 2007), which are summarized in Box 65.2. The Canadian food guide was extensively revised in 2007 and is an integral part of Canadian health policy (Bush *et al.*, 2007; Health Canada, 2007; Tarasuk, 2010). It employs six food groups: vegetables and fruit, grain products, milk (Barr, 2006b; Bush *et al.*, 2007) and alternatives, meat and alternatives, oils and fats, and beverages. It also includes advice on physical activity and specific advice for individuals of different ages (children, men and women over age 50 years) and stages (women of childbearing age).

Note that the North American guidelines from the United States and Canada are similar in their basic messages because the populations, cultures, and economic and environmental conditions are alike in the two countries. They both recommend a food-based approach to eating, and the same foods/constituents to eat and to avoid. The differences are largely in the style of their presentation, language (Canadian guidelines are published in both French and English), timing (Canada's last update was in 2007 while the USA's was in 2010), and graphics used to convey the gist of the recommendations (rainbow in the Canadian guidelines vs. the US pyramid). For determining food patterns, the modeling process and foods chosen differ somewhat between the US and Canadian guidelines but again the final result is basically similar. Neither coun-

### BOX 65.2 Canada's Guidelines for Healthy Eating

1. Enjoy a variety of foods.
2. Emphasize cereals, breads, other grain products, vegetables, and fruits.
3. Choose lower-fat dairy products, leaner meats and foods prepared with little or no fat.
4. Achieve and maintain a healthy body weight by enjoying regular physical activity and healthy eating.
5. Limit salt, alcohol, and caffeine.

Health Canada also endorses these specific messages about the Canadian diet:

- provide energy consistent with the maintenance of body weight within the recommended range;
- include essential nutrients in amounts specified in the recommended nutrient intakes (RNIs);
- include no more than 30% of energy as fat (33 g/1000 kcal or 39 g/5000 kJ) and no more than 10% as saturated fat (11 g/1000 kcal or 13 g/5000 kJ);
- provide 55% of energy as carbohydrate (138 g/1000 kcal or 165 g/5000 kJ) from a variety of sources;
- be reduced in sodium content;
- include no more than 5% of total energy as alcohol, or 2 drinks daily, whichever is less;
- contain no more caffeine than the equivalent of 4 cups of regular coffee per day;
- ensure that community water supplies containing less than 1 mg/L fluoride should be fluoridated to that level.

Data from Katamay *et al.* (2007).

try's planners appear to have modeled the effect of use of dietary supplements into guideline recommendations.

### World Health Organization/Food and Agricultural Organization Recommendations for Food-Based Dietary Guidelines

In the 1990s the WHO/FAO undertook a major project to help countries develop food-based dietary guidelines (FAO/WHO, 2006). The methods for developing country-specific guidelines were outlined, and workshops were held to facilitate the process. At the same time, generic dietary guidelines were issued that the international organizations asserted belonged in all countries. However, since the year 2000, the WHO/FAO efforts have led a large number of countries to develop their own set of dietary guidelines

(Food and Agriculture Organization of the United Nations, 2009). They differ most markedly because of the different problems the various countries face, the resources available to deal with them, and the affluence of the various country populations.

### United Kingdom

The food-based dietary guidelines developed by the UK's Food Standards Agency for all healthy individuals are summarized in Box 65.3 (Food Standards Agency, 2006). They reflect recommendations for nutrient intake that are based on advice from the UK's Committee on Medical Aspects of Food and Nutrition Policy (COMA) and the Scientific Advisory Committee on Nutrition (SACN). The Department of Health's 1991 report on Dietary Reference Values (DRVs) was used in devising the guidelines. The UK's national food guide was subjected to consumer testing before it was issued (Hunt, 2007; Hunt *et al.*, 2007). *The Balance of Good Health* is the UK's pictorial representation of the proportion that different food groups should make up in the diets of older children and adults in the UK.

### Australia/New Zealand

Box 65.4 shows the dietary guidelines for Australia and New Zealand. They were developed in 2003 in a process that included systematic reviews and grading of the evidence (Baghurst, 2003; Australian National Health and Medical Research Council and New Zealand Ministry of Health, 2006).

### European Union

In the year 2000, the EU issued a countrywide integrated non-communicable disease intervention strategy (World Health Organization, 2000). It included an emphasis on physical activity and a 12-point guide to eating patterns provided in Box 65.5. This was a beginning, but many European countries preferred to formulate their own dietary guidelines since food habits and food availability differed so much between countries (World Health Organization, 2003a; EFSA Panel on Dietetic Products, 2010a). The European Food Information Council (EUFIC) has compiled a comprehensive compendium of dietary guidelines and graphics for most of the European countries (European Food Information Council, 2009). The WHO's European office has provided a report on food-based dietary guidelines in Europe (World Health

### BOX 65.3 Food-based dietary guidelines for the United Kingdom issued by the Food Standards Agency

All healthy individuals should consume:

- Plenty of starchy foods such as rice, bread, pasta, and potatoes (choosing whole-grain varieties when possible).
- Plenty (at least 5 portions) of a variety of fruit and vegetables each day.
- Moderate amounts of protein-rich foods such as meat, fish, eggs, and alternatives such as nuts and pulses.
- Moderate amounts of milk and dairy, choosing reduced fat versions, or eating smaller amounts of full-fat versions, or eating them less often.
- Less saturated fat, salt, and sugar. A special report issued by the Scientific Advisory Committee on Nutrition in 2003 recommended no more than 6g salt daily.
- The UK guidelines recognize that, although most individuals should be able to get all the nutrients they need from following a healthy balanced diet, certain groups within the population may need to take dietary supplements, including the following:
  - Pregnant women and those women who may become pregnant should take 400 micrograms ( $\mu\text{g}$ ) of folic acid daily until the 12th week of pregnancy, and folate-rich foods such as green vegetables, brown rice, and fortified breakfast cereals.
  - Pregnant and breastfeeding women should also take a daily 10- $\mu\text{g}$  supplement of vitamin D.
  - Children under the age of 5 years who are not good eaters may need to take a supplement containing vitamins A, D, and C. Children who have a good appetite and eat a wide variety of foods, including fruit and vegetables, may not need them.
  - Individuals should consider taking a daily 10- $\mu\text{g}$  vitamin D supplement if they are of Asian origin, rarely get outdoors or are housebound, wear clothes that cover all the skin when outdoors, or eat no meat or oily fish.

Organization, 2003a). Recently the European Food Safety Authority (EFSA) issued a scientific opinion endorsing the development of food-based dietary guidelines in Europe (European Food Safety Authority, 2008, 2010b; EFSA Panel on Dietetic Products, 2010a).

### BOX 65.4 Dietary guidelines for Australia and New Zealand

Enjoy a wide variety of nutritious foods:

- Eat plenty of vegetables, legumes, and fruits.
- Eat plenty of cereals (including breads, rice, pasta, and noodles), preferably whole grain.
- Include lean meat, fish, poultry, and/or alternatives.
- Include milks, yoghurts, cheeses, and/or alternatives. Reduced-fat varieties should be chosen where possible.
- Drink plenty of water.

Take care to:

- Limit saturated fat and moderate total fat intake.
- Choose foods low in salt.
- Limit your alcohol intake if you choose to drink.
- Consume only moderate amounts of sugars and foods containing added sugars.

Prevent weight gain: be physically active and eat according to your energy needs.

- Care for your food: prepare and store it safely.
- Encourage and support breastfeeding.

## Future Directions

### *Dietary Reference Values*

#### **Reconcile Differences in Reference Values and Speed Harmonization Efforts**

Harmonization by the Institute of Medicine/Health Canada, WHO/FAO, EURECCA, the German-speaking countries of continental Europe, and Australia/New Zealand is gaining traction. Over the next decade it is to be hoped that even more consultation and collaboration will occur between these various bodies to avoid over-duplication. Ongoing efforts on harmonization include efforts of the United Nations University/WHO/FAO, EURECCA (European Recommendations Combined), fledgling efforts in Southeast Asia, the United States and Health Canada, the Nordic countries, and German-speaking countries in continental Europe.

#### **Refine and Improve Concepts Such as the UL, the AI, and Models for Non-Nutrient Bioactives**

The ULs are currently set on the basis of relatively scanty data, with functional criteria that are sometimes not clini-

**BOX 65.5 European Union Twelve-Point Guide to Eating Patterns (part of the European Union's countrywide integrated non-communicable disease intervention strategy)**

1. Eat a nutritious diet based on a variety of foods originating mainly from plants rather than animals.
2. Eat bread, grains, pasta, rice, or potatoes, several times a day.
3. Eat a variety of vegetables and fruits, preferably fresh and local, several times a day (at least 400 g/day).
4. Maintain body weight between the recommended limits (a BMI of 20–25) by taking moderate levels of physical activity, preferably daily.
5. Control fat intake (not more than 30% of daily energy) and replace most saturated fats with unsaturated vegetable oils or soft margarines.
6. Replace fatty meat and meat products with beans, legumes, lentils, fish, and poultry or lean meat.
7. Use milk and dairy products (kefir, sour milk, yoghurt, and cheese) that are low in both fat and salt.
8. Select foods that are low in sugar, and eat refined sugar sparingly, limiting the frequency of sugary drinks and sweets.
9. Choose a low-salt diet. Total salt intake should not be more than one teaspoon (6 g) per day, including the salt in bread and processed, cured and preserved foods. (Salt iodization should be universal where iodine deficiency is endemic.)
10. If alcohol is consumed, limit intake to no more than 2 drinks (each containing 10 g of alcohol) per day.
11. Prepare food in a safe and hygienic way. Steam, bake, boil or microwave to help reduce the amount of added fat.
12. Promote exclusive breastfeeding and the introduction of safe and adequate complementary foods from the age of about 6 months, but not before 4 months, while breastfeeding continues.

cally meaningful, and they are difficult to manipulate statistically. A model for nutrient risk assessment that would deal with ULs has been proposed by a joint WHO/FAO committee shows promise (Aggett, 2007). A conceptual framework for developing recommendations for non-

nutrient bioactive components in food such as polyphenolics is also needed.

**Refine Population Nutrient Intake Goal Use**

The quantitative intake goals for a population and those for individuals are not the same, because the target for the population depends on the distribution of intakes within the population. For example, if the goal is a mean population intake of 30% of calories from fat, individual goals must be much lower since some will surely not adhere to the targets completely and thus their intakes will exceed the mean population intake. This fact is widely misunderstood in formulating guidelines and targets, and needs to be addressed.

**Clarify the Influence on Nutrient Requirements of Diet and Host-Related Factors that Vary from Country to Country**

Habitual diets differ greatly from one country to another and affect the bioavailability of many micronutrients including calcium, magnesium, iron, zinc, protein, folate, vitamin A, and carotenoids. Host-related factors that may also vary from one country to the next and affect bioavailability and thus nutrient requirements are intestinal factors (e.g. secretion of hydrochloric acid, gastric acid, or intrinsic factor, other alterations in the permeability of the intestinal mucosa), and systemic factors (host, age, sex, ethnicity, genotype, and life stages such as pregnancy and lactation, as well as chronic and acute infections). These factors all may influence estimates of dietary requirements and may necessitate country-specific recommendations that take them into account (Gibson, 2007)

**Fill Data Gaps Needed to Refine Requirements**

Gaps in requirement data are quite large for some ages and life stages, especially for very young infants, weanlings, and the very old. Dose-response data also often do not exist for these and other age/sex/life-stage groups. When data are lacking, extrapolation and interpolation must be used, introducing further uncertainty. Although the needs for further research are usually mentioned in committee recommendations, once reports are issued, the research agenda tends to be neglected. When the time comes to update recommendations, the relevant research is then unavailable. Efforts now being made to synthesize research needs in a systematic way, and to call the attention of

researchers to them, should help to move the process forward in the future (Suitor and Meyers, 2007).

### **Adopt Meaningful Triggers for Revising and Updating Nutrient Reference Values**

Until recently, countries usually updated the dietary standards for all nutrients simultaneously. This was an expensive, time-consuming process which meant that only a few experts could be engaged to deal with each nutrient. Recently, selective updating has become popular. It is triggered by indicators that a substantial amount of new data exists that may affect requirements. Selective updating permits greater focus on nutrients of public-health significance at a given time. Focusing on only a few nutrients makes it possible to have more expertise on targeted nutrients on scientific advisory committees, and permits the preparation of systematic evidence-based reviews that would be too costly to do for many nutrients all at once.

### **Refine Procedures for Setting Dietary Reference Intakes**

The process currently used by the Institute of Medicine/Health Canada for setting DRIs relies heavily on funders asking critical questions which are then addressed by systematic evidence-based reviews of the literature. Systematic reviews are expensive and time consuming, and yet, to improve the quality of dietary reference values and guidelines, they must be funded by the public sector since the questions are not of interest to other sectors. The reviews are done by informatics experts who ensure the completeness of the search and who are assisted by content experts. The systematic reviews are then provided to an expert committee that reviews the data and other evidence, and sets the final values. Further refinements in the DRI process have been summarized (Institute of Medicine, 2008).

### **Find Functional Criteria Involving Chronic Disease**

There is great interest in using chronic-disease endpoints as functional criteria for setting requirements, but there are so many data gaps that it has not proven possible to do so for any micronutrients, including calcium (Trumbo, 2008). The AMDRs have been set using chronic-disease endpoints derived from epidemiological data, but they are not based on experimentally determined data, nor can they ever be. Thus the standards of evidence for setting the

AMDRs are far less than that used for estimating micronutrient needs.

### **Link Personalized Nutrition and Functional Criteria Using New Genetic Findings**

The idea of establishing nutrient requirements and dietary guidelines based on an individual's nutrient needs generated by profiling the different single nucleotide polymorphisms (SNPs) involved in nutrient metabolism has been proposed for minimizing DNA damage and to maximize genomic and ultimately human health. Also of interest is whether single nucleotide polymorphisms that create metabolic inefficiencies are distributed by race and ethnicity so that certain large populations are differentially affected. If so, it is possible that needs for certain nutrients and dietary reference intakes for specific population groups might be quite different. While it may be possible to know if this is the case in a decade or two, at present there is little consensus on the nutrient needs and chronic-disease-related implications of various SNPs. Also, the measures of DNA damage and methods for minimizing these using nutrients are not yet standardized or reliable enough to permit their use (Fenech, 2010).

### **Make Appropriate Applications in Dietary Assessment and Planning**

Over the past decade techniques for estimating usual intakes and using DRI for assessment and planning have become available (Barr, 2006a). They have been put to use in many studies of dietary adequacy in the United States, Canada, and elsewhere. Because the methods are relatively new, those who apply them need to be wary of pitfalls that can occur in assessing individuals and groups (Murphy, 2008; Murphy and Vorster, 2007; Murphy *et al.*, 2006b). It is important that editorial boards of scientific journals refine their publication standards to insist that appropriate statistical analytic methods be used for dietary assessment and planning. The quality of surveys used for assessing nutrient adequacy varies, and this may affect the results obtained (Garcia-Alvarez *et al.*, 2009). One problem is in determining whether the dietary reference value is flawed or if a true deficiency exists. For example, in the United States, most individuals are deficient in vitamin E according to intake data from the National Health and Nutrition Examination Survey, and yet no known adverse clinical or functional effect seems to have resulted. Such findings should trigger additional study of the reference standard to determine whether or not adjustments need to be made.

## **Dietary Guidelines**

### **Use Systematic Evidence-Based Reviews in Dietary Guideline Formulation**

Many of the questions that arise in formulating dietary guidelines require the daunting and time-consuming task of collecting and synthesizing a large body of literature if systematic reviews are to be used. Nevertheless, the evidence-based approach for establishing dietary guidelines proved useful in the United States in 2005 (Dietary Guidelines Advisory Committee, 2005; King and Dietary Guidelines Advisory Committee, 2007) and it has now been institutionalized in producing the Dietary Guidelines for Americans. However, much of the literature is not directed to the questions of greatest interest in formulating guidelines, and the quality of the evidence available is sometimes poor (Marantz *et al.*, 2008), signaling the need for more studies that directly approach the questions of importance to guideline formation.

### **Consider Topics to Include in Dietary Guidelines**

There is ongoing debate over how several topics should be dealt with in guidelines. Fortified foods are often not dealt with at all or only very briefly. Food-based dietary guidelines often fail to mention dietary supplements although in many countries nutrient-containing supplements contribute large amounts to the intakes of some nutrients among groups at certain life stages. Moreover, in modeling efforts to assess shortfalls in current diets, the contributions of nutrient-containing supplements are not usually included. Yet it is well known that in some cases, such as with vitamin B<sub>12</sub> among older adults, or folic acid in some women in the pre-conceptional period who are eating poor diets, intakes from food alone may not suffice to meet nutrient needs. These issues need to be recognized and dealt with. “Processed” and “organic” and “whole” foods are another controversial topic. They are viewed by some as less desirable than “unprocessed” foods, although the definitions and meanings of such terms are vague. These need to be defined, and clear rationales given, if available, for the statements made. In fact food processing has a positive role to play in improving food safety and decreasing waste (Frisch and Elmadfa, 2007). Also it is essential that the food production sector be engaged in aligning products available with the dietary guidelines (Roodenburg *et al.*, 2008). Other challenges are whether recommendations about “biotech” or genetically modified foods, foods from cloned animals such as cloned salmon, and nanotechnological applications in foods belong in dietary guide-

lines. Current evidence suggests that they do not pose health and safety concerns and that they are rather matters of individual preference. Alcohol is a problematic topic because it is both a food and a drug, and because its use is regarded as a moral issue by significant segments of the population in many countries. Also, some individuals simply are unable to tolerate even small amounts of alcohol without suffering adverse behavioral effects. Although alcohol produces health benefits in some individuals, such as increased HDL cholesterol levels that are clear from moderate consumption, others accrue health risks, such as increased risk of breast cancer. Thus guidance about alcohol needs to be carefully crafted by advisory committees.

### **Consider the Costs of Adhering to Dietary Guideline Patterns**

It is important that the dietary patterns recommended in dietary guidelines be economically realistic for the population they are directed to. Low-energy-density foods can be expensive (Cassady *et al.*, 2007; Monsivais and Drewnowski, 2007) and people with low BMI have more expensive diets (Schroder *et al.*, 2006). Feasibility testing of guidelines needs to take this into account, and food policy must be considered as well.

### **Strengthen Links between Guidelines and the Production, Agriculture, Health, and Education Sectors**

The feasibility of implementing guidelines in light of the country's existing commodities and food supplies must be taken into account, if for no other reason than to identify gaps and shortfalls and to make plans to remedy them (Duxbury and Welch, 1999). Unfortunately, most dietary guidelines are used primarily by the health sector, with little attention paid to food and agricultural sectors and in education, or in setting policies that cut across sectors (Albert, 2007).

### **Tailor Dietary Guidelines to Individuals**

How best to develop more personalized guidelines will continue to be an issue. Dietary guidelines may need to be adapted for individuals in special groups at risk such as pregnant women or the very old and frail. Other groups call for tailoring because of their unconventional eating habits, such as vegetarians (Jacobs *et al.*, 2009). Using modern communications technology, it is now possible for consumers and health professionals to tailor and then

download gender- and age-specific dietary guidelines from on-line web-based applications; such tools are available now in several countries (Stehle, 2007). In the United States one can create a personalized eating plan at <http://www.MyPyramid.gov>.

### **Integrate Dietary Guidelines with Other Community Efforts**

Dietary guidelines must fit into the broader context of activities devoted to nutrition. Dietary guidelines are only one of a number of nutrition information and education tools. Harmonization of the guidelines with nutrition labels and other aids is important to increase their effectiveness.

Some experts have called for greater attention to issues such as sustainability of food resources, and the “carbon footprint” of foods suggested in guidelines. These issues are increasingly important parts of government policies (Yeatman, 2008).

### **Communicate Dietary Guidelines Better**

One of the greatest challenges in dietary guidelines development is to ensure that messages motivate changes in behavior, which they often do not. Some messages, such as guidance to eat higher-nutrient-density, lower-caloric-density foods, are difficult to communicate, although they may be scientifically appropriate (Miller *et al.*, 2009). There is also the danger of over-medicalizing eating and implying that dietary changes can accomplish more than is realistic to expect (Fitzpatrick, 2006). The guidelines need to be communicated more widely both to consumers and to relevant policy makers (Albert, 2007). The assistance of professional communicators and dietitians can help to ensure that this is done (Brown, 2005).

### **Measure Adherence to Dietary Guidelines**

There are several indices of dietary quality to assess adherence to dietary guidelines or other recommendations, of which the best known is the Healthy Eating Index or HEI (Guenther *et al.*, 2007; Fransen and Ocke, 2008). Indices of dietary quality have been criticized because energy intake is often not taken into account, components are scored in an arbitrary manner, and it is not clear how or if they relate to health outcomes. Alternative measures are available but it is not clear that they perform better than the HEI itself (Fogli-Cawley *et al.*, 2006). The latest version of the Healthy Eating Index and scoring information can be accessed at <http://www.cnpp.usda.gov/>

[HealthyEatingIndex.htm](#). Unfortunately in spite of years of dietary guidance, the healthfulness of the US food supply has not increased dramatically (Krebs-Smith *et al.*, 2010).

### **Measure Guideline Effectiveness**

The effectiveness of dietary guidelines has been measured in a number of ways. In the United States, dietary guidelines have become one of the major policy tools for government and are used to assess the advisability of many government programs as well as serving as nutrition education tools for communicating to consumers. While it is to be hoped that consumers will follow the guidelines and improve their health, there is little evidence that this is happening. Several efforts have been made to evaluate whether those individuals with “guideline-like” diets in post-hoc modeling of cohorts in epidemiological studies fare better health-wise than those whose diets did not conform to them.

### **Develop Triggers for Guideline Revision**

In many countries such as the United States, dietary guidelines are revised on a regular basis every 5 or 10 years. There may be a need for the development of other criteria for revising guidelines. This has been done for the DRI, and perhaps it would be useful to do so for dietary guidelines as well.

## THE ROLE OF UNITED NATIONS AGENCIES IN ESTABLISHING INTERNATIONAL DIETARY STANDARDS\*

ROBERT WEISELL, PhD AND JANICE ALBERT, PhD

*Food and Agriculture Organization of the United Nations, Rome, Italy*

### Summary

Information about human nutrient requirements is essential for ensuring the adequacy of food supplies and preventing food/nutrient deficiencies. This information is also required for preventing excessive consumption of some nutrient substances. Food-based dietary guidelines are examples of national policies that make use of nutrient requirement dietary standards.

In this chapter, the work of the Food and Agriculture Organization and the World Health Organization related to nutrient requirements is explained. The recommended levels of intake for essential nutrients produced by these UN agencies take into consideration the diversity of situations in countries, and are used to promote actions to encourage healthy eating patterns. The work of the Codex Alimentarius Commission in providing guidelines for the presentation of specific nutrition information on the label of food products is discussed. Over time, there has been an evolution in the types and quality of data available as well as the efforts to strengthen the process of decision-making regarding scientific advice.

### Introduction

In its most pragmatic sense, knowledge of human nutrient requirements is essential for assessing whether food supplies are adequate to meet a population's nutritional needs.

The views expressed are those of the authors and do not necessarily reflect the views of the Food and Agriculture Organization of the United Nations.

\*Authors' note: This chapter is an update of Chapter 64 in the 9th edition publication. Thus, while there is new information included, some of the information given in the earlier edition remains accurate and important.

In turn, this information can contribute to the estimation of the numbers of persons globally, regionally or nationally who may be food/nutrient deficient or at nutritional risk. Such knowledge also underpins the ability to plan for food production to meet nutritional needs and for nutrition interventions such as food fortification. More recently, interest has expanded to include concerns about excess consumption of nutrient substances as well as dietary choices that may contribute to reducing the risk of some diseases. Food-based dietary guidelines and efforts to provide nutrition information on food labels are examples of national policies that are designed both to assist consumers in making better food choices and in turn to

support the implementation of nutrition-related health programs. These nutrition interventions are based on nutrient recommendations.

This chapter explains the United Nations' work related to nutrient requirements and some of their practical applications. Primary emphasis is given to the Food and Agriculture Organization (FAO) and the World Health Organization (WHO), although in some instances the collaborative work has extended to other UN organizations such as the United Nations University (UNU) and the International Agency for Atomic Energy (IAEA). The activities relate primarily to the normative work and complementary mandates of the FAO and WHO in their efforts to periodically quantify and, in turn, recommend levels of intake for essential nutrients which take into consideration the diversity of situations in countries, and to promote actions to encourage practical guidance for healthy eating patterns. In addition it highlights the work of the Joint FAO/WHO Food Standards Programme (commonly known as the Codex Alimentarius Commission<sup>1</sup>) in providing guidelines for the presentation of specific nutrition information on the labels of food products. Although the activities are listed as distinct and separate entities, it should be remembered that they actually form an interrelated mosaic of initiatives with continual and frequent overlapping.

Attention is drawn to the range of terms used to refer to various review processes, e.g. Expert Committee, Expert Consultation, Technical Workshop, and Scientific Update; each type of review has its own protocol and rules of procedures; these rules continually change. Together, these procedures lead to a variety of forums for carrying out the Organizations' work.

Experts from academia and research institutes have always been the central players and contributors to the reviews. In addition, the reports of national agencies have often been part of the background documentation of the meetings. At times the recommendations from these reports became in full or in part the UN reports' recommendations after careful consideration and debate. One

important development in recent reports and also in current work is the more systematic application of criteria to describe the strength of evidence and to draw conclusions from the scientific review of the totality of the evidence. Thus, over time, there have been improvements in the types and quality of data available as well as the efforts to strengthen the process of decision making in relation to scientific advice.

## Recommended Nutrient Intakes

Throughout history, human societies have observed relationships between the consumption of certain foods and the preservation of good health or the avoidance of disease. However, today's concept of nutrition that human health requires a steady intake of a variety of specific dietary substances in defined amounts is less than 200 years old. During the 20th century a number of countries established expert committees to provide scientific advice on topics related to nutrient requirements and other information important to consumers in order to address the public-health needs of their respective populations.

International efforts to address food and nutrition issues were a component of the work of the League of Nations during the 1930s (League of Nations, 1936), and the United Nations took up this task during its earliest days in 1948 when the Standing Advisory Committee to the newly formed FAO considered that "the problem of assessing the calorie and nutrient requirements of human beings, with the greatest possible degree of accuracy, is of basic importance to FAO" (FAO, 1950). Over time, scientific and technical recommendations about nutrient requirements have been made by expert groups established by the FAO and WHO. In 1949, when FAO and WHO began their collaborative efforts on nutrition, the FAO/WHO Expert Committee on Nutrition was formed to provide technical advice to the Director-Generals of the two organizations in all areas of nutrition on a regular basis (WHO, 1950). The outcomes of these discussions have been widely used internationally.

### **Energy and Protein**

Although a range of nutrition topics have been covered by expert groups convened by the FAO and WHO, macronutrients and in particular energy and protein have received the most attention over the years. This is because of the considerable concern about hunger and food insufficiency

<sup>1</sup>The Codex Alimentarius Commission and its committees deal with a wide range of food quality, food safety, and trade topics. The nutrition work described in this chapter relates primarily to food quality. In recent years, a transition has begun with a shift from trade-based standards to consumer-based standards and guidelines. (See Randell, 2010, and CAC, 2006.)

that predates the 1950s and continues through to the present. More recently, micronutrients and concerns for overnutrition (notably energy intake) have received increasing attention. In the past, no defined process existed for selecting a particular nutrient for investigation, and the decision had been based largely on the immediate concern at that particular moment.

Reports focusing solely on energy requirements, or “calorie needs,” the original term used, were issued in 1950, 1957, and 2004 (FAO, 1950, 1957a, 2004). Reports concerning protein requirements were made available in 1957, 1964/1965, and 2007 (FAO, 1957b, 1964; WHO, 1965, 2007). There have been several instances when FAO and WHO published the report of a joint meeting under their respective publication series and at times not in the same year. Such was the case for FAO (1964) and WHO (1965); FAO (1973) and WHO (1973a); FAO (2002) and WHO (2004b). Energy and protein intake recommendations were considered together in reports published in 1973 and 1985 (FAO, 1973; WHO, 1973a, 1985). Owing to a number of issues following the 1973 report, two “informal” gatherings of experts took place in 1975 and 1979 to discuss the issues that were emerging (FAO, 1975; WHO, 1979) and to prepare for the next expert consultation which occurred in 1981, and the report was issued in 1985.

Many of the considerations outlined by these first expert meetings are still pertinent today. They noted that requirements set by experts were intended for groups of persons rather than individuals, and they specified that an average requirement can never be compared directly with an individual requirement.

### **Energy**

In the 1981 meeting report (WHO, 1985), the experts corrected some of the information in the 1973 report (FAO, 1973; WHO, 1973a) and rejected the concept of a reference man or woman as too restrictive and not reflective of the wide range of both body size and patterns of physical activity. The use of a reference man or woman was replaced by actual body weights, which were increasingly available as well as the set of ideal body weights.

For energy a new methodology for calculating requirements was presented. It was based on total energy expenditure (TEE) values for various activities and lifestyles, representative body weights for various populations throughout the world, and a set of equations for calculat-

ing basal metabolic rate (BMR) values. The approach specified that estimates for energy requirements should be based, as much as possible, on estimates of TEE since the prevailing method of determination – from observed intakes of food energy – was and still is problematic and at the same time served to support a circular argument that access to food determined energy needs. The experts were, however, aware of the limited data on energy expenditures, particularly among children, and they acknowledged that no reliable and widely usable method was available to collect such data from the range of population groups worldwide. They encouraged immediate work to address this data gap. Moreover, in specifying the importance of the BMR in expressing energy requirements, they indicated that research was needed to obtain a database of BMR values, an activity that began immediately after the consultation (Schofield *et al.*, 1985).

By 2000, scientific understanding related to energy requirements and protein as well as amino acids had advanced to a stage that they required independent deliberations. To facilitate two expert meetings, one on energy and one on protein, a series of working groups were tasked with addressing key issues and presenting their results as background papers.

An expert consultation on energy requirements was convened in 2001, and its report (FAO, 2004) contains a considerable level of new information including requirements based on improved data for TEE, most notably for infants and the elderly. Among the most important new concepts and recommendations are the following.

- The calculations of energy requirements for all ages are based on measurements and estimates of total daily energy expenditure, and on the energy needs for growth, pregnancy, and lactation.
- The requirements and dietary energy recommendations for infants/children and adolescents have been modified in the light of new data and correct previous overestimations for the former group and underestimations for the latter.
- Starting as early as 6 years of age, proposals are made for differentiating the requirements for populations with lifestyles that involve different levels of habitual physical activity.
- Reassessment of energy requirements for adults based on energy-expenditure estimates expressed as multiples of basal metabolism.

- A classification of physical activity levels based on the degree of habitual activity was devised that is consistent with long-term good health, the reduced risk of diseases associated with sedentary lifestyles and the maintenance of a healthy body weight.
- The energy needs of pregnancy and lactation were based on newly developed factorial estimates.
- The total additional dietary energy needs during pregnancy should be distributed within the two last trimesters.

Following this consultation, a technical workshop was held to discuss the specific issue of “food energy” since recommendations for optimal energy requirements become practical only when they are related to foods that provide the energy to meet these requirements. The gains in understanding of the digestion and metabolism of food and the increasing sophistication of analytical techniques meant that the various options available to express the energy value of foods needed to be standardized and harmonized. The recommendations of this workshop were published in 2003 (FAO, 2003).

### **Carbohydrates**

Recommendations concerning carbohydrates in human nutrition were first issued in 1980 (FAO, 1980). A second expert meeting was held and a report issued in 1998 (FAO, 1998). The latter report continued the discussions begun in 1980, but also focused on the role of carbohydrates in the maintenance of health and in reducing the risk of chronic diseases. Further, it included a section on goals and guidelines for carbohydrate food choices.

Several key points from the 1998 report are listed in Table 66.1. The report specified terminology and classification nomenclature for carbohydrate components, and encouraged the production and consumption of root crops and pulses. Discussions focused not only on the maintenance of health and reduction of disease risk, but also on glycemic index, which was regarded as a potentially useful indicator of the impact of foods on the blood glucose response. Further, the report text indicates there is no evidence of a direct involvement of sucrose, other sugars and starch in the etiology of lifestyle-related diseases.

Following the 1997 Expert Consultation, discussions were initiated to determine the best approach to update

**TABLE 66.1** Highlights of the recommendations on carbohydrate from the 1997 Joint Expert Consultation FAO

Issue	Recommendation
Definition of carbohydrate	Carbohydrates are polyhydroxy aldehydes, ketones, alcohols, acids, their simple derivatives and their polymers having linkages of the acetal type. They may be classified according to their degree of polymerization and may be divided initially into three principal groups, namely sugars, oligosaccharides, and polysaccharides.
Role in maintenance of health	Optimum diet of at least 55% of total energy from a variety of carbohydrate sources for all ages except for children under the age of 2 years. Fat should not be specifically restricted below the age of 2 years. Optimum diet should be gradually introduced beginning at 2 years of age.
Role in disease risk reduction	The bulk of carbohydrate-containing foods consumed should be those rich in non-starch polysaccharides and with a low glycemic index. Appropriately processed cereals, vegetables, legumes, and fruits are particularly good food choices. Excess energy intake in any form will cause body fat accumulation, so that excess consumption of low-fat foods, while not as obesity-producing as excess consumption of high-fat products, will lead to obesity if energy expenditure is not increased. Excessive intakes of sugars which compromise micronutrient density should be avoided.

Adapted from FAO (1998).

the recommendations on carbohydrates. This was considered necessary given the developments and other relevant recommendations made during the intervening period, including those from the 2002 Joint WHO/FAO Expert Consultation on Diet, Nutrition and the Prevention of Chronic Diseases (WHO, 2003). As a result the FAO and WHO agreed to undertake a scientific update on some of the key issues related to carbohydrates in human nutrition. The issues identified included terminology and classification, measurement, physiology, carbohydrates and associated diseases such as obesity, diabetes mellitus, cardiovascular diseases, and cancer, as well as the roles of glycemic index and glycemic load (Nishida *et al.*, 2007).

The Scientific Update drew a number of conclusions, some of which endorsed those from the 1997 Expert Consultation. An improvement in the definition of dietary fiber was noted, and the experts recommended that it be based on well-established health benefits and the ability to fulfill regulatory requirements. The experts went further and proposed that dietary fiber be defined as intrinsic plant cell wall polysaccharides and thus the methods of analysis should be such as to accommodate this definition. The scientific update endorsed the recommendation of the 2002 Joint WHO/FAO Expert Consultation (WHO, 2003) concerning the restriction of beverages high in free sugars and the limitation of total intake of free sugars to reduce the risk of overweight and obesity; this recommendation was considerably more emphatic than that from the 1997 Expert Consultation (FAO, 1998). Whereas the 1997 Expert Consultation recommended the use of a particular food's low glycemic index as a guide to the quality of a carbohydrate-containing food, the Scientific Update urged caution in relying on it as a sole determinant. The scientific update closed with a call for research and discussion in a number of scientific areas which would hopefully lead to a subsequent expert consultation on carbohydrates.

### **Protein and Amino Acids**

The most recent meeting on protein requirements was held in 2002, and the subsequent report was issued in 2007 (WHO, 2007). Within that report, as was the case in its predecessor (WHO, 1985), the dietary requirements for protein and amino acids are based on an intake which balances all losses observed in a healthy, weight-stable subject. In using nitrogen equilibrium as the proxy measure of protein intake and losses, the minimum protein requirement (MPR) is determined as the intake resulting in zero

balance. The intake for nitrogen equilibrium was derived from a meta-analysis of nitrogen balance studies by linear regression for each individual studied (Rand *et al.*, 2003).

The 2007 report differs from previous reports in distinguishing between safe intakes for individuals and for populations. For an individual, as in previous reports, the safe individual intake is defined as the 97.5th percentile of the distribution of individual requirements, nominally the average + 1.96 SD. However, for a population, a safe intake (<2.5% risk of deficiency) must also account for the distribution of individual intakes as well as requirements, which is accomplished via an algorithm. In almost all circumstances the safe population intake is greater than the safe individual intake. The approximate deficiency prevalence is the proportion of the population with intakes below the mean requirement. A tolerable upper limit (TUL) is not identified although the report reviews the evidence of harm or toxicity from very high protein diets and concludes that, because intakes of three to four times the safe individual intakes are consumed without obvious harm, the TUL may be much higher than the value of twice the safe intake assumed in previous reports.

Table 66.2 summarizes all protein requirement values identified in the report, shown in terms of the method adopted and the components of the requirement values: i.e. the metabolic demand and efficiency of utilization used to calculate the average requirement; the requirement coefficient of variation (CV) and safe intake for individuals.

Although it adopted the nitrogen balance method, the 2007 report reviewed extensively its main limitations, noting both the difficulties of making the appropriate measurements with sufficient accuracy, and those associated with the interpretation of the results. Of primary concern was the fact that the shape of the observed balance response curve does not conform to the predicted balance responses of well-nourished adults fed varying intakes of high-quality protein. Some deviation from this theoretical curve might be expected, but few reported balance studies conform to the theoretical response in any way and the individual variation in balance studies is very large with individual requirement values ranging from 0.34 to 2.8 g/kg protein per day.

In addition, concerns about nitrogen balance extend to the possible overestimation of requirements through use of efficiency values for dietary protein utilization, which are too low in the factorial models adopted for children and pregnancy. While the overestimation of requirements

TABLE 66.2 Protein requirements for various population groups from the 2002 Joint Expert Consultation

Population group	Method	Demand g protein/kg/day	Efficiency	Mean requirement g/kg/day	CV %	Safe level g/kg/day
Infants (0–6 months)	Factorial: maintenance plus growth; maintenance from N-balance studies with milk and egg (0.58 g protein/kg/day): growth from TBK measurements of body composition.	0.385 + deposition	0.66: maintenance and growth	1.41–0.98	8–13%	1.77–1.14
Children (6 months–18 years)	Factorial: maintenance plus growth; adult maintenance value (0.66 g protein/kg/day), plus growth costs from TBK studies of protein gain adjusted with efficiency value (0.58), from N balance studies on children 6 months to 12 years.	0.30 + deposition	0.47: maintenance; 0.58: growth	1.12–0.66(f) 1.12–0.69(m)	8.9–12%	1.31–0.82(f) 1.31–0.85(m)
Adults, all ages, men and women	N-balance(meta-analysis): linear regression: $n=235$ individual multilevel studies; demand = median intercept; efficiency = median slope.	0.30 (–48.1 mg N/kg)	0.47	0.654	>12%	0.83
Pregnancy	Factorial: demand from increased maintenance costs associated with increased body weight (0.5, 3.2, 7.3 g/day), plus mean protein deposition estimated from TBK accretion in normal healthy pregnant women gaining 13.8 kg (0, 1.9, 7.4 g/day). Efficiency from N balance studies in primiparous teenagers.	g/day 0.5+0 3.2+1.9 7.3+7.4	0.42: deposition 0.42: deposition	g/day 0.5 7.7 24.9	12% 12% 12%	g/day 0.7 9.6 31.2
Lactation	Factorial: demand from mean milk protein output (total N less non-protein nitrogen), by well-nourished women exclusively breastfeeding (first 6 months postpartum) and partially breastfeeding (second 6 months). Efficiency from N balance studies in non-lactating adults.	0–6 months 6–12 months 4.69	0.47: milk protein production 0.47: milk protein production	14.3–16.2 10	12% 12%	17.9–20.2 12.5

Adapted from WHO (2007).

for infants and children is unlikely to result in harm, the report reviews evidence that excessive protein intakes in pregnancy can have adverse effects on pregnancy outcomes, and advises that any additional protein during pregnancy should consist of additional normal food rather than high-protein supplements.

The magnitude of *amino acid* requirements has been a major controversy since the 1985 report (WHO, 1985), especially that of lysine, the limiting amino acid in wheat and other cereals. The 1985 report defined amino acid requirement patterns from nitrogen balance studies, which had been extensively reviewed in the 1971 Expert Consultation (FAO, 1973; WHO, 1973a) and recommended that the protein quality of protein sources and diets be assessed in terms of digestibility and amino acid score, subsequently defined as the protein digestibility corrected amino acid score (PDCAAS) method (FAO, 1991). The 1985 report adopted an adult scoring pattern with very low levels of indispensable amino acids so that protein quality ceased to be an issue for adults apart from digestibility. A considerable body of new stable-isotope studies together with a re-evaluation of the older nitrogen balance studies was examined in the new report, enabling the development of a new amino acid scoring pattern for adult maintenance. The cogent feature of this new pattern is the considerably higher values of all indispensable amino acids (IAA). With the exception of histidine, the sulphur amino acids, and tryptophan, this resulted in all values being close to twice as high as the values in the 1985 report (WHO, 1985). Scoring patterns for all the age groups less than 18 years of age were devised from the adult maintenance pattern and the amino acid pattern of tissue protein.

### **Implications of the 2007 Recommendations**

As an initial reaction, the new lower protein requirements for infants and preschool children could relax the concern for this group including those in developing countries. However, because no long-term studies have been reported at these new requirement intakes, caution is advisable.

The impact of the 10% increase in protein requirements for adults is difficult to assess. A risk assessment study of protein deficiency described in the report (WHO, 2007) identified a significant problem of inadequate protein quantity and quality which is most serious for the typical diet of a developing country, but is also identified within some groups consuming vegetarian diets typical of developed countries, and even to a limited extent a typical omnivore diet. However, because of assumptions and

uncertainties in the risk assessment, the report is cautious in its consideration of risk management in terms of increasing supplies of animal protein as has been suggested (Young *et al.*, 1998). The main uncertainty relates to the adaptive metabolic demands model of the protein requirement within which protein intakes and requirements are correlated and thus would markedly reduce the risk of deficiency (Millward and Jackson, 2004). Given the considerable impact which the underlying assumptions about the protein requirement carry for policy formulation, the report calls for continuing research into processes and mechanisms which enable health to be achieved on protein intakes as habitually consumed.

### **Fats (and Oils) and Fatty Acids**

Nutritional needs for dietary fats, oils and fatty acids were addressed during meetings in 1977 (FAO, 1977), 1993 (FAO, 1994), and 2008 (FAO, 2010). All expert groups found it necessary to develop recommendations that take into consideration poorer populations whose diets may lack sufficient fat and more affluent populations that may experience health risks related to excessive consumption of fat.

The most recent consultation in 2008 was prompted by the recognition of the dramatic changes in diets and lifestyles occurring in the period since the 1994 report. These changes have been caused partly but not exclusively by enhanced industrialization, urbanization, economic development, and market globalization, particularly in the developing countries where major socioeconomic changes are occurring. Unhealthy dietary patterns and insufficient physical activity have also increased, resulting in greater prevalence of diet-related chronic diseases in all socioeconomic groups; these conditions now represent the main cause of global deaths and disability (WHO, 2011).

In addition there have been a number of major developments in this field, resulting in the need for an update. Primary among these developments is the large number of population-based cohort studies and randomized control trials conducted and addressing the impact of fats and specifically of different fatty acids on health. There is an enhanced knowledge of the role of particular fatty acids in determining health and nutritional well-being. More is known about how they are metabolized in the body, how they control gene transcription and expression, and how they interact with each other. In addition, fat and fatty acids are now recognized to be key nutrients that affect early growth and development as well as nutrition-related

chronic disease later in life. The health consequences of these nutrients go well beyond their role as fuels; specific n-3 and n-6 fatty acids are essential nutrients while others affect the prevalence and severity of cardiovascular disease, diabetes, cancer, and age-related functional decline. This makes the process of defining requirements and recommendations more complex, and thus there is a need to focus on the role of individual fatty acids and on how needs vary with age and physiological status.

With respect to the recommendations in the previous 1993 Consultation (FAO, 1994), the 2008 Consultation placed more emphasis on the role of certain fatty acid categories, an example being the convincing role of long-chain polyunsaturated fatty acids in neonatal and infant mental development as well as a beneficial role in the maintenance of long-term health and prevention of some chronic diseases. A high intake of saturated fatty acids and to an even greater extent *trans* fatty acids contributes substantially to adverse blood lipid changes and the development of the cardiovascular diseases that claim many lives in affluent societies and that are now also the main cause of adult death in developed and developing countries. The 2008 Consultation also recognized that the entities n-3 PUFA or n-6 PUFA include more than one fatty acid, each with its individual properties, and the umbrella term lacks precision, particularly in the area of food labeling. A summary of the Report's recommendations for adults is given in Table 66.3, and those for infants and children are summarized in Table 66.4.

### Trans Fatty Acids

A WHO Scientific Update on *trans* fatty acids (TFAs) (Nishida and Uauy, 2009) was conducted during in late October 2007, a year before the 2008 Expert Consultation on Fats and Fatty Acids in Human Nutrition. The conclusions of this scientific update contributed substantially to the deliberations of the 2008 Expert Consultation.

Earlier gatherings such as the 1993 Joint FAO/WHO Expert Consultation on Fats and Oils in Human Nutrition (FAO, 1994), the WHO Expert Consultation on Obesity: Preventing and Managing the Global Epidemic (WHO, 2000), and the Joint WHO/FAO Expert Consultation on Diet, Nutrition and the Prevention of Chronic Diseases (WHO, 2003) had expressed alarm concerning the growing evidence of harm from the consumption of *trans* fatty acids. It was decided that, by 2007, sufficient new data were available to conduct a review and update. The Scientific Update concluded as follows:

**TABLE 66.3** Recommended dietary intakes from the 2008 Joint Expert Consultation for total fat and fatty acid intake: adults

Fat/FA	Measure (Explanations of the abbreviations are listed below Table 66.4)	Numeric amount
Total fat	AMDR	20–35%E
	U-AMDR	35%E
	L-AMDR	15%E
SFA	U-AMDR	10%E
MUFA	AMDR	By difference <sup>a,b</sup>
Total PUFA	AMDR (LA + ALA + EPA + DHA)	6–11%E
	U-AMDR	11%E
	L-AMDR	6%E
	AI	2.5–3.5%E
n-6 PUFA	AMDR (LA)	2.5–9%E
	EAR	2%E (SD of 0.5%)
	AI	2–3%E
n-3 PUFA	AMDR (n-3 <sup>c</sup> )	0.5–2%E
	L-AMDR (ALA)	≥ 0.5%E
	AMDR (EPA + DHA)	0.250–2 <sup>d</sup> g/day
TFA	UL (total TFA from ruminant and industrially produced sources)	<1%E

<sup>a</sup>Total fat [%E] – SFA [%E] – PUFA [%E] – TFA [%E].

<sup>b</sup>Can be up to 15–20%E, according to total fat intake.

<sup>c</sup>(ALA + n-3 long-chain PUFA.)

<sup>d</sup>For secondary prevention of CHD.

Adapted from FAO (2010).

- The evidence on the effects of TFAs and disease outcomes strongly supports the need to remove partially hydrogenated vegetable oil (PHVO) from the human food supply.
- The evidence available from controlled trials and observational studies indicates that TFA consumption from PHVO adversely affects multiple cardiovascular risk factors and contributes significantly to increased risk of CHD events.
- Controlled studies and observational studies suggest that TFA may worsen insulin resistance, particularly among predisposed individuals with risk factors, e.g. pre-existing insulin resistance, visceral adiposity, or lower physical activity.
- Further studies are needed to confirm the apparent effects of TFA on weight gain and diabetes incidence in humans.

**TABLE 66.4** Recommended dietary intakes from the 2008 Joint Expert Consultation for total fat and fatty acid intake: infants (0–24 months) and children (2–18 years)

Fat/FA	Age group	Measure	Numeric amount
Total fat	0–6 months	AMDR	40–60%E
		AI	Based on composition % of total fat in HM
	6–24 months	AMDR	Gradual reduction, depending on physical activity, to 35%E <sup>a</sup>
SFA	2–18 years	AMDR	25–35%E
	2–18 years	U-AMDR	8%E Children from families with evidence of familial dyslipidemia (high LDL cholesterol) should receive lower SFA but not reduce total fat intake
MUFA	2–18 years	AMDR	Total fat [%E] – SFA [%E] – PUFA [%E] – TFA [%E]
Total PUFA	6–24 months	U-AMDR	<15%E
	2–18 years	U-AMDR	11%E
LA and ALA	0–24 months	Comment	Essential and indispensable
n-6 PUFA	0–6 months	AI	0.2–0.3%E
AA	0–6 months	AI	HM composition as %E of total fat
LA	6–12 months	AI	3.0–4.5%E
	6–12 months	U-AMDR	<10%E
	12–24 months	AI	3.0–4.5%E
	12–24 months	U-AMDR	<10%E
n-3 PUFA ALA	0–6 months	AI	0.2–0.3%E
	6–12 months	AI	0.4–0.6%E
	6–12 months	U-AMDR	<3%E
	12–24 months	AI	0.4–0.6%E
DHA	12–24 months	U-AMDR	<3%E
	0–6 months	AI	0.1–0.18%E
	0–6 months	U-AMDR	No upper value within the HM range up to 0.75%E
	0–6 months	Comment	Conditionally essential due to limited synthesis from ALA
EPA+DHA	6–12 months	AI	10–12 mg/kg
	12–24 months	AI	10–12 mg/kg
	0–24 months	Comment	Critical role in retinal and brain development
TFA	2–4 years	AI	100–150 mg (age adjusted for chronic disease prevention)
	4–6 years	AI	150–200 mg (bridged from an infant value of 10 mg/kg)
	6–10 years	AI	200–250 mg to the adult value assigned at age 10 years)
	2–18 years	UL	<1%E (total TFA – from ruminants and industrially produced sources)

<sup>a</sup>For infants 6–12 months, the proposed fat intake as a %E is lower than those recommended in the 1994 report. The primary reasons are the concern over increased obesity rates and the redefined growth standards based on human milk-fed infants, associated with leaner growth in later infancy (WHO MGRS, 2006).

%E, percent of energy; AI, adequate intake (expressed as a range); EAR, estimated average requirement; AMDR, acceptable macronutrient distribution range; L-AMDR, lower level of acceptable macronutrient distribution range; U-AMDR, upper level of acceptable macronutrient distribution range; UL, upper level; this term was developed for instances where biochemical indicators are needed to confirm any adverse effects, measurable with a probability of occurrence. In the case of FA this only applies to TFA.

L-AMDR and U-AMDR refer to the upper and lower range of the AMDR, very much similar to the use of UCI and LCI for the upper and lower bounds of confidence intervals.

Adapted from FAO (2010).

- Although TFAs from ruminant sources and industrial partially hydrogenated oils appear to be not dissimilar in their detrimental health effects, to date there is no conclusive evidence supporting an association of the former with coronary heart disease (CHD) risk due to the amounts usually consumed.
- TFAs produced by partial hydrogenation of fats and oils should be considered industrial food additives having no demonstrable health benefits and clear risks to human health. The result would be a substantial health gain for the population at large, with greatest health benefits obtained when replacement oils are rich in n-3 and n-6 polyunsaturated fatty acids (PUFA) and in monounsaturated fatty acids (MUFA).

Based on the above, the participating experts at the Scientific Update acknowledged the need to review the current recommendation that the mean population intake of TFAs, i.e. partially hydrogenated oils and fats, should be less than 1% of daily energy intake. There is sufficient epidemiological and experimental evidence to support revising this recommendation so that it encompasses the great majority of the population, and not just the population mean, to protect large subgroups from having high intakes. This could be accomplished (and has been in some countries and cities) by the virtual elimination of PHVO in the human food supply. The outcomes of this Scientific Update provide the evidence and scientific bases to promote discussions in the international scientific community involved in nutrition and health as well as agriculture and food production, and among relevant health professionals, national and international food regulatory agencies, civil society, and the private sector in order to achieve this goal.

### ***Vitamins and Minerals***

The human requirements for vitamins, minerals, and trace elements have been the subject of several FAO/WHO expert meetings. Calcium was reviewed in 1961 (FAO, 1962). Later, an expert meeting was held in 1965 on vitamin A, thiamin, riboflavin, and niacin (FAO, 1967) and was followed in 1969 by a meeting focused on ascorbic acid, vitamin D, vitamin B<sub>12</sub>, folic acid, and iron (FAO, 1970). Vitamin A, iron, folate, and vitamin B<sub>12</sub> were reviewed again in 1985 (FAO, 1988), the first two because they were major nutritional public health problems and the latter two because of their close association with anemia.

The WHO convened the first expert group on trace elements in 1973 (WHO, 1973b). By 1990, additional information regarding the role and importance of many trace elements had come to light, and a second expert consultation on trace elements was held under the auspices of the FAO and WHO as well as the International Atomic Energy Agency (IAEA) (WHO, 1996). This group attempted to ensure a reasonable degree of uniformity in the analysis and presentation of the many nutrients considered. A notable conclusion was that trace element requirements can change according to the type and amount of food consumed, interrelationships with other nutrients, and the nutritional status of the individual.

In 1998 a joint FAO/WHO expert consultation on human vitamin and mineral requirements was held (FAO, 2002; WHO, 2004b). This expert group met to deliberate on all vitamins and minerals in the human diet and to derive recommendations about levels of intake that were specified as recommended nutrient intakes or RNIs. These values were based on the available scientific evidence, although, as is often the case, difficulties in data interpretation resulted in some issues being left unresolved.

Further, the meeting report highlights the question as to whether changes in recommended intakes for vitamins and minerals are the result of better scientific knowledge and understanding of the biochemical role of the nutrients, or whether the criteria for setting the levels of the requirements have changed. The report also suggests that, while RNIs for vitamins and minerals were initially established on the understanding that they are meant to meet the basic nutritional needs of over 97% of the population, a fundamental criterion in industrialized countries has become the presumptive roles these nutrients may play in “prevention” against an increasing range of disease conditions that characterize these populations. The latter approach implies the notion of “optimal nutrition” relative to recommended intakes. Further, the report notes that questions have been raised as to whether some of the developments in approaches to establishing recommended intakes are applicable to developing country populations. and acknowledges that, from an international perspective, the RNIs for several if not many micronutrients such as folate, vitamin A, and selenium will need to be re-evaluated as soon as significant additional data become available.

The tables listing the RNIs for minerals and for water-fat-soluble vitamins issued as a result of this meeting, as well as estimated average requirements (EARs) for several

nutrients, can be found in the meeting reports (FAO, 2002; WHO, 2004b).

The FAO and WHO continue work to update the requirements for vitamins and minerals. In 2002, the FAO provided a report to the Codex Committee on Nutrition and Foods for Special Dietary Uses (CAC, 2003). This committee works under the mandate of the Codex Alimentarius, an international foods-standards-setting organization. The report responds to an earlier communication from the Commission of the Codex Alimentarius on behalf of the Committee, requesting that the FAO and WHO, under their mandate to provide scientific advice to Codex committees, work to include upper levels of intake for vitamins and minerals in their future efforts to develop recommended nutrient intakes. The FAO report specifies the intent to produce a general technical document outlining the principles to be adopted in addressing the topic of upper levels of intake and the safety of specific vitamins and minerals.

### **Upper Levels of Intake for Nutrients and Related Substances**

In 2004, the FAO and WHO responded to the request from Codex by announcing a joint effort to develop a framework for establishing upper levels of intake of nutrients and related substances (WHO, 2006). The workshop participants were asked to develop an internationally applicable approach (or “model”) intended to specify the scientific process of nutrient risk assessment. Such a model can be used in the future to identify upper levels of intake for nutrients and related substances. The workshop tasks did not include identifying such levels of intake, but rather focused on the important first step of establishing a scientifically sound approach for assessing the risk, if any, associated with nutrients and related substances. The workshop addressed the scientific decisions relating to the nutrient risk assessment process; nutrient risk management decisions and policy-setting activities were considered outside its scope.

### **Harmonization of Nutrient Intake Values**

The United Nations University’s Food and Nutrition Program, in collaboration with the FAO, WHO, and UNICEF, convened in December 2005 a group of international experts to review the harmonization of approaches for developing nutrient-based dietary standards. The group did not address the setting of numeric values for any nutrient but instead the development of a theoretical

framework for setting nutrient intake values. The report was published in the *Food and Nutrition Bulletin* (King and Garza, 2007). The recommended terminology coming from this meeting is summarized below.

- **Nutrient intake values (NIV)** is the umbrella term for the full set of recommendations. (*Analogous to DRI [US] or DRV [UK]*).
- **Average nutrient requirement (ANR)** is the average or median requirement estimated from a statistical distribution of requirements for a specific criterion and for a particular age- and sex-specific group. (*Analogous to EAR [US and UK]*).
- **Individual nutrient level (INL<sub>x</sub>)** is the recommended level for all healthy individuals in a specific population and will cover the needs of most (*x*) individuals where *x* refers to the percentile chosen for setting the INL, based on the CV of the requirements. (*Analogous to RDA [US] and RNI [UK]*).
- **Upper nutrient level (UNL)** is the highest level of habitual nutrient intake that is likely to pose no risk of adverse health effects in almost all individuals in the general population. (*Analogous to UL [US] upper end of safe intake range [UK]*).

## **Public Health Applications of Nutrient Recommendations**

FAO and WHO recommendations have always aimed to inform government authorities in their activities to improve public health. In this section, two public health endeavors that are commonly led by national authorities, dietary guidelines and nutrition labeling, are discussed. While this chapter focuses on these two strategies, it should be noted that there is extensive debate about innovative approaches to improve consumer information to enable consumers to select foods that will enable them to create healthier diets. Other forms of consumer information are emerging that may augment food-based dietary guidelines and nutrition labels.

### **Food-Based Dietary Guidelines**

Quantitative recommendations for the intake of nutrient substances provide the nutritional goals needed to ensure the health of populations. It is, however, difficult for consumers to apply this information when selecting foods and planning meals. There is a need to “transform” such quantitative recommendations into general advice about dietary choices.

While international recommendations on nutrient needs provide critical information for the development of dietary guidelines, an international set of such guidelines is neither feasible nor practical. The types of foods available differ among regions and countries, and foods vary in their nutritional content. The vast differences in food availability and accessibility coupled with differences in lifestyles, cultures, and public-health priorities mean that national authorities are in the best position to establish dietary guidelines suitable for their population and for their food supply. For this reason, international organizations such as the FAO and WHO have as their goal the support of national and regional efforts to develop food-based dietary guidelines (FBDGs). The discussion here focuses on guidelines targeted at the general public, but separate dietary guidelines are at times developed for segments of the population with specific nutritional needs such as infants and young children, as well as for persons with disease conditions such as autoimmune deficiency, hypertension, and diabetes.

In brief, the purpose of FBDGs is to assist the targeted population in implementing nutrition and related-health recommendations. Such guidelines present information using language and symbols that the public can easily understand. They usually focus on common foods, portion sizes, and behaviors. A complementary objective of developing FBDGs is to provide a tool for nutrition education to be used by health providers, teachers, journalists, extension agents, and others working directly with the public.

The FAO and WHO have promoted the concept of FBDG for nearly two decades. In 1992, the International Conference on Nutrition (ICN) was held. During this high-level intergovernmental meeting, 159 nations endorsed the “World Declaration and Plan of Action for Nutrition” which called upon governments to promote appropriate diets and healthy lifestyles (FAO/WHO, 1992). In 1995, the FAO and WHO sponsored an Expert Consultation on the Preparation and Use of Food-Based Dietary Guidelines in Cyprus (WHO, 1998) which reviewed experiences and elaborated a process for developing FBDG. Following the consultation, FAO and WHO promoted the development of FBDG through their regional offices and institutions and technical cooperation projects.

### **Main Features of FBDGs**

Although FBDGs from different countries often appear to be similar, they have usually been developed to meet the specific needs of a nation’s population and to suit the cultural, social, and economic contexts. The food graphics

associated with FBDG are highly promoted and may become important symbols in a nation’s nutrition communication and education strategy.

Existing FBDGs from countries throughout the world share certain commonalities. These are as follows:

- All promote consumption of a variety of foods.
- All promote maintenance of a healthy weight.
- All encourage increased consumption of fruits and vegetables.
- Most encourage lowering consumption of salt or sodium.
- Most encourage lowering consumption of sugar.
- Most encourage physical activity.
- Some specify types of fats and discourage consumption of saturated fats.
- Some specify carbohydrates and encourage consumption of whole-grain products.
- Some encourage increased consumption of water.
- Some mention specific nutrients.

In countries where deficiencies in iron, vitamin A, and/or iodine are common, the guidelines may address these nutritional problems. FBDGs in some countries contain recommendations that reflect societal values and may be intended to motivate positive behaviors that have an indirect impact on diets and health. For example, some FBDG encourage meals being regarded as social occasions. Some promote the consumption of local and/or traditional foods. Many FBDGs contain negative messages such as discouragement of smoking. It is common for FBDGs to encourage moderation in alcohol consumption. Some guidelines contain information about food preparation and food safety.

Whereas the importance of consuming a variety of foods is easily appreciated by nutritionists, the concept of variety is often misunderstood by consumers. Many countries have used an illustration as part of FBDG to convey the concept of variety. The graphics attempt to specify types of foods, proportions of foods, and portion sizes organized according to cultural perceptions of foods. Examples of FBDG graphics can be found on the FAO Food and Nutrition website, <http://www.fao.org/ag/humannutrition/nutritioneducation/49741/en/>

As appropriate, the graphics take different forms and usually have social significance for the population; for example, national symbols may be used. Although the text and graphics are designed to be used together, some FBDG graphics appear alone on packages and posters. Therefore, consumer testing should be carried out to ensure that the graphic is interpreted accurately.

### **Process for Developing FBDGs**

FBDGs are usually created through a comprehensive process that includes methods to ensure that the recommendations are understood and feasible for the average consumer and widely supported by the various government agencies, professional societies, and food-industry and consumer associations. The development of FBDG follows a series of steps, each of which requires different types of activities and expertise. The process of developing FBDGs may take several years and should include the following activities:

- Planning with multisectoral committee;
- Characterization of target group(s);
- Setting nutrition and health objectives;
- Preparing technical guidelines;
- Testing feasibility of recommendations;
- Preparing FBDG;
- Validation of recommendations and food graphic;
- Implementation;
- Evaluation.

### **Nutrition Labeling of Packaged Foods and Codex**

Nutrition labeling is intended to assist consumers to select food products according to their specific health needs and preferences. In terms of food policies, nutrition labeling is considered to be less restrictive than regulations that would require that a product have specific nutritional qualities. Through the market, nutrition labeling can motivate food producers to increase the availability of food products that possess the nutritional qualities that are desired by consumers. For instance, consumers who wish to avoid sodium, sugar, or saturated fats are provided with the information they need to select products; at the same time, products that are high in sodium, sugar, or saturated fats are available for consumers who desire them.

During the past 20 years, nutrition labeling has been evolving rapidly, with complex debates ongoing in a number of countries. After the United States implemented the Nutrition Labeling and Education Act of 1990, which required that the vast majority of packaged foods carry a nutrition fact label, a number of other countries (e.g. Canada, Australia, New Zealand, Brazil, Chile, Uruguay, and Malaysia) implemented similar policies requiring panels containing nutrient information on the side or back of packages (Hawkes, 2010). Other types of nutrition labels, which feature simple graphics and could appear on the front of the package, are under discussion in a number

of countries. In addition to information on food packages, there is consideration of the provision of nutrition information at the point of sale in retail food outlets.

Regardless of whether a label is voluntary or mandatory, governments seek to prevent nutrition labeling that could mislead consumers. Fraudulent labels are unfair to other producers, and undermine consumer confidence in food products. Governments and private organizations establish standard formats for labeling nutrients to ensure that consumers can read the labels and compare products.

The WHO Global Strategy on Diet, Physical Activity and Health provides an example of the linkages between scientific recommendations about nutrition and United Nations initiatives to stimulate governments and other societal actors to implement measures to improve public health. The WHO issued the World Health Report 2002: Reducing Risks, Promoting Healthy Life (WHO, 2002) which describes how, in most countries, a few major risk factors account for much of the morbidity and mortality. The report notes that unhealthy diets and physical inactivity are among the leading causes of three of the major non-communicable diseases (cardiovascular diseases, diabetes, and some cancers). In response to a request from member states through a resolution (WHA 55.23) of the World Health Assembly held in 2002, the WHO developed the Global Strategy on Diet, Physical Activity and Health. It was endorsed through Resolution 57.17 by the World Health Assembly in 2004 (WHO, 2004a).

The Strategy specifies recommendations for populations and individuals intended to (1) assist in reducing the risk factors for non-communicable diseases stemming from diet and physical activity; (2) increase awareness of the influences of diet and physical activity on health; (3) encourage development of appropriate policies; and (4) monitor scientific data and influences on diet and physical activity. In the WHO strategy, the Codex Alimentarius Commission (CAC) was identified as having a role to play in achieving the aims of reducing the risk of diet-related chronic diseases. Through work on food standards, there can be positive effects on the nutritional qualities of foods and consumers' abilities to make informed food choices. The FAO and WHO proposed specific actions that the CAC could take in support of the WHO Global Strategy, and improvements in nutrition labeling were among the proposals that were accepted.

The Codex Committee on Food Labelling (CCFL) and the Codex Committee on Nutrition and Foods for Special Dietary Uses (CCNFSDU) have been the main committees through which Codex is addressing nutrition- and

diet-related chronic diseases. After these committees have carried out their technical work, their recommendations will be deliberated by the CAC at large. Changes in the Codex standards could influence the nutritional qualities of foods worldwide.

At the 38th session of the CCFL in 2010, the Committee made proposals to amend the current Codex guidelines on nutrition labeling. The Committee decided that nutrient declarations that constitute the mandatory declaration – that is, declarations that should be present when a nutritional claim is made – should include saturated fat, total sugars, and sodium/salt, in addition to the energy value, amounts of protein, available carbohydrate, and fat that were required previously (CAC, 2010a). The Committee also established “Principles and Criteria for Legibility of Nutrition Labelling” (CAC, 2010a) that address issues of format, numerical presentation and design elements.

The current Codex guidelines for labeling indicate that vitamins and minerals may be listed when recommended intakes have been established and/or when they are of nutritional importance in the country concerned. It specifies that, when nutrient declarations occur, only those vitamins and minerals that are present in significant amounts should be listed (a footnote is included to indicate that, as a rule, 5% of the recommended intake constitutes a significant amount). Numerical information on vitamins and minerals is to be expressed in metric units and/or as a percentage of the Nutrient Reference Value (NRV). The existing NRVs are listed within the guidelines and include values for: protein, vitamin A, vitamin D, vitamin C, thiamin, riboflavin, niacin, vitamin B<sub>6</sub>, folic acid, vitamin B<sub>12</sub>, calcium, magnesium, iron, zinc, and iodine. However, the CCNFSDU is currently reviewing the guideline NRVs for the purposes of nutrition labeling of foods for the general population (CAC, 2010b).

## Future Directions

In the 21st century, the world is considerably different from when FAO and WHO were created just over 60 years ago. A number of countries, mainly in Africa and Asia, were not independent nations; the member states belonging to FAO and WHO numbered about 50 and most were from the developed world. The populations of each country still consumed what was considered a national diet. The volume and variety of food that was traded was less, and there was less dissemination of scientific information about nutrition.

The *modus operandi* within FAO and WHO was also different from today. In the area of scientific reviews and establishing standards, recommendations, and codes, the process was largely an internal process. The Director-Generals of each organization would confer with the member states, usually through the ministries of agriculture for the FAO and ministries of health for the WHO. Studies and meetings would then be initiated, very often consisting of outside experts who would advise the agency heads on a particular subject in their personal capacities. Whereas the reports of these studies were of interest to many outside the organizations, they aimed primarily to assist the organizations in carrying out their work. Further, the UN system was smaller and less complex as agencies such as UNICEF and the World Food Programme did not exist; today these agencies play important roles in relation to undernutrition.

Increasingly the nutrition community has become larger while the similarities among countries make the world seem smaller. The range of parties interested in the work of the FAO and WHO has expanded, and these parties seek to be included in that work. Originally the contact of the FAO and WHO with the world was only through its member states; now non-governmental organizations (NGOs), consumer advocates, and industry expect to be included, and some may be able to play large roles. There is an increased call for transparency in how the organizations function, including how they develop scientific recommendations. National regulations are being influenced by international standards and agreements. In this regard, the impact of FAO and WHO scientific recommendations on nutrition will no doubt become more far-reaching and significant.

## Acknowledgment

The authors would like to acknowledge the contribution from D.J. Millward to the section on Protein and Amino Acids.

## EMERGENCE OF DIET-RELATED CHRONIC DISEASES IN DEVELOPING COUNTRIES

BARRY M. POPKIN, PhD

*University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA*

### Summary

Over the past 20 years the way individuals eat, drink, and move has changed remarkably across the globe. Related to this has been an increase in energy imbalance and obesity throughout the world. The changes in diets, activity, and obesity have been linked with major increases in hypertension and diabetes (best documented) as well as other dimensions of cardiovascular disease and most cancers. Key points discussed in this chapter include the following.

- The underlying causes are shifts in use and availability of technology, major changes in the processing, distribution and marketing of food and drinks, and mass media changes.
- The technological changes that have affected movement and food are discussed. Prime examples relate to edible oils, added caloric sweeteners, access to supermarkets and their role in the entire vertical chain from production to consumer purchases. Later in the chapter examples of key changes are presented.
- The influence of multinational companies is discussed and shown to have evolved within a much more complex economic environment with many local clones and options.
- The biological mismatch between our preferences and the mechanisms related to hunger and thirst and satiation as contrasted with the vast shifts linked to modern technology in options for eating, drinking, and moving are discussed.
- Global dynamics of obesity are examined. The prevalence of overweight and obesity status are presented, as are other statistics related to age and social class burden.

Examples of the chronic disease burden estimates are presented, especially for well-measured examples.

### Introduction

In the past two decades there has been a remarkable global transformation in the way individuals eat, drink, and move. A consequence of this has been not only a marked increase in positive energy imbalance and weight gain but also a large shift in the nature of diets that is having pro-

found effects on the patterns of chronic diseases. This chapter will focus mainly on changes that have occurred in what we have often termed developing countries. This includes the very poorest, such as Haiti and sub-Saharan African countries, and also transitional economies that in many cases are emerging as global superpowers, such as Brazil, China, and India. We will exclude the former Soviet

Union, as it represents a unique case of countries with very poor diets and high levels of nutrition-related non-communicable diseases (NR-NCDs).

The transformation in how people eat, drink, and move has been going on for many millennia; however, the changes in the stages of the nutrition transition in the past 20 to 25 years in the developing world are unprecedented (Popkin, 2002, 2006a). Billions of people live in countries that have essentially conquered undernutrition and famine and have only pockets of malnutrition while experiencing major shifts toward positive energy balance. The dietary and activity pattern shifts associated with these changes have led to rapid increases in NR-NCDs, while at times they have also led to rapid inequality in access to new technologies and food-and-drink options. The complex phenomena of the double burden of malnutrition and obesity have arisen at the household and national levels in many countries, whereas other countries have shifted more rapidly toward minimal malnutrition.

This chapter explores all of these issues, discussing first the next social, technological, and economic forces underlying dietary shifts. It then examines some of the major issues that have led to a profound mismatch between biology and the technology that provides food and drink and reduces physical movement and exertion.

## **The Major Global Forces Underlying Dietary Shifts: Globalization of Economic, Demographic, Social, and Technological Forces**

Dietary shifts are not a case of McDonald's, Pepsi, and Walmart changing how the world eats and drinks. Rather, the major factors include: (a) the worldwide trade of technology innovations that affect energy expenditures during leisure, transportation, and work; (b) the globalization of modern food processing, marketing, and distribution techniques (most frequently linked with Westernization of the world's diet); (c) the vast expansion of the global mass media; and (d) other changes that constitute the rubric of impacts resulting from an increased opening up of the world economy (Popkin, 2006b). Globalization has certainly enhanced the interconnectedness of the world in terms of the trade in goods, technology, and services and the spread of the modern mass media. These changes began in the last half of the twentieth century and were accelerated by a push from higher-income countries for

more open markets for their goods, services, and technologies. During this period, international agencies (e.g. the International Monetary Fund (IMF) and the World Bank) and most higher-income countries promoted a "free trade" agenda as the panacea for the ills of the developing world. This chapter does not focus on the exact linkages among aspects of globalization and how each affects the increased trade in services, commodities, processed products, technology, and investments; rather, the focus is on understanding how technological and other shifts are linked to and affect diet, activity, and obesity throughout the world. It is impossible at this time, with the available databases, to fully link each aspect of globalization exactly to each one of these elements; we can, however, document many threads of change that clearly relate to their global shifts.

In the post-World War II period, urbanization and major demographic changes began to occur as societies, first in Asia, then in Latin America and the Middle East, and finally in sub-Saharan Africa, began the demographic transition toward increased child spacing, later ages at marriage, and ultimately reduced total fertility. At the same time, economic and social pressures began the inexorable shift in population to urban areas. These changes occurred very unevenly across the developing world and have been carefully documented by demographers, first by Kingsley and later by a great many other scholars (Davis, 1945).

An equally profound epidemiological transition accompanied these demographic changes in a complex weaving of shifts in fertility, morbidity, and mortality (Omran, 1971). Jointly these led to major shifts in population age distribution, and they were linked to a demographic set of changes unprecedented in human history.

Urbanization, linked to these changes but also equally linked to social, economic, and technological forces that created excess food in rural areas to feed urban populations, provided opportunities for improved education, and economic welfare moved rapidly across the developing world. These changes, which mirrored those in Europe one to two centuries earlier, occurred quite rapidly (United Nations, 2002). The underlying economic, technological, and social transformations that were complexly intertwined with these demographic shifts are critical for understanding how we eat, drink, and move.

### **Technology of Movement**

Since the 1980s the pervasive shifts in technological innovations related to all dimensions of movement and energy

expenditure at work in urban areas have become omnipresent, and similar shifts are rapidly reaching all rural areas. While several major shifts are occurring, including a global increase in the proportion of service-sector jobs and a reduction in the effort required by each job, it is the change of energy expended in each occupation that appears to be most important (Popkin, 2008b). We have also documented important shifts in home technology and the resulting reduced energy expenditures, and the same is true for leisure movement.

### **Food Systems**

Some might call this the McDonaldization or Coca-colonization of the world; however, this is the trivial tip of the iceberg of changes and is not as important as many would argue. Far before Walmart or Coke or Kentucky Fried Chicken appeared in the developing world in any meaningful way, a number of diet-related revolutions were occurring. They included the following.

#### **The Edible Oils Story**

The edible vegetable oils story is particularly important, as its effects have been quite profound. Until the decade following World War II, the majority of fats available for human consumption were animal fats, milk, butter, and meat. Subsequently, a revolution in the production and processing of oilseed-based fats occurred. The principal vegetable oils include soybean, sunflower, rapeseed, palm, and peanut. Technological breakthroughs in the development of high-yield oilseeds and in the refining of high-quality vegetable oils greatly reduced the cost of baking and frying fats, margarine, butter-like spreads, salad oils, and cooking oils in relation to animal-based products (Williams, 1984). Worldwide demand for vegetable fats was fueled by health concerns regarding the consumption of animal fats and cholesterol. Furthermore, a number of major economic and political initiatives led to the development of oil crops, not only in Europe and the United States but also in Southeast Asia (palm oils) and in Brazil and Argentina (soybean oil). The net effect was that from 1945 to 1965 there was an almost fourfold increase in US production of vegetable oils, while animal fat production increased by only 11% (US Department of Agriculture, 1966).

In developing nations one of the earliest shifts toward a higher-fat diet began with major increases in domestic production and imports of oilseeds and vegetable oils rather than increased imports of meat and milk. At this

stage, vegetable oils contributed far more energy to the human food supply than meat or animal fats (Morgan, 1993). With the exception of peanut oil, global availability of vegetable oils (soybean, sunflower, rapeseed, and palm) approximately tripled between 1961 and 1990. Soybeans now account for the bulk of vegetable oil consumption worldwide. It is also important to note that many of these processed oils are not regulated well, and some of the new edible oils or other foods are highly pathogenic (Wallingford, 2004).

#### **The Added Sugar Revolution**

It is difficult to understand quite how the global sweetening of the food supply occurred. During this same period, however, all processed food companies began to put increased types and amounts of added sugars from many food sources into processed food, and sugar became an increasingly cheap global product (Popkin and Nielsen, 2003).

#### **The Animal Source Food Revolution**

Delgado and others have documented the profound shift in global production and consumption of beef, pork, poultry, and dairy products and to a much lesser extent seafood and fish (Delgado, 2003a). Many agricultural scholars have shown how this shift grew out of an approach to diet and agriculture developed in the United States and Europe that globally influenced the increased subsidization of all components related to the production of animal source foods (Gardner, 2002). Elsewhere I have provided discussions of this history and its impact on US and global prices and consumption patterns of animal source foods (Popkin, 2008b, 2011).

#### **Food Systems Changes**

Simultaneously to the changes just outlined, there have been major revolutions in the way food is processed, distributed, and marketed. One of the primary influences is the modern food distribution system, personified by Walmart and the modern mass media.

An important change in the global food system is occurring in food distribution. No research to date has provided any analysis of the consequences of these food distribution shifts for dietary intake patterns. Fresh markets (“wet” or open public markets) are disappearing as the major source of food supplies in the developing world. They are being replaced by large, multinational, regional, and local supermarkets, usually part of global chains (e.g. Carrefour,

Tesco, or Walmart). In some countries, such as South Africa and China, domestic chains have been patterned to function and look like the global chains and have even grown into global giants. Megastores are increasingly encountered. For example, in Latin America, the supermarkets' share of all retail food sales increased from 15% in 1990 to 60% by 2000 (Balsevich *et al.*, 2003). In comparison, 80% of retail food sales in the United States in 2000 occurred in supermarkets. In one decade the role of supermarkets in Latin America expanded equivalent to about a half-century of expansion in the United States. Supermarket use has spread across both large and small countries, from capital cities to rural villages, and from upper- and middle-class families to the working class (Hu *et al.*, 2004). This same process is also occurring at varying rates and stages in Asia, Eastern Europe, and Africa (Minten and Reardon, 2008).

Many factors are causing this food system phenomenon (Wilkinson, 2004). Consumer demand for processed and safer foods is on the rise in developing countries. Additionally, as countries modernize, the opportunity cost of women's time has grown, and building a market for time-saving prepared foods has become more important. Transportation and access to technology such as refrigerators have also played a role in the demand for and access to supermarkets. Other factors include the liberalization of direct foreign investment, loosening trade restrictions, and the saturation of Western markets that has pushed growing companies into other locales. Furthermore, improvements in supermarkets' logistics and procurement systems have allowed them to compete on cost with the more typical outlets in developing countries: the small "mom-and-pop" stores and wet markets for fruits, vegetables, and other products.

Supermarkets are large providers of processed, higher-fat, added-sugar, and salt-laden foods in developing countries, but they have also been the purveyors of some good. For example, supermarkets were instrumental (a) in developing the ultraheat treatment (UHT) that gives milk a long shelf life, thereby providing a safe source of milk for all income groups; and (b) in establishing food safety standards (Balsevich *et al.*, 2003). Most importantly, supermarkets have solved the cold chain for animal source foods (dairy, beef, pork, poultry, and fish/seafood) to keep them sanitary.

It remains to be understood how the shift in marketing to these mega-supermarkets will affect the structure of diets and the total amount of food consumed (Minten and

Reardon, 2008). Research is needed into the ways in which these new food markets affect overall prices as well as the relative prices of different food-group categories. Other research needs to address how the new food markets change the consumption of refined versus complex carbohydrates, calorically sweetened foods, animal source foods, and fruits and vegetables, among other key issues.

### **Mass Media Changes**

One of the least discussed and least understood areas of change affecting dietary and physical activity patterns is the role of the modern mass media. Throughout the developing world, there has been a profound increase in the ownership of television sets accompanied by the penetration of modern television programming and advertising. More recently the media have penetrated via computers and cell phones. This has been accompanied by a proliferation of modern magazines and ready access to DVDs of Western movies. The health implications of this phenomenon are not understood. Examples from China are used to illustrate this set of changes. Many scholars directly attribute responsibility for child obesity to television viewing, both as a result of its effect on energy expenditure and because of the direct marketing of food on television. This remains to be studied in most developing countries in a rigorous causal manner.

### **Do Coca-Cola and McDonald's Have Any Responsibility?**

There is a view among some researchers that the US fast-food sector and soft-drink industry have led to the decline of healthy diets throughout the developing world (Zimmet, 2000; Lobstein *et al.*, 2004). American food companies have certainly spread across the globe. Coca-Cola is sold in more than 200 countries, and more than half of McDonald's sales are made outside the United States. Many other examples can be found to show that McDonald's, Pizza Hut, and Kentucky Fried Chicken restaurants are rapidly spreading across the globe. They are quickly followed or even preceded by local food chains that imitate their models, even to the point of serving the same dishes and being equally hygienic and efficient (Popkin, 2008b).

Major questions include: What are these companies doing to impact diets in the developing world? Are they leading people away from their healthy traditional diets to higher-fat and added-sugar-laden food products prepared away from home? Are they leading to increased portion

sizes worldwide, as they have in the United States? The answer might be “yes” or “no” depending on which country one studies and how one examines the data. We have shown in one study of four countries a huge variance in the proportions of food consumed from away-from-home and fast-food sources (Adair and Popkin, 2005).

## Biological Mismatch

Many scholars, including this author, have discussed one or more ways in which our evolved biology is mismatched with modern food and drink and the technologies of marketing and distribution (Trevantham, 1999; Gluckman and Hanson, 2004). This perspective in many ways argues that fatness and not thinness is self-selected and that obesity is a selective adaptation that was critical to earlier survival. However, the components noted below are critical to energy imbalance. In my work I identify four major domains where this mismatch between modern food-and-drink consumption and energy expenditure clashes with our evolved biology and profoundly affects overall energy imbalance.

### *Our Evolved Biology*

- sweet preferences
- thirst and hunger vs. satiety mechanisms are not linked
- fatty food preference
- desire to reduce exertion

### *Modern Technology*

- cheap caloric sweeteners, use of sugars in food processing
- caloric beverage revolution
- edible oils revolution, cheap edible oils
- technology in all phases of movement and exertion

The area most discussed recently is the issue of beverage compensation. Richard Mattes and others have led a revolution in our understanding of the way the body deals differentially with food and beverages of any composition (DiMeglio and Mattes, 2000; DellaValle *et al.*, 2005; Flood *et al.*, 2006; Mattes, 2006; Mourao *et al.*, 2007). In the history of beverages, only recently have we shifted from water to caloric beverages (Wolf *et al.*, 2008). We do not fully understand why we do not compensate for sugar-sweetened and any other caloric beverages by reducing food intake, but it has been shown that we do not. As a result of modern production and marketing of sugar-

sweetened beverages (SSBs), juices, and other fatty and/or sweet drinks, an increase in consumption of high-calorie beverages is occurring globally.

The other areas are documented by scholars in the field and are not addressed in this paper (Eaton and Konner, 1985; Eaton *et al.*, 1988, 1997; Trevantham, 1999; Cordain *et al.*, 2000, 2002, 2005; Gluckman and Hanson, 2004; Jönsson *et al.*, 2006; Power and Schulkin, 2009).

## Major Global Dietary and Eating Behavior Shifts

Globally, the overall diet appears to have become increasingly energy dense and sweeter. At the same time, high-fiber foods are being replaced by processed versions. There is enormous variability in eating patterns worldwide, but the broad themes seem to fit most countries. The studies and literature on dietary shifts in low- and middle-income countries are very sparse. The lack of data, the lack of scientists skilled in going beyond simple descriptive analyses of major nutrient and food-group patterns, and the lack of rigorous work on trends cause major gaps.

The global shifts in the energy density of diets are difficult to document. Yet one can document large increases in the consumption of edible oils and animal source foods for selected countries with the help of well-collected, repeated 24-hour recall measures of dietary intake (Du *et al.*, 2002; Popkin and Du, 2003). However, in general most research has had to rely on food disappearance data from the Food and Agricultural Organization (Popkin and Drewnowski, 1997). These data, which do not accurately pick up small shifts in consumption and waste (Crane *et al.*, 1992), demonstrate that shifts in edible oil intake are universal. One set of analyses that compared edible oil intake patterns in the 1960s with those in the 1990s based on food disappearance data shows large increases in the edible oils available for intake, particularly in lower-income countries (Guo *et al.*, 2000). Looking at daily average intake in a country such as China, where we have measured the intake with recall plus direct measures of daily household consumption, we find very high levels of intake. For example, average individual edible oils consumption for all Chinese age 2 years and older was about 12.9% of the caloric intake in 2006 (Popkin, 2008a).

Animal source food changes are equally dramatic (Delgado *et al.*, 2001; Delgado, 2003b; Catelo *et al.*, 2008). In China, for example, we have documented very large increases in animal source food intake (Popkin and

Du, 2003; Popkin, 2008a). Egg, poultry, beef, and pork consumption have increased rapidly in China, and milk intake has recently begun to rise. Today the average Chinese adult consumes more than 1300 kcal/day of pork, poultry, beef, mutton, fish, eggs, and dairy. As we have shown elsewhere, the structure of consumption shifts in China is such that, for each additional increase in income, adults proportionally increase their intake of animal source foods (Guo *et al.*, 2000; Popkin and Du, 2003; Du *et al.*, 2004).

Concurrent shifts are occurring in the use of caloric sweeteners. Only a few countries have published studies on the exact foods in which added caloric sweeteners are found; the United States and South Africa are two of these (Steyn *et al.*, 2003; Duffey *et al.*, 2007; Popkin, 2010). In the United States, calorically sweetened beverages (e.g. soft drinks and fruit drinks) account for more than half of the increase in added-calorie sweeteners in the past several decades; the pattern is much broader in South Africa and Mexico (Barquera *et al.*, 2008).

The studies on fiber intake and other changes toward processed foodstuffs are much less complete to date. Since the issue of reduced fiber intake in the Western diet was first discussed as a source of major health concerns, there have been few systematic studies of shifts in fiber intake throughout the world. There is documentation of specific shifts in diet from coarse grains to refined grains in a few countries.

Similarly, studies on fruit and vegetable intake indicate declines in many countries and regions of the world, but again the declines have not been systematically studied (Popkin *et al.*, 2001a,b). There are also selected countries where fruit and vegetable intakes remain very high (e.g. Spain, Greece, and South Korea) (Kim *et al.*, 2000; Lee *et al.*, 2002; Moreno *et al.*, 2002).

Minimal research has examined frequency of food consumption and snacking and the relation to the types of processing and cooking. Carlos Monteiro and his colleagues are working to document a trend he calls disturbing: the increased shift toward consumption of ultraprocessed foods as contrasted with partly processed foods (Monteiro, 2009).

Snacking and eating frequency have been studied for a few countries. For China we found the emergence of these phenomena among a population that previously had eaten only two or three meals and nothing between meals except tea or water. In unpublished data on China we found a tripling of snacking events between 2004 and 2006, and expect the 2009 data to reveal a further increase. We found

this shift in all income groups and in both urban and rural areas.

A second shift we documented in China is a major increase in fried-food consumption and preparation (Wang *et al.*, 2008). There is no research on this topic for other countries; however, in China the vast increase in the consumption of edible oils seems to have led to this large shift toward frying food instead of boiling or baking.

## Global Obesity Dynamics

UNC scholars have completed a major project that analyzed 44 developing countries in nationally representative surveys of women of childbearing age. All women aged 20–49 were weighed and measured with the same equipment and same methods to obtain the measure of overweight status ( $25 \text{ kg/m}^2 \leq \text{BMI}$ ) (Popkin *et al.*, 2011).

The surveys were repeated two to five times for each country during the past two decades (Jones-Smith *et al.*, 2011) and represent a set of surveys conducted with identical sampling and protocol for collection of directly measured weight and height, date of birth, gender, and other sociodemographic data. These data provide a current, highly controlled set of measurements that are comparable in collection methodology, sampling, weighting for national representation, and analysis.

### Prevalence

Figure 67.1 provides the current data on each country ranked by the country's per capita gross national product (GNP). These are mainly from the past 3 to 5 years and represent the most up-to-date, accurate assessment possible. In urban areas only four of these countries (Vietnam at 10.7%, Cambodia at 15.7%, Madagascar at 13.9%, and Ethiopia at 15.9%) are below the 20.0% level of prevalence for overweight and obesity. Another eight countries have a prevalence between 20% and 29%, and all the rest have a higher prevalence.

In rural areas a large number of countries have lower levels. Eighteen countries have overweight plus obesity levels over 20%, and a number of large countries have levels that are far higher. These results are presented in more detail elsewhere and represent a set of surveys conducted with identical sampling and protocol for collection of directly measured weight and height, date of birth, gender, and other sociodemographic data (Jones-Smith *et al.*, 2011).

FIG. 67.1 The prevalence of overweight and obesity (BMI  $\geq 25$ ) among women in rural and urban areas of 42 countries by region. Data from Jones-Smith *et al.* (2011) and Popkin *et al.* (2012).

There are too few countries with data for children aged 6–18 for us to systematically discuss child and adolescent overweight status. Elsewhere we have reviewed the trends and levels of child overweight for a small number of developing countries (Popkin *et al.*, 2006). There are studies on preschoolers, however, in which the authors use weight-for-height *z*-scores above 1 as a criterion (Martorell *et al.*, 2000). We have data for a few countries, including China (13.0% prevalence in ages 6–18 in 2006), Vietnam (1.2% prevalence in ages 6–18 in 2002), Bangladesh (4.4% in ages 10–17 in 2007), and Zambia (9.6% in ages 10–17 in 2007). All used International Obesity Task Force (IOTF) standards (Cole *et al.*, 2000).

### Trends for Adults

The absolute change in prevalence between two points in time is divided by the length of time in years to create the absolute annual rate of change in prevalence (expressed in percentage points). The annualized rate of change in prevalence is particularly useful in handling issues where initial prevalence rates are much lower for adults. The results are presented in Figure 67.2 for all countries. As can be seen, in urban areas only Rwanda and in rural areas only Nigeria, Burkina Faso, Rwanda, and Mozambique experienced a decline in overweight plus obesity prevalence. Overall the results show in urban areas an average change in the prevalence of obesity and overweight of about 1.0%. In rural

**FIG. 67.2** Absolute annual % point change in prevalence in women in 42 developing countries ranked by gross domestic product (GDP) per capita in 2009 US dollars. Data from Jones-Smith *et al.* (2011) and Popkin *et al.* (2012).

areas there is much greater variability, but the overall average is about 0.9%.

**Shifting the Burden Toward the Poor**

A cross-sectional study of 38 countries found that countries with GNPs above \$2500 per capita, plus half the poorer countries, had a higher prevalence of overweight among the poor than among the rich (Monteiro *et al.*, 2002, 2004a,b, 2007). The work of Monteiro and col-

leagues in Brazil was important, but focused mainly on cross-sectional snapshots. It did not tell us whether the rich reduce excessive weight gain relative to the poor as a country or an individual gains GNP per capita or income per capita.

A new set of studies (Jones-Smith *et al.*, 2011) explored the same issue of higher prevalence of obesity and overweight status for higher versus lower socioeconomic status (SES) groups. In this work, trends for the same countries

were examined. Forty-one countries provided two to five nationally represented cross-sectional surveys for a sample of women aged 18–49 ( $n = 556\,352$ ). In the majority of country-years, the groups with the highest wealth and education still had the highest age-standardized prevalence of overweight and obesity (97 out of 111 total country-years). However, in approximately half of the countries (21 out of 41), the increases in prevalence over time were greater in the lowest SES group compared with the highest SES group (Jones-Smith *et al.*, 2011).

### The Double Burden of Under- and Overnutrition

A phenomenon first explored by Doak and later by others is the double burden of obesity and concurrent undernutrition within the same household (Doak *et al.*, 2002, 2005; Garrett and Ruel, 2005; Custodio *et al.*, 2010; Motlagh *et al.*, 2011). These papers show that, as very poor countries added income and new technologies, the proportion of households with individuals who were both acutely malnourished and overweight (based on body mass index for both measures) increased before being reduced. Doak *et al.* (2005) presented data for seven countries and found that the proportions of dual-burden households were largest in Kyrgyzstan (15.5%) and Indonesia (11.0%), which were then low- to middle-GNP countries based on a GNP comparison of the seven countries. The lowest prevalence of dual-burden households occurs at both ends of the per capita GNP comparison, in Vietnam (3.7%) and the United States (5.4%), respectively (Doak *et al.*, 2005). Ruel and colleagues extended this work to chronically malnourished (stunted) children as one component of the pair and overweight mothers as the other (Garrett and Ruel, 2005).

In many ways these initial studies were part of a broader phenomenon that has now been studied in depth, namely countries with large coexisting undernourished and overweight populations. This is the broader social and health problem. One of the earliest studies on this much more prevalent and important topic was conducted in India (Griffiths and Bentley, 2001).

This issue of populations with large proportions that are malnourished and increasing segments that are becoming overweight is of great concern. In an earlier paper we documented that across the developing world, in both urban and rural areas, the occurrence of maternal obesity was greater than that of maternal underweight (Mendez

*et al.*, 2005). As shown in Figures 67.1 and 67.2, overweight has grown in prevalence in all of these countries, yet, in Haiti, India, and most of the sub-Saharan African countries, large proportions of preschoolers and smaller proportions of other children, adolescents, adults, and the elderly are also undernourished.

This represents a major global problem. Consider India, home to probably half of the world's malnourished children and low-weight infants and a quarter or more of its adults with BMIs below 17. At the same time diabetes, heart disease, and many co-morbidities are caused by excessive visceral fatness and other metabolic issues associated with relatively low BMIs of 22 to 24 (Shetty, 2002; Yajnik *et al.*, 2002; Yajnik, 2004; Ghosh, 2005). Reddy, in a vast number of publications, has critically documented this topic for India (e.g. Reddy, 2002, 2004; Chow *et al.*, 2007).

For governments, the complications of having to focus on undernutrition while addressing emerging obesity and all other NR-NCDs are great. Furthermore, the politics of addressing hunger are appealing, while those of addressing obesity are not.

### Hypertension, Diabetes, Cardiovascular Disease Mortality, and Cancers

A vast number of studies document the growing threat of diabetes and hypertension across the developing world and in turn the growing burden of cardiovascular disease and an array of cancers. In the cancer area, the World Cancer Research Foundation (WCRF) and the American Institute for Cancer Research completed a thorough study of the increases in the array of cancers across the developing world and the ever-growing role of obesity and abdominal fat in the incidence and prevalence of cancers and cancer survivorship (WCRF, 2007). In the cardiovascular area, a new Institute of Medicine volume has examined this issue (Fuster *et al.*, 2010; Institute of Medicine, 2010). Many other papers document hypertension increases (Gu *et al.*, 2005; Kearney *et al.*, 2005) or diabetes increases (Zimmet *et al.*, 1997; King *et al.*, 1998; Wild *et al.*, 2004). For instance, about 6.6% of adults have diabetes, and another 7.9% have impaired glucose tolerance. There are no global studies with the new guidelines for measurement of diabetes yet.

These same studies note that India and China already exceed all the new cases of diabetes in all other countries. They also show that, among the top ten countries with

adult diabetes, Brazil, Pakistan, Indonesia, and Mexico are also in the top ten in terms of prevalence, along with India and China.

There are a number of critical dimensions to this rapid increase in chronic diseases. Foremost is what appears to be a much greater susceptibility at much lower BMI levels across Asian, Middle Eastern, and Latin American populations. In one or two cases, such as Pacific Islanders, it appears that a much higher BMI level is associated with the same risk of the chronic diseases that we find at lower BMI levels for non-Hispanic whites in the United States (WHO Expert Consultation, 2004). In most situations, however, higher levels of visceral fat are found for the same BMI levels among these populations. There also appear to be some populations more susceptible to diabetes (South Asians) and others more susceptible to hypertension and stroke (East Asians) (Carter *et al.*, 1996; Eastern Stroke and Coronary Heart Disease Collaborative Research Group, 1998; Ramachandran *et al.*, 2001, Lee *et al.*, 2007).

We do not fully understand the genetic or epigenetic dimensions of this phenomenon. One potential key to the much higher visceral fat levels among the South Asian population may be the fact that South Asian women with BMIs of 16.5 or 17.0 can reproduce successfully, whereas it might take a much higher BMI level in other societies to achieve reproductive success.

For whatever reasons, we are seeing very rapid increases in the risk of type 2 diabetes in Mexico and other South American countries, remarkably rapid increases in hypertension in China, and equally rapid increases in diabetes in India and the Middle East. The epicenter for cardiovascular disease and cancer has shifted toward these low- and middle-income countries.

Conservative estimates of diabetes show a global estimate of 6.6% and an additional 7.9% with impaired glucose tolerance in 2010 from the WHO. More importantly, both the WHO and the World Diabetes Federation show that, of the top ten countries with diabetes among individuals ages 20–79, the United States is ranked third, with 36 million cases. India and China, with 87.0 and 62.6 million cases, respectively, are numbers one and two, and Pakistan, Brazil, Indonesia, Mexico, Bangladesh, Russia, and Egypt round out the top ten.

When we shift from just diabetes to all the nutrition-related non-communicable diseases, diet and obesity emerge as major causes of most cancers and cardiovascular disease, both new cases and consequent deaths from, in the low- and middle-income countries. In China we have

documented an increased rate of adult mortality, and the causes are mainly cancers and cardiovascular disease (Popkin, 2008a). In China, after decades of very rapid declines in mortality from infectious diseases, smoking, poor diet, and obesity represent the major causal factors in this huge increase among men and women. For India, the discussion is focused mainly on the 100 million cases of diabetes that will emerge over the next several decades, but the cardiovascular burden from this has been noted to be very large (Institute of Medicine, 2010).

## Future Directions

The low- and middle-income world is not prepared for the large shift in causes of disability, morbidity, and mortality from NR-NCDs. Some basic scientific questions need to be understood, and there are many programmatic and policy issues as well.

Foremost from a scientific point of view is the need for a greater understanding of susceptibility as it varies across racial and ethnic national and regional subpopulations. Why do South Asians gain excessive visceral fat at BMI levels of 20–22 and become so susceptible to diabetes? Are there issues in their dietary and activity patterns that can explain this? Is this the result of a unique shared history in that subcontinent of intergenerational malnutrition and stunting and all the other issues often discussed in research into the developmental origins of disease research? Similarly, why are East Asians more susceptible to hypertension and stroke? Is this a dietary issue, or are there other explanations that can be evaluated to reduce this risk? There are many related questions for Hispanics and persons from the Middle East, the Arabian Gulf states, and sub-Saharan Africa.

The double burden of under- and overnutrition poses a major set of research issues heretofore not fully explored. When malnutrition becomes a small and focused problem, as in Chile and Mexico, it can be managed through targeted programs. However, when both under- and overnutrition have large public health impacts and reach 10–40% of the population, targeting does not work. What, then, are the major program and policy options for addressing both problems while not exacerbating one or the other?

Resource constraints force most of these countries to develop prevention activities. What are they? Just what can we do to reduce caloric intake while also promoting a healthier eating and activity pattern? There is literally no case study at the national level of effective prevention

options. Are there price policy, regulatory, and other macro options that will work? And where does public education fit in?

Underlying the program and policy research needs is an almost total lack of detailed data on individual dietary intake. At a time when household food consumption and food purchases are becoming less relevant for the diets of many individuals of different age–gender subgroupings, only one or two countries even collect systematically detailed dietary intake data episodically. For these countries, few individuals are skilled in analyzing the data at the disaggregated food level necessary to understand dynamic shifts, the causes of these shifts, and the program options. Furthermore, up-to-date food composition tables are not available. What are the low-cost options for updating these food composition tables? Are there user fee options? How do we develop the resources to train the next generation of scholars needed for public policy research? Only India, which is investing in a new generation of public health schools, has begun to address this topic nationally.

In addition to issues unique to each country and region, there are of course the same basic scientific questions. However, the nutrition community, which does not have the extensive national and multinational institutions available to agriculture, urgently needs not only basic science but also ways to adapt to the unique environments and genetics of each country.

### Suggestions for Further Reading

There are few broad-based data-driven studies and books exploring diet-related chronic diseases in the low- and middle-income world. In general, aside from small case studies and explorations of changes within each country, only Carlos Monteiro and Barry Popkin have examined issues across a range of countries. One collection of articles and two books provide handy overviews. Other than these publications, the reader should consult the references from this volume to study this topic.

## FOOD INSECURITY, HUNGER, AND UNDERNUTRITION

DAVID L. PELLETIER<sup>1</sup>, PhD, CHRISTINE M. OLSON<sup>1</sup>, PhD, AND EDWARD A. FRONGILLO<sup>2</sup>, PhD

<sup>1</sup>*Cornell University, Ithaca, New York, USA*

<sup>2</sup>*University of South Carolina, Columbia, South Carolina, USA*

### Summary

Food insecurity, hunger, and undernutrition are poverty-related problems that affect all of the world's population to varying extents. The United Nations estimated that nearly 925 million people (16%) in developing countries were "undernourished" in 2010, but this method does not yield an accurate measure of food security at the household or individual level. Chronic undernutrition (stunting) is found in 33% of preschoolers in developing countries, and underweight is found in 19% of this age group. The United States uses definitions and methods very different from those used in low-income countries, but in 2009 it was estimated that 14.7% of US households were food insecure and about one-third of these (5.7%) had very low food security. Despite decades of research and an increasing level of attention by national governments and international organizations, the exact relationships among these problems and the most effective policy, programmatic and political means for eliminating them remain elusive. Doing so is becoming even more challenging in light of the emergence of nutrition-related chronic diseases in these same countries and population groups.

### Introduction

Recent decades have witnessed some fundamental changes in the way food insecurity, hunger, and undernutrition are understood within scientific and policy communities. In previous eras these three problems typically were viewed as a causal or chronological continuum, with food insecurity representing a situation of inadequate access to food owing to social and economic circumstances, hunger representing the immediate physiological manifestation

of inadequate intake, and undernutrition representing the physical consequences of chronically or acutely inadequate intake. Such a view has a variety of distorting effects on how each is measured and on notions of their prevalence, causes, consequences, and appropriate policy responses. This chapter describes the current understanding of the nature of each of these problems, their relationships with each other, what is known about prevalence, causes and consequences, and policy implications. For convenience the food-security situation in

developed and developing countries is described in separate sections.

## **Food Insecurity and Hunger in Food-Rich Countries: The United States as a Case Example**

### ***Nature of the Problem***

Though food insecurity and hunger have long been nutrition concerns among poorer countries of the world, these problems have re-emerged as nutrition concerns for food-rich countries such as the United States. This section of the chapter will briefly describe food insecurity, its measurement, and prevalence in the United States, and then review its consequences.

In 1989 an expert panel convened by the American Institute of Nutrition for the Life Sciences Research Organization identified food insecurity and hunger as core indicators of an individual's nutritional state (Anderson, 1990). This group put forth the initial consensus definitions of food insecurity and hunger. Food insecurity is the "limited or uncertain availability of nutritionally adequate and safe foods or limited or uncertain ability to acquire acceptable foods in socially acceptable ways." Hunger, a narrower and more severe form of deprivation, is "the painful or uneasy sensation caused by a lack of food, the recurrent and involuntary lack of food." Hunger can result in malnutrition over time and is a potential, although not necessary, consequence of food insecurity (Anderson, 1990). Food insecurity is experienced primarily at two different levels of social organization: the household or family eating unit, and the individual level. Hunger is generally used to describe an experience of food deprivation at the individual level.

In early research to define the concept and components of food insecurity, Radimer and colleagues (1992) described food insecurity and hunger as a managed process. The household food manager, generally a woman in US society, has some control over the sequence in which the various components of food insecurity are experienced and who in the household experiences them. Adults and children in the same household experience different components of food insecurity at different times and to different degrees. None the less, there is a general sequence to the phenomenon: household-level food insecurity with the depletion of household food supplies and anxiety are generally experienced first; the quantity and quality of women's

food intake, as well as the quality of the household food supply, are affected next; and finally the quantity and quality of children's food intake are affected. This basic understanding of the sequenced nature of the phenomenon has been incorporated into instruments for measuring the problem.

In 2004, the US Department of Agriculture requested the Committee on National Statistics (CNSTAT) of the National Academies to convene a panel of experts to review the concepts and methodology for measuring food insecurity and hunger in the United States. One particular conceptual issue included in the charge to the panel was "the appropriateness of identifying hunger as a severe range of food insecurity" (National Research Council, 2006, p. 2). The panel concluded: "hunger is a concept distinct from food insecurity, which is an indicator and possible consequence of food insecurity, that can be useful in characterizing the severity of food insecurity. Hunger itself is an important concept, but should be measured at the individual level distinct from, but in the context of food insecurity" (Wunderlich and Norwood, 2006). The CNSTAT panel indicated that hunger is more than the painful and uneasy sensation caused by the lack of food. It is the result of prolonged, involuntary lack of food and should result in physiological symptoms such as discomfort, illness, weakness, or severe pain. In addition, the panel recommended that USDA use alternative labels for the more severe levels of food insecurity, particularly food insecurity with hunger. Table 68.1 shows the revised labels used by USDA to describe the range of food security.

### ***Measurement***

The 10-year comprehensive plan for the National Nutritional Monitoring and Related Research Program set in motion a series of collaborative efforts across government agencies, academia, and the private sector to create a measure of food insecurity and hunger that could be used annually to assess the prevalence of food insecurity and hunger in the US population (US Department of Health and Human Services, 1993; Food and Consumer Service, 1995). The process of developing this measure is well described in the nutrition literature (Carlson *et al.*, 1999). The development and testing of questionnaire items by two groups, the Community Childhood Hunger Identification Project sponsored by the Food Research and Action Center (Wehler *et al.*, 1992) and the Division of Nutritional Sciences at Cornell University (Kendall *et al.*, 1995), were of critical importance to this effort. In April

**TABLE 68.1** Old and new labels for describing the ranges of food security

General categories (old and new labels are the same)	Detailed categories		
	Old label	New label	Description of conditions in the household
Food security	Food security	High food security	No reported indications of food-access problems or limitations
		Marginal food security	One or two reported indications – typically of anxiety over food sufficiency or shortage of food in the house. Little or no indication of changes in diets or food intake
Food insecurity	Food insecurity without hunger	Low food security	Reports of reduced quality, variety, or desirability of diet. Little or no indication of reduced food intake
	Food insecurity with hunger	Very low food security	Reports of multiple indications of disrupted eating patterns and reduced food intake

1995, the US Bureau of the Census administered the 18-item food-security scale to 45 000 households in its regular Current Population Survey. With data from this survey and methods from item-response theory (Rasch modeling), the scale was further refined, cut-points in the scale for differentiating levels of severity of the phenomena were defined, and categories of responses representing different levels of food insecurity were created (Carlson *et al.*, 1999).

The US Household Food Security Survey Module is an 18-item scale with a 12-month time reference (Bickel *et al.*, 2000). The scale has been shown to have good reliability, with a reliability coefficient of 0.81 for households with children and 0.74 for all households (extreme values that would inflate the reliability coefficient were omitted) (Hamilton *et al.*, 1997). In addition, responses to the Current Population Survey items follow a similar pattern across samples from diverse populations including racial and ethnic minorities (Frongillo, 1999). Scale scores are significantly related to the poverty income ratio (income relative to the poverty line) and weekly food expenditures in the expected ways, thus indicating validity (Hamilton *et al.*, 1997).

The Household Food Security Survey Module has now been administered to participants in the Current Population Survey conducted by the US Census Bureau for 14 years (1995–2008). The CNSTAT panel confirmed the importance of continuing to measure food insecurity in the US population and recommended that: “USDA should con-

tinue to measure and monitor food insecurity regularly in a household survey” (Wunderlich and Norwood, 2006, p. 49). The panel made several additional recommendations concerning measurement issues with the survey, item response theory, and other potential survey vehicles that could be used in measuring food insecurity in the population.

Other advances that have been made in the measurement of food insecurity are described in the Food Security Briefing Room of the USDA Economic Research Service web site ([www.ers.usda.gov/Briefing/FoodSecurity](http://www.ers.usda.gov/Briefing/FoodSecurity)). One particularly noteworthy advance has been the development of the Children’s Food Security Scale (Nord and Hopwood, 2007).

### Prevalence

In 2009, 14.7% of US households were food insecure. About one-third of food-insecure households or 5.4% had very low food security (Nord *et al.*, 2010). About 50 million persons including 17.1 million children lived in food-insecure households. Households with very low food security generally experienced the condition for 7 months of the year, for a few days in each month.

Food insecurity varies by household characteristics in expected ways. In 2009, households with incomes below the official poverty line had a prevalence of 43.0%, nearly three times the national average. Households with children had a rate (23.1%) that is nearly twice the rate of those

without children (11.4%). Black and Hispanic households had a prevalence of 24.9% and 26.9%, and 36.6% of households headed by a single woman with children were food insecure.

From 1995 through 2000, there was a downward trend in the prevalence of household-level food insecurity in the United States. From 2000 to 2004 there was a gradual increase from 10.1% to 11.9% in the prevalence of food insecurity, a drop to 11% in 2005, and then a near level prevalence until 2008. The 2009 prevalence of food insecurity was the highest observed since the food security surveys began in 1995 (Nord *et al.*, 2010).

### Consequences

The early research of Radimer *et al.* (1992) suggests that individual household members experience food insecurity differently, with adults experiencing negative changes in diet quality and quantity before children. Available research supports this hypothesis, specifically that mothers compromise their own nutritional status to feed their children (Rose and Olivera, 1997; McIntyre *et al.*, 2003; Olson, 2005).

While there is a large research literature on the adverse consequences of food insecurity in food-rich countries, most studies are cross-sectional and thus are constrained in specifying the direction of causality. In recent years, a few longitudinal studies have investigated the relationship between food insecurity and a variety of different outcomes. Since these types of studies are more supportive of making causal inferences, only longitudinal studies concerning consequences will be discussed here. Reviews of cross-sectional studies will be cited.

Several reviews, including an earlier version of this chapter in the ninth edition of *Present Knowledge in Nutrition*, show that adults living in food-insecure households consume diets that are low in essential nutrients and some food groups, particularly fruits and vegetables (Olson, 2005; Holben, 2006; Pelletier *et al.*, 2006). In addition, adults in food-insecure household are more likely to have poorer health and functional status, as well as being at greater risk for chronic health conditions and compromised management of these conditions. There are few longitudinal studies with adults to support causal inferences of food insecurity resulting in poorer health, although knowledge of how these factors are related certainly makes such inferences plausible.

The noted exception to the generalization above is with the health outcomes of weight gain and obesity. Three

different longitudinal studies of adult women, one using a national sample of US women and one each with urban and rural samples of women, found no significant relationship between initial food insecurity status and weight gain or risk of becoming obese over follow-up periods of about two years (Jones and Frongillo, 2007; Whitaker and Sarin, 2007; Olson and Strawderman, 2008). However, Olson and Strawderman (2008) found an interaction between initial obesity and food insecurity, with women who were both obese and food insecure in early pregnancy at the greatest risk of major weight gain at 2 years postpartum, pointing to the possibility of a third factor associated with both constructs. None the less, these authors found stronger support for obesity leading to food insecurity than food insecurity leading to obesity. In a national sample, Jones and Frongillo (2007) found that, among overweight women who were on a weight-gain trajectory, those who were food insecure gained significantly less. This relationship was not observed in healthy-weight or obese women. Finally, again in a national sample of women, Jones and Frongillo (2006) found persistently food-insecure women gained less weight across time, but full participation in the Food Stamp Program offset this weight change. Taken together, these studies do not support a strong causal inference of food insecurity leading to major weight gain or obesity in adult women.

In 2008, 22.5% of children in the United States lived in food-insecure households and 1.5% of children lived in households with very low food security among children, a statistic from the children's measure of food insecurity (Nord *et al.*, 2010). These statistics indicate that a large proportion of US children are potentially affected by exposure to food insecurity. Cross-sectional as well as a small number of short-term longitudinal studies described in several reviews indicate that household insecurity and children's food insecurity are associated with poorer nutritional status, as well as poorer growth, health, mental and psychological functioning, and cognitive and academic achievement (Ashiabi and O'Neal, 2008; Cook and Frank, 2008; Kursmark and Weitzman, 2009).

Three different longitudinal studies from three different countries, the United States, Canada, and the United Kingdom, found adverse health and developmental outcomes associated with food insecurity in children ranging in age from the preschool years to adolescence (Jyoti *et al.*, 2005; Belsky *et al.*, 2010; Kirkpatrick *et al.*, 2010). Using data from the Early Childhood Longitudinal Study–Kindergarten Cohort, Jyoti *et al.* (2005) found that chil-

dren who lived in marginally food-insecure households during their kindergarten years had significantly lower social and mathematics skills in third grade. Using data from the Canadian National Longitudinal Survey of Children and Youth that followed children for 10 years, hunger measured using one question was associated with a 2.5-fold increased risk of overall poor health among children who entered the cohort as preschoolers (Kirkpatrick *et al.*, 2010). Among these children, no significant relationships between hunger and being diagnosed with one of six chronic health conditions or asthma were found, nor were any significant relationships found in the cohort of older youth. Among the younger cohort, the experience of two or more episodes of hunger was associated with nearly a five-fold increase in risk of poorer general health. Belsky and colleagues (2010) studied children from a cohort of 1116 families with twins from the United Kingdom called the Environmental Risk Longitudinal Twin Study (E-Risk). Food insecurity was measured using seven items from the USDA Household Food Security Survey Module when the children were 7 to 10 years old, with food insecurity defined as two or more positive responses. Child development outcomes were measured when the children were 12 years old. Children from food-insecure households had lower IQs and higher levels of behavioral and emotional problems. But when differences in household income, mothers' personalities, and household organization were accounted for, the only outcome for which food insecurity remained a significant predictor was emotional outcomes. Cognitive development outcomes were totally accounted for by household income, and behavior outcomes were accounted for by maternal personalities and household organization around the children's needs. Concerning their finding on emotional outcomes, the authors conclude, "This finding . . . constitutes the strongest evidence to date that food insecurity, and not just impoverished, chaotic, and neglectful households prone to disrupted food situations, can influence children's mental health" (Belsky *et al.*, 2010, p. 5). Thus there is reasonably strong evidence from longitudinal studies that food insecurity influences children's physical and emotional health.

Four different longitudinal studies have examined the relationship of food insecurity and weight outcomes in children (Jyoti *et al.*, 2005; Rose and Bodor, 2006; Bronte-Tinkew *et al.*, 2007; Bhargava *et al.*, 2008). Three have used data from the US Early Longitudinal Study – Kindergarten Cohort with follow-up periods of 1 to 5

years and several different measures of the weight outcomes (Jyoti *et al.*, 2005; Rose and Bodor, 2006; Bhargava *et al.*, 2008). Food insecurity was measured using the US Household Food Security Scale and operationalized as  $\geq 1$  positive response,  $\geq 3$  positive responses and as a continuous scale score. No consistent results emerged from these three studies: One study found a positive association, one a negative association and one no association. The fourth study used data from the US Early Childhood Longitudinal Study-Birth Cohort, 9- and 24-month surveys (Bronte-Tinkew *et al.*, 2007). Using structural equation modeling to examine the direct and indirect associations between food insecurity and toddlers' overweight, investigators found the food insecurity did not directly affect overweight. Food insecurity worked through parenting practices and infant feeding to indirectly influence overweight. Overall, the evidence does not support a strong causal inference that food insecurity in households causes overweight in children.

Substantial progress has been made in the last several years in research on food insecurity and hunger in food-rich countries. A major review of the concept, measure, and measurement processes used in national surveillance and research has affirmed the validity and utility of food insecurity, while suggesting that additional research is needed on more severe food insecurity that previously had been called hunger. In addition, substantial progress has been made in uncovering the mechanisms through which food insecurity affects health and development. Much less has been accomplished in understanding the causes of food insecurity, and few, if any, major intervention studies have been conducted on preventing food insecurity. These are fruitful areas for further research.

## Food Insecurity and Hunger in Poor Countries

### *Nature of the Problem*

The concept of food security gained international prominence with the World Food Conference of 1974 (Maxwell, D., 1996). The most commonly cited definition is "access by all people at all times to enough food for an active, healthy life" (World Bank, 1986). This definition emphasizes that food security is relevant for individuals, implies each individual's entitlement and right to food, requires sufficient and sustainable access to food, and has consequences. The complexity of food security (Maxwell and

**FIG. 68.1** Simplified conceptual framework for food security from the global and the national to the household and the individual. Adapted from Smith (1998).

Frankenberger, 1992) is reflected in three significant shifts in thinking about food security over the past 30 years: (a) from global and national levels to household and individual levels, (b) from a food-first to a livelihood perspective, and (c) from objective to subjective understandings (Maxwell, D., 1996).

Food security is salient at global, regional, national, provincial, community, household, and individual levels (Figure 68.1). At the global and national levels, food security concerns the overall availability of food, and at the national level results from importing and producing food.

At the household level, food security concerns the availability and access to food by the household, which results from household production and availability from the market or others in the community. At the individual level, food security concerns the utilization or consumption of food, which results from its availability to and access by the household and also the distribution within the household (Riely *et al.*, 1997). "An individual person is food secure when his or her consumption of food is sufficient, certain (not vulnerable to consumption shortfalls), and sustainable" (Smith, 1998).

Food is a fundamental need in that each individual must have access to necessary nutrients to survive and to participate actively in society. But, food is only one of the needs that people must attempt to meet. The term “livelihood security” captures the understanding that households often make trade-offs to ensure their long-term viability as productive and reproductive units (Maxwell, D., 1996). Livelihood security refers to the stocks and flows of assets and cash to meet basic needs, offset risk, ease shocks, and meet contingencies (Maxwell and Frankenberger, 1992; Davies, 1996). People may go hungry in the present to preserve assets and future ability to make their living. They may forgo eating now to preserve seed for future planting or to save an animal for future use (Maxwell, D., 1996). Livelihood security implies other trade-offs as well, such as forgoing some food to be able to buy medication to treat illness.

Food insecurity is a form of deprivation, and one can refer to both the conditions and feelings of deprivation (Maxwell, S., 1996). Whereas previously the tendency was to consider food security solely as referring to the adequacy of food or nutrients in objective terms, the understanding now is that the subjective experience of individuals is central. From this understanding, which is consistent with that discussed in the previous section on the United States, the relevant food security is that which is actually perceived by a household or individual rather than that which is decided on by researchers or policy makers, given that households will behave according to their perception and not according to indicators defined by outsiders (Maxwell, S., 1996). Important categories of behaviors potentially influenced by one’s perceptions of food insecurity are investment (e.g. in productive assets, education, and children), risk avoidance (e.g. regarding adoption of new agricultural technologies or management practices), and survival strategies (e.g. rural–urban migration, diversification of livelihood strategies).

These three shifts in thinking about food security shape our current understanding of its nature in poor countries. This understanding has important implications for how food security is assessed and for efforts to improve food security.

### **Measurement**

At the global and national levels, food security has primarily been measured by estimating “the number of people whose food intake does not provide enough calories to

meet their basic energy requirements” (Food and Agriculture Organization, 1999). The FAO refers to these people as the undernourished. The FAO method largely reflects national food availability, and does not adequately reflect people’s ability to access food (Smith, 1998). Therefore, this method yields a direct measure of food security at the national level if it is defined in terms of national food availability (see Figure 68.1). But the FAO method does not yield an accurate measure of food security at the household or individual level because it does not adequately reflect access to and utilization of food.

The Food Insecurity and Vulnerability Information and Mapping System at FAO provides information about global and national food security. The system draws on existing information, such as crop forecasting and early warning systems, household food security and nutritional information systems, and vulnerability assessment and mapping systems (Food and Agriculture Organization, 1999; Anon., 2000).

At the household and individual levels, food security has been measured in various ways, often indirectly. Food security affects dietary intake and ultimately nutritional status and physical well-being, as well as other outcomes. While measures of dietary intake of individuals can assess some aspects of food security such as energy insufficiency and nutrient inadequacy, they do not assess the cognitive and affective components of uncertainty (expressed as anxiety), unacceptability, or unsustainability. For example, current intake may be adequate but food insecurity still may be experienced because of concern over future intake. Alternatively, intake may be inadequate, but only temporarily so as to protect supplies and prevent future food insecurity. Growth status is also used as an indicator, but again does not assess most of the components of food security and depends on factors such as health and child care.

Food security is related to available economic and social resources. Precursors such as income or total expenditure are correlated with energy sufficiency, but they only capture this component of food insecurity and are indirect (Haas *et al.*, 1992). Food-related management or “coping” strategies have also been used to assess food insecurity (Maxwell, D., 1996; Maxwell, *et al.*, 1999). Management strategies both result from and affect the experience of food insecurity and may be useful as early indications of future food insecurity. The presence or absence of particular management strategies, however, often is not indicative of food security, and measures of management strategies do not

include all components of the experience of food insecurity.

Because the more directly linked a measure is to the phenomenon of interest, the more accurate that measure will be, it is important to measure the experience of food insecurity itself, including whatever its key components are in a given location (Frongillo, 1999). This experience could be objectively and definitively measured by observing in detail a household over time (Frongillo, 1999; Hamelin *et al.*, 1999). Because such an approach is not feasible for a large number of households, this experience can instead be measured subjectively by assessing not only aspects of the availability of, access to, and utilization of food, but also how a person feels about it (e.g. anxiety, worry) and what a person thinks about it (e.g. perceptions, social acceptability). Because these manifestations are overt, we can tap into these to directly measure the experience of food insecurity in a comprehensive manner.

One way to develop direct measures that include these components and can complement existing measures is to base them on an in-depth understanding of the experience of food insecurity at the household level (Eilerts, 1999; Wolfe and Frongillo, 2000). This approach was first used in the United States but has now been used in many low- and middle-income countries (Studdert *et al.*, 2001; Frongillo *et al.*, 2003; Pérez-Escamilla *et al.*, 2004; Coates *et al.*, 2006b; Frongillo and Nanama, 2006; Melgar-Quinonez *et al.*, 2006; González *et al.*, 2008). Furthermore, the Food and Nutrition Technical Assistance Project has developed technical guides for developing new measures (Frongillo *et al.*, 2004) and for adapting a generic questionnaire developed and tested through consensus of international experts (Coates *et al.*, 2007). This research demonstrates that (1) experience-based measures are valid for differentiating households both at a given time and with changes over time, (2) developing such measures is feasible in programmatic settings, and (3) many, but not all, aspects of the experience of food insecurity are common across locations and cultures (Coates *et al.*, 2006a).

### Prevalence

Information about the prevalence of food insecurity at the global, regional, and national levels is primarily available from FAO estimates of undernourishment. According to these estimates, nearly 925 million people or 16% of people in developing countries are undernourished (Table 68.2; <http://www.fao.org/publications/sofi/en/>). Because of its large population, Asia has by far the largest number

**TABLE 68.2** Prevalence of undernourishment in developing countries

Region	Undernourished in total population (2010)	
	Number (millions)	Prevalence (%)
Asia and Pacific	578	16
Latin America and Caribbean	53	8 <sup>a</sup>
Near East and North Africa	37	8 <sup>a</sup>
Sub-Saharan Africa	239	30
All developing countries	925	16

<sup>a</sup>Provisional.

Data from Food and Agricultural Organization of the United Nations (2010).

of undernourished people. Sub-Saharan Africa has by far the largest prevalence of undernourishment at 30%. As explained earlier, these estimates are likely to be an accurate reflection of food availability at the global, regional, and national levels, but not of food security at the household or individual levels.

### Consequences

Food insecurity adversely affects well-being in many ways. Mechanisms that bring about such effects may be biological, acting through decreased nutrient intake, or social and behavioral. In the latter case this may act through, for example, compromised time, energy, and attention for care of self and dependents. Some adverse effects of food insecurity include infants with low birth weight and high risk of mortality, children with impaired cognitive and neurological development that leads to reduced learning capacity and school performance, and adults with low work productivity and capacity to be food secure. The cycle is completed as these adults have children (Tweeten *et al.*, 1992). Other consequences are a range of behavioral responses to uncertainty (including investment, risk avoidance, and survival strategies); the experience of stress, alienation, deprivation, and adverse family and social interactions (Hamelin *et al.*, 2002); and those conditions described earlier in relation to the United States which are presumed also to affect children in poor countries.

## Undernutrition

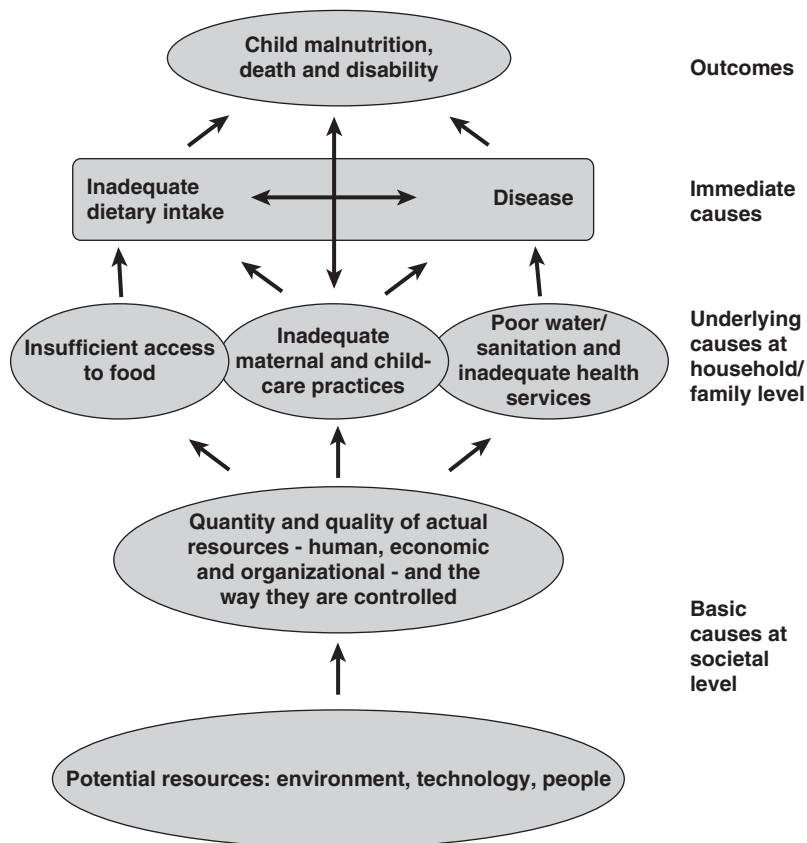

### **Nature of the Problem**

Scientific understanding of the nature, causes, and solutions related to undernutrition in developing countries has shifted significantly in the last 50 years as a result of new evidence, experience, disciplinary perspectives, and ideology (Jonsson, 2010). From mid-century through the 1960s, the major focus was on protein deficiency. Based on the earlier description of kwashiorkor by Williams (1933) and the prevailing nutrient-deficiency paradigm then current in nutritional sciences, attention was directed toward estimating human requirements for protein and individual amino acids under varying physiological states and conditions of health and disease prevalent in developing countries. Simultaneously, a variety of other disciplines (e.g. animal and agricultural sciences, food science), development agencies, and governments sought to develop and implement technological and food-based means for increasing animal protein or essential amino acids in the food supplies and diets in developing countries. This protein era came to an unusually rapid end in the 1970s, at least in the expert communities, with the downward revision of estimated protein requirements (World Health Organization, 1973), but the protein focus continues to influence thinking and food and nutrition policy in many countries even today. This episode also has negatively affected nutrition's image within scientific and development communities, an impact that reverberates to this day, resulting from the perception that nutritionists directed attention to protein deficiency and then changed their mind after many other scientists and institutions had redirected their work to help close the protein gap.

Further shifts in thinking have involved the era of the energy gap in the 1960s and 1970s (Food and Agriculture Organization, 1969; Reutlinger and Selowsky, 1976), multisectoral nutrition planning, applied nutrition programs, and nutrition surveillance in the 1970s and 1980s (Levinson, 1995), and micronutrient deficiencies in the 1990s to the present (World Bank, 1994; Micronutrient Initiative, 2009). Since the 1990s the discourse in international nutrition has included a wide array of problems and causes (e.g. growth faltering, low birth weight, maternal undernutrition, iodine, vitamin A, iron and zinc deficiencies, diarrhea, human immunodeficiency virus (HIV) and other infectious diseases, inadequate infant and child feeding practices, female time constraints, limited house-

hold income and agricultural production, food insecurity, environmental degradation, and urbanization), and a wide array of partial solutions (e.g. growth monitoring, supplementary feeding, exclusive breastfeeding, complementary feeding, nutrition education, behavior-change communications, oral rehydration, child spacing, fortification, vitamin A, iron and multiple micronutrient supplementation, income generation, food aid, home gardening, and agricultural intensification). In more recent years, the field has experienced yet another controversial shift, with the interest in the potential for ready-to-use foods (RUF), fortified complementary foods, lipid-based supplements, and other formulations to be used at community rather than clinic level, to address severe acute malnutrition and possibly mild and moderate undernutrition (Briend *et al.*, 2006; Nackers *et al.*, 2010).

These diverse perspectives on nutrition, exacerbated by institutional interests and rivalries, have contributed to the perception among many policy makers and donors that the nutrition problem is too complicated, it has created a fragmentation of effort across international and government agencies, and it has inhibited the development of a consensus about priority problems, actions, and strategies (Morris *et al.*, 2008; Pelletier, 2008b). In an effort to respond to this situation in the early 1990s, the nutrition section of the United Nations Children's Fund (UNICEF) developed and promoted an inclusive conceptual framework for organizing scientific knowledge and experience, fostering a common understanding and developing coherent strategies for addressing them (Figure 68.2). The framework explicitly recognizes that the relative importance of the three underlying causes of malnutrition (food, health, and care) can vary widely across households, communities, and countries. This context specificity implies that universal causes and solutions do not exist and that the binding constraints must be assessed and acted upon in each national or local setting. The potential impact of such an approach has been documented by the Iringa Nutrition Program in Tanzania, which gave rise to the UNICEF strategy, and was repeated in Thailand, Indonesia, and Vietnam (United Nations Standing Committee on Nutrition, 1996; Sternin *et al.*, 1999). Much work is still required, however, to counter the tendency for specialized scientists, professionals, and institutions to single out and promote that part of the framework that suits their particular interests and agendas even when the context suggests that other actions may be more appropriate (Pelletier, 2000; Morris *et al.*, 2008).

**FIG. 68.2** United Nations Children's Fund (UNICEF) conceptual framework for the causes of malnutrition. Adapted from UNICEF (1991).

### Measurement and Prevalence

In contrast to the diversity in perspectives about causes and solutions, there has been a long-standing agreement that anthropometric indicators represent a satisfactory basis for estimating the prevalence and trends in general undernutrition among preschool children at global, national and local levels (WHO, 1995). These indicators include: height for age, which indicates the cumulative effects of malnutrition in the life of the child; weight for height, which indicates recent nutritional experiences (typically weeks or months); and weight for age, which reflects the combined effects of recent and longer-term conditions. These indicators are considered to be sensitive to the immediate and underlying causes of malnutrition as depicted in Figure 68.2, although they are not specific to any particular cause such as food insecurity, infectious disease, or inappropriate child care and feeding.

For the developing world as a whole, 19.3% of preschoolers were estimated to be underweight in 2007 (low

weight for age, Table 68.3) and 32.5% were stunted (low height for age, Table 68.4). In Sub-Saharan Africa the prevalence of underweight (19.6%) and stunting (38.5%) in 2007 has remained virtually unchanged since 1990. Asia and its sub-regions have experienced greater improvements, eliminating about one-third of the underweight and stunting that was present in 1990. However, the overall levels remained high in 2007 in the populous South-Central region (32.5% underweight and 30.6% stunted). The overall prevalence of stunting in Latin American and the Caribbean was 23.7 in 1990 and had reduced to 15.7 in 2007.

### Consequences

An impressive body of evidence suggests that undernutrition has pervasive effects on human performance, health, and survival (United Nations Standing Committee on Nutrition, 2002; World Bank, 2006). This includes effects on morbidity (Lanata and Black, 2001), mortality (Pelletier

**TABLE 68.3** Prevalence (%) of underweight<sup>a</sup> among preschool children<sup>b</sup> by region, 1990–2007

*et al.*, 1993, 1995), intrauterine growth (Kramer, 1987), cognitive and social development (Pollitt *et al.*, 1993; Grantham-McGregor, 1995), schooling (Victoria *et al.*, 2008), adult physical work capacity (Haas *et al.*, 1996), adult-onset chronic diseases (Victoria *et al.*, 2008), economic productivity (Haddad and Bouis, 1990; Victoria

*et al.*, 2008), and economic growth (Fogel, 1994). It is estimated that undernutrition is responsible for 35% of all deaths to children under 5 years in developing countries (Black *et al.*, 2008) and increases cause-specific mortality due to neonatal disorders, diarrhea, pneumonia, and malaria (Caulfield *et al.*, 2004).

### Recent Policy Developments

Since the turn of the millennium a series of significant events have converged that present major opportunities for addressing food insecurity and malnutrition in developing countries. These include the prominent role given to these issues in the Millennium Development Goals (United Nations Development Programme, 2003), a set of eight development goals advanced by the United Nations in 2000 and since ratified by over 190 UN member states; the conclusions of the Copenhagen Consensus (Lomborg, 2007) that nutrition interventions represent one of the most cost-effective investments in all of international development; the publication of the high-profile Lancet Child Survival Series (Black *et al.*, 2003) and Child Nutrition Series (Black *et al.*, 2008) documenting the profound impacts of malnutrition; the greater attention to nutrition paid by the World Bank (World Bank, 2006); the Global Food Security Initiative endorsed by the G8 Nations after the world food crisis in 2008 (L'Aquila Food Security Initiative, 2009); and the convergence on a framework for action by major multilateral, bilateral, and private organizations (Bezanson and Isenman, 2010). These events and initiatives have generated unprecedented attention and resources for addressing food insecurity and malnutrition, representing important key steps in the policy process, but the ultimate success of these will depend upon the level of commitment, convergence, and capacity-building that occurs as they are implemented at country level (Pelletier *et al.*, 2011).

### Future Directions

This chapter has attempted to illustrate some of the similarities and common themes among hunger, food insecurity, and undernutrition as they occur in developed and developing countries. The reality, however, is that research, policies, and programs have tended to neglect the potentially important commonalities among them. This section highlights some of these and suggests that our scientific understanding of these problems and our ability to address them through policies and programs would be enhanced by focusing on these and other commonalities.

In developed and developing countries, undernutrition and food insecurity often coexist in the same populations with obesity and chronic disease. There are multiple biological, social, and behavioral causes for this coexistence that operate through life-course, intergenerational, genetic, and epigenetic mechanisms. For example, undernutrition

in gestation brings greater biological risk for obesity and chronic disease, either through changing the sensitivity of the hypothalamic–pituitary–adrenal axis, which in turn alters appetite and physical activity, or through the action of components of the maternal diet on gene expression (Victoria *et al.*, 2008). Undernutrition and food insecurity may also increase risk of obesity and chronic disease because of compromised dietary quality or quantity, or because of psychological stress that affects behavior (Jyoti *et al.*, 2005). This coexistence suggests a need for two types of research. One is to better understand the factors, conditions, and processes that produce this “dual burden” at household, community, and national levels. The other is to develop and evaluate policy and programmatic strategies that address both problems simultaneously and/or that address one problem (e.g. food insecurity or undernutrition) while not inadvertently exacerbating the other (e.g. obesity). There has been some conceptual treatment of this issue (Hamm and Bellows, 2003; Rayner *et al.*, 2006; Dixon *et al.*, 2007), but the feasibility and effectiveness of various proposals have yet to be examined. This requires research at multiple levels of analysis (individual, household, community, and national) because the causes and the intervention options vary across these levels.

Integrative or cross-boundary research and theory development should also be done to advance the translation of scientific knowledge into effective large-scale action, in settings as diverse as the mega-cities, towns and rural areas of Sub-Saharan Africa, South Latin America, Europe, the United States, and all other regions of the developed and developing world. Each of the problems discussed here, from hunger to obesity and from undernutrition to chronic disease, is complex in its etiology and suffers from major gaps in the scientific knowledge of “what works.” This is true on a small scale and even more so on a large scale. Superimposed upon this is enormous sociocultural, ecological, economic, and political diversity, as well as wide variation in the administrative and organizational capacities to implement effective action on a large scale. A large number of theories and frameworks exist in political and policy sciences, management sciences, sociology, and other fields that could guide efforts to develop and implement effective actions in these varied contexts (Parsons, 1995; Sibeon, 1997; Vasu *et al.*, 1998; Clark, 2002). However, it is still uncommon for these to be applied in research and policy related to the focal problems in this chapter and public health more broadly (Walt and Gilson, 1994; Pelletier, 2008a; Breton and de Leeuw, 2010). The applica-

tion and further development of these theories and frameworks for the purpose of improving population health are important opportunities and challenges as the field of nutrition matures from its current status as a largely bench, clinical, and epidemiological science.

The emergent interest in implementation sciences has the potential to stimulate this maturation of the field (Alegria, 2009; Satterfield *et al.*, 2009). As yet there is not a widely shared understanding of the boundaries and content of “implementation sciences,” and related terms such as translational research, operations research, knowledge translation, and health systems research. A broad definition useful for present purposes is the study of the social, cultural, behavioral, economic, management, and political factors that can facilitate or inhibit the adoption, adaptation, and use of evidence-based interventions, practice guidelines, scientific knowledge and real-world experience into the process of policy formulation, the implementation of policies and programs, and efforts to enhance the quality and effectiveness of implementation. This definition is useful for the problems discussed in this chapter because it acknowledges the importance of varied contextual factors, is relevant at multiple scales (clinical, community, national, and global), acknowledges that policy formulation and implementation pose distinctive challenges, and can be applied to policies and interventions outside of health care such as community health, agriculture, social protection, education, and so on. The conceptual development and real-world application of implementation sciences, as a fundamentally integrative and transdisciplinary endeavor (Satterfield *et al.*, 2009), constitute an urgent priority for understanding and addressing food insecurity, undernutrition, obesity, and nutrition-related chronic disease in the coming years.

Finally, while the above research topics are important for informing the design of effective interventions, programs, and policies specifically aiming to address food insecurity, undernutrition, and obesity, it is also important to consider the impact of macro-level forces on these problems. The forces include climate change; global food and economic crises; maldistribution of water and arable land; the growing influence of transnational food companies; the sustainability of food systems, health-care systems, and social protection programs; and the weak state of national and global governance systems for addressing these issues. Individually and collectively, these forces pose urgent threats to the food security and nutritional status of populations, can undermine the impact of the more direct

nutrition interventions, and are likely to become more severe in the coming years. The nutrition community can play important roles by partnering with other organizations in research, advocacy, and policy development related to these issues.

## PUBLIC NUTRITION IN HUMANITARIAN CRISES

HELEN YOUNG<sup>1</sup>, PhD, KATE SADLER<sup>1</sup>, PhD, AND ANNALIES BORREL<sup>2</sup>, MSc

<sup>1</sup>Tufts University, Medford, Massachusetts, USA

<sup>2</sup>UNICEF Office of Emergency Programmes – Humanitarian Policy and Advocacy, New York, USA

### Summary

Populations affected by humanitarian crises are prone to increases in nutritional risk, malnutrition, and micronutrient deficiency diseases. Nutrition in humanitarian crises is usually both a public-health and food-security priority, and requires a multi-sectoral response to reduce the nutritional risks and treat malnutrition directly.

This chapter describes five broad categories of public nutrition interventions, including strategies that:

- Address the nutritional needs of populations, including food security and livelihoods programs, general food distribution, and public health programs.
- Address the needs of the nutritionally vulnerable.
- Prevent and treat micronutrient deficiency diseases.
- Prevent and treat moderate acute malnutrition.
- Treat severe acute malnutrition.

The objectives, program design, and target groups for each of these are described, and remaining challenges are discussed. The importance of this sector has increased markedly as reflected by commitments in the broader policy environment and an increasing body of relevant policies and best practices. Significant progress has been made in a range of areas, and, for the future, improved evidence about what works will serve to further strengthen policy and program guidance.

### Introduction

Emergencies capture news headlines, ranging from sudden-onset floods in Pakistan to the frequent occurrence of

drought-related food insecurity in Niger (Gronewold, 2010; Khristof, 2010). News coverage is patchy, focusing on high-profile visible emergencies while ignoring the more chronic, protracted crises, which are less well docu-

mented and have been termed “silent disasters” (Eriksson, 2007).

This chapter provides an overview of the characteristic nutritional problems that occur in natural disasters and complex emergencies, and the progress and challenges for defining and assessing these. It then reviews the core public nutrition interventions in emergencies, emphasizing the important role of a *public nutrition* approach<sup>1</sup>.

Many emergency contexts are associated with fragile and conflict-affected states, and war and conflict are consistently the main causes of famine (United Nations ESC/ECA, 2009). At the same time, trends over the past 30 years show an increase in the number and frequency of natural disasters<sup>2</sup> (EM-DAT, 2009), the effects of which may be exacerbated by conflict and insecurity, or political and economic instability. The number of African countries facing food crises and requiring emergency assistance annually has climbed from 15 before 2001, to more than 25 since then (UN ESC/ECA, 2009). Populations affected by crises include those displaced across international borders (refugees living in camp situations and or integrated with host populations<sup>3</sup>), those internally displaced within their own countries, as well as those remaining in their places of origin who are affected by war or drought or a combination of both.

International emergency response is often referred to as international “humanitarian action,” which includes both the provision of humanitarian assistance to meet material needs, and also humanitarian protection – which means ensuring safety from acute harm and broader protection considerations of protecting and upholding rights. Humanitarian action has strong legal foundations in international humanitarian law, and the core humanitarian principles of humanity, impartiality, neutrality, and independence that are derived from this (IASC, 2002).

<sup>1</sup>Public nutrition is a broad-based, problem-solving approach to addressing malnutrition in complex emergencies that combines analysis of nutritional risk and vulnerability with action-oriented strategies, including policies, programs, and capacity development (Young *et al.*, 2004a).

<sup>2</sup>A natural hazard may be classified as either “slow onset” (e.g. drought) or “sudden onset” such as floods, tropical cyclones, tsunamis and strong wind, storm surges, forest fires, landslides, and sand- or dust storms.

<sup>3</sup>A refugee is a person who: “owing to well-founded fear of being persecuted . . . is outside his country of nationality” (1951 Refugee Convention, <http://www.unhcr.org/pages/49da0e466.html>). In contrast an internally displaced person (IDP) has been forced to migrate within their own country.

Within the context of climate change, disaster management is also increasingly becoming encapsulated by the newer concept of disaster risk reduction, which is concerned with the development of policies and practices that will reduce risk and vulnerabilities throughout society. It has been widely adopted by the UN system and has its own global platform and initiatives (Schipper and Pelling, 2006). Increasing attention has been given over recent years to early recovery in conflict settings as part of a broader stabilization policy agenda that is aimed at building foundations for transition and recovery and includes a strong capacity-development component (Bailey and Pavanello, 2009). In the short term the humanitarian imperative may need to take priority, but should build upon and strengthen local systems where possible. Irrespective of the nature of the natural disaster or complex emergency, the overall approach to nutrition in emergencies described in this paper will apply, and is reflected in the wider body of best practice and literature referenced here.

### **Malnutrition in Emergencies**

An elevated prevalence of acute malnutrition, as measured by the weight-for-height z-score of children under 5 years of age, is the most widely used indicator to gauge the severity of an emergency and plan for an adequate response. Generally higher rates of acute malnutrition have been recorded in emergencies in East Africa and countries bordering the Sahara, with relatively lower rates in southern Africa and Asia. There are, however, always exceptions, with high rates of acute malnutrition reported in Bangladesh and Nepal. Recent examples are shown in Table 69.1. Extreme crises, usually associated with conflict, forced displacement and insecurity, have produced prevalence rates exceeding 50%, for example in southern Sudan during the 1998 famine (Borrel and Salama, 1999). In the past decade, similar extreme rates have not been reported. This may be indicative of a more effective and efficient international response (there have been a number of acute crises, including Darfur, Niger, and Pakistan), but could also be a result of a relative lack of data characteristic of protracted and “silent emergencies.”

The prevalence cut-off point used by the World Health Organization to indicate an emergency is 15% (WHO, 2000), although prevalence of acute malnutrition varies widely on a seasonal basis, intra-annually and also geographically (Young and Jaspars, 2009). In some protracted crises, global acute malnutrition (GAM) may appear to

**TABLE 69.1** Examples of prevalence of acute malnutrition and other indicators from recent emergencies

Country	Region	Date	Context	GAM	Remarks
SE Ethiopia	Metta Woreda, East Hararghe zone	10/2009	Chronic food insecurity is a problem	11.4 (8.6–14/2) <sup>a</sup>	Stunting: 26.5% (20.6–32.4)
NE Kenya	Mandera East and West Districts	03/2009	Residents recovering from drought – surveys done before long rainy season	Ranges from 20.5% (16.6–24.4) to 32.3% (28.2–36.4) <sup>a</sup>	Low dietary diversity also reported
Somalia	Countrywide problems of drought and conflict-related insecurity	2010	South and central most affected	National average GAM 16% <sup>a</sup>	42% of the population in need of assistance
Sudan	North Darfur State	05–07/2009	Displaced and residents	Ranges from 16.9% to 34.5% <sup>b</sup>	Conflict- and drought-related food insecurity
Democratic Republic of Congo	Lubunga, Oriental Province	2009	Displaced by Lord's Resistance Army attacks	8.7% (6.1–11.4) <sup>a</sup>	Large numbers of abandoned illegitimate children
Uganda	West Nile, Northern Region	08/2009	Refugee settlements	<5% <sup>a</sup>	Anemia rates (children 6–59 months and women of reproductive age) ranged between 54% and 79%
Afghanistan	Jawsan province	05/2009	Residents	6.8 (5.2–8.8) <sup>a</sup>	Prevalence of stunting 55.3% (50.8–59.7)
Haiti	Port-au-Prince and nearby cities	2009	Earthquake 01/2010	Pre-crisis GAM 4.5%	Increase in GAM expected

<sup>a</sup>WHO growth standards.<sup>b</sup>NCHS reference population.

GAM, global acute malnutrition.

Reproduced with permission from SCN NICS, (2010).

remain at unacceptably high levels for several years if not decades after the original emergency occurred. For example, Table 69.1 shows the range in rates in North Darfur in mid-2009 which all exceeded the emergency threshold. Increasing emphasis is being placed on context-specific trends, especially where the baseline prevalence is low to start with and therefore would have to rise dramatically to reach the emergency threshold.

Not all emergencies are characterized by increases in acute malnutrition, and in some situations micronutrient deficiency diseases (MDDs) may be a greater public health priority than acute malnutrition. For example, among refugees in northern Uganda the level of acute malnutrition remained well below 5%, although rates of anemia were between 54% and 79% (Table 69.1). Dye (2007) reviewed prevalence of micronutrient deficiencies in refugee settings worldwide and concluded that significant micronutrient deficiency continues to occur with regularity. Comparatively few studies have documented prevalence of micronutrient deficiencies in emergencies compared with assessments of acute malnutrition (Dye, 2007; Seal and Prudhon, 2007; Seal *et al.*, 2007).

### **Nutritional Risk and Causes of Malnutrition in Emergencies**

As a result of most emergencies there is likely to be increased nutritional risk associated with forced displacement, overcrowding, inadequate supplies of clean water, and poor sanitation. These all contribute to increased incidence of infectious disease. At the same time vulnerability is heightened by food insecurity, reliance on limited food rations, and social disruption that negatively affects child-caring behaviors. This represents a worsening of all three clusters of underlying causes of malnutrition, which relate to food, health, and care. UNICEF's original conceptual framework for the analysis of the underlying causes of malnutrition as part of its "triple A" approach (UNICEF, 1990) has been widely adopted in policies and good-practice guidelines for emergencies. It has been used to help decision-makers recognize and understand the principal causes of malnutrition (Young and Jaspars, 2006). In the most severe emergencies, a sudden deterioration in all three groups of underlying causes accounts for the extremely high prevalence and occurrence of "hotspots" (Young and Jaspars, 2006), although in less severe situations there are frequently debates between sectors as to the priority problem: food, health or care. In some protracted crises there are no obvious external shocks or hazards that

have precipitated the emergency; rather, it is the combination of economic and political crises, and possibly conflict and insecurity, which undermines nutrition.

## **Assessment and Analysis of Nutrition in Emergencies**

### **Assessing Nutritional Status of Children**

Weight-for-height is the preferred nutritional index in emergency contexts as it reflects recent nutrition and wasting, and does not require the exact estimation of age, which might be difficult. The weight-for-height z-score of an individual child is calculated by comparing their measurements with an international reference or standard. In 2006, the WHO introduced a set of child growth standards which are now gradually replacing the 1977 NCHS/WHO growth reference for weight-for-height in surveys (Seal and Kerac, 2007; SCN, 2009). The growth standards are based on prescriptive criteria, which seek to define how children should grow. This involves value or normative judgments (de Onis *et al.*, 2007a).

Categories of severe acute malnutrition (SAM) include less than  $-3$  z-scores for severe acute malnutrition (SAM) or nutritional edema. The category of GAM includes less than  $-2$  z-scores and nutritional edema. Children classified as suffering from moderate acute malnutrition (MAM) fall between the two, i.e.  $>-2$  and  $<-3$  z-scores with no nutritional edema.

The switch from the NCHS reference to the WHO standards has implications for prevalence estimates and numbers admitted into feeding programs. Studies indicate that the overall prevalence of GAM (wasting and/or edema) changes relatively little, but there is a significant increase in the prevalence of SAM. In turn this means an increase in the number of children eligible for admission into therapeutic feeding programs (Seal and Kerac, 2007; SCN, 2009). To allow comparisons, information systems such as SCN NICS report results in relation to both the NCHS reference and WHO standards.

The measurement of mid-upper-arm circumference (MUAC) for children aged between 1 and 5 years is a tool used for nutritional screening and increasingly for admission criteria for therapeutic and supplementary feeding programs. The arm circumference of infants and young children increases on average 1 to 2 cm up to 5 years of age. This means proportionally more younger children will be eligible for therapeutic feeding if a standard cut-off of 11.5 cm is used (WHO and UNICEF, 2009). This may

be desirable as younger children tend to suffer higher mortality rates. MUAC may be used in surveys to estimate numbers of children eligible for therapeutic feeding programs, but is not useful for overall estimates of GAM as the results are not comparable with weight-for-height estimates (Myatt *et al.*, 2009).

### **Assessing Nutritional Status of Adults and Adolescents**

Underweight among adults, often referred to as chronic undernutrition, has been reported as a public health problem in emergencies, for example in Somalia in 1992 (Collins and Myatt, 2000), Ethiopia in 2000 (Salama *et al.*, 2001), and South Sudan in 1998 (Borrel and Salama, 1999). Debate continues over the indices that should be used (MUAC vs. BMI), cut-off points and interpretation. A recent review recommended that low BMI (<18.5) among non-pregnant women aged 15 to 49 years, as used by WHO and WFP and in recent global meta-analyses (Black *et al.*, 2008), should be included as an indicator for monitoring food security and humanitarian crises (Young and Jaspars, 2009). Several issues affect interpretation of BMI data, including the need to adjust for body shape (sitting height to standing height ratio), the decline in height with older age, adaptation, and seasonal fluctuations (Young and Jaspars, 2006). The adjustments for body shape can be made using the Cormic Index (Collins, 2001), although this is not routine practice (Busolo, 2002).

There is no universally agreed definition of acute malnutrition in older people. If anthropometric measurement such as MUAC is used, HelpAge International recommends the WHO standard cut-off points in conjunction with the contextual, social, and clinical criteria and risk factors which are the key determinants of nutritional vulnerability among older people (Wells, 2005). Arm span and knee height can be used as proxies for height among the elderly, although their relationship to height for different ethnic groups has not been established (Busolo, 2002).

MUAC, in conjunction with clinical criteria (ability to stand, edema, and dehydration), has been used as a tool for rapid assessment of adults and older people, although the functional outcomes of different MUAC cut-offs are unknown. While child acute malnutrition is a composite indicator of poor health, lack of food, poor caring practices, etc., chronic undernutrition of adults at the population level is more intuitively a direct outcome of food insecurity and therefore potentially useful in emergencies.

However, the HIV epidemic does mean that there are increasing numbers of severely wasted adults, particularly in parts of Africa.

For adolescents, the variable age for the onset of puberty complicates measures of nutritional status. WHO has published the WHO 2007 Reference for school-aged children and adolescents, comprising BMI-for-age and height-for-age, for 5–19 years, and weight-for-age for 5–10 years (de Onis *et al.*, 2007b). In emergencies the WHO recommends that BMI-for-age be used by programs that target this group.

### **Assessing Nutritional Status of Populations**

In emergencies, the two-stage 30-cluster nutrition survey is a well established and standardized tool for estimating the prevalence of acute malnutrition among children less than 5 years of age (SCF UK, 2004). While this approach has acceptable levels of precision for most contexts, in some cases a context-specific sample size is calculated (Kaiser *et al.*, 2006; Bilukha, 2008).

Nutrition surveys may include other nutrition and health indicators including crude mortality rate (CMR) and under-five mortality rates (Cairns *et al.*, 2009). Other useful indicators include vaccination coverage, vitamin A distribution coverage, or access to safe water sources. Food security indicators include receipt of rations, food frequency, and dietary diversity (Coates *et al.*, 2007), although these are usually collected as part of a broader household survey.

### **Interpretation; Classification Systems and Decision-Making Frameworks**

The standardization of survey methods and analysis over the past decade has resulted in more reliable data. Challenges, however, remain with interpretation and in reaching valid conclusions. Two approaches and sets of tools have been developed for the interpretation of nutrition indicators. The first relates to the use of benchmarks as part of classification systems intended to monitor the severity of a humanitarian emergency or food security situation (see Case Study 1). The second are the decision-making frameworks designed to assist in prioritizing the most appropriate direct nutrition interventions.

Selective-feeding decision-making frameworks that combine benchmarks of nutritional status with “aggravating factors” (such as mortality, morbidity, and access to food) have been proposed and used to advise practitioners on the most appropriate intervention. However, the utility

### Case Study 1 Nutritional surveillance as part of the Integrated Food Security Phase Classification System for classifying the severity of food insecurity and humanitarian crisis

Nutrition indicators have been used to gauge the severity of famine and complex emergencies for nearly half a century. There have been considerable efforts to standardize their use, including reaching agreement on reference levels that correspond to particular stages of food insecurity and humanitarian crises. A partnership of UN agencies, NGOs, and donor agencies has jointly developed a globally applicable food security severity scale, known as the Integrated Food Security Phase Classification (IPC, <http://www.ipcinfo.org/>). The IPC aims to provide a common technical approach to classify food security according to reference outcomes that are based on recognized international indicators. Indicators of wasting, chronic malnutrition, and mortality have been included in the IPC as “key reference outcome indicators” since its inception in 2004. Reference levels for each indicator (thresholds) have been attributed to each of the five phases of the classification (from generally food secure to famine/humanitarian catastrophe). For example, Phase 5 Humanitarian Catastrophe/Famine corresponds to a prevalence of acute malnutrition >30%; while Phase 4 Humanitarian Emergency corresponds to >15%, or GAM greater than usual and increasing. Such a scale facilitates comparisons between countries and over time, for decision-making about appropriate policies, programs, and resource allocation. The IPC has been introduced in several countries in Africa and Asia, and continues to gain momentum among governments, the UN, NGOs, and donors.

of this framework may be limited in some contexts. For example, the prevalence of acute malnutrition may remain consistently higher than the benchmark (see, for example, Darfur in Table 69.1). A further limitation of this decision-making framework is that it is prescriptive and does not allow for possible non-food interventions that may positively affect population nutritional status or encourage more innovative interventions tailored for the context.

#### **Nutritional Surveillance and International Tracking Systems**

Nutritional surveillance monitors changes in malnutrition and population nutritional status over time for the purposes of problem identification and advocacy, timely

warning and intervention, resource allocation and targeting, and program monitoring. In emergencies, usually one or more of the following three methodological approaches are used. These include: representative nutrition surveys conducted every 2–12 months (Johnecheck and Holland, 2007), clinic-based surveillance data (based on existing growth monitoring data), and a purposively selected sentinel-site food security and nutritional surveillance system (Myatt, 2009). These approaches all have advantages and drawbacks. Regularly conducted nutrition surveys are relatively resource intensive but do provide valid and reliable data. Clinic-based surveillance potentially strengthens the capacity of existing clinics although the data may not be representative or timely. Sentinel-site surveillance provides timely and relevant data but it cannot be extrapolated to the wider population.

Nutritional status is limited as an early warning indicator since it is generally considered to be a late indicator for the deterioration in the nutritional situation. None the less, an analysis of trends can reveal deviations from normal patterns.

Internationally, there are a number of systems designed to monitor nutrition in emergencies. These include regular bulletins from the Nutrition Information in Crisis Situations [formerly the Refugee Nutrition Information System (RNIS), available on <http://www.unscn.org/en/publications/nics/>]; the Health and Nutrition Tracking System [Health and Nutrition Tracking Service (HNTS), 2009]; and the CRED (CE DAT, 2010).

#### **Food Security and Livelihood Assessments**

Assessments of food insecurity and the impact of emergencies on livelihoods are assessed using specific approaches and methods (Seaman *et al.*, 2000; Young *et al.*, 2001; WFP/VAM, 2005). Many food security assessment approaches share the same conceptual understanding of food security and use similar data collection tools, although methods tend to be less standardized than nutrition survey tools. In general, they identify and disaggregate information using different livelihood or food economy groups and use qualitative methods to investigate the food security situation. Components of food security that are considered include access to food, food availability, and, in some situations, food utilization. An analysis of trends and recent changes in food security and livelihoods is crucial for understanding the situation and for designing the appropriate response.

## Addressing the General Nutritional Needs of Populations

A range of intervention strategies are required to address the multiple nutritional risks that occur in emergencies, the choice of which is based on a process of assessment, analysis and prioritization and, in most cases, will be unique for a given situation.

### **Food Security Interventions and Protection of Livelihoods**

Addressing food insecurity and protecting livelihoods has become a recognized component of a nutritional response in complex emergencies (Sphere Project, 2004; Jaspars, 2006) since these are critical for protecting and supporting nutrition albeit through indirect pathways. Increasingly a

range of food security interventions are applied that help people meet their food needs, earn income, and protect their assets, and these are summarized in Box 69.1 (Maxwell *et al.*, 2010). For example, recognizing the importance of livestock for maintaining the nutritional status of children in pastoralist areas across the developing world has long been recognized (Sadler *et al.*, 2009) and there is now an increasing interest in using emergency livestock-related interventions to protect primary resources during drought, to maintain access to milk and animal products for nutritionally vulnerable groups, and to improve the cost-benefit of drought-based interventions (Catley, 2008; Catley *et al.*, 2009).

Different contexts will determine which types of strategies are required. For non-displaced populations whose livelihoods are relatively intact, the interventions described

### **BOX 69.1 Examples of food security projects in emergency contexts**

*Definition:* Food security exists when all people at all times have physical and economic access to sufficient, safe and nutritious food for a healthy and active life (World Food Summit Plan of Action, paragraph 1, 1996: FAO, 1996).

#### *Agricultural production*

1. Distribution of seeds, tools, and fertilizer.
2. Seed vouchers and fairs: bring together sellers and buyers.
3. Training and education in relevant skills.
4. Livestock interventions: animal health services; emergency destocking; restocking of livestock; distribution of livestock fodder and nutritional supplementation; and provision of alternative water sources.
5. Distribution of fishing nets and gear, or hunting implements.
6. Promotion of food processing, milling, and fortification.
7. Local agricultural extension and veterinary services.

#### *Safety nets*

8. Cash or Food-for-Work (CFW) provides food-insecure households with opportunities for paid work that at the same time produce outputs of benefit to themselves and the community
9. Income generating schemes allow people to diversify their sources of income in small-scale, self-employment business schemes.

#### *Market interventions*

10. Support of market infrastructure, e.g. transportation to allow producers to take advantage of distant markets.
11. Destocking: livestock purchase usually from pastoralists in times of drought.
12. Fair-price shops: sale of goods at controlled or subsidized prices.
13. Vouchers: which can be used to purchase or "redeem" a specified and predetermined range of goods and services.
14. Cash transfers: the provision of cash, which can either be unconditional or tied to a particular type of expenditure.

#### *Microfinance projects*

15. Credit and saving schemes: grants, loans, cattle or other livestock banks; cooperative savings accounts.

### Case Study 2 Understanding the impact of livestock interventions on milk production and child nutrition

A recent study in the Shinile and Liben zones of Somali Region, Ethiopia, in 2009 documented the large contribution of animal milk to the dietary intake of young pastoralist children. When available, mothers added milk to most complementary foods. During a normal wet season, the average milk intake of a 1-year-old was estimated to provide about two-thirds of the mean energy required and 100% of the protein required by a child of this age. During a drought year, mothers estimated that milk intake by young children declined to negligible amounts and, in all cases, was replaced by cereal grain cooked and consumed with little else but water. Such a severe reduction in milk intake had a serious impact on dietary quality by reducing the amount of high quality protein, fatty acids, and micro-nutrients that young children consumed.

In a separate program in Ethiopia in 2008, Save the Children USA implemented an animal supplementary feeding project in Borana zone. Two of the feeding centers were evaluated and 48.6% (191/393) of cows either returned to milk production or began milk production following the birth of calves while in the feeding centers. These results were compared with the performance of cows outside the feeding centers, where lactation ceased. In one center the mean daily milk yield was 0.7 L/day (95% CI 0.44, 0.97;  $n = 46$ ) and the estimated total milk production was 2276 L while cows were fed in the feeding center. In the other feeding center the mean daily milk yield was 0.9 L/day (95% CI 0.64, 1.22;  $n = 63$ ) and the estimated total milk production was 3364 L while cows were fed in the feeding center. Informants stated that this milk was fed to children.

Studies such as these have shown that pastoralists themselves make logical associations between livestock health and production, milk supply, and human health and nutrition. However, there remain many opportunities for livelihoods projects in emergencies to design livestock interventions through a child-nutrition lens. Documentation of the impact of such projects would go some way to providing a better understanding of the most appropriate and effective responses in pastoral areas to protect the nutritional status of children.

Adapted from Bekele and Tsehay (2008) and Sadler and Catley (2009).

in Box 69.1 may be appropriate. In contrast, for populations displaced to camps, both refugees and IDPs, the opportunities for such innovative interventions may be

limited as a consequence of lack of land or employment opportunities and the absence of markets that function. The process of prioritizing different interventions is a balance between relatively top-down short-term responses intended to save lives and reduce mortality (such as provision of general food assistance), and longer-term solutions that protect and support people's livelihoods and in so doing indirectly save lives and preserve people's dignity. This concept, and the challenges linked to it, are illustrated well by the international response to the ongoing crisis in Darfur (Young, 2007).

### The Food Assistance Toolbox

General food distribution is the provision of dry food rations to those households deemed in need of food assistance. It has long been the most common strategy for ensuring that the nutritional needs of an emergency-affected population are met, and it remains the biggest single category of emergency response (Harvey *et al.*, 2010b). More recently there has been considerable debate about what types of intervention fit within the food assistance toolbox, with a particular focus on the use of vouchers and cash transfers as an appropriate alternative or complement to food aid for the protection and/or improvement of a population's food security and nutritional status. This is reflected in revised policy positions by, for example, WFP: "Food assistance refers to the set of instruments used to address the food needs of vulnerable people. The instruments generally include in-kind food aid, vouchers and cash transfers" (WFP, 2008b), and in practice, where the use of cash in responding to disasters is growing (Harvey, 2007).

### General Food Distribution

A well-established body of best practice exists for the planning, distribution, and targeting of nutritionally adequate food rations including for populations suffering high levels of HIV (UNHCR *et al.*, 2002; WFP, 2002; FANTA/WFP, 2007). A nutritionally adequate ration is calculated on an average per capita energy requirement basis. An initial planning figure of 2100 kcal (8.8 MJ) per person per day is used, which is adjusted to suit specific conditions of the crisis; for example, the ambient temperature, demographic profile, activity levels, and the health status of the population. The recommended amount of total fat and protein in the ration is calculated based on percent of energy that each provides; 10–12% of energy should be obtained from protein and 17% of energy from fat.

Nutritionally adequate rations must also provide a source of micronutrients (see later in this chapter). In addition, general food rations should be culturally acceptable and safe for human consumption, comprise a variety of foods, be digestible for children, be fuel efficient, and be easy to store and prepare.

To fulfil these criteria, rations typically consist of a cereal such as sorghum, maize, wheat, or rice, a legume or pulse, and some oil or fat. These commodities are supplied in bulk, which facilitates the logistics and their distribution. High-profile acute crises continue to attract donations of foodstuffs unsuitable for emergency responses, which present challenges as to their practical use or their disposal, for example, US military ready-to-eat ration packs (MREs), high-protein biscuits, and infant food.

It is the policy of WFP and UNHCR either to provide the cereal grain in the form of milled flour, or to supply milling equipment during the initial response to a crisis. Milling greatly improves the digestibility of cereal grain for young children and older persons and the fuel efficiency of the cooking process. Where prevention of malnutrition in vulnerable groups such as children and pregnant or lactating women is a priority, a fortified blended food (FBF) is usually provided. The US government developed FBFs in the 1960s to serve as a protein-rich, micronutrient-dense food supplement appropriate for preschool-aged children in developing countries. Recent review has suggested that the formulation of these foods could be optimized to better meet the nutritional requirements for different vulnerable groups (de Pee and Bloem, 2009; Fleige *et al.*, 2010). In addition, they are likely to be increasingly used with other highly fortified foods such as the new lipid-based nutrient supplements (LNS) which are being considered for use in rations for groups with particularly high nutritional requirements (such as young children and pregnant and lactating women) (Chaparro and Dewey, 2009). Frequently, ration commodities may be sold or exchanged in order to obtain cooking fuel, to pay for milling costs, or to access a range of food items not provided in the ration.

Targeting strategies and distribution mechanisms are planned to ensure that the food ration reaches the affected communities in the most efficient and effective way. Targeting is closely linked with the assessment process, which identifies the worst affected geographical areas and/or the worst affected population groups within these areas. Identifying and reaching these groups is often challenging, particularly in areas where geographical access is limited;

a common characteristic of complex emergencies (see Case Study 3).

### **Case Study 3 From an acute to a protracted crisis: shifts in programming approach in the Darfur context, 2010**

In the 7 years since the eruption of the civil war and mass forced displacement that triggered the Darfur complex emergency, there has been little evidence of significant permanent returns of the displaced to their places of origin. Instead conflict and insecurity continue to restrict mobility and access, and the long-term displaced have sought to adapt their livelihoods to their new settings, which includes some seasonal returns to their farms. But despite these adaptations the long-term displaced remain chronically vulnerable, and emergency levels of global acute malnutrition are common. Food assistance remains the single largest sector reaching, at the time of writing, up to 3 million conflict-affected people.

The World Food Programme and their operational partners have taken several strategic steps to tailor their programs to the changing context. First they have replaced their annual food security and nutrition assessments with a more appropriate sentinel-site food-security monitoring system. In their food distribution programs they have sought to reduce “errors of inclusion,” i.e. to ensure food does not flow to those who do not need it, by further targeting the food-insecure. The mode of distribution has also changed from distributing to individual households to group distribution, which is managed by a community-based Food Relief Committee (FRC) comprising community-nominated representatives. The FRCs are intended to promote more community participation in the actual distribution and targeting of food aid in line with WFP policies. The introduction of the FRCs took place prior to the government expulsion of 13 INGOs in 2009, and their presence enabled WFP to continue food distributions throughout this difficult period.

In 2009, to complement the ongoing general food distribution program, WFP introduced a safety-net program (distribution of fortified blended food) to all households with children under 5 years of age in those areas with emergency levels of acute malnutrition. At the same time, on a trial basis, they introduced a voucher scheme to be scaled up in 2010. Such initiatives reflect a transition from emergency programming in an acute crisis to an approach that is better suited to a protracted emergency, although capacity to respond to acute humanitarian crises needs to be maintained.

Adapted from Young and Maxwell (2009).

### **Cash and Vouchers**

Despite the relatively recent experience of cash and voucher schemes, numerous best practice guidelines and policy documents already exist (Creti and Jaspars, 2006; ACF, 2007; WFP, 2008b; Harvey *et al.*, 2010a). The most common interventions in this category used to address the nutritional needs of a population affected by crisis are:

- Cash transfers: the provision of cash, which can be either unconditional or tied to a particular type of expenditure.
- Vouchers: which can be used to purchase or “redeem” a specified and predetermined range of goods and services.

Generally cash transfers appear to be most suited to stable or peaceful contexts, where strong and accessible markets and banking systems exist. These conditions most often apply to later stages of a crisis (Harvey, 2007). Vouchers require that traders in targeted areas be identified and agreements set up with them for exchange. There is limited evidence to date that documents the direct impact of either cash or vouchers on the nutritional status of a population, but the evidence that does exist suggests that vouchers may be more effective than cash in meeting particular nutritional objectives (WFP, 2008b). This may be due to the greater control that women generally have over food and vouchers as opposed to cash resources, and to the fact that cash may be used for meeting needs that are not directly related to nutrition. Cash and vouchers can be productively combined with food transfers to mutually reinforce objectives that relate to addressing food insecurity and malnutrition.

### **Public Health Interventions**

Malnutrition may be caused or exacerbated by disease, therefore a range of public health strategies are required to promote and protect health. In the emergency phase the priorities include initial assessment, public health surveillance, control of communicable diseases and epidemics (diarrheal diseases, measles, acute respiratory infections, and malaria), water and sanitation, and shelter and site planning (Salama and Roberts, 2005). Other specific issues of direct relevance to nutrition include curative health care, child health care, HIV/AIDS, and psychosocial and mental health services. The prevailing HIV/AIDS epidemic in southern Africa is undermining the ability of communities to recover from famine, as it directly affects able-bodied adults who are the most productive in terms

of food security (de Waal and Whiteside, 2003). Despite great advances in knowledge around the basic interventions that should be prioritized in emergencies, reviews of the global relief system suggest an ongoing failure to deliver (Checchi *et al.*, 2007). This reflects the huge challenges to delivery often seen in humanitarian emergencies, including very large geographic areas, extremely poor infrastructure, and conflict.

### **Reaching the Physiologically At-Risk Groups**

Nutritional vulnerability in humanitarian crises is often exacerbated for certain groups because of their particular nutritional requirements or because of the physiological risks that they face. Examples include infants and young children, older people, women of reproductive age, and people with specific health conditions such as HIV/AIDS. Often referred to as nutritionally vulnerable groups, their specific needs may be met by additional programs including, for example, those targeted at specific population groups, or the adaptation of broad-based safety-net programs. Targeting individuals within a population requires a system for identifying and registering those who will then benefit from the intervention. This type of parallel program is not always cost-effective or feasible, although it is attractive as it potentially reduces the likelihood of resources reaching those who are not at greatest risk.

### **Adapting Broad-Based Safety-Net Programs**

Safety-net programs seek to protect the vulnerable and prevent them from falling further into poverty or food insecurity by providing safety-net transfers such as food stamps or vouchers, subsidies, cash transfers, public works, etc. Broad-based safety-net programs can be adapted to better meet the needs of the nutritionally vulnerable, which mitigates the need for additional parallel programs targeting these groups. For example, the International Committee of the Red Cross (ICRC) has for many years implemented a policy whereby the general ration has been increased above that of other international agencies (2400 kcal per person per day, as opposed to the 2100 kcal recommended by other agencies) in order to obviate the need for a separate nutrition program (Navarro-Colorado *et al.*, 2008). Cash transfers, rather than food assistance, are increasingly being considered as a means to support the vulnerable, particularly in protracted humanitarian crises. While cash transfers are targeted on the basis of

socioeconomic criteria, when combined with targeting of women of reproductive age and implemented with nutrition education, these programs enable women to meet their own and their children's additional requirements through the additional household income received. Monitoring of intra-household food distribution and/or nutrition education and awareness may be necessary to ensure that the most physiologically vulnerable do benefit.

### **Targeting Specific Age Groups with Nutrition Interventions**

Exclusive breastfeeding for a duration of 6 months reduces morbidity and mortality among children (WHO, 2002). Humanitarian crises present additional risks for infants who are not breastfed. Poor sanitation and overcrowding, high prevalence of infectious diseases, a lack of access to clean water and cooking fuel for safe preparation of breast-milk substitutes (BMS), and a lack of a regular supply of BMS imply even greater risks associated with not breastfeeding (Kelly, 1993). Adherence to World Health Assembly legislation is frequently compromised, and unsolicited donations of BMS are often reported (Borrel *et al.*, 2001), including in the recent catastrophe in China (Coutsoudis *et al.*, 2009). A number of inter-agency and agency-specific policies and guidelines address the protection, promotion, and support for exclusive breastfeeding in humanitarian crises (Seal *et al.*, 2001). However, the application of these policies in practice is often poor, constrained by a lack of institutional memory and available expertise as well as a failure in agency leadership and coordination (Borrel *et al.*, 2001).

There are well-recognized challenges associated with designing effective programs and policies in countries which have pre-existing poor breastfeeding practices. For example, changes in practice brought about through individual counseling may not always be possible in humanitarian crises because of a loss of skilled community health workers and poorer access to the population. Recent evidence from Zimbabwe has highlighted the importance of ensuring that women receive support from their husbands, mothers-in-law, and other influential community members. Positive attitude change among family members can be achieved through innovative, feasible, and effective interventions such as road shows that reach a high proportion of the population (Jenkins, 2011). The increase in prevalence of HIV/AIDS has brought new challenges, and the absence of clear and consistent guidance for HIV-positive women in the past may have had a negative impact and

undermined exclusive breastfeeding practices in the broader population. It is now recommended that mothers known to be HIV-infected should exclusively breastfeed their infants for the first 6 months of life, introducing appropriate complementary foods thereafter, and continue breastfeeding for the first 12 months of life (WHO, 2009). For women known to be HIV-positive and intending to breastfeed, extended antiretroviral prophylaxis for mother and infant throughout the breastfeeding period is recommended. Mothers known to be HIV-infected may consider expressing and heat-treating breast milk as an *interim feeding strategy*. For mothers whose status is not known, which is common in humanitarian crises, exclusive breastfeeding for 6 months is promoted and it is recommended that mothers are counseled for testing (Leyenaar, 2004).

The nutritional requirements for women during pregnancy and lactation are higher than the population average (WHO, 2000). Consequently, macronutrient (food) and micronutrient (iron and folic acid) supplements are usually provided to all pregnant and lactating women during pregnancy and for the first 6 months of breastfeeding, through emergency supplementary feeding programs (SFPs) or mother-and-child health clinics. If food resources are scarce, only some pregnant and lactating women are targeted, those with a MUAC of less than 21–23 cm (WHO, 1995). Evidence of the impact of providing macronutrient and micronutrient supplements to women for this short period is limited. Poor impact may be as a result of intra-household distribution patterns, ambiguity of the outcomes to be measured, a lack of opportunity to improve pre-pregnancy nutritional status, and limited possibilities for integrating nutrition interventions with other public health programs.

The nutritional risks that older people normally face are likely to be exacerbated in humanitarian crises because of the loss of support systems as a result of family separations or the disruption of informal and formal social networks. Furthermore, their needs may extend well beyond the acute crisis. For example, following the cyclone in Myanmar, older people received adequate food assistance, but equal emphasis needed to be placed on their longer-term food security needs (HelpAge International, 2009). Increased nutritional risk for older people may be as a result of lack of access to health care, exposure to the cold, psychological stress, and constraints on food preparation (Vespa and Watson, 1995), and a lack of mobility, limited employment opportunities, lack of access to land, food, and basic services, and psychosocial trauma (Pieterse and

Ismail, 2003). However, older people are still seldom involved in nutritional assessments, in decision-making about food aid requirements or in program design. As a result, programs often do not include them, or reflect their needs.

### **Populations Affected by Disabilities and Chronic Illnesses such as HIV and Tuberculosis**

Food supplements are frequently targeted to individuals with disabilities, those with chronic illness, those receiving TB treatment, and, increasingly, persons with HIV/AIDS. The objectives of nutrition in this context are usually multiple, including strengthening household food security, meeting specific additional requirements, facilitating recovery from secondary acute malnutrition, and improving compliance with treatment regimes. While humanitarian crises do not necessarily cause an increase in HIV prevalence (Samuels, 2009), regional and national food insecurity is frequently associated with epidemics of HIV/AIDS. At the individual level, malnutrition and HIV/AIDS are inextricably linked. Malnutrition, reduced food intakes, and micronutrient deficiencies are associated with more rapid disease progression of HIV/AIDS. Nutrition interventions potentially have a wide range of benefits for HIV-related outcomes; however, their impact depends on the type of intervention, the duration for which it is given, and the underlying vulnerability of the infected person. Interventions range from support for appropriate breastfeeding regimes, nutrition-relevant education, micro- or macronutrient supplements, referral for treatment of secondary acute malnutrition, and interventions to strengthen household food security. HIV-affected persons should consume 20–100% above normal energy intakes depending on whether the individual is an adult or child, asymptomatic or symptomatic, and experiencing weight loss or no weight loss (Ivers *et al.*, 2009). Furthermore, multi-micronutrient supplements have been shown to have beneficial effects on morbidity and other outcomes for HIV-affected children and adults, and have been recommended as interventions complementary to treatment regimes (Fawzi *et al.*, 2005). Nutrition supplements alone are, however, insufficient, and need to be combined with other interventions such as treatment, counseling, care, and food security. There is increasing evidence to show that HIV-positive children who are malnourished respond well to adapted treatment protocols in regular community-based management of acute malnutrition (CMAM) programs, which can also be an opportunity to strengthen the

referral system for these children for ART treatment (Fergusson, 2009). In the absence of testing and treatment of HIV/AIDS, the targeting of these combined interventions remains problematic. While there is an increase in the available guidance on food assistance in the context of HIV/AIDS (FANTA/WFP, 2007; World Bank, 2007; WFP, 2008a), documentation and institutional experience of effective strategies are limited.

In conclusion, in most humanitarian crises there is a need to consider how nutrition programs can reach those with additional nutritional requirements, through both broad-based approaches and parallel programs targeting specific groups. In chronic protracted crises, it becomes increasingly important to adapt broad-based safety-net programs.

### **Preventing and Treating Micronutrient Deficiency Diseases**

There are several risk factors common to emergency-affected populations that precipitate micronutrient deficiency diseases (MDDs). These include a reliance on general food rations; reduced access to markets or livelihood systems that would normally support access to a diverse range of foods; and increased exposure to infectious diseases such as diarrhea due to a poor public health environment. Consequently, micronutrient deficiencies have been reported for years in emergency settings, particularly among refugees, where they are most frequently assessed (Seal and Prudhon, 2007). MDDs most commonly reported include those that are endemic across the developing world such as vitamin A, iron, and iodine deficiency disorders as well as other MDDs that are specific to the emergency context including pellagra, scurvy, and beriberi (Cheung *et al.*, 2003; Seal *et al.*, 2005, 2007).

As a result of these outbreaks, the last two decades have seen increasing acknowledgment by UN agencies and NGOs that the nutrient content of a ration should not only meet minimum energy needs but should also help to prevent micronutrient deficiencies (Webb *et al.*, 2009b). This is particularly important for nutritionally vulnerable groups such as young children and pregnant and lactating women, who have increased requirements. To achieve this and, where necessary, to treat MDDs, a range of strategies are used. These include improving access to foods rich in micronutrients, the provision of fortified food commodities, and supplementation.

### **Improving Access to Foods Rich in Micronutrients**

A diverse diet is the most preferred method to ensure consumption of sufficient micronutrients to meet requirements. Although the provision of a fresh food commodity in the general food ration that is rich in one or more micronutrient(s), such as pulses, groundnuts, red palm oil, fruits, and vegetables, can be a strategy to prevent one or more deficiencies (Malfait *et al.*, 1993), it is costly and logistically difficult and is therefore rarely implemented. The move by WFP to increase the use of vouchers and cash transfers in place of direct food assistance was discussed earlier. In the right context, where markets are functioning and accessible and food supply is stable, evidence has shown that both types of intervention can improve households' access to nutrient-dense foods without the high costs of including fresh commodities in the food basket (WFP, 2008b). The use of livestock interventions is also a means to improve access to micronutrient-rich animal source foods for emergency-affected populations. Documented evidence of the impact of these interventions on nutritional status is, however, scarce.

### **Food Fortification**

Food fortification in emergencies is most commonly applied through the provision of fortified food commodities or through community-based fortification of grain. WFP policy stipulates several food-aid commodities that must be fortified for use in the food-aid basket including vegetable oil with vitamin A, salt with iodine, and fortified, blended flours with multiple micronutrients (WFP, 2004). More recently, efforts have been made to fortify cereals using custom-designed milling and fortification equipment at refugee-camp level. There is some evidence to show that this is feasible and can improve the micronutrient status of some groups (Seal *et al.*, 2008). See Case Study 4 below. However, even where fortified grain and/or flour are provided, the micronutrient needs of some groups with high nutritional requirements may not be met (Chaparro and Dewey, 2010). For these groups, and where the provision of FBF is not possible, the provision of home-based fortificants and lipid-based nutrient supplements (or ready-to-use foods) is becoming more common.

Home-based fortificants (such as Sprinkles™) come in the form of single-dose sachets containing micronutrients in a powdered form, which are easily sprinkled on to foods prepared in the household. There is evidence that these products can impact the micronutrient status of vulnerable

### **Case Study 4 Fortification of food at refugee camp level in Zambia**

In 2002, World Food Programme, CARE-Zambia, and Micronutrient Initiative (MI) established a pilot program for on-site milling, using mobile milling and fortification units (MFUs) in a remote refugee camp in Zambia. The aim of the program was to assess the feasibility of such an intervention and to assess the impact on the micronutrient status of the population.

At the outset, a task force was established comprising representatives from UNHCR, WFP, the government of Zambia, and two NGOs. They agreed that the new MFUs would need to have an output level sufficient to meet needs, produce a quality product in terms of acceptability and standards, and be easily maintained. A nutritional survey including assessment of micronutrient deficiencies was conducted as well as a community assessment with the refugees. The latter highlighted considerable skepticism toward the use of mills (previous experience had seen mills frequently breaking down) and to the fortification process. Consequently, a significant investment was made in sensitizing the population, which included supporting a visit to an established fortification program elsewhere in the country and the development of extensive education and communication materials to be used by community development workers.

The benefits of the fortification process were quickly evident. The fortified maize flour was widely accepted in terms of texture and taste. Refugees no longer had to wait for prolonged periods to mill their flour. Investment was made in training and providing new skills to those supervising and managing the installed MFUs. A follow-up survey showed that anemia had decreased from 47.7% to 24.3% and vitamin A deficiency had decreased from 46.3% to 20.3%. In general, the refugee population perceived that their health status had improved significantly since the program began.

This program demonstrated that on-site fortification using MFUs was a feasible intervention with a positive impact on nutritional status, particularly micronutrient status. With relatively small investment costs at the outset and even smaller recurring costs (fortificants and maintenance), this approach was considered a feasible approach for fortifying rations, especially in isolated camps.

Adapted from van den Briel *et al.* (2006).

groups and reduce the prevalence of MDDs such as anemia (Zlotkin *et al.*, 2005) and that they are a feasible intervention in humanitarian emergencies (De Pee *et al.*, 2007).

“Lipid-based nutrient supplement” (LNS) refers generically to a range of highly fortified, lipid-based foods that includes products such as ready-to-use therapeutic food (RUTF), which has been widely adopted for the outpatient treatment of severe acute malnutrition (see below). There is currently considerable interest in using smaller doses of LNS to help meet the recommended nutrient intakes (both macro- and micro-) for nutritionally vulnerable groups such as young children in combination with other foods provided in the general ration (Chaparro and Dewey, 2010).

### **Supplementation**

The distribution of micronutrient supplements is necessary to treat MDD outbreaks in an emergency-affected population and can be used to meet high requirements and prevent MDDs in vulnerable sub-groups in the short term (WHO/UNHCR, 1999a,b; Cheung *et al.*, 2003). WHO, WFP, and UNICEF now recommend that, because of their particular nutritional vulnerability, all pregnant and lactating women and young children affected by emergencies receive a daily multiple micronutrient supplement until the emergency is over and access to nutrient-rich foods is restored (WHO *et al.*, 2007). Vitamin A supplementation is routinely provided every 4 to 6 months for all children aged 6 to 59 months to prevent vitamin A deficiency and is known to be particularly important in humanitarian emergencies to reduce the risk of mortality and other complications of measles (Salama and Roberts, 2005). Vitamin A supplementation is often conducted in conjunction with measles or other vaccination campaigns.

### **Preventing and Treating Moderate Acute Malnutrition**

Supplementary feeding programs (SFPs) are a standard emergency response strategy usually established to address high or increasing prevalence of GAM. They are designed to provide a good quality food supplement that is in addition to the normal diet. To be effective, the extra food provided must be additional to, and not a substitute for, the base diet (Sphere Project, 2004).

#### **Types and Objectives of SFPs**

There are two main types of SFP: targeted and blanket programs. Targeted SFPs typically aim to rehabilitate individuals suffering from MAM, particularly those from nutri-

tionally vulnerable groups such as children or pregnant and lactating women, and to prevent an increase in the number of individuals suffering from severe acute malnutrition. They also commonly aim to reduce GAM and reduce or prevent excess mortality. A blanket SFP provides a food supplement to all individuals within a defined vulnerable group. This type of SFP is usually implemented where GAM levels are high, or where the general food ration is not yet well established. Where SFPs are used as a “holding operation” to prevent the deterioration of nutritional status of vulnerable groups until wider food security can be secured, advocacy for general nutritional support should be a key element of the program (Sphere Project, 2004)

#### **Program Design**

Implementation of an SFP usually requires multiple decentralized program sites, which might take advantage of existing structures and services such as health centers. Most commonly, dry take-home rations are provided weekly or fortnightly, and are taken home for preparation and consumption. Wet on-site feeding requires daily attendance and requires one to four prepared meals daily to be consumed “on-site”. The former are preferable in most circumstances because they are less resource intensive, hold fewer opportunity costs for program beneficiaries, and reduce the risk of communicable disease transmission (WHO, 2000). Most guidance, including that published by the WHO, recommends that a supplementary ration should provide 500–700 kcal per beneficiary per day and should include 15–25 g of protein. They also recommend that these amounts should be doubled for dry take-home feeding with the assumption that some of the supplement will be shared with other family members. The foods distributed in SFPs vary, but almost always include FBFs such as corn-soy blend (CSB).

#### **Challenges and Alternative Designs**

Doubts about the efficacy of supplementary feeding programs using fortified blended flours have been raised repeatedly over the past 25 years (Briend and Prinzo, 2009). Many reasons have been put forward for the apparent poor performance of these programs, including inappropriate design (i.e. opportunity costs to participants that outweigh the perceived benefit of program attendance), poor acceptability of the treatment offered, and questionable effectiveness of FBFs for the treatment of wasting. Such supplements often have a nutritional profile (high protein, low fat, and high dietary fiber and anti-nutrient

content) that does not seem the best adapted to promote rapid growth of malnourished children (de Pee and Bloem, 2009). Recent studies and programs that have compared the use of FBFs with new lipid-based nutrient supplements (LNSs) for the treatment of MAM have generally shown that LNSs hold potential for improving rates of weight gain and recovery in SFPs (Matilsky *et al.*, 2009; Nackers *et al.*, 2010). Use of these new commodities is also moving into the realm of programs that aim to *prevent* malnutrition in vulnerable groups, particularly in areas that experience very high levels of child wasting every year. Médecins Sans Frontières (MSF), for example, found that the distribution of a small dose of RUTF to all children for 3 months prior to the hungry season in one area of Niger considerably reduced the prevalence and incidence of acute malnutrition compared with previous years (Defourny *et al.*, 2009). However, there remain questions around the costs of this approach and its benefits vs. other child-survival interventions that also hold potential to prevent MAM and severe acute malnutrition (SAM) in some contexts (Schaezel and Nyaku, 2010).

## Treating Severe Acute Malnutrition

Therapeutic feeding programs (TFPs) are usually established when there are large numbers of children suffering from severe acute malnutrition (SAM). These children have a significantly increased risk of mortality (compared with well nourished individuals).

### **Types and Objectives of TFPs**

Until recently, treatment of SAM in emergencies was restricted to in-patient management in therapeutic feeding centers (TFCs) or hospital units (WHO, 1999). This approach ignored the many barriers to accessing treatment that exist for poor people in the developing world (Collins, 2001) and, as a result, such programs were associated with poor coverage and late presentation of individuals with SAM. Individuals who present late are more likely to suffer from the many complications often associated with SAM such as hypoglycemia, hypothermia, severe infection, and refeeding syndrome, and these make the condition much more difficult to treat successfully. Evidence published over the last decade has shown that, by reducing barriers to access and supporting earlier presentation, large numbers of children with SAM can be treated from out-patient facilities without being admitted to in-patient units (Collins *et al.*, 2006b). This treatment approach, now

known as community-based management of severe acute malnutrition (CMAM), is supported by the WHO, the WFP, the UN SCN, and UNICEF as the most appropriate strategy for the treatment of SAM in emergencies and beyond (WHO/WFP/UN SCN/UNICEF, 2007) and can achieve both high coverage of children suffering from SAM in emergencies and high rates of recovery (Collins *et al.*, 2006a; Sadler *et al.*, 2007).

A typical objective of a TFP (whether delivered through a TFC or a CMAM program) is to treat severe acute malnutrition in the targeted group and to prevent excess mortality.

### **Program Design**

CMAM programs focus on finding and treating SAM early in the progression of the condition, before metabolic and immunological status becomes severely compromised and requires in-patient treatment. To achieve this, and to ensure that individuals can stay in treatment with few costs to them or to their families, programs are designed to minimize barriers to access. Treatment services are decentralized close to where the target population lives and where possible provided from the same sites as those delivering supplementary feeding. Ideally, programs also ensure that target communities understand the services available to them and participate in design and implementation of programs. This helps to sustain early presentation and high coverage (Guerrero *et al.*, 2010).

Once identified, children are classified according to the severity of their clinical condition. Those suffering from SAM with medical complications require admission to in-patient facilities such as TFCs, and are treated according to WHO protocols with formula milks known as F75 and F100 (WHO, 1999). Discharge from the TFC to an out-patient treatment happens as soon as appetite returns. This takes an average of 2–5 days after admission to an in-patient facility. Ready-to-use therapeutic food (RUTF) is designed to be nutritionally equivalent to the F100 milk, and studies have shown that it is effective at rehabilitating severely malnourished children and promotes faster weight gain than F100 (Diop *et al.*, 2003). This food has made feasible the safe treatment of severely malnourished patients at home. In out-patient treatment RUTF is given in quantities that provide 150–220 kcal/kg/day. Those suffering from SAM with no medical complications do not require admission to in-patient facilities and are treated directly in out-patient treatment according to CMAM protocol (Valid International/Concern Worldwide, 2006).

### Case Study 5 Integrating CMAM into national service delivery in Ethiopia

Because of the chronically high levels of acute malnutrition in many parts of Ethiopia, Concern's National CMAM (N-CMAM) program focused on supporting the Ministry of Health (MoH) to provide services to treat SAM as part of routine health delivery. Previously, the vertical nature of emergency programming meant that it was often difficult for the MoH to assume responsibility for a program that had not been "theirs" in the first place.

The N-CMAM program was implemented using a partnership approach, with the focus firmly on "ownership" by the MoH. The aim was for the program to establish a much needed service during "normal" times, and also to provide a base of capacity from which services could be rapidly scaled-up at times of crisis. The program provided a package of "minimal support" to the MoH, which consisted of training (set-up, on-the-job and training-of-trainers), joint supervision, workshops, experience-sharing visits, and community mobilization support. The program emphasized learning and innovation, in order to regularly refine and adapt the approach. Considerable support was also provided to the MoH at Federal level for the development of National SAM guidelines and a CMAM component in the National Nutrition Program Strategy.

While the minimal support package was important, the most crucial aspect of the program was the *nature* of the dialogue between the partners. Concern found the right balance between providing the support that was required and ensuring that the MoH were in the driving-seat at all times. In this way a strong partnership developed with all levels of the MoH steadily gaining confidence in their ability to offer quality CMAM services. When the food crisis of 2008 hit across much of the country, the MoH (with support from UNICEF) were able to rapidly scale-up decentralized CMAM services and implement the required policy changes. To date, approximately 30% of health facilities are offering CMAM services, a huge achievement in a vast country.

This case study demonstrates many of the key aspects involved in creating an enabling environment for the integration of nutrition services into national health systems. These include support for MoH technical leadership and coordination; the development of National Guidelines which are a powerful tool for promoting, strengthening, and maintaining harmonized services; and a long-term commitment by donors and INGO partners for capacity development and supplies.

Contribution by Emily Mates, Health and Nutrition Advisor, Concern Worldwide Ethiopia.

### Special Groups

There is increasing evidence to show that infants and adults suffering from SAM can also respond well to treatment although there are more challenges linked to these groups. A recent review of the management of acutely malnourished infants <6 months old in emergency programs highlighted a general lack of guidance and wide variation in treatment approaches across programs (Kerac *et al.*, 2010). Strategies with potential to improve inpatient outcomes of infants with SAM include implementation of routine kangaroo care, breastfeeding "corners" with skilled breastfeeding support including support for the "supplementary suckling technique,"<sup>4</sup> and tailored psychosocial stimulation/support of infants under 6 months. Strategies with potential for effective out-patient-based care of infants under 6 months with MAM or SAM include community-based breastfeeding support, psychosocial support programs, and women's group programs. Good recovery rates have been reported for severely malnourished adults in therapeutic feeding programs in Sudan, Somalia, and Angola, despite challenges such as relatively poorer compliance, increased risk of population displacement, and higher rates of underlying chronic illnesses such as HIV (Collins *et al.*, 1998; Bahwere *et al.*, 2009). There are opportunities for better integration of programs that treat SAM with HIV testing, treatment, and prevention of mother-to-child transmission (PMTCT) programs since SAM is closely linked to HIV, particularly in these groups.

### Policy Development, Best Practices, and Capacity Development

Over the past two decades, positive shifts in the broader policy environment have influenced and strengthened the emergency nutrition sector. The nutrition sector as a whole has enjoyed higher visibility and profile, largely as a result of the global commitment to the Millennium Development Goals (MDGs) where reducing undernutrition is widely recognized as central to achieving MDG 1 and malnutrition is a key factor underpinning many of the other MDGs. Furthermore, a comprehensive review series recently published in *The Lancet* described a number of high-impact evidence-based nutrition interventions (Bhutta *et al.*, 2008; Bryce *et al.*, 2008). This series of

<sup>4</sup>This aims to simultaneously treat infants with SAM and maintain or re-establish breastfeeding where it has stopped.

publications and others have also highlighted the health implications and economic costs of not addressing under-nutrition (World Bank, 2006; Black *et al.*, 2008; Victora *et al.*, 2008). This has led to a greater commitment to the nutrition sector by a number of agencies including the World Bank to identify the challenges and implement solutions (Horton *et al.*, 2008).

Secondly, building on the UN agencies' public commitments to address nutrition in humanitarian crises, agency accountability for nutrition has been further defined. For example, UNICEF's recently revised Core Commitments for Children in Humanitarian Action (UNICEF, 2010) refer to their commitment to facilitate co-ordination mechanisms, rapid assessments, provision of vitamin A supplements, support for infant and young-child feeding, and treatment for severe acute malnutrition using explicit results-based interventions. Similarly WFP has reaffirmed the role of nutrition within their food aid assistance responses, including the role of fortification for addressing micronutrient deficiencies (WFP, 2004). The humanitarian reform agenda, which was led by the Inter-Agency Standing Committee (IASC) and launched in 1995, aims to improve the impact in humanitarian responses through greater accountability, improved preparedness, development of standards and best practice, including monitoring mechanisms, as well as strengthening the sector's skilled human resource capacity (IASC Global Nutrition Cluster, 2010). In particular, the humanitarian reform presents an opportunity to ensure that there is a more coherent and shared process for planning and prioritization among all partners, leading to greater results within the sector. The nutrition cluster, led by UNICEF, has made efforts to further consolidate and strengthen the emergency nutrition sector. For example, it has undertaken activities aimed at improving nutritional assessment and in-country coordination, improving timeliness and deployment of skilled professionals, and bringing about the merging of guidelines, and a longer-term approach to capacity development. However, some challenges remain, for example a lack of a defined, coherent, and long-term vision for the nutrition cluster and short-term funding, which limit commitments to short-term time-bound projects rather than longer-term institutional change initiatives.

Thirdly, there are further efforts and mechanisms established now to bridge the prevailing divide between the humanitarian and development sectors. This is reflected by policies, commitments, and actions that explicitly reflect efforts to support early recovery of the sectors

(including nutrition) from the outset of the humanitarian response. In practice this is leading to a greater emphasis being placed on strengthening national policies, systems, and capacities, and not just the delivery of life-saving services. For example, in Mozambique, the cluster "transformed" after the acute flooding crisis to focus more specifically on preparedness and capacity development, particularly in line with government priorities. In some countries, however, this remains challenging to implement in practice, particularly in fragile states in the context of ongoing conflict and insecurity as found in parts of Sudan.

Fourthly, building on the Sphere Project initiative which mobilized the international humanitarian community to develop a set of Minimum Standards for Disaster Response (Sphere Project, 2004) (see Case Study 6), results-based monitoring is increasingly reflected in donor and agency policies and guidelines which are being revised to reflect the highest standards of accountability and quality management (HAP, 2010; UNICEF, 2010).

Fifthly, the global architecture of nutrition is also evolving, albeit slowly, towards a multi-sectoral approach that explicitly links the sectors of nutrition food security as well as other sectors. A recent high-level UN Task Force and inter-agency initiative, which arose out of the recent global food crisis, has reaffirmed the need for a multi-sectoral approach to nutrition<sup>5</sup>. The inter-agency initiative, with broad ownership, has recommended that national nutrition strategies and key national stakeholders in nutrition should apply the "Three Ones" including "one agreed framework that provides the basis for co-ordinating the work of all partners; one national coordinating authority, with a broad multi-sectoral mandate; and one agreed national monitoring and evaluation system" (Bezanson and Isenman, 2010). Although as yet this policy shift has had limited impact, this emerging architecture may create new potential opportunities for emergency nutrition to have greater accountability within the broader sector and likewise to have better ownership by different sectors – particularly in the context of protracted and persistent crises such as climate change, HIV/AIDS, and the ongoing global economic crisis.

Humanitarian crises can present valuable opportunities to positively influence the development of new national legislation and policy, such as in Afghanistan (Islamic

<sup>5</sup>This multi-sectoral approach is also reinforced by specific donor policies such as DFID's: see DIFD, 2010.

Republic of Afghanistan: MOPH, 2008), or to revise earlier policies such as in Iraq (Tolvanen and Kumar, 2003) or reinforce existing policies such as following the cyclone in Bangladesh (Bangladesh Breastfeeding Foundation, 2007).

Operational practice in the emergency nutrition sector has also significantly influenced policy development and application (Heikens *et al.*, 2008). For example, community-based management of severe malnutrition, which developed based on the well-researched experiences of large-scale humanitarian nutrition programs, has influenced international policies. Furthermore, community-based treatment of severe malnutrition is increasingly institutionalized within national structures and government policies.

Other examples of best practice influencing policy include the standardization of nutrition surveys and the use of MUAC as admission criteria based on risk of mortality. Despite the wide array of best practice and policies that do exist, there are, however, inconsistencies in the application and adherence to these policies for a number of reasons. This includes some ambiguity and discrepancies that exist between the different agency-specific guidelines, a general lack of awareness of policies because of a rapid agency staff turnover, lack of systematic mechanisms that ensure adherence to policies and standards, and a failure to invest in national capacities.

It is widely recognized that capacity development is much broader than just training. While there is still no overarching capacity development framework that encompasses the broader institutional change initiatives necessary to strengthen the emergency nutrition sector as a whole, there are some efforts to embrace a more comprehensive approach. For example, the IASC cluster recognizes complementary strategies for capacity development, namely preparedness, strengthening the foundation of nutrition, and real-time learning (IASC Global Nutrition Cluster, 2007). Important training initiatives in emergency nutrition are being scaled up and are beginning to address the major challenges that continue to exist (NutritionWorks, 2010). The first of these challenges is that training continues to be *ad hoc* and, when undertaken, is overly focused on strengthening technical skills rather than on addressing the functional and core skills critical for effective leadership and change in nutrition. Furthermore, the training continues to focus on health and nutrition professionals rather than on professionals among multiple sectors. A second challenge is that the academic curricula for professional nutritionists frequently do not include the relevant

skills and knowledge that are considered necessary to function effectively in humanitarian crises, such as the ability to design nutritional surveys, to develop food aid interventions, and to carry out Community-Based Management of Acute Malnutrition (CMAM). Professional training initiatives can no longer be left to ad hoc training initiatives within the operational agencies themselves, but need to be systematically incorporated into academic curricula, particularly within the national training and academic institutions located in crisis-affected countries themselves.

### Case Study 6 Sphere Project: Minimum Standards in Food Security, Food Aid, and Nutrition

An important inter-agency initiative that has contributed to improved practice in humanitarian response over the past decade is the Sphere Project. Through a global consultative process, the Sphere Project has developed a set of Minimum Standards and related key indicators for different sectors including Food Security, Nutrition, Food Aid, Health, Water, and Shelter, plus common standards on Participation, Targeting, etc. The cornerstone of the Sphere Project is the Humanitarian Charter, which is based on the principles and provisions of international humanitarian law, international human rights law, and refugee law. The Humanitarian Charter reasserts the rights of emergency-affected populations to life with dignity. The Minimum Standards and their related indicators are considered by some to be a practical interpretation of what these rights mean in the context of humanitarian response, i.e. it aims to link human rights with standards for operation. The current version of the Sphere Project (2004) attempts to incorporate relevant human rights principles and values into the Sphere Standards as reflected in the Humanitarian Charter, including the right to life with dignity, non-discrimination, impartiality and participation. Although the Minimum Standards potentially establish a mechanism for transparency and accountability, ensuring their implementation will require more reflection on the precise modes and mechanisms of accountability (Young *et al.*, 2004b). The Sphere Project is currently being updated to reflect the evolving challenges of humanitarian crisis (Sphere Project, 2011).

### Future Directions

The speed in development of new nutrition supplements during the last decade has been phenomenal. Policy and clear program guidance have lagged behind and, as a result, there is a polarization of views on the “for” and

“against” use of these products. Use of these new products will continue to grow in future programming. Building consensus among a broad range of stakeholders for evidence-based guidance will be important for both program design and resource allocation.

Concentration on the nutritional quality of food assistance, and the large number of new nutrition supplements on the market, have served to narrow the focus on nutrition as a clinical condition, and have swung attention toward a more medicalized model of treatment of individuals rather than having a broader public-nutrition approach of addressing problems at the population level, including causal analysis, risk reduction and prevention. The pendulum is just now beginning to swing toward increasing concerns for the broader nutrition problems of society, and to a broader view of the interventions needed to impact nutrition as part of a more integrated approach.

Progress has been accomplished within the sector in terms of maintaining and developing a body of best practice and a considerable degree of standardization internationally. With the advent of the IASC Nutrition Cluster, and earlier ongoing efforts to improve quality such as the Sphere and FANTA projects, etc., and renewed commitments to nutrition in emergencies by UN agencies, there is now greater consensus, awareness, and application of tried and tested tools and approaches.

A crucial and continuing challenge remains the lack of documented evidence on impact and outcomes. This knowledge gap is a big challenge linked to every type of intervention, and a major hindrance to further advances. Improved documentary evidence about what works will serve to strengthen this sector for the future.

While acute malnutrition among children was widely recognized as the most common characteristic of complex emergencies in the past, other forms of malnutrition (stunting, underweight, and MDDs) and nutritional risk among other age groups are increasingly recognized as important. Consequently, analytical frameworks need to broaden their concept of nutritional vulnerability and risk to incorporate all three groups of underlying causes that require both qualitative studies as well as epidemiological data. Furthermore, as a result of the multi-causal nature of malnutrition, direct nutrition interventions as described in this chapter should rarely be implemented in isolation of integrated health and food security programs.

The design and delivery of food and nutrition interventions in complex emergencies are frequently constrained by the characteristic breakdown of local infrastructure,

including government, civil society, and community networks. Humanitarian agencies also face difficulties in identifying and accessing the most vulnerable groups, particularly in contexts where vulnerability is influenced by a complex number of determinants, not just physiological. Poor security and lack of access to the affected populations, rapidly changing situations, and a lack of timely and representative information for appropriate decision-making, are all critical challenges for designing appropriate nutrition responses.

The promotion and support to national capacity and to developing professional leadership in the countries directly affected by crises, within both the technical and policy domains, will be critical toward achieving more effective responses in future nutritional crises.

## Acknowledgment

With acknowledgment of contributions by Emily Mates, Concern Worldwide Ethiopia and Lena Nguyen, Tufts University.

<sup>2</sup>Brown University, Providence, Rhode Island, USA

### Summary

Our food supply comes from millions of farms around the world, is processed in many thousands of packing sheds, slaughter plants, and canneries, and is prepared in millions of kitchens. It is a dynamic system, as changing foods, food sources, cuisines, and processing technologies lead to new food safety challenges. Along the way, the foods and food ingredients can be contaminated with a variety of pathogens, which can harm the final consumer. Infections caused by eating contaminated foods are common. They have been estimated to cause 48 million illnesses each year in the United States, with 128 000 hospitalizations and 3000 deaths. A wide array of pathogens can be foodborne, which can cause a variety of syndromes. Some have reservoirs in the animals we eat, and contaminate the foods that are made from those animals. Others are present in the environment, and can contaminate foods in a number of ways. Still others have a human reservoir, and can contaminate food indirectly through sewage or by direct contact with an infected person. Though some level of contamination may be inevitable, much foodborne illness can be prevented. Preventing foodborne disease depends on measures taken from farm to table, which provide a series of hurdles that lower the risk. Taking care at each step of the food chain to prevent contamination can make food safer. For the riskiest foods and pathogens, definitive pathogen reduction steps such as heat-process canning and pasteurization have long been used to prevent serious harm. The many members of the food industry, the regulators and public health authorities, and the consumers themselves all have important roles to play in making food safer.

### Introduction

Foodborne diseases caused by foods contaminated with microbes and their toxins have long complicated the search for a safe and nourishing food supply. For most of these microbes, the human is an accidental host, made ill by the

chance presence of microbes that circulate in the animals we eat, or in the environments in which we raise and harvest our foods. For some microbes, such as those that cause typhoid fever, cholera, and bacillary dysentery, we humans are a primary reservoir, and contaminated food and water have been primary routes by which they move

from one host to the next. In general, the transmission of foodborne organisms has probably intensified over the centuries as humans have crowded together in cities, as animal husbandry has intensified, and as the distance from farm to plate has lengthened. The safety of foods has also changed significantly. Early in the 20th century, efforts to improve urban drinking water and sewage treatment systems largely controlled typhoid fever and cholera, and more recent disease-control efforts on farms and routine pasteurization have largely eliminated trichinosis from pork, and brucellosis and bovine tuberculosis transmitted through milk, and better slaughter practices have decreased the frequency of *E. coli* O157 infections. We are, however, left with a substantial burden of infections that still contaminate the foods we eat. The globalization of food supplies, the changing food habits of consumers and the mutation of microbes mean that newer challenges have emerged even as some of the longstanding ones have been controlled. This review summarizes the clinical and public-health perspective on foodborne diseases.

The concept that food can cause human illness dates back to antiquity. The germ theory of disease and, since the late 1800s, the microbiological identification of predominantly bacterial agents, laid the groundwork for the

concept that food could be made safer by interventions limiting pathogen growth and survival. Improved water sanitation, better animal husbandry practices, the pasteurization of milk, and the widespread use of refrigeration have contributed to the steep decline in foodborne illnesses such as bovine tuberculosis, dysentery, and typhoid fever during the 20th century in the United States and other industrialized nations (CDC, 1999; Tauxe and Esteban, 2006) (Figure 70.1).

On the heels of these achievements, however, has come a very different set of issues in food safety during the last three decades. A far broader array of agents have come to be recognized as significant contributors to foodborne disease, including newly emergent bacterial pathogens and previously undescribed viruses and parasites. Several non-diarrheal human illnesses have been shown to have an infectious etiology that is foodborne in origin. In the natural evolution of analyses of food safety, their conceptual framework has become more dynamic, and at present the aim of such assessments is to define acceptable levels of risk.

This chapter will focus on newer developments in foodborne illness, including the expanded spectrum of human disease, recently described causative agents, changes in the

epidemiology of foodborne disease, and current progress in prevention. It is beyond the scope of this chapter to include a comprehensive description of clinical manifestations, diagnosis, and treatment, and the reader is referred elsewhere (Butterton and Calderwood, 2008; Sodha *et al.*, 2010).

## Causative Agents

Diverse etiologic agents are capable of causing diarrhea or other forms of foodborne disease in humans (Table 70.1). Infectious agents include bacteria, viruses, and parasites, each with its own ecological niche in nature. These agents may be normal inhabitants of animal gastrointestinal tracts, soil, or water ecosystems. For some the primary host is human, and for many others the reservoir is in other animals. Their pathogenic properties for humans may often be the accidental result of evolutionary changes conferring selective survival advantages in the host animal or environment.

Prions (proteinaceous infectious particles) are novel transmissible agents that do not contain any nucleic acids. Prions cause a group of diseases known as the transmissible spongiform encephalopathies (TSEs); in animals TSEs can be transmitted following oral inoculation with a species-specific prion protein. An epidemic in Great Britain of bovine spongiform encephalopathy (BSE, “mad cow disease”) has been followed by an increase in humans of a fatal degenerative neurological disease, new variant Creutzfeldt-Jacob disease (nvCJD), most probably related to consumption of BSE-contaminated foods.

In addition to infectious microorganisms, other entities are capable of causing foodborne disease. Non-bacterial toxins produced by dinoflagellates can cause paralytic shellfish poisoning and ciguatera. Chemical causes of

foodborne illness include histamine, the causative agent of scombroid fish poisoning. Serious clinical illness can result from consumption of poisonous mushrooms, and clinical manifestations range from delirium to gastroenteritis with hepatorenal failure. Species of mushrooms that produce amatoxins and phallotoxins are causes of the latter form of illness. Heavy metals, including copper, zinc, tin, and cadmium, have caused acute nausea, vomiting, and abdominal cramps within 1 hour of consuming contaminated food.

Unfortunately, there is no 1:1 correspondence of an etiologic agent to a specific clinical scenario, and there can be considerable overlap among the categories in considering the etiologies of a patient’s illness. The usefulness of this classification is to remind clinicians of all causes of a clinical illness with a possible foodborne etiology in order to ensure that appropriate questions are asked of the patient to ascertain whether significant exposures have occurred.

## Types of Illness

Diarrhea and vomiting are most often considered the main manifestations of foodborne disease, but it is now recognized that a much wider range of human illness can be seen. Foodborne disease can present as an acute illness whose main manifestation is vomiting, diarrhea, sepsis, jaundice, or paralysis, or as a chronic illness with persistent diarrhea, neurological findings, or chronic anemia (Table 70.2). Common among these different forms of illness is an initial step in pathogenesis that takes place at the mucosal surface of the gastrointestinal tract. This may range from adherence and colonization by a bacterial pathogen, to viral replication within the cells that form the wall of the intestine, to absorption of a non-bacterial toxin.

The features of acute enteric illness following ingestion of contaminated food may be quite varied. Clues to the diagnosis are to discern the types of symptom and their relative predominance in the context of the illness as well as their intensity. Patients who experience nausea and vomiting with onset within 1–6 hours of a meal have likely ingested foods contaminated with a preformed toxin from either *Staphylococcus aureus* or *Bacillus cereus*. The vomiting is abrupt in onset and is intense, lasting for a few hours and resolving within a day with no specific therapy. Diarrhea is a less common component. Staphylococcal food poisoning was a major form of foodborne disease recognized during the middle of the 20th century.

**TABLE 70.2** Clinical spectrum of illness in foodborne disease and examples of common causative agents

Type of Illness	Examples of Causative Agents
Acute enteric illness	
Nausea and vomiting within 6 hours	<i>Staphylococcus aureus</i> , <i>Bacillus cereus</i>
Vomiting and diarrhea	Rotavirus, norovirus
Diarrhea and abdominal cramping	ETEC, EPEC, <i>Clostridium perfringens</i>
Diarrhea and fever	Non-typhoidal Salmonellae, Vibrio
Bloody diarrhea	<i>Escherichia coli</i> O157:H7, <i>Campylobacter jejuni</i> , <i>Shigella</i> spp <i>Vibrio parahaemolyticus</i>
Enteric fever	<i>Salmonella</i> Typhi, <i>Brucella</i>
Acute sepsis	<i>V. vulnificus</i>
Acute hepatitis	Hepatitis A virus
Acute pseudoappendicitis	<i>Yersinia enterocolitica</i> , <i>Y. pseudotuberculosis</i>
Acute neurologic illness	
Paralysis	Botulism, Paralytic shellfish poisoning, Guillain-Barré syndrome
Paresthesias	Scombroid, ciguatera
Meningitis	<i>Listeria monocytogenes</i>
Encephalitis	<i>Cronobacter sakazakii</i>
Chronic enteric illness	
Diarrhea >3 weeks	<i>Giardia</i> , <i>Cryptosporidium</i> , <i>Cyclospora</i> , Brainerd diarrheal syndrome
Chronic neurologic illness	
Seizures (neurocysticercosis)	<i>Taenia solium</i>
Congenital abnormalities	<i>Toxoplasma gondii</i>
Encephalitis (AIDS patients)	<i>T. gondii</i>
Chronic anemia	Hookworm
Vitamin B <sub>12</sub> deficiency	<i>Diphyllobothrium latum</i>

An illness consisting of vomiting and diarrhea without abdominal cramping is usually due to norovirus or rotavirus. Rotavirus occurs commonly in young children but may affect adults as well. Community-wide outbreaks of norovirus infections have been a particular challenge in wintertime.

Watery diarrhea accompanied by abdominal cramping, typically but not invariably without fever, may be due to specific types of diarrheagenic *Escherichia coli* (Nataro and Kaper, 1998) [enterotoxigenic *E. coli* (ETEC), enteropath-

ogenic *E. coli* (EPEC) or *Clostridium perfringens*]. ETEC are a major cause of diarrhea worldwide and are the most frequently implicated pathogen in travelers' diarrhea. EPEC were originally described as causative agents of nursery outbreaks in the 1940s and are relatively uncommon in the developed world today. In the developing world, they are a significant cause of diarrhea in infants, particularly at the time of weaning.

Fever accompanying abdominal cramps and diarrhea suggests an inflammatory or invasive diarrhea. When the diarrhea is non-bloody, in the developed world this is most commonly associated with the non-typhoidal salmonellae (Goldberg and Rubin, 1988). Bloody diarrhea accompanied by moderately severe cramping and/or abdominal pain indicates a serious infection, and should be treated as a medical emergency. In the developed world, causative agents include *Campylobacter jejuni* (Allos and Blaser, 1995) and *E. coli* O157:H7 (Tarr *et al.*, 2005). *Vibrio parahaemolyticus* infection is common in Japan and along coasts of the United States (Daniels *et al.*, 2000). In the developing world, other infectious causes of bloody diarrhea include *Shigella flexneri* and *Shigella dysenteriae*, and *Entamoeba histolytica*.

Enteric fever is the designation for an illness characterized by fever for several days with headache, malaise, anemia, and splenomegaly. When the causative agent is *Salmonella* serotype Typhi, the illness is referred to as typhoid fever. *Brucella* can cause a similar syndrome. Typhoid fever is extremely uncommon in the United States today, but remains common in the developing world, and most currently reported cases are acquired through overseas travel. Some non-typhoidal *Salmonella* serotypes can cause a similar illness in immunocompromised persons (Levine *et al.*, 1991).

Sepsis (fever, chills, hypotension) is a very infrequent form of foodborne disease. A specific association exists with sepsis from *Vibrio vulnificus* infection in persons with underlying liver disease, particularly alcoholic cirrhosis.

Jaundice with nausea and anorexia can be the manifestation of acute infectious hepatitis. As a foodborne illness, this may be due to hepatitis A virus infection. The overall incidence of hepatitis A in the developed world is considerably lower than that in the developing world or in countries whose economies are in transition, and is decreasing rapidly where immunization is routine (CDC, 2009a). Infection early in childhood is often asymptomatic or unaccompanied by jaundice, and confers life-long immunity. Infection in adulthood is more frequently clinically

symptomatic and is usually more serious. Hepatitis A is the most common travel-related illness that is vaccine preventable.

Focal abdominal pain and fever, mimicking appendicitis, is often how infections with *Yersinia enterocolitica* or *Y. pseudotuberculosis* present; though rare in the United States, they have been more commonly described in Europe (Ostroff *et al.*, 1992; Nuorti *et al.*, 2003; Long *et al.*, 2010).

A variety of acute neurological illnesses may be manifestations of a foodborne infection. Muscle weakness leading to frank paralysis may be due to botulism or paralytic shellfish poisoning (Underman and Leedom, 1993); Guillain-Barré syndrome has a similar presentation. This latter entity is now recognized in many cases as being a post-infectious complication of antecedent *Campylobacter jejuni* infection (Mishu *et al.*, 1993). Paresthesias (a tingling sensation in the skin) can occur in scombroid poisoning (histamine fish poisoning). Paresthesias occurring several hours after fish consumption and accompanied by reversal of hot and cold sensation in the mouth, and abdominal cramps, vomiting, and diarrhea is suggestive of ciguatera (Underman and Leedom, 1993). A distinctive feature of this illness is the propensity for pain in the extremities to persist for months to years after the acute illness.

Acute meningitis (fever, headache, stiff neck, and photophobia) can be a manifestation of foodborne disease when the causative illness is *Listeria monocytogenes* (Lorber, 1997). In contrast to many of the microorganisms already mentioned, *L. monocytogenes* is an opportunistic pathogen, mainly affecting those with a compromised immune system. Such immune compromise can be physiologic (associated with pregnancy), age related (infancy, the elderly), due to an underlying malignancy (that is either diagnosed and being treated or not yet diagnosed), or due to human immunodeficiency virus (HIV) infection. A febrile diarrheal illness in normal individuals has been noted in several listeriosis outbreaks; however, the overall frequency of *Listeria* as a cause of diarrhea is not yet known. *Cronobacter sakazakii* (formerly known as *Enterobacter sakazakii*) causes a devastating encephalitis in newborns; some cases have been linked to powdered infant formula (Bowen and Braden, 2006).

Chronic forms of enteric illness, such as diarrhea for more than 3 weeks, can be a form of foodborne disease from particular pathogens. In addition to *Giardia*, two other parasites, *Cryptosporidium* and *Cyclospora*, cause chronic diarrhea in previously healthy persons (Guerrant

and Bobak, 1991; Herwaldt, 2000). The prolonged diarrheal illness known as Brainerd diarrhea, associated once with drinking raw milk and more often with drinking untreated water, remains of unknown etiology, but causes a distinctive debilitating illness (Mintz, 2003).

Chronic neurologic illness can result from foodborne infection, often months to years after the initial infection. Seizures can result from the cyst forms of the pork tapeworm, *Taenia solium*, in the central nervous system. Neurocysticercosis is the most common cause of seizures worldwide (Carpio, 2002). A variety of congenital abnormalities (e.g. blindness, microcephaly, mental retardation) are associated with congenital toxoplasmosis. A form of encephalitis has been seen in AIDS patients as a consequence of reactivation of the latent cyst forms of *T. gondii*.

## Pathogenic Mechanisms

The mechanisms by which foodborne illness develops are best characterized for bacterial causes. Presently four main mechanisms are recognized by which bacterial enteric pathogens cause disease, and recent progress has suggested a fifth mechanism (Table 70.3). Some organisms produce illness after a period of growth in food during which a toxin is elaborated. Ingestion of this preformed toxin can produce excessive vomiting shortly after consumption, such as from *S. aureus* or *B. cereus* contamination, or frank paralysis, as in botulism. Other ingested pathogens may secrete a toxin following attachment to and colonization of a particular section of the gastrointestinal tract. ETEC produce a toxin closely related to cholera toxin from *Vibrio*

**TABLE 70.3** Pathogenic mechanisms in bacterial foodborne disease

Mechanism	Organism
Preformed toxin	<i>Staphylococcus aureus</i> <i>Bacillus cereus</i> <i>Clostridium botulinum</i>
Toxin secretion within the GI tract	<i>Escherichia coli</i> 0157:H7 and other Shiga-toxin producing <i>E. coli</i> Enterotoxigenic <i>Escherichia coli</i> <i>Vibrio cholerae</i> O1, O139
Cell penetration	<i>Campylobacter jejuni</i> <i>Salmonella</i>
Cell invasion	<i>Shigella</i> <i>Yersinia enterocolitica</i>
Adherence and signal transduction	Enteropathogenic <i>E. coli</i>

*cholerae*; both toxins cause a net secretion of water and electrolytes, resulting in watery diarrhea. By contrast, *E. coli* O157:H7 produces a Shiga toxin (closely related to that produced by *Shigella dysenteriae* type 1), which causes cell death and results in bloody diarrhea.

Apart from toxin production, two other mechanisms of disease induction are well recognized. Both *Salmonella* and *C. jejuni* can penetrate the mucosal layer of the gastrointestinal tract without causing cell death. Pathogens that invade the mucosal layer and cause cell death include *Shigella* and *Yersinia enterocolitica*. Bloody diarrhea is more common among pathogens with this latter mechanism of action.

Recent work to elucidate the pathogenic basis for EPEC-associated diarrhea has suggested a mechanism distinct from those already described. EPEC have been shown to produce certain attachment factors, including several secreted proteins. The interaction of these proteins with the cell surface receptor appears to initiate a series of events involving signal transduction. This in turn leads to changes in cellular ion fluxes, with subsequent secretion of water and electrolytes into the lumen of the gastrointestinal tract.

Some bacterial pathogens have overlapping mechanisms of pathogenicity, and not all members of a genus may have the same mechanism of causing diarrhea. Grouping organisms by their mechanism of action none the less serves a number of purposes: first, to function as an existing framework for classifying new pathogens; secondly, to discern genetic relationships among diverse bacterial species; and, thirdly, to use as a basis to predict the therapeutic usefulness of new therapies.

## Epidemiology

The epidemiology of foodborne disease is a complex interplay of the expression of a pathogen's virulence traits, host susceptibility, physical characteristics of the contaminated food, geographic location, and season of the year. Some pathogens have a predilection for particular foods, usually resulting from an overlap between their ecological niche and the harvest and/or processing environment for the food (Table 70.4). Raw meat, raw poultry, and shellfish are typically contaminated with the pathogens that have animal reservoirs, including *Salmonella*, *Campylobacter*, *E. coli* O157:H7, vibrios, and *Toxoplasma*, which can cause illness if the food is inadequately cooked, or if other foods are secondarily contaminated through direct or indirect

contact with the meat and poultry. Processed foods such as peanut butter, salami, and commercial pot pies can be contaminated with organisms that persist in dry ingredients or in the processing environment itself, such as *Salmonella* and *Listeria monocytogenes*. Foods that are handled extensively before eating without an intervening kill step, such as salads and sandwiches, can transmit pathogens for which humans are the main reservoir, from foodhandlers infected with norovirus, hepatitis A or *Shigella*.

Substantial changes have occurred in the epidemiology of foodborne disease in the United States in the last half of the 20th century. In the early 1900s, milk-borne tuberculosis, staphylococcal food poisoning, and typhoid fever were the main forms of foodborne disease (Tauxe and Esteban, 2006). Today the spectrum of causative organisms, the risk factors for enteric infection, and the type of foods involved are vastly different (Hedberg *et al.*, 1994; Tauxe, 2002). Use of antimicrobials in food animals has selected for increasingly resistant strains of *Campylobacter* and *Salmonella* (Anderson *et al.*, 2003). Changes in diet in the United States have occurred because of recognition of the relationship between diets rich in saturated fat and subsequent cardiovascular disease. This has led some Americans away from the traditional meat and potatoes diet of the 1950s to a diet that emphasizes fresh fruits and vegetables, grains, and fish and poultry consumption. Changes in food distribution systems have led to an end of seasonality for many fresh fruits and vegetables. Commodities formerly considered exotic are now routinely available in most grocery stores in the United States, and they are likely to have arrived within several days of harvest or production elsewhere in the world. Consumption of prepared, preprocessed, or ready-to-eat foods from commercial establishments has increased, providing a context in which transmission from food handlers has been seen with some frequency, particularly with norovirus, and of cold food items requiring hand contact. Substantial demographic changes also have occurred, with increases in populations with an increased susceptibility to particular pathogens.

## Surveillance

The purpose of surveillance for foodborne disease is to monitor disease trends over time, to implement and monitor the effectiveness of interventions for control, and to detect outbreaks. Disease reporting is usually laboratory based, with the isolation or detection of a pathogen in the

**TABLE 70.4** Etiology of foodborne disease outbreaks by food, season, and geographic predilection

Etiology	Foods	Season	Geographic predilection
<b>Bacterial</b>			
<i>Salmonella</i>	Beef, poultry, eggs, dairy products, produce, processed foods	Summer, fall	None
<i>Staphylococcus aureus</i>	Ham, poultry, egg salads, pastries	Summer	None
<i>Campylobacter jejuni</i>	Poultry, raw milk	Spring, summer	Higher in California and Hawaii
<i>Clostridium botulinum</i>	Vegetables, fruits, fish, honey (infants)	Summer, fall	None
<i>Clostridium perfringens</i>	Beef, poultry, gravy, Mexican food	Fall, winter, spring	None
<i>Shigella</i>	Egg salads, lettuce	Summer	None
<i>Vibrio parahemolyticus</i>	Shellfish	Spring, summer, fall	Coastal states
<i>Bacillus cereus</i>	Fried rice, meats, vegetables	Year-round	None
<i>Yersinia enterocolitica</i>	Milk, tofu, pork chitterlings	Winter	Unknown
<i>Vibrio cholerae</i> O1	Shellfish	Variable	Tropical, Gulf Coast, Latin America
<i>V. cholerae</i> non-O1	Shellfish	Unknown	Tropical, Gulf Coast
Shiga toxin-producing <i>Escherichia coli</i>	Beef, raw milk, fresh produce	Summer, fall	Northern states
<b>Viral</b>			
Norwalk-like agents	Shellfish, salads	Year-round	None
<b>Chemical</b>			
Ciguatera	Barracuda, snapper, amberjack, grouper	Spring, summer (in Florida)	Tropical reefs
Histamine fish poisoning (scombroid)	Tuna, mackerel, bonito, skipjack, mahi-mahi	Year-round	Coastal
Mushroom poisoning	Mushrooms	Spring, fall	Temperate
Heavy metals	Acidic beverages	Year-round	None
Monosodium-L-glutamate	Chinese food	Year-round	None
Paralytic shellfish poisoning	Shellfish	Summer, fall	Temperate coastal zones
Neurotoxic shellfish poisoning	Shellfish	Spring, fall	Subtropical

Adapted with permission from Fry *et al.* (2005)<sup>3</sup>.

clinical microbiology laboratory. In general, only a small fraction of actual illnesses are reported, but this can vary considerably among pathogens according to the severity of illness and the ease and access to laboratory testing (Hedberg *et al.*, 1994). For *Salmonella*, this has been estimated directly from FoodNet surveys of populations and laboratories; an estimated 38 illnesses occur for every one that is diagnosed and reported (Voetsch *et al.*, 2004). Some pathogens are transmitted exclusively through food (e.g. *Trichinella spiralis*), whereas others may be transmitted most often through water (e.g. *Giardia*) or by person-to-person spread (e.g. *Shigella*), and only occasionally through food. In 2010, an analysis took many of these aspects into consideration in developing estimates of the burden of foodborne disease on health in the United States (Scallan *et al.*, 2011a,b). In that estimate, approximately one in 46 persons in the United States were estimated to have a foodborne illness each year, of which 3000 died. *Salmonella*, *Listeria*, norovirus, and *Toxoplasma* were responsible for 82% of deaths from known pathogens. A provocative estimate from this analysis, described in Scallan *et al.* (2011a), was that the 31 pathogens in the estimate did not account for the majority of illnesses nor of deaths. These disease estimates were based on data from several sources, and contained a number of assumptions, including estimates

of the total number of illnesses for each pathogen, the proportion of pathogen transmission that is foodborne, and the incidence of acute gastroenteritis with unknown agents. Continued refinements in surveillance will test the validity of these assumptions. FoodNet, the sentinel-site network for active surveillance of foodborne infections [a program of the Centers for Disease Control and Prevention (Scallan, 2007)], develops population-based estimates of incidence and tracks the trends of known foodborne pathogens. The FoodNet sites now have nearly 14% of the US population within the surveillance network, and important trends are emerging in the 14 years since FoodNet's inception in 1996 (Scallan, 2007; CDC, 2010). *Campylobacter*, initially the highest-incidence pathogen, varies markedly among the participating sites. The most recent data for 2010 (CDC, 2011) show a decline in incidence of *Campylobacter* infection by 27% since 1996 to below that for *Salmonella*, as well as a decline in *E. coli* O157 infections to 0.9/100 000, which reached the 2010 national goal. The incidence of *Listeria* and *Yersinia enterocolitica* infections has also declined during the surveillance period. These declines may indicate the success of current disease prevention efforts aimed at multiple points along the "farm to fork" continuum (Figure 70.2). Most of the declines occurred in the first decade; there has been

**FIG. 70.2** Relative incidence of five infections as tracked in FoodNet from baseline in 1996–1998 through 2010. A decrease to 0.5 represents a 50% decrease in modeled incidence relative to the baseline period. Numbers for 2010 are preliminary. Reproduced from Centers for Disease Control and Prevention (2011), public domain.

little change in recent years, and the salmonellosis has not declined at all, so more efforts are clearly needed to reach even lower goals for 2020 (CDC, 2011). Since 1996–98, *Vibrio* infections increased, indicating the need for more prevention efforts focused on the risks associated with raw shellfish. Limitations to the FoodNet data include how well the population under surveillance captures the variety of the US population in terms of demographics and risk factors, and the fact that the system can only gather information on persons for whom diagnostic specimens were submitted and on pathogens which are routinely identified in clinical laboratories. However, FoodNet represents a significant advance over traditional public health surveillance in providing comparable information from different states, and provides more reliable estimates of the disease burden from particular foodborne pathogens.

PulseNet, developed under the auspices of the Centers for Disease Control and Prevention, is a system of laboratory-based electronic surveillance of foodborne bacterial infections that was also introduced in 1996 (Gerner-Smidt *et al.*, 2006). After *E. coli* O157, *Listeria* or *Salmonella* is isolated from an ill patient, the bacterial strain is sent to state public health laboratories, where a pulsed-field gel electrophoresis (PFGE) analysis is done. The PFGE “fingerprint” of that bacterial strain is stored, analyzed, and compared electronically with a national database of such “fingerprints.” In this manner, PulseNet has been instrumental in identifying and investigating many geographically dispersed outbreaks. Because the typical interval between specimen collection and PFGE analysis is 14–16 days or more (Hedberg *et al.*, 2008), PulseNet operates with some delay, but this system has proven extraordinarily useful in detecting outbreaks that would otherwise have been missed until they were much bigger, and in facilitating epidemiological investigations of them (Tauxe, 2006). Food testing laboratories in the Food and Drug Administration (FDA) and Department of Agriculture (USDA) have joined the network, making it possible to link patterns isolated from ill people with those of isolates from foods. Adoption of the same laboratory protocols in Canada, Europe, Japan, and other regions is making it easier to identify and investigate international outbreaks (Swaminathan *et al.*, 2006).

Surveillance based on laboratory subtyping has greatly increased the recognition of outbreaks that are geographically dispersed. Large multi-state outbreaks have in recent years been traced to bagged baby spinach, to shredded lettuce served in fast-food tacos, and to raw cookie dough

(Grant *et al.*, 2008; CDC, 2009c; Sodha *et al.*, 2011). Large nationwide outbreaks of salmonellosis have been linked to peanut butter, other peanut-flavored products, broccoli flakes used on a vegetarian snack marketed at children, imported hot peppers, and fresh tomatoes (CDC, 2007a,b, 2008a, 2009b; Gupta *et al.*, 2007). Many of these outbreaks would not have been identified or successfully investigated without PulseNet (Tauxe, 2006). With molecular subtyping it has also become possible to find outbreaks that recur over time from the same source. In 2000 an outbreak of listeriosis was caused by the same strain, and traced to the same turkey-processing plant as a fatal case that had occurred 12 years before (Olsen *et al.*, 2005). In 2007, an outbreak of dry-cereal-associated infections was caused by the same strain of *Salmonella* serotype Agona as an outbreak in 1998, and linked to the same factory (CDC, 2008b). Recurrent outbreaks of *Salmonella* serotype Newport infection were linked to tomatoes from the eastern shore of Virginia in 2002 and 2005 (Greene *et al.*, 2008). All of these illustrate the important challenge of persistence of the organism in reservoirs and microniches that would not be clear without subtyping.

CDC also gathers reports of outbreak investigations from local and state health departments in order to track trends and better understand the sources of foodborne outbreaks. About 1200 foodborne outbreaks, with 20 000 to 40 000 associated cases, are reported each year (CDC, 2006). The great majority of these are investigated by local health departments.

Another, albeit sobering aspect of surveillance is that it needs to be viewed as the first line of defense in a bioterrorist event. Food processing today has increasingly centralized production and wide geographic distribution, which may have economic advantages but which make the food supply more vulnerable. Discussions of bioterrorism preparedness have often focused on airborne agents (e.g. anthrax), but consideration has also been given to scenarios involving the food supply. An unheralded attack may well resemble an unintentional outbreak, and is very likely to be identified and investigated with standard public-health procedures. Agricultural biosecurity will also need to be a component of the bioterrorism preparedness portfolio. A strong public-health infrastructure with efficient surveillance systems is likely to be the most effective defense against both naturally occurring epidemic disease and bioterrorism-related events. The importance of robust public-health surveillance in supporting both the public-health and national-security interests cannot be overemphasized.

## The Challenges of Special Populations

As epidemiological investigations of outbreaks have delineated new and/or emerging pathogens as causative agents of foodborne disease, so too have new risk factors been defined for the acquisition of infection. The identification of groups with an increased risk for clinical illness following exposure is one of the most notable trends in foodborne disease epidemiology (Table 70.5). The magnitude of increased risk and the spectrum of pathogens differ among these groups. Young infants are particularly at risk for enteric infections, though they do not eat the foods that adults eat. *Yersinia enterocolitica* infections may offer a model for how indirect exposure can happen; bottle-fed infants get this infection when their caregiver is also cleaning pig intestines, and likely transfers the organism to the infant's bottle via their unwashed hands (Lee *et al.*, 1990). Persons over 60 years of age may have an increased susceptibility to infection irrespective of other risk factors such as malignancy. Older women seem to be particularly susceptible to salmonellosis (Reller *et al.*, 2008). The aging of the US population along with that in Western Europe and several other countries has clear-cut public health implications in underscoring the need to ensure a safe food supply. Advances in clinical medicine have created populations that never previously existed, for example, transplant recipients and those receiving immunosuppressive drugs. The epidemic of HIV infection has irrevocably changed modern society in numerous ways. With respect to foodborne pathogen exposures, HIV-infected patients are more likely to become ill, to have a more severe illness, and to have extraintestinal or unusual clinical manifestations.

These at-risk populations were previously estimated to constitute 10–20% of the population (CAST, 1994), but today the proportion is thought to be even higher. Many

persons within these categories have no or only limited perception of their increased risk for foodborne disease. Although educational efforts seem a logical approach to disease prevention, this is often easier said than done. Some educational efforts, even when specifically targeted and culturally appropriate, have had disappointing results (Mouzin *et al.*, 1997). Because educational efforts alone may be insufficient to reduce risk, and because for some populations even one organism may represent an infective dose, additional measures of protection will need to be built into the food supply. Making food safe from farm to table is a joint responsibility of the food industry, the regulators, and the consumers. Technological interventions such as pasteurization of milk and retort canning of vegetables have long played a critical role in making food safer. Irradiation and high-pressure treatment are examples of new supplemental intervention to enhance food safety (Osterholm and Potter, 1997; Tauxe, 2001; Torres and Velazquez, 2005).

## New Infectious Agents

Several infectious agents were added to the list of foodborne pathogens during the closing decades of the 20th century. Common to their “discoveries” was the magic combination of astute recognition of clinical illness and dogged epidemiological investigation backed up by intensive laboratory investigation. The yield from this combined approach ranged from new information for an “old” pathogen (the foodborne nature of *Listeria* transmission) to the discovery of a truly new pathogen (e.g. *E. coli* O157:H7).

*Escherichia coli* O157:H7 was first discovered as a human pathogen in 1982. It is now recognized as the most common cause of bloody diarrhea in North America and Western Europe, and has caused outbreaks on an unprecedented scale that have strained clinical and public health resources (Tarr *et al.*, 2005). Hemolytic uremic syndrome (HUS) may develop as a complication of this infection, and HUS caused by *E. coli* O157:H7 is the most common cause of acute renal failure in childhood. Diverse food vehicles, including undercooked ground beef, alfalfa sprouts, unpasteurized juice, unpasteurized milk, and lettuce, have transmitted this infection (Rangel *et al.*, 2005).

*Salmonella* has appeared in a variety of forms and foods. In the 1980s a worldwide pandemic of *Salmonella* serotype Enteritidis infections began that continues today. This

pandemic is related particularly to eggs, as this type of *Salmonella* colonizes the ovaries of hens so that the internal contents of the eggs they lay are contaminated with it (Braden, 2006). In the late 1990s, two highly resistant strains of *Salmonella*, *Salmonella* serotype Typhimurium defined type 104 (DT104) and *Salmonella* serotype Newport with the multi-drug resistant AmpC gene (MDR AmpC) appeared in the United States, in cattle and in people. While they have been transmitted through various foods, they are most strongly associated with dairy cattle and with foods derived from them such as lean ground beef and unpasteurized milk (Glynn *et al.*, 1998; Gupta *et al.*, 2003). These two strains now represent 11% of human salmonellosis in the United States, and are not controlled by current measures.

Two newly described parasitic causes of foodborne disease include *Cryptosporidium* and *Cyclospora*. Originally considered a veterinary pathogen, *Cryptosporidium* had only on rare occasions been described as a human pathogen prior to 1980. This changed considerably with the advent of the HIV epidemic, in which HIV-infected patients, mainly those with extremely low CD4 lymphocyte counts, developed severe and unremitting watery diarrhea from *Cryptosporidium*. Contaminated water accounts for a larger proportion of transmission of this pathogen than contaminated foods (Roy *et al.*, 2004). A waterborne outbreak in Milwaukee in 1993 affected more than 400 000 persons and illustrated the vulnerability of some municipal water supplies (MacKenzie *et al.*, 1994).

Contaminated raspberries from Guatemala were the source for numerous outbreaks of diarrhea in 1996 in both the United States and Canada. Recognition of outbreaks was facilitated by extremely high attack rates (often greater than 80%) and a notably severe diarrheal illness. Yet these aspects were at odds with the largely negative diagnostic testing of stool samples. More intensive laboratory investigation ultimately identified *Cyclospora* as the causative agent (Herwaldt, 2000).

Novel foodborne diseases have been described for which there is as yet incomplete understanding of the pathogenic agent. Brainerd diarrhea is the designation for a chronic diarrhea syndrome that originally occurred in Brainerd, Minnesota. Illness was associated with raw milk consumption and was both severe and long lasting, with diarrhea for more than 1 year in many patients (Mintz, 2003).

New variant Creutzfeldt–Jacob disease (nvCJD) is a dementing, ultimately fatal illness that occurred in otherwise healthy young and middle-aged adults, mainly in the

United Kingdom in the late 1990s (Will *et al.*, 2000). Pathological changes in the brains of these patients and characterization of the prion in them indicates that nvCJD is a form of BSE (Bruce *et al.*, 1997). The human nvCJD cases were recognized after an epidemic of BSE in the United Kingdom that had occurred approximately 6 years earlier. It is likely that changes in rendering practices allowed meat and bonemeal to remain infectious with the BSE prion agent and that subsequent foodborne transmission to cattle ensued when these were used in feeds. The link is thought to be that the BSE agent crossed the species barrier and the human nvCJD cases resulted from acquisition of infection through consumption of BSE-contaminated beef or beef-derived products (Brown *et al.*, 2001).

## Different Risks in Food Production

There are marked differences in food production practices today compared with those earlier in the 20th century. Agricultural products and food animals were raised in smaller groupings, and food products were usually only seasonally available to a population in the immediate vicinity of the harvest. Food technologies that are now commonplace (e.g. aquaculture, extended-shelf-life products) did not even exist. Today the scale of production within the food industry has markedly increased; for example, hamburger may be ground in lots of several thousand kilograms. Finished products are distributed over a much broader geographic region, and even raw materials may be transported in bulk over considerable distances. A large-scale outbreak of salmonellosis was the result of a tanker truck being used to transport pasteurized ice cream premix immediately after it had transported raw eggs contaminated with *Salmonella*. The subsequently contaminated ice cream product was distributed over the entire continental United States (Hennessy *et al.*, 1996). When an ingredient is contaminated, the resulting outbreak can be large and complex. In 2009, peanut butter and peanut paste from one small factory contaminated with *Salmonella* led to a large nationwide outbreak, and the recall of 3900 products (CDC, 2009b).

Foodborne outbreaks due to fresh produce have increased markedly in the last three decades as the consumption of fresh produce increased and as produce imported from around the world became available (Sivapalasingham *et al.*, 2004). This means that the health of the consumer in the United States is now linked directly

to the sanitary conditions of field workers and the food safety systems of many countries.

Low-level contamination of a foodstuff may cause outbreaks that are difficult to detect because there may be a relatively small number of cases dispersed over a broad geographic area. New food and ingredient sources may introduce pathogens that were previously rare or geographically restricted. Pathogens that survive in low moisture environments or that multiply at refrigerator temperatures may persist in niches in the processing environment. New harvest and processing technologies may be implemented without full regard for the microbiological implications, leading to new opportunities for contamination. Efforts to enhance food safety must have built-in mechanisms that enable them to continually evolve, because challenges from new pathogens, new vehicles of transmission, and new risk factors will undoubtedly continue to arise.

## Vaccine Prospects

Of the microbial agents commonly recognized as being transmitted by food, only three have an effective, licensed, human vaccine for prevention: hepatitis A, *Salmonella* serotype Typhi, and *Vibrio cholerae* O1. Typhoid and cholera occur at such exceedingly low rates in the United States that vaccination is not warranted; travelers to high-risk countries are advised to get typhoid immunization. Hepatitis A vaccination is increasingly being used to control local outbreaks or more broadly in states with high case rates. Some institutions and commercial establishments have chosen to provide hepatitis A vaccine for food handlers and others involved in food preparation.

An experimental human vaccine for *E. coli* O157:H7 has been developed that induces antibody to the O157 lipopolysaccharide. Vaccine constructs have been developed for *Shigella* and *Salmonella* that have been tested in animal models. Considerable work remains to be done to demonstrate their safety and efficacy.

Another avenue of pursuit in vaccine development has been the development of animal vaccines. Many foodborne pathogens are colonizers of animal digestive tracts. These include *E. coli* O157:H7 and ETEC in cattle and *Salmonella* and *Campylobacter* in poultry. *Salmonella* vaccines for chickens played an important part in the dramatic reduction of *Salmonella* serotype Enteritidis in egg-laying chicken flocks in Great Britain, and increasingly are used in the United States. Two commercial cattle vac-

cines are now licensed for use against *E. coli* O157. The optimum use of these vaccines and how best to combine them with other on-farm ("pre-harvest") control measures are areas of active investigation. Whether for humans or animals, the ultimate success of a vaccine will rest with defining the target group to be immunized, accessing that group consistently, and ensuring high vaccination rates.

## Prevention

Surveillance for foodborne disease has become the ultimate cornerstone for preventive efforts. In recent years the major focus of outbreak investigations triggered by surveillance has been to ascertain a root cause for how a food became contaminated, whether as a raw product, during processing, or afterward. The findings are then used to devise control strategies to reduce or eliminate the problem of pathogen contamination. In the eyes of most public-health authorities, surveillance has been transformed from a slow, paper-pushing effort to one that is dynamic, interactive, and increasingly web-based.

Similarly, the field of prevention has seen rapid progress in recent years as the food industry has embraced the need to reduce the contamination of foods before they reach the final consumer. Food processing equipment manufacturers now routinely consider microbiological outcomes in their designs, and the processes themselves are being overhauled to produce a product that is microbiologically safer, as well as tasty, nutritious, and economically sound.

Much foodborne disease can be prevented by using multiple steps to reduce contamination from farm to fork. Much of the prevention of foodborne diseases occurs before the food is prepared and served. Minimizing contamination starts in the farm, field or fishery, where good practices may reduce the likelihood of contamination even before harvest. After harvest, our industrialized food supply offers many points at which contamination can be prevented or eliminated. A safety engineering approach that identifies those points, and sets controls in place to guarantee that they are effectively used, has become the new standard for much of the food industry. This approach, the Hazard Analysis and Critical Control Point (HACCP) approach, is geared to prevent contamination before it occurs rather than to inspect for contamination that has already occurred (Doores, 1999). An HACCP program depends on continuous monitoring of steps in food processing that are critical in preventing the introduction, survival, or outgrowth of pathogens, such as heating or

acidification, as well as those that reduce the pathogen burden, such as retort canning, pasteurization, high-pressure treatment or irradiation. It is essential that documentation of the measurements of the parameter considered critical for control be recorded. Deviation from the accepted parameters for process control requires corrective action, which must also be documented. HACCP is well established for processed foods exposed to an adequate kill step. HACCP has been implemented in meat and poultry and seafood processing plants. The FDA Food Safety Modernization Act, which was signed January 4, 2011, mandates that similar approaches be implemented for other foods, among many other important changes (Government Printing Office, 2011).

Food-handling errors in the kitchen can lead to illness, and educating food handlers and consumers about food safety at the point of preparation can help prevent the occurrence of such mistakes. In a study comparing restaurants that had outbreaks with those that did not, the presence of a food service manager certified in food safety was significantly associated with not having an outbreak (Hedberg *et al.*, 2006). Some jurisdictions are requiring restaurants to have such a manager on staff, in addition to passing standard restaurant inspections. In the kitchen at home, careful attention to the precepts of “Cook, Clean, Chill, and Separate” can reduce the risk of foodborne illness ([www.fightbac.org/safe-food-handling](http://www.fightbac.org/safe-food-handling), accessed February 28, 2011). This means: using a thermometer to be sure that meat and poultry are adequately cooked; washing hands and food preparation surfaces frequently; prompt refrigeration of leftovers in a refrigerator that is below 40°F (4.4°C); and keeping raw and cooked foods separate during purchase, storage, and preparation with careful attention to avoid cross-contaminating other foods with the utensils or hands that have touched raw meat and poultry.

## Future Directions

Unpredictably but reliably, new foodborne diseases will continue to emerge. The constantly changing food supply will continue to offer opportunities for pathogens to infect us through new and unsuspected routes. Enhanced public-health vigilance, investigation of outbreaks, and microbiological and food science research will continue to be critical components of food safety. The globalization of the food supply will need to be matched by the expanded collaborative surveillance networks around the world, and by a

commitment in many countries to address the identified hazards. Surveillance will increasingly include monitoring the circulation of human pathogens among animals and plants, and those present in foods, to provide an integrated view of the ecologies that drive them. The inappropriate uses of antibiotics in agriculture to promote growth and prevent disease will diminish, and with it the threat of antimicrobial-resistant strains of food-associated pathogens should decrease. The growing science of probiotics, at both the animal and human level, offers the hope of broad-scale prevention of infection by bolstering the resistance of gut flora to colonization by external pathogens.

The future of food safety lies in the joint efforts of consumers, food producers, public health authorities, and government. One major step in this direction is the recognition of a “farm to fork” continuum. Ensuring a safe food supply depends on efforts all along that continuum. Improved consumer education is needed that targets specific populations and/or food practices, and that results in consistent and long-lasting behavioral change, but by itself is insufficient. Safer processing is critical at animal slaughter and food-fabrication plants, and more critical pathogen control technologies, such as pasteurization, irradiation, and pressure treatment, will be needed for foods likely to be contaminated with deadly pathogens. Introducing safer practices in animal husbandry, fresh vegetable production, and shellfish harvesting will have long-term benefits for public health. Introducing safety specifications into purchase contracts can rapidly make the concerns of consumers and retailers heard all the way back at the primary producers. The food industry and governmental authorities need to adapt to both the global marketplace and to pathogens, for which national boundaries are irrelevant. Because much of the burden of foodborne disease is preventable, it is a reasonable expectation that scientifically based efforts can significantly reduce that burden and improve human health.

## FOOD ALLERGIES AND INTOLERANCES

STEVE L. TAYLOR, PhD AND JOSEPH L. BAUMERT, PhD

*University of Nebraska, Lincoln, Nebraska, USA*

### Summary

Food allergies and intolerances affect a small but significant portion of the population. Symptoms can range from mildly annoying to severe and life-threatening. The true food allergies present the biggest risk because symptoms can occasionally be quite severe and the threshold dose of the offending food needed to provoke a reaction is quite small. The only management strategy for individuals with food allergies and intolerances is the specific avoidance of the offending food. Development of safe and effective avoidance diets can be quite difficult for individuals with true food allergies.

### Introduction

Centuries ago, Lucretius stated, “What is food to one is bitter poison to another.” Food allergies and sensitivities can be collectively referred to as *individualistic* adverse reactions to foods because these illnesses affected only certain individuals within the population. Although these diseases are often grouped together under the general heading of “food allergy,” a variety of different types of illnesses are involved. The existence of several different types of adverse reactions to foods with varied symptoms, severity, prevalence, and causative factors is not recognized by some physicians. Consumers are even more likely to be confused regarding the definition and classification of adverse reactions to foods. Consumers perceive that “food allergies” are quite common (Sloan and Powers, 1986), but many self-diagnosed cases of “food allergy” incorrectly associate foods with a particular malady or ascribe various mild forms of postprandial eating discomfort to this category of illness.

### Classification

Table 71.1 provides a classification scheme for the different types of illnesses that are known to occur in association with food ingestion and that only involve certain individuals in the population. Two major groups of individualistic adverse reactions to foods are known: true food allergies and food intolerances. The true food allergies involve abnormal immunological mechanisms whereas the food intolerances do not. Knowing and recognizing the difference between immunological food allergies and non-immunological food intolerances is crucial. True food allergies can be provoked in some cases by very low doses of the offending foods while those with intolerances can often tolerate larger doses of the offending food. A food allergy is an abnormal immunological response to a food or food component, usually a naturally occurring protein (Taylor and Hefle, 2001). Two different types of abnormal immunological responses are known to occur. Immediate

hypersensitivity reactions are antibody-mediated, whereas delayed hypersensitivity reactions are cell-mediated.

In contrast, food intolerances do not involve abnormal responses of the immune system (Taylor and Hefle, 2001). Three major categories of food intolerances are recognized: anaphylactoid reactions, metabolic food disorders, and food idiosyncrasies.

**TABLE 71.1** Classification of individualistic adverse reactions to foods

Classification	Example
<i>True food allergies</i>	
Antibody-mediated food allergies	IgE-mediated food allergies (peanut, cows' milk, etc.) Exercise-associated food allergies
Cell-mediated food allergies	Celiac disease Other types of delayed hypersensitivity
<i>Food intolerances</i>	
Anaphylactoid reactions	
Metabolic food disorders	Lactose intolerance
Idiosyncratic reactions	Sulfite-induced asthma

## IgE-Mediated Food Allergy

### Mechanism

Immediate hypersensitivity reactions are mediated by allergen-specific IgE antibodies (Figure 71.1). In IgE-mediated food allergies, allergen-specific IgE antibodies are produced by B cells in response to the immunological stimulus created by exposure of the immune system to the allergen (Burks and Ballmer-Weber, 2006). Food allergens are usually naturally occurring proteins present in the food (Breiteneder and Mills, 2008). The allergen-specific IgE antibodies bind to the surfaces of mast cells in the tissues and basophils in the blood. This is the sensitization phase of the allergic response. The sensitization phase is asymptomatic. On subsequent exposure to the specific allergenic food, the allergens cross-link two or more of the IgE-antibodies affixed to the surfaces of mast cells or basophils. This interaction triggers the degranulation of the mast cell or basophil membrane and the release of a variety of potent physiologically active mediators into the bloodstream and tissues. The granules within mast cells and basophils contain many of the important mediators of the allergic reaction. These potent mediators are actually responsible for the symptoms of immediate hypersensitivity reactions. Histamine is perhaps the most important of the mediators

**FIG. 71.1** Mechanism of IgE-mediated food allergy.

released from mast cells and basophils in an allergic reaction. It can elicit inflammation, pruritus, and contraction of the smooth muscles in the blood vessels, gastrointestinal tract, and respiratory tract (Taylor and Hefle, 2001). Other important mediators include various leukotrienes and prostaglandins. The leukotrienes are associated with some of the symptoms that develop more slowly in IgE-mediated food allergies, such as late-phase asthmatic reactions. This same type of IgE-mediated reaction is also responsible for allergic reactions to other environmental substances such as pollens, mold spores, animal danders, and bee venoms; only the source of the allergen is different.

During the sensitization phase, an individual forms allergen-specific IgE antibodies after exposure to a specific food protein. However, even among individuals predisposed to allergies, exposure to food proteins does not usually result in the formation of IgE antibodies. In normal individuals, exposure to a food protein in the gastrointestinal tract results in oral tolerance through either the formation of protein-specific IgG, IgM, or IgA antibodies or no immunological response whatsoever (clonal anergy) (Ko and Mayer, 2005). Heredity and other physiological factors are important in predisposing individuals to the development of IgE-mediated allergies including food allergies (Hourihane *et al.*, 1996). Studies with monozygotic and dizygotic twins demonstrate that genetics is an extremely important parameter and that identical twins may even inherit the likelihood of responding to the same allergenic food, e.g. peanuts (Sicherer *et al.*, 2000). Approximately 65% of patients with clinically documented allergy have first-degree relatives with allergic disease (Hourihane *et al.*, 1996). Conditions that increase the permeability of the small intestinal mucosa to proteins such as viral gastroenteritis, premature birth, and cystic fibrosis also seem to increase the risk of development of food allergy.

### Symptoms

The onset time for these reactions ranges from a few minutes to several hours after the consumption of the offending food. IgE-mediated food allergies involve numerous symptoms ranging from mild and annoying to severe and life-threatening (Table 71.2). No individual with IgE-mediated food allergy suffers from all of the symptoms noted in Table 71.2. Furthermore, the symptoms are not necessarily consistent from one episode to another for an individual. The nature and severity of symptoms can also vary as a result of the amount of the

**TABLE 71.2** Symptoms associated with IgE-mediated food allergy

Type	Symptom
Gastrointestinal	Nausea Vomiting Diarrhea Abdominal cramping
Cutaneous	Urticaria Dermatitis or eczema Angioedema Pruritus
Respiratory	Rhinitis Asthma Laryngeal edema
Generalized	Anaphylactic shock

offending food that has been ingested and the length of time since the previous exposure. An individual who experiences only mild symptoms on ingestion of a specific food, e.g. oral pruritus, may develop more serious manifestations on subsequent occasions, especially if avoidance of the offending food is not routinely practiced.

Gastrointestinal and cutaneous symptoms are among the more common manifestations of IgE-mediated food allergies. Respiratory symptoms are less commonly encountered but can be severe and life-threatening. Mild respiratory symptoms such as rhinitis and rhinoconjunctivitis are more likely to be encountered with exposure to environmental allergens such as directly inhaled airborne pollens or animal danders. However, respiratory reactions associated with food allergies can occasionally be severe (asthma and laryngeal edema). Those few food-allergic individuals who experience severe respiratory reactions in connection with the inadvertent ingestion of the offending food are most likely to be at risk for life-threatening episodes (Sampson *et al.*, 1992). Of the many symptoms involved in IgE-mediated food allergies, systemic anaphylaxis is the most severe manifestation. Systemic anaphylaxis, also sometimes referred to as anaphylactic shock, involves multiple organ systems and numerous symptoms. The symptoms can involve the gastrointestinal tract, respiratory tract, skin, and cardiovascular system. Death can occur from severe hypotension coupled with respiratory and cardiovascular complications. Anaphylactic shock is the most common cause of death in the occasional fatalities associated with IgE-mediated food allergies (Yunginger *et al.*, 1988; Sampson *et al.*, 1992; Bock *et al.*, 2007; Pumphrey

and Gowland, 2007). The number of deaths occurring from IgE-mediated food allergies is not recorded in most countries, but more than 100 deaths are thought to occur in the United States each year (Sampson, 2003).

### **Oral Allergy Syndrome**

Oral allergy syndrome is one of the more common and most mild forms of IgE-mediated food allergy (Wang, 2008). In this syndrome, ingestion of the offending foods – often fresh fruits and vegetables – elicits mild oropharyngeal symptoms: pruritus, urticaria, and angioedema. Fresh fruits and vegetables contain comparatively low quantities of the protein allergens, but oral allergy syndrome is an IgE-mediated response involving reactions to certain specific proteins (Wang, 2008). Apparently, the allergens in these fresh fruits and vegetables are rapidly digested by the proteases of the gastrointestinal tract (Taylor and Lehrer, 1996), and systemic reactions are rarely encountered. The allergens are also apparently heat labile (Taylor and Lehrer, 1996) because heat-processing eliminates their effects. Individuals with oral allergy syndrome are initially sensitized to one or more environmental pollens, frequently from birch or mugwort (Wang *et al.*, 2008). Once sensitized to the pollen allergens, these individuals are reactive to proteins that exist in foods, which cross-react with these allergens.

### **Exercise-Induced Food Allergies**

Exercise-induced food allergies are a subset of the immediate hypersensitivity reactions to foods. They involve allergen-specific IgE antibodies, but occur only when the food is eaten in conjunction with exercise (Williams and Simon, 2008). Numerous foods have been implicated, including shellfish, wheat, celery, and peach. The symptoms are as individualistic and variable as those for other food allergies. Exercise-induced allergies can also exist without any role for food intake (Williams and Simon, 2008). The mechanism of this illness is not well understood but the involvement of IgE antibodies is clear. With the recent national emphasis on increased physical activity, reports of this condition may increase.

### **Prevalence**

The overall prevalence of IgE-mediated food allergies for all age groups is likely in the range of 3.5–4.0% for the United States. A recent analysis of the prevalence of food allergies revealed that the evidence basis was remarkably weak (Rona *et al.*, 2007). For example, few epidemiologi-

cal investigations involving clinical confirmation of IgE-mediated food allergies have been conducted using representative groups of adults. Most clinical investigations on the prevalence of IgE-mediated food allergies among adults have involved groups of patients seen at allergy clinics. Such selected groups of adults are unlikely to represent the entire population, and the prevalence rates for these groups are likely to be higher than for the general population. A large-scale epidemiological investigation of the prevalence of IgE-mediated food allergy was conducted in The Netherlands (Neistijl Jansen *et al.*, 1994). This study revealed that although >10% of Dutch adults believed that they had adverse reactions to foods, the prevalence of these reactions was ~2% when clinical histories were confirmed by blinded food challenges (Neistijl Jansen *et al.*, 1994). The prevalence rate for IgE-mediated food allergies among infants and young children is more clearly defined and is likely considerably higher than for adults (Sampson, 1990). Clinical trials among groups of unselected infants suggest that the prevalence of IgE-mediated food allergies is in the range of 4–8% (Bock *et al.*, 1978; Sampson, 2004). Despite the lack of clinical epidemiological trials among adults, recent surveys conducted in the United States, Canada, and England indicate that the self-perceived prevalence of peanut allergy alone is 0.5–0.8% among all age groups (Emmett *et al.*, 1999; Ben-Shoshan *et al.*, 2010; Sicherer *et al.*, 2010). Surveys in the United States of the self-perceived prevalence of tree nut, fish, and crustacean shellfish allergies indicate that 0.5%, 0.4%, and 1.9%, respectively, believe that they have these particular food allergies (Sicherer *et al.*, 2004, 2010). These surveys did not include clinical investigations to confirm that peanut, tree nut, fish, or crustacean shellfish allergies truly existed in these individuals. Because these food allergies are often rather profound, overestimates associated with reliance on self-diagnosis are probably minimal. If the prevalence of these four food allergies is estimated at 3.4% and the prevalence of all food allergies among infants is 4–8%, then an overall estimate for IgE-mediated food allergies of 3.5–4.0% seems reasonable.

### **Persistence**

Many food-allergic infants outgrow their food allergies within a few months to several years after the onset of the sensitivity (Sampson, 1996). Allergies to certain foods, such as cows' milk, are more commonly outgrown than are allergies to certain other foods such as peanut. Allergies to peanuts were considered to be a lifelong affliction until

recently when clinical researchers have demonstrated that peanut allergy, especially when acquired very early in life, can be outgrown (Skolnick *et al.*, 2001), although that does not seem to be a frequent occurrence. While milk and egg allergy are more frequently outgrown than peanut allergy, recent studies have documented that these allergies are increasingly persistent in a sub-group of patients with milk and egg allergy (Savage *et al.*, 2007; Skripak *et al.*, 2007). The mechanisms involved in the loss of sensitivity to specific foods are not precisely known, but the development of immunological tolerance is definitely involved (Ko and Mayer, 2005).

### **Prevention of Sensitization**

IgE-mediated food allergies are most likely to develop in high-risk infants – those born to parents with histories of allergic disease of any type (pollens, mold spores, animal danders, bee venoms, food, etc.). Preventing the development of food allergies in such infants has been a subject of great interest. Various strategies have been investigated. The restriction of the diet of the mother during pregnancy (excluding commonly allergenic foods such as peanuts) does not appear to help prevent allergy in the infant (Lack and Du Toit, 2008). These observations suggest that sensitization does not occur in utero. Breastfeeding for extended periods of time appears to delay but may not prevent the development of IgE-mediated food allergies (Zeiger and Heller, 1995), and infants can be sensitized to allergenic foods through exposure to the allergens in breast milk (Van Asperen *et al.*, 1983). Apparently, allergenic food proteins can resist digestion, can be absorbed at least to a small extent from the small intestine, and can be secreted in breast milk, leading to sensitization. The exclusion of certain commonly allergenic foods from the maternal diet during the lactation period will help to prevent sensitization through breast milk. The elimination of peanuts from the diet of lactating women with high-risk infants is often recommended, but milk and eggs are usually considered to be too important nutritionally to exclude from the diets of lactating women. The use of probiotics during lactation may also help to lessen the likelihood of allergic sensitization (Kirjavainen *et al.*, 1999). Hypoallergenic infant formula may also prevent the development of food allergies in high-risk infants (Businco *et al.*, 1993), although these formulas are more often used to prevent reactions after sensitization has already occurred. The use of partial whey hydrolysate

formula has been advocated because the partial hydrolysate is more likely to prevent sensitization than a formula based on whole milk (Vandenplas *et al.*, 1995). High-risk infants may still develop food allergies once solid foods are introduced into the diet (Zeiger and Heller, 1995).

### **Common Allergenic Foods and International Lists**

Eight foods or food groups – milk, eggs, fish, Crustacea (shrimp, crab, lobster, etc.), peanuts, soybeans, tree nuts (walnuts, almonds, hazelnuts, etc.), and wheat – are responsible for the vast majority of IgE-mediated food allergies worldwide (FAO, 1995), but regional differences exist. Examples of food allergies that occur more frequently in certain parts of the world than in others would include celery allergy in Europe (Wuthrich *et al.*, 1990), sesame seed allergy in several areas of the world (Kanny *et al.*, 1996; Sporik and Hill, 1996), and buckwheat allergy in Japan (Ebisawa *et al.*, 2003). These regional differences likely relate to food preferences in those areas and sometimes to coexistent pollen allergies (e.g. celery allergy in individuals sensitized to mugwort pollen). Beyond the eight major foods or food groups, >160 other foods have been documented to cause IgE-mediated food allergies (Hefle *et al.*, 1996). Because food allergens are proteins, any food that contains protein is likely to elicit allergic sensitization on at least rare occasions. The eight most commonly allergenic foods or food groups contain comparatively high amounts of protein and are commonly consumed in the diet. However, several other commonly consumed foods with high protein contents, such as beef, pork, chicken, and turkey, are rarely allergenic.

Ingredients derived from the commonly allergenic foods will also be allergenic if they contain sufficient residual protein from the source material. The most common questions concerning food ingredients involve edible oils, protein hydrolysates, lecithin, flavors, gelatin, spices, and colors. The passage of the Food Allergen Labeling and Consumer Protection Act of 2004 (FALCPA) mandates source labeling of ingredients derived from commonly allergenic sources with few exceptions (highly refined oils and ingredients that become exempt through notifications or petitions that must be approved by the US Food and Drug Administration). Similar ingredient labeling regulations exist in other parts of the world including the European Union, Canada, Australia, and New Zealand, although differences do occur in the lists

of commonly allergenic foods among different countries or regions.

When edible oils are highly refined through a process that involves hot solvent extraction with bleaching and deodorizing, virtually all of the protein is removed from the source material. Clinical challenge trials have shown that highly refined oils from peanut, soybean, and sunflower seed are safe for ingestion by individuals allergic to the source material through use of clinical challenge trials (Crevel *et al.*, 2000). Oils from other sources such as sesame seed and tree nuts may receive less processing and contain allergenic residues (Kanny *et al.*, 1996; Teuber *et al.*, 1997). Cold-pressed oils may also contain allergenic residues (Hoffman and Collins-Williams, 1994).

Protein hydrolysates are often obtained from commonly allergenic sources: soybean, wheat, milk, and peanuts. Several processes, including acid hydrolysis and enzymatic hydrolysis, are used to obtain these hydrolysates. The degree of hydrolysis of the proteins in hydrolysates varies according to the functional use, source, and method of hydrolysis. If the proteins are only partially hydrolyzed, they are likely to retain their allergenicity. If they are extensively hydrolyzed, they may be safe for most individuals allergic to the source material. However, even extensively hydrolyzed casein in hypoallergenic infant formula has triggered allergic reactions in some infants exquisitely sensitive to milk (Nilsson *et al.*, 1999). Infant formulas based upon partial whey hydrolysates are even more likely to elicit allergic reactions in infants allergic to milk (Businco *et al.*, 1989).

Lecithin can be derived from soybean, egg, rice, or sunflower seed, although soybean is by far the most common source. Commercial soy lecithin contains trace residues of soy proteins. The soy protein residues in lecithin include IgE-binding proteins (Müller *et al.*, 1998), but the levels may be insufficient to elicit allergic reactions in most soybean-allergic individuals. Many soybean-allergic individuals do not avoid lecithin.

Most flavoring formulations do not contain protein, and few formulations contain any components derived from allergenic sources (Taylor and Dormedy, 1998). Flavoring has only rarely caused well documented allergic reactions (Gern *et al.*, 1991; Taylor and Dormedy, 1998).

Gelatin is most frequently derived from beef and pork and is generally not considered allergenic when ingested. Gelatin can also be derived from fish, but fish gelatin is unlikely to elicit reactions in fish-allergic individuals (Hansen *et al.*, 2004).

Spices are rare causes of allergic reactions (Niinimäki *et al.*, 1989). A few spices have been occasionally implicated in allergic reactions including mustard (Rance *et al.*, 2001) and fenugreek, a common component of curry (Faeste *et al.*, 2009). Avoidance of specific spices in the diet can be quite difficult.

None of the colorants used in foods are derived from commonly allergenic sources. However, the natural colorants, carmine and annatto, contain protein residues, and both have been implicated in rare allergic reactions (Lucas *et al.*, 2001).

Many other food ingredients are derived from commonly allergenic sources, e.g. phytosterols, vitamin E, and isoflavones from soybean, lactose, butter acid and butter esters from milk, and isinglass and fish oil from fish. FALCPA and similar legislation or regulation in other countries mandates the source labeling of all of these ingredients. Many of these ingredients are not known to pose hazards to individuals allergic to the source food, although clinical evidence of the lack of allergenicity is typically not available. Source labeling of these ingredients will further restrict the dietary choices for food-allergic consumers.

### Food Allergens

Food allergens are almost always naturally occurring proteins (Breiteneder and Mills, 2008). Foods contain hundreds of thousands of different proteins, and only a small percentage are known allergens. The major allergens have been identified, purified, and characterized for most of the commonly allergenic foods (Breiteneder and Mills, 2008). Multiple allergenic proteins exist in some commonly allergenic foods. Foods may contain both major and minor allergens. Major allergens are defined as proteins that bind to serum IgE antibodies from >50% of patients with a specific food allergy. For example, milk contains three major allergens: casein,  $\beta$ -lactoglobulin, and  $\alpha$ -lactalbumin (Wal, 2002). These also happen to be the major milk proteins. Milk may also contain several minor allergens, e.g. bovine serum albumin, although the level of evidence for clinical relevance is less convincing for these minor allergens (Baldo, 1984). Peanuts contain at least three major allergens, named *Ara h 1*, *Ara h 2*, and *Ara h 3* (Breiteneder and Mills, 2008). Peanuts also contain numerous minor allergens (Bannon *et al.*, 2000). In contrast, codfish (*Gad c 1*), Brazil nut (*Ber e 1*), and shrimp (*Pen a 1*) contain primarily one major allergenic protein (Breiteneder and Mills, 2008).

### **Treatment – Pharmacological, Immunotherapy, and Avoidance Diets**

Pharmacological approaches (epinephrine and antihistamines) are available for treating the symptoms of an allergic reaction (Wang and Sampson, 2007). Antihistamines are often used to treat the symptoms of mild to moderate food allergy reactions. However, epinephrine is the drug of choice to treat severe anaphylactic reactions to foods. Immunotherapeutic approaches are under development, show some promise, but remain experimental. The first of the immunotherapeutic approaches involved administration of anti-IgE antibodies (Leung *et al.*, 2003). More recently, oral and sublingual immunotherapies have shown initial promise (Burks *et al.*, 2008). However, at present, avoidance diets remain as the mainstay approach for preventing allergic reactions to foods (Taylor *et al.*, 1999). For example, if allergic to peanuts, simply avoid peanuts in all forms.

### **Threshold Doses**

Practical experience demonstrates that exposure to trace levels of the offending food can elicit adverse reactions. Anecdotal reports suggest that reactions could occur from exposure to the small quantities through using shared utensils or containers, kissing the lips of someone who has eaten the offending food, opening packages of the offending food, or inhalation of vapors from the offending food. Although these situations are not well documented, the amount of the offending food that would be ingested from such occurrences would be quite low. Other episodes have been more thoroughly documented. Allergic reactions have occurred to peanut protein in sunflower seed butter prepared on equipment used for peanut butter (Yunginger *et al.*, 1983), milk protein in sorbet manufactured with equipment also used for ice cream (Laoprasert *et al.*, 1998), and milk protein in tofutti manufactured with equipment also used for ice cream (Gern *et al.*, 1991). Although complete avoidance must be maintained, threshold doses do exist below which allergic individuals will not experience adverse reactions (Taylor *et al.*, 2002, 2010). Recent evidence suggests that the threshold dose for peanuts is in the low milligram range with an ED<sub>10</sub> (minimal eliciting dose for 10% of peanut-allergic subjects) of 14.4 mg of whole peanuts (Taylor *et al.*, 2010). The most sensitive individuals reacted to as little as 0.4 mg of whole peanuts, and individual peanut thresholds varied over several orders of magnitude (Taylor *et al.*, 2010). The possibility exists that the threshold doses will not be the

same for every allergenic food, but this remains to be fully elucidated.

### **Cross-Reactions**

In the construction of safe and effective avoidance diets, questions often arise regarding the need to avoid closely related foods. For some foods, cross-reactions do seem to occur with closely related foods. For example, shrimp-allergic individuals will also typically be sensitive to other crustaceans including crab and lobster (Daul *et al.*, 1993). Similarly, cross-reactions commonly occur between different species of avian eggs (Langeland, 1983) and between milk from cows and goats (Bernard *et al.*, 1999). In contrast, some peanut-allergic individuals are allergic to other legumes such as soybean (Herian *et al.*, 1990), but this is not common. Clinical hypersensitivity to one legume, such as peanuts or soybeans, does not warrant exclusion of the entire legume family from the diet unless allergy to each individual legume is confirmed by clinical challenge trials (Bernhisel-Broadbent and Sampson, 1989). However, there are a few instances with legumes where cross-reactions become a more serious concern. The best example would be cross-reactions between lupine and peanut (Moneret-Vautrin *et al.*, 1999).

Cross-reactions are also known to occur between certain types of pollens and foods. Examples would include ragweed pollen and melons, mugwort pollen and celery, mugwort pollen and hazelnut, and birch pollen and various foods including carrots, apples, hazelnuts, and potatoes (Van Ree, 2004).

Cross-reactions are also known to occur between allergies to natural rubber latex and banana, chestnut, avocado, and kiwi among others (Blanco *et al.*, 1994).

### **Effect of Processing on Allergenicity**

Allergenic food proteins are remarkably stable to food processing conditions (Taylor and Lehrer, 1996; Mills and Mackie, 2008). As noted earlier, proteins can be removed from products derived from allergenic sources; the highly refined edible oils are the best example. Most allergenic food proteins are quite stable to heat so that typical heat processing conditions do not affect the allergenicity of the resulting products (Taylor and Lehrer, 1996). Some exceptions are certain fruit and vegetable allergens that are sensitive to heat (Jankiewicz *et al.*, 1997), and fish allergens, which may be destroyed by canning but not other heat processes (Bernhisel-Broadbent *et al.*, 1992). Food allergens also tend to be resistant to proteolysis (Bannon *et al.*,

2002), which allows them to survive digestive processes and arrive in the intestine in immunologically active form. The resistance to proteolysis means that these allergens may survive, in whole or in part, the acid and enzymatic hydrolysis methods used to prepare protein hydrolysates (Taylor and Lehrer, 1996).

### **Impact of Agricultural Biotechnology**

Concerns have arisen regarding the possible allergenicity of foods developed through agricultural biotechnology (Goodman *et al.*, 2005). Genetic modifications result in the transfer of one or more genes from one biological source to another. These genes code for specific proteins. Because food allergens are usually proteins, these novel proteins have some potential to be or become allergens. Millions of proteins exist in nature, including many in foods, and only a small percentage are allergens, so the probability of transferring a protein with allergenic potential into a transgenic food is quite small. Several strategies have been developed to assess the likelihood of allergenicity of these novel proteins from genetically modified foods (Goodman *et al.*, 2005). Certainly, the probability of transferring an allergen is enhanced if the gene is derived from a known allergenic source. The reliability of allergy assessment strategies was documented with the discovery that a gene from Brazil nuts cloned into soybeans to enhance the methionine content of soybeans coded for the major allergen from Brazil nuts, *Ber e 1* (Nordlee *et al.*, 1996); commercialization of that transgenic variety of soybeans was immediately halted.

### **Cell-Mediated Allergy**

Delayed hypersensitivities are cell-mediated allergic reactions and involve tissue-bound T lymphocytes that are sensitized to a specific foodborne substance that triggers the reaction (Taylor and Hefle, 2001). These reactions often result in localized tissue inflammation. In such reactions, symptoms begin to appear 6–24 hours after consumption of the offending food.

### **Celiac Disease**

Celiac disease – also known as celiac sprue, non-tropical sprue, or gluten-sensitive enteropathy – is a malabsorption syndrome occurring in sensitive individuals upon the consumption of wheat, rye, barley, triticale, spelt, and kamut (Taylor and Hefle, 2001; Rubio-Tapia and Murray, 2008).

Celiac disease is characterized by mucosal damage in the small intestine resulting from consumption of the offending grains or protein-containing products derived from those grains (Rubio-Tapia and Murray, 2008). This mucosal damage leads to nutrient malabsorption. The loss of absorptive function along with the ongoing inflammatory process results in diarrhea, bloating, weight loss, anemia, bone pain, chronic fatigue, weakness, muscle cramps, and, in children, failure to gain weight and growth retardation (Taylor and Hefle, 2001). Evidence suggests that intraepithelial T cells in the small intestine are involved in the inflammatory mechanism occurring with celiac disease (Maiuri *et al.*, 1996). The precise role of the intestinal T cells in celiac disease remains to be defined.

Celiac disease is an inherited trait, although its inheritance is complex (Taylor and Hefle, 2001). It occurs in ~5% of first-degree relatives of celiac patients, and ~75% of monozygotic twin pairs are concordant for it (Holtmeier *et al.*, 1997). Histocompatibility locus antigen (HLA) class II genes are the major genes associated with celiac disease, but concordance for celiac disease is only 25–40% in siblings who are identical for one or both HLA haplotypes. Thus, genes outside of the HLA locus likely have some as yet undefined role in disease susceptibility.

The exact prevalence of celiac disease is a matter of some debate. Prevalence estimates from different parts of the world are complicated by use of different diagnostic approaches. Celiac disease appears to be latent or asymptomatic in some individuals whose symptoms only appear occasionally (Duggan, 1997; Rubio-Tapia and Murray, 2008). The prevalence of celiac disease appears to be highest in certain European regions and in Australia (Logan, 1992), occurring in about 1 in every 250 people. Even within European populations, considerable variability is observed in the prevalence of celiac disease (Logan, 1992). In the United States, symptomatic celiac disease occurs in about 1 of every 3000 individuals (Taylor and Hefle, 2001), but 1 in every 133 individuals may be at risk for development of symptoms (Fasano *et al.*, 2001). Recently, gluten-free foods have become quite popular in the United States, leading to the widespread belief that the prevalence of celiac disease is increasing. Many consumers of gluten-free foods are selecting these foods without a confirmed diagnosis of celiac disease or a serological indication that they may be at risk for development of celiac disease. In reality, the prevalence may not have changed but both awareness and diagnostic confirmation have increased.

Celiac disease is associated with the ingestion of gliadin from wheat and related prolamin proteins from other grains (Taylor and Hefle, 2001). The prolamin fraction of wheat is known as gluten; hence celiac disease is sometimes called gluten-sensitive enteropathy. A defect in mucosal processing of gliadin in celiac patients provokes the generation of toxic peptides that contribute to the abnormal T-cell response and the subsequent inflammatory reaction (Inman-Felton, 1999). The mechanism involved in celiac disease and the exact role of gliadin remain to be determined.

The tolerance for wheat, rye, barley, and related grains among celiac sufferers is unknown. Clearly, the threshold dose may vary from one individual to another because, in latent forms of celiac disease, normal dietary quantities of the offending grains seem to cause little problem. Many celiac sufferers attempt to avoid all sources of these grains, including a wide variety of common food ingredients derived from these grains (Taylor, 2009). Most of these individuals also avoid oats, although the role of oats in the elicitation of celiac disease was refuted (Janatuinen *et al.*, 1995). Because oats are often contaminated with wheat in commerce, some caution may still be necessary. Although evidence is scant, spelt and kamut, which are basically varieties of wheat, are likely to trigger celiac disease in susceptible individuals.

The risk of death as a direct result of celiac disease is low (Corrao *et al.*, 2001), but individuals suffering from celiac disease for prolonged periods are at increased risk for development of T-cell lymphoma (Meijer *et al.*, 2004). Celiac patients also appear more likely to have various other autoimmune diseases including dermatitis herpetiformis, thyroid diseases, Addison's disease, pernicious anemia, autoimmune thrombocytopenia, sarcoidosis, insulin-dependent diabetes mellitus, and IgA nephropathy (McGough and Cummings, 2005; Rubio-Tapia and Murray, 2008).

## Food Intolerances

In contrast to true food allergies, food intolerances involve one of several non-immunological mechanisms. The distinction between food allergies and intolerances is important with respect to treatment as well as mechanism. Individuals with various types of food intolerances are typically able to tolerate some amount of the offending substance in their diet. In contrast, the threshold doses for the offending food with true food allergies are quite small.

Thus, the management of food intolerances is much easier. With a few very notable exceptions, little research has been conducted on food intolerances. In many cases, the cause-and-effect relationship between ingestion of the offending food or food ingredient and the adverse reaction has not been carefully established.

### Anaphylactoid Reactions

Anaphylactoid reactions are a non-IgE-mediated release of mediators from mast cells and basophils (Taylor and Hefle, 2001). Because the same mediators are involved as in true IgE-mediated food allergies, the symptoms are quite similar. Although anaphylactoid reactions are documented with adverse reactions to drugs, no proof exists that anaphylactoid reactions occur with foods.

### Metabolic Food Disorders

Metabolic food disorders occur as the result of genetically determined metabolic deficiencies that either affect the ability to metabolize a specific substance in foods or heighten sensitivity to a particular foodborne chemical (Taylor and Hefle, 2001). Lactose intolerance is an example of a metabolic food disorder (Taylor and Hefle, 2001). Inborn errors of metabolism such as phenylketonuria could be discussed within this context as some of them do respond to dietary restrictions. Conditions such as phenylketonuria are much more serious than lactose intolerance and involve special clinical oversight. They will not be discussed further in this chapter.

Lactose intolerance is associated with a deficiency of the enzyme,  $\beta$ -galactosidase (lactase), in the intestinal tract that leads to an inability to metabolize lactose from milk and other dairy products (Suarez and Savaiano, 1997). The symptoms of lactose intolerance are mild and are confined to the gastrointestinal tract, and include abdominal discomfort, flatulence, and frothy diarrhea (Suarez and Savaiano, 1997). Lactose intolerance affects a large number of people worldwide with a frequency as high as 60–90% among blacks, Native Americans, Hispanics, Asians, Jews, and Arabs (Taylor and Hefle, 2001). In contrast, the prevalence among North American Caucasians is ~6–12% (Taylor and Hefle, 2001). The usual treatment for lactose intolerance is the avoidance of dairy products containing lactose, but lactose-intolerant individuals can tolerate some lactose in their diets (Taylor and Hefle, 2001) and most have virtually no symptoms on consumption of the amount of lactose in 235 mL (1 cup) of milk (Taylor and Hefle, 2001). Additionally, some dairy products

(e.g. yogurt, acidophilus milk) are better tolerated than others, apparently because they contain bacteria with  $\beta$ -galactosidase (Taylor and Hefle, 2001). Thus, lactose intolerance is a manageable condition.

### **Food Idiosyncrasies**

Food idiosyncrasies are adverse reactions to foods or food ingredients that occur through unknown mechanisms. The best example of an idiosyncratic reaction is sulfite-induced asthma (Taylor *et al.*, 2008). Cause and effect are well established for sulfite-induced asthma but have not been well established in other types of food idiosyncrasies. Psychosomatic illnesses are also included in this category.

Sulfites are common food additives that also occur naturally in certain foods, especially fermented foods, usually in small amounts (Taylor *et al.*, 2008). Although asthma is the only well established symptom associated with sulfite sensitivity, only a small percentage of asthmatics are sulfite sensitive (Taylor *et al.*, 2008). Individuals with severe asthma who require steroids for control of symptoms are the primary risk group for sulfite sensitivity, but only ~5% of these are sulfite sensitive (Taylor *et al.*, 2008). Sulfite-induced asthma can be quite severe, and deaths have been documented (Taylor *et al.*, 2008). Sulfites added to foods must be declared on product labels so avoidance diets are reasonably easy to develop (Taylor *et al.*, 2008). Sulfite-sensitive individuals with asthma can tolerate the ingestion of small quantities of sulfite, especially when the sulfites are incorporated in certain types of foods (Taylor *et al.*, 1988). Although sulfite-induced asthma poses a considerable risk to sensitive individuals, this condition is manageable once it is recognized.

Many of the other idiosyncratic reactions also involve various food additives. Examples include tartrazine (a commonly used food colorant also known as FD&C Yellow 5) in asthma and/or chronic urticaria, other food colors in chronic urticaria, monosodium glutamate (a commonly used flavor enhancer) in asthma and monosodium glutamate symptom complex, and aspartame in migraine headache and urticaria (Bush and Taylor, 2009). Although tartrazine has been implicated in the elicitation of asthma and chronic urticaria for several decades, criticisms have arisen regarding the design of the clinical studies (Bush and Taylor, 2009). Both asthma and chronic urticaria are chronic conditions that are likely to flare at unpredicted times in susceptible individuals, many of whom take various medications continually to control symptoms. In the clinical studies, medications were with-

drawn from the patients for variable periods before the challenges, which were often not blinded. When the symptoms were exacerbated, the investigators concluded that tartrazine was responsible. However, the alternative explanation might be that the symptoms flared simply because critical medications were withdrawn. In studies where some of the medications were continued, tartrazine challenges had no effect on similar patients (Bush and Taylor, 2009).

Monosodium glutamate symptom complex, a mild subjective illness, has not been confirmed by double-blind, placebo-controlled food challenges (Kenny, 1986; Bush and Taylor, 2009), and a national panel concluded that the role of monosodium glutamate in the elicitation of the complex was not proven, especially at doses <3 g (Raiten *et al.*, 1995). Monosodium glutamate has also been implicated as a causative factor in asthma, but the clinical studies linking it to asthma are subject to the same criticisms as mentioned for tartrazine (Bush and Taylor, 2009).

### **Future Directions**

Although research on food allergies has increased in recent years, much uncertainty remains. The prevalence of true food allergies is not well understood in many countries including the United States, although a recently completed EU project called EuroPrevall holds considerable promise to improve the understanding of prevalence in that part of the world. The factors involved in sensitization certainly merit more attention. Oral tolerance to food proteins is the norm but we do not yet understand why tolerance does not develop in certain individuals, why certain proteins are more likely to become allergens, and the role of dietary practices in preventing sensitization. If IgE-mediated food allergies are increasing in prevalence as appearances indicate, that increases the importance of understanding the factors involved in the increase. The minimal threshold doses needed to provoke an adverse reaction in individuals with IgE-mediated food allergies need better understanding. Considerable variation exists among individuals with respect to individual threshold doses, and differences may also exist between different allergenic foods. A more complete understanding of individual and population threshold doses is needed to provide clear guidance for the protection of food-allergic consumers. The identity of many food allergens is known, but improved methods are needed to determine whether or not novel proteins introduced into the diet as part of novel foods, including

genetically modified foods, have the potential to become new allergens. With respect to food intolerances, basic information such as the mechanism of sulfite-induced asthma is not available, and the cause-and-effect relationship between various food additives and possible food intolerances requires better elucidation.

## Summary

During the past 20 years there has been a dramatic increase in obesity and diabetes across the globe. Escalation in prevalence and progression of this global, diet-linked epidemic is generally attributed to caloric-rich, nutrient-poor diets, increase in the aging population, and a sedentary lifestyle. Significant scientific support exists that increased consumption of vegetables is associated with lower risk of chronic diet-linked diseases. In spite of the inherent nutritive value and need for enhanced consumption, there is not enough consumption of vegetables because of their perceived poor taste, appearance appeal, and convenience. Enhancing the levels of precursors to essential nutrients and phytonutrients in vegetables would have a favorable impact on consumer sensory appeal, at the same time delivering higher nutritional value. Significant opportunity exists to integrate advances in breeding, biotechnology, high-throughput analytical, and molecular nutrition tools to address unmet consumer need and meet global demands for agricultural productivity. Germplasm diversity for various consumer and agronomic traits along with whole-genome sequence information, molecular markers, biochemical pathway insights, and high-throughput phenotyping enable rapid innovation of new crop varieties for enhancing consumption and ensuring crop productivity. In this chapter we have attempted to review the genetic and biotechnology approaches to enhance a few essential nutrients and bioactive phytonutrients in vegetables that are associated with nutritive value and consumer appeal. Progress in improving soybean oil quality with reduced saturated fat, improved shelf life, and elevated beneficial omega-3 fatty acids is also briefly discussed.

## Introduction

Epidemiological studies suggest that consumption of diets rich in fruits and vegetables is associated with a reduction in diet- and age-related chronic illness. Per capita consumption of fruits and vegetables is very low compared with that recommended across the globe. USDA estimates that 90–97% of the US population have an inadequate intake of well-recognized nutrients such as dietary fiber, vitamin E, potassium, etc. As the human population is predicted to be nearly 9 billion by 2050, sufficient quantities of nutritious crops need to be produced. Hence, there is an urgent need and growing interest in the development of nutritionally fortified crop varieties with higher yield to alleviate the global obesity epidemic and address malnutrition that still persists in developing countries (Connolly, 2008).

Essential nutrients are generally perceived to be dietary substances that impact growth and survival of an organism. Recent studies suggest that essential nutrients play a role beyond these basic needs, and impact biological processes associated with chronic illnesses due to systemic inflammation and oxidative stress. Foliates, for example, are crucial for nucleotide biosynthesis and amino acid metabolism in human cells (Bassett *et al.*, 2005; Rébeillé *et al.*, 2006). The repercussions of insufficient dietary folate include perturbation of one-carbon (C1) metabolism, which contributes to reduced turnover of erythrocytes (megaloblastic anemia), birth defects (neural tube defects [NTD]), as well as elevated plasma homocysteine levels (an emerging risk factor for vascular diseases) (Scott *et al.*, 2000; Jang *et al.*, 2005). In addition to dietary fortification, biofortification in staple crops and vegetables would meet the demand for higher consumption of this essential nutrient from fresh foods.

Along similar lines, calcium deficiency is a significant problem globally because of the growth in aging populations. Prolonged calcium deficiency leads to reductions in bone mass and disability due to osteoporosis. Biofortification of calcium in fruits and vegetables would not only increase dietary levels but also deliver other synergistic phytonutrients in crops that impact bioavailability and bone metabolism.

Chronic oxidative stress and inflammation are implicated in the incidence and progression of illnesses such as cardiovascular disease, neurological disorders, cancer, cataracts, inflammatory diseases, and age-related macular degeneration (Bramley *et al.*, 2000).  $\alpha$ -Tocopherol is com-

monly recognized as the antioxidant, vitamin E. Emerging scientific evidence suggests that  $\gamma$ -tocopherol, which is naturally abundant in soy and corn, possesses predominantly anti-inflammatory activity and lower antioxidant activity compared with  $\alpha$ -tocopherol. Significant progress has been made in altering both the quality and quantity of these vitamin E congeners in crops using both biotechnology and breeding approaches.

Not only are vegetables rich sources of essential nutrients but they also contain several bioactive phytonutrients such as lycopene, anthocyanins, and beneficial glucosinolates. Several of these components have been studied in isolation for their putative health benefits. In new and emerging research, epidemiologic, cell-based, and preclinical animal studies reveal the role of anthocyanins in lowering the risk of cardiovascular disease, diabetes, arthritis, and cancer, as a result of their antioxidant and anti-inflammatory activities (Middleton, 1998). Thus, it is conceivable that the primary mode of action of these phytonutrients or bioactive dietary components may be to reduce the rate of age-related increases in inflammation, which predisposes tissues to a range of chronic conditions. This hypothesis is supported by mechanistic studies in animal models and, to a lesser extent, by human intervention studies. Development of plant varieties with a combination of phytonutrients along with the essential nutrients, using breeding and biotechnology tools, would enable evaluation of their effects on human health and wellness in a whole-diet context rather than in isolation.

In addition to nutrition and health, some of these nutrients and phytonutrients, such as  $\beta$ -carotene, lycopene, flavonoids, and anthocyanins, bring about enhanced consumer appeal owing to their color (appearance) and their impact on taste and flavor. Carotenoid-derived volatiles are implicated in the production of the favorable aroma that is associated with fruits. There is also significant opportunity to remove unfavorable flavor components in dark-green leafy and cruciferous vegetables. For example, Iceberg lettuce is one of the most frequently consumed vegetables, but it has poor levels of such nutrients as vitamins A and C. Improving the nutritional content of this lettuce variety while maintaining its flavor could contribute significantly to public health. In contrast, bitter components in nutrient-rich Romaine lettuce varieties limit their consumption. Diets rich in brassica vegetables such as broccoli have been associated with health, and in particular the lower incidence of certain cancers. Broccoli accumulates significant amounts of the phytonutrient glucoraphanin, which is the

dietary source of sulforaphane. There is significant scientific evidence that sulforaphane is a potent inducer of phase II antioxidant enzymes, which help reduce damage from oxidative stress and inflammation. Considerable biochemical evidence exists for a role of the antioxidant enzymes in potentiating or maintaining the activity of vitamins A, C, and E. Significant progress has been made in developing broccoli varieties that have higher levels of glucoraphanin, using genetic markers, without impacting

broccoli taste. Hence, advanced metabolomics tools, combined with molecular marker tools, offer opportunities to discover and develop fruits and vegetables enhanced for both essential nutrients and phytonutrients in conjunction with improving their taste and appearance.

Biofortification refers to the nutritional enhancement of plants through conventional breeding, molecular breeding, and/or transgenic approaches (Figure 72.1). Access to a diversified germplasm coupled with robust and high-

FIG. 72.1 Overview of approaches for enhancement of plant-derived bioactive compounds.

throughput crop-analytics methods form the basis for biofortification. Once the germplasm sources with desired attributes are identified, appropriate breeding strategies are employed to derive advanced breeding lines having acceptable agronomic and improved consumer benefits. Selecting for multiple traits by conventional plant breeding methods is difficult and quite time consuming. Modern plant breeding strategies that deploy marker-assisted breeding and high-throughput phenotyping tools accelerate the plant breeding process. Product development using breeding technologies is often limited by lack of availability of germplasm with a diversity of traits. In such cases, biotechnology approaches coupled with recent advances in genome sequencing, and in our understanding of biosynthetic pathways and detailed functionality of candidate genes, enable incorporation of novel traits into crops.

In this review we have attempted to describe progress in understanding the biosynthetic pathways and genetic regulation of nutrients such as folate, vitamin E, calcium, and bioactive phytonutrients such as anthocyanins, lycopene, and glucoraphanin. In addition to these micronutrients, which are abundant in vegetables, macronutrients such as edible oils have a major impact on overall health and wellness of consumers. Significant progress has been made in deploying biotechnology and breeding to decrease saturated fatty acids and incorporate stearidonic acid (SDA), a precursor to healthful omega-3 fatty acids, in soybean. Specific examples of progress in the development and commercializing of soybean-oil quality traits are also reviewed.

## Biofortification of Crops with Essential Nutrients

### Folate

Folate (vitamin B<sub>9</sub>) is a generic term representing a family of molecules derived from tetrahydrofolate (THF) (also, see Chapter 21). THF and its derivatives or “folates” are essential cofactors for one-carbon transfer reactions, such as those crucial for nucleotide biosynthesis and amino acid metabolism (Bassett *et al.*, 2005; Rébeillé *et al.*, 2006). Folates are synthesized in plants and microorganisms. Hence, humans and animals depend for folates on the dietary supply (Scott *et al.*, 2000). The recommended dietary allowance (RDA) for folate is 400 µg/day for adults and 600 µg/day for pregnant women (DellaPenna, 2007). Clinical and epidemiological evidence shows that folate intake is suboptimal in most populations of the world. Insufficient dietary folate intake perturbs C1 metabolism,

which contributes to reduced turnover of erythrocytes (megaloblastic anemia), elevated plasma homocysteine levels (a risk factor for vascular diseases), birth defects (neural tube defects), increased risk of cardiovascular disease, aberrant DNA-methylation patterns (Scott *et al.*, 2000; Jang *et al.*, 2005), and several neurodegenerative disorders (Stover, 2004).

Folate is a complex molecule assembled from three different components: pteridine, para-aminobenzoic acid (PABA), and glutamate. In bacteria, folate synthesis takes place in the cytosol, whereas in plants, in addition to the cytosol, plastids and mitochondria are involved in this process. The pteridine moiety of folate is formed from guanosine triphosphate (GTP) in the cytosol, and the PABA moiety is formed from chorismate in plastids. Pteridine and PABA are then transported to the mitochondria, where they are coupled together, glutamylated and reduced to produce THF. THF with one glutamine (THF-Glu1), synthesized in the mitochondria, is exported to other cell compartments through folate transporters. A short chain of  $\gamma$ -linked glutamates is then added in mitochondria, plastids or cytosol, yielding folate polyglutamates (THFGlu<sub>n</sub>). In *Arabidopsis*, three genes have been identified encoding folylpolyglutamate synthase (FPGS) isoforms located in the mitochondria, the cytosol, and the chloroplasts, respectively (Ravanel *et al.*, 2001).

No information is available in the literature on mapping of folate biosynthetic genes in crop plants. Transgenic approaches for folate enhancement in vegetables are summarized in Table 72.1. GTP-cyclohydrolase 1 (GCH-1) from a mammal and aminodeoxychorismate synthase (ADCS) from *Arabidopsis* were overexpressed in tomato under the control of E8, a fruit-specific promoter. Transgenic tomatoes with the mammalian gene showed a two-fold increase in folate levels whereas there was no change in folate levels with the *Arabidopsis* gene. Plants obtained by crossing *GCHI*<sup>+</sup>/*AtADCS* (double transgenics) accumulated up to 25-fold more folate than wild-type plants. The folate levels in these double transgenics were comparable to those in leafy vegetables and sufficient to provide the recommended dietary allowance of folate for a pregnant woman. Similarly, lettuce overexpressing GCH1 from chicken showed an 8.5-fold increase in folate levels. These results support the success of a transgenic approach for folate enhancement in vegetables.

### Vitamin E

Vitamin E is the common name for eight naturally occurring compounds possessing  $\alpha$ -tocopherol activity,

**TABLE 72.1** Transgenic over-expression studies for enhancement of folate in selected vegetables

Crop	Gene(s)	Gene source	Promoter	Magnitude of increase	Reference
Tomato	GCH-1	Mammal	Fruit specific (E8)	Fruit folate increased by twofold	Díaz de la Garza <i>et al.</i> (2004); Garza <i>et al.</i> (2007)
	ADCS	<i>Arabidopsis</i>	Fruit specific (E8)	No difference	Garza <i>et al.</i> (2007)
	ADCS and GCH1	Cross between ADCS from <i>Arabidopsis</i> and GCH1 from mammal	Fruit specific (E8)	25-fold increase	Garza <i>et al.</i> (2007)
Lettuce	foIE (GCH1)	Chicken	35S CaMV promoter	2.1- to 8.5-fold increase	Nunes <i>et al.</i> (2009)

representing lipid-soluble vitamins synthesized exclusively by plants and other oxygenic, photosynthetic organisms (Bramley *et al.*, 2000) (also, see Chapter 14). Tocopherols and tocotrienols have four derivatives, namely alpha ( $\alpha$ ), beta ( $\beta$ ), delta ( $\delta$ ), and gamma ( $\gamma$ ), which differ in the number and location of ring methyl groups. They play important roles in the oxidative stability of vegetable oils and in the nutritional quality of crop plants. Natural  $\alpha$ -tocopherol has a higher biological activity than synthetic tocopherols; however, all tocopherols have the ability to quench free radicals in cell membranes and to protect polyunsaturated fatty acids (Brigelius-Flohe and Traber, 1999; Hunter and Cahoon, 2007). Oxidized LDL levels are increased in atherosclerosis, and higher levels predict cardiovascular events. Vitamin E is shown to inhibit LDL oxidation both in vivo and by supplementation to people. Free radical tissue damage is related to cardiovascular disease, neurological disorders, cancer, cataracts, inflammatory diseases, and age-related macular degeneration (Bramley *et al.*, 2000). Among vegetables, broccoli (*Brassica oleracea* var *italica*) stem tissues contain a higher tocopherol content than flowers and leaves (Guo *et al.*, 2001). Regular consumption of broccoli at recommended dietary levels increases serum concentrations of  $\gamma$ -tocopherol (and lutein) without affecting  $\alpha$ -tocopherol (or  $\beta$ -carotene) status in serum (Granado *et al.*, 2006).

The tocopherol biosynthetic pathway in plants utilizes cytosolic aromatic amino acid metabolism for synthesis of

the tocopherol head group, homogentisic acid (HGA), and the plastidic deoxyxylulose-5-phosphate pathway for synthesis of the hydrophobic tail. The biosynthetic pathway can be divided into upstream reactions that are important for flux regulation, and downstream reactions that control the composition. The first potential flux control points involve hydroxyphenyl pyruvate dioxygenase (HPPD) and geranyl geranyl diphosphate reductase (GGDPR), which synthesize the aromatic head group precursor HGA and the prenyl tail precursor phytyl-diphosphate (PDP), respectively. Another important flux-regulating enzyme is homogentisate phytyltransferase (HPT, also referred to as VTE2). This enzyme catalyzes the condensation of HGA and PDP to form the first prenylquinone intermediate, methylphytylbenzoquinone (MPBQ). MPBQ is further converted to DMPBQ (2,3-dimethyl-6-phytyl-1,4-benzoquinol) by the action of 2-methyl-6-phytyl-1,4-benzoquinol methyltransferase (VTE3). DMPBQ is converted to  $\gamma$ -tocopherol by tocopherol cyclase (VTE1). VTE1 also converts MPBQ to  $\delta$ -tocopherol. Finally, VTE4 ( $\gamma$ -tocopherol methyltransferase) converts  $\delta$ -tocopherol to  $\beta$ -tocopherol and  $\gamma$ -tocopherol to  $\alpha$ -tocopherol (Bergmüller *et al.*, 2003; Ajjawi and Shintani, 2004) depending upon the substrate.

Vitamin E has been enhanced in both model plants and commercial crops through breeding and biotechnological approaches. In the model plant *Arabidopsis*, QTLs have been identified for tocopherol levels in seeds using recom-

**TABLE 72.2** Transgenic over-expression studies for enhancement of vitamin E in selected vegetables

Crop	Gene(s)	Gene source	Promoter	Magnitude of increase	Reference
Lettuce	HPT/VTE2 and tocopherol cyclase (TC/VTE1)	<i>Arabidopsis</i>	CaMV 35S promoter	>Twofold	Lee <i>et al.</i> (2007)
Lettuce	$\gamma$ -TMT	<i>Arabidopsis</i>	CaMV 35S promoter	Twofold	Cho <i>et al.</i> (2005)
Potato	HPPD, HPT	<i>Arabidopsis</i>	Constitutively over-expressed	Twofold	Crowell <i>et al.</i> (2008)

binant inbred lines (RIL) developed from Landsberg *erecta* (Ler) and Columbia (Col) or Cape Verde Islands (Cvi) accessions (Gilliland *et al.*, 2006). VTE4 is also mapped to QVE3, a quantitative trait locus (QTL) for vitamin E. Vitamin E is enhanced in some plants through breeding but not in vegetables.

Vitamin E has been enhanced in some vegetables by a transgenic approach (Table 72.2). Seed-specific over-expression of VTE4 in *Arabidopsis* led to an 80-fold increase in seed  $\alpha$ -tocopherol content and a corresponding decrease in its substrate,  $\gamma$ -tocopherol (Shintani and DellaPenna, 1998). Increased HPPD expression in *Arabidopsis* resulted in an increase of up to 37% in leaf tocopherol levels and a 28% increase in seed tocopherol levels relative to control plants (Tsegaye *et al.*, 2002). Hence, the allelic variations in VTE4 and HPPD could potentially impact  $\alpha$ -tocopherol levels. The variation in the levels of vitamin E depended mainly on its accumulation in different plant organs, the highest level being in the seeds. Also, promoter choice is important for generating transgenics with enhanced vitamin E.

### Calcium

Most fruits and vegetables are relatively poor sources of bioavailable calcium (Morris *et al.*, 2007). About 70% of dietary calcium comes from milk and dairy products. Only a few green vegetables and dried fruits are good sources of calcium whereas drinking water, including mineral water, provides 6–7% of the required daily dietary calcium (Guéguen and Pointillart, 2000). While there is no question of the nutritional effectiveness of the calcium provided by milk, debate still exists about whether milk provides biologically better calcium than other sources.

Calcium deficiency is a significant problem in human populations worldwide (also, see Chapter 28). Prolonged calcium deficiency leads to reductions in bone mass and osteoporosis. The Dietary Reference Intake (DRI) for calcium is set at levels associated with desirable retention of body calcium. Since high bone density decreases the incidence of bone fractures and the chances of osteoporosis, 1300 mg/day of calcium per person is recommended. Although osteoporosis affects both men and women, the incidence is higher in women. One important factor in achieving high bone density is maintaining a maximal level of calcium through absorption and retention. Enhancing the concentration of bioavailable calcium in fruits and vegetables could boost calcium uptake and thus reduce calcium-deficiency-related disorders.

In plants, calcium/H<sup>+</sup> antiporters are high-capacity, low-affinity transporters that efficiently sequester large amounts of calcium when cytosolic calcium concentrations are elevated during a signaling event (Hirschi, 2001). After the cytosolic calcium burst, plant vacuolar and plasma membrane transporters rigorously reset the cytosolic calcium level. The level of intracellular calcium is regulated in part by active efflux transporters that remove calcium from the cytosol. P-type calcium-ATPases perform a variety of roles, which include the restoration of the cytosolic calcium concentration to its resting level after a signal transduction event, replenishment of internal calcium stores, and resistance to toxic concentrations of calcium (Sanders *et al.*, 1999; Sze *et al.*, 1999).

*Arabidopsis* is reported to have up to 12 other putative cation/H<sup>+</sup> antiporters, termed CAX (**C**Alcium **eX**changer) genes. *Arabidopsis* CAX1 and CAX2 have proven functionality in suppressing calcium hypersensitivity in yeast mutants (*vcx1 pmc1*) (Hirschi *et al.*, 1996). *Arabidopsis*

**TABLE 72.3** Transgenic studies for enhancing calcium in vegetables using *Arabidopsis* CAX genes

Crop	Gene(s)	Promoter	Magnitude of increase	Reference
Carrot	sCAX1	35S CaMV CDC	1.4- to 1.6-fold in roots	Park <i>et al.</i> (2004); Morris <i>et al.</i> (2008)
Potato	sCAX1	35S CaMV CDC	1.5- to 3.0-fold in tubers and 1.2- to 1.7-fold in leaves	Park <i>et al.</i> (2005b)
Tomato	sCAX1 CAX4	35S CaMV CDC	1.2- to 1.5-fold in fruits	Park <i>et al.</i> (2005a)
Lettuce	sCAX1	35S CaMV CDC	1.27- to 1.29-fold in leaves	Park <i>et al.</i> (2009)
Tomato	sCAX2A	35S CaMV	~1.5-fold in fruits	Chung <i>et al.</i> (2010)

CAX genes sCAX1 (shorter variant of CAX1), sCAX2A (shorter variant of CAX2A), and CAX4 have been expressed in different crop plants (tomato, lettuce, carrot, and potato). Among these, sCAX1 has been the most studied (Table 72.3) and its expression in carrot shows increased bioavailable calcium. In addition to increasing calcium levels, CAX genes are also reported to provide additional advantages such as reducing blossom-end rot and increasing shelf life in tomatoes.

## Biofortification of Crops with Phytonutrients

### Anthocyanins

Anthocyanins are vacuolar, water-soluble pigments that impart a red, purple, or blue color depending on the pH. They belong to a class of molecules called flavonoids. Generally, anthocyanins have a carbohydrate molecule (sugar, usually glucose) esterified at the 3-position of the aglycone anthocyanidins. About 17 anthocyanidins are found in nature and are classified according to functional groups. Of these, six anthocyanidins, namely cyanidin (Cy), delphinidin (Dp), petunidin (Pt), peonidin (Pn),

pelargonidin (Pg), and malvidin (Mv), are ubiquitous. The antioxidant activity of anthocyanidins is mainly attributed to delphinidin, followed by cyanidin, pelargonidin, kuromanin, and callistephin. The aglycones such as cyanidin and delphinidin are the most abundant anthocyanins in daily foods and may possess the ability to inhibit the growth of human tumor cells in vitro in micromolar concentrations (Meiers, 2001). Epidemiologic studies have revealed the role of anthocyanins in lowering the risk of cardiovascular diseases, diabetes, arthritis, and cancer as a result of their antioxidant and anti-inflammatory activities (Middleton, 1998).

Anthocyanins are derivatives of the phenylpropanoid pathway. They are derived from a branch of the flavonoid pathway, for which chalcone synthase (CHS) provides the first committed step by condensing one molecule of *p*-coumaroyl-CoA with three molecules of malonyl-CoA to produce tetrahydrochalcone. The closure of the C-ring to form flavanones is carried out by chalcone isomerase (CHI). Flavanones provide a central branch point in the flavonoid pathway and can serve as substrates for enzymes that introduce –OH groups at the 3' and 5' positions of the B-ring, or for the hydroxylation of the C-ring by flavanone 3-hydroxylase (F3H), a soluble di-oxygenase. Dihydroflavonol 4-reductase (DFR) provides one entry step to the biosynthesis of anthocyanins. It can utilize as a substrate either one or all three of the possible dihydroflavonols (dihydromyricetin, dihydrokaempferol, or dihydroquercetin). This results in the formation of the corresponding leucoanthocyanidins, providing structure to the anthocyanin biosynthetic grid. The leucoanthocyanidins are converted into the corresponding anthocyanidins by the action of a leucoanthocyanidin dioxygenase/anthocyanidin synthase (LDOX/ANS) (Grotewald, 2006). Anthocyanidins also serve as substrates for anthocyanidin reductases, key enzymes in the formation of proanthocyanidins (Xie *et al.*, 2003). The next step in the anthocyanin pathway is catalyzed by ANS. ANS is similar to F3H, flavone synthase I (FNSI), and flavonol synthase (FLS). It is a member of the non-heme ferrous and 2-oxoglutarate-(2OG)-dependent family of oxygenases, which convert leucoanthocyanidin to the corresponding anthocyanidin (Nakajima *et al.*, 2001; Grotewald, 2006).

Tomatoes with enhanced anthocyanins have been produced through breeding (Willits *et al.*, 2005) as well as genetic engineering efforts (Mol *et al.*, 1998; Brown *et al.*, 2003; Jones *et al.*, 2003; Koes *et al.*, 2005; Torres *et al.*, 2005; Willits *et al.*, 2005; Mes *et al.*, 2008). Several studies

indicate that R2R3 MYB-type and bHLH-type transcription factors (TFs) are involved in anthocyanin production (Goff *et al.*, 1992; Borevitz *et al.*, 2000; Ramsey and Glover, 2005; Tohge *et al.*, 2005; Gonzali *et al.*, 2009).

Heterologous expression of *Petunia* CHI in tomato resulted in higher levels of quercetin glycosides in their fruit peel (Muir *et al.*, 2001). Regulated expression of endogenous regulatory genes, ANT1 (*Aintegumenta 1*) (Mathews *et al.*, 2003) and DET1 (*DE-ETIOLATED1*) (Davuluri *et al.*, 2005), resulted in purple fruits in tomato. Expression of snapdragon TFs, Del (*Delila*, a bHLH TF) and Ros1 (*Rosea 1*, an R2R3 MYB-type TF), under the control of a fruit-specific E8 promoter resulted in tomato fruits enriched with anthocyanin (Butelli *et al.*, 2008). *Del* and *Ros1* stimulated the transcription of most of the structural genes involved in the biosynthetic pathway, including phenylalanine ammonia-lyase (PAL), CHI, and flavonoid 3O-hydroxylase (F3O5OH), which are necessary for the accumulation of anthocyanin (Table 72.4). Although there was anthocyanin accumulation, the levels of carotenoids remained unchanged. A group of cancer-susceptible mice that were fed with a diet supplemented with these high-anthocyanin tomatoes showed a significant extension of their average lifespan compared with those that were fed a diet supplemented with normal tomatoes (Butelli *et al.*, 2008).

In red and green cabbages, a comparative transcription analysis revealed the up-regulation of BoMYB2 and BoTT8 (*Transparent Testa 8*) genes and down-regulation of BoMYB3 expression in red cabbage. Hence, these were identified as probable candidate genes for anthocyanin biosynthesis in cabbage (Yuan *et al.*, 2009).

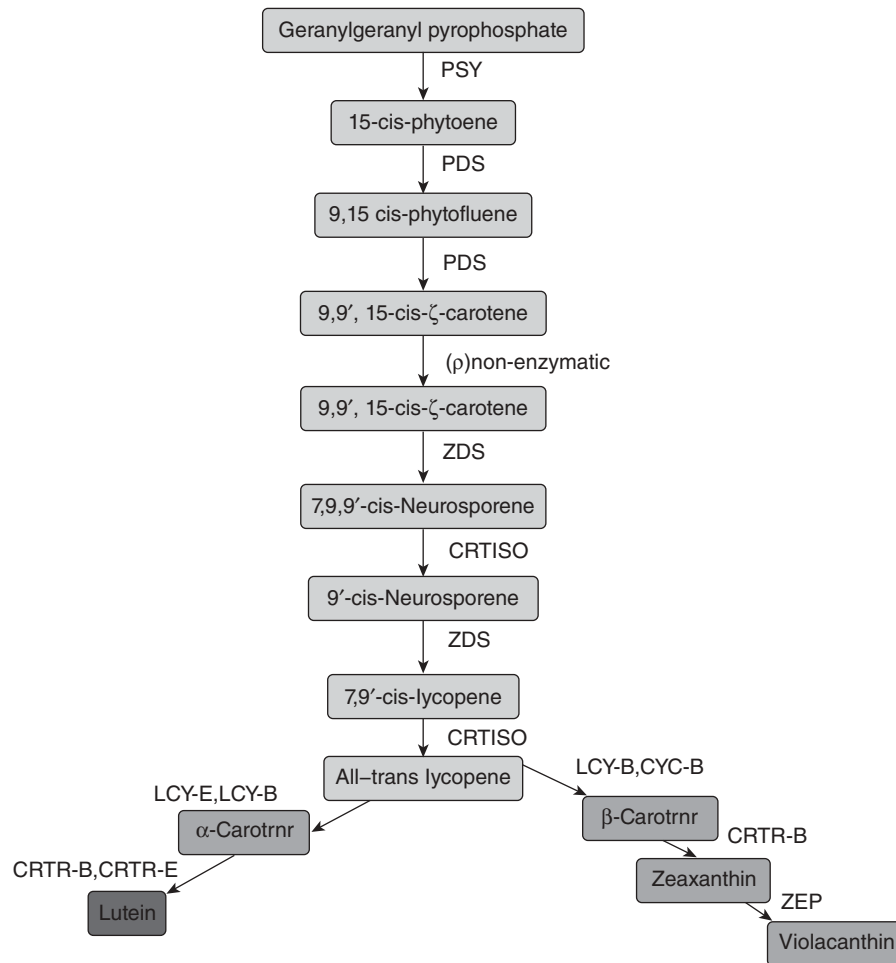

### Lycopene

Lycopene is a natural, red, fat-soluble carotenoid synthesized by plants and microorganisms, but not by animals. It is an acyclic isomer of  $\beta$ -carotene, without provitamin A activity. It is a highly unsaturated, straight-chain hydrocarbon containing 11 conjugated and two non-conjugated double bonds. It undergoes *cis-trans* isomerization that is induced by light, thermal energy, or chemical reactions. In addition to its antioxidant properties, lycopene shows cardioprotective, anti-inflammatory, antimutagenic, anticarcinogenic, and chemopreventive activities (Bhuvanewari and Nagini, 2005).

Lycopene is mainly available from fruits and vegetables such as tomatoes, carrots, watermelons, pink grapefruits, apricots, papaya, and pink guavas. Dietary intake of tomatoes and tomato products containing lycopene has been shown to be associated with a decreased risk of chronic diseases such as cancer and cardiovascular disease. Positive effects are also hypothesized for osteoporosis,

**TABLE 72.4** Transgenic approaches for enhancement of anthocyanins in tomato

**FIG. 72.2** Pathway of carotenoid biosynthesis. PSY, phytoene synthase; PDS, phytotene desaturase; ZDS,  $\zeta$ -carotene desaturase; CRTISO, carotene isomerase; LCY-E, lycopene  $\epsilon$ -cyclase; CRTR-B+CRTR-E,  $\epsilon$ -ring hydroxylase; LCY-B,CYCB, lycopene  $\beta$ -cyclase; CRTR-B,  $\beta$ -ring hydroxylase; ZEP, zeaxanthin epoxidase.

neurodegenerative diseases, and hypertension (Bánhegyi, 2005). Carotenoids are biosynthesized in the plastids; chloroplasts in photosynthetic tissues, and chromoplasts in ripe fruits and flowers. Carotenoid biosynthesis (Figure 72.2) and its regulation in tomato are reviewed by Fraser *et al.* (2009). Geranyl geranyl pyrophosphate (GGPP) is a ubiquitous isoprenoid precursor in the formation of carotenoids. Two molecules of GGPP are condensed to form phytoene by phytoene synthase. Phytoene, a 15-*cis* geometric isomer, possesses three conjugated double bonds. Phytoene desaturase introduces a double bond at the 9' of the phytoene molecule to create 15,9'-*di-cis*-phytofluene. Another double bond is then introduced at position 9, forming 9,15,9'-*tri-cis*- $\zeta$ -carotene. This molecule, with

seven conjugated double bonds, has a yellow/green coloration. The involvement of an enzymatic reaction for further desaturation and isomerization to yield 9,9'-*di-cis*- $\zeta$ -carotene needs to be investigated. Following the formation of 9,9'-*di-cis*- $\zeta$ -carotene, desaturation to 7,9,7',9'-*tetra-cis*-lycopene (prolycopene) via 7,9,9'-*tri-cis*-neurosporene is catalyzed by  $\zeta$ -carotene desaturase (Isaacson *et al.*, 2004). Cyclization of lycopene forms either  $\beta$ - or  $\alpha$ -carotene via  $\beta$ - and  $\epsilon$ -cyclase, respectively.

In tomato, 16 quantitative trait loci (QTLs) that modify the intensity of the red color in ripe fruits were identified (Liu *et al.*, 2003). Mutants with high pigment levels (hp1 and hp2) are also well characterized (Mustilli *et al.*, 1999; Liu *et al.*, 2004), but, as some of these mutants have weak

stems and poor vigor, they were unsuitable for commercial exploitation (Liu *et al.*, 2004; Kolotilin *et al.*, 2007). In carrots, 24 genes involved in the carotenoid biosynthesis pathway were cloned and mapped over eight linkage groups (Santos and Simon, 2002; Just *et al.*, 2007). In watermelon, the sequence comparison of full-length cDNA of *LCYB* (lycopene b-cyclase) identified three single nucleotide polymorphisms (SNPs) in the coding region of *LCYB* between canary yellow and red. These SNPs showed perfect co-segregation with flesh-color phenotypes. One of the SNPs introduces an amino acid replacement of evolutionarily conserved Phe226 to Val, which may impair the catalytic function of *LCYB*. This SNP was used to develop a cleaved amplified polymorphic sequence (CAPS) marker, which perfectly co-segregated with flesh-color phenotypes (Cloutault *et al.*, 2008).

In addition to regulation of lycopene through breeding, transgenic efforts have been made to regulate lycopene in several vegetables. Carotenoid genes from bacteria, yeast, *Arabidopsis*, pepper, and tomato were expressed to obtain transgenic tomato and carrot with varied levels of carotenoids (Table 72.5).

In addition to the potential health benefits, lycopene is a precursor in the production of volatiles that are responsible for aroma in tomato (Vogel *et al.*, 2010). Thus, altering lycopene levels impacts not only color appeal but also the sensory perception and liking of tomatoes.

### Glucoraphanin (Sulforaphane Precursor)

Glucosinolates (GSLs) are S- and N-containing secondary metabolites found in Capparales and a few other families. GSLs are a group of ~120 anionic plant metabolites with a core structure comprising a sulfonated oxime, a  $\beta$ -thioglucose residue and a variable side chain. Both glycone and aglycone moieties are important in mediating herbivore interactions (Giamoustaris and Mithen, 1996). In humans they are important as progenitors of taste and flavor compounds of cruciferous vegetables. Following tissue damage, aliphatic GSLs are hydrolysed by myrosinases to give a complex mixture of products, of which glucose, sulphate, and isothiocyanates are major components. Although approximately 120 kinds of GSL have been identified in plants, each plant species has only a few major GSLs. *Brassica* species predominantly contain aliphatic (derived from methionine) and indolyl (derived from tryptophan) GSLs (Li and Quiros, 2003).

The formation of GSLs can be divided into three phases. First, certain aliphatic and aromatic amino acids are elon-

gated by inserting methylene groups into their side chains, followed by reconfiguration of the amino acid moiety to the core structure of the GSL. This is followed by formation of secondary transformations of the GSL. The biochemistry and biosynthesis of glucosinolates have been reviewed by Halkier and Gershenzon (2006).

MAM (methylthioalkylmalate synthase) genes are involved in the amino acid chain elongation in GSL biosynthesis (Kroymann *et al.*, 2001). Four MAM genes (MAM1, MAM2/MAML, MAML3, and MAML4) have been reported in *Arabidopsis*. The biosynthesis of the core glucosinolate structure involves the *conversion* of amino acids to aldoximes, aldoximes to thiohydroxamic acids, and thiohydroxamic acids to GSL. Conversion of amino acids to aldoximes involves cytochrome P450 genes (Hansen *et al.*, 2001; Kroymann *et al.*, 2001; Reintanz *et al.*, 2001; Wittstock and Halkier, 2002; Li and Quiros, 2003) whereas formation of thiohydroxamic acids involves CYP83B1 (Barlier *et al.*, 2000; Bak *et al.*, 2001; Hansen *et al.*, 2001; Smolen and Bender, 2002), CYP83A1 (Bak and Feyereisen, 2001; Hemm *et al.*, 2003; Naur *et al.*, 2003), C-S lyase (Mikkelsen *et al.*, 2004), and UGT74B1 and AtST5a (Grubb *et al.*, 2004). Some of the genes involved in secondary transformations are *AOP2*, *AOP3* (Li *et al.*, 2001; Gao *et al.*, 2004), 2-ODD (2-oxoglutarate-dependent dioxygenase) (Hall *et al.*, 2001) and FMO (flavin-monooxygenase) (Hansen *et al.*, 2007). In addition, upstream regulators of the aliphatic glucosinolate pathway (MYB28, MYB29 and MYB76) have also been identified (Gigolashvili *et al.*, 2007a,b; Hirai *et al.*, 2007). Based on the homology to *Arabidopsis* gene sequences, GSL biosynthetic genes have been isolated from vegetable species such as broccoli and cauliflower (Mithen *et al.*, 1995; Li and Quiros, 2002).

Genetic and functional epistasis between the genes in the GSL biosynthetic pathway has been demonstrated in *Arabidopsis* (Kliebenstein, 2009). Six QTLs controlling GSL accumulation showed genetic epistasis (Kliebenstein *et al.*, 2005). The GSL desaturation gene, *BoGLS-ALK*, was successfully mapped on the L1 linkage group at 1.4 cM from the marker SRAP133 (Li and Quiros, 2001).

Metabolic engineering of glucosinolate profiles has included altering the expression of one or more CYP79 enzymes (Mikkelsen *et al.*, 2000). GSL biosynthetic genes of *Arabidopsis* have been overexpressed in different crops. Among vegetables, Chinese cabbage overexpressing *Arabidopsis* MAM1, CYP79F1, and CYP83A1 with CaMV 35S promoter resulted in significant enhancement of

**TABLE 72.5** Summary of carotenoid enhancement through genetic engineering in selected vegetables

Gene	Source	Promoter	Strategy	Magnitude of increase	Reference
<i>Tomato</i> Dxs (1-deoxy-D-xylulose-5-phosphate synthase)	<i>E. coli</i>	CaMV 35S and fibrillin from pepper	Over-expression	2-fold increased phytoene and other carotenoids	Enfissi et al. (2005)

Carrot Crt	<i>Erwinia herbicola</i>	CaMV 35S	Over-expression	2- to 5-fold increase in carotenoids	Hauptmann et al. (1997)

gluconapin and glucobrassicinapin, leading to enhanced glucosinolates (Zang *et al.*, 2008).

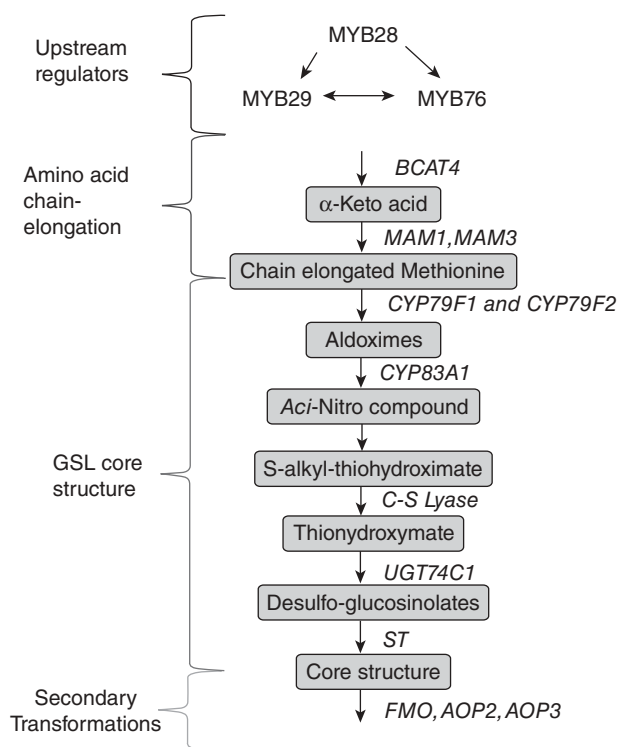

Broccoli is one of the healthiest vegetables. In addition to being a good/excellent source of vitamins A, C, folate, and fiber, broccoli is also the major dietary source for sulforaphane (metabolite of precursor glucosinolate, glucoraphanin). Increasing scientific evidence indicates that sulforaphane naturally enhances enzymes that help protect the body from oxidative stress and inflammation caused by the harmful effects of free radicals and environmental pollutants. Sarikamis *et al.* (2006) developed hybrid broccoli with enhanced levels of glucoraphanin and glucoiberin, by introgression of genomic segments from the wild ancestor, *Brassica villosa*. The total level of glucoraphanin and glucoiberin is predominantly dependent upon the presence of *B. villosa* alleles at QTL1, but the ratio of these GSLs is dependent upon genotype at both QTL1 and QTL2 located on chromosomes 2 and 5. Figure 72.3 shows the biosynthesis pathway of aliphatic glucosinolates.

Clinical studies with the high-glucoraphanin broccoli varieties indicate higher blood levels of sulforaphane as well as a higher level of expression of phase II antioxidant enzymes compared with regular broccoli (Mithen *et al.*, 2003; Traka *et al.*, 2005). Antioxidant enzymes are involved in detoxification of environmental pollutants and are implicated in recycling of antioxidant vitamins A, C, and E. Effect of broccoli varieties with various levels of aliphatic glucosinolates on perception of taste is reported. Higher levels of glucoraphanin in cooked broccoli were not associated with liking (Baik *et al.*, 2003).

## Biotechnology-Derived Soybean Traits

Biotechnology efforts concerning soybeans continue to focus on enhancing yield potential and improving the nutritive composition for use in food and feed products to help address growing global food and feed demands. Since 1996, agricultural biotechnology has had a major impact on soybean production globally; more than 90% of the soybeans in the United States and more than 70% of the soybeans grown globally today include a modified biotechnology component, in particular, herbicide-resistant Roundup Ready® soybeans.

Nutritionally enhanced soybean products present opportunities to bring direct benefits to consumers by enhancing the nutritional value of oils and fats. The 2009 global demand for vegetable oil in food was approximately

**FIG. 72.3** Biosynthesis pathway of aliphatic glucosinolates. Upstream regulators, transcription factors involved in regulation of aliphatic glucosinolates. Amino acid chain elongation, elongation of aliphatic and aromatic amino acids by inserting methylene groups into their side chains. Glucosinolate core structure, reconfiguration of amino acid moiety to form core structure of glucosinolates. Secondary transformations, modification of initially formed glucosinolates.

110 MMT and is forecasted to grow to over 170 MMT by 2020. Soybean oil represents approximately 30% of the total vegetable oil produced worldwide, with the highest consumption of vegetable oils occurring in China, India, the European Union, and the United States (Goldbitz, 2005–2008; Mielke, 2006; USDA, 2009). Fat is the most concentrated source of energy in the diet. Structure and function of the fatty acids in oils impact human health, shelf stability, and taste (International Food Information Council, 2006).

It is recommended that healthy people consume less than 10% of calories from saturated fats daily. Replacing saturated fats with unsaturated fats in foods helps reduce the levels of low-density lipoprotein (LDL) cholesterol, a risk factor for heart disease. The *Dietary Guidelines for*

*Americans* (DHHS and USDA, 2005) recommend keeping total fat intake between 20% and 35% of calories, with most fats coming from sources of polyunsaturated and monounsaturated fatty acids such as fish, nuts, and vegetable oils. Hydrogenated oils contribute important textural and stability properties in food. However, hydrogenation results in the formation of *trans* fatty acids. The National Academy of Sciences' Institute of Medicine concluded that *trans* fatty acids are similar to saturated fats and dietary cholesterol with regard to their effect on blood LDL cholesterol, which is considered bad for heart health. In addition, some studies suggest that increased intake of *trans* fats may lower high-density lipoprotein (HDL) or good cholesterol. The Institute of Medicine recommends that the intake of *trans* fatty acid be as low as possible. In 2006 the US Food and Drug Administration required mandatory *trans* fat labeling on consumer packages. This resulted in the reformulation of many food products. Several municipalities and states followed with *trans* fat bans, resulting in quick adoption of *trans* fat alternatives in the food service industry (International Food Information Council, 2009). The median intake of total fat in the United States ranges from about 32% to 34% of total calories. Saturated fats provide approximately 11–12% of calories in adult diets in the United States.

Omega-3 fatty acids are considered essential fatty acids, meaning they are essential to human health but cannot be manufactured by the body. Some researchers (e.g. Burr *et al.* [1989] and GISSI-Prevenzione Investigators [1999]) found that, when long-chain omega-3s are incorporated in the diet, there is a dramatic reduction in overall and cardiac mortality in heart-attack patients. The American Heart Association (AHA) recommends long-chain, omega-3 intake of 1 g/day for heart patients and the incorporation of two servings of fatty fish per week for healthy individuals (which equates to approximately 500 mg/day, depending on the fish source). Unfortunately, current intake of long-chain omega-3 in most people's diets is well below these recommendations (Harris *et al.*, 2008).

Long-chain omega-3 fatty acids play an important role in maintaining health, including heart health. Currently, long-chain omega-3s can be found in fish, but, unfortunately, many consumers find it difficult or too expensive to incorporate fatty fish in the diet on a regular basis. Others are concerned about levels of heavy metals and pressure on natural resources. Recently, commercial efforts have resulted in the development of omega-3 enhanced soybeans containing stearidonic acid (SDA) that represent

a renewable land-based source of essential omega-3 fatty acids. Common sources of omega-3 fatty acids include ALA ( $\alpha$ -linolenic acid) found in canola, soybean and other vegetable oils, flax, walnuts, fatty fish, and algae. Studies have shown that the conversion of ALA to the more desirable long-chain forms of EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid) present in fatty fish, fish oils, and algal oils is inefficient because of the lack of the delta-6-desaturase enzyme in human bodies (Burdge *et al.*, 2002, 2003; Whelan, 2009). Studies have shown that, as a result, it can take a minimum of 14–20 g of ALA to get the same level of tissue enrichment as 1 g of EPA (Harris *et al.*, 2008).

SDA is an intermediate between ALA and EPA on the biosynthetic pathway and does not require the delta-6-desaturase for conversion to EPA. As a result, conversion of SDA to EPA is much more efficient than conversion of ALA to EPA. Using plant and fungal sources for the genes encoding these key enzymes, soybeans have been modified to express SDA which is not typically found in soybeans. The oil from these soybeans contains 20% SDA. SDA has been incorporated in several human clinical studies. James *et al.* (2003) found that, by incorporating SDA in the diet at 1500 mg/day, EPA levels in red blood cells could be increased significantly. SDA was approximately one-third as efficient as EPA in that study. In a human clinical study using SDA soybean oil over a 16-week period, Harris *et al.* (2008) found that there was a significant increase in red blood cell EPA levels whereas none was observed for participants using only conventional soybean oil, containing ALA as the omega-3 source at levels higher than adequate intake recommendations. These results were confirmed in a larger trial of 252 healthy volunteers (Lemke *et al.*, 2010).

Incorporation of SDA-enriched soybean oil using conventional processing methods resulted in acceptable flavor. Studies have been completed in a range of everyday food applications that incorporate SDA-enriched soybean oil in foods to determine impact on shelf life and consumer liking. In many foods, such as granola bars, spreads, baked goods, crackers, confectionery products, dressings, soups, and mayonnaise, flavor attributes are similar to those of control products throughout the shelf life.

## Future Directions

Edible crops such as vegetables and oil seeds are the fundamental source of macro- and essential micronutrients

and phytonutrients. Considerable progress has been made in understanding the basis for usefulness and enhancement of these beneficial dietary components. A majority of studies report the effects of dietary components in isolation that overlook the important aspect of interaction of these nutrients and dietary components as it relates to relative bioavailability, absorption, metabolism, and benefit. Lack of such knowledge leads to conflicting data between consumption and intervention studies with components in isolation. Availability of crops with or without modified levels of (phyto)nutrients enables well-designed dietary intervention studies to evaluate the effects of biofortified crops in comparison with conventional varieties. Examples of such products that are reviewed in this chapter include high-glucoraphanin broccoli and SDA-enhanced soybean. Advances in both molecular breeding and biotechnology coupled with understanding of biosynthetic pathways and “omics” tools enable rapid discovery and development of such crop varieties. Product development using conventional breeding approaches along with molecular breeding and phenotyping tools offers the advantages of speed to market and low cost. Biotechnology offers the advantage of introducing novel traits that are not limited by germplasm diversity and compatibility of trait sources. In addition, identification and validation of candidate biosynthetic genes and their regulation in crop plants could herald opportunities for marker-assisted breeding. With the scale and speed of generation of transgenic model crops, biotechnology tools provide excellent leverage for validating the candidate genes, highlighted by the examples of folate and calcium enhancement in vegetables reviewed in this chapter. Literature is insufficient on vitamin E enhancement in vegetables. As biosynthetic pathways and target genes are identified in model plants, application of breeding/biotechnology approaches could offer more possibilities for vitamin E enhancement. Among the emerging nutrients, there is compelling evidence for enhancement of anthocyanins using a transgenic approach. However, commercial viability of these varieties would be limited by consumer acceptance of overtly different-looking varieties coupled with the need for regulatory approval. Several studies report on enhancement of lycopene in tomatoes by breeding and transgenic approaches. Elevating lycopene levels by molecular breeding would increase consumption of tomatoes as a result of higher consumer appeal in flavor and appearance along with the potential nutritive value.

New and exciting products will be commercialized in the near future as a result of this knowledge, which will provide significant benefits to the consumer and the food industry. In the coming decades, the intersection between biology, agriculture, and human nutrition should continue to create new solutions to enhance the nutritional value and appeal of crops to consumers.

## BIOACTIVE COMPONENTS IN FOODS AND SUPPLEMENTS FOR HEALTH PROMOTION

PAUL M. COATES<sup>1</sup>, PhD, HOLLY NICASTRO<sup>2</sup>, PhD, AND JOHN A. MILNER<sup>2</sup>, PhD

<sup>1</sup>*National Institutes of Health, Bethesda, Maryland, USA*

<sup>2</sup>*National Cancer Institute, Rockville, Maryland, USA*

Disclaimer: The opinions expressed are those of the authors and do not constitute official policy of the National Institutes of Health.

### Summary

Linkages among dietary habits, supplement use, and overall health emanate from a multitude of epidemiological, preclinical, and clinical studies. Unfortunately, inconsistencies arising from these investigations raise serious concerns about the factors that contribute to a response and about whether or not the available evidence is appropriate for public health – much less personalized – recommendations. These inconsistencies result in part from variations in experimental designs that have been used to address nutritional interventions for health outcomes, but they also reflect the multifactorial and complex nature of health and the specificity and interactions among dietary constituents when they are consumed in foods or individually as dietary supplements. The challenge of defining the best intervention strategy is underscored by the numerous and diverse agents which may alter cellular processes that are linked with growth, development, and disease resistance. The explosion of information about the interrelationships among genomics, proteomics, metabolomics, and dietary components is beginning to shed light on why variation in response may arise. Greater attention to these variables, along with a better understanding about the quantity and speciation of bioactive food components required to bring about a desired response, will surely help distinguish responders from non-responders. Ultimately, this will guide future research that will provide a sounder basis for dietary recommendations.

### Introduction

Belief in the medicinal powers of foods and its components is not a new concept but has been handed down from generation to generation. Almost 2500 years ago, Hippocrates suggested, “Let food be thy medicine and medicine be thy food.” Today consumers are bombarded

by claims about the ability of foods and their constituents to modify health and/or the risk of chronic disease. Undeniably, strategies that utilize foods and dietary supplements to optimize nutrition for achieving one’s “genetic potential,” for improving physical and cognitive performance, and for reducing the risk of chronic diseases, are highly commendable and appropriate, particularly in this

era of mounting health-care costs. Defining the most effective use of foods or their isolated components will not be simple, but there is mounting scientific evidence to believe that such a personalized approach is feasible.

## Why Foods and Dietary Supplements?

The putative health-promoting effects of bioactive components are often first identified by observational or ecological studies in populations with certain food preferences. Examples of this include the observations that populations consuming large quantities of oily fish have lower population burdens of cardiovascular disease, or that populations consuming large quantities of soy have lower rates of certain cancers. These observations have usually led to investigation and characterization of the bioactive principles responsible for these effects *in vitro* or in animal models – in the examples above, long-chain polyunsaturated fatty acids and isoflavones, respectively (Sarkar and Li, 2003; Schmidt *et al.*, 2005). Frequently, these components have been isolated and characterized and then studied in various pre-clinical models in attempts to better understand their mechanisms of action outside the food matrix. Many of these isolated components are marketed as dietary supplements. In the United States, for example, the prevalence of use of dietary supplements is very high, with more than 50% of Americans consuming dietary supplements on a regular basis. By far the largest component of the US dietary supplement market comprises vitamins, minerals, and other nutrient supplements, although botanical dietary supplements (e.g. echinacea, ginseng, and ginkgo) are also commonly consumed.

In some instances, the health effects of individual components as part of foods have been borne out when single ingredients have been used as dietary supplements; in other cases, however, such as with tomatoes, it is the presence of the multiple components of the food matrix that is important in bringing about the desired response (Kim *et al.*, 2004). It is possible – but not automatically true – that the health benefit of a food component will be realized by consuming it as a supplement with one or more active components. Generally speaking, when consumers opt for a food-based and/or supplement-based choice for promoting health or for reducing the risk of chronic disease, they expect several features to be in place: the products are known to be safe, since they have been in use in the human diet for long periods; there are proven benefits; and there is reasonable consistency in the products from batch to

batch and over time. Research on all of these issues is needed, particularly as it relates to dietary supplements.

## An Evidence-Based Approach to the Literature

Several questions arise about how to document the health benefits and risks of nutrients. Are ecological studies, in which particular patterns of food intake are associated with health benefits and low apparent risk for harm, sufficient to enable people to make informed decisions for proposing dietary change to populations or individuals? Are randomized, controlled, double-blind clinical trials most appropriate? Since genomics is increasingly recognized as modifying the response to food components, would haplotype-specific trials rather than randomized trials be a better way to evaluate health effects? Do we have reliable biomarkers of disease progression or surrogate endpoints for chronic diseases? The goal of an evidence-based approach is to sift through the relevant, available literature in a systematic fashion (Figure 73.1) and, based on the totality of the evidence, to assist researchers, policy-makers, clinicians, and ultimately consumers to make decisions about the role of bioactive food components in health promotion. For example, evidence-based reviews have

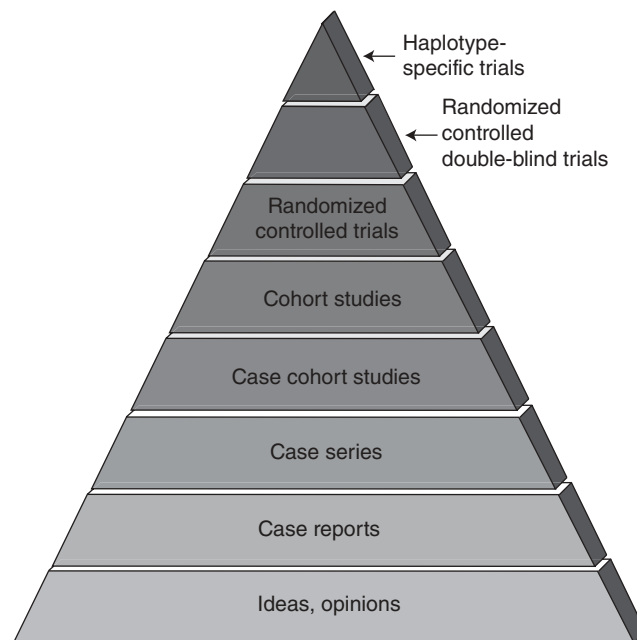

FIG. 73.1 Pyramid of evidence.

been used to assess the efficacy and safety of the probiotic supplement *Saccharomyces boulardii* for treatment of several types of diarrhea (McFarland, 2010) and to evaluate the potential cardioprotective effects of  $\alpha$ -linolenic acid (Geleijnse *et al.*, 2010).

## Dietary Modifiers and Biological Responses

Numerous reviews extolling the merits and possible risks associated with bioactive food components have surfaced in recent years (Kim *et al.*, 2009; Astrup *et al.*, 2010; Davis *et al.*, 2010; Messina, 2010). An estimated 25 000 phytochemicals exist, and approximately 5000 have been identified while many more remain unknown (Liu, 2003; Heber, 2004). Collectively, more than 500 dietary compounds have been recognized as potential modifiers of human health. Both essential and non-essential allelochemicals arising from plants, along with zoochemicals occurring in animal products, fungochemicals from mushrooms, and bacterochemicals from bacteria may be physiologically relevant modifiers of health. Compounds encompassing such diverse categories as minerals, amino acids, carbohydrates, fatty acids, carotenoids, dithiolthiones, flavonoids, glucosinolates, isothiocyanates, and allyl sulfurs may influence multiple pathways associated with growth, development, and disease resistance. For example, garlic (*Allium sativum*) has been valued for its medicinal properties for centuries. It has been suggested that garlic can reduce the risk of heart disease and cancer (Khanum *et al.*, 2004; Blomhoff, 2005), serve as a source of antioxidants and thereby reduce tissue damage (Banerjee *et al.*, 2003), and influence immunocompetence (Kyo *et al.*, 2001) and possibly mental function (Yamada *et al.*, 2004). Such data suggest that the health implications of bioactive food components may be extremely widespread and are likely not explained by a single cellular mechanism.

## Population and Personalized Experimental Designs

The study of nutritional genomics has the potential to identify definitively which components in foods bring about either positive or negative consequences, and to clarify their relevant mechanisms of action and most importantly when they can be manipulated to optimize growth and development and reduce disease risk (Davis and Milner, 2004). Knowledge about how diet-induced

phenotypic responses depend on an individual's genetic background (nutrigenetics), the expression of genes (epigenomics and transcriptomics), changes in the amounts and activities of proteins (proteomics), shifts in small molecular weight compounds (metabolomics), and the diversity of the microbial flora of the gastrointestinal tract (microbiomics) – collectively referred to as “-omics” – will be key to distinguishing responders from non-responders.

## Polymorphisms

It is now recognized that close to 21 000 protein-coding genes are found in the human genome (HUPO, 2010). Single nucleotide polymorphisms (SNPs) occurring in a gene coding sequence are of particular interest because they may cause an amino acid substitution and hence alter the biological function of a protein. For example, a SNP in the human gene encoding the low-density lipoprotein receptor results in a A370T codon substitution that leads to asparagine being replaced by serine; this change is associated with higher plasma cholesterol levels and an increased risk of developing cardiovascular disease. Polymorphisms occur at approximately one in every 1200 bases of DNA, with over 10 million SNPs estimated in the human genome. Genomic data for human and mouse (including SNPs, expressed sequence tags, gene expression patterns, and cluster assemblies) and cytogenetic information are increasingly available through a number of databases; these provide opportunities to evaluate genomics as a factor in explaining variation in response to food components in terms of human growth, development, performance, and health. Examples of websites that manage such databases include: [hapmap.ncbi.nlm.nih.gov](http://hapmap.ncbi.nlm.nih.gov); [www.gmod.org](http://www.gmod.org); [www.genome.gov](http://www.genome.gov); [www.ebi.ac.uk](http://www.ebi.ac.uk); and [www.nugo.org](http://www.nugo.org).

Increasingly, genetic polymorphisms are thought to have a role in determining the response to foods and their components. Unfortunately, while this area is receiving increased attention, it remains unclear whether these polymorphisms are directly linked to outcome. Nevertheless, it is certainly plausible that polymorphic differences have contributed to the inconsistencies among studies of the health effects of dietary components. In a random sample of participants in the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (ATBC Study), for example, the low prevalence of polymorphisms in genes coding for activation (phase I) enzymes CYP1A1 (0.07) and CYP2E1 (0.02) and the high prevalence in genes coding for detoxification (phase II) enzymes GSTM1 (0.40) and NQO1

(0.20) (Woodson *et al.*, 1999) may have influenced the outcomes and conclusions of the study. Further, in a nested case-control study within the ATBC Study, glutathione peroxidase 1 (hGPX1), a selenium-dependent enzyme involved in detoxification of hydrogen peroxide, was found to have a polymorphism exhibiting a proline to leucine replacement at codon 198. This polymorphism conferred a relative risk for lung cancer of 1.8 for heterozygotes and 2.3 for homozygous variants compared with homozygote wild types (Ratnasinghe *et al.*, 2000).

Several common genetic polymorphisms may also modulate cancer and cardiovascular disease risk through their influence on folate metabolism, including polymorphisms of the methylenetetrahydrofolate reductase (*MTHFR*) gene. Substituting C for T at nucleotide 677 in the *MTHFR* gene (C677T) results in reduced conversion of 5,10-methylenetetrahydrofolate to 5-methylenetetrahydrofolate, the form of folate that circulates in plasma. Women with the TT genotype have been reported to be at increased risk of squamous cell carcinoma when they have low plasma folate concentrations (Han *et al.*, 2007). Another common polymorphism is an A-to-C transition at nucleotide 1298 (A1298C), which leads to the replacement of glutamine by alanine and results in mild hyperhomocysteinemia and increased plasma folate levels compared with levels of carriers of the wild type (Boccia *et al.*, 2009). The *MTHFR* SNP A1298C is associated with increased risk of cardiovascular disease in patients with rheumatoid arthritis (Palomino-Morales *et al.*, 2010). These and other polymorphisms in *MTHFR* may be associated with risk of various cancers, including breast and colorectal cancer, although results have been mixed (Hazra *et al.*, 2010). Part of the inconsistency in results may relate not just to intake of folate, but also to intake of other vitamins, methyl donors, or other factors that influence DNA stability.

Polymorphisms in the vitamin D receptor (*VDR*) gene have been linked to bone health as well as the risk of some types of cancer. Common polymorphisms include BsmI, TaqI in intron 8 and exon 9, and a poly-A site in the 3' end of the gene. The femoral and vertebral bone mineral density was greater in children with the homozygous recessive (bb) version of the *VDR* polymorphism BsmI compared with those with the dominant genotype (BB). Likewise, BsmI B and short poly-A polymorphisms in the 3' end of the *VDR* gene have been associated with increased breast cancer risk, with a trend for increasing risk with increasing number of BsmI B alleles or short (S) poly-A

alleles (Ingles *et al.*, 2000). Using data from two large case-control studies, investigators found that the CDX2 polymorphism was not independently associated with colon or rectal cancer. However, the bLFA haplotype was associated with an increased risk of colon cancer, the BSfG haplotype was associated with an increased risk of rectal cancer, and the BSFA haplotype was associated with a decreased risk of rectal cancer, where A or G of the haplotype designations indicate the CDX2 allele (Slattery *et al.*, 2007).

Literally millions of SNPs occur within the human genome, making it unlikely that a single base change will be found that is sufficient to account for a number of chronic diseases. However, since genetic variants are often inherited together in segments of DNA called haplotypes which are shared by a majority of the human population, they may be useful in deciphering the genetic differences that make some people more susceptible to disease than others, and likewise in determining how diet will impact their susceptibility. The International HapMap Project (<http://www.hapmap.org/>) and genome-wide association studies (GWAS) (Ferguson, 2010) may be particularly useful in teasing out genetic differences that determine the response to specific foods and their components. GWAS allow scanning of the entire genome covering over 1 million polymorphisms potentially associated with disease states, eliminating the bias that stems from choosing candidate genes. Recent GWAS have begun to take diet into account. When using a GWAS model that includes meat, fish, and milk intake, and work and leisure physical activity, investigators were able to identify novel susceptibility loci in the *SLC2A1* and *HP* genes that are associated with total cholesterol levels (Igl *et al.*, 2010). In another study, investigators confirmed prior candidates and identified new candidate SNPs associated with plasma homocysteine, vitamin B<sub>12</sub>, and vitamin B<sub>6</sub> (Hazra *et al.*, 2009).

### **Epigenomics and Dietary Exposure**

Epigenomic modifications regulate expression and activity of genes without modifying genomic sequences. Mechanisms include DNA methylation, histone modifications, gene silencing by microRNA, and chromosome stability (Davis and Milner, 2007; Davis and Ross, 2007, 2008). Evidence already exists that the transcriptional silencing of genes by DNA methylation plays a crucial role in a number of disease states (Ross, 2003). Genes involving cell cycle regulation, DNA repair, angiogenesis, and apoptosis are all inactivated by the hypermethylation of their respective 5' CpG islands. Key regulatory genes – including E-cadherin,

pi-class glutathione S-transferase, the tumor suppressors cyclin-dependent kinases (CDKN2) and phosphatase gene (PTEN), and insulin-like growth factor (IGF-II) targeted histone acetylation and deacetylation – are influenced by DNA hypermethylation. While folate intake is recognized to influence DNA methylation patterns, other nutrients such as selenium can also have an impact (Davis and Uthus, 2003). Restoring proper methylation may represent a fundamental process by which selected nutrients are able to influence gene expression. Several recent studies have provided evidence that genistein, epigallocatechin gallate (EGCG), or potentially other bioactive food components can reverse hypermethylation and reactivate methylation-silenced genes in various tissue types (Fang *et al.*, 2005; King-Batoon *et al.*, 2008; Li and Tollefsbol, 2010).

Covalent modifications of histone tails, including phosphorylation, acetylation, methylation, ubiquitination, or biotinylation, regulate gene expression by changing the structure of chromatin. MicroRNAs inhibit the expression of target genes by binding to complementary sequences on mRNA. These epigenetic modifications are also subject to regulation by dietary components. Butyrate, sulforaphane from cruciferous vegetables, and diallyl disulfide from garlic function as histone deacetylase (HDAC) inhibitors (Myzak and Dashwood, 2006; Myzak *et al.*, 2006). This disrupts the cell cycle by derepressing the cell cycle inhibitor *P21* and induces apoptosis by depressing the proapoptotic *BAX*. Folate is a potential modulator of microRNA expression. In patients with head and neck squamous cell carcinoma, the oncogenic microRNA miR-222 is overexpressed in those with the lowest folate intake compared with those with the highest folate intake (Marsit *et al.*, 2006). Further research is necessary to determine the extent to which dietary compounds regulate histone modifications and microRNA expression, and how such regulation modulates disease processes.

### **Bioactive Components and Transcriptomics**

A fundamental action of several bioactive food components is that they serve as regulators of gene expression and/or modulate gene products. Typically, increasing intensity and duration of the exposure increases the number of gene expressions that are influenced (Prima *et al.*, 2004; El-Bayoumy and Sinha, 2005). Thus, dose and duration of exposure become fundamental considerations in interpreting findings from microarray studies. Lin *et al.* (2007) have used a transcriptomics approach to

determine changes in gene expression resulting from a low-fat/low-glycemic load diet in patients undergoing radical prostatectomy. Expression of 23 cDNAs in the experimental group versus none in the control group was significantly changed at the end of the intervention. While most studies are simple snapshots of genomic expression changes that can help identify important possible targets, they must be interpreted cautiously because of inherent biological variability (Barnes, 2008).

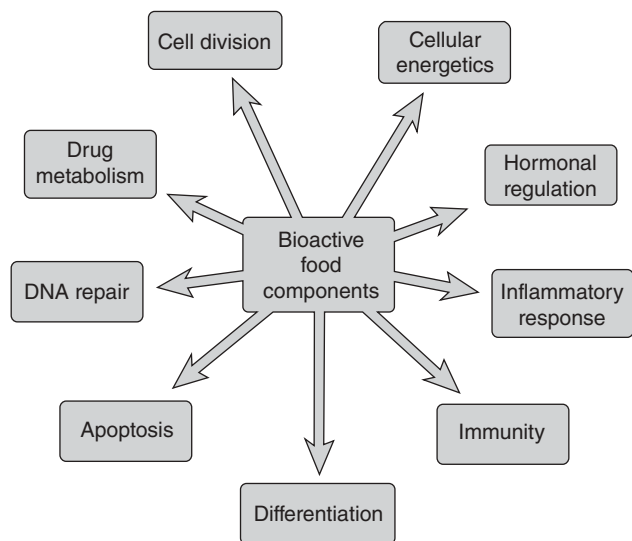

### **Molecular Targets**

The era of molecular nutrition holds promise not only for increasing our understanding of the specific site(s) of action of food components but also for the development of a “nutritional preemption” strategy that will incorporate bioactive food components at points of initiation and progression of pathways that lead to unhealthy or lethal conditions. Success with this strategy will depend on early predictors of the response to food components rather than gross phenotypic changes. Similar to the USDA pyramid for dietary guidance, it is likely that the early predictive biomarkers will not be at the apex because of the lateness of the observation but will be focused at the base where they will be more specific and timelier for preemptive strategies. Molecular biomarkers (the “-omics” approach) will likely offer the sensitivity and reliability to evaluate dietary exposures and to provide invaluable insights into behaviors of specific molecular targets and predictors of individual responsiveness to dietary change (Milner, 2004). These biomarkers must be readily accessible, easily and reliably assayed, differentially expressed in normal and diseased conditions, directly associated with disease progression, modifiable, and – most importantly – predictive (Figure 73.2). The future of biomarkers of nutritional exposures, effect and susceptibility likely resides in the enhanced use of molecular technologies to help distinguish responders from non-responders.

Complementary and overlapping mechanisms appear to account for the response to bioactive food components in foods or dietary supplements (Figure 73.3). These biological responses encompass such diverse functions as serving as an antioxidant, promoting the activity of detoxification enzymes, shifting hormonal homeostasis, influencing cellular energetics, regulating cell division, and cellular differentiation. Since the responses may occur simultaneously, it is difficult to determine which is most important in dictating the change in health. Figure 73.3 demonstrates

**FIG. 73.2** Predictive biomarkers of response to bioactive components.

**FIG. 73.3** Diet may influence several health-related processes.

some of the plausible processes by which dietary components may influence health outcomes. The ability of several nutrients to influence the same or multiple biological processes raises issues about possible synergy – as well as antagonistic interactions – that may occur within and among foods (Kensler *et al.*, 2000; Ikeda *et al.*, 2003).

### **DNA Instability**

A host of factors can contribute to DNA instability and ultimately to cellular proliferation. Endogenous agents, including methylating species and reactive oxygen species arising during normal cellular respiration, can lead to DNA damage. Some nutrients such as unsaturated fatty acids and iron may influence this process by promoting the formation of the damaging agents, while other components (such as some flavonoids and folate) may function to enhance endogenous repair mechanisms (Fenech, 2005). Support for this comes from the observation that an aqueous fraction of Fushimi sweet pepper increases repair against UV-induced cyclobutane pyrimidine dimers in human fibroblasts (Nakamura *et al.*, 2000). Other data point to the essentiality of folate in maintaining normal DNA synthesis and repair (Beetstra *et al.*, 2005; Friso and Choi, 2005). Multiple studies suggest that berries and their individual components such as anthocyanins prevent DNA damage by scavenging free radicals, chelating damage-inducing metals, and increasing the expression of DNA repair genes (Duthie, 2007; Aiyer *et al.*, 2008). Some dietary components may also retard repair, as has been suggested following exposure to alcohol, the metabolites of which can form adducts with DNA repair enzymes (McKillop and Schrum, 2009). Unquestionably, DNA replication is central to cell growth, development, and generation of tissues and organs. Recent advances in understanding replication machinery have revealed striking conservation of components involved in the DNA replication processes from yeast to humans, thus raising the possibility of using various models to test the site of action of nutrients (Mathers, 2004).

### **Cellular Proliferation and Death**

Cell homeostasis is regulated by a delicate balance among proliferation, growth arrest, differentiation, and apoptosis (programmed cell death). While vitamin A has been repeatedly linked to differentiation, other nutrients such as vitamin D may also be involved (Dong *et al.*, 2005). Numerous foods and dietary components inhibit or promote cell cycle progression by varied mechanisms. For example, indole-3-carbinol from *Brassica* vegetables inhibits elastase, which results in decreased cleavage of cyclin E to a low-molecular-mass form associated with increased proliferation (Nguyen *et al.*, 2008). Dysregulation of apoptosis frequently accompanies a wide array of conditions including cancer, neurodegeneration, autoimmunity, and heart disease. Diverse nutrients, including plant

sterols, selenium, and even butyrate arising from fermentable fibers may promote apoptosis (Awad and Fink, 2000; McEligot *et al.*, 2005).

### **Inflammation and Immunonutrition**

The immune system represents a primary defense against invading pathogens, non-self components, and cancer cells. Inflammation is a basic process by which the body reacts to infection, irritations, or other injuries, and is recognized as a type of non-specific immune response. The inflammatory processes, including the release of pro-inflammatory cytokines and formation of reactive oxygen and nitrogen species, are critical factors driving this process and can be influenced by several dietary components. Although pro-inflammatory actions are usually followed almost immediately by anti-inflammatory responses, excessive production of pro-inflammatory cytokines may lead to chronic inflammation. The ability of bioactive food components including zinc, epigallocatechin gallate, and omega-3 fatty acids appears to be mediated through unique molecular targets (Li *et al.*, 2004; Philpott and Ferguson, 2004; Calder, 2005; Cunningham-Rundles *et al.*, 2005).

The immune system protects against infection by producing specific antibodies in response to antigens. Vaccine-specific serum antibody production, delayed-type hypersensitivity response, vaccine-specific or total secretory IgA in saliva, and the response to attenuated pathogens are classic markers which can be influenced by dietary habits. Markers including natural killer cell cytotoxicity, oxidative burst of phagocytes, lymphocyte proliferation, and the cytokine pattern produced have also surfaced as potential predictors of immunocompetence. Since no single marker permits firm conclusions about the ability of diet to modulate the entire immune system, combining markers appears to be a suitable strategy. It is also clear that excesses of some nutrients can enhance the immune system while other food components can have detrimental effects (Calder and Kew, 2002).

### **Angiogenesis**

The availability of nutrients can also influence angiogenesis. In adipose tissue, vascular endothelial cells provide oxygen and nutrients to the growing mass of adipocytes. In fact, the formation of new blood vessels from existing ones often precedes adipogenesis. Insights into how food components alter angiogenesis may be particularly useful in combating the growing global incidence of obesity. Likewise, the importance of angiogenesis in tumor growth

and metastasis serves as additional justification for examining the impact of diet on this process. It is known that vascular endothelial cell proliferation, migration, and capillary formation can be stimulated by several angiogenic growth factors as well by as eicosanoids synthesized from omega-6 fatty acids (Rose and Connolly, 2000). Lipoxygenase and cyclooxygenase products of omega-6 fatty acid metabolism are angiogenic in in-vitro assays. The activity of both of these enzymes can be suppressed by the consumption of resveratrol found in grapes or omega-3 fatty acids occurring in fish (Rose and Connolly, 2000; Kaga *et al.*, 2005). Likewise, genistein, selenium, curcumin, and green tea polyphenols have been reported to influence angiogenesis (Bhat and Singh, 2008).

### **Summary of Molecular Targets**

Collectively, overwhelming evidence demonstrates that a variety of nutrients can influence a number of key intracellular targets. Determining which one of these targets is most important in altering tumor growth will not be a simple task. Likewise, unraveling the multitude of interactions among nutrients and other food components with these key events makes the challenge even more daunting. Finally, inter-individual differences probably reflecting genetic polymorphisms can mask the response to a compound and thereby complicate this undertaking to an even greater extent. Nevertheless, deciphering the role of diet is fundamental to optimizing health. Access to this information should help resolve the inconsistencies within the literature and provide clues to strategies that may be developed to assist individuals to improve their health.

### **Biomarkers and Long-Term Intervention**

Scientifically sound intervention studies must be viewed as the cornerstone for establishing nutrition guidance. Unfortunately, the number of long-term intervention studies that would be needed to adequately define the needs for bioactive food components is likely impractical in terms of speed of discovery and cost. Alternative procedures that utilize validated and sensitive biological markers will need to be developed to assist in determining who might benefit most and who might be placed at risk, and the minimum quality of the food and/or component needed to bring about the intended response. The Biomarkers Consortium, a partnership between United States government agencies and private industry, was launched in 2006 with the aim of identifying and

validating quantitative biomarkers. To date, the consortium has studied potential biomarkers for cancer, cardiovascular disease, rheumatoid arthritis, Alzheimer's disease, diabetes, and other chronic conditions. Their work has led to the identification of adiponectin as a predictive biomarker for type 2 diabetes (Wagner *et al.*, 2009).

In order to assess whether a food or its constituent has a physiological effect, it is imperative that stringent experimental design characteristics be followed, including: appropriateness of controls, randomization of subjects, blinding, statistical power of study, presence of bias, attrition rates, recognition and control of confounding factors (e.g. weight change or nutrition status), and appropriateness of statistical tests and comparisons. Each of these factors must become the mainstay for all clinical investigations. These same factors must also be considered in the conduct of preclinical investigations.

The question arises as to whether typical intakes of these dietary components are sufficient to bring about these effects and how frequently these food components must be consumed. Combs and Gray (1998) emphasized that the responses in antioxidant status, drug metabolism, and cell proliferation to a bioactive food component – in this case, selenium – was highly dependent on total intakes/exposures. Therefore, the development of “intended use” models represents a logical approach for determining the quantity of a food component needed for health promotion within specific segments of society, while building on the belief that not every individual will benefit from the same type of nutritional preemption strategies. There is also evidence that individuals do acclimate and accommodate to inadequacies in the food supply, and therefore the biological response cannot be considered constant (Young *et al.*, 1987). It is known that drug resistance frequently involves an induction mechanism thereby reducing or eliminating the response (Kohno *et al.*, 2005). Since bioactive food components have molecular targets, at least some of which are identical to those of specific drugs, it is logical to assume there is adjustment to their biological consequences as well.

Increasing the consumption of a wide variety of fruits, vegetables, and whole grains daily continues to be advocated as a practical strategy for consumers to optimize health and to reduce the risk of chronic diseases. The superiority of food blends is evident from the enhanced antioxidant potential achieved by combining multiple fruits rather than simply providing individual portions (Liu, 2004). Exposure to food blends may also result in

synergistic response by modifying multiple biological processes. For example, since quercetin and genistein block different phases of the cell cycle, their combined use is more effective in inhibiting the growth of human ovarian carcinoma cells than either provided alone (Shen and Weber, 1997). This has significance for dietary supplements, where the effects of individual constituents, as well as combinations of them, outside the food matrix will need to be carefully studied.

## Omega-3 Fatty Acids as an Example

For more than 25 years, clinical studies have provided data on the potential health benefits of consuming polyunsaturated fatty acids (PUFAs) and particularly omega-3 fatty acids. Dietary omega-3 fatty acids may come from fish and fish oils [chiefly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)], plant sources such as canola oil, walnuts, soybeans, and flaxseed primarily as  $\alpha$ -linolenic acid (ALA), and most recently some novel genetically modified plants with exaggerated amounts of EPA and DHA (Miller *et al.*, 2008).

Results of several studies have suggested that long-chain omega-3 fatty acid intake is associated with reduced risk of numerous diseases, including cardiovascular disease (CVD), stroke, certain cancers, immune disorders, asthma, and neurological disorders; rarely, however, has causality been established. Recently a series of evidence-based reports about the health effects of omega-3 fatty acids were developed by scientists in the Evidence-Based Practice Centers at Tufts–New England Medical Center, RAND–Southern California, and the University of Ottawa (summarized on <http://ods.od.nih.gov/FactSheets/Omega3FattyAcidsandHealth.asp#ref>). The primary goal of these reports was to assess the nature and quality of the evidence relating omega-3 consumption from foods and supplements to health outcomes such as CVD prevention and treatment. The reports systematically reviewed the evidence from numerous lines of inquiry. Systematic review of the randomized controlled trials of the effects of omega-3 fatty acids on CVD risk factors (Balk *et al.*, 2004; Jordan *et al.*, 2004; Wang *et al.*, 2004) showed that there is considerable heterogeneity in treatment effects. It is apparent from these and other reports that the speciation of the bioactive components must be considered along with the multiple interactions with other dietary/environmental factors that may influence the overall response. For example, it is recognized that omega-3 fatty acids are not

all equivalent in bringing about a biological response, and that confounders such as the total omega-6 fatty acid intake may influence the magnitude of the response (Luan *et al.*, 2001; Gago-Dominguez *et al.*, 2003; Leitzmann *et al.*, 2004).

### **Which Risk Factor Is Most Important?**

There was a strong, consistent, dose-dependent beneficial effect on plasma triglyceride levels (10–30% lowering) that was generally significant across studies (Balk *et al.*, 2004). In addition, there was a small but significant beneficial effect on systolic and diastolic blood pressure (about 2 mmHg decrease). There were possible beneficial effects on coronary artery restenosis after angioplasty, on exercise capacity in patients with coronary atherosclerosis, and on heart rate variability, especially in patients with recent myocardial infarction. There were non-significant increases in LDL- and HDL-cholesterol, and no consistent effects on carotid intima-medial thickness, on blood levels of apolipoproteins, lipoprotein(a), hemoglobin A1c, glucose, insulin, or C-reactive protein, or on any measures of hemostasis. A conclusion from these analyses is that if CVD benefits of omega-3 fatty acids exist, they are not well explained by their effects on the CVD risk factors examined, unless the overall benefit is due to the accumulation of small effects on several of them (e.g. triglycerides, blood pressure, etc.). Furthermore, it is obvious that, whatever criteria are used, all individuals do not respond identically to the same intervention strategy.

### **Generalizing Information for Prevention and Treatment**

A fundamental question remains: do pathologic evaluations reflect what occurs normally (Prentice *et al.*, 2004)? Is it appropriate to extrapolate information about omega-3 fatty acids in the prevention of cardiovascular disease in unselected populations (primary prevention) from data obtained on prevention in patients with previous disease events (secondary prevention)? To date there is strong evidence that omega-3 fatty acid consumption in patients who have suffered myocardial infarction can reduce the risk of subsequent cardiovascular events and all-cause mortality, although the data regarding primary prevention in otherwise unselected subjects are less secure.

Likewise, information about the potential role of omega-3 fatty acids in one condition may not be sufficient for judging their importance in another condition. For example, in type 2 diabetes mellitus, omega-3 fatty acids

reduce serum triglycerides, but have no effect on total cholesterol, high-density lipoprotein cholesterol, or low-density lipoprotein cholesterol; there is insufficient evidence to draw conclusions regarding their role in altering insulin resistance. In rheumatoid arthritis, one measure (tender joint count) appears to be improved, but there is no obvious effect on other clinical outcomes. For most of the other indications in which omega-3 fatty acids have been suggested to have benefits (such as inflammatory bowel disease, renal disease, bone density or fractures, need for anti-inflammatory or immunosuppressive drugs), there are insufficient data to draw firm conclusions (MacLean *et al.*, 2004).

Questions also remain about the generalizability of information across various populations with different genetic backgrounds. Recent studies suggest that polymorphisms in genes involved in essential fatty acid metabolism can determine whether or not an individual will respond favorably or negatively to changes in intake of omega-3 fatty acids (Simopoulos, 2010). For example, intake of marine omega-3 fatty acids in individuals with two variant 5-lipoxygenase alleles is inversely associated with intima-medial thickness of the carotid artery, an indicator of atherosclerosis (Dwyer *et al.*, 2004). The highest and lowest intakes of monounsaturated fatty acids are associated with increased intima-medial thickness, although this finding was not statistically significant. These associations are not observed in individuals with the common allele. Such nutrient–gene interactions, the number of which is unknown, can account for variability in randomized, controlled trials on the efficacy of omega-3 fatty acids on disease prevention and treatment. Therefore, it is difficult to make recommendations on fatty acid intake that apply to broad populations.

### **Health Consequences of Omega-3 Fatty Acids as a Model**

The example of omega-3 fatty acids illustrates the challenges in documenting health effects of bioactive food components. Overall, there is considerable potential for the role of omega-3 fatty acids in fish or in dietary supplements to reduce the risk of CVD events in previously affected patients, but the data are less certain in the context of primary prevention. Even though for some treatment effects the results were positive, there was considerable heterogeneity in the data. This undoubtedly reflects differences in experimental design (background diets, form and dose of intervention, duration of exposure, inclusion/

exclusion criteria for subjects, etc.), but it also reflects genetic differences among subjects, a topic dealt with earlier in this chapter. In any event, the evidence-based approach will allow us to more clearly delineate research directions and strategies for the future. In the case of omega-3 fatty acids, for example, more research is needed in well-designed primary prevention settings to determine the form (i.e. food vs. supplements), dose, duration, and subject selection where health effects can be assessed. The effects of omega-3 fatty acids in other settings need much more investigation. This does not mean that omega-3 fatty acids are without effect in these settings, but it does mean that the data are insufficient to make firm recommendations.

The same issues discussed with omega-3 fatty acids could reasonably apply to other nutrients and bioactive food components. Detailed discussion of each compound is beyond the scope of this chapter, but many of these compounds, including carotenoids, vitamin D, and flavonoids, are discussed in great detail in other chapters (Chapters 12, 13, and 27, respectively).

## Future Directions

In the setting of health effects of bioactive components of foods and dietary supplements, it is important to remember that the effect sizes are very likely to be small and perhaps only realized over a long period of time. This could explain why it has been difficult in intervention trials to document the putative benefits of food-based ingredients (such as omega-3 fatty acids) found in epidemiologic studies. Most reports included a small number of subjects who were studied for only short periods of time. There was considerable heterogeneity in the interventions that were used and the outcomes that were measured. There was little indication, however, of serious adverse events, although these studies may not have been sufficiently powered to detect rare events. Systematic review of the literature, using appropriate analytical tools, can be valuable in judging the state of science, detecting modest effects (both positive and negative), and leading to the development of recommendations. Recommendations may include what further research is necessary and what research designs are most appropriate to pursue; they may also include messages for the public about health-promoting dietary habits or supplementation.

Research in nutrition and health must give greater attention to studies aimed at understanding the basic

molecular mechanisms by which bioactive components influence cellular processes. Well-coordinated, multidisciplinary efforts among scientists – including nutrition scientists, molecular biologists, geneticists, statisticians, and clinical cancer researchers – will be needed to advance this molecular approach to nutrition and health. Many research questions and issues will need to be addressed for this approach to become a reality. For example, can the impact of a nutrient be evaluated by the use of a single molecular target, or do multiple targets need to be evaluated simultaneously to predict a response? What interactions are critical in modifying the response to bioactive food components? Additional attention to the importance of the time and duration of exposures for the overall response is needed. Key to moving this science forward will be the identification and validation of biomarkers that can be used to assess intake, effect, and susceptibility.

The development and implementation of a successful multidisciplinary effort that emphasizes a molecular approach to nutrition and health will take motivation, dedication, and specialized training. The challenges to this research are enormous, but so also are the potential rewards in terms of improving health.

 alcohol consumption 917  
 eye disease **947**, **951**, **958**  
 vitamin E 220, **958**
- Women's Intervention Nutrition Study (WINS) 845
- workplace, obesity and 1052
- World Food Programme (WFP) 1190, **1190**, 1194, 1198
- World Health Organization (WHO) 1135–50  
 cardiovascular disease prevention 770, **776**, 783, **785**  
 child growth standards 1185  
 diabetes prevention 785, **786**  
 Diabetes Programme 825  
 dietary guidelines 1122, 1125  
 Global Strategy on Diet, Physical Activity and Health 1147–8  
 nutrient intake goals for populations 1118, **1119**  
 nutrient reference values **1114**, 1117–18  
 nutrition monitoring activities 1103  
 physical activity recommendations 786, **787**  
 public health applications of nutrient recommendations 1145–8  
 recommended nutrient intakes 1136–45  
 wound healing, pantothenic acid and 385–6
- xanthophylls 185, **186**  
 bioavailability and bioconversion 187–8
- xerophthalmia 158, 170–1
- X-linked inhibitor of apoptosis (XIAP) 543, 543
- Yersinia enterocolitica* 1210, 1211  
 at-risk populations 1215  
 epidemiology **1212**  
 surveillance 1213–14
- Yersinia pseudotuberculosis* 1210
- youth behaviors, US surveys 1099–100
- Youth Risk Behavior Surveillance System (YRBSS) **1089**, 1099
- ySAMdc* gene **1246**
- Zambia, refugee camp **1194**
- zeaxanthin 186, **186**  
 age-related macular degeneration and 192–4, 959–60, **961–2**, 966  
 cataracts and 194, 946–52, **950–1**  
 chemistry 187  
 cleavage 190  
 uptake in tissues 189, **189**
- meso-zeaxanthin 187, 194
- zinc (Zn) 521–39  
 absorption 522–4  
 adolescent nutrition 642  
 age-related macular degeneration and 960–4  
 cataracts and 952  
 chemistry 521–2  
 copper interaction 524, 534, 545  
 deficiency 526–31, 529, **530**  
 alcoholic liver disease 899, 923  
 chronic kidney disease 882  
 Crohn's disease 860  
 immune function 528–30, **530**, 699  
 liver disease 894, 899, 902  
 dietary sources 532–3  
 excess and toxicity 533–5  
 excretion 524  
 homeostasis 524–5  
 infant nutrition **625**  
 maternal nutrition **611**, 615–16, **619**  
 metabolism 522–5  
 physiological function 525–6  
 plasma 522, 532  
 requirements **531**, 531–2  
 status assessment 532  
 supplements, liver disease 899  
 tissue 522
- zinc finger domains 526
- zinc importer proteins (ZIPs) 523
- zinc oxide nanoparticles 534
- zinc protoporphyrin, red-cell 512–13
- zinc transporters (ZnTs) 523, 525, 532
- Zone diet 765, 1061
- Zrt/Irt-like proteins (Zips) 523, 525, 532
- zyklopen 542
