# Contents

List of Contributors . . . . .	ix	13 Vitamin D	
Preface . . . . .	xxi	<i>Anthony W. Norman and Helen L. Henry . . . . .</i>	199
Acknowledgments . . . . .	xxii	14 Vitamin E	
1 Systems Biology Approaches to Nutrition		<i>Maret G. Traber . . . . .</i>	214
<i>James C. Fleet . . . . .</i>	1	15 Vitamin K	
2 Nutritional Epigenetics		<i>Guyllaine Ferland . . . . .</i>	230
<i>Robert A. Waterland . . . . .</i>	14	16 Vitamin C	
3 Genetic Variation and Nutrient Metabolism		<i>Carol S. Johnston . . . . .</i>	248
<i>Leah E. Cahill and Ahmed El-Sohemy . . . . .</i>	27	17 Thiamin	
4 Metabolomics		<i>Lucien Bettendorff . . . . .</i>	261
<i>Thomas M. O'Connell and Wei Jia . . . . .</i>	38	18 Riboflavin	
5 Energy Metabolism in Fasting, Fed, Exercise, and Re-feeding States		<i>Donald B. McCormick . . . . .</i>	280
<i>Sai Krupa Das and Susan B. Roberts . . . . .</i>	58	19 Niacin	
6 Protein and Amino Acids		<i>W. Todd Penberthy and James B. Kirkland . . . . .</i>	293
<i>Paul B. Pencharz . . . . .</i>	69	20 Vitamin B <sub>6</sub>	
7 Carbohydrates		<i>Vanessa R. da Silva, Katelyn A. Russell, and Jesse F. Gregory III . . . . .</i>	307
<i>Lisa M. Sanders and Joanne R. Lupton . . . . .</i>	83	21 Folate	
8 Dietary Fiber		<i>Lynn B. Bailey and Marie A. Caudill . . . . .</i>	321
<i>Ian T. Johnson . . . . .</i>	97	22 Vitamin B <sub>12</sub>	
9 Lipids: Absorption and Transport		<i>Sally P. Stabler . . . . .</i>	343
<i>Alice H. Lichtenstein and Peter J.H. Jones . . . . .</i>	118	23 Biotin	
10 Lipids: Cellular Metabolism		<i>Janos Zempleni, Subhashinee S.K. Wijeratne, and Toshinobu Kuroishi . . . . .</i>	359
<i>Peter J.H. Jones and Andrea A. Papamandjaris . . . . .</i>	132	24 Pantothenic Acid	
11 Vitamin A		<i>Joshua W. Miller and Robert B. Rucker . . . . .</i>	375
<i>Noel W. Solomons . . . . .</i>	149	25 L-Carnitine	
12 Carotenoids		<i>Charles J. Rebouche . . . . .</i>	391
<i>Brian L. Lindshield . . . . .</i>	185		

26 Choline <i>Steven H. Zeisel and Karen D. Corbin</i> . . . . .	405	43 Sports Nutrition <i>Louise M. Burke</i> . . . . .	669
27 Dietary Flavonoids <i>Gary Williamson</i> . . . . .	419	44 Nutrient Regulation of the Immune Response <i>Philip C. Calder and Parveen Yaqoob</i> . . . . .	688
28 Calcium <i>Connie M. Weaver</i> . . . . .	434	45 Obesity as a Health Risk <i>Sue D. Pedersen, Anders Sjödin, and Arne Astrup</i> . . . . .	709
29 Phosphorus <i>Robert P. Heaney</i> . . . . .	447	46 Hypertension <i>Thomas A.B. Sanders</i> . . . . .	721
30 Magnesium <i>Stella Lucia Volpe</i> . . . . .	459	47 Insulin Resistance and the Metabolic Syndrome <i>Jennie Brand-Miller and Stephen Colagiuri</i> . . . . .	732
31 Sodium, Chloride, and Potassium <i>Harry G. Preuss and Dallas L. Cloutre</i> . . . . .	475	48 Atherosclerotic Cardiovascular Disease <i>Simone D. Holligan, Claire E. Berryman, Li Wang, Michael R. Flock, Kristina A. Harris, and Penny M. Kris-Etherton</i> . . . . .	745
32 Human Water and Electrolyte Balance <i>Robert W. Kenefick, Samuel N. Chewront, Scott J. Montain, Robert Carter, III, and Michael N. Sawka</i> . . . . .	493	49 Diabetes <i>Lindsay M. Jaacks, Judith Wylie-Rosett, and Elizabeth J. Mayer-Davis</i> . . . . .	806
33 Iron <i>Peter J. Aggett</i> . . . . .	506	50 Osteoporosis <i>John J.B. Anderson</i> . . . . .	833
34 Zinc <i>Roberta R. Holt, Janet Y. Uriu-Adams, and Carl L. Keen</i> . . . . .	521	51 Cancer <i>Holly Nicaastro and John A. Milner</i> . . . . .	843
35 Copper <i>Joseph R. Prohaska</i> . . . . .	540	52 Nutrition and Gastrointestinal Illness <i>Alan L. Buchman and Stephen A. McClave</i> . . . . .	857
36 Iodine and Iodine Deficiency Disorders <i>Michael B. Zimmermann</i> . . . . .	554	53 Kidney Disease <i>Thiane G. Axelsson, Michal Chmielewski, and Bengt Lindholm</i> . . . . .	874
37 Selenium <i>Emily N. Terry and Alan M. Diamond</i> . . . . .	568	54 Liver Disease <i>Craig J. McClain, Daniell B. Hill, and Luis Marsano</i> . . . . .	889
38 Manganese, Molybdenum, Boron, Chromium, and Other Trace Elements <i>Forrest H. Nielsen</i> . . . . .	586	55 Alcohol: Its Role in Nutrition and Health <i>Paolo M. Suter</i> . . . . .	912
39 Maternal Nutrient Metabolism and Requirements in Pregnancy and Lactation <i>Lindsay H. Allen</i> . . . . .	608	56 Eye Disease <i>Rohini Vishwanathan and Elizabeth J. Johnson</i> . . . . .	939
40 Infant Nutrition <i>William C. Heird</i> . . . . .	624	57 Specialized Nutrition Support <i>Vivian M. Zhao and Thomas R. Ziegler</i> . . . . .	982
41 Adolescence <i>Asim Maqbool, Kelly A. Dougherty, Elizabeth P. Parks, and Virginia A. Stallings</i> . . . . .	637	58 Body Composition Evaluation <i>Krista Casazza and Tim R. Nagy</i> . . . . .	1000
42 Nutrition and Aging <i>Marion Secher, Patrick Ritz, and Bruno Vellas</i> . . . . .	654	59 Estimation of Dietary Intake <i>Wija A. van Staveren, Marga C. Ocké, and Jeanne H.M. de Vries</i> . . . . .	1012

<p>60 Taste and Food Choices <i>Adam Drewnowski and Pablo Monsivais</i> . . . . . 1027</p> <p>61 Energy Intake, Obesity, and Eating Behavior <i>Alexandra M. Johnstone</i> . . . . . 1043</p> <p>62 Strategies for Changing Eating and Exercise Behavior to Promote Weight Loss and Maintenance <i>Rena R. Wing, Amy Gorin, and Deborah F. Tate</i> . . . . . 1057</p> <p>63 Epidemiologic Approaches to Evaluation of Nutrition and Health <i>Susan E. Steck</i> . . . . . 1071</p> <p>64 Nutrition Monitoring in the United States <i>Ronette R. Briefel and Margaret A. McDowell</i> . . . . . 1082</p> <p>65 Dietary Standards and Guidelines: Similarities and Differences Among Countries <i>Johanna T. Dwyer</i> . . . . . 1110</p> <p>66 The Role of United Nations Agencies in Establishing International Dietary Standards <i>Robert Weisell and Janice Albert</i> . . . . . 1135</p> <p>67 Emergence of Diet-Related Chronic Diseases in Developing Countries <i>Barry M. Popkin</i> . . . . . 1151</p>	<p>68 Food Insecurity, Hunger, and Undernutrition <i>David L. Pelletier, Christine M. Olson, and Edward A. Frongillo</i> . . . . . 1165</p> <p>69 Public Nutrition in Humanitarian Crises <i>Helen Young, Kate Sadler, and Annalies Borrel</i> . . . . . 1182</p> <p>70 Foodborne Infections and Food Safety <i>Robert V. Tauxe and Marguerite A. Neill</i> . . . . . 1206</p> <p>71 Food Allergies and Intolerances <i>Steve L. Taylor and Joseph L. Baumert</i> . . . . . 1222</p> <p>72 Food Biofortification: Breeding and Biotechnology Approaches to Improve Nutrients in Vegetables and Oil Quality in Soybean <i>Prasad Bellur, Shantala Lakkanna, Jaya Joshi, Joseph Cornelius, Federico Tripodi, and Sekhar Boddupalli</i> . . . . . 1236</p> <p>73 Bioactive Components in Foods and Supplements for Health Promotion <i>Paul M. Coates, Holly Nicastro, and John A. Milner</i> . . . . . 1255</p> <p>Index . . . . . 1269</p>

# Preface

**W**e are honored to have been asked to edit the tenth edition of *Present Knowledge in Nutrition*. The first edition was published in 1953, and throughout the book's history its authors have been a "Who's Who" of nutritional science. The current volume is no exception. With this edition, we aimed to find productive, knowledgeable, and well-known authors to help us provide integrated information on nutrition, physiology, health and disease, and public-health applications – all in one text. This ambitious goal was set for one purpose: to provide readers with the most comprehensive and current information covering the broad fields within the nutrition discipline. Reflecting the global relevance of nutrition, our authors come from a number of countries. It is hoped that this edition captures the current state of this vital and dynamic science from an international perspective.

New to this edition are chapters on topics such as epigenetics, metabolomics, and sports nutrition – areas that have developed significantly in recent years. The remaining chapters have all been thoroughly updated to reflect developments since the last edition. Suggested reading lists are now provided for readers wishing to delve further into specific subject areas.

To make this edition as accessible and continuously relevant as possible, it is available in both print and electronic formats. An accompanying website (visit [www.pkn10.org](http://www.pkn10.org)) provides book owners with access to an Image Bank of tables and figures as well as to any updates the authors may post to their chapters in the future.

We hope this volume will be a valuable reference for researchers, health professionals, and policy experts, and a useful resource for educators and advanced nutrition students.

# Acknowledgments

A great deal of work and dedication was involved in producing this extensive volume. First and foremost, we thank the authors of the 73 chapters who reviewed and condensed a vast amount of knowledge and literature. Their undertaking was significant, and our gratitude for their dedication cannot be overstated. The editors of the ninth edition, Barbara Bowman and Rob Russell, are thanked for the critical help they provided in the conceptualization of this edition as well as in the author selection. All of the chapters in this edition were externally reviewed by leaders in each chapter's field; their generous, voluntary assistance was invaluable. We thank the International Life Sciences Institute for continuing to foster the production of *Present Knowledge in Nutrition*, and we especially thank Allison Worden for her guidance and hundreds of hours of work, and for keeping everything on track.

# 1

## SYSTEMS BIOLOGY APPROACHES TO NUTRITION

JAMES C. FLEET, PhD

*Purdue University, West Lafayette, Indiana, USA*

### Summary

Systems biology is an integrative approach to the study of biology. It integrates information gathered from reductionist experiments and various high-density profiling tools to understand how the parts of the system interact with each other and with other external factors such as diet. The science of nutrition is well suited to a systems biology approach. The tools of systems biology can be applied to settings relevant to nutrition with the goal of better understanding the breadth and depth of the impact that changing nutrient status has on physiology and chronic disease risk. However, there are many challenges to appropriately applying the systems biology approach to nutritional science. Among the challenges are those related to cost, study design, statistical analysis, data visualization, data integration, and model building.

### Introduction

#### ***Reductionism versus Systems Biology: A Changing Paradigm***

Nutrition requires an understanding of disciplines such as physiology, cell biology, chemistry, biochemistry, and molecular biology among others. In contrast to this broad view, we apply reductionist experimental approaches to advance our understanding of specific nutrient functions. However, while these approaches have been useful, significant issues limit their utility. For example, it can be difficult to translate mechanism-focused research in cells into the complex physiology of a whole organism. As a result, biological models developed from reductionist experiments often fail to explain why gene knockout mice studies do not have the expected phenotype (e.g. the facilitated diffusion model used to describe intestinal calcium absorption

is being challenged by the results from calbindin  $D_{9k}$  and TRPV6 knockout mice (Benn *et al.*, 2008; Kutuzova *et al.*, 2008)). Even after extensive examination of a problem with reductionist approaches, we often find that gaps exist in our understanding. It is clear that re-applying the approaches we have traditionally used to investigate nutritional questions is unlikely to yield a different outcome. Because of this we need new approaches that complement traditional reductionist approaches but which give us a new, broader perspective of how nutrients are influencing human biology. Systems biology is such an approach.

Systems biology has been described as an approach to biological research that combines reductionist techniques with an “integrationist” approach to identify and characterize the components of a system, and then to evaluate how each of the components interacts with one another and with their environment. The goal of the systems

**TABLE 1.1** Definitions related to systems biology

Term	Description
Genomics	The study of the genomes of organisms including influences of DNA sequence variation on biology and the impact of modifying DNA and histones on DNA function (i.e. epigenomics)
Transcriptomics	The study of transcripts from the genome including messenger RNA and non-coding RNA such as micro RNA
Proteomics	The study of proteins in a biological system including their level, location, physical properties, post-translational modifications, structures, and functions
Metabolomics	The study of the unique chemicals (metabolites) that are produced as a result of cellular processes, e.g. small molecules such as lipids, metabolites of intermediary metabolites
Ionomics	The study of the mineral nutrient and trace element composition of an organism
Next-generation sequencing	High-throughput DNA sequencing technologies that parallelize the sequencing process thereby producing millions of sequences at once
Cluster	A graphical representation of relationships between data based on similarities in their concentrations or changes in concentrations
Pathway	A graphical representation of biological data organized on the basis of accepted relationships (e.g. glycolysis; signaling through the insulin receptor; lipoprotein transport)
Network	A complex graphical representation of biological data that is developed from the experimental data. This will include known relationships (pathways) and new relationships linking pathways

biology approach is to integrate many types of information so that you get a more complete view of a system (Kohl *et al.*, 2010). This definition has a flexibility that is very attractive to nutrition. The notion of a “system” can be applied narrowly to a cell, where the parts are individual biochemical and signaling pathways and the “environment” is the growth factors and hormones that regulate these pathways. However, it can be applied more broadly to a person, where the integration relates to the physiologic systems and the “environment” is lifestyle variables such as diet. For example, we know that calcium influences bone metabolism *but* we know that this relies upon the efficiency of intestinal calcium absorption and renal calcium excretion as well as on hormones produced at various sites (e.g. PTH in the parathyroid gland, 1,25-dihydroxyvitamin D in the kidney). Thus, our understanding of how dietary calcium intake influences bone is enhanced by looking at the interactions between multiple tissues rather than just focusing only on bone.

### **Systems Biology as Discovery Tool**

Systems biology is an approach but within this approach are also three classes of novel tools necessary for a success-

ful systems biology analysis. First, there are the high-density phenotyping platforms that allow simultaneous measurement of whole classes of biological compounds, i.e. omics methods such as genomics, transcriptomics, proteomics, metabolomics, and ionomics (Table 1.1). Next, the information from these platforms must be analyzed to identify the important changes resulting from a treatment. This requires the application of sophisticated statistics. Third, the information must be annotated and integrated with prior knowledge: this is the field of bioinformatics.

### **Systems Biology and Omics Tools for Biomarker Discovery**

Omic analyses are often used to profile a biological state and then essential elements of the profile are used as a biomarker. Theoretically, the more independent traits one incorporates into a biomarker, the less likely it will be that the biomarker will be influenced by extraneous/confounding factors. To illustrate this point we can look to the field of iron metabolism. Nutritional iron status can be evaluated by measuring serum ferritin (high ferritin = high iron status) but this parameter is confounded by chronic inflammation (high inflammation = high fer-

ritin) that can mask iron deficiency (Wang *et al.*, 2010). The serum levels of other proteins are also affected by the changes in iron status, e.g. hepcidin (high levels = high iron status) and soluble transferrin receptor (low levels = high iron status). Whereas hepcidin is affected negatively by inflammation (Nemeth and Ganz, 2009), transferrin receptor is not (Beguin, 2003). Thus, by simultaneously assessing the serum levels of ferritin, transferrin receptor, and a serum marker of chronic inflammation (e.g. C-reactive protein), one can assess iron status and remove the confounding caused by the inflammation associated with acute or chronic disease. The approach of using omics to identify measurements that can be combined to make an effective biomarker has been applied to the assessment of certain cancers (Sikaroodi *et al.*, 2010) and some argue that this approach may be useful for the assessment of nutrient status or of nutrition-related conditions that have proved resistant to the single marker approach (e.g. micronutrients such as zinc) (Lowe *et al.*, 2009).

### Use of Systems Biology to Define New Modes of Regulation by a Nutrient or Metabolic State

A second way to use systems biology is to identify the groups of genes/transcripts/proteins/metabolites coordinately regulated under specific conditions. These groups

could be organized within known biological pathways or as random groupings driven by statistical correlation, i.e. networks that expose new relationships not previously recognized from traditional reductionist research.

## Understanding the Systems Biology Approach

It is an over-simplification to imply that there is just one way to do systems biology research but this section will attempt to provide a framework for approaching a nutritional research problem from the systems biology perspective (see Figure 1.1 for a summary of the steps in the framework).

### Experimental Design

This is the single most important step of a systems biology research project for several reasons (Allison *et al.*, 2006). First, adequate experimental planning is necessary to focus the research and to use resources efficiently. One will likely need multiple time points to collect data on multiple phenotypes. For example, early time points may be more informative for measurement of direct transcriptional regulation (e.g. using transcriptomics or chromatin immunoprecipitation coupled to high-density DNA sequencing

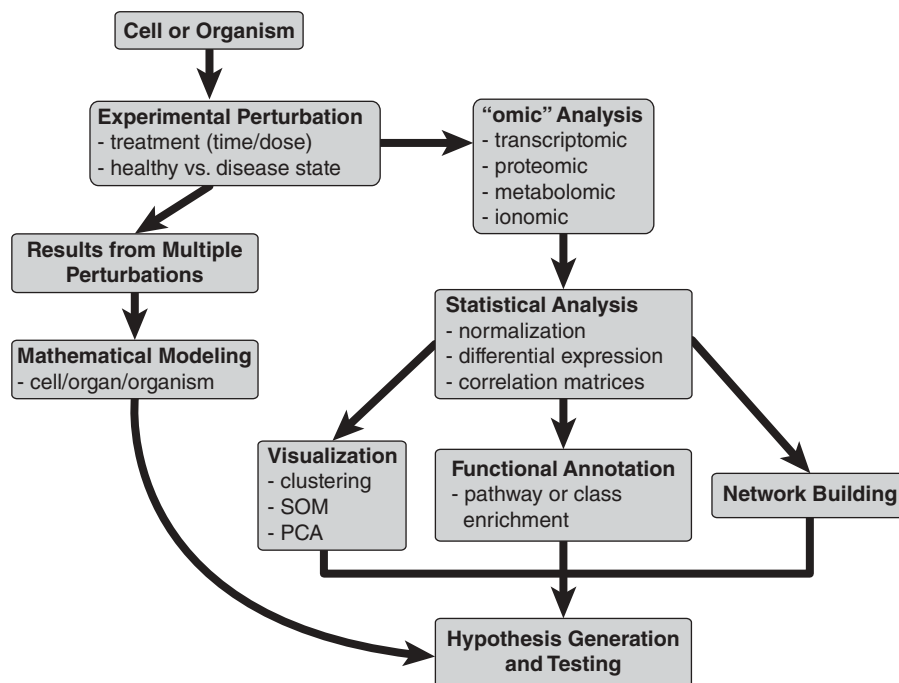

FIG. 1.1 An overview of the steps in a systems biology analysis.

[ChIP-seq]). However, later time points will be more informative for evaluating protein production or changes in metabolism. Second, the use of multiple conditions should be examined so that a broader, more representative view of the regulation can be determined. Work from model systems such as yeast, where a knockout line exists for each of the 6700 yeast genes, shows us that combining transcriptomic analysis for all of these lines permits computer modeling that can reveal new biological relationships and coordination of regulatory processes (Beer and Tavazoie, 2004). Third, sample replication is necessary so that the study has sufficient statistical power to detect biologically important differences between treatments. Finally, the experimental plan should control all extraneous variables so that any changes can be unambiguously attributed to the treatment of interest.

### High-density Phenotyping Platforms

#### Genomics

**Gene Promoter Analysis.** Genetic regulation involves coordinated molecular regulation through transcription factor binding sites within groups of promoters (e.g. molecular regulation of cholesterol and lipid metabolism (Desvergne *et al.*, 2006)). A large number of computational methods are available to locate transcription factor binding sites in mammalian gene promoters (Elnitski *et al.*, 2006). Unfortunately, because transcription factor binding sites tolerate sequence heterogeneity, these computational methods have a high false-positive detection rate (Tompa *et al.*, 2005).

Recently a direct method has been developed to directly determine transcription factor binding sites throughout the genome. This approach starts with a chromatin immunoprecipitation (ChIP) assay where transcription factors are cross-linked to DNA at the site of their binding and the complex is isolated using antibodies to the transcription factor (Collas, 2010). The DNA from the ChIP assay is then used either to probe a genome-wide DNA tiling array (ChIP on chip) or sequenced directly using next-generation sequencing methods (ChIP-seq) (Park, 2009). This approach was recently used to identify 2776 genomic positions occupied by the vitamin D receptor (VDR) after treating lymphoblastoid cell lines with 1,25-dihydroxyvitamin D. These VDR binding sites were significantly enriched near autoimmune and cancer-associated genes identified from genome-wide association (GWA) studies (Ramagopalan *et al.*, 2010), suggesting this infor-

mation will help us understand the relationship between transcriptional regulation and various disease states.

**Genetic Mapping and Forward Genetics.** Forward genetics, the measurement of phenotype and then determining the associations with variations in genotype, is an important approach that has been virtually untapped for the study of nutrient metabolism and function. The basic concept for this approach starts with the fact that natural sequence variations exist within the genome (e.g. single nucleotide polymorphisms or SNP, copy number variations or CNV), and that this variation is heritable. To be useful in forward genetics, these genetic variations must also influence phenotypes, e.g. tissue mineral levels or fatty acid oxidation rate. Finally, unlike the rare mutations that underlie various genetic diseases and cause extreme phenotypes (such as the mutations in copper transporting ATPases responsible for Wilson's and Menkes disease), the phenotypic changes resulting from the natural variation identified by forward genetics are not fatal but could result in extreme differences between individuals. The goal is to use variations in phenotypes that result from controlled breeding strategies or within pedigrees to map the location of the natural genetic variation that controls the phenotype. The forward genetics approach makes no assumptions about the genes that influence the trait. Rather, it lets variations in phenotype direct us to the regions of the genome containing genetic variants that have a significant biological impact. Forward genetics is particularly useful in instances where we don't know enough about the metabolism of a nutrient to justify making gene knockout or transgenic mice (i.e. use of reverse genetics) or when mice continue to have normal biology when a candidate gene is deleted (e.g. suggesting redundancies in the system that need to be revealed).

Relating nutritionally important phenotypes to natural variation can be accomplished in two ways: gene mapping and gene association. Linkage analysis within large families and quantitative trait loci (QTL) mapping in controlled crosses between genetically well-characterized inbred mouse lines have been traditionally used to correlate the variation in a phenotype to sequence variations in the genome (Flint *et al.*, 2005). More recently researchers have begun using the genome-wide association (GWA) study approach whereby a multitude of individual variants or haplotypes of variants are examined for their association with a nutritionally relevant trait within large populations of free-living individuals (Manolio, 2010). However, some

are concerned that the GWAS approach is subject to false positives and that GWAS findings are difficult to replicate. Regardless of which approach one takes, once the genetic region or candidate polymorphism is identified, additional studies must be conducted to identify the genes that contain the variation controlling the trait, and traditional reductionist research must be done to learn how the genes identified are involved in the regulation of the trait. Because forward genetics approaches are unbiased and hypothesis free, they can lead to the identification of new biological roles for genes and their protein products (Flint *et al.*, 2005).

The promise of forward genetics for nutrition was recently demonstrated for iron metabolism (Wang *et al.*, 2007) where the genes controlling 30% of the variation in spleen iron levels between inbred mouse lines were mapped to chromosome 9. Within this locus, variation was identified in the *Mon1a* gene and this information was used to determine that *Mon1a* is a critical component of spleen iron uptake and recycling of red blood cell iron within macrophages. Thus, even though we have learned a tremendous amount about iron metabolism over the last 15 years from traditional approaches (Andrews, 2008), forward genetics permitted researchers to add another piece to this already complex picture.

**Epigenomics.** In addition to the regulation mediated through DNA sequences, DNA and histones can be modified and this will influence gene transcription (Mathers, 2008) (also, see Chapter 2). In humans, DNA is organized into a nucleosome complex with four histone proteins (H2A, H2B, H3, and H4). The amino terminal tails of the histones can be post-translationally modified in a variety of ways. Histone acetylation reduces histone association with DNA and is permissive for gene transcription whereas histone methylation is associated with both transcription repression and activation. DNA can also be methylated at the C5 position of cytosine in regions of DNA called CpG islands. Cytosine- and guanine-rich sequences are located near coding sequences in about 50% of mammalian genes. When the CpG islands are methylated, these regions become more compact and this prevents gene transcription (Attwood *et al.*, 2002). DNA methylation is responsible for X chromosome inactivation, genomic imprinting, and tissue-specific gene transcription that occur during cellular differentiation.

Because of its importance in gene repression, researchers have developed DNA microarrays and next-generation

DNA sequencing approaches for epigenetic profiling of CpG islands in the human genome (Fouse *et al.*, 2010). Folate and other micronutrients are involved in the production of the universal methyl donor S-adenosyl methionine, so it has been proposed that dietary inadequacy may have a global influence on DNA methylation (Oommen *et al.*, 2005). However, the evidence for this diet-induced regulatory paradigm is not yet secure.

### Transcriptomics

It is now possible to simultaneously measure the primary transcripts and all of the alternatively spliced forms of transcripts produced from each gene in the genome of humans and several model organisms (i.e. the transcriptome). Transcript levels are a reflection of both primary regulation by a treatment and secondary regulation that follows from the initial regulatory events (Figure 1.2). There are many high quality options from assessing the transcriptome including spotted cDNA arrays, tiling oligonucleotide arrays, and even direct sequencing of RNA (Kirby *et al.*, 2007; Forrest and Carninci, 2009). Many factors can influence the choice of a transcript profiling platform including cost, reproducibility of results, breadth of transcript coverage, and availability. Readers should consult other reviews for additional discussion of the strengths and weaknesses of various array platforms (Hoheisel, 2006; Kawasaki, 2006).

For some nutrients that are known to have a direct impact on gene transcription through the activation of a nuclear receptor (e.g. vitamin D and VDR, vitamin A and the retinoic acid receptor bioactive lipids and the peroxisome proliferator-activated receptor, [PPAR]), transcriptomics is a primary endpoint for understanding the impact of the nutrient on biology. A simple example of the value of transcriptomics comes from the area of lipid metabolism. The synthesis of fatty acids and cholesterol is regulated by the sterol regulatory element-binding proteins (SREBP)-1a, -1c, and -2. Horton *et al.* (2003) used transcriptomics to study transgenic mice overexpressing each SREBP isoform and mice lacking all three nuclear SREBPs (i.e. in SREBP cleavage activating protein (SCAP)-deficient mice). They found several hundred transcripts that were changed in the liver and from this data they defined a subset of 33 genes as SREBP targets that included 20 new SREBP target genes. Thus, in one short, directed set of experiments they dramatically expanded our understanding of how lipid metabolism is regulated.

**FIG. 1.2** A schematic demonstrating the interactions between the various levels of regulation within a cell. Regulatory events occur at the level of transcription (gene space), RNA translation (protein space), protein stability or interactions (protein space), and protein function (gene space, metabolic space). Inorganic elements are involved in all of these processes (ionic space), and events occurring in one regulatory space can influence events occurring within another regulatory space (e.g. lipid metabolites bind to protein transcription factors with zinc finger DNA binding domains such as PPAR gamma and this interaction regulates gene transcription). Systems biology attempts to model these complex interactions. Reduced omic phenotyping (e.g. in just the gene space or the metabolic space) – combined with previously published research findings – can be used to infer regulatory interactions between these levels.

### Proteomics

The proteome refers to all of the proteins expressed and functional in a system. Unfortunately, the methods to assess the proteome cannot measure the entire proteome simultaneously. As a result, experiments usually measure one or more subproteomes, e.g. the phosphoproteome reflecting the proteins that are targets for protein kinases, proteins within subcellular compartments (e.g. mitochondrial proteome) or specific tissues (serum proteome), or proteins with specific physical properties (e.g. the membrane proteome).

There are two approaches to proteomics. The first is a “top-down” approach whereby whole proteins are studied using multidimensional separation techniques, e.g. separation by isoelectric point followed by size separation (2D polyacrylamide gel electrophoresis [PAGE]) or tandem mass spectrometry (Reid and McLuckey, 2002). In the top-down approach the proteins are isolated, then fragmented (e.g. through trypsin digestion), and the peptide

fragments are compared with a database to determine the identity of the protein. In contrast, the “bottom-up” approach digests proteins at the outset, isolates and identifies the peptide fragments using mass spectrometry methods, and then relates the peptide fragments to databases of known proteins to determine the identity of the proteins in a complex mixture.

The major challenge to proteomics is that the spectrometry methods are not standardized. This leads to problems of reproducibility across and within labs. In addition, there are some challenges to separating signal from noise that limit peak detection and quantification. Finally, some proteomic methods are not very sensitive. Specifically, 2D PAGE approaches are often used for serum proteomics and biomarker discovery. However, the ability of radioimmunoassay to detect proteins in serum is 100- to 1000-fold greater than 2D PAGE methods. Even with this weakness, 2D PAGE has been useful for identifying serum biomarkers of nutritional status. For example, Fuchs *et al.* (2007)

used this approach to identify biomarkers of a cardioprotective response to isoflavone supplementation in the peripheral blood mononuclear cells of postmenopausal women.

### Metabolomics

Evaluating the metabolome gives a snapshot of the physiology of a cell or organism by simultaneously measuring the levels of metabolites within a biological space (also, see Chapter 4). Like proteomics, the metabolome is assessed by coupling separation techniques (e.g. electrophoresis, chromatography) with sophisticated detection methods (e.g. mass spectrometry, nuclear magnetic resonance imaging). As such, it suffers from the same problems as proteomics, namely the lack of method standardization and reproducibility. Also, like proteomics, the entire metabolome is too complex for one method to measure all possible metabolites simultaneously, and so submetabolomes based on location or chemical characteristics are commonly analyzed. While many studies use metabolomics for biomarker discovery, this approach can also be used to better understand the impact of physiologic conditions on the flow of information through specific metabolic pathways. For example, in a study of diet-induced insulin resistance, Li *et al.* (2010) identified many serum and liver metabolites as different between safflower-oil-fed wild-type and glycerol-3-phosphate acyltransferase deficient mice. Many of these were not previously known to be associated with insulin resistance and they point to the utility of metabolomics analysis for identifying biochemical pathways important in understanding the pathophysiology of diabetes. In addition to the standard metabolomic approach that measured changes in steady-state levels of metabolites, others have used radio- or stable isotopes to label compounds and trace their metabolic fate. This is a more dynamic approach that can give a picture of how physiologic states or treatments affect the flow of compounds through specific metabolic pathways (Hellerstein, 2004).

### Ionomics

Mineral elements are involved at all levels of biological regulation, e.g. in transcription factors (zinc), in enzymes (zinc, iron, copper, calcium), and in establishing electrochemical gradients in cells (calcium, sodium, potassium). It is also well established that direct and indirect interactions exist between mineral elements that can affect biology (Hill and Matrone, 1970). Because the mineral elements are integrated into the overall biology of a cell (i.e. with

links to the metabolome, proteome, transcriptome, and ultimately the genome: Figure 1.2), examination of the entire elemental profile of a system (i.e. the ionome) may reflect broader, biologically relevant disturbances and may have the potential to capture information about the functional state of an organism under different environmental and physical conditions (Salt *et al.*, 2008). Evaluating the ionome is accomplished using high-throughput elemental analysis technologies (e.g. inductively coupled plasma-atomic emission spectroscopy [ICP-AES] or ICP-mass spectroscopy [ICP-MS]).

An early example of ionomics was reported by Eide *et al.* (2005), who examined how gene deletions in budding yeast were linked to changes in the ionome. They conducted a 13-element profile for each of 4385 yeast gene deletion mutants and found that 212 mutants had significant disturbances in at least one member of the ionome. By using bioinformatic tools to identify clusters of functionally related genes within the list of the 212 mutants, they found that shifts in the ionome were a reflection of specific biological functions. For example, 27 of the 212 gene deletion mutants influenced mitochondrial function and these mutants were characterized by lower Se and Ni accumulation. This highlights the point that alterations in the ionome reflect changes in critical biological functions. Readers are encouraged to read one of several interesting reviews describing the use of ionomics in biology (e.g. Salt *et al.*, 2008; Baxter, 2009).

### How Important Is Validation of Results from High-Density Omic Tools?

A well-conducted omics experiment should be robust and reproducible. However, it is standard practice to confirm the changes in a subset of differentially expressed transcripts or proteins with traditional tools. While this raises confidence in the quality of the results from the omic platform, comprehensive validation is not feasible or desirable. Extensive re-evaluation of changes detected in omic analysis is conceptually the opposite approach to the systems biology approach where the breadth of changes is as important as any one specific change.

**Balancing Cost and Content.** By this time it should be obvious that the ideal collection of data for a systems biology experiment will be expensive. This is an unavoidable reality of the systems biology approach. While a time and dose response study in cells, animals, or people is not out of the ordinary, the costs of application of multiple

**TABLE 1.2** Selected databases of omics data available for data mining

Name	Website	Description
Gene Expression Omnibus (GEO)	<a href="http://www.ncbi.nlm.nih.gov/projects/geo/">www.ncbi.nlm.nih.gov/projects/geo/</a>	National Center for Biotechnology Information (NCBI) database of microarray experiments
ArrayExpress	<a href="http://www.ebi.ac.uk/arrayexpress">www.ebi.ac.uk/arrayexpress</a>	European Bioinformatics Institute of the EMBL database of microarray experiments
Human Metabolome Database (HMDB)	<a href="http://www.hmdb.ca/">www.hmdb.ca/</a>	Database containing detailed information about small molecule metabolites found in the human body
Cancer Biomedical Informatics Grid (caBIG)	<a href="http://cabig.nci.nih.gov/">cabig.nci.nih.gov/</a>	National Cancer Institute site for cancer studies; includes data sets from genomic, transcriptomic, proteomic, and imaging analysis
Expert Protein Analysis System (ExPASy) Server	<a href="http://ca.expasy.org/">ca.expasy.org/</a>	Database dedicated to the analysis of protein sequences and structures as well as 2D PAGE
Database of Genotype and Phenotype (dbGaP)	<a href="http://www.ncbi.nlm.nih.gov/sites/entrez?Db=gap">www.ncbi.nlm.nih.gov/sites/entrez?Db=gap</a>	National Institutes of Health database for studies on the interaction of genotype and phenotype
WebQTL	<a href="http://www.genenetwork.org/">www.genenetwork.org/</a>	Linked resources and analysis tools for systems genetics in mouse and some other models

“omic” tools, especially to multiple tissues, could become astronomical. For this reason, most scientists use two strategies for cost containment. First, individual investigators will focus on one “omic” tool that has the most relevance for their biological question. Researchers studying vitamin A or vitamin D may choose to examine the transcriptome because of the well-established understanding that metabolites of these compounds are direct regulators of gene expression. Researchers examining the effects of branched-chain amino acids on physical performance might choose to study the muscle proteome because of the anabolic effect mediated through mTOR signaling at the protein level. Others may examine the serum metabolome after feeding diets with changing macronutrient content. In these settings, the investigator will gain a great deal of insight into one aspect of the system but the full power of the systems biology approach may take a long time to be realized as an investigator slowly pieces together various “omic” views of their system over time. The second approach does not reduce the cost of these experiments but disperses the cost across many research groups. In this case, scientists will work as teams rather than individual labs. Each team member will take responsibility for a different aspect of the system where their interest and exper-

tise are greatest. Related to this, researchers will pool related data from complementary experiments. This is proving fruitful for a number of integrative science projects and is the reason why many funding agencies now require a data sharing plan – so that people interested in integrating data have access to it (see Table 1.2 for a partial list of databases).

### **Identifying Significant Changes in a System after Perturbation**

Statistical analysis is one of the unappreciated aspects of systems biology. Others have carefully reviewed the importance of statistical analysis for microarray experiments and other aspects of systems biology (Nadon and Shoemaker, 2002; Allison *et al.*, 2006) so here we will simply summarize a few crucial points.

First, in the absence of statistics one cannot assess the reliability of: a difference observed between treatment groups, the association of genetic variation with relevant phenotypes, or the enrichment of specific pathways or regulatory networks after a treatment or dietary intervention. Without statistics only a fold-change is available for assessing the “importance” of differences between groups. While large fold-changes may be biologically important, a

collection of small fold-changes in the transcript levels for many of the components of a pathway or biological process is also important.

Second, a simple t-test with a significance level of  $p < 0.05$  is inadequate to test statistical significance because it ignores the importance of type I error rates (false positives). For example, at  $p < 0.05$  we would expect 5% of the t-tests to be false positives (i.e. 1000 targets on a 20 000 transcript array, 50 000 single nucleotide polymorphisms [SNPs] on a 1 million SNP chip). However, multiple test correction methods like Bonferroni (p-value/number of comparisons; e.g.  $0.05/20\,000 = 2.5 \times 10^{-6}$ ) are too conservative because they lead to a high type II error rate (false negative). As a result, statisticians have developed methods such as the false-discovery rate (FDR) approach to balance the type I and II error rate problems inherent when multiple independent comparisons are being conducted (Pounds and Cheng, 2006). Another way to reduce the multiple comparison problem is to filter out noise in the detection procedure. For example, although microarrays can measure all of the transcripts expressed in the human body, not all transcripts are expressed in every cell or tissue type. By removing “absent” transcripts from the dataset, one can reduce the number of independent comparisons to be conducted, reduce the multiple comparison problem that causes high type I error rates, and increase the power to detect differences between treatment groups.

Finally, the ability to detect significant differences is improved by sample replication. Replication is particularly useful when the biological variability in protein, metabolite, or transcript level is high.

### **Bioinformatics**

The fundamental purpose of bioinformatics is to identify patterns within the complexity of the data from high-density omic analysis methods. In many ways, this is a problem of visualization (Gehlenborg *et al.*, 2010). In the next several paragraphs some bioinformatic approaches that have been taken to reduce the complexity of omic data will be discussed.

### **Clustering**

The large number of endpoints analyzed in an omic experiment (e.g. >20 000 transcripts) make it impossible to see important patterns in the data even after filtering and statistical analysis (Tamayo *et al.*, 1999). A number of clustering methods have been developed to overcome this

problem. The most common methods are the tree-based methods such as hierarchical clustering and the graphical views based on self-organizing maps (SOM). These methods may require additional normalization so that important patterns are not lost due to issues of scale (i.e. combining data from metabolites that are present at high and low levels). In addition, mean values are used so prior filtering to eliminate low-fold change or non-significant changes is necessary. Ultimately functions of genes can be inferred from the patterns identified by clustering (e.g. genes whose transcripts cluster together may have similar functions (Iyer *et al.*, 1999)).

### **Pathway Mapping**

Functional annotation and pathway mapping identify changes in biological relationships that have previously been experimentally determined. Programs have been developed to permit grouping of omic data based upon gene ontology classes, e.g. gene set enrichment analysis (GSEA) (Subramanian *et al.*, 2005) or on whether changes are accumulating in the proteins/transcripts of a known biological pathway or within the group of biological factors known to be important for a specific physiological or disease process (Werner, 2008). This sort of grouping can be represented easily in a graph or figure of a pathway. By relating omic data from an experiment to the known body of information in these ways, researchers can more easily find themes that describe the impact of a treatment on biology.

### **Network Analysis**

The hope of systems biology is that it will identify relationships between molecules that represent new ways of understanding the complexity of biological regulation (Huang *et al.*, 2007). These relationships can be between proteins (e.g. dimerization that activates a complex, kinases phosphorylating other proteins), proteins and DNA (e.g. transcription factor binding), nucleic acids (e.g. microRNA regulating expression of a specific mRNA), or proteins and metabolites (e.g. bioactive lipids regulating receptors). Some of these relationships are present in traditional pathway structures. However, other relationships are links between pathways. As a result, one can think of a network as a combination of interacting modules where each module is a regulatory pathway or process that is recognized by the scientific community. Conceptually, this is similar to what happened in the early days of biochemistry when metabolic pathways were studied independently and later joined as people recognized that metabolites in

one pathway became substrates in other pathways (e.g. acetyl CoA joins pathways for glycolysis, the citric acid cycle, steroid synthesis, and fatty acid biosynthesis into a network). Finding these networks becomes a problem of identifying the connections, assessing their strength, and visualizing them. There are many network building algorithms that can be used on omic data. In these networks proteins or metabolites are visualized as nodes, and interactions between proteins or metabolites are viewed as lines (edges) (Aittokallio and Schwikowski, 2006). Readers interested in the procedure for building networks can refer to one of several reviews for more in-depth discussion of this topic (Alvarez-Buylla *et al.*, 2006; Li *et al.*, 2008).

### **Mathematical Modeling of Metabolic and Physiologic Processes**

The relationship between variables in a biological system can be represented as a mathematical model. In a simple sense, this is what we do when we graph a dose response where the relationship between the dose and the outcome is expressed as a regression line. However, as the complexity of the system increases, simple graphical relationships between two parameters are insufficient to represent biology. Under these circumstances more elaborate mathematics can be applied to experimental observations to create a simplified model of the system. This approach is at the heart of kinetic modeling of nutrient metabolism (e.g. for calcium metabolism: Weaver, 1998) and was pioneered in nutrition by Dr R. Lee Baldwin in an attempt to develop predictive models for how nutrition regulates energy metabolism and performance of ruminants (Baldwin *et al.*, 1994).

One of the barriers to effective mathematical modeling is the quality and depth of the data available for building the models (Klipp and Liebermeister, 2006). With the advances that have occurred in our data generation capabilities as a result of the omics era, researchers have begun to believe that comprehensive mathematical modeling of biological systems is possible. Nonetheless, reliable quantitative models are hard to develop. As a result, the first step in the process is to take existing experimental knowledge and use it to build a raw model. This process is not, however, implemented simply to reproduce all the parts of the system, but to direct researchers to areas where gaps exist in the model so that additional experimentation can be conducted. In other words, the raw model is improved over time by conducting additional experiments. In theory, by repeated cycles of developing and testing models fol-

lowed by new hypothesis-based experiments, we have the potential to better understand the system and use the model for predictive purposes.

### **The Power of Public Databases**

The expense of conducting a systems biology experiment using omics tools can be intimidating to many researchers. An alternative to conducting primary experiments is to re-analyze experiments that are available in public databases. Several useful databases for datamining are presented in Table 1.2. For example, a repository for genomic and transcriptomic datasets is the Gene Expression Omnibus (GEO) at NCBI. In the fall of 2010, a simple search using “intestine” as the keyword revealed 81 datasets and 440 data series (with some overlap in the lists). A search for “folate” identified 7 datasets and 34 data series. Of course, the value of data from public databases can be variable, e.g. in GEO some datasets provide replicates whereas others do not. In addition, there may be a substantial commitment for researchers to learn how to use the bioinformatic tools that allow one to make sense of these datasets (see Table 1.3 for a list of some tools that can be used for the analysis of omic data). However, the analysis of these datasets may allow an investigator to generate preliminary data for a hypothesis that could be used as a foundation for additional research or as preliminary data for a grant application.

### **Future Directions**

#### **Computer Infrastructure**

Many of the steps in a systems biology approach are computationally intensive (Heath and Kavraki, 2009). While small studies can be analyzed on desktop computers, even these may challenge a computer unless it is set up appropriately in terms of RAM, operating system, and processor speed. For more sophisticated analysis, high-performance computing will be necessary to speed up the analysis. Finally, computer storage will become an issue for large integrative systems biology projects. This is particularly true if the project also includes an imaging component (e.g. histology or magnetic resonance imaging).

#### **Integration of Data Types**

The ultimate goal of systems biology is to generate a predictive model of the system. Most researchers work with only one type of data (e.g. metabolome or transcriptome)

**TABLE 1.3** A Selection of Publicly Available Data Analysis Tools for Systems Biology<sup>a</sup>

Name	Website	Description
Bioconductor	<a href="http://www.bioconductor.org/">www.bioconductor.org/</a>	Open source and open development software project for the analysis and comprehension of omic data (based on R programming language)
Significance Analysis of Microarrays (SAM)	<a href="http://www-stat.stanford.edu/~tibs/SAM/">www-stat.stanford.edu/~tibs/SAM/</a>	Excel-based tool for statistical analysis of omic data
GenePattern	<a href="http://www.broad.mit.edu/tools/software.html">www.broad.mit.edu/tools/software.html</a>	A genomic analysis platform with access to more than 125 tools for analysis of omic data
Gene Set Enrichment Analysis (GSEA)	<a href="http://www.broad.mit.edu/tools/software.html">www.broad.mit.edu/tools/software.html</a>	A computational method that determines if a set of genes with a common function (e.g. lipid metabolism) are significantly altered by treatment/condition
GenMAPP	<a href="http://www.GenMAPP.org">www.GenMAPP.org</a>	Tool for visualizing omic data on maps representing biological pathways and groupings of genes. Statistical analysis for enrichment of changes in maps can be determined

<sup>a</sup>See Gehlenborg *et al.* (2010) for a comprehensive list of various omic analysis tools.

but the ideal is to use all types of data simultaneously. This not only includes the various omic data types but also clinical data on patients, image data from biological samples, text-based information from the literature, etc. Some methods already permit integration of multiple data types. For example, principal components analysis (PCA) is a mathematical procedure used to transform a number of correlated variables into a smaller number of uncorrelated variables called principal components. Each step in PCA attempts to account for as much of the variability in the data as possible. Jones *et al.* (2007) used PCA to integrate information from multiple iron-related phenotypes for use in QTL analysis and found that the combination of hemoglobin, hematocrit, and plasma total iron binding capacity were more useful for mapping than the individual traits. Bayesian statistics incorporate prior knowledge into an analysis of an experiment (see below) and can also be used to incorporate multiple data types into analysis. However, even these methods only scratch at the surface of what researchers believe can be done. This will be an active area of research in systems biology for the foreseeable future (Sullivan *et al.*, 2010).

### ***Application of Bayesian Statistical Approaches that Incorporate Prior Knowledge into the Analysis***

There are several issues that limit the utility of traditional “frequentist” statistical approaches when applied to systems biology research, e.g. high false-positive detection rates due to the multiple comparison problem; violation of the assumption of independence between genetic markers; inability to incorporate environmental variables and multiple, related traits into models and analysis. In contrast to frequentist statistics, Bayesian inference is a statistical approach that accepts the reality that there is prior knowledge that can influence our evaluation of a hypothesis (Shoemaker *et al.*, 1999; Beaumont and Rannala, 2004). By combining the inherent likelihood of a hypothesis with the compatibility of the observed evidence, one can better assess the likelihood that a particular hypothesis is true. There are many statisticians who use the Bayesian approach to test hypotheses. However, since most biologists are taught statistics from a frequentist perspective, approaching analysis from a Bayesian perspective will require more training. In addition, there are fewer

packaged programs for Bayesian statistics, and the computational demands of Bayesian statistics are likely to be a barrier to most biologists.

## NUTRITIONAL EPIGENETICS

ROBERT A. WATERLAND, PhD

*Baylor College of Medicine, Houston, Texas, USA*

### Summary

This chapter is intended to provide a timely overview of the current state of research at the intersection of nutrition and epigenetics. I begin by describing epigenetics and molecular mechanisms of epigenetic regulation, then highlight four classes of nutritional exposures currently being investigated for their potential to induce epigenetic alterations: dietary perturbation of one-carbon metabolism, prenatal energy restriction/growth retardation, assisted reproductive technologies, and histone deacetylase inhibitors. The chapter concludes with a discussion of outstanding questions in the field, and an elaboration of epigenetic technologies available to nutrition scientists.

### Introduction

The science of nutrigenomics seeks to improve human health by understanding how dietary constituents interact with the genome, and how individual genetic heterogeneity affects these interactions (Stover and Garza, 2002; Kaput, 2007). This complex field is further complicated by the growing recognition that nutrition, in addition to acutely affecting gene regulation, can influence epigenetic processes and thereby induce persistent changes in transcriptional regulation and associated phenotypes (Waterland and Jirtle, 2004; Jirtle and Skinner, 2007) (Figure 2.1). Epigenetic dysregulation, long recognized as playing a role in cancer and various developmental syndromes (Egger *et al.*, 2004), is increasingly being investigated as a potential factor in the etiology of a wide range of human diseases (Feinberg, 2008; Gluckman *et al.*, 2009). Given that epigenetic mechanisms are most susceptible to environmental perturbation when they are undergoing developmental changes (Waterland and Michels, 2007), nutritional influences on epigenetic processes must

be considered in a developmental perspective. Accordingly, a major goal of nutritional epigenetics is to understand the extent to which human nutrition affects developmental epigenetics to cause persistent changes in disease susceptibility (pathway g–e in Figure 2.1). This chapter will introduce the field of epigenetics and review data indicating nutritional influences on epigenetic regulation. Lastly, I will discuss outstanding questions in this field and important obstacles to research progress, and offer suggestions for nutrition scientists planning to examine epigenetic effects.

### Epigenetic Mechanisms

The term “epigenetics” was proposed by Conrad Waddington several decades ago to describe the study of “the causal interactions between genes and their products which bring phenotype into being” (Waddington, 1968). Waddington coined a *double-entendre*, spanning and potentially unifying different disciplines of developmental

**FIG. 2.1** Conceptual framework linking genetics, nutrition, epigenetics, and disease. Nutrigenomics has traditionally focused on the interactions between genetic susceptibility and nutrition in determining risk of disease (pathways a, b, c, d). Epigenetic mechanisms provide another pathway through which genetics and nutrition can affect risk of disease. While recognizing the potential influence of genetic variation on epigenetic processes (pathway f), nutritional epigenetics seeks to understand how nutrition affects epigenetic mechanisms, altering risk of disease (pathway g–e).

biology. As originally defined, epigenetics is the study of epigenesis, the process by which an animal develops from a single cell into an increasingly complex integrated system of differentiated cells and tissues. Additionally, however, “epigenetics” literally means “above genetics”, evoking a system of gene regulatory mechanisms layered on top of the DNA sequence information. This latter connotation is more consistent with the currently accepted definition; epigenetics is the study of mitotically heritable alterations in gene expression potential that are not caused by changes in DNA sequence (Jaenisch and Bird, 2003). Hence, rather than encompassing all of developmental biology, modern epigenetics is focused on understanding the specific molecular mechanisms that convey cellular memory.

Within the nucleus, the mammalian genome is wrapped around nucleosomes, each comprised of an octamer of histone proteins; this complex of DNA and nucleosomes is called chromatin. The overall chromatin conformation of specific genomic regions – either more open and transcriptionally competent, or more condensed and transcriptionally down-regulated – is an integrated outcome of interacting epigenetic mechanisms (Cedar and Bergman, 2009; Margueron and Reinberg, 2010). Methylation of cytosines within CpG dinucleotides in DNA appears to be the most stable epigenetic mechanism. Once estab-

lished during development, cell-type specific patterns of CpG methylation are maintained during mitosis by the action of the “maintenance” DNA methyltransferase (Dnmt1). Regional patterns of CpG methylation regulate chromatin structure and gene expression by affecting the affinity of methylation-sensitive DNA binding proteins. The N-terminal tails of histone proteins protrude from the nucleosome and are subject to various post-translational modifications including acetylation, methylation, phosphorylation, and ubiquitination (Margueron and Reinberg, 2010). Regional patterns of specific histone modifications are associated with transcriptional activity, and may help regulate chromatin conformation. Cross-talk between DNA methylation and histone modifications serves to fine-tune establishment and reinforce maintenance of epigenomic states. During development, for example, histone modifications appear to guide regional de novo CpG methylation (Cedar and Bergman, 2009). Since DNA is believed to detach completely from nucleosomes during DNA replication, however, it remains unclear whether histone modifications can convey locus-specific information through mitosis (i.e. whether they are in fact epigenetic) (Ptashne, 2007). Hence, histone modifications are more dynamic and associated with establishment and modification of epigenetic states, whereas CpG methylation is a stable mark capable of conferring mitotic memory (Cedar and Bergman, 2009). The role of non-coding RNA in epigenetic regulation has been studied extensively in lower organisms such as yeast, and likely plays a role in regulating mammalian chromatin states (Aravin *et al.*, 2008).

Feed-forward autoregulation by proteins that can perpetuate alternate cellular states through mitosis comprises another level of epigenetic regulation. Such “stable feedback loops” were widely listed as key epigenetic mechanisms 15 years ago (Tilghman and Willard, 1995; Riggs and Porter, 1996), but now receive relatively little attention. Decades ago it was shown that *E. coli* can maintain alternate, mitotically heritable states of induction of the lac operon via a stable feedback loop (Novick, 1957). The lytic/lysogenic switch of the bacteriophage  $\lambda$  comprises a similar bistable epigenetic switch (Riggs and Porter, 1996). Epigenetic feed-forward autoregulation plays an important role in maintaining transcriptional states established during mammalian development. For example, in addition to regulating genes involved in muscle differentiation, the myogenic transcription factors MyoD and myogenin promote their own transcription, serving to perpetuate

**FIG. 2.2** The mammalian transmethylation pathway. Several nutrients including folate (shown here as 5-methyltetrahydrofolate), vitamin B<sub>12</sub>, vitamin B<sub>6</sub>, choline, betaine, and methionine serve as either methyl donors or cofactors in the transmethylation pathway. DNA is one of many biological substrates (indicated here as “X”) for methyltransferase reactions which transfer methyl groups from S-adenosylmethionine (SAM). Glycine N-methyltransferase (reaction 7) is distinguished from other methyltransferases to emphasize its apparent role in regulating intracellular SAM concentrations.

their expression in committed muscle cells (Olson and Klein, 1994).

Most previous studies of nutritional epigenetics have focused on DNA methylation. This is highly stable, and only a small quantity of DNA is required for its measurement. DNA methylation in specific genomic regions is generally correlated with other epigenetic marks such as histone modifications, and our understanding of its association with gene expression is improving rapidly. It may therefore be logical in many cases to use DNA methylation as an integrative outcome by which to explore influences of nutritional exposures on epigenetic regulation.

## Nutritional Influences on Epigenetics

### *Dietary Perturbation of One-carbon Metabolism*

Methylation of DNA (and histones) is intimately dependent on nutrition. The methyl groups that are incorporated into DNA ultimately come from the diet (for example from methionine, choline, and betaine) and many nutrients, including folate, vitamin B<sub>12</sub>, and vitamin B<sub>6</sub>, are

critical cofactors in one-carbon metabolism (Figure 2.2). Extensive research in nutritional epigenetics has therefore focused on understanding how diet affects DNA methylation by influencing one-carbon metabolism (Van den Veyver, 2002; Ulrey *et al.*, 2005). Work in the agouti viable yellow (*A<sup>vy</sup>*) mouse provided the first clear demonstration that a transient nutritional stimulus during a critical ontogenic period can cause a permanent phenotypic change via an epigenetic mechanism. The murine *agouti* gene regulates the production of a yellow pigment in fur; the *A<sup>vy</sup>* mutation causes epigenetic dysregulation of *agouti*, and consequent interindividual variation in coat color among genetically identical *A<sup>vy</sup>/a* mice. Supplementing the diet of female mice before and during pregnancy with folic acid, vitamin B<sub>12</sub>, betaine, and choline caused a permanent change in the coat color distribution of *A<sup>vy</sup>* heterozygous offspring (Wolff *et al.*, 1998) by increasing DNA methylation at *A<sup>vy</sup>* (Waterland and Jirtle, 2003).

While it remains unclear which dietary components are the most potent modulators of DNA methylation capacity, effects of folate and folic acid intake on epigenetic regulation have been studied extensively. “Folate” describes

various forms of polyglutaminated pteridine-p-aminobenzoic acid, some of which (such as 5-methyltetrahydrofolate) are methyl donors. “Folic acid”, on the other hand, is a synthetic form of folate that is not a dietary methyl donor (Smith *et al.*, 2008); ingested folic acid must be reduced and methylated (probably in the liver) before it can serve as a cofactor in the methionine synthase reaction (Figure 2.2) (also, see Chapter 21). An early study demonstrated that interindividual genetic variation interacts with folate status to determine DNA methylation. Healthy adults were assessed for plasma folate concentrations and peripheral blood global DNA methylation, and genotyped for the C677T polymorphism in the gene encoding methyl-entetrahydrofolate reductase (MTHFR). Plasma folate was positively correlated with global DNA methylation, but only in individuals homozygous for the T variant of *MTHFR* (which causes reduced enzymatic activity) (Friso *et al.*, 2002). This gene–nutrient–epigenome interaction was corroborated in a subsequent folate depletion–repletion study (Shelnutt *et al.*, 2004). Recent data indicate that maternal supplementation with folic acid before and during pregnancy may affect epigenetic regulation in the offspring. Methylation of Long Interspersed Elements (LINE-1) (an indicator of global DNA methylation) in cord blood DNA at delivery was slightly elevated in offspring whose mothers took folic acid supplements (Stegers-Theunissen *et al.*, 2009).

Since folate is a critical cofactor in one-carbon metabolism, DNA methylation is generally expected to correlate positively with folate status. This is not always the case. In a large epidemiologic study, dietary folate intake was inversely correlated with LINE-1 methylation in colonic epithelium (Figueiredo *et al.*, 2009); the association was strongest in DNA from the ascending colon. Similarly, in a rat model, feeding a folate-free synthetic diet from age 21–56 days induced a persistent *increase* in hepatic global DNA methylation (Kotsopoulos *et al.*, 2008). One potential explanation for this unexpected finding is that dietary methyl donor deficiency induces dramatic increases in expression of the DNA methyltransferases Dnmt1 and Dnmt3a in rat liver (Ghoshal *et al.*, 2006).

Elevated plasma homocysteine is associated with both nutritional and genetic factors, and is a risk factor for vascular disease (Selhub, 2006). Because homocysteine is a secondary product of biological methylation reactions (Figure 2.2), elevated homocysteine should impair DNA methylation. Indeed, in a small study of ~20 newborn infants (Fryer *et al.*, 2009), LINE-1 methylation in cord

blood DNA was inversely correlated with cord plasma homocysteine. The combined effects of dietary and genetic promotion of hyperhomocysteinemia by cystathione  $\beta$ -synthase (*Cbs*) haploinsufficiency (see Figure 2.2) were studied in mouse liver, kidney, brain, and testis (Caudill *et al.*, 2001). Despite dramatic differences in plasma total homocysteine concentrations, however, in most tissues global DNA methylation did not differ between wild type and *Cbs*<sup>+/-</sup> mice. Similarly, human patients with *CBS* deficiency showed no changes in either global or locus-specific DNA methylation (Heil *et al.*, 2007), despite exceptionally elevated plasma homocysteine concentrations. A small study of male patients with hyperhomocysteinemia and uremia, however, did find reduced genomic DNA methylation in patients relative to controls (Ingrosso *et al.*, 2003); patients also displayed biallelic expression of *H19* in peripheral blood mononuclear cells. (*H19* is a genomically imprinted gene, at which monoallelic expression is normally regulated by allele-specific methylation at a differentially methylated region [DMR]). Remarkably, in three patients who initially showed strong biallelic expression of *H19*, 60 days of treatment with oral 5-methyltetrahydrofolate (15 mg/day) restored normal monoallelic expression (Ingrosso *et al.*, 2003). The effects of hyperhomocysteinemia on epigenetic regulation of *H19* were subsequently examined in a mouse model; *Cbs* haploinsufficiency combined with a hyperhomocysteinemic diet resulted in a 20-fold elevation in plasma total homocysteine concentrations in adult mice (Devlin *et al.*, 2005). As expected, DNA methylation at the *H19* DMR was significantly reduced in the liver of hyperhomocysteinemic mice relative to controls. Paradoxically, however, in aorta and brain, *H19* DNA methylation was significantly elevated (dramatically so in brain).

Choline, required for the synthesis of phosphatidylcholine and acetylcholine, is also an important methyl donor (Zeisel, 2006) (also, see Chapter 26). Choline appears to be particularly important for brain development (Zeisel, 2006); prenatal choline supplementation in rats leads to enhanced cognitive functioning in adulthood (Meck and Williams, 2003). In mice, maternal choline deficiency initiated in mid-pregnancy reduced DNA methylation at specific genes in the fetal hippocampus at 17 days of fetal development (Niculescu *et al.*, 2006). It remains unclear, however, the extent to which the long-term cognitive benefits of choline supplementation are attributable to effects on epigenetic mechanisms such as DNA methylation. Following choline supplementation during fetal

development, adult rats were found to have increased hippocampal neurogenesis (Glenn *et al.*, 2007), suggesting that early choline supplementation may induce persistent epigenetic changes in the neurogenic stem cell population.

The substantial body stores of creatine and phosphocreatine, which play central roles in energy metabolism, are spontaneously lost to creatinine and must be continuously synthesized (Brosnan and Brosnan, 2007). Creatine synthesis consumes about 40% of all S-adenosylmethionine in young adults (Brosnan and Brosnan, 2007), a huge methyl sink. Creatine supplementation therefore has the potential to facilitate DNA methylation by sparing S-adenosylmethionine. A recent study in adult rats, however, reported just the opposite. After just 14 days of supplementation with creatine monohydrate (2% wt/wt in diet), global DNA methylation in peripheral blood was significantly reduced (Taes *et al.*, 2007).

### **Prenatal Energy Restriction/Growth Retardation**

Retrospective studies of individuals exposed to famine in early life have provided extensive insights into the potential for nutrition during critical periods of development to induce persistent changes in human metabolism and disease risk. A recent study of survivors of the Dutch famine of 1944–1945 tested the hypothesis that maternal exposure to famine leaves a permanent epigenetic mark on the offspring (Heijmans *et al.*, 2008). In peripheral blood from individuals almost 60 years old, bisulfite sequencing was used to measure DNA methylation at a DMR within the imprinted *IGF2* gene. Recognizing the potential for genetic variation to obscure induced epigenetic variation, *IGF2* DMR methylation in each periconceptionally exposed individual was compared with his or her same-sex unexposed sibling. The *IGF2* DMR was slightly but significantly less methylated in individuals exposed to famine periconceptionally, relative to unexposed siblings, providing the first convincing demonstration that an environmental exposure during early development can cause a persistent epigenetic alteration in humans (Heijmans *et al.*, 2008). Famine exposure during late fetal development was not associated with *IGF2* methylation, indicating that the period of susceptibility for this effect is limited to early embryonic development. The same group subsequently reported a study of DNA methylation at 15 candidate genes implicated in metabolic and cardiovascular disease (Tobi *et al.*, 2009). Periconceptional exposure was significantly associated with methylation at six of 15 genes meas-

ured; in most cases DNA methylation was higher in famine-exposed individuals (Tobi *et al.*, 2009).

The effects of maternal undernutrition before and during pregnancy have been studied extensively in rodents. Providing a low-protein diet (9% protein compared with 18% control) to mothers before and during pregnancy induces persistent physiological changes in the offspring. Effects of maternal low-protein diet on epigenetic regulation in the offspring are now being explored. Global DNA methylation in liver (but not heart or kidney) of day 21 fetal rats was reported to be elevated in response to maternal low-protein diet (Rees *et al.*, 2000). Focusing on the promoter of the *Ppar $\alpha$*  gene, it was reported that specific CpG sites in hepatic DNA show reduced methylation in rat offspring of mothers fed a low-protein diet (Lillycrop *et al.*, 2008). Although the average methylation in this region was less than 10%, the epigenetic consequences of maternal diet were persistent; the same CpG sites showed reduced methylation in low-protein offspring at 34 and 80 days of age. Epigenetic effects of prenatal undernutrition have also been investigated in sheep (Stevens *et al.*, 2010). Ewes undernourished during the first month of pregnancy were subsequently allowed free access to feed until their fetuses were collected at fetal day 130. Despite the 100-day recuperation period, fetuses undernourished during early fetal development had increased expression of glucocorticoid receptor in the hypothalamus, associated with reduced DNA methylation and increased histone 3 lysine 9 (H3K9) acetylation of the *glucocorticoid receptor* promoter.

In a rat model, fetal growth restriction by intrauterine artery ligation cause permanent impairment of glucose tolerance. The developmental dynamics of epigenetic changes induced by intrauterine growth restriction were characterized at the *Pdx1* promoter in isolated pancreatic islets (Park *et al.*, 2008). *Pdx1* is a homeobox transcription factor that regulates pancreas development and  $\beta$  cell differentiation. In pancreatic islets of 14-day-old rats that had been growth restricted *in utero*, reduced *Pdx1* expression was associated with lower density of several histone modifications at the *Pdx1* promoter, but no differences in DNA methylation. By age 6 months, however, extensive DNA methylation at the *Pdx1* promoter was found only in islets of previously growth-restricted rats (Park *et al.*, 2008), leading the authors to propose that aberrant epigenetic silencing at *Pdx1* is initiated by histone modification and subsequently stabilized by DNA methylation. Epigenetic changes associated with intrauterine growth retardation

have also been explored in humans; genome-wide DNA methylation profiling identified epigenetic changes in hematopoietic stem and progenitor cells associated with intrauterine growth retardation (Einstein *et al.*, 2010).

### **Assisted Reproductive Technologies**

Children conceived by assisted reproductive technologies (ART) have an elevated risk for rare developmental syndromes involving dysregulation of imprinted genes (Hansen *et al.*, 2002; DeBaun *et al.*, 2003). The synthetic medium bathing the cultured embryo essentially represents a nutritional exposure; the process of in vitro fertilization and subsequent embryo culture could therefore interfere with epigenetic reprogramming in the early embryo. Indeed, mouse studies have shown that embryo culture can affect epigenetic regulation at imprinted (Rivera *et al.*, 2008) and non-imprinted loci (Morgan *et al.*, 2008). A recent study (Katari *et al.*, 2009) used a methylation profiling technique to examine DNA methylation at over 700 genes in DNA isolated from cord blood and placenta of individuals conceived by ART, compared with those conceived naturally. Of 1536 CpG sites analyzed, hundreds showed differential methylation in either cord blood or placenta of in vitro compared with naturally conceived infants (Katari *et al.*, 2009). The methylation differences, though numerous, were slight in magnitude. It must be acknowledged that associations between in vitro conception and DNA methylation could be explained not only by an effect of early environment on epigenetic programming, but also by inheritance of genetic or epigenetic defects. For example, epigenetic aberrations in the sperm or egg could both contribute to infertility and be transmitted to the next generation following ART (Maher, 2005). This alternative explanation is supported by a recent study that compared DNA methylation profiles in both ART conceptuses and paternal sperm (Kobayashi *et al.*, 2009). In almost half of 17 cases showing abnormal DNA methylation in ART-conceived offspring, the identical epigenetic alteration was detected in the paternal sperm.

### **Histone Deacetylase Inhibitors**

Locus-specific histone acetylation is dynamically regulated by histone acetyltransferases (which acetylate histones) and histone deacetylases (HDACs). Several diet-derived compounds are powerful HDAC inhibitors, and can therefore influence epigenetic regulation. One example is butyrate, a short-chain fatty acid. Although found in the diet (milk fat is a rich source), the principal source of butyrate in

humans is from microbial digestion of dietary fiber in the colon (Wachtershauser and Stein, 2000); butyrate is the dominant energy source for colonic mucosal enterocytes. In rats fed diets of various wheat bran contents for 2 weeks, global histone H4 acetylation in colonic epithelial cells was directly correlated with butyrate concentration in the colonic lumen (Boffa *et al.*, 1992), providing an intriguing potential epigenetic link between dietary fiber intake and risk of colon cancer. Another dietary HDAC inhibitor, sulforaphane, an isothiocyanate found in cruciferous vegetables, is also implicated in cancer prevention (Ho *et al.*, 2009). A recent in vitro study (Meeran *et al.*, 2010) showed that sulforaphane inhibits the proliferation of breast cancer cells but not normal breast cells. Further, sulforaphane caused a dose-responsive increase in DNA methylation and epigenetic silencing of the gene encoding telomerase reverse transcriptase, offering a potential explanation for how sulforaphane specifically affects cancer cells.

## **Outstanding Questions in the Field**

The preceding summary was not intended to be exhaustive but rather to indicate the breadth of research questions currently being pursued in nutritional epigenetics. Diet has important influences on epigenetic mechanisms, and epigenetic dysregulation is implicated in a broad range of human disease (Feinberg, 2008; Gluckman *et al.*, 2009). So far, however, there are no examples of nutritional exposures causing epigenetic changes that lead to human disease (pathway *g-e* in Figure 2.1). Elaboration of such causal pathways will pose numerous challenges. This section will summarize outstanding issues in this field, and provide guidance for nutrition investigators who wish to examine epigenetic effects.

### **By What Specific Mechanisms Does Nutrition Affect Epigenetic Regulation?**

Nutritional influences on epigenetics have been studied most extensively from the perspective of dietary perturbation of one-carbon metabolism. Enhancing or impeding DNA methylation by nutritional manipulations affecting one-carbon metabolism seems straightforward, but many studies using various approaches have obtained paradoxical results (Devlin *et al.*, 2005; Ulrey *et al.*, 2005; Taes *et al.*, 2007). There are several potential explanations. Of central importance to so many biochemical functions, mammalian one-carbon metabolism is regulated at multiple levels. For example, attempts at dietary perturbation

of the supply of S-adenosylmethionine may be trumped by the regulated expression of glycine-N-methyltransferase, which appears to exist primarily to regulate intracellular S-adenosylmethionine concentrations (Luka *et al.*, 2009) (Figure 2.2). Also, even if a dietary manipulation does alter transmethylation flux, DNA methylation represents such a small fraction of biological methylation reactions that the net impact on DNA methylation may be minor or unpredictable. For example, whereas DNA methylation at gene promoters is generally associated with gene repression, methylation of specific lysine residues on histone tails is associated with transcriptional activity (Margueron and Reinberg, 2010). Hence, dietary enhancement of transmethylation capacity could promote histone methylation at specific loci, with the secondary effect of impeding regional DNA methylation.

A much broader framework is envisaged if one acknowledges that any dietary stimulus that can affect transcriptional activity during a period of epigenetic development or maturation could have secondary effects on epigenetic regulation (Waterland and Michels, 2007). A vivid example was provided by the generation of induced pluripotent stem cells; simply by overexpressing four pluripotency-associated transcription factors, differentiated cells can undergo a dedifferentiation process involving genome-scale epigenetic reprogramming (Takahashi and Yamanaka, 2006). It is likely that myriad nutritional influences on epigenetic regulation, including many unrelated to one-carbon metabolism, are primarily mediated at the level of transcriptional activation during critical periods of epigenetic development.

### **During What Developmental Periods Are Epigenetic Mechanisms Most Susceptible to Nutrition?**

Human and animal model data clearly indicate that, even in adulthood, epigenetic regulation can be influenced by nutrition. But what most clearly distinguishes epigenetic changes from other forms of transcriptional regulation is stability; the definitive mitotic stability of epigenetic mechanisms enables a transient environmental stimulus to have a lasting effect on transcriptional regulation. It appears that such persistent epigenetic effects can generally be induced only during developmental periods when epigenetic processes are undergoing developmental change or maturation. This is not so narrow a focus as it may seem; epigenetic development occurs over a wide range of life stages. Much emphasis has been placed on epigenetic

reprogramming that occurs in the early embryo (Santos and Dean, 2004; Reik, 2007) and during gametogenesis (Sasaki and Matsui, 2008). Indeed, the persistent effect of maternal nutrition on phenotype of  $A^{y/a}$  mice occurs by affecting stochastic establishment of  $A^{y}$  epigenotype during early embryonic development (Waterland and Jirtle, 2003). Additionally, however, epigenetic development continues in myriad cell types throughout fetal (Song *et al.*, 2009) and even early postnatal development (Waterland *et al.*, 2009; Kellermayer *et al.*, 2010), and may be influenced by environment. For example, maternal caregiving behavior was shown to affect postnatal developmental epigenetics in specific brain regions in the offspring (Weaver *et al.*, 2004; Champagne *et al.*, 2006), providing a plausible link between early postnatal environment and behavioral programming. Mouse studies indicate that epigenetic maturation of the gametes occurs during pre-adolescence (Janca *et al.*, 1986), suggesting another life stage during which nutrition might affect developmental epigenetics. To the extent that environmentally induced epigenetic information can be inherited transgenerationally (Whitelaw and Whitelaw, 2008), this offers a potential explanation for intriguing human epidemiologic observations in which nutritional status in pre-adolescence affects mortality in subsequent generations (Pembrey *et al.*, 2006). Lastly, even aging can be viewed as a developmental process. Extensive epigenetic changes occur with aging (Issa *et al.*, 1994), and may be affected by diet. In any case, investigators wishing to demonstrate that a transient nutritional exposure induces a persistent epigenetic effect must show that the specific epigenetic change is present both directly after the nutritional exposure, and later in life (Waterland and Garza, 1999).

### **What Genomic Regions Are Epigenetically Responsive to Nutrition?**

The  $A^{y}$  locus is characterized as a “metastable epiallele,” meaning that in each individual the epigenetic state is established stochastically during early development, then maintained in all tissue lineages throughout life (Rakyan *et al.*, 2002). After it was demonstrated that early nutrition persistently affects epigenetic regulation in  $A^{y}$  mice (Waterland and Jirtle, 2003), investigators studied effects of early environment on establishment of DNA methylation at the murine metastable epialleles  $Axin^{Fused}$  and  $Cabp^{LAP}$ . Dietary methyl donor supplementation of female mice before and during pregnancy increased DNA methylation at  $Axin^{Fused}$ , reducing the incidence of tail kinking

in *Axin<sup>Fused</sup>/+* offspring (Waterland *et al.*, 2006a). Conversely, maternal exposure to the environmental contaminant bisphenol-A (a key component of polycarbonate plastic) decreased DNA methylation at *Cabp<sup>LAP</sup>* in the offspring (Dolinoy *et al.*, 2007). Cumulatively, these data indicate that stochastic developmental establishment of DNA methylation at metastable epialleles is, in general, labile to maternal environment. Importantly, a recent study (Waterland *et al.*, 2010) indicates that human metastable epialleles exist and, as in the mouse, are epigenetically labile to the maternal periconceptional environment.

Metastable epialleles represent just one subset of genomic regions that may be epigenetically labile to nutritional stimuli during development. Over a decade ago (Pembrey, 1996) it was proposed that the unique epigenetic requirements for monoallelic expression may render genomically imprinted genes especially sensitive to epigenetic dysregulation. On this basis, genomically imprinted genes have been popular candidate genes in studies of environmental epigenetics (Biniszkiwicz *et al.*, 2002; Ingrosso *et al.*, 2003; Waterland *et al.*, 2006b). Recent data on humans exposed periconceptionally to famine (Tobi *et al.*, 2009) or conceived by ART (Turan *et al.*, 2010), however, while indicating that early environment can affect epigenetic regulation at genomically imprinted genes, do not support the hypothesis that genomically imprinted genes are especially susceptible to epigenetic dysregulation.

Most studies linking epigenetic modifications to transcriptional regulation have focused on gene promoters. In particular, many studies attempted to correlate developmental or tissue-specific differences in gene expression with DNA methylation at CpG-rich regions (CpG islands) in gene promoters (Ehrlich, 2003). Now, with the increasing sophistication of epigenomic studies that can map epigenetic marks and levels of associated transcripts in various cell and tissue types, it is clear that the focus on CpG island promoters has largely been misplaced. The majority of CpG island promoters are normally unmethylated in all tissues, regardless of tissue-specific expression; only about 4% of CpG island promoters regulate transcriptional activity via tissue-specific methylation (Shen *et al.*, 2007). Clearly, CpG islands are not the only important site of regulatory DNA methylation; developmental changes in DNA methylation at CpG-poor promoters correlate with developmental changes in gene expression (Waterland *et al.*, 2009). Human studies indicate that

DNA methylation in genomic regions up to 2 kilobases (kb) away from CpG islands (dubbed “CpG island shores”) plays an important role in both cancer and normal development (Irizarry *et al.*, 2009). A recent epigenomic study showed that DNA methylation at intragenic CpG islands affects tissue-specific gene expression by regulating expression from alternate promoters (Maunakea *et al.*, 2010). A study of enhancer regions in various human cell types *in vitro* (Heintzman *et al.*, 2009) provided the broadest perspective of the complex distribution of epigenetic marks that regulate tissue-specific gene expression. Unlike gene promoters, at which histone modifications were largely invariant between different cell types, enhancer regions carried histone modification signatures that clearly distinguished different cell types (Heintzman *et al.*, 2009). Enhancers operate tissue-specifically and can be located up to 200 kb away from genes, underscoring the enormous challenge of linking nutritionally induced epigenetic changes to associated changes in gene expression.

A way forward is provided by the conjecture that epigenetic mechanisms are most susceptible to environmental influences during development or maturation; if this holds true, the genomic regions most susceptible to a specific exposure are those in flux during the exposure. Limited information is currently available on epigenetic ontogeny in various organs and cell types. But such information is rapidly being generated. For example, the NIH Roadmap Epigenomics Mapping Consortium is currently working to produce a public resource of human epigenomic data across various healthy cell and tissue types and developmental stages (Bernstein *et al.*, 2010). For those who wish to investigate potential epigenetic effects of nutrition but who do not have the resources or expertise to perform epigenomic assays, candidate gene regions may be selected by searching publicly available data sets to identify genomic regions at which epigenetic marks are changing in the tissue of interest during the time of the nutritional exposure.

### ***How Can We Improve Our Understanding of the Role of Epigenetic Dysregulation in Disease?***

The inherent tissue specificity of epigenetic regulation is arguably *the* major obstacle to studying epigenetics and human disease. In studies of genetic epidemiology, DNA from peripheral blood can be used to assay for a genetic variant present throughout the body. Conversely, epigenetic regulation (and dysregulation) will often be

tissue- and cell-type specific (Waterland and Michels, 2007; Gluckman *et al.*, 2009); in most cases, therefore, epigenetic information present in easily obtainable biopsy samples will not provide insights into the epigenetic etiology of disease. Even within a given tissue, different cell types may have dramatically different epigenomes. This level of complexity was demonstrated in a recent study of genome-wide binding of the methyl-CpG binding protein MeCP2 in brain. Brain tissue is comprised generally of two cell types, neurons and glia. Taking advantage of the neuronal nuclear surface marker NeuN, fluorescence-activated cell sorting was used to separate neuronal and glial nuclei from mouse brain (Skene *et al.*, 2010). MeCP2 protein was highly enriched on neuronal compared with glial DNA, and appeared to play an important role in regulating chromatin architecture specifically in neurons. In studies of nutritional influences on epigenetic regulation, analysis of separated cell types will often be required to develop meaningful insights. Clearly, it will in many cases be highly advantageous to initially study nutritional epigenetics in animal models of human disease, in which tissues and cell types of interest can be readily obtained. The identification of human metastable epialleles (Waterland *et al.*, 2010) may enable investigators to circumvent the problem of epigenetic tissue specificity. As at murine metastable epialleles (Waterland and Jirtle, 2003; Waterland *et al.*, 2006a), the dramatic interindividual epigenetic variation at human metastable epialleles occurs systemically. Hence, at these loci, epigenetic regulation within cells and tissues of pathophysiologic relevance may be inferred from, say, a peripheral blood DNA sample (Waterland *et al.*, 2010). To the extent that human epigenetic metastability affects expression of genes implicated in human disease, currently archived peripheral blood DNA samples may be used to assess associations between nutrition, epigenetic regulation, and human disease (Waterland and Michels, 2007).

### **What New Epigenetic Technologies Are Available to Nutrition Scientists?**

It has been common for investigators to assess effects of nutrition on global cytosine methylation or histone modifications. Global measurements are difficult to interpret, however, and will fail to detect important locus-specific epigenetic changes. Future studies should focus on candidate gene regions and/or apply genome-scale methods to screen for genomic regions of interest. Histone modifications in specific genomic regions are analyzed by chroma-

tin immunoprecipitation (ChIP); chromatin (genomic DNA still attached to nucleosomes) is cleaved into small fragments, then antibodies are used to isolate the fraction enriched for specific histone modifications. The DNA from this fraction is isolated, and quantitative PCR in genomic regions of interest is used to determine the relative enrichment of histone modifications across different samples. Genome-scale studies of histone modifications are becoming increasingly common. The ChIP “pull-down” can be labeled and hybridized to a tiling array (ChIP-microarray) (van Steensel and Henikoff, 2003), or shotgun sequenced (ChIP-seq) (Park, 2009). Shotgun sequencing – also called “short-read” or “next-generation” sequencing – offers several advantages over microarrays. Artifacts associated with non-linear hybridization dynamics are avoided; counting sequence reads potentially offers unbiased and highly sensitive quantitation of relative enrichment. Further, unlike microarrays, in which repetitive elements are not represented, shotgun sequencing offers the potential to “anchor” specific repetitive elements and thereby probe the nearly half of the genome that they comprise.

Most quantitative methods of DNA methylation analysis rely on bisulfite modification. Bisulfite modification followed by PCR converts unmethylated cytosines to thymines, while methylated cytosines remain cytosines (Frommer *et al.*, 1992), converting epigenetic information to genetic information. Post-bisulfite PCR products can then be sequenced by various methods. Coupling bisulfite modification with pyrosequencing (Shen and Waterland, 2007) is currently the “gold standard” technique for quantitative measurement of site-specific CpG methylation. Post-bisulfite PCR products can also be sub-cloned and sequenced. The molecule-specific data provided by this classic technique is often useful if analyzing DNA from mixtures of cells, for example, or in the study of genomic imprinting (Shen and Waterland, 2007). If a sufficient number of clones (~20 or more) from each sample are sequenced, quantitative results can be obtained. Genome-scale data on DNA methylation can be obtained in several ways. Methylated DNA immunoprecipitation (MeDIP) uses an antibody directed against 5-methylcytosine, and is generally analogous to ChIP. The MeDIP pull-down can be analyzed either on a tiling array (Weber *et al.*, 2005) or by shotgun sequencing (Maunakea *et al.*, 2010). One major caveat: MeDIP is not efficient in genomic regions of low CpG density (i.e. most of the genome). Various methods employ methylation-sensitive restriction endonucleases to generate genomic libraries representing methyl-

ated or unmethylated genomic regions; these can also be coupled with either microarray or shotgun sequencing to obtain genome-scale data (Khulan *et al.*, 2006; Shen *et al.*, 2007; Irizarry *et al.*, 2008). Although potentially quite sensitive, these methods provide low genomic coverage; methylation information is only obtained on the very small subset of CpG sites within the informative restriction enzyme sites. The only technique that currently offers the potential to provide truly genome-wide information on site-specific CpG methylation is shotgun sequencing of bisulfite-treated genomic DNA (Bisulfite-seq) (Lister *et al.*, 2009; Harris *et al.*, 2010). Although now prohibitively expensive for most applications, Bisulfite-seq will become more widespread as sequencing costs decline. Investigators planning to apply any of these epigenomic methods will need access to sophisticated bioinformatics infrastructure and personnel to effectively analyze the large and complex datasets.

## Future Directions

The field of nutritional epigenetics faces extraordinary challenges: diverse nutritional exposures have the potential to influence epigenetic regulation in myriad genomic regions, potentially in a tissue-specific and cell-type-specific fashion. But this field also promises extraordinary opportunities to improve human health. Short-term nutrition interventions targeted to critical ontogenic periods could potentially optimize developmental epigenetics, conferring lifelong health benefits. Moreover, although characteristically stable, epigenetic mechanisms are inherently malleable, offering the promise of nutritional therapies designed to correct pathogenic epigenetic dysregulation. Such ambitious goals will become reality, however, only if we can improve dramatically our understanding of how diet affects the establishment and maintenance of epigenetic mechanisms, and how epigenetic dysregulation contributes to human disease. Controlled experiments in refined animal models are essential to identify the critical developmental periods, specific cell types, and genomic loci in which induced epigenetic alterations affect metabolic processes and disease susceptibility.

### Summary

One of the continuing challenges of nutrition research is dealing with the variability in response to nutrients and other bioactive substances that are consumed. Response can be any phenotype such as blood levels of a nutrient, biomarker or disease. There is growing interest among researchers and health-care practitioners in utilizing genomic information to predict and manage the large interindividual differences in response to nutrient intakes. Recent advances in human genomics have uncovered extensive variations in genes affecting nutrient metabolism, but their full impact on nutrient requirements remains to be elucidated. Developments in high-throughput technologies have enabled cost-effective and rapid detection of genetic variants, which facilitates their incorporation into clinical and observational studies of nutrition. Differences in the rates of absorption, distribution, uptake, utilization, biotransformation, and excretion ultimately impact the concentration of a nutrient at a target site of interest. Variations in genes that code for target proteins such as receptors, enzymes, transporters or ion channels can also impact the response to a nutrient. Nutrigenomics describes the use of high-throughput “omics” technologies to study how nutrients interact with the genome at all levels of regulation, and nutrigenetics is sometimes used specifically to refer to the effect of genetic variations on nutrient response. The purpose of this chapter is to provide an overview of the current state of knowledge of the role of human genetic variation in nutrient metabolism, and to present some notable examples that illustrate particular developments in the field. Incorporating markers of genetic variation into studies of nutrition and health aims to benefit those seeking personalized dietary advice, and should also improve public health recommendations by providing sound scientific evidence linking diet and health.

## Introduction

Nutrigenomics (or nutritional genomics) refers to the application of high-throughput “omics” technologies, together with systems biology and bioinformatics tools, to understand how nutrients interact with the flow of genetic information to impact various health outcomes (Ordovas *et al.*, 2007; Ordovas, 2008). Gene–nutrient interactions can be viewed as two sides of the same coin. On the one hand, nutrients can alter the expression or function of a gene (including epigenetic modifications), which is a topic that is discussed elsewhere in this book (Chapter 2). On the other hand, genetic polymorphisms can alter the response to a nutrient, which is sometimes referred to as *nutrigenetics* (El-Sohemy, 2007). This latter approach also includes the study of how genetic variations influence food intake and eating behaviors (Garcia-Bailo *et al.*, 2009; Eny and El-Sohemy, 2010), but this will not be elaborated on in this chapter. Although genetics can play a major role in the variable responses to nutrient intakes, it is also important to consider other factors such as age, sex, physical activity, smoking, and nutritional status.

The completion of the first draft sequence of the human genome about a decade ago ushered in a new era of nutrition research that began to focus more on understanding the variability in responses to nutrients and other dietary substances. Single nucleotide polymorphisms (SNPs) are the most abundant form of genetic variation with over 10 million SNPs cataloged in public databases such as dbSNP (Thorisson and Stein, 2003). Other types of genetic variations include nucleotide repeats, insertions, deletions, and copy number variants (CNVs). Depending on the region of the genome where the polymorphism occurs, the impact on nutrient metabolism can be negligible or profound. Early examples of how genetic variations have a severe effect on nutrient response are seen with inborn errors of metabolism such as phenylketonuria (PKU). This usually involves a mutation in a single gene along with the intake of a single nutrient to cause a specific disorder (Levy, 1989). The discovery that an essential amino acid such as phenylalanine could be toxic to some individuals has impacted labeling requirements in certain countries so that diet beverages containing aspartame, for example, must be labeled as containing phenylalanine. This is an example of a food product that is labeled primarily for individuals with a particular genotype. Lactose intolerance is another well known example of gene–nutrient interaction and demonstrates how food products can also be

developed for specific genotypes, as in the case of lactose-free dairy products (Swallow, 2003). Individuals with lactose intolerance are unable to efficiently break down the primary milk sugar (lactose) from dairy products, and are consequently advised to limit lactose-containing foods or to use lactase supplements or lactose-free dairy products to prevent the acute gastrointestinal discomfort that can occur (Swagerty *et al.*, 2002). Unlike these examples, however, nutrition-related chronic diseases are polygenic, have complex etiologies and often take years or decades to develop. As such, a huge challenge has been to determine the role of specific dietary factors and gene variants in the development of complex chronic diseases such as diabetes, osteoporosis, cancer, and cardiovascular disease (CVD).

The daily ingestion, absorption, digestion, transport, uptake, utilization, biotransformation, and excretion of nutrients and food bioactives involve many proteins such as enzymes, receptors, transporters, ion channels, and hormones. Variations in genes encoding these proteins can alter both the amount of the protein produced as well as how efficiently that protein functions. If a genetic variation leads to altered production or function of a protein involved in the metabolism of a nutrient, then nutritional status could be affected. Studies that have incorporated markers of human genetic variation have traditionally relied on the candidate gene approach, which requires existing knowledge of the various metabolic processes that act on the nutrient of interest. Genome-wide association scans (GWAS) utilize more cutting-edge technologies and provide an *unbiased* approach to identifying genetic variants that modify a nutrient’s response by examining the effect of large numbers of SNPs and CNVs; usually anywhere from 100 000 to ~2 million markers spread out across the genome. Rapid advances in sequencing technologies will continue to drive down the cost of genotyping and ultimately make whole genome sequencing of large numbers of individuals a reality (Levy *et al.*, 2007). In the meantime, the candidate gene approach remains the method of choice for most studies that include measures of both nutrition and genetics. Genes that are often selected as candidates tend to be those that are the targets of a nutrient or food bioactive, or those that lie in the metabolic pathway of the bioactive compound (El-Sohemy, 2007). Since several SNPs can be inherited together in a single block (called haplotype), “tag” SNPs are typically used to capture most of the variation in a gene of interest. Studies to date have tended to focus on single SNPs or a few SNPs in a single gene, but there is growing interest in

exploring multiple genetic variants along the metabolic pathway of a nutrient (van Ommen *et al.*, 2010). A number of resources are available to help select candidate genetic variants in candidate genes (Table 3.1).

Nutritional epidemiologic studies relating most nutrients to most health outcomes have often yielded inconsistent results. Although this is partly due to issues surrounding experimental study design such as inadequate control for confounders or misclassification of exposure, the genetic heterogeneity between studies certainly accounts for some of the discrepancies. As such, the incorporation of genetics into nutritional studies aims to improve their consistency (Figure 3.1). Genetic association studies that link gene variants to health outcomes have also yielded inconsistent results (Ioannidis *et al.*, 2001), even though genetic variants can be measured much more reliably and accurately than dietary exposures. Thus, not only can inconsistencies among nutrition studies be reconciled by the incorporation of genetic data, but conflicting and contradictory gene-association studies can also be explained by incorporating measures of environmental exposures such as diet (Luan *et al.*, 2001). Since the study of gene–diet interactions is a relatively young field with few laboratories conducting such research, there has been a paucity of studies

**FIG. 3.1** Genetic variation modifies response to nutrient intake.

that have aimed to replicate previous findings. Evidence is beginning to emerge that some interactions can be replicated in diverse populations, but others have not been replicated, which could be due to genetic epistasis (i.e. gene–gene interactions) or other environmental or physiological differences between populations (Helgadóttir *et al.*, 2006).

### Dietary Fat

Some of the earliest work in this field was pioneered by Jose Ordovas and colleagues, and focused on identifying

genetic variants that modified the blood lipid response to dietary fat and cholesterol (Ordovas, 2008). Genes involved in lipid metabolism along with dietary fat probably represent the most widely studied group of gene–diet interactions (also, see Chapters 9 and 10). Apolipoproteins (apo) A-I and A-II, coded by the *APOA1* and *APOA2* genes, respectively, play an important role in lipid metabolism. The interaction between a common functional *APOA2* polymorphism (-265T>C, rs5082) and saturated fat intake in relation to body mass index (BMI) was investigated using three populations in the United States: the Framingham Offspring Study (1454 Caucasians), the Genetics of Lipid Lowering Drugs and Diet Network Study (1078 Caucasians), and the Boston-Puerto Rican Centers on Population Health and Health Disparities Study (930 Hispanics of Caribbean origin) (Corella *et al.*, 2009). The prevalence of the CC genotype in the three populations ranged from about 10% to 16%. Statistically significant interactions between the *APOA2* -265T>C SNP and saturated fat intake in relation to BMI were identified in all three populations. Estimations of obesity for individuals with the CC genotype were approximately two-fold compared with carriers of the T allele among the subjects with high-saturated-fat intake, but no association was observed in the low-saturated-fat group. This study represented the first time that a diet–gene interaction influencing risk of obesity has been strongly and consistently replicated in three independent populations. The replication increases the robustness of the finding and is noted because few attempts have been made previously to replicate findings of diet–gene interactions. The finding that the results for the diet–*APOA2* polymorphism interaction effect was similar in genetically diverse populations (i.e. European Americans and Hispanic-Americans) suggests that this gene may interact directly with saturated fat intake to influence energy balance across distinct populations (Corella *et al.*, 2009). The same research group has since replicated this gene–diet interaction in two additional populations, providing further validation for this gene–diet interaction (Corella *et al.*, 2011).

Another notable example involving dietary fat is an interaction with the peroxisome proliferator-activated receptor-gamma (*PPAR $\gamma$* ) gene. *PPAR $\gamma$*  influences lipid metabolism, and common variations have been linked to metabolic disorders. *PPAR $\gamma$*  is a nuclear receptor that is involved in many processes, including lipid metabolism and adipocyte differentiation. Since the natural ligands for *PPAR $\gamma$*  include polyunsaturated fatty acids (PUFA), it has

been hypothesized that the effect of the common Pro12Ala variant of *PPAR $\gamma$*  may be altered by the type of dietary fat, especially the polyunsaturated to saturated fat ratio. Results of an earlier study showed that, when the dietary polyunsaturated fat to saturated fat ratio is low, the BMI of carriers of the Ala allele was greater than that of non-carriers, but when the dietary ratio is high, the opposite effect is observed (Luan *et al.*, 2001). This observation was made during a time when it became evident that genetic association studies, including those linking *PPAR $\gamma$*  to cardiometabolic diseases, were yielding inconsistent findings from one population to the next. The observation that the effect of *PPAR $\gamma$*  genotype is strongly influenced by the type of dietary fat suggested that genetic association studies needed to consider the dietary habits of the populations studied, a concept that has not yet been embraced fully by genetic epidemiologists.

Dietary PUFA can also alter HDL-cholesterol concentrations in humans (Wijendran and Hayes, 2004), although the effects of both n-3 and n-6 PUFA have not been consistent (Russo, 2009). For example, a common genetic polymorphism in the *APOA1* gene (-74G>A) modifies the association between dietary PUFA intake and plasma HDL-cholesterol concentrations among women in the Framingham Offspring Study (Ordovas *et al.*, 2002). Dietary PUFA has also been shown to interact with other genes to influence HDL-cholesterol concentrations. A common polymorphism in the nuclear factor kappa B (NF- $\kappa$ B) *NFKB1* gene (-94Ins/Del ATTG) interacts with PUFA intake to affect HDL-cholesterol (Fontaine-Bisson *et al.*, 2009). Among individuals with the Ins/Ins genotype, an increase in % energy from PUFA was associated with an increase in HDL-cholesterol whereas the inverse relationship was observed among those with the Del/Del genotype. This observation was made in two distinct populations, one consisting of young, healthy adults representing different ethnocultural groups, and the other an older population with type 2 diabetes (Fontaine-Bisson *et al.*, 2009).

Although most experiments that investigate potential gene–diet interactions have been observational studies, clinical studies that examine the difference in response to dietary treatment among genotypes have also started to be conducted. These are often based on initial findings from observational studies. For example, the plasma omega-3 fatty acid response to an omega-3 fatty acid supplement was found to be modulated by apoE  $\epsilon$ 4, but not by the common *PPAR- $\alpha$*  L162V polymorphism (Plourde *et al.*, 2009). After supplementation, only non-carriers of  $\epsilon$ 4 had

increased omega-3 in their plasma (Plourde *et al.*, 2009). After 3 months of supplementation with 3.6g of omega-3 fatty acids per day or placebo capsules containing olive oil, changes in serum cholesterol concentrations were similar among the *PPAR- $\alpha$*  L162V genotypes (Lindi *et al.*, 2003). Confirming gene–diet interactions from observational studies in a clinical setting is an important step towards personalized nutrition.

## Vitamin B<sub>12</sub>

Vitamin B<sub>12</sub> is necessary for important functions such as DNA synthesis during cell division, the formation of red blood cells, and the preservation of the myelin sheath around neurons (also, see Chapter 22). Clinically, vitamin B<sub>12</sub> deficiency is associated with conditions such as pernicious anemia, cardiovascular disease, cancer, and neurodegenerative disorders. It has been observed that vitamin B<sub>12</sub> deficiency is often related to altered intestinal vitamin B<sub>12</sub> absorption rather than inadequate intake of the vitamin (Watanabe, 2007). Furthermore, in some extreme cases, the ability to digest, absorb, and utilize vitamin B<sub>12</sub> has been linked to rare genetic mutations, resulting in diseases such as juvenile megaloblastic anemia (Tanner *et al.*, 2004). As such, there has been an interest in determining whether more common polymorphisms could be affecting vitamin B<sub>12</sub> status in the general population.

Hazra and co-workers were among the first to apply GWAS to identify genetic variants that influence nutrient metabolism (Hazra *et al.*, 2008). Using data from 1658 women, a GWAS was conducted to identify genetic loci that influence plasma vitamin B<sub>12</sub> concentrations. The associations between >500,000 SNPs and plasma vitamin B<sub>12</sub> levels were examined. A strong association between an SNP (rs492602) in *FUT2*, the gene that codes for fucosyltransferase 2, and plasma vitamin B<sub>12</sub> levels was observed. Women homozygous for the G allele had higher B<sub>12</sub> levels than carriers of the A allele. The rs492602 SNP is in strong linkage disequilibrium with another *FUT2* variant, which determines *FUT2* secretor status, suggesting a plausible mechanism for altered B<sub>12</sub> absorption and plasma levels. Absorption of vitamin B<sub>12</sub> requires the secretion of the glycoprotein intrinsic factor from the gastric cells and the binding of intrinsic factor to vitamin B<sub>12</sub>. The *FUT2* secretor status has been associated with both *Helicobacter pylori* infection and gastritis, and can lead to reduced secretion of intrinsic factor (Carmel *et al.*, 1987). Insights gained from this GWAS of plasma vitamin B<sub>12</sub> are likely to have

implications for future research into complex diseases linked to inadequate intake such as cancer and CVD. Identifying genetic determinants of vitamin status opens the door for certain studies to explore hypotheses related to the vitamin when intake data are not available. Mendelian randomization refers to the concept of using a genetic variant associated with an environmental exposure, such as a specific nutrient, as a surrogate measure for the exposure itself when information on the exposure is lacking (Davey Smith, 2011). This may be the case with some of the large biobanks or genetic epidemiologic studies. Such a genetic marker could be viewed as more informative than assessing intake, which is often done at a single point in time whereas the gene variant would likely have influenced exposure over a lifetime.

## Folate

Folate (folic acid, vitamin B<sub>9</sub>) is important for a number of biological pathways, and inadequate levels have been implicated in the development of several chronic diseases (Jiang *et al.*, 2003) (also, see Chapter 21). For example, low levels of folate are associated with elevated blood homocysteine levels, which may increase risk of CVD (Boushey *et al.*, 1995). Deficient folate status can also lead to abnormal DNA synthesis, methylation, and repair, which may increase the risk of certain types of cancer (Blount *et al.*, 1997). Although higher total folate intake is inversely associated with the risk of some cancers such as colorectal cancer (Bailey, 2003), folate may actually increase the development of established tumors (Smith *et al.*, 2008). Thus, it is important to establish dietary recommendations that not only prevent deficiency, but also minimize the harmful effects of excess intake.

Methylenetetrahydrofolate reductase (MTHFR) is a key enzyme involved in the metabolism of folate. The *MTHFR* 677C/T (rs1801133) polymorphism is a non-synonymous SNP that results in impaired enzyme activity and is associated with a reduced risk of some forms of cancer (Frosst *et al.*, 1995). However, the protective effect of this folate-related polymorphism is dependent on adequate folate status (Bailey, 2003). Therefore, cancer risk may be increased in individuals with the homozygous genotype for the *MTHFR* 677C/T polymorphism who have low status of methyl-related nutrients such as folate (Bailey, 2003). Modeling analyses have recently been developed to project recommended dietary allowances (RDA) for nutrients based on genotype, as used in a study that assessed

the effect of the *MTHFR* 677C/T polymorphism on the current folate RDA for American adults (400 µg/day) by race and ethnicity (Robitaille *et al.*, 2009). This assessment concluded that the *MTHFR* 677C/T variant, the most widely studied genotype affecting folate metabolism, may not necessarily affect individual requirements because the projected RDA for each genotype was similar to the current RDA (Robitaille *et al.*, 2009). Similar analyses could be conducted for determining upper limits for other nutrients since genetic variations can also impact the levels of nutrients that cause toxicity.

## Choline

The normal function of all cells requires choline, which is particularly important for brain development and memory (also, see Chapter 26). Choline provides the first example of the integration of genetic polymorphisms in candidate genes into a classic depletion–repletion study of a nutrient. In addition to dietary sources, choline can also be synthesized endogenously. When fed a low-choline diet, some people deplete more quickly than others, potentially because of varying amounts of endogenous production of choline. A series of studies was carried out using a set study design in which adult men and women were fed diets containing adequate choline, followed by a diet containing almost no choline, until they were clinically determined to be choline-deficient. Organ dysfunction, a sign of choline deficiency, developed in 77% of men, 80% of postmenopausal women, and only 44% of premenopausal women (Fischer *et al.*, 2007). Higher circulating estrogen levels among premenopausal women were proposed to be the reason why this group is less prone to develop symptoms associated with deficiency because estrogen induces phosphatidylethanolamine N-methyltransferase (*PEMT*) gene expression, which contributes to increased endogenous choline synthesis. Polymorphisms in the *MTHFD1* gene were examined and shown to limit the availability of methyltetrahydrofolate, thereby increasing the use of choline as a methyl donor. Individuals with the common 5,10-methylenetetrahydrofolate dehydrogenase-1958A allele were seven times more likely than non-carriers to develop signs of choline deficiency (Kohlmeier *et al.*, 2005). Remarkably, premenopausal women with this allele had a 15-fold increased risk of developing organ dysfunction on a low-choline diet (Kohlmeier *et al.*, 2005). These findings indicate that nutrient needs can vary substantially

for different individuals and that gene variants could have different effects depending on age and sex.

## Vitamin C

Vitamin C (ascorbic acid) is required for the synthesis of carnitine, collagen, norepinephrine, and epinephrine (also, see Chapter 16). Vitamin C functions to reduce oxidative damage, recycle other antioxidants, facilitate iron absorption, and aid in the conversion of cholesterol to bile acids. An inverse association has been observed between serum ascorbic acid concentrations and risk of chronic diseases such as CVD (Jacob and Sotoudeh, 2002; Boekholdt *et al.*, 2006) and diabetes (Paolisso *et al.*, 1994; Sinclair *et al.*, 1994). However, the findings remain inconsistent (Loria *et al.*, 1998). This discrepancy could be due to individual variability in serum ascorbic acid concentrations since studies report variable dose–response curves between dietary vitamin C and serum ascorbic acid (Levine *et al.*, 1996; Loria *et al.*, 1998). Although several non-genetic determinants of serum ascorbic acid have been identified, they only explain a small portion of the large individual variability (Block *et al.*, 1999).

Studies on the genetic determinants of serum ascorbic acid provide an example of how the effect of the gene variants is most pronounced among those with suboptimal intakes. Significant diet–gene interactions have been observed between dietary vitamin C and glutathione S-transferase (*GST*) (theta and mu classes) genotypes on blood concentrations of ascorbic acid (Cahill *et al.*, 2009). *GSTs* are a family of detoxifying enzymes that contribute to the glutathione–ascorbic acid antioxidant cycle in the human body. The omega class of *GST* is directly able to reduce dehydroascorbic acid back to ascorbic acid, but it is not known whether any of the other classes of *GST* can carry out this function as well. The mu and theta classes of *GST* each contain a common genetic polymorphism that results in a non-functional enzyme. The association between the *GST* genotype and serum ascorbic acid concentrations seems to depend on the amount of dietary vitamin C consumed. Individuals with the *GST* non-functional mu and theta genotypes were found to have an increased risk of serum ascorbic acid deficiency if they did not meet the RDA for vitamin C (Cahill *et al.*, 2009). For example, the odds ratio (95% confidence interval (CI)) for serum ascorbic acid deficiency (<11 µmol/L) was 2.17 (1.10, 4.28) for subjects with the functional *GSTT1\*1* allele who did not meet the RDA of vitamin C compared

with those who did. However, the odds ratio (95% CI) was 12.28 (4.26, 33.42) for individuals with the non-functional *GSTT1\*0/0* genotype. The corresponding odds ratios (95% CI) were 2.29 (0.96, 5.45) and 4.03 (2.01, 8.09) for the functional *GSTM1\*1* allele and non-functional *GSTM1\*0/0* genotype, respectively. This study demonstrated that the RDA for vitamin C is protective against serum ascorbic acid deficiency, regardless of genotype. However, some individuals appear to be more vulnerable to deficiency if the RDA for vitamin C is not achieved. Moreover, because the functional version of the gene appears to protect against deficiency, these findings suggest a novel biological role for the GST theta and mu enzymes in sparing serum ascorbic acid, possibly by aiding in the reduction of dehydroascorbic acid to ascorbic acid. Variations in other genes that affect vitamin C transport (Cahill and El-Sohemy, 2009) and utilization (Cahill and El-Sohemy, 2010) have also affected circulating concentrations, and show that other pathways impacting ascorbic acid metabolism can modify the association between intake and plasma concentrations. Nevertheless, other genes remain to be identified since the polymorphisms identified to date still do not account for most of the variability in serum ascorbic acid concentrations.

## Vitamin D

Vitamin D is essential for the maintenance of musculoskeletal health, but inadequate vitamin D has also been associated with an increased risk of several chronic diseases (also, see Chapter 13). The primary circulating form of vitamin D is 25-hydroxyvitamin D [25(OH)D], which can be influenced by both sun exposure and diet. The high heritability estimates from twin studies suggest that genetic factors are also important determinants of circulating 25(OH)D. Vitamin D provides another example of the use of GWAS, and in this case by more than one research group. One study assessed approximately 4500 individuals of European ancestry and found significant associations between 25(OH)D concentrations and SNPs in the following genes: *GC* (encoding vitamin D binding protein); *NADSYN1* (encoding nicotinamide adenine dinucleotide synthetase), and *CYP2R1* (encoding cytochrome P450, family 2, subfamily R, polypeptide 1, a C-25 hydroxylase that converts cholecalciferol to an active vitamin D receptor ligand) (Ahn *et al.*, 2010). A separate study evaluated serum levels of 25(OH)D and genetic variation in about 34,000 individuals of European descent (Wang *et al.*,

2010). That study also found significant associations between 25(OH)D levels and variants within or near *GC* and *CYP2R1*, as well as the *CYP24A1* gene, which encodes a cytochrome p450 hydroxylase (Wang *et al.*, 2010). Candidate gene studies have also found associations between common variations in some of these genes and circulating 25(OH)D concentrations (Fu *et al.*, 2009; Sinotte *et al.*, 2009). Taken together, these GWAS studies of circulating vitamin D demonstrate that several genetic variants affecting different aspects of a nutrient's metabolism can each influence nutrient status.

## Caffeine

Caffeine is the most widely consumed stimulant in the world and is found primarily in coffee, tea, cola beverages, and energy drinks. Because of its widespread use there has been considerable interest in the health effects of caffeine. One of the challenges of studying the effects of caffeine is differentiating it from other bioactive substances found in the major dietary contributors of caffeine such as coffee or tea, each of which contain a diverse mixture of phytochemicals (Cornelis and El-Sohemy, 2007). Furthermore, those who consume large quantities of caffeine often have different lifestyles and attributes compared with moderate drinkers or abstainers. There is also evidence that polymorphisms in the primary target of caffeine action, the adenosine  $A_{2a}$  receptor, influence habitual consumption (Cornelis *et al.*, 2007). As such, it may be difficult to account for all potential confounders, and any associations could be a result of residual confounding.

Prior to the incorporation of genetic variants the association between coffee intake and CVD risk had been controversial. It was not clear whether it was caffeine, some other compound in coffee, or another environmental factor associated with coffee consumption that may have been responsible for the association between coffee and CVD, including hypertension and myocardial infarction (MI). Distinguishing between the effects of caffeine and other compounds found in coffee is a challenging task because of the strong co-linearity between caffeine and coffee intake in many populations. Caffeine is metabolized primarily by the cytochrome P450 1A2 (*CYP1A2*) enzyme, and a polymorphism in the *CYP1A2* gene influences the rate of caffeine metabolism. Individuals can be classified as either “fast” caffeine metabolizers (those who are homozygous for the -163 A allele) or “slow” caffeine metabolizers (carriers of the -163 C allele) based on the

rs762551 SNP in *CYP1A2*. Knowledge of this genetic difference in caffeine metabolism led to the hypothesis that, if caffeine is involved in the development of CVD, then the *CYP1A2* genotype should modify the association between intake of caffeinated coffee and risk. The findings showed that, indeed, coffee consumption was associated with an increased risk of myocardial infarction (MI) only among individuals with slow caffeine metabolism (Cornelis *et al.*, 2006). This observation suggests that caffeine is the component in coffee that increases risk of MI because it is the only major compound that is known to be detoxified by CYP1A2. Furthermore, a protective effect of moderate coffee consumption was observed among the fast metabolizers, suggesting that other components of coffee might be protective and their effect was “unmasked” in those who eliminated caffeine efficiently. This coffee–*CYP1A2* genotype interaction with CVD risk has since been replicated in a prospective study investigating the effect of coffee intake on hypertension (Palatini *et al.*, 2009). That study found that the risk of hypertension associated with coffee intake varies according to *CYP1A2* genotype. Slow caffeine metabolizers were at increased risk of hypertension from drinking coffee, whereas individuals with the fast-caffeine-metabolizing genotype had no increased risk (Palatini *et al.*, 2009). This study also measured epinephrine and norepinephrine in the urine of the subjects because these catecholamines have been shown to increase after caffeine administration in humans. Urinary epinephrine was significantly higher in coffee drinkers than in abstainers, but only among slow caffeine metabolizers. This is particularly interesting because increased sympathetic activity is considered a main mechanism through which caffeine raises blood pressure.

A similar approach involving genetic variation in caffeine metabolism was used in an observational study of coffee and breast cancer (Kotsopoulos *et al.*, 2007). By grouping subjects into *CYP1A2* genotypes, this study aimed to determine if caffeine was the compound in coffee that explains the protective effect that had previously been observed between coffee and breast cancer risk (Baker *et al.*, 2006; Nkondjock *et al.*, 2006). Indeed, a gene–diet interaction was observed, but unlike the studies on risk of MI and hypertension, where slow caffeine metabolizers were at increased risk from drinking coffee, in this study coffee was associated with a lower risk of breast cancer among slow metabolizers (Kotsopoulos *et al.*, 2007). No protective effect was observed among fast metabolizers, suggesting that caffeine is likely the protective component

in coffee. This is consistent with findings from animal studies showing that caffeine inhibits the development of mammary tumors in rodents (Wolfrom *et al.*, 1991; Yang *et al.*, 2004).

## Future Directions

As progress continues to be made in unravelling the complexities of human genetic variation, nutrition researchers will need to become proficient in applying state-of-the-art techniques in genotyping and sequencing along with the various databases and bioinformatics tools in order to advance knowledge of the variable response to nutrient intakes. Practitioners in the field of nutrition will need to understand how best to translate those findings into clinical practice (Zeisel, 2007). The knowledge gained from incorporating genetic variation into studies of nutrition and health should provide a more rational basis for giving personalized dietary advice while improving the quality of evidence used to make population-based dietary recommendations for the prevention of specific diseases. The application of nutrigenomics by health-care professionals for the prevention and treatment of complex chronic diseases has not yet been widely adopted. Whether such practice will be feasible for the population at large in the immediate future remains to be determined, but the principles and tools of nutrigenomics are expected soon to allow for earlier and more targeted interventions than currently exist (DeBusk, 2009). As the current research in nutrigenomics often focuses on how gene–diet interactions influence phenotypes that are predictive biomarkers of disease (Kaput *et al.*, 2007), it is likely that the path from research to applications will proceed into clinical practice using these markers of chronic disease as outcome measures.

Replication of current findings of gene–diet interactions and further research in the form of genotype-specific nutritional intervention studies are needed. The future of research involving human genetic variation should provide additional knowledge of biological function and individual response to diet. As GWAS studies and whole genome sequencing become more affordable and are integrated into studies with nutrition-related phenotypes, efforts will need to be made to account for differences in dietary intake levels, which is a limitation of the GWAS studies conducted to date. It is possible that different genetic loci influence a nutritional phenotype of interest, such as blood concentrations of a nutrient, depending on dietary intake

### BOX 3.1 Benefits to using markers of genetic variation in nutritional epidemiology

- Minimize residual confounding
- Eliminate recall bias
- Address “reverse causation”
- Identify specific bioactive or nutrient in a food/beverage
- Improve measurement of biologically effective dose of nutrient
- Elucidate molecular mechanisms
- Identify potential responders and non-responders

levels. The application of genetic variation to nutrition research will help clarify the role of specific nutrients and food bioactives in health and disease, and will improve the quality of evidence from observational studies by addressing a number of issues that are often identified as limitations in nutritional epidemiology (Box 3.1). Research in this area is paving the way for personalized nutrition where dietary advice can ultimately be tailored to an individual's unique genetic profile in order to improve on the current one-size-fits-all approach to dietary guidance.

## METABOLOMICS

THOMAS M. O'CONNELL<sup>1</sup>, PhD AND WEI JIA<sup>2</sup>, PhD

<sup>1</sup>*LipoScience Inc., Raleigh, North Carolina, USA*

<sup>2</sup>*University of North Carolina at Greensboro, Kannapolis, North Carolina, USA*

### Summary

As the goal of genomics is to study all of our genes, the goal of metabolomics is to profile the entire complement of the small molecules that are involved in processes from signaling to transcription, from building proteins, to creating and shuttling energy. This chapter describes the challenges of nutritional metabolomics along with the current ways that nutrition scientists can overcome these challenges to gain more insights into the downstream metabolic effects of nutrition. Metabolomic applications in nutritional research are growing rapidly, primarily because metabolomics and nutrition address the same questions in metabolism, metabolic perturbations, oxidation, and inflammation as primary processes that maintain human health. Analytical and profiling techniques in metabolomics also are evolving rapidly, and the analytical platforms currently employed in metabolomic studies are summarized in this chapter along with the required data processing software. The examples provided in this chapter demonstrate that metabolomics is playing an increasingly important role in nutritional research, serving as a dietary assessment tool, a predictive tool for nutritional effects (nutrimetabonomics) and an epidemiological profiling tool, all of which involve gut microbial–mammalian co-metabolism.

### Introduction

The genome is often referred to as the blueprint of what can happen in our bodies. Pushing this analogy further would suggest that the proteome describes the tools that make things happen and the metabolome would be the end result of that work. The interrelationships of these three components are shown in Figure 4.1. The small molecules that compose the metabolome do much of the work in our bodies from signaling transcription to building proteins to creating and shuttling energy. As the goal

of genomics is to study all of our genes, so the goal of metabolomics is to profile the entire complement of the small-molecule metabolites in our bodies. Numerous definitions for metabolomics can be found in the literature, but one of the simplest and most succinct is “the comprehensive and quantitative analysis of all metabolites” (Fiehn, 2001). Note that this area of research is sometimes referred to as metabonomics and these terms have become interchangeable. There is a similarly large number of definitions of what constitutes a metabolite. In the broadest sense, total metabolite pool, or metabolome, includes the

**FIG. 4.1** Relationship between the genome, proteome, and metabolome.

complete complement of endogenous metabolites as well as metabolites derived from diet, medication, environmental exposures, and the gut microbiome (Dunn, 2008). Estimates of the size of the metabolome are also subject to debate, with estimates exceeding 10 000 if dietary components and all combinatorial possibilities of long chain fatty acids are considered. The Human Metabolome Database has been described as the blueprint of the human metabolome, in a fashion analogous to the Human Genome Project (Wishart *et al.*, 2009). This database currently consists of extensive clinical and chemical data for over 7900 compounds (HMDB version 2.5).

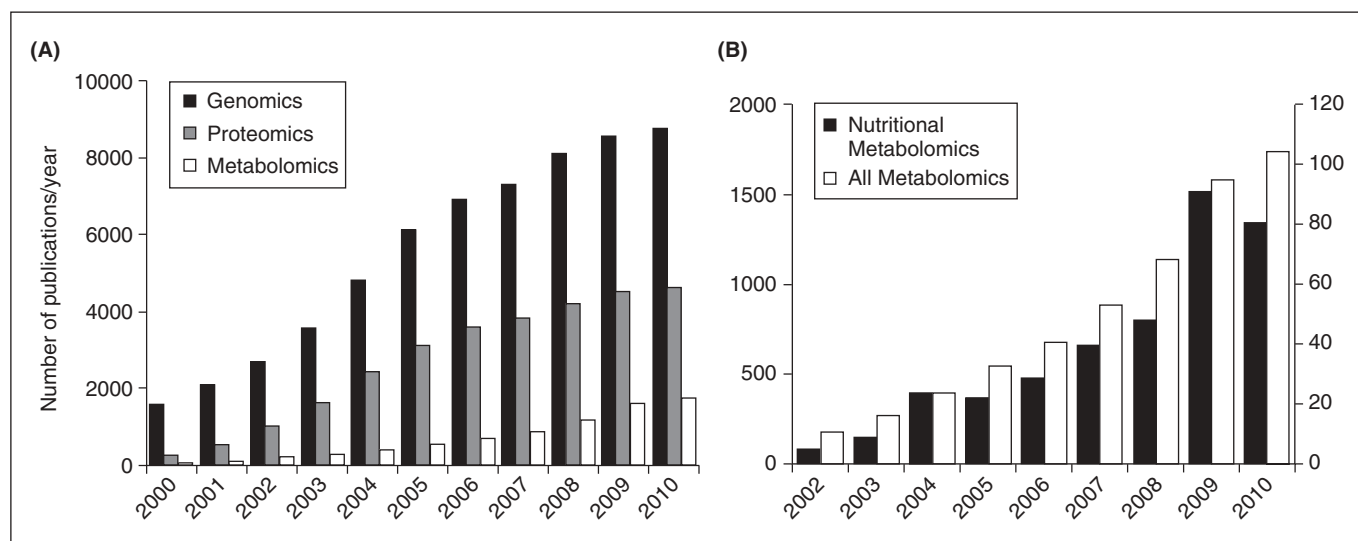

Being the newest of the post-genomics technologies, metabolomics is in a rapid growth phase. Figure 4.2 (left) shows the number of publications over the last 10 years in genomics, proteomics, and metabolomics. The earliest work in metabolomics focused heavily on toxicology studies. The development of metabolomics in this area is the subject of an excellent review by Robertson *et al.* (2011). Nutrition scientists realized the potential for metabolomics somewhat later. Figure 4.2 (right) compares the growth of the overall field of metabolomics with the applications specifically in the area of nutrition. Part of this delay may be due to the fact that nutritional interventions are almost always going to be more subtle, yielding smaller metabolic perturbations than pharmaceutical interventions. As the technologies used to profile the metabolome have matured, the ability to detect more subtle perturbations above the standard variability that is expected in the human population has increased. In this chapter the challenges of nutritional

metabolomics will be described along with current ways in which nutritional scientists can overcome these challenges to gain more details of the downstream metabolic effects of nutrition.

## Measuring the Metabolome

The vast chemical diversity of the metabolome presents a tremendous challenge when the goal is to provide an unbiased and quantitative measurement of all of it. The concentration ranges of metabolites span over a dozen orders of magnitude with compounds such as glucose in the millimolar range in blood, and compounds such as some eicosanoids down in the femtomolar range. The differences in size and polarity also present challenges for different platforms. No single analytical platform can measure the entire metabolome, so metabolomics studies need to select the optimal technology or combination of technologies to maximize the coverage.

The approaches to metabolomics can be broadly divided into three areas: fingerprinting, untargeted analysis, and targeted analysis. The selection of the approach depends upon the nature of the question and the goals of the study. The goal of metabolic fingerprinting is to look for spectroscopic signatures that distinguish one group from another. Insights into mechanisms of disease or toxicity are not sought in these studies. This is often the first step in metabolomics investigations, and ensures that the biological matrix being studied (e.g. plasma, urine, saliva, etc.) contains enough information to discriminate the different groups.

**FIG. 4.2** Growth in omics publications. (A) The growth in genomics, proteomics, and metabolomics over the last decade. (B) Comparison of the growth of metabolomics and those metabolomics studies focusing on nutrition. These data were collected by PubMed searches by year using keywords: (genomics), (proteomics) and (metabolomics OR metabonomics OR metabolic profiling). The nutritional metabolomics studies were determined by appending (AND nutrition) to the last search term.

Untargeted metabolomics, sometimes called global metabolomics, seeks a comprehensive snapshot of as much of the metabolome as possible. This is a discovery approach in which new hypotheses on biochemical mechanisms of action are sought. It is critical in these studies to actually identify the metabolites that are perturbed in the study. Annotation of the spectra with specific metabolite names is a major emphasis for these studies. These metabolite changes can then be translated into perturbations in metabolic pathways. In this manner, untargeted metabolomics can confirm the involvement of metabolic pathways or suggest new ones.

Targeted metabolomics studies start with an initial hypothesis and focus on specific sets of metabolites that are quantitatively profiled. These studies typically contain panels of metabolites from selected chemical classes such as amino acids, acylcarnitines, or fatty acids. These panels are designed to reveal perturbations in suspected biochemical pathways. For example, acylcarnitine panels have been shown to correlate with changes in the extent of  $\beta$ -oxidation (Van Hove *et al.*, 1993). Panels of organic acids can reflect specific changes in tricarboxylic acid cycle functioning. Each of these approaches has its own value, and investigations can progress through each type as shown in Figure 4.3.

The workflow of a metabolomics investigation can be described as follows. The first step is to ensure that the groups (e.g. control and treated) can indeed be separated based on spectroscopic signatures. The next step is to annotate the signatures with specific metabolite names. Through this process specific metabolic pathways are implicated and new hypotheses may be generated. The untargeted approach may not yield enough detail on a specific pathway to make unequivocal conclusions about specific pathways, but may suggest specific metabolite classes that warrant further investigation. Targeted panels of metabolites are then specifically measured to test the new hypotheses generated in the untargeted approach. If the hypothesis is confirmed, then a set of mechanistically based biomarkers has been found. If not, the process can cycle back to the untargeted analysis state where the data can be re-interrogated or additional analyses with other analytical platforms to increase the metabolome coverage can be carried out.

## Analytical Technologies

A wide variety of spectroscopic platforms have been applied to metabolomics including infrared (IR) spectroscopy, nuclear magnetic resonance (NMR) spectroscopy, and

**FIG. 4.3** Process of metabolomics investigations. Once the fingerprinting step has confirmed that a metabolic effect can be detected, the untargeted metabolomics approach is used to generate new hypotheses. The results can confirm this hypothesis or suggest a new one that may be further tested with a targeted metabolomics approach. The results of the targeted approach can confirm the hypothesis, or the process can cycle back to another round of untargeted metabolite analyses.

mass spectrometry (MS), often coupled with various chromatographic separation methods. Details on these methods are well described in numerous reviews and books (Robertson *et al.*, 2005; Vaidyanathan *et al.*, 2005). As the field has matured, two spectroscopic techniques, NMR and MS, have become the dominant platforms for metabolomics. Each of these platforms has its own set of advantages and disadvantages with the critical characteristics revolving around sensitivity, specificity, reproducibility, quantitation, and information content. Table 4.1 summarizes some of the key features of both technologies.

### Nuclear Magnetic Resonance Spectroscopy

Most of the early work in metabolomics was based on NMR spectroscopy, and this work has been summarized in a number of excellent reviews (Reily and Lindon, 2005; Daykin and Wulfert, 2006; Ala-Korpela, 2008). NMR has long been a primary method for organic compound structure elucidation. When applied to complex mixtures, the

high information content, quantitative signal intensities, and very large linear dynamic range ( $>10^5$ ) make it ideal for global metabolomics studies. High reproducibility, both inter- and intra-laboratory, make it well suited for large-scale metabolomics studies (Dumas *et al.*, 2006). The NMR instrumentation is highly stable, which ensures that spectra can be acquired over a long period of time with no instrumental batch effect. Samples for untargeted NMR analysis require minimal preparation. Urine and serum samples are typically prepared with the addition of a small amount of buffer containing a chemical shift and quantitation standard (Beckonert *et al.*, 2007). No chromatographic separation is required, which eliminates one source of potential metabolite loss and analytical variability. The non-destructive nature of NMR makes it possible to acquire spectra on samples and subsequently forward them on to mass spectrometry for further targeted or untargeted analyses.

The main drawback of NMR is the relatively low sensitivity. Metabolite concentrations must typically be at least in the low micromolar range in order to detect enough signal for structure elucidation and quantitation. Several avenues of development are improving the sensitivity of NMR. Increasing the magnetic field strength provides increases in sensitivity, and in 2010 the 1-GHz barrier was broken (Bhattacharya, 2010). Note that NMR spectroscopists refer to the strength of NMR magnets by the corresponding proton resonance frequency, rather than the actual unit of magnetic fields, the Tesla. A 14-Tesla magnet would be referred to as a 600-MHz magnet. Higher-field systems provide a linear increase in resolution but the sensitivity increases as  $B_0^{3/2}$  ( $B_0$  = field strength). Thus a 900-MHz magnet provides a less than two-fold increase in sensitivity over a more routine 600-MHz magnet, yet the cost of the ultra high field systems can be up to an order of magnitude greater. Ultra low temperature detection probes ("cryo-probes") can provide an increase of up to three- to four-fold in signal intensity by decreasing the noise from the electronic circuitry (Logan *et al.*, 1999). Micro-coil NMR probes in which samples can be concentrated down to volumes as low as 10  $\mu$ L have been applied to metabolomics to provide added sensitivity (Grimes and O'Connell, 2011).

Most commonly, proton ( $^1\text{H}$ ) NMR spectra are collected in metabolomics investigations due to the ubiquity of protons in metabolites and the high sensitivity.

An example of a  $^1\text{H}$  NMR spectrum of healthy human urine and serum is shown in Figure 4.4. These spectra were

**TABLE 4.1** Analytical features of NMR and mass spectrometry for metabolomics

	NMR	Mass spectrometry
Sample preparation	No sample preparation required Non-destructive	Extraction and deproteinization Chemical derivatization for GC-MS
Experiment time	<sup>1</sup> H spectra in 5–20 minutes depending upon field strength and sample size	Typically ~ 30 minutes for GC-MS A few minutes with UPLC-MS; up to an hour with standard HPLC-MS methods
Sensitivity	m-molar to μ-molar	p-molar to f-molar
Sample requirements	Typically 100 μL for standard probe μ-coil probes allows for volumes of <10 μL	Typically 100 μL or more to allow for sample processing and preparation of replicates
Quantitation	Signals are inherently quantitative without the need for standards Highly reproducible within and across laboratories	Quantitation is achieved with reference standards Accurate, reproducible quantitation can be achieved with isotope-labeled chemical standards
Metabolome coverage	Thousands of metabolite signals detected No inherent compound bias although long-chain aliphatics (e.g. fatty acids) not well resolved Targeted approach can detect/ quantify higher concentration metabolites without standards	Thousands of metabolite signals detected High-polarity, differing ionization efficiencies and lack of volatility can hinder detection of various compounds Targeted approach detects/ quantifies specific sets of metabolites with chemical standards
Structure identification	Spectra have high structural information content Spectral libraries available for hundreds of compounds	Extensive GC-MS libraries available for structure identification (thousands of compounds) Fragmentation patterns aid in structure identification

collected on a typical “workhorse” 600-MHz NMR spectrometer in about 10 minutes. Unlike mass spectrometry, in which each peak represents a single chemical entity, e.g. a metabolite or metabolite adduct, in the NMR spectrum each peak represents a part of a metabolite, e.g. a methyl group or proton on an aromatic ring. Most metabolites are composed of several sets of peaks which, taken together, can provide structural information and unique evidence of identity. The drawback is that, with hundreds of metabolites each contributing multiple peaks, the spectra can be very crowded and overlapping, thereby hindering interpretation. As mentioned above, higher field magnets can reduce this spectral overlap, but this is an expensive solution that is often unavailable. Advanced experiments, including two-dimensional and multinuclear experiments,

spread the peaks out into a second dimension based on their <sup>1</sup>H or <sup>13</sup>C chemical shifts (Gronwald *et al.*, 2008; Xi *et al.*, 2008; Rai *et al.*, 2009; Ludwig and Viant, 2010). This orthogonal axis separates the signals in a manner analogous to two-dimensional chromatographic methods. These experiments can come at a significant cost in time and therefore are typically run on selected samples to aid in metabolite identification.

### Mass Spectrometry

The use of mass spectrometry in metabolomics has increased dramatically in the last decade. Mass spectrometry measures the mass-to-charge ratio of charged particles and offers qualitative and quantitative analyses of metabolites with very high selectivity and sensitivity. The high

**FIG. 4.4** The 600-MHz NMR spectrum of human urine (top) and serum (bottom) with some annotations of the metabolites that are seen in different spectral regions.

sensitivity enables the measurement of compounds at very low levels (down to femtomole) and can, with the right instrumentation and experiments, provide structural details (Want *et al.*, 2005). Although direct injection of complex mixtures into the MS has been carried out in metabolomics studies, various chromatographic methods are usually incorporated (Bedair and Sumner, 2008). Coupling of high resolution separations such as capillary

electrophoresis (CE), gas chromatography (GC), and liquid chromatography (LC) methods including high-performance liquid chromatography (HPLC) and ultra-performance liquid chromatography (UPLC) offers substantial enhancement in metabolome coverage.

Achieving fully quantitative results with mass spectrometry can be challenging due to the issue of ion suppression. The efficiency of generating a charge on a molecule is

influenced by the other compounds in the source at that time. The chromatographic methods listed above greatly improve the problems of ion suppression by limiting the types of compound that are in the source at any given time. In this way, the efficiency of ionization of a compound will be much less variable over a large sample set. Fully quantitative results can be reliably achieved with the use of isotopically labeled standards as reviewed by Rychlik and Asam (2008).

GC–MS is one of the most widely used analytical techniques in metabolomics (Dettmer *et al.*, 2007). The typical GC–MS platforms used in metabolomics have very high analytical reproducibility and are relatively low cost compared with NMR or some of the other MS platforms. GC–MS is used to analyze volatile compounds or those compounds that can be made to be volatile through well established chemical derivatization protocols. A major prerequisite for GC–MS analysis is a sufficient vapor pressure and thermal stability of the analytes. The analysis of polar metabolites usually requires derivatization at the functional groups to reduce polarity and increase thermal stability and volatility. GC is traditionally coupled to quadrupole MS, which provides high sensitivity and large dynamic range, but relatively slow scan speeds. Recently, more advanced instrumentation such as GC time-of-flight MS (TOF–MS) and GC  $\times$  GC TOF–MS are becoming more popular for metabolite profiling due to their higher mass accuracy and mass resolution relative to the quadrupole MS systems (Pasikanti *et al.*, 2008). With GC–MS,

universal electron ionization (EI) is most often used, providing a platform for the identification of characteristic and reproducible metabolite markers.

The application of LC–MS in metabolomics has been growing rapidly over the past few years. LC is a more universal separation technique that can be utilized in a non-targeted manner or tailored for the targeted analysis of specific metabolite groups. As mentioned earlier, LC can reduce the ion suppression that can occur with co-eluting compounds. The chromatographic retention time is a function of the polarity of the compound and can also yield useful structural information. For example, isobaric compounds (i.e. having the exact same molecular formula) may yield an identical mass spectrum, but the retention time can be taken into account to help decide which peak belongs to which isobaric metabolite.

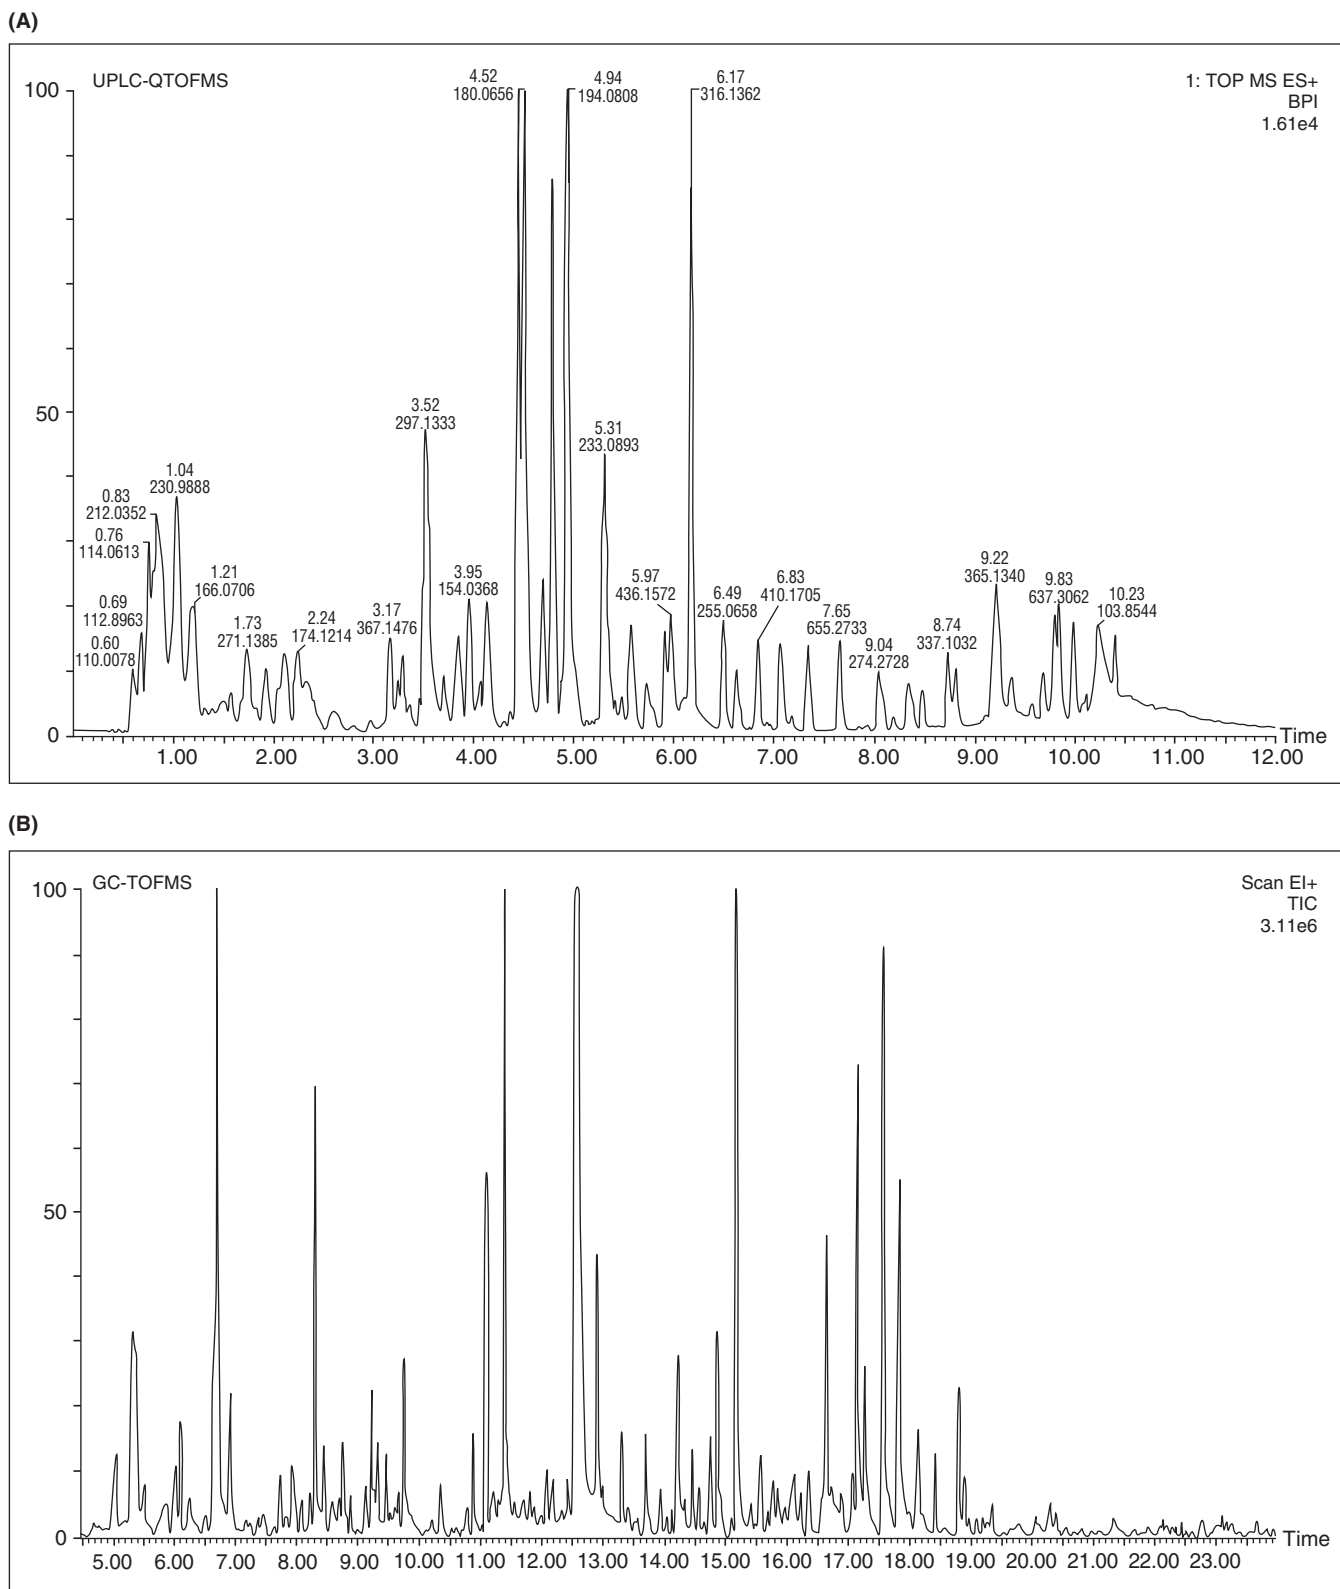

MS-based metabolomics usually require a sample preparation or pretreatment step, which can be labor intensive and possibly cause metabolite losses (Bruce *et al.*, 2009). Metabolites of interest in different chemical classes may be discriminated depending on the analytical platforms used (Figure 4.5). Examples of GC–TOF–MS and UPLC–QTOF–MS spectra of healthy human urine are shown in Figure 4.6.

### Statistical Analyses

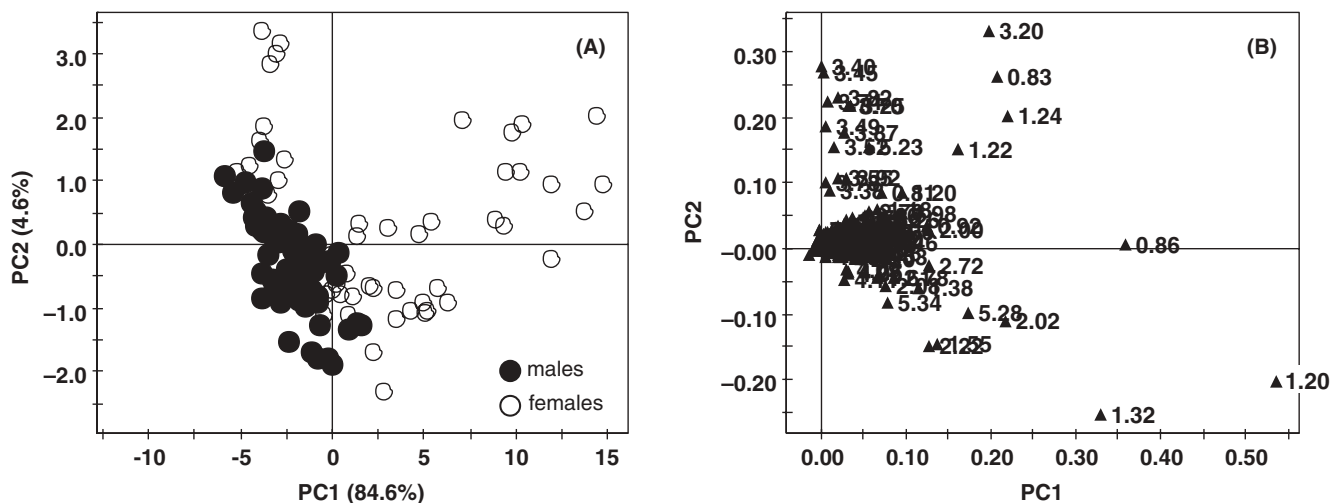

Metabolomics datasets typically contain a large number of highly complex spectra, and the first step in deriving useful information from this abundance of data involves pattern

**FIG. 4.5** Classes of chemicals and the analytical techniques with which they are most compatible (Agilent application note 5989-6328EN, 2007).

**FIG. 4.6** GC-TOF-MS and UPLC-QTOF-MS spectra of human urine. (A) The total ion current (TIC) chromatogram of GC-TOF-MS collected on an Agilent 6890N gas chromatograph coupled with a Leco Pegasus HT time-of-flight mass spectrometer. It represents the summed intensity across the entire range of masses ( $m/z$  30–600) being detected in a 24-minute run. (B) The base peak intensity chromatogram (BPI) of UPLC-QTOF-MS. This chromatogram was collected on a Waters ACQUITY Ultra performance liquid chromatograph coupled with a Waters Q-TOF micro MS in about 12 minutes.

**FIG. 4.7** Principal components analysis of serum from healthy adult males and females. (A) The scores plot maps the spectrum of each individual subject. The major axis of separation of the males and females is along the first principal component which explains 84.6% of the variation in the data. The second principal component accounts for only 4.6% of the remaining variation in the data and could be related to factors such as age, ethnicity or BMI. (B) The loadings plot indicates which spectral variables are most influential for each principal component. The features near the zero crossing are not related to the gender difference, but those peaks at the far right, e.g. 1.20, 1.323, and 0.86, are very influential in discriminating males from females. These peaks correspond to some of the major lipid/lipoprotein component in the serum.

recognition and multivariate statistical analysis. The simplest and most common statistical method is principal components analysis (PCA). This method aims to simplify the dataset by combining variables (such as spectral peaks from NMR or MS) that are correlated in order to reduce the dimensionality of the data. The end result is the reduction of the dataset from potentially thousands of spectral features to a small number (often less than 10) of linear combinations of variables that still explain the majority of the data.

Figure 4.7 shows a PCA analysis separating healthy males from females in a controlled dietary standardization study. Figure 4.7A is the scores plot in which each point represents a subject (actually the NMR spectrum of the serum of one subject). The separation of males and females is observed based on the entirety of their metabolic signatures. Figure 4.7B shows the corresponding loadings plot in which the critical features of the spectra which discriminate males from females are highlighted. The spectral features clustered around the zero crossing of the axes are those that are not significantly different between the groups, but the features at the edges of the plot, i.e. the “highly loaded” features, are significantly different. These

features comprise the unique spectroscopic features of males and females. In a typical metabolomics investigation, the next step after PCA analysis is to go back to the spectra and identify the metabolites corresponding to the highly loaded variables.

The PCA method is termed “unsupervised” as no information regarding the classification of the samples is input into the model. In this manner, all of the variation in the data is explained. Often the main source of variation may not be related to the focus of the study, e.g. nutritional intervention, but may be age, gender, or other such confounding factors. PCA is a valuable way to detect outliers in a sample set from biological or analytical variation, and is a routine, first-pass analysis in most metabolomics investigations.

A wide array of more advanced statistical methods have been developed and applied to extract information from rich metabolomics datasets (Waterman *et al.*, 2009; Madsen *et al.*, 2010). Methods such as partial least squares (PLS) analyses and orthogonal partial least squares discriminant analysis (OPLS-DA) methods are a frequent next step after PCA analysis. Note that PLS methods are also referred to as projection to latent structures with the same

acronym. These methods are “supervised” in that the class membership (i.e. control versus treated) is input into the model. Unlike PCA, the goal is no longer to explain all of the variation in the data; with supervised analyses, the goal is to explain only the variation that is correlated to a classification. This is often a binary variable such as control versus treated or it can be a continuous variable such as a body mass index (BMI), age, or variable exposure to a food or toxin.

In the ever expanding arsenal of multivariate statistical methods, techniques such as linear discriminant analysis, support vector machines, and random forests are playing an increasing role. Recently the performance of these methods was compared with PLS in an untargeted GC–MS dataset. The performance characteristics, including accuracy, predictive capacity, stability, degree of over-fitting, and consistency in variable ranking were evaluated. In this study the performance of the random forests method was found to be superior. Currently the choice of which statistical method to employ in a metabolomics study is influenced by the sophistication of the bioinformatics group participating in the project and the availability and ease of use of statistical software packages to apply these methods. This recent comparison indicates that, as software packages mature, the statistical analyses available for routine use will continue to grow.

## Stability of the Human Metabolome

When studying the potentially subtle effects of nutritional interventions, the stability of the human metabolome must be considered. Factors such as genetics, diet, age, gut microflora, and environmental factors can all contribute to the day-to-day as well as long-term stability in the human metabolome (Bictash *et al.*, 2010). Numerous studies have been conducted to determine the metabolic signatures related to these potentially confounding influences. In a review by Bollard and co-workers, the intrinsic factors (species, strain, age, and hormonal effects) and extrinsic factors (diurnal effects, diet, stress, and gut microflora) were examined in animal models for their influence on the composition of the urinary metabolome (Bollard *et al.*, 2005). In a study of healthy humans, Kochhar *et al.* (2006) demonstrated clear metabolic signatures that discriminated subjects based on age, gender, and BMI.

It is not surprising that each person's metabolome is different, but how distinct are our individual metabo-

lomes? In a large-scale, longitudinal study, Assfalg *et al.* (2008) showed that a sophisticated statistical analysis of human urine samples contained an invariant part of the metabolome that is characteristic of each individual. A subsequent study by the same group demonstrated that these individual metabolic features were stable over the course of several years (Bernini *et al.*, 2009). It was proposed that this metabolic phenotype be considered a metagenomic entity that is influenced by both the gut microbiome and the host metabolic phenotype.

## Normalizing the Human Metabolome with Diet

Above the invariant core there still remain a large number of highly variable components of the metabolome so the challenge in clinical studies is to find ways to minimize these. The application of standardized diets has been investigated for their potential to normalize the metabolomes in subjects. In a study by Walsh *et al.* (2006), urine, serum, and saliva were collected from 30 healthy human subjects once per week over 4 weeks. For the first two study days, free food choice was allowed on the day before the visit. The third visit was meant to mimic the second visit and the subjects were instructed to eat as they had done on the day before the second visit. On the day before the last visit, all subjects consumed the same standardized meals. Above the considerable intra- and inter-subject variability, it was found that the standardized meal provided a detectable decrease in the variability of the urine samples. No normalization was observed with the plasma or saliva. The urine samples in this study were first void and evening collections. This study suggests that the urinary metabolome is a sensitive reflection of acute dietary intake whereas plasma and saliva are not.

In another study of the effects of an acute dietary intervention, Lenz *et al.* (2003) studied the urinary and plasma metabolome of subjects on two days, 14 days apart. In this study, serum samples were collected as well as first-void, 0–12 hours and 12–24 hours urine samples. The subjects were fed a standardized diet on the collection days. In the plasma there was relatively little variability between subjects and study days. Considerable inter-subject variability was found with the urine samples, but less intra-subject variability. This is consistent with the individuality of the urinary metabolome. The most significant finding of this study was that the first-void urines showed considerably greater diversity than the 0–12 hours and 12–24 hours collections. It seems that the first-void diversity may be

more susceptible to variations from diet and lifestyle differences.

Acute dietary interventions appear to confer some normalizing effect on the urinary metabolome, but could this effect be enhanced with a more prolonged dietary intervention? In the study by Winnike *et al.* (2009) a group of 10 healthy human subjects was admitted to a clinical research center for 2 weeks and received a standardized whole-food diet. Pooled 24-hour urine samples were collected daily throughout the study. Daily overnight fasted serum samples were collected as well as on a single return visit 2 weeks after the study. The urinary metabolome of all of the subjects showed considerable inter-subject variability, consistent with the studies by Walsh *et al.* (2006) and Lenz *et al.* (2003). In contrast, the standardized diet appeared to provide no normalization over the course of the study. Each subject remained in their individual “metabolic space” for the 2-week period. The lack of an effect from the imposition of this standardized diet may be due to the fact that 24-hour urine samples were collected in this study. This would indicate that acute dietary interventions may be detectable in single collections such a first void, but that these differences are literally diluted out in the 24-hour collections.

The serum metabolome of the acute intervention studies indicated that no normalization could be detected. In the prolonged standardized diet, a distinct difference was observed in about half of the subjects in the first day and/or the 2-week follow-up. There are two possible reasons why this effect was seen in this study and not in the others. First, by extending the dietary standardization, a clearer picture of each person’s metabolic space was obtained and therefore the outlier days are more distinct. Secondly, the more stringent dietary and environmental controls in this inpatient clinical setting may have created a new homeostasis in the serum metabolome, giving rise to detectable differences from the free-living metabolome. Taken together, these studies indicate that a standardized meal prior to the start of a study may provide some detectable decrease in the urinary and serum metabolome, but extended normalization does not provide a progressive decrease in variation.

## Metabolomics as a Dietary Assessment Tool

The accurate measurement of dietary intake is essential to understanding how diet relates to disease development and

prevention. Conventional tools for collecting quantitative information on dietary intake include food frequency questionnaires (FFQ), dietary recalls, and diet diaries. These methods are subject to significant random and systematic errors. Bingham *et al.* (1994, 1997) investigated the accuracy of several dietary assessment methods by comparing weighed food records, FFQs, 24-hour recall, and a 7-day food diary. The results showed that the FFQ tended to overestimate almost all intake, the 24-hour recall underestimated carbohydrates, vitamin C, and alcohol intake, and the food diary over-estimated fat intake but underestimated carbohydrate and calcium intake. These errors clearly confound any comparison of results from nutritional studies utilizing different methods.

To overcome the problems associated with self-reporting methods, a number of targeted biomarkers have been developed which indicate consumption of particular foods or food groups. One such biomarker is urinary potassium to measure potassium intake (Bingham, 2002). The correlations between consumption and excretion have been demonstrated to be at least 0.7, but 24-hour urine collections are required which are more difficult to collect in a non-clinical setting. Total protein intake has been correlated with urinary nitrogen output, but again requiring 24-hour urine collections. The serum level of pentadecanoic acid (C15:0) has been shown to have a strong correlation with the intake of fats from milk or dairy products (Smedman *et al.*, 1999). These individual markers for specific dietary components are very valuable, but less subjective and more comprehensive tools are needed to evaluate dietary exposures.

Metabolomics holds great promise as a tool to provide comprehensive assessments of the dietary intake in humans. When food is consumed, the chemical components of the food, i.e. the food metabolome, are absorbed either directly or after digestion, followed by biotransformations in the gastrointestinal tract (including the microbiome) and/or liver, and are then detectable either in the serum or urine. This interrelationship between the mammalian, microbial, and food metabolomics is diagrammed in Figure 4.8. The search for potential biomarkers of exposure has been described as “top-down” indicating that specific components of the food metabolome are sought in the biofluids (Mennen *et al.*, 2006; Jenab *et al.*, 2009). This targeted approach has been successfully applied to a number of foods, but kinetics of biological processing and excretion can make some specific biomarkers more challenging to detect (Fave *et al.*, 2009; Manach *et al.*, 2009; Scalbert

**FIG. 4.8** Interactions of the host–food–microbial metabolomics to generate new metabolite signatures of consumption, absorption, transformation, and metabolism.

*et al.*, 2009; Primrose *et al.*, 2011). The other approach, termed “bottom-up” involves the application of global metabolic profiling. The advantage of the latter approach is that no assumptions of the processing of the food metabolome are necessary. Experience in this area has shown that biomarkers found in the bottom-up approach are often unexpected, based on incomplete knowledge of the food metabolome and the subsequent absorption and biotransformation.

A large-scale study of the potential of global metabolomics to reveal biomarkers of food exposure is underway in the METabolomics to characterize Dietary Exposure (MEDE) study (Primrose *et al.*, 2011). In this study each subject received a standard dinner and subsequent breakfast on two occasions. In the test breakfast, one component of the standard breakfast (cornflakes and milk) was replaced with one of four foods of significant public health interest: broccoli (a cruciferous vegetable), smoked salmon (an oily fish), raspberries (berry fruit), and whole-wheat biscuit (whole-grain cereal). Fasting and postprandial changes in the urine were detected in all subjects. It was determined that urine and plasma samples collected 3 hours after test meals were the most informative about recent dietary intake. A consistent set of metabolites was

always highly ranked in the metabolome after the test breakfast, allowing these metabolites to be filtered from the data and enabling easier detection of the metabolites associated with the test foods. The results of this study identified putative biomarkers for several of the breakfast components including orange juice, raspberries, smoked salmon, and broccoli.

One finding of particular interest in this study involved the discrimination of which subjects consumed the cornflakes versus the whole-wheat biscuit. When all subjects were analyzed together, no robust discrimination from these two dietary components could be found. When a subset of subjects with similar overall metabolite profiles were examined, however, a good separation based on these two breakfast components could be achieved. It appears that the inter-subject differences initially overshadowed the more subtle dietary effect, but, by considering a more homogeneous subset of subjects based on their overall metabolotype, this difference was revealed.

The search for dietary biomarkers is not limited to just acute exposure studies, but also includes biomarkers that indicate that the habitual intake patterns will also be very valuable. In a study by O'Sullivan *et al.* (2011), the urinary and serum metabolomes of 125 free-living subjects were analyzed. Dietary intakes were assessed by the use of 3-day estimated food records, completed at week 2 of the 3-week study. Individual foods and ingredients were aggregated into 33 groups based on cluster analysis of the dietary patterns in the Irish population in this study (Hearty and Gibney, 2009). Some food groups were comprised of single foods such as eggs, potatoes, and alcohol. Others were more general such as vegetables, poultry dishes, and confectionery. Cluster analysis of the data revealed three dietary patterns that distinctly influenced the total energy intake of each group. The first cluster was characterized by a high contribution from wholemeal bread, whole milk, fish, confectionery, and ice cream and desserts. This cluster had a lower contribution from low-energy beverages (e.g. water, tea, and sugar-free soft drinks). Cluster two had a high contribution from low-fat milk, yogurt, fruit, poultry, and sauces, and a low contribution from high-energy beverages (e.g. fruit-based concentrate drinks and soft drinks). Cluster three was considered the least healthy and contained higher concentrations of white bread, red meat and red-meat dishes, meat products, and alcohol, and had a lower contribution from vegetables. These dietary patterns were significantly different with respect to sex, but no discrimination could be made based on age or BMI.

In order to interrogate the specific metabolic differences between these groups, PLS–DA models were created for each pairing of the groups. The most significant model was the comparison of groups one and three. These clusters had the highest and lowest intakes of nine different food groups. The concentrations of glycine, phenylacetylglutamine, and acetoacetate were all higher in cluster one, whereas trimethylamine N-oxide (TMAO), O-acylcarnitine, and n,n-dimethylglycine were higher in cluster three. Further linear regression analysis revealed that the phenylacetylglutamine was positively correlated to vegetable consumption. A positive correlation between O-acylcarnitine and red-meat intake was found. This study demonstrated the ability of metabolomics to discriminate distinct dietary patterns in free-living adults and derive biomarkers for some critical components of those dietary patterns.

The controls imposed in a clinical setting can be very insightful, but the metabolic perturbations observed under those strictly controlled conditions may not be detectable in a free-living environment. Conversely, the large variation in the diets in free-living conditions may mask many important perturbations. One clever intermediate study design that can be implemented in long-term studies and mimics free-living conditions involves the “supermarket model” (Skov *et al.*, 1997; Rasmussen *et al.*, 2007; Bladbjerg *et al.*, 2010). In these studies, all participants obtained their food from a purpose-built shop stocked with all of the nutritional needs of the participants. Food items were selected by the participants *ad libitum* within the frame of the dietary design and the individual shopping selections were recorded in a specially designed computerized system. The supermarket method has been utilized in a number of long-term (up to 6 months) nutritional intervention studies to examine the effects of various fats and carbohydrates on weight loss, cardiovascular disease, and diabetes (Due *et al.*, 2008a,b). The model has significant potential to provide an intermediate level of control for large-scale, long-term metabolomics investigations.

### Epidemiological Scale Metabolomics

Metabolomics will play an increasingly important role in responding to the challenges of population health and well being in the future. These epidemiological metabolomics studies are now possible with the advent of high-throughput, high-sensitivity methods that require minimal

sample volumes and preparation. One of the critical challenges of metabolomics across populations is to understand the differences in the metabolotypes that arise from cultural and environmental factors. One of the earliest untargeted metabolomics studies to examine the baseline metabolome differences in different countries was published by Zuppi *et al.* (1998). In this study, urine samples from 25 healthy subjects living in Rome were compared with an age- and gender-matched group living in Svalbard in the Arctic region of northern Norway. The Rome group ate a typical Mediterranean diet of about 3000 kcal/day containing 50–55% carbohydrates, 25–30% lipids, and 20% proteins. The Svalbard group ate a diet of about 4500 kcal/day with 30–33% carbohydrates, 47–50% lipids, and 20% protein. The lower levels of urinary alanine, lactate, and citrate in the Svalbard group were ascribed to the lower carbohydrate portion of the diet. TMAO is a well established marker of fish consumption and was found to be higher in the Svalbard group. The increased amounts of preservatives in the diet of that group led to higher exposure to benzoic acid. Lower glycine levels were also observed as glycine can conjugate to the benzoic acid resulting in the higher observed levels of hippurate. This type of controlled study to mimic the cultural and geographic preferences in different regions was a valuable demonstration of the ways in which the baseline metabolome must be considered in epidemiological metabolomics studies.

A metabolomic comparison of British and Swedish subjects was conducted without any dietary restrictions to look for culturally driven differences in the baseline metabolome under free-living conditions (Lenz *et al.*, 2004). In this study 20 healthy Swedish subjects and 10 healthy British subjects were enrolled. Each group contained males and females age 21 to 65 years. Principal components analysis revealed some distinction between the two countries based mainly on the levels of hippurate, TMAO, and creatinine. The higher TMAO concentrations in the Swedish subjects are concordant with the study by Zuppi *et al.* (1998), indicating that the Scandinavian diet is higher in fish consumption (Svensson *et al.*, 1994).

Interestingly, one British subject in this study had abnormally high levels of taurine. This particular metabolite has been reported to be an indicator of liver injury. Clinical follow-up with this subject found normal liver function, but examination of the dietary record indicated that she was on the Atkins diet which is very rich in meat. This high meat consumption can lead to elevated urinary

taurine (Rana and Sanders, 1986; Laidlaw *et al.*, 1988). This is a good example of what can be learned from an examination of outliers and how diet must be considered in order to discern the difference between a biomarker of diet versus dysfunction.

After baseline metabolome differences are understood, metabolomics studies can be integrated into epidemiological studies to look for biomarkers of disease risk. The INTERSALT study is an example of a large-scale study in which relationship between salt intake and blood pressure was investigated (ICRG, 1988, 1989). In this study, 10 000+ men and women, age 20 to 59 years, from 32 countries with 52 discrete population groups, were studied to assess the role of salt in accounting for differences in blood pressure. A study of this magnitude requires rigorous protocols including standardization of blood pressure measurement techniques as well as assessment of salt intake and related data such as alcohol, potassium intake, and BMI. To minimize analytical variation, all analytical tests were conducted in a single laboratory. The results of this study demonstrated for the first time the positive correlation between salt, alcohol, and BMI with increased blood pressure.

An outgrowth of INTERSALT was the INTERMAP study, designed to evaluate the role of multiple dietary factors in accounting for interindividual differences in blood pressure (Beever and Stamler, 2003; Stamler *et al.*, 2003). Comprehensive high-quality databases on the nutrient composition of foods were required for this study, therefore only four of the 32 countries in the INTERSALT study were included. Databases were available or could be created in these countries from existing national tables. Subjects from 17 population centers in China ( $n=832$ ), Japan ( $n=1138$ ), USA ( $n=2164$ ), and UK ( $n=496$ ) were included. Metabolomics was applied in order to develop a metabolic phenotyping approach to elucidate the mechanisms of the global cardiovascular disease epidemic. The study involved four 24-hour dietary recalls and two 24-hour urine collections. The aim was to identify a set of urinary metabolites that correlate with blood pressure across individuals and populations.

The results showed the unique metabolic patterns that distinguished the different populations. Geographic metabolic differences were greater than gender differences. The East Asian and western populations had well differentiated metabolotypes. The metabolotypes of southern (Guangzi) and northern (Beijing and Shanghai) China were also readily differentiated as were those of the USA and UK popula-

tions. Discriminatory metabolites were identified from pairwise comparisons across countries. The most significant metabolites included several that are predominantly of dietary origin such as amino acids, creatine, and TMAO. Significant differences in metabolic intermediates of energy metabolism included acetylcarnitine, tricarboxylic acid intermediates, and dicarboxylic acids. Gut microbial-mammalian co-metabolites such as hippurate, phenylacetylglutamine, and methylamines were also shown to be significant. Previous studies have shown that Chinese and American populations have structural differences in their gut microbial speciation, resulting in detectable differences in the metabolomes (Li *et al.*, 2008).

Four metabolites from this study were evaluated for correlations with systolic and diastolic blood pressure (SBP) and (DBP). These metabolites were alanine, formate, hippurate, and N-methylnicotinate. Multiple linear regression models of these metabolites were generated considering different adjustments for age, sex, supplement use, cardiovascular disease or diabetes or other confounding variables. Inverse associations of formate with both SBP and DBP were found in all eight models and similar associations were found with hippurate in six of the models. A direct association with alanine was found with five of the models.

The metabolic sources of each of these candidate biomarkers could reveal important mechanistic insights as to the coronary heart disease risks across different populations. Formate is mainly derived from the one-carbon metabolism from serine hydroxymethyltransferase activities and the tetrahydrofolate pathway. Formate is also generated from the fermentation of dietary fiber by the gut microbiome. The correlation of formate with urinary  $\text{Na}^+$  excretion also points out the involvement with chlorine reabsorption in the kidney.

The inverse correlation with hippurate may further implicate the role of the gut microbiome in blood pressure. Polyphenols from many dietary plant sources such as black and green tea can be processed by gut bacteria into hippurate (Mulder *et al.*, 2005). Benzoic acid is commonly found in many berries and is also used as a preservative in many foods. Another action of the gut microbiome is to modulate availability of calories from the diet, which can influence the development of obesity which has a direct link with blood pressure (ICRG, 1988, 1989).

The positive correlation between urinary alanine levels and blood pressure could be related to differences in protein consumption. Dietary alanine levels are higher in those who consume higher animal-based protein rather

than vegetable protein. Higher levels of the latter have been shown to have an inverse relationship with high blood pressure. Alanine also modulates cardiovascular responses to circulating catecholamines and increases blood pressure (Conlay *et al.*, 1990).

The cross-population metabolic differences revealed in the INTERMAP study confirm the role that metabolomics can play in epidemiological scale studies. The untargeted metabolomics data were effectively mined for culturally based dietary differences and disease risk. Global metabolite profiles will be a critical data component of epidemiological risk assessment as well as in the development of dietary recommendations.

## Nutrimetabonomics and the Effects of Nutritional Challenges

### **Metabolomic Profiling as a Predictive Tool**

The idea that the baseline metabolome of an individual contains information to predict the outcome of some physiological intervention was first demonstrated in the pharmacotherapy realm with acetaminophen. Clayton *et al.* (2006) demonstrated that the urinary metabolome of rats collected 24 hours prior to dosing with a toxic threshold dose of acetaminophen could discriminate those rats which would go on to develop moderate liver injury from those that would develop only mild liver injury. This approach, termed pharmaco-metabonomics, has been used in subsequent human clinical trials with some success. Pre-dose metabolite profiles in human subjects were found to be significantly correlated with the metabolism of both the anticoagulant ximelagatran (Andersson *et al.*, 2009) and the anti-rejection drug tacrolimus (Phapale *et al.*, 2010).

The nutrimetabolomic approach has been used to determine metabolic phenotypes which are correlated to dietary preferences. In a study by Rezzi *et al.* (2007) distinct metabolotypes were found to correlate to predilection of a person to consume chocolate. Baseline urinary and plasma metabolic phenotypes were significantly correlated with the status of a person categorized as “chocolate desiring” or “chocolate indifferent”. Plasma metabolic signatures were mainly different in their lipoprotein profiles while the urinary metabolomes were mainly distinguished by metabolites related to interactions with the gut microbiome. The ability to classify the dietary preferences of individuals and potentially of populations could have a significant impact in the development of dietary recommendations.

The nutrimetabolomic approach has been applied to predict the outcome of dietary choline deprivation in humans (Sha *et al.*, 2010). Choline is an essential nutrient, and deficiency can lead to liver and muscle dysfunction. In this study 53 subjects were fed a standard choline-containing diet for 10 days. A choline-deficient diet was then imposed for up to 42 days and subjects were monitored for signs of organ dysfunction. Finally subjects were given a 3-day choline repletion treatment. An untargeted analysis of the baseline metabolome was found to be strongly predictive of the outcome of the choline depletion phase. Distinct metabolic signatures were found for those who would develop liver dysfunction and those who would not. Choline deficiency is a common side-effect in patients treated with total parenteral nutrition (TPN), leading to a risk of liver dysfunction (Buchman *et al.*, 2001). This nutrimetabolomic approach may be useful in predicting the potential for liver dysfunction in patients on TPN treatment and in helping to develop more individualized therapy.

### **Metabolic Profiling of the Response to Nutritional Challenges**

Some metabolic disorders may be difficult to detect above the noise inherent in the baseline metabolome. In order to detect some disorders, a dietary challenge may be required. For example, the oral glucose tolerance test (oGTT) is a common tool to use to provoke the metabolic processes that work to maintain glucose homeostasis. During an overnight fast, glucose levels are maintained through the action of glycogenolysis and gluconeogenesis. The large dose of glucose consumed in an oGTT triggers the rapid release of insulin, promoting glucose uptake and shifting the metabolism from a catabolic to an anabolic state. Currently, the time-dependent changes in glucose and insulin levels are used to draw conclusions on insulin sensitivity. The transition from fasting also leads to changes in a large number of metabolic pathways. Metabolomics offers a means to detect many of the suspected and unsuspected perturbations that may yield important biochemical insights into the processes that lead to insulin resistance.

An untargeted metabolomics study was undertaken by Zhao *et al.* (2009) to investigate the metabolic consequences of an oGTT. In this study a group of 16 individuals who were all classified as normal glucose tolerant were given an oGTT. Plasma was collected from all subjects

over a 2-hour time window. Perturbations in four major metabolite groups were observed: free fatty acids (FFA), acylcarnitines, bile acids, and lysophosphatidylcholines (lyso-PC). The LC–MS platform used in this study utilized a reversed-phase-chromatography step so that polar metabolites (such as glucose) were not well detected. The nature of the lyso-PC and bile acid perturbations was not clear and warrants further investigation. The decrease in the plasma fatty acids is consistent with the expected decrease in lipolysis as the release of insulin inhibits the action of hormone-sensitive lipase. The decreases in acylcarnitines indicate a significant shift in energy metabolism. Acylcarnitines are generated from their respective acyl-CoA intermediates and are byproducts of mitochondrial  $\beta$ -oxidation. They can pass efficiently into the cytosol and then into the bloodstream so that plasma acylcarnitines are a reliable surrogate for the substrate flux through  $\beta$ -oxidation. The reduction in plasma levels therefore indicates a decreased reliance on  $\beta$ -oxidation after the glucose challenge. This untargeted metabolomics investigation resulted in a set of novel biomarkers to monitor the ability of a subject to regain metabolic homeostasis after an oGTT.

In a subsequent study, an untargeted metabolomics approach was used to investigate the ability of insulin-insensitive subjects to handle an oGTT (Shaham *et al.*, 2008). In this manner, the metabolomics approach sought mechanistic as well as diagnostic biomarkers for the malfunctioning that occurs in insulin-insensitive individuals. This study also utilized an LC–MS analytical platform, but differences in the chromatography enabled the detection of more polar metabolites such as glucose, amino acids, and organic acids. This study identified 18 metabolites that implicated four distinct axes of insulin action. The metabolite markers indicate that, after an oGTT, glycolysis is up-regulated whereas lipolysis, ketogenesis and proteolysis are all down-regulated. Statistical analyses found that the blunted alterations in the levels of branched-chain amino acids plus the alteration in glycerol yielded a robust metabolic profile of insulin resistance. The branched-chain amino acid levels reflect perturbations in protein catabolism and the glycerol levels indicate changes in lipolysis. This result suggests that the same level of insulin resistance in two individuals could be the result of a different balance of these two insulin-sensitive pathways. This added detail from the metabolomics measurements could yield valuable insights into more individualized treatment for insulin resistance.

## The Importance of the Gut Microbiota on Metabolic Profiles

The symbiotic relationships between microbes and the mammalian and plant hosts are an important factor in shaping our world. The gut microbiome tremendously increases the diversity of metabolic pathways accessible to mammalian hosts, enabling them to metabolize many things that they otherwise could not. As a result, gut microbes have been associated with various essential biological functions in humans through a “network” of microbial–host co-metabolism to process nutrients and drugs and modulate multiple pathways in a variety of organ systems (Martin *et al.*, 2007, 2009; Claus *et al.*, 2008). These studies by Nicholson and co-workers demonstrate that the metabolic variations in gastrointestinal compartments such as the duodenum, jejunum, and ileum, mammalian tissues such as kidney and liver, and biofluids such as blood and urine are directly related to the activities of the gut microbiota (Martin *et al.*, 2008). Perhaps most importantly, gut microbes enable us to digest cellulose, the single largest nutritional energy source on the planet, and to survive on diets with low levels of particular nutrients and high levels of particular toxins. For example, gut microbes metabolize unabsorbed carbohydrates to short-chain fatty acids (SCFA),  $\text{CO}_2$ , and  $\text{H}_2$  in the colon. SCFAs are monocarboxylic acids with a chain length up to six carbon atoms, i.e. acetic, propionic, butyric, isovaleric, valeric, isocaproic, and caproic acids. SCFAs function both as energy sources and as signaling molecules, and their abundance and type are directly related to the speciation of the microbiota and their syntrophic interactions. Other signaling pathways (such as through the SCFA receptor GPR43, for example) are similarly involved in host energy balance, and different microbial communities interact differently with these molecules (Ley *et al.*, 2008). Most mammals can obtain essential amino acids, such as lysine, from their diet, but there is evidence that they also obtain them from their gut microbes (Metges *et al.*, 2006). Many amino acids and perhaps other nitrogen-containing compounds may be cycling between humans and their microbiota, a process that could reduce dietary requirements for those nutrients (Metges *et al.*, 2006). However, whether the fluxes of those amino acids or other essential nutrients between microbes and humans are great enough to contribute significantly to nutritional requirements is unresolved.

Diversity in gut microbial communities and function creates differences in nutrient milieu, digesta retention

times, and temperatures that create diverse microbial environments. With the recent advances in molecular profiling technologies such as metagenomics and metabolomics, the direct correlation of global metabolic changes with the gut microbiome becomes increasingly important in the deciphering of the host–microbe relationships and in order to gain a mechanistic understanding of nutritional and drug interventions. Scientists from different disciplines are working together to determine the details of gut microbial diversity and to manipulate the complex interactions between the host metabolism and its symbionts for improved nutrition and disease treatment (Pang *et al.*, 2007; Li *et al.*, 2008, Wei *et al.*, 2010).

## Future Directions

Gaining a better understanding of the nutritional status of individuals and populations is a major goal of metabolomics in the future. Generating databases of metabolotypes could provide the means to detect variations that may signal disease risk at both individual and population levels. The analytical platforms are rapidly advancing so that a more sensitive and comprehensive coverage of the metabolome is generated. Biostatistical tools are also being developed so that critical metabolic features may be detected above the inherent noise from the confounding factors such as culture, age, BMI, etc. In the future, nutritional scientists will need to integrate into the network of scientists that includes analytical chemists, plant biologists, biostatisticians, and clinicians, to design and implement studies that generate a complete picture of the interaction of foods with our mammalian and microbial metabolism. These studies should enable the development of libraries containing metabolite biomarkers of food consumption as well as biomarkers of disease and dysfunction. The diagnostic and mechanistic knowledge that can be gained from metabolomics studies will have a tremendous impact on the development of personalized health in the future.

## ENERGY METABOLISM IN FASTING, FED, EXERCISE, AND RE-FEEDING STATES

SAI KRUPA DAS, PhD AND SUSAN B. ROBERTS, PhD

*Tufts University, Boston, Massachusetts, USA*

### Summary

Energy balance is achieved when energy intake equals energy expenditure. Perturbations to this homeostatic model impact body weight regulation. A net energy surplus leads to weight gain and obesity and a net energy deficit results in weight loss and underweight. Energy metabolism in the fasted state is dependent on the duration of the fast, the type of meal ingested before the fast, and available body energy stores. Energy metabolism in the fed state is mediated by the cephalic phase response to a meal, meal size, meal type, structure and consistency, meal composition, and the metabolic processes required to digest, absorb, and store the ingested energy. Both energy intake and body energy stores affect activity-/exercise-related energy expenditure. Human beings, especially adults, do not maintain energy balance from one day to the next but do so over a period of several days with energy intake playing a stronger role in this regulatory process.

### Introduction

Energy is expended by the body to maintain electrochemical gradients, transport molecules, support biosynthetic processes, produce the mechanical work required for respiration and blood circulation, and generate muscle contraction. Most of these biological processes cannot directly harness energy from the oxidation of energy-containing substrates (primarily carbohydrate and fat from food and body energy stores). Instead, the resulting energy from the oxidation of metabolic fuels is captured by adenosine triphosphate (ATP) in the form of high-energy bonds. ATP is the major energy carrier to body sites and releases the

energy required for chemical and mechanical work. Use of that energy results in the production of heat, carbon dioxide, and water, which are all eliminated from the body. Definitions in energy metabolism, and relationships among oxygen consumption, carbon dioxide production and energy expenditure, and the stoichiometry of oxidation of different nutrients, are shown in Box 5.1 and Tables 5.1 and 5.2.

Nutrient degradation pathways (including the Krebs cycle and the  $\beta$ -oxidation of fatty acids) are linked to the formation of ATP from adenosine diphosphate (ADP) and inorganic phosphate (Pi) and are often referred to as ATP- or energy-generation pathways. Likewise, the term “energy

### BOX 5.1 Definitions in energy metabolism

**Calorie and Joule:** A calorie is the amount of heat required to raise the temperature of 1 g of H<sub>2</sub>O from 14.5 to 15.5°C. One kilocalorie (1 kcal) is 1000 times greater than 1 calorie (1 cal); 1 calorie is equivalent to 4.184 joules (J); and 1 kilocalorie to 4.184 kilojoules (kJ).

**Energy balance:** Attained when energy intake equals total energy expenditure (TEE) and body stores are stable. An individual is said to be in *positive energy balance* when energy intake exceeds TEE (and consequently body energy stores increase). *Negative energy balance* occurs when energy intake is less than TEE and body energy stores decrease.

**Energy expenditure:** The amount of energy used by the body, and equivalent to the heat released by hydrolysis of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) or adenosine monophosphate (AMP) and inorganic phosphate (Pi).

**Energy metabolism:** The general term used to collectively describe the multiple biochemical pathways that govern the production and use of ATP and the reducing equivalents.

**Energy regulation** is the process by which energy intake and energy expenditure are balanced.

**Malnutrition** is the general term that denotes both undernutrition and overnutrition.

**Overnutrition:** Occurs when energy intake exceeds energy expenditure and results in excess body fat accumulation. Several levels of overnutrition are defined in adults using the body mass index (BMI, weight in kilograms divided by height in meters squared, kg/m<sup>2</sup>) (Food and Agriculture Organization of the United Nations, 2001): Overweight BMI = 25–29.9, Class I Obesity BMI = 30–34.9, Class II Obesity BMI = 35–39.9, Class III Obesity BMI ≥40.0 kg/m<sup>2</sup>. In children BMI changes with development; BMI definitions of overweight and obesity at different ages are now available (see Cole *et al.*, 2000; Roberts and Dallal, 2001).

**Undernutrition:** Occurs when energy intake is less than TEE over a considerable period of time, resulting in clinically significant weight loss. In adults undernutrition is classified using BMI (WHO, 1995). A BMI of 18.5–24.9 is considered normal, a BMI of 17–18.49 is mild undernutrition, a BMI of 16–16.99 is moderate undernutrition, and a BMI <16 is severe undernutrition. In children, undernutrition is classified using the weight-for-height (or length) index and height-for-age index with reference values derived from World Health Organization data (Food and Agriculture Organization of the United Nations, 2001).

**Wasting** is defined as low weight for height, with <–1SD (i.e. –1 z-score) being mild, <–2 SD being moderate, and <–3 SD being severely wasted relative to National Center for Health Statistics and the World Health Organization International Growth Reference. Similarly, **stunting** is associated with a low height for age with <–1 SD being mild, <–2 SD being moderate, and <–3 SD of the reference values being severely stunted.

Data from Kinney and Tucker (1992).

expenditure” is used to describe the degradation of ATP to ADP and Pi. In a resting adult ~25–35 g ATP is used every minute to drive the life-sustaining processes, and this is approximately the total amount contained in the body at any one time. Although ATP turnover at rest is relatively high, the enzymatic machinery in the body operates below its maximal capacity, and is poised to effectively maintain a high ratio of ATP to ADP. During vigorous exercise, when several hundred grams of ATP are required per minute, ATP levels fall because of increased use, the rate of ATP generation is adjusted rapidly to match ATP utilization, and synthesis of ATP is accelerated.

The circulating levels of energy substrates needed for ATP production are kept relatively constant despite wide variations in the availability of nutrients from the gastrointestinal tract by the balance of insulin and the counter-regulatory hormones, such as glucagon, glucocorticoids, adrenaline, and growth hormone. These hormones jointly serve to facilitate the rapid storage of incoming nutrients from the gastrointestinal tract (carbohydrate in the form of glycogen in the liver and muscle, and fat as triacylglycerol in adipose tissue) and maintain circulating levels in the fasting state by mobilization of body stores.

The close relationship between energy metabolism and oxygen consumption stems from the fact that oxygen is required to transform food to a usable source of energy. One liter of oxygen consumed generates approximately 5 kcal (20.92 kJ). Given that there is proportionality between  $\text{VO}_2$  and ATP synthesis, and because each mole of ATP synthesized is accompanied by a given amount of heat, it would be possible to calculate heat production from  $\text{VO}_2$  measurements alone. However, the heat produced by the utilization of 1 L oxygen varies somewhat with the foodstuff consumed (Tables 5.1 and 5.2). The combustion of 1 L oxygen during fat oxidation yields 4.682 kcal (19.60 kJ), whereas protein alone yields 4.655 kcal (19.48 kJ) and carbohydrate starch alone yields 5.048 kcal (21.12 kJ) (Livesey and Elia, 1988). Moreover, the amount of carbon dioxide produced also varies with nutrient type, with the amount produced per mole oxygen consumed during oxidation of fat, protein, and carbohydrate being 0.710, 0.835, and 1.00 mol, respectively. Thus, for precise conversion of oxygen utilization to energy expenditure, the balance of metabolic fuels being oxidized or carbon dioxide production must be known.

Because the ratio of carbon dioxide produced to oxygen consumed (i.e. the respiratory quotient) varies with nutri-

ent type, it can be used to predict the ratio of metabolic fuels being oxidized provided that additional information on urinary nitrogen excretion is also available. The first step in this calculation is to determine protein oxidation, with the assumption that urinary nitrogen reflects protein oxidation, and 1 g urinary nitrogen is equivalent to 6.25 g protein.  $\text{VO}_2$  and  $\text{VCO}_2$  not from protein (the non-protein  $\text{VO}_2$  and  $\text{VCO}_2$ ) are then calculated by subtracting the amount of oxygen and carbon dioxide equivalent to protein oxidation using the values in Table 5.1. After this, the non-protein respiratory quotient is used to calculate the ratio of fat to carbohydrate oxidation using values for the respiratory quotient of carbohydrate and fat.

Simple equations can also be used to predict energy expenditure from oxygen consumption and carbon dioxide production, of which de Weir’s is probably most widely used today (de Weir, 1949). When 24-hour urine collections are made on the day of measurement of  $\text{VO}_2$  and  $\text{VCO}_2$ , the complete de Weir equation, which includes an adjustment for energy expenditure for protein oxidation, is used. However, because of the difficulties obtaining complete 24-hour urine nitrogen measurements and because the difference between correcting for urinary N and not correcting for nitrogen is <2%, the abbreviated de Weir equation is often used. The complete de Weir equation is:

$$\text{RMR (kcal/day)} = 1.44 (3.941 \cdot \text{VO}_2 + 1.106 \cdot \text{VCO}_2) - 2.17 \cdot \text{UN}$$

The abbreviated de Weir equation is:

$$\text{RMR (kcal/day)} = 1.44 (3.941 \cdot \text{VO}_2 + 1.106 \cdot \text{VCO}_2)$$

Resting metabolic rate (RMR);  $\text{VO}_2$  and  $\text{VCO}_2$  are measured in milliliters per minute and urinary nitrogen (UN) is measured in grams per day.

The following sections discuss the components of total energy expenditure in relation to the fasting state, namely basal metabolic rate (BMR) or resting metabolic rate (RMR); the fed state or the thermic effect of feeding (TEF); and the activity- and exercise-related energy expenditure which is termed activity energy expenditure (AEE) or physical activity energy expenditure (PAEE). Combined, these three components are equivalent to total energy expenditure (TEE), which in turn is equivalent to dietary energy requirements for non-growing individuals. In addition, the effects of changes in energy balance on energy expenditure are also considered.

## Energy Expenditure in the Fasting State

Energy expenditure measured in the fasting state reflects energy use of the body for such basic functions as maintenance of electrochemical gradients, transporting of molecules around the body, and biosynthetic processes, and is an important measurement in energy expenditure research because it typically accounts for 60–70% of TEE. Basal metabolic rate is a standardized measurement of energy expenditure in the fasting state, defined as the rate of energy expenditure while lying supine in bed at physical and mental rest 12–14 hours after the last meal (i.e. in the postabsorptive state) and under thermoneutral conditions. Resting metabolic rate is another standardized measurement, which is similar to BMR except that the conditions are less rigid for the duration of the overnight fast, and that posture may differ (some measurements are performed in the semi-inclined rather than supine position) and thermoneutrality is not guaranteed. BMR and RMR are often used interchangeably. Both BMR and RMR are highly correlated with lean body mass, more commonly known as fat-free mass (FFM), and to a smaller extent with fat mass. Note that there is a positive intercept in the relationship between BMR/RMR and FFM, which is thought to result from the fact that organs have a high metabolic rate and sizes are relatively constant between adult individuals. One consequence of the non-zero intercept is that BMR per kilogram FFM is lower for higher levels of FFM than for lower ones. Thus, differences in BMR between groups of individuals should always be assessed using regression analysis to test the effect of a group in a model also incorporating FFM and fat mass; otherwise, heavy individuals (such as the obese) may falsely appear to have a low BMR relative to their body size.

There is also some variability in BMR because of age (elderly individuals have lower BMR after adjusting for differences in FFM between young and old groups [Roberts *et al.*, 1995]), and women may have lower adjusted BMR values than men (Ferraro *et al.*, 1992). Among young women, BMR variations of the order of 6–10% have been reported to occur in the course of the menstrual cycle, with values in the luteal phase tending to be higher than in the follicular phase (Solomon *et al.*, 1982). Factors such as exercise and conditions such as hyperthyroidism, catecholamine release, fever, stress, cold exposure, and burns increase BMR. There is also a hereditary component to BMR, seen in the fact that variations in FFM-adjusted metabolic rate are smaller among members of the same

**TABLE 5.3** Equations to predict BMR from body weight

Age range (years)	Basal metabolic rate	
	kcal/day	MJ/day
<i>Males</i>		
0–3	$60.9W - 54$	$0.255W - 0.226$
3–10	$22.7W + 495$	$0.0949W + 2.07$
10–18	$17.5W + 651$	$0.0732W + 2.72$
18–30	$15.3W + 679$	$0.0640W + 2.84$
30–60	$11.6W + 879$	$0.0485W + 3.67$
>60	$13.5W + 487$	$0.0565W + 2.04$
<i>Females</i>		
0–3	$61.0W - 51$	$0.255W - 0.214$
3–10	$22.5W + 499$	$0.0941W + 2.09$
10–18	$12.2W + 746$	$0.0510W + 3.12$
18–30	$14.7W + 496$	$0.0615W + 2.08$
30–60	$8.7W + 829$	$0.0364W + 3.47$
>60	$10.5W + 596$	$0.0439W + 2.49$

family than between unrelated individuals (Bogardus *et al.*, 1986).

Several equations have been developed to predict BMR from weight, height, and other simple measures. The Schofield equations (Schofield *et al.*, 1985) were derived from an analysis of the world literature on BMR. They consist of a series of simple linear regression equations predicting BMR for different gender and age categories from either weight alone or weight and height. These equations have an uncertainty of prediction of only  $\pm 7$ –10% for individual values, and are widely used. Although such equations may not be suitable for unusual populations such as the extremely obese or very old, they do provide a basis for predicting energy requirements in the general population (Table 5.3).

## Energy Expenditure in the Fed State

The thermic effect of feeding, previously known as specific dynamic action, is the increase in energy expenditure above basal that is associated with consuming, digesting, and assimilating food. Some of the increase in energy expenditure associated with feeding can be directly attributed to the metabolic costs of eating and digestion and related processes (termed “obligatory thermogenesis”),

while the other component of the increase appears to be due to concomitant activation of the sympathetic nervous system (termed “facultative thermogenesis”) (Murgatroyd, 1984). A significant component of the TEF (estimated at 50–75%) is directed toward the obligatory thermogenesis component and is used for such work as regenerating the ATP used in the processing and storage of ingested nutrients (Flatt, 1978). Facultative thermogenesis (Major *et al.*, 2007) may include such factors as increased activity of the sympathetic nervous system resulting from the sensory and metabolic stimulation resulting from food. TEF typically accounts for 7–13% of energy intake over the 4-hour period after eating, and is directly proportional to the size of the meal consumed (Schutz *et al.*, 1984; Melanson *et al.*, 1998). TEF appears to be reduced in obese individuals (Segal *et al.*, 1990), but the question of whether this is a cause or consequence of excess weight gain has not been resolved (Golay *et al.*, 1989; Segal *et al.*, 1990). A separate estimate of the energy needed for TEF is not usually shown in predictions of energy requirements (see below), because measurements of total energy expenditure include energy expenditure attributable to the TEF.

### Activity Energy Expenditure or Physical Activity Energy Expenditure

The final component of TEE is the AEE or PAEE, which is generally the second largest component of TEE and the most variable because to a large extent it is under voluntary control. This component will thus account for an increasing proportion of TEE as individuals become more physically active. In sedentary persons, AEE or PAEE may be only 15–20% of TEE, whereas it may be up to 50–60% in highly active individuals. In some individuals an important component of AEE or PAEE is subconscious (e.g. fidgeting, posture maintenance) and is referred to as spontaneous physical activity (SPA) (Levine *et al.*, 1999). The difficulty of measuring AEE or PAEE using traditional methods for determining energy expenditure has made this the least accurately measured component of TEE. Energy expenditure for different activities varies widely, and typical values are summarized in Table 5.4. These values are for the acute effects of exercise, and it is also recognized that chronic exercise may have effects on energy expenditure that extend beyond the period of exercise to influence RMR and TEF (Van Zant, 1992).

**TABLE 5.4** Approximate energy expenditure for individual activities (expressed as multiple of resting metabolic rate)<sup>a</sup>

Activity category and activity examples	Activity factor X (RMR)
<i>Resting</i> Sleeping, reclining	1.0
<i>Very light</i> Seated and standing activities, painting trades, driving, laboratory work, typing, sewing, ironing, cooking, playing cards, playing a musical instrument	1.5
<i>Light</i> Walking on a level surface at 2.5 to 3 mph, garage work, electrical trades, carpentry, restaurant trades, house-cleaning, child care, golf, sailing, table tennis	2.5
<i>Moderate</i> Walking 3.5 to 4 mph, weeding and hoeing, carrying a load, cycling, skiing, tennis, dancing	5.0
<i>Heavy</i> Walking with a load uphill, tree felling, heavy manual digging, basketball, climbing, football, soccer	7.0

<sup>a</sup>When reported as multiples of basal needs, the energy expenditures of males and females are similar.

Data from Durnin and Passamore (1967) and WHO (1985).

### Energy Requirements

TEE is equivalent to energy requirements for non-growing individuals, and energy requirements can be defined as (WHO, 1985):

the level of energy intake that will balance energy expenditure when the individual has a body size and composition and a level of physical activity consistent with long-term good health; and that will allow for the maintenance of economically necessary and socially desirable physical activity. In children and pregnant or lactating women, the energy requirement includes the energy needs associated with the deposition of tissues or secretion of milk at rates consistent with good health.

Requirement refers to habitual or usual intake over a period of time, because many human beings (especially adults) do not maintain energy balance from one day to the next but do so over a period of several days or even over weeks. Energy requirements are equivalent to TEE when the individual is in “energy balance”, i.e. neither gaining nor losing body fat, and in this case total energy intake will be equivalent to “metabolizable energy intake”, which is energy metabolically available to the body after obligatory losses in urine and feces. Approximate metabolizable energy contents of fat, protein, and carbohydrate are 9 kcal (37.66 kJ/g), 4 kcal/g (16.74 kJ/g), and 4 kcal/g (16.74 kJ/g), respectively.

Currently, most estimations of energy requirement worldwide are based on estimates of components of energy expenditure summed together into 24-hour values in a “factorial” approach (WHO, 1985). However, while the factorial approach is recognized as relatively imprecise, it is preferred over measurement of energy intake during weight stability because energy intake is highly variable and most individuals under-report habitual intake by 25–50%, depending on their body fatness (Schoeller, 1990).

To avoid the pitfalls of the factorial method, substantial effort has been directed towards developing the doubly labeled water method as an alternative, longer-term, and more accurate technique for measurement of TEE. This method was originally developed for use in small animals (Lifson *et al.*, 1955; Lifson and McClintock, 1966), based on the principle that if two isotopes of water ( $\text{H}_2^{18}\text{O}$  and  $^2\text{H}_2\text{O}$ ) are administered and their disappearance rates from a body fluid such as urine are monitored, the disappearance rate of  $^2\text{H}_2\text{O}$  reflects water flux and the disappearance rate of  $\text{H}_2^{18}\text{O}$  reflects water flux plus carbon dioxide production rate (Lifson *et al.*, 1949). The difference between the two disappearance rates can therefore be used to calculate carbon dioxide production rate over a period of 1–2 weeks, from which total energy expenditure can be calculated if information is available on respiratory quotient (RQ) (Surrao *et al.*, 1998). Validation studies of the doubly labeled water method have been conducted in human infants and adults of different ages using respiratory gas exchange or dietary energy intake as the reference method (Schoeller, 1988; Roberts, 1989). All these studies showed a close agreement between total energy expenditure determined by doubly labeled water and total energy expenditure determined by a reference method, with a coefficient of variation for the new method of 2–6%. In consequence,

the doubly labeled water method is now widely recognized as an accurate and precise method for assessment of total energy expenditure in human subjects, and has recently been assessed as giving broadly comparable results to the factorial method (Shetty, 2005). Because the doubly labeled water method calculates the rate of carbon dioxide production, rather than the rate of energy expenditure, and because the heat equivalent of carbon dioxide varies with the substrates being oxidized (Schoeller, 1988; Roberts, 1989), it is necessary to have an estimate of the RQ of the subject during the measurement period. Usually, RQ is estimated from information on the subject’s dietary intake – either their reported macronutrient intakes or normative data from population surveys – and errors from necessary assumptions and errors in dietary records are recognized to be small and usually <2% (Surrao *et al.*, 1998).

A critical mass of doubly labeled water data has been accumulated, making it possible to evaluate typical changes in TEE and energy expenditure for physical activity (calculated as the difference between total energy expenditure and basal metabolic rate plus the thermic effect of feeding, or indicated by a physical activity level calculated as the ratio of total energy expenditure to basal metabolic rate). Equations predicting the energy requirements of humans throughout the lifespan were developed by the Institute of Medicine (2002) based on available doubly labeled water data, and are summarized in Table 5.5. Figure 5.1 shows

	1.48 if activity level is very active (PAL $\geq 1.9$ <2.5)	1.45 if activity level is very active (PAL $\geq 1.9$ <2.5)

PAL, the physical activity level expressed as a ratio of total energy expenditure to basal or resting for the whole day.

W, weight, kg; H, height, inches; A, age, years; the coefficient 20 and 25 are the estimated energy needs for energy deposition at these ages (3–8 years, 9–18 years).

the data for TEE throughout the lifecycle used to generate the Institute of Medicine equations (Institute of Medicine, 2002).

A notable feature of Figure 5.1 is that there is a progressive increase in TEE throughout childhood, followed by a substantial decline in total energy expenditure with age after maturity, reflecting a modest decline in RMR and a greater decline in PAEE. The causes of declining physical activity with age are not well understood (Roberts and Dallal, 2005). The declines with age are reported to parallel an increase in body fat mass, suggesting that changes in body composition may be important (Roberts and Dallal, 1998). However, Westerterp and colleagues

(Meijer *et al.*, 2000; Westerterp and Meijer, 2001) have pointed out that the decline in energy requirements with age is most strongly predicted by age itself and not by body composition, indicating an effect of aging on expenditure independent of the quantity of lean tissue and fat mass. It is also noteworthy that maximal oxygen consumption is recognized to decline progressively with age, and very active individuals have declines of about 50% between 20 and 80 years that are a similar magnitude (albeit higher absolute values) to those experienced by sedentary individuals (DHHS, 1996). These observations suggest that some parallel changes in fitness, energy expenditure for physical activity, and body composition with age are an

inevitable consequence of the aging process, probably due to underlying hormonal and biochemical changes in skeletal muscle and the cardiovascular system rather than a cumulative consequence of long-term inactivity. Further studies are needed to determine the extent to which energy expenditure for physical activity can be maintained in old age in the general population, since the potential specific effects of either low-intensity or high-intensity intentional exercise on energy balance will depend on compensatory changes in activity during other times of the day and this topic is currently controversial (Meijer *et al.*, 2000; Westerterp and Meijer, 2001; Westerterp, 2003; McLaughlin *et al.*, 2006). However small the effects on energy balance, additional effects of exercise include positive effects on cardiovascular and bone health, and prevention of falls and frailty (DiPietro, 2001).

## Energy Expenditure During Refeeding and Energy Imbalance

Perturbations in energy balance underlie the most common public health nutrition problems today. In the United States, 68% of adults and 35% of children are now overweight or obese (Flegal *et al.*, 2010; Ogden *et al.*, 2006). The prevalence of obesity is also increasing in developing countries, where undernutrition has traditionally been the primary nutrition challenge and remains prevalent (Kurpad *et al.*, 2005). For example, the prevalence of obesity has increased recently in both Brazil and China, especially in urban areas but also in very low-income families such as those living in shantytowns (Sawaya *et al.*, 1995, 1998; Popkin *et al.*, 1996). In addition to being associated with increased risks of type 2 diabetes, osteoarthritis, angina, and hypertension, obesity is also associated with premature death and increased health-care costs (Uauy and Diaz, 2005). The estimated number of deaths attributable to obesity in the United States alone is ~300,000 per year.

The excess weight gain that accumulates in obesity results from energy intake exceeding energy expenditure over a considerable period of time and has both genetic and environmental origins. This positive energy balance can occur because energy expenditure is low or energy intake is high, or a combination of these two factors. The importance of energy expenditure is suggested by several (Ravussin *et al.*, 1988; Roberts *et al.*, 1988; DeLany, 1998; Goran *et al.*, 1998) though not all (Stunkard *et al.*, 1999) prospective studies showing that low energy expenditure

is a risk factor for excess weight gain, and mechanistically may result from the effects of energy expenditure on both energy requirements and insulin sensitivity (Ravussin *et al.*, 1988; Sigal *et al.*, 1997). In addition, the fact that excess energy intake is important, at least in the United States, is suggested by national survey statistics showing that per capita energy availability (adjusted for spoilage and waste) has increased over the past 20 years (Putnam, 1999; Economic Research Service, 2010).

Some studies suggest that humans possess a considerable capacity to increase energy expenditure (for RMR and TEF) during overfeeding with the result that in some individuals weight gain is less than expected for the magnitude of energy intake, and variability between individuals may be influenced by a genetic susceptibility or resistance to weight gain (Bouchard *et al.*, 1990; Levine *et al.*, 1999). However, even in studies that showed a significant capacity for energy dissipation during overeating, weight gain still occurred. Furthermore, other overfeeding studies suggest a substantially lower capacity for energy dissipation in normal volunteers (Ravussin *et al.*, 1985; Roberts *et al.*, 1990). Thus, although increased energy dissipation appears to occur during overeating, it is concomitant with positive energy balance and does not entirely prevent weight gain in most individuals.

Concerning negative energy balance, experimental underfeeding studies show a reduction in energy expenditure during weight loss (loss of both fat mass and FFM) that is disproportionate to the weight lost (Saltzman and Roberts, 1995). It is also important to note that the capacity for adaptive variations in energy expenditure appears to be greater in response to undereating than to overeating (Saltzman and Roberts, 1995). This implies that there is a greater metabolic priority in preventing weight loss than in preventing weight gain, a suggestion consistent with the presumption that food shortages were more common than food abundance during early human evolution. The question of whether energy expenditure remains depressed if weight is stabilized at a lower weight remains controversial (Leibel *et al.*, 1995; Saltzman and Roberts, 1995; Das *et al.*, 2003; Rosenbaum *et al.*, 2008), with different study approaches yielding different experimental findings. However, this issue has important implications in the formulation of refeeding energy requirements, for weight loss maintenance in individuals following dietary, pharmacological, or surgical weight loss, and for previously malnourished populations exposed to high-calorie low-nutrient-dense foods who may not be metabolically

equipped to handle the caloric load and may be at risk of developing obesity.

## Future Directions

Energy expenditure for resting metabolism, the thermic effect of feeding, and physical activity and arousal will balance energy intake in individuals maintaining energy balance, and are contributors to energy dysregulation in the obese state. Determinants of energy expenditure are the subject of considerable research but further studies are needed to accurately quantify the relative importance of genetic inheritance, early life influences, and current environmental factors in the prevention, development, and treatment of obesity.

## PROTEIN AND AMINO ACIDS

PAUL B. PENCHARZ, MB, ChB, PhD, FRCP(C)

*University of Toronto, Ontario, Canada*

### Summary

This chapter considers selected recent advances in amino acid function, and protein and amino acid utilization, during the prandial and postprandial period of amino acid metabolism. The importance of the gut and the splanchnic region as a whole in the regulation of whole-body amino acid metabolism has become better appreciated and understood. There remains uncertainty about quantitative aspects of amino acid nutrition, especially in healthy adults, but there is now a consensus that the current international requirement estimates for adults are far too low. This has potentially important implications for the evaluation of dietary protein quality and for the planning, now and in the future, of food protein supplies for population groups. Improved in vivo metabolic tools combined with molecular and cellular techniques appear to offer great promise for resolving some of the outstanding issues that limit our ability to predict precisely the effect of the dietary protein and amino acid component on function and the quantitative and qualitative character of the intake that optimizes development and health maintenance.

### Introduction

Jac Berzelius invented the term “protein,” which was accepted by the Dutch chemist, Gerardus J. Mulder, in the *Bulletin des Sciences Physiques et Naturelles en Neerlande* in 1838 (Korpes, 1970). A readable account of the history behind the development and understanding of protein and amino acid nutrition has appeared (Carpenter, 1994), and the earlier practical recommendations about dietary intakes for protein have been summarized by Munro (1985). This chapter will be confined to a discussion of selected, more recent developments in the general area of protein and

amino acid metabolism and its nutritional corollaries, with particular emphasis on relevance to human protein and amino acid nutrition.

### The Currency of Protein Metabolism and Nutrition – Amino Acid Functions

Proteins comprise one of the five classes of complex biomolecules found in cells and tissues, the others being DNA, RNA, polysaccharides, and lipids. The building blocks of proteins are amino acids and, as such, they are the currency of protein nutrition and metabolism.

Although there are hundreds of amino acids in nature, only ~20 of these commonly appear in proteins, via charging by their cognate tRNAs and subsequent recognition of a codon on the mRNA. In the special case of certain selenoproteins, such as glutathione peroxidase and type 2 iodothreonine 5'-deiodinase, there is formation and incorporation of selenocysteine into these proteins, which involves a complex process including conversion of a seryl-tRNA to selenocysteinyl-tRNA, which is then recognized by a UGA codon (Burke and Hill, 1993). Selenomethionine is also present in body proteins but this is derived from ingestion of this amino acid in plant foods or supplements such as yeasts (Schrauzer, 2000). Finally, other amino acids, such as hydroxyproline or *N*<sup>ε</sup>-methylhistidine, are also present in proteins. These arise via a post-translational modification of specific amino acid residues, which gives particular structural and functional properties to proteins; a good example of this relates to the vitamin K-dependent carboxylation of glutamic acid residues in a number of proteins involved in blood coagulation and bone matrix deposition (Ferland, 1998). However, the 20 common amino acids, along with a few others not in peptide-bound form, such as ornithine, citrulline, and taurine, are of more immediate interest in discussions of the nitrogen economy of the body and the protein and amino acid nutritional status of the human subject.

In addition to their role as substrates for polypeptide chain formation, amino acids serve multiple and diverse roles. Some of these are listed in Table 6.1. Many of these

roles have been recognized for some time but an important new development relates to an increased understanding of the mechanisms that account for the stimulation of specific or global protein synthesis by amino acids. It is now clear that amino acids, especially the branched-chain amino acid leucine, can affect the initiation of mRNA translation (Pain, 1996; Jousse *et al.*, 1999; Vishwannah *et al.*, 1999; Anthony *et al.*, 2000; Lynch *et al.*, 2000).

Tissue and organ protein content is also determined by the rate at which proteins are degraded. This overall process of protein degradation or breakdown plays many essential roles in the functioning of organisms, including, for example, cell growth, adaptation to different physiological conditions, elimination of abnormal or damaged proteins, and normal functioning of the immune system (Lecker *et al.*, 1999). Multiple pathways for protein breakdown occur in all cells, with the bulk of intracellular protein being degraded via the energy-dependent, ubiquitin-proteasome pathway. Here the proteins are digested to small peptides and amino acids within a multisubunit 20S proteasome, which, in association with a large 19S regulatory particle, forms the 26S complex. The proteasome may account for up to 1% of cellular proteins. This powerful proteolytic enzyme system cleaves peptide bonds in a unique way involving an ordered cyclical bite-chew mechanism. The ubiquitin-proteasome pathway is activated under a number of conditions, including fasting (Lecker *et al.*, 1999). Studies of whole-body protein turnover have shown that protein degradation is inhibited with feeding

**TABLE 6.1** Some functions of amino acids

Function	Example <sup>a</sup>
Substrates for protein synthesis	Those for which there is a codon
Regulators of protein turnover	Leucine, glutamine
Regulators of enzyme activity	Arginine and <i>N</i> -acetyl glutamate synthesis Phenylalanine and phenylalanine dehydroxylase activation
Precursor of signal transducer	Arginine, nitric oxide
Neurotransmitter	Tryptophan, glutamate
Ion fluxes	Taurine, glutamate, oxoproline
Precursor of nitrogen compounds	Nucleic acid, creatinine
Transporter of nitrogen	Glutamine, alanine, leucine (in the brain)
Translational regulator	Leucine (4E-BP1 and P70(s6k) via MTOR-dependent pathway)
Transcriptional regulator	Leucine limitation induces CHOP expression

<sup>a</sup>MTOR, Mammalian target of rapamycin; CHOP, CCAAT/enhancer binding protein (C/EBP) homologous protein.

and with increased protein intakes (Waterlow, 1995), although it remains unclear which organs and tissues contribute most to this decline, and the relative effect of the amino acids versus carbohydrate and other energy-yielding sources still is not entirely determined. For example, oral amino acids alone do not appear to alter the rate of protein breakdown in the vastus lateralis (Volpi *et al.*, 1999) whereas a mixed meal was shown to inhibit forearm muscle protein breakdown (Tessari *et al.*, 1996). Thus, it is possible, at least in muscle, that amino acids enhance the inhibitory effect of proteolysis because of a carbohydrate-induced rise in insulin availability (Flakoll *et al.*, 1989). In turn, insulin reduces proteolysis, possibly by decreasing ubiquitin-mediated proteasomal activity (Bennett *et al.*, 2000). The gut may be an important site of the meal-induced decline in whole-body protein breakdown (Tessari, 2000). In addition the balance of amino acids, or protein quality, may influence whole-body protein breakdown. In human low-birth-weight infants it has been shown that a higher quality amino acid mixture enhanced growth and amino nitrogen utilization by reducing whole-body protein breakdown and not by enhancing protein synthesis (Duffy *et al.*, 1981).

The other multiple functions of the different amino acids and their putative mechanisms of action will not be elaborated here because other accounts are available (Cynober, 1995; Fürst and Young, 2000). Two further points need to be made here. First, the functions of some of the amino acids can be varied and extensive, as indicated by the multiple functions played by glutamine (Box 6.1). These non-proteinogenic functions are relevant to dietary intake and requirement considerations, as suggested from the analysis made by Reeds (2000) and presented in Table 6.2. Some of the pathways of end-product production can substantially affect the overall utilization of the amino acid precursor (e.g. creatinine synthesis, glycine or glutathione synthesis, cysteine or glycine utilization). Second, from a nutritional perspective, in carrying out their roles as substrates in protein synthesis (e.g. for neurotransmitter signaling and detoxification functions) the amino acids turn over and part of their nitrogen and carbon is removed from the body via catabolic and excretory pathways. Thus, the maintenance of an adequate body protein and amino acid status requires a sufficient intake of some preformed amino acids together with a utilizable source of nitrogen for the synthesis of the other amino acids and for production of physiologically important nitrogen-containing compounds.

### BOX 6.1 Functions of glutamine

- Substrate of protein synthesis (codons; CAA, CAG)
- Anabolic and trophic substance for muscle, intestine (competence factor)
- Control for acid–base balance (renal ammoniogenesis)
- Substrate for hepatic ureagenesis
- Substrate for hepatic and renal gluconeogenesis
- Fuel for intestinal enterocytes
- Fuel and nucleic acid precursor and important for generation of cytotoxic products in immunocompetent cells
- Ammonia scavenger
- Possible substrate for citrulline and arginine synthesis, although in vivo proline appears to be used instead of glutamine/glutamate
- Nitrogen donor (nucleotides, amino sugars, coenzymes)
- Nitrogen transport (one-third circulating nitrogen) (muscle, lung)
- Precursor of  $\gamma$ -aminobutyric acid (via glutamate)
- Shuttle for glutamate (central nervous system)
- Preferential substrate for glutathione peroxidase production?
- Osmotic signaling mechanism in regulation of protein synthesis?
- Stimulator of glycogen synthesis
- Metabolism of L-arginine–nitric oxide

## Nutritional Corollaries of the Amino Acids

It is no longer thought useful to classify the amino acids into two groups – those that are nutritionally indispensable (essential) or dispensable (non-essential) – as was done originally by Rose (1948) based on a series of now-classical qualitative nitrogen-balance experiments in adult men. Instead it is better to classify amino acids into three groups, the original two plus a third that is intermediate and is called conditionally indispensable (Table 6.3) (Pencharz *et al.*, 1996). An obligatory dietary requirement exists for tryptophan, leucine, isoleucine, valine, phenylalanine, methionine, lysine, threonine, and histidine, or more specifically, for the ketoacid derivatives of the first five of these. The last three of this indispensable group of amino acids cannot be transaminated and so must be supplied in the diet as such. The other common amino acids in proteins can be synthesized from carbon and nitrogen donors: transamination of  $\alpha$ -ketoisocaproate, oxaloacetic acid, and

**TABLE 6.2** Potential contribution of functionally important end-product synthesis to amino acid needs in adult humans<sup>a</sup>

	Glutamate	Glycine	Cysteine ( $\mu\text{mol/kg/day}$ )	Arginine	Methionine
Precursor kinetics					
Plasma flux	4200	3960	1320	1800	528
Net synthesis	358	2730	96	180	168
End-product production					
Creatine		170		170	170
Taurine			7		
Nitric oxide				15	
Glutathione	550	550	550		

<sup>a</sup>Modified from Table 7 in Reeds (2000), where original references for these values are given.

**TABLE 6.3** Categorization of dietary amino acids<sup>a</sup>

Indispensable (Essential)	Conditionally indispensable (Conditionally essential)	Dispensable (Non- essential)
Histidine	Arginine	Alanine
Isoleucine	Cysteine	Aspartate
Leucine	Glutamine	Asparagine
Lysine	Glycine	Glutamate
Methionine	Proline	Serine
Phenylalanine	Tyrosine	
Threonine		
Tryptophan		
Valine		

<sup>a</sup>Modified from Pencharz *et al.* (1996).

pyruvate for glutamate, aspartic acid, and alanine, respectively; glycine from serine via serine hydroxymethyltransferase and serine from pyruvic acid; glycine from threonine; arginine from proline and glutamate; and asparagine from glutamine and aspartate. Tyrosine and cyst(e)ine are synthesized from their parent indispensable amino acids, phenylalanine and methionine, respectively. These two latter amino acids, tyrosine and cysteine, are included in the conditionally indispensable amino acid group together with glutamine, arginine, and perhaps glycine and proline, because each does not appear to be synthesized at a rate sufficient to meet cellular needs under certain physiological or pathological conditions (Jaksic *et al.*, 1991; Reeds *et al.*, 2000a). Thus, in severe burn injury, metabolic studies indicate that a dietary source of arginine is needed

to maintain arginine homeostasis; low-birth-weight infants are unable to synthesize cysteine, proline, and possibly glycine, in sufficient quantities (Pencharz *et al.*, 1996).

A more recent development concerns the possible need for a preformed source of  $\alpha$ -amino nitrogen. Hitherto, it had been considered that, if intake of the indispensable amino acids was sufficient, only a source of non-specific nitrogen – which might be in the form of a simple mixture, such as urea and diammonium citrate – would be needed additionally (Williams *et al.*, 1974). However, this may not be a sufficient description of what is actually required to sustain an adequate state of protein nutrition, for several reasons. The first relates to the utilization of urea nitrogen. Thus, recent emphasis has been given to a potentially key role played by the hydrolysis of urea nitrogen within the intestinal lumen (assumed to be largely a function of the activity of the microflora in the large bowel) and the significant contribution made by this liberated nitrogen to the nitrogen homeostasis of the host (Jackson, 2000). However, this concept has been questioned (Young *et al.*, 2000a) because in other studies the production of urea has been shown to increase linearly with increased protein intake, and the nitrogen released from urea via hydrolysis appears to have been rechanneled into pathways of urea formation. Thus, the extent to which urea nitrogen might be a net source of utilizable nitrogen, even under conditions of a low protein intake, remains unclear. Furthermore, as clearly outlined by Waterlow (1999), a great deal of uncertainty still exists about *in vivo* mechanisms responsible for both short- and longer-term regulation of urea production and therefore about the mechanisms responsible for maintenance of body protein balance.

It has been suggested that glutamate is a key amino acid in making net amino nitrogen available to the mammalian organism; this glutamate would be derived ultimately from plant protein (Young and Ajami, 2000; Pencharz and Young, 2006). Despite the significant role of glutamate as a nitrogen portal, it remains unclear whether a specific dietary need for glutamate exists if a sufficient amount of  $\alpha$ -amino nitrogen is supplied, for example, as alanine and for aspartate. This question cannot be answered unequivocally at present but it is clear that indispensable amino acids alone or in high concentration relative to the dispensable amino acids will not support adequate growth in experimental animals. In sum, a source of preformed  $\alpha$ -amino nitrogen from other than the indispensable amino acids and glycine appears to be required, but whether glutamate is needed specifically or would be a more efficient source of this  $\alpha$ -amino nitrogen than its homologues (Young and Ajami, 2000), for example, remains to be determined. Reeds (2000) reviewed a number of findings that revealed that diets completely devoid of glutamine and glutamate result in poorer growth in the otherwise healthy rat and pig, suggesting the possibility of a specific need for glutamate.

If the foregoing argument is correct, it introduces a new perspective on the nonspecific nitrogen component of the total protein requirement. In 1965, a Food and Agriculture Organization of the United Nations and the World Health Organization (FAO/WHO) Expert Group (1965) stated:

The proportion of non essential amino acid nitrogen, and hence the E/T [g total essential amino acids to total nitrogen] ratio of the diet, has an obvious influence on essential amino acid requirements . . . To make the best use of the available food supplies there is an obvious need to determine the minimum E/T ratios for different physiological states . . . Finally, the question arises whether there is an optimal pattern of non-essential amino acids.

This statement can just as well be repeated today, but recent studies are beginning to provide deeper insight into the nature of the non-specific nitrogen needs of the human body. Not only is there an optimal E/T, as noted above, but it now seems likely that there is a desirable qualitative character to the non-specific nitrogen supply – which raises the issue of the optimal sources and levels of  $\alpha$ -amino nitrogen compounds in enteral formulations. This issue, for example, includes considerations of glutamate–proline–arginine interrelations (Wu and Morris, 1998) not

only in terms of the nitrogen economy of the host but also with respect to specific functions such as capacity to maintain or stimulate the immune system and promote wound and tissue repair and the effect that non-specific nitrogen may have on polyamine and hormonal balance. The effect of a relatively high arginine intake in healthy subjects on arginine–citrulline–ornithine kinetics (Beaumier *et al.*, 1995) has been examined; although changes were not observed in the activity of the whole-body L-arginine–nitric oxide pathway, the generous level of arginine supplementation reduced rates of urea production and excretion and increased circulating insulin concentrations. How this apparent protein anabolic effect of high arginine supplementation is brought about (perhaps enhanced by insulin action) and what significance it has for the immune system are not known. Also, in light of current interest in immune-enhancing diets and the role arginine plays in aggravating or attenuating renal injury (Narita *et al.*, 1995; Reckelhoff *et al.*, 1997), there are many unresolved questions about the quantitative role played by the non-specific nitrogen component in supporting protein metabolism and function in the host.

## Postprandial Nitrogen and Amino Acid Utilization

The daily maintenance of body protein content is achieved through a complex set of integrated changes in rates of whole-body protein turnover, amino acid oxidation, urea production, and nitrogen excretion that occur at different rates during the postabsorptive, prandial, and postprandial periods of the 24-hour day (Millward and Pacy, 1995). Depending on diet composition, smaller or larger gains and losses of body proteins occur during the diurnal cycle of feeding and fasting. Amino acid and nitrogen requirements are met normally via ingestion of food proteins that undergo sequential metabolic and physiological processes. The processes include gastrointestinal digestion, peptide and amino acid absorption, transfer of amino acids into and among organs, and entry of the amino acids into metabolic pathways, quantitatively most notably into protein synthesis. We have termed this overall process the metabolic availability of dietary amino acids and have developed a method to determine the metabolic availability from protein in pigs (Moehn *et al.*, 2005) and in humans (Humayun *et al.*, 2007b; Elango *et al.*, 2009).

### Dietary Protein Nitrogen Distribution after Protein Ingestion

$^{15}\text{N}$ -labeled proteins have been used to follow the metabolic fate of dietary nitrogen after the ingestion of protein, and a number of these studies were summarized by Tomé and Bos (2000). As summarized in Figure 6.1, for  $\sim 100\text{ g}$  intake of well-balanced protein in the adult human, the fate of the dietary nitrogen is  $\sim 30\text{--}40\%$  directed to anabolism, with a  $17\text{--}25\%$  loss via oxidative metabolism. A detailed model – based on data for  $[^{15}\text{N}]$  nitrogen kinetics determined in the intestine, blood and urine after ingestion of  $^{15}\text{N}$ -labeled milk protein in humans – developed by Fouillet *et al.* (2000) predicted that, 8 hours after a meal,  $\sim 28\%$  of the nitrogen is retained as free amino acids and  $72\%$  as protein. Approximately  $30\%$  of this protein retention occurred in the splanchnic region and  $70\%$  in peripheral tissues. This type of approach involving use of intrinsically labeled proteins will continue to help define the factors, the mechanisms, and their quantitative significance that affect the postprandial utilization of ingested protein.

The extent and regulation of postprandial protein utilization has also been studied by acute  $^{13}\text{C}$ -leucine balance

studies (Millward, 2000). Although postprandial protein utilization is not influenced by adult age in a healthy population, it is affected by the quality of protein and size of meals (Millward, 2000). This tracer-based approach also has the potential for assessing efficacy of enteral formulations (e.g. in the nutritional support of institutionalized subjects and sick patients).

Among the additional factors that can influence the postprandial utilization of proteins is the time course of release and absorption of peptides and amino acids. This has led to the concept of slow and fast dietary proteins based on studies using  $^{13}\text{C}$ -leucine-labeled whey and caseins. Beaufrere *et al.* (2000) showed that postprandial whole-body leucine oxidation over 7 hours was lower with casein than with whey protein despite a similar leucine intake (i.e. the postprandial protein utilization for casein was higher than for whey). Both of these protein sources are of high quality in adult human nutrition. Hence, a difference in postprandial protein utilization under some circumstances might give a false indication of the comparative nutritional value of different formulations. Clearly, this new tracer-based metabolic paradigm requires further definition and standardization but in a general context it

**FIG. 6.1** Contribution of dietary protein to the principal pathways of protein metabolism.

promises to be a valuable tool for understanding the metabolic basis of the requirement for protein and amino acids.

The temporal nature of the amino acid supply or pattern of feeding influences the efficiency of nitrogen and amino acid utilization. Studies involving 24-hour [1-<sup>13</sup>C]leucine tracer balance determinations showed that daily leucine oxidation is lower when three discrete meals versus ten small hourly meals are given over a 12-hour period (El-Khoury *et al.*, 1995). This appears to be the case at both generous and limiting intakes of leucine, suggesting a better retention of oral amino acids with a less frequent meal intake. Whether this phenomenon might be explained by the so-called anabolic drive of amino acids (Millward and Pacy, 1995) cannot be determined yet, but it is evident that the pattern of protein and amino acid ingestion is a determinant of the efficiency of postprandial utilization. Furthermore, Arnal *et al.* (1999) showed in studies with elderly subjects that protein retention was higher when 80% of the daily intake was consumed at midday as compared with the daily protein supply given in four meals over 12 hours.

### **Amino Acid Utilization by the Splanchnic Bed and the Gut**

The intestines and liver modify the profile and amount of amino acids that disappear from the intestinal lumen and enter the portal and peripheral blood circulation. Although this has been known for some time, in recent years a more elaborate account of the quantitative removal and metabolic transformations of amino acids by the splanchnic region after their uptake from the lumen has been developed in humans and animal models, particularly those involving the use of different isotope tracer paradigms. For example, the combined use of tracers given orally and intravenously showed that the extent of uptake by the splanchnic region in adults differs among amino acids (Table 6.4) (Young *et al.*, 2000b) and that this might also depend on the level of amino acid intake. The uptake of cystine shown here is very high, which is consistent with the data obtained in the pig (Rerat *et al.*, 1992). The high uptake might also explain why the concentration of cysteine in the circulation shows little postprandial response to a wide range of cystine intakes (Raguso *et al.*, 1997).

Two important issues emerge from this rather global description of splanchnic amino acid metabolism, namely the relative importance of the gut versus the liver and the metabolic fate of the amino acids within these organ systems. This is a nutritionally important topic for several

**TABLE 6.4** Dual isotope tracer model estimates of splanchnic uptake of amino acids: fed state in healthy adults<sup>a</sup>

Amino acid (intake)	Uptake (% of intake)
Leucine (adequate)	21 ± 6
Leucine (low)	37 ± 5
Leucine (adequate)	10 ± 6
Phenylalanine (adequate)	25
Phenylalanine (low)	58 ± 4
Tyrosine (adequate)	37
Arginine (adequate)	34 ± 8
Methionine (adequate)	23 ± 2
Cystine	>50

<sup>a</sup>Modified from Young *et al.* (2000b) where references to original studies are cited.

reasons. First, for example, Bertolo *et al.* (1998) have concluded that the threonine requirement of neonatal piglets during parenteral nutrition is 45% of the mean oral requirement. This could be a result of one or a combination of factors, including a lower rate of threonine oxidation by intestinal tissues when threonine is given intravenously and also reduced losses of threonine by the gastrointestinal tract because of reduced mucin production, these glycoproteins being rich in threonine. Second, Boirie *et al.* (1997) reported that the splanchnic extraction of dietary leucine was twice as high in elderly men (50 ± 11%) as it was in young men (23 ± 3%), although whole-body leucine oxidation was similar for the two age groups. These investigators concluded that this difference in splanchnic uptake might limit the availability of leucine for peripheral tissue metabolism. On the other hand, Volpi *et al.* (1999), while also observing that the splanchnic extraction of oral phenylalanine was significantly higher in the elderly (47 ± 3%) than in the young (29 ± 5%), found that, after an oral amino acid mixture, muscle protein synthesis was stimulated similarly in the young and the elderly.

Our understanding of the role of the gut and liver as the components of the splanchnic bed have been advanced by work from the laboratories of Reeds *et al.* (2000b) and Brunton *et al.* (2000). From this work it is now apparent that the small intestinal enterocyte plays an active role in amino acid metabolism, including the biosynthesis of arginine (Wilkinson *et al.*, 2004). Arteriovenous differences and tracer studies have focused recently on the immediate fate of absorbed amino acids (Wu *et al.*, 1998; Reeds *et al.*, 2000b). From studies of the portal availability

of amino acids in pigs, Reeds *et al.* (2000b) concluded that the portal outflow varies widely among amino acids, with the portal balance of dietary threonine being consistently lower than that of other essential amino acids; nutritionally significant quantities of dietary glutamate and aspartate rarely appear in the portal blood (also, a net extraction of glutamine occurs across the gut, and systemic glutamate, aspartate, and glutamine are derived almost exclusively from synthesis within the body); and some amino acids either appear in quantities similar to those ingested in dietary protein (arginine and tyrosine) or greatly exceed them (alanine).

Further details concerning the relative contributions of the arterial and dietary sources of amino acids to amino acid utilization by the intestine are given by Reeds *et al.* (2000b). Particularly important are the observations that the total utilization of lysine, leucine, and phenylalanine by the portal drained viscera might account for >40% of the whole-body flux; the utilization of dietary glutamate, aspartate, and glutamine is considerable and these amino acids contribute significantly to intestinal energy transformation; intestinal oxidation of leucine and lysine in milk-fed piglets accounts for around one-fifth to one-third of whole-body oxidation; with protein restriction the intestine continues to use a disproportionately large amount of indispensable amino acids (Van Goudoever *et al.*, 2000); the gut is an important site for synthesis of citrulline (Wu, 1998) that is then used for arginine synthesis, especially in the kidney (Young and El-Khoury, 1995); and mucosal glutathione is synthesized mainly from enteral precursor amino acids (Reeds *et al.*, 2000b).

In summary, beyond doubt the intestine plays a quantitatively and qualitatively crucial role in determining the amino acid needs of the individual and the availability of amino acids for the support of the body's physiological and organ systems.

### Intestinal Amino Acid Synthesis

As reviewed recently by Metges (2000), the gastrointestinal microflora may make an important contribution to the status of nitrogen metabolism in the host. Tracer studies in animals and humans have shown a transfer of non-specific nitrogen (ammonia, urea nitrogen, glutamate, etc.) into dispensable and indispensable amino acids (Metges *et al.*, 1999b). For most amino acids this input of  $^{15}\text{N}$  from urea may reflect nitrogen exchange or reversible transamination. However, lysine and threonine do not

undergo transamination in mammalian tissues, so the appearance of  $^{15}\text{N}$ -labeled lysine or threonine in body proteins and plasma amino acids must reflect de novo synthesis of lysine and threonine by the intestinal microflora and the subsequent absorption of the labeled amino acids from the gastrointestinal tract. Comparative experiments with germ-free and conventional rats have confirmed that de novo synthesis of lysine is due to the activity of the indigenous microflora in the gastrointestinal tract.

However, a more cautious conclusion is possibly warranted. Although these recent studies (Metges *et al.*, 1999a) establish the significant presence of lysine and threonine of microbial origin in the plasma free amino acid pool, the quantitative significance of this source of amino acids is still unknown. Further, these new studies raise the question as to how various clinical states and diseases might affect the nutritional and metabolic interrelationships between the microbial flora of the intestine and the amino acid economy of host tissues.

### Nitrogen (Protein) Requirements

Requirements for protein (and for amino acids) are determined by the change in physiological outcome to graduated intakes (Pencharz and Ball, 2003) (see Figure 6.2). As is detailed by Pencharz and Ball (2003) and by Elango *et al.* (2008a), it is important that each subject be studied across a full range from below the requirement level to

**FIG. 6.2** Determination of amino acid (protein) requirements – patterns of response. DAAO, direct amino acid oxidation; IAAB, indicator amino acid balance; IAAO, indicator amino acid oxidation.

significantly above it. This approach was introduced by our group (Pencharz and Ball, 2003; Elango *et al.*, 2008a) but it has been adopted by others (Kurpad *et al.*, 2003, 2005, 2006). Further this response should be analyzed using non-linear regression. In practice we have found that two-phase linear regression crossover analysis is the best way of defining the average population requirement (Pencharz and Ball, 2003; Elango *et al.*, 2008b). Until recently the approach used to determine protein requirements was based on the nitrogen balance seen in response to graded intakes of protein (Institute of Medicine, 2002/2005; FAO/WHO, 2007; Humayun *et al.*, 2007a). Expert committees have reported recently from the National Academy of Sciences (Institute of Medicine, 2002/2005) and the United Nations Food and Agriculture Organization and World Health Organization (FAO/WHO, 2007) in which the relationship between protein intake and nitrogen balance was analyzed using monoliner regression. The author was a member of both expert committees but the closer I looked at the data the more reservations I had. Hence I and my colleagues recently reanalyzed this data using non-linear regression and published results that show that adult protein requirements have been underestimated by around 30% (Humayun *et al.*, 2007a; Elango *et al.*, 2010). In addition to this reanalysis of the nitrogen balance data, we introduced the use of indicator oxidation to determine protein requirements in humans (Humayun *et al.*, 2007a). The two independent approaches both showed that the mean adult population protein requirement was ~0.91 g/kg/day rather than the 0.66 g/kg/day reported by the expert committees (Institute of Medicine, 2002/2005; Campbell *et al.*, 2008). Our observations require confirmation from other groups, but the correspondence of the two independent methods is strong evidence that current protein recommendations are in error.

These observations raise the question as to whether protein requirements in other age groups are also in error. Except for the first 6 months of life when the intake of protein from human milk was used, protein requirements were based on nitrogen balance studies. Those in childhood were based on much more limited data than that available in adults (Institute of Medicine, 2002/2005; Campbell *et al.*, 2008). Because of the uncertainty, we have omitted a table of protein requirements that was in the previous version of this chapter (Pencharz and Young, 2006). The mean value of 0.91 g/kg/day using the same variance as used by the DRI and FAO of 12% would,

however, suggest an RDA or safe level of 1.0 g/kg/day. The protein intakes from human milk were estimated by the FAO/WHO (2007) report to range from 1.77 g/kg/day at 1 month to 1.14 g/kg/day at 6 months.

There are those who have written that the protein requirements in the elderly may be higher than in younger adults, approaching requirement values of 1 g/kg/day (Millward and Roberts, 1996; Millward *et al.*, 1997; Campbell *et al.*, 2008). However, when young adults and elderly subjects were studied using the same nitrogen balance techniques, no differences were seen (Campbell *et al.*, 2008). Hence, with our reappraisal of the mean protein requirements for young adults of 0.91 g/kg/day, we expect that future studies will show similar levels in the elderly.

## Requirements for Indispensable Amino Acids

The expert committees at the National Academy of Sciences (Institute of Medicine, 2002/2005) and the United Nations (FAO/WHO, 2007) concluded that the indicator amino acid oxidation (IAAO) approach (Figure 6.2) should be the standard used, and the older nitrogen balance data was not used. At the time, a modification of IAAO, namely 24-hour indicator oxidation and balance, should be preferred over the fed-state IAAO, principally because the 24-hour studies had a week's adaptation to the changes in the test amino acid intake. It has subsequently been shown that the length of adaptation needed was only a matter of a few hours and hence that the fed-state IAAO model was valid (Elango *et al.*, 2008a, 2009). This opened the way to applying the IAAO model to children (Kurpad *et al.*, 2003; Elango *et al.*, 2007; Hsu *et al.*, 2007; Pillai *et al.*, 2010). Table 6.5 summarizes the adult indispensable amino acid requirements. Currently there are no studies reported determining amino acid requirements in the elderly. Clearly, this matter requires attention.

Prior to the application of IAAO to the determination of the amino acid requirements of children there were studies that reported using nitrogen balance. These are reviewed in the expert committee reports (Institute of Medicine, 2002/2005; FAO/WHO, 2007). Since, in the view of the expert committees, the data were limited, the nitrogen balance data were not used and instead a factorial approach was employed, based on the adult requirement plus that required for growth. Our recent studies in children for lysine (Elango *et al.*, 2007; Pillai *et al.*, 2010),

**TABLE 6.5** Amino acid requirements in healthy adults

Amino acid <sup>a</sup>	Indicator amino oxidation based <sup>b</sup>	Dietary reference intakes (2002/2005)	FAO/WHO/UNU (2007)
Histidine	–	11	10
Isoleucine	42	15	20
Leucine	55	34	39
Lysine	35	31	30
Methionine + cystine	13	15	15
Phenylalanine + tyrosine	42	27	25

Tryptophan	4	4	4
Valine	47	19	26

<sup>a</sup>Values expressed as mg/kg/day.

<sup>b</sup>Modified from Elango *et al.* (2008b).

branched chain amino acids (Mager *et al.*, 2003) and methionine (without cysteine) (Turner *et al.*, 2006) provide confirmation of the factorial approach. As mentioned earlier in this chapter in the protein requirement section, sufficient levels need to be tested in order to apply two-phase linear regression analysis. In some cases the 24-hour IAAO studies did not have enough levels, and, as can be seen in Table 6.5, the DRI and FAO/WHO/UNU values are significantly lower than those derived by fed-state IAAO with a full range of intake values. The growth component of amino acid requirements is small so that except in infancy the maintenance level dominates (Mager *et al.*, 2003; FAO/WHO, 2007).

### Excessive Intakes of Protein and of Amino Acids

The upper limit of protein intake in adults has been set at no more than 30% of total energy intake (Institute of Medicine, 2002/2005, to which the reader is referred for full details). Briefly, consideration of maximal urea synthesis rates and observations of explorers who lived on exclusively animal-based diets provided the basis for this recommendation. For example, early American explorers suffered in the winter from “rabbit starvation” when they subsisted on a diet of rabbit meat which contains very little fat (Institute of Medicine, 2002/2005), resulting in protein intakes greater than 30% of total energy intake.

Data on excessive intakes of individual amino acids are limited except for phenylalanine where most of the data are centered on brain damage in persons with phenylketonuria. A recent review of available information on this topic, which systematically considers all amino acids, can be found in a report from the Institute of Medicine (2002/2005). An approach to the determination of the upper limits of amino acid intakes can be found in a previous report by Pencharz *et al.* (2008).

### Protein Malnutrition

Protein is the fundamental component for cellular and organ function (Institute of Medicine, 2002/2005). The diet must contain not only enough protein and amino acids but also enough non-protein energy to permit optimal utilization of dietary protein (Duffy *et al.*, 1981). Protein energy malnutrition (PEM) is quite common in the world as a whole and has been reported by the United Nations Food and Agriculture Organization in 2000 to be associated with 6 million deaths in children (FAO, 2000). In the industrialized world PEM is seen predominantly in hospitals and in association with disease (Bistrrian, 1990; Wilson and Pencharz, 1997; Institute of Medicine, 2002/2005).

Protein deficiency has adverse effects on all organs (Cornish and Kennedy, 2000) and is of particular concern in infants and young children. PEM may have long-term adverse effects on brain function (Pollitt, 2000). Patients with PEM have reduced immune function and are hence more susceptible to infection (Bistrrian, 1990). Total starvation will result in death in an initially normal-weight adult in 70 days (Allison, 1992); since these persons still had some adipose tissue reserves, their death can be regarded as primarily being due to protein deprivation. By way of contrast, protein and energy reserves are much lower in very-low-birth-weight premature infants, and with total starvation the survival of 1000-g neonates has been calculated to be only 5 days (Heird *et al.*, 1992).

### Conclusion

Knowledge continues to grow about the physiology of protein and amino acid metabolism in the mammalian organism and especially in relation to human protein and amino acid nutrition. This chapter has focused attention on selected recent advances in relation to amino acid function and protein and amino acid utilization during the

prandial and postprandial period of amino acid metabolism. The importance of the gut and the splanchnic region as a whole in the regulation of whole-body amino acid metabolism has become better appreciated and understood. Now that the postgenome era has begun, the mechanisms underlying the effect of amino acids on physiological functions and metabolic processes – including transport, catabolism, and anabolic processes – will soon be more completely described. There remains uncertainty about quantitative aspects of amino acid nutrition, especially in healthy adults, but there is now a consensus that the current international requirement estimates for adults are far too low. This has potentially important implications for the evaluation of dietary protein quality and for the planning, now and in the future, of food protein supplies for population groups. Improved in vivo metabolic tools combined with molecular and cellular techniques appear to offer great promise for resolving some of the outstanding issues that limit our ability to predict precisely the effect of the dietary protein and amino acid component on function and the quantitative and qualitative character of the intake that optimizes development and health maintenance.

## Future Directions

The issue of whether protein requirements have been significantly underestimated is important, especially since the underestimation of protein requirements of children in the developing world may be a key factor in stunting. There is a general consensus about this underestimation, but it is not universally accepted and more work is needed to confirm it. This will then lead to the need to evaluate protein requirements in a variety of conditions, including pregnancy and aging, taking into account the need for appropriate periods of adaptation to a new level of amino acid intake.

Another area of interest is the metabolic availability of amino acids from dietary protein, which was the focus of an FAO Expert Committee meeting in early 2011. The potential cause for concern is that defining protein requirements using crystalline amino acids may not be readily applicable to dietary protein without clear knowledge of the metabolic availability for protein synthesis of the amino acids within that protein.

Finally since health food stores are selling and promoting the ingestion of large doses of amino acid supplements, it is important that the safe upper limit of amino acid requirements be determined.

## Acknowledgments

We are grateful to the late Dr Vernon Young (a former author of this chapter) for his stimulation and encouragement, and to the Canadian Institutes for Health Research for their support of our work in the areas of protein and amino acid metabolism and requirements.

## CARBOHYDRATES

LISA M. SANDERS<sup>1</sup>, PhD, RD AND JOANNE R. LUPTON<sup>2</sup>, PhD

<sup>1</sup>*Kellogg Company, Battle Creek, Michigan, USA*

<sup>2</sup>*Texas A&M University, College Station, Texas, USA*

### Summary

Carbohydrates are the primary energy source for most people in the world. This makes carbohydrate *quality* a critical issue, since those who consume too few calories need nutrient-dense carbohydrate sources so that every calorie counts; and those who consume too many calories also need high-quality carbohydrates since they cannot afford to waste calories on less nutritious sources. This chapter reviews the primary classifications of carbohydrates (mono-, di-, oligo-, and polysaccharides; glycemic and non-glycemic; and endogenous or added sugars). It tracks their digestion, absorption, and metabolism. It translates the biochemistry of carbohydrates into physiological effects and explains the most current recommendations for carbohydrate intake and the science behind those recommendations. Finally, intake of carbohydrates is related to key diseases including obesity, diabetes, cardiovascular disease, and cancer.

### Introduction

Carbohydrates, which are found in fruits, vegetables, grains, and dairy products, are the major source of energy for most of the world's population. However, the role of carbohydrates in human health extends beyond their importance as an energy source. Carbohydrates vary tremendously in structure and physiological function, and much of the recent carbohydrate research has focused on these differences and their impact on chronic diseases such as diabetes and heart disease. Within the past several years, this research has led to the development of significant nutrition public-policy recommendations regarding carbohydrate intake for optimal health.

### Carbohydrates in the Food Supply

Carbohydrates have traditionally been accepted as compounds containing carbon, hydrogen, and oxygen in a molar ratio of 1:2:1. As this definition is not universal for all carbohydrates (e.g. sugar alcohols and some polysaccharides), it is more precise to define carbohydrates as polyhydroxy aldehydes, ketones, alcohols, and acids that exist as monomeric units or as polymers. The degree of polymerization is frequently used as a system by which to classify carbohydrates, with the major classes being monosaccharides and disaccharides (commonly referred to as sugars), oligosaccharides, and polysaccharides.

## Sugars

### Monosaccharides

According to the Food and Agriculture Organization of the World Health Organization (FAO/WHO, 1998) the term “sugars” refers collectively to monosaccharides, disaccharides, and sugar alcohols. Monosaccharides include glucose, fructose, and galactose, which are found naturally in small amounts in fruits, vegetables, and honey. However, over the past 30 years, corn syrups and high-fructose corn syrup (HFCS) have replaced refined sugars (such as sucrose) as a major source of monosaccharides in the American diet because of their increased use by the food industry as a low-cost sweetener (White, 1992). Corn syrups contain only individual glucose units. The term “high-fructose corn syrup” is accurate, but in some ways it is misleading since many interpret this to mean that there is more fructose than would be in an equivalent amount of table sugar (sucrose). The reason for the word “high” is that it contains more fructose than corn syrup, which is only glucose. However, compared with sucrose, which is 50% glucose and 50% fructose, it is not high. HFCS is made by hydrolyzing corn starch to individual glucose units and then using enzymes to convert glucose to fructose. The final corn syrup is made up of either 42% or 55% fructose, with the remaining sugars being glucose and higher sugars. HFCS-55 is predominant in carbonated soft drinks, whereas HFCS-42 is found in canned fruits, baked goods, flavored milks, yogurt, and ice cream (White, 1992; Hanover and White, 1993).

### Disaccharides

Disaccharides consist of two monosaccharides covalently linked by a glycosidic bond. The major dietary disaccharides include sucrose (glucose + fructose) and lactose (glucose + galactose). Sucrose occurs naturally in plants, but most often is consumed as an extract of sugarcane or beet. Sucrose is widely used as a sweetener and preservative. Milk and other dairy products are the only source of lactose. Maltose and trehalose, both disaccharides of glucose (differing only in the configuration of the glycosidic bond), are also present in small amounts in the food supply. Maltose is found in wheat and barley, and is also a product of starch hydrolysis. Trehalose is found in yeast products, mushrooms, and crustacean seafood.

### Sugar Alcohols

Also commonly referred to as polyols, sugar alcohols are derived from the hydrogenation of mono- and disaccha-

rides, and include sorbitol, mannitol, xylitol, isomalt, lactitol, maltitol, and erythritol. Polyols are not as easily digested as other sugars, so they produce a lower glycemic response and a reduced caloric value. Additionally, sugar alcohols are less cariogenic than other carbohydrates (FDA, 1997). As a result, the food industry often uses sugar alcohols as bulk sweeteners to produce low-calorie or sugar-free candies, chewing gum, baked goods, sauces, jams, jellies, beverages, and frozen desserts.

### Oligosaccharides

Carbohydrates with three to nine degrees of polymerization (i.e. three to nine monosaccharide units) are classified as oligosaccharides. Some oligosaccharides occur naturally in plants: stachyose and raffinose in soybeans and other legumes and fructooligosaccharides in fruits, vegetables, and grains (e.g. wheat, rye, onions, bananas, and garlic). However, because of their usefulness as food ingredients and their possible health benefits, an increasing number of oligosaccharides are now synthesized from sugars or obtained through extraction and/or partial hydrolysis of longer-chain plant polysaccharides. These manufactured oligosaccharides, such as inulin extracted from chicory root, can be found in a number of food items such as dairy products (e.g. yogurt), breads, beverages, and dessert foods. Being fairly resistant to digestion in the small intestine, oligosaccharides display physiological effects similar to fiber, and some appear to promote the growth of beneficial colonic microflora. Additionally, as a food additive, they do not change the texture or taste of the product significantly, making them ideal for creating healthier products with limited alteration in taste or mouth feel (Meyer, 2004).

### Polysaccharides

The majority of carbohydrates consumed in the food supply are polysaccharides. As the name implies, these carbohydrates have a high degree of polymerization, ranging from 10 sugar units to several thousand. Polysaccharides can be subdivided into starch and non-starch polysaccharides.

### Starch

Starch is a polymer of glucose units covalently bound by either  $\alpha$ -(1,4) or  $\alpha$ -(1,6) linkages. Amylose contains only  $\alpha$ -(1,4) bonds and thus maintains a constant linear form. Amylopectin contains  $\alpha$ -(1,6) bonds in addition to  $\alpha$ -(1,4) bonds, allowing for a highly branched structure.

Starch is the primary storage form of carbohydrate in plants, but is found primarily in grains and grain products (e.g. cereals, corn, flour, and rice) and in some root vegetables (e.g. potatoes and beets) and legumes. Most other vegetables and fruits contain very little starch.

**Resistant Starch.** While most starch is digested and absorbed in the small intestine, a small portion escapes digestive enzymes and passes into the colon, where it may be fermented. This is referred to as resistant starch. There are four types of resistant starch, which either occur naturally or are a consequence of food processing. Resistant starch-1 (RS1) is present in the cell walls of plants, but is physically inaccessible to digestive enzymes such as  $\alpha$ -amylase. It is most frequently found in whole grains, whole-grain products (e.g. breads and cereals), seeds, and legumes. The amount of RS1 in a food is decreased by processing techniques such as milling and refining. Raw starch granules that are resistant to digestive enzymes due to their crystalline structure and size are classified as RS2. These can be found in raw potatoes and green bananas. Food processing, particularly gelatinization (making starch more soluble using heat, water, and/or enzymes), increases the accessibility of starch to digestive enzymes, thereby decreasing the amount of RS2. Because RS1 and RS2 occur naturally in plants, they are considered dietary fiber by some. RS3 and RS4 are both formed during food processing and do not occur naturally. RS3, also called retrograded starch, is formed during the cooking and cooling or extrusion process of starchy foods such as potatoes, rice, and cereals. RS4 is chemically modified starch, such as starch esters, starch ethers, and cross-linked starches, which are manufactured by the food industry to impart desired characteristics to food products such as color, temperature stability, and altered viscosity (Tunland and Meyer, 2002).

### Non-Starch Polysaccharides

Similar to resistant starch, non-starch polysaccharides also escape digestion and absorption in the small intestine and are fermented in the colon. However, their resistance to digestion is due not to physical or structural barriers to digestive enzymes, but rather to the lack of enzymes capable of breaking the glycosidic bonds between the monomeric units. As a result of their indigestibility, non-starch polysaccharides are considered dietary fiber and include cellulose, hemicelluloses (e.g.  $\beta$ -glucans), gums

and mucilages, and pectins. For more detailed information, see Chapter 8 on dietary fiber in this book.

### Other Classifications of Carbohydrates

One of the difficulties in the classification of carbohydrates is reconciling their chemical composition with their physiological functions. Each of the chemical classes described above contains carbohydrates with varying physiological effects, some of which overlap among the categories (e.g. the indigestibility and colonic fermentation of oligosaccharides and non-starch polysaccharides). This can create confusion for the consumer and the food industry with regard to dietary guidelines, labeling guidelines, and health claims, and has therefore resulted in new terminology and classifications for dietary carbohydrates.

### Added Sugars

Added sugars are sugars and syrups that are added to foods during processing or preparation (USDA, 2005). This does not include sugars that occur naturally in the food, such as lactose in milk or fructose in fruits. Added sugars are typically in the form of white table sugar, brown sugar, corn syrup, HFCS, molasses, honey, pancake syrups, fruit-juice concentrates, and dextrose. The major sources of these sugars include soft drinks, fruit beverages, candy, and sugar-sweetened grain-based dessert items, which account for 72% of the US added sugar intake (Figure 7.1) (Marriott *et al.*, 2010). Non-diet soft drinks account for 33% of added sugars in the American diet (Marriott *et al.*, 2010). Most of these food items also have lower micronutrient densities than foods and beverages with naturally occurring sugars. Therefore, beginning in 2000, the Dietary Guidelines for Americans included the term “added sugars” to assist consumers in identifying foods that are high in added sugars. Currently, US food labels are not required to distinguish between naturally occurring sugars and those that are added to the food. This is because there is a lack of methods for differentiating between naturally occurring and added sugars. Thus it is difficult for the consumer to identify the amount of added sugars they are getting in their foods.

### Glycemic and Non-Glycemic Carbohydrates

This classification system is based on the digestibility of carbohydrates and thus their ability to provide glucose to the body for metabolism. Glycemic carbohydrates are digested and absorbed in the small intestine, thereby increasing blood glucose for metabolism by tissues, whereas

**FIG. 7.1** Percent contribution of different food categories to added sugar intake. Data from Marriott *et al.* (2010).

non-glycemic carbohydrates remain undigested and pass into the colon where they can be fermented. Non-glycemic carbohydrates may still provide energy through fermentation; however, this energy is not in carbohydrate form such that it would alter blood glucose levels. Sugars and starches make up most of the glycemic carbohydrates, and oligosaccharides, resistant starches, and non-digestible polysaccharides (fiber) constitute the non-glycemic carbohydrates. The rate at which different glycemic carbohydrates are absorbed can also be measured and will be discussed further in the following section.

## Digestion and Absorption of Carbohydrates

### Digestion

Enzymatic digestion of carbohydrates begins immediately when food is placed in the mouth. Salivary  $\alpha$ -amylase hydrolyzes the glycosidic bonds between glucose moieties in starches to yield glucose, maltose, and other starch fragments. Once food enters the stomach, salivary amylase is inactivated and carbohydrate digestion pauses. In the small intestine, pancreatic  $\alpha$ -amylase completes the digestion of starch to glucose, maltose, maltotriose (a trisaccharide), and dextrans, oligosaccharide units containing one or more

$\alpha$ -(1,6) linkages. All carbohydrates must be broken down to individual monosaccharide units before absorption is possible. Therefore, bound to the brush border of the small intestine are enzymes that hydrolyze dextrans, trisaccharides, and disaccharides to their respective monosaccharides for absorption. These enzymes include glucoamylase, maltase, lactase, and sucrase, which hydrolyze dextrans, maltose, lactose, and sucrose, respectively. A deficiency of disaccharidases in the intestine can occur in rare genetic disorders such as sucrase–maltase deficiency and alactasia (absence of lactase). These deficiencies typically result in diarrhea, abdominal pain, and/or gas following the consumption of sucrose or lactose, and the condition can generally be controlled by removing the indigestible disaccharides from the diet or by predigestion of the sugars with commercially available enzymes (e.g. lactase). Additionally, the expression of the lactase enzyme decreases in most humans following weaning, allowing undigested lactose to reach the colon where it is fermented. This fermentation can result in the generation of gases, causing abdominal discomfort and possibly diarrhea. However, not all lactase activity is lost, as in the case of alactasia, and small amounts of milk products can be tolerated without adverse side effects according to the 2010 National Institutes of Health (NIH) Consensus

Development Conference on lactose intolerance and health (Suchy *et al.*, 2010).

Any carbohydrates that are not digested (e.g. resistant starches and fiber) pass into the colon, where they can be fermented by the colonic microflora to short-chain fatty acids and gases such as hydrogen, carbon dioxide, and methane. Again, more information can be found on this process in Chapter 8 on dietary fiber.

### Absorption

Monosaccharide absorption occurs in the small intestine by one of two mechanisms: active transport and facilitated diffusion. At the brush-border surface, glucose and galactose are actively transported from the lumen into the enterocyte by a sodium/glucose co-transporter, SGLT1. In this process, glucose and galactose move against a concentration gradient, while sodium moves down a concentration gradient. The sodium gradient is maintained by pumping sodium out of the enterocyte at the basolateral membrane, a process requiring energy in the form of ATP. Fructose absorption at the brush border occurs passively and is facilitated by one of the GLUT family of glucose transporters, GLUT5. The GLUT5 uniporter has a high affinity for fructose and appears to move glucose very poorly. Once inside the enterocyte, movement of monosaccharides across the basolateral membrane and into the bloodstream is a passive process and is facilitated by GLUT2 and GLUT5 uniporters (Wright *et al.*, 2003). GLUT2 facilitates the movement of all three monosaccharides into the bloodstream, while GLUT5 appears to again be specific to fructose.

Mutations in these monosaccharide transporters, while rare, can lead to clinical disorders such as glucose–galactose malabsorption and Fanconi-Bickel syndrome. Glucose–galactose malabsorption, a congenital disorder, occurs when a defective SGLT1 transporter prevents the absorption of glucose and galactose, resulting in severe diarrhea when sugars and starches containing these monosaccharides are consumed. Treatment of this condition requires the removal of glucose and galactose from the diet, but fructose consumption may continue because there is no impairment of fructose absorption in this disorder. Fanconi-Bickel syndrome results from a congenital defect in the GLUT2 transporter. In addition to the intestine, GLUT2 is also expressed in the liver, kidney, and pancreas. Therefore, loss of function of this transporter results not only in monosaccharide malabsorption, but also in widespread systemic effects such as tubular

nephropathy, hepatomegaly, and rickets (Wright *et al.*, 2003).

### Glycemic Index and Response

As mentioned previously, glycemic carbohydrates are those that stimulate an increase in blood glucose levels after their digestion and absorption. This change in blood glucose over time is called the “glycemic response.” A number of factors can influence the glycemic response to foods, including the nature of the carbohydrate consumed, the rate of digestion and absorption, the rate of clearance from the bloodstream, and the presence of other food components (e.g. fiber, fat, and protein). In an effort to better understand how different foods impact the glycemic response, Jenkins *et al.* (1981) proposed the use of the glycemic index (GI) as a relative indicator of blood glucose response to the carbohydrate contained in a particular food. The GI is determined by comparing the blood glucose response (area under the curve) of a test food containing a specified amount of available carbohydrate to a standard food containing the same amount of carbohydrate. The response to the test food is then expressed as a percentage of the response to the standard to give the GI. Originally, glucose or white bread was the traditional reference standard, but over time other standards have been used, such as rice and potato. Many of these foods can have different glycemic responses due to differing factors, including variety of the grain used and cooking conditions. As a result, GI values have become more difficult to interpret and compare as the same food may have a different GI based on what reference standard is used.

Foods are sometimes categorized into “high” and “low” GI foods based on their glycemic response. Typically, high-GI foods would include items with easily digested starches (e.g. refined grains and potatoes), free glucose, or large amounts of disaccharides rapidly hydrolyzed to glucose. Alternatively, low-GI foods (e.g. unprocessed grains, non-starchy fruits, and vegetables) would contain more slowly digested or resistant starches or higher fiber content, or are rich in free fructose. Low-GI foods may also be high in fat, which slows carbohydrate digestion and absorption. A limitation of classifying foods by GI is that human subjects can have highly variable glycemic responses to the same food. Even the same person can vary in their glycemic response from day to day (FAO/WHO, 1998). This variation is often large enough that a food could transition from a “low” GI food to a “high” GI food if tested in different people or in the same subject on different days.

**TABLE 7.1** Glycemic index based on glucose as index food. Glycemic load is calculated as the glycemic index multiplied by the grams of carbohydrate per serving and divided by 100.

Food	Glycemic index	Glycemic load
Apple	36 ± 3	5
Banana	48 ± 3	11
Cake, chocolate with frosting	38 ± 3	20
Carrot	92 ± 20	6
Kidney beans	34 ± 6	9
Lentils, red	26 ± 4	5
Macaroni and cheese	64	33
Oatmeal	55 ± 7	14
Orange juice	50 ± 2	12
Peaches, canned in light syrup	52	9
Peanuts	7 ± 4	0
Popcorn, plain	65 ± 5	7
Potato, baked	76	23
Raisin bran	61 ± 5	12
Rice, long grain	75 ± 7	28
Soda, non-diet	63	16
Spaghetti	38 ± 3	18
White bread	70	10
Whole milk	40	4

Data from Atkinson *et al.* (2008).

Considering some of the limitations in the measurement of GI, its utility and accuracy as a marker of carbohydrate quality are highly debated. Nevertheless, the GI has been determined for a number of foods (Atkinson *et al.*, 2008; see Table 7.1) and has become more frequently used with limited success in studies relating carbohydrate intake to chronic disease, as will be discussed later in this chapter.

## Metabolism of Carbohydrates

### Energy Value of Carbohydrates

Traditionally, carbohydrates have been assigned an energy value of 4 kcal/g (17 kJ/g). This value is derived from Atwater's calculations of the heat of combustion of carbohydrates from various food commodities (Merrill and Watt, 1973). However, the actual caloric values of carbohydrates can vary from practically zero in the case of some fibers (e.g. gums and cellulose) to 4.2 kcal/g for most digestible starches. Most sugars have a lower caloric value than starches, ranging from 3.75 to 3.95 kcal/g. The great-

est difficulty has come in assigning caloric values to non-digestible polysaccharides and oligosaccharides, which are primarily fermented in the colon. Short-chain fatty acids produced by fermentation (e.g. acetate, propionate, and butyrate) are quickly metabolized and therefore provide a source of energy. However, the amount of energy varies with the degree of fermentability. Smith *et al.* (1998) determined metabolizable energy values for several non-starch polysaccharides with values ranging from 0 to 2.3 kcal/g. The FAO/WHO consultation on carbohydrates recommended that the energy value for carbohydrates that enter the colon be set at 2 kcal/g (FAO/WHO, 1998). Polyols are also incompletely absorbed and thus provide fewer calories than most other digestible carbohydrates. The caloric values of polyols range from 0.2 to 3 kcal/g (Warshaw and Powers, 1999); however, for labeling purposes, the European Union has established a standard value of 2.3 kcal/g for sugar alcohols, whereas the United States assigns values on an individual-case basis (Zumbe *et al.*, 2001). The American Diabetes Association (2000) advises health professionals to use a value of 2 kcal/g for sugar alcohols.

### Fate of Absorbed Monosaccharides

Absorbed monosaccharides are transported through the bloodstream to tissues, where they are used as an energy source. Cellular uptake is achieved by GLUT transporters. All three monosaccharides can be taken up in the liver by non-insulin-dependent GLUT2 transporters (Scheepers *et al.*, 2004). In the liver, galactose is phosphorylated and converted to glucose-1-phosphate, the precursor for glycogen synthesis. Fructose is phosphorylated to an intermediate in the glycolytic pathway (fructose-1-phosphate). As it continues through the glycolytic pathway, it will be cleaved to form dihydroxyacetone phosphate and glyceraldehyde. These intermediates can then continue through glycolysis or, under certain conditions, serve as precursors for glycogen and triglyceride synthesis. Glucose is also taken up by most cells in the body to be used for energy. A number of tissue-specific isoforms of GLUT transporters are responsible for glucose uptake, including: GLUT2 in the liver, pancreas, kidney, and small intestine; GLUT3, primarily in the brain; GLUT4, in insulin-sensitive tissues such as adipose and skeletal muscle; and GLUT1, which is ubiquitously expressed but predominates in erythrocytes and the brain. Many other glucose transporters have been identified and are more thoroughly discussed by Scheepers *et al.* (2004).

### Glycolysis

The initial steps in the metabolism of glucose, which occurs in the cytoplasm of all cells, is called glycolysis, and results in the generation of ATP and two three-carbon molecules of pyruvate. If the cell is under anaerobic conditions (or lacks mitochondria in the case of erythrocytes), pyruvate will be reduced to lactate and exported to the liver for gluconeogenesis (the Cori cycle). Under aerobic conditions, pyruvate can enter the mitochondria and be decarboxylated to acetyl coenzyme A, which then enters the citric acid cycle. This cycle completes the catabolism of glucose to carbon dioxide and water, accompanied by the oxidation of coenzymes (NAD<sup>+</sup> and FAD), which can then pass off their electrons in the electron transport system to generate large amounts of ATP.

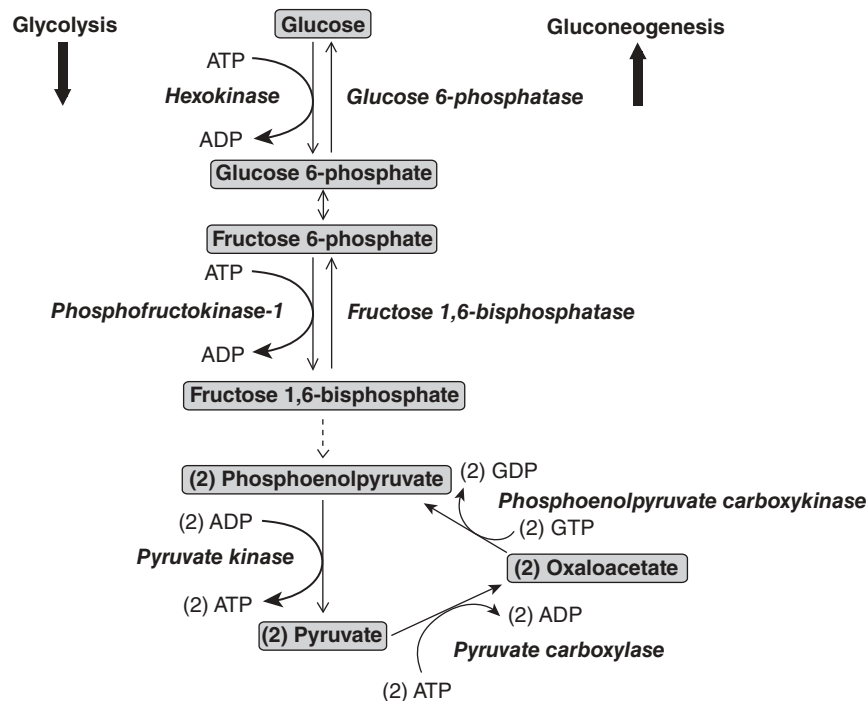

### Gluconeogenesis

Because glucose is the primary energy source for the body, it is critical that blood glucose levels be maintained (70–100 mg/dL or 3.9–5.5 mmol/L) to supply tissues with needed fuel. Glucose can be generated from a number of precursors, including pyruvate, lactate, glycerol, and most amino acids. The synthesis of glucose is basically a reversal

of glycolysis, with many of the same enzymes utilized; however, gluconeogenesis occurs only in the liver and kidney. The glucose produced is then released into the bloodstream for use by all tissues.

### Regulation of Glycolysis and Gluconeogenesis

A number of controls are present in the glycolytic and gluconeogenic pathways to insure that adequate energy is supplied to cells and that blood glucose levels are maintained. These controls include allosteric and/or covalent modification of key enzymes, alterations in the expression of enzymes, and hormonal regulation. The three key regulatory enzymes in the glycolytic pathway are glucokinase/hexokinase, phosphofructokinase-1, and pyruvate kinase. Because these steps in glycolysis are irreversible, the gluconeogenic pathway utilizes four corresponding enzymes (glucose 6-phosphatase, fructose 1,6-bisphosphatase, phosphoenolpyruvate carboxykinase, and pyruvate carboxylase), which are also irreversible in the pathway of glucose generation. These “paired” enzymes are regulated such that the stimulation of one coordinates with the inhibition of the other (Figure 7.2). For example, elevated blood glucose levels will positively affect the glycolytic

**FIG. 7.2** Glycolysis and gluconeogenesis pathways. Left side of the diagram represents glycolysis, and the right side represents gluconeogenesis. Dashed arrow represents steps that were left out of the diagram.

enzyme glucokinase/hexokinase, while simultaneously inhibiting the activity of glucose 6-phosphatase, the corresponding gluconeogenic enzyme.

These enzymes are also subject to hormonal regulation by insulin, glucagon, epinephrine, and glucocorticoids. Insulin, an anabolic hormone, is secreted by the  $\beta$ -cells of the pancreas in response to an increase in blood glucose, such as that which follows a carbohydrate-containing meal. Insulin acts to decrease blood glucose levels by increasing glucose uptake by tissues and by decreasing gluconeogenesis by the liver. To increase tissue uptake, insulin triggers the translocation of GLUT4 receptors to the cell surface in skeletal muscle and adipose tissue. Insulin also stimulates each of the regulatory enzymes in the glycolytic pathway, while also inhibiting the key enzymes of gluconeogenesis. An increase in glucose storage in the form of glycogen is also stimulated by insulin. Glucagon, epinephrine, and glucocorticoids are counter-regulatory hormones to insulin, and are released when blood glucose levels are low, such as during fasting or starvation. Glucagon, produced by the  $\alpha$ -cells of the pancreas, and epinephrine and glucocorticoids, produced by the adrenal gland, enhance gluconeogenesis and glycogenolysis (release of glucose from glycogen storage) and inhibit glycolysis. Epinephrine also increases lipolysis during fasting (McGrane, 2000).

### **Storage of Glucose**

The liver and skeletal muscle are able to store excess glucose in the form of glycogen, a branched-chain glucose polymer. The liver is able to store 10% of its weight as glycogen, while skeletal muscle stores approximately 1% (McGrane, 2000). When blood glucose levels fall, the breakdown of liver glycogen is triggered and the glucose released is used to maintain blood glucose levels. During continued fasting, the liver will be depleted of its glycogen stores within 24 hours. Skeletal muscle glycogen can be broken down and used as fuel by the skeletal muscle, which occurs primarily during exercise. Skeletal muscle glycogen is not as effective as liver glycogen at normalizing blood glucose levels during fasting; however, lactate generated in the muscle can be circulated to the liver for gluconeogenesis. Glycogen synthesis and degradation are regulated by hormones, as described in the previous section.

### **Contribution to Amino Acid and Triglyceride Synthesis**

Some metabolites of glucose, such as pyruvate and intermediates in the citric acid cycle, can be used in the syn-

thesis of certain amino acids. Additionally, fatty acids can be formed from oxaloacetic acid and acetyl-coenzyme A (cleavage products of the tricarboxylic acid cycle intermediate citrate). Intermediates in the glycolysis pathway can be modified to serve as the glycerol backbone for triglycerides.

### **Inborn Errors in Metabolism**

A number of disease states associated with deficiencies or genetic defects in certain key enzymes responsible for carbohydrate metabolism have been characterized. Some errors in metabolism, such as those involved in fructose or galactose metabolism, are discovered early and are treated by removal of those monosaccharides from the diet. However, genetic defects in enzymes involved in gluconeogenesis or glycogenolysis are much more life-threatening because individuals with these diseases suffer from frequent hypoglycemia, hepatomegaly, and acidosis. Treatment typically involves small, frequent feedings of carbohydrate to prevent hypoglycemia and acidosis.

## **Carbohydrate Requirements and Recommendations**

In 2002 the US Institute of Medicine established a recommended dietary allowance (RDA) for carbohydrates of 130 g/day for adults and children which is based on the average minimum amount of glucose used by the brain (Institute of Medicine, 2002). This recommendation was based on human studies in which arteriovenous gradients of glucose were measured with estimates of brain blood flow. Although there is not an absolute requirement for glucose, since the brain can switch to using ketone bodies (primarily from fat metabolism), the 130 g/day represents a recommendation that would not require the brain to resort to the use of ketone bodies. This RDA is not the recommendation for overall carbohydrate intake, but rather the recommendation for what is needed by the brain. Most people consume well over the RDA for carbohydrate.

A second recommendation for carbohydrate is the acceptable macronutrient distribution range (AMDR) value of 45% to 65% of total calories in the form of carbohydrate (Institute of Medicine, 2002). The low end of the range was set to allow for sufficient intake of dietary fiber, which would be very difficult to obtain from foods below a level of 45% of calories coming from carbohydrate since all fiber (with the exception of lignin) is carbohydrate. Also, as the intake of one macronutrient gets too

low, another macronutrient (either fat or protein in this case) could become too high. There was concern that less than 45% of calories from carbohydrate could result in the intake of excess fat, which in turn could contribute to obesity. At the higher end of the range (65% of calories from carbohydrate), the concern was hypertriglyceridemia and that intakes of fat or protein could be too low.

There is also an adequate intake (AI) value for total fiber of 14g/1000 calories, which equates to 38g/day for men under 50 and 25g/day for women under 50. The fiber recommendation was based on decreased risk of coronary heart disease with higher-fiber diets.

### **Added Sugars Recommendations**

The dietary reference intake (DRI) macronutrient report (Institute of Medicine, 2002) made a recommendation that added sugar intake should not exceed 25% of total calories. This recommendation was based on diminishing intake of micronutrients as the percent of calories from added sugars increased. Although the significant “drop-off” in micronutrient intake was not always at the 25% added sugar intake level for each age and gender group, the overall pattern showed a decline at the 25% intake level. Since the release of the Macronutrient Report in 2002, the 2010 US Dietary Guidelines Advisory Committee (DGAC) completed an evidence-based review of human studies on added sugar intake, particularly from sugar-sweetened beverages, and the relationship to energy intake and body weight (DGAC, 2010). Sugar-sweetened beverages were targeted as numerous studies (Block, 2004; Wang *et al.*, 2008; Bleich *et al.*, 2009; Nelson *et al.*, 2009; Duffey *et al.*, 2010) show them to be the largest contributor of energy in the US and intake has increased significantly since the 1970s. Likewise the prevalence of obesity has also increased since the 1970s. The 2010 DGAC reviewed 14 scientific articles published since 1990 (including systematic reviews, randomized control trials and prospective observational studies) which evaluated intake of sugar-sweetened beverages and energy intake and body weight. The panel concluded the following (DGAC, 2010):

Limited evidence shows that intake of sugar-sweetened beverages is linked to higher energy intake in adults. A moderate body of epidemiological evidence suggests that greater consumption of sugar-sweetened beverages is associated with increased body weight in adults. A moderate body of evidence suggests that under isocaloric controlled conditions, added sugars, including sugar-sweetened

beverages, are no more likely to cause weight gain than any other sources.

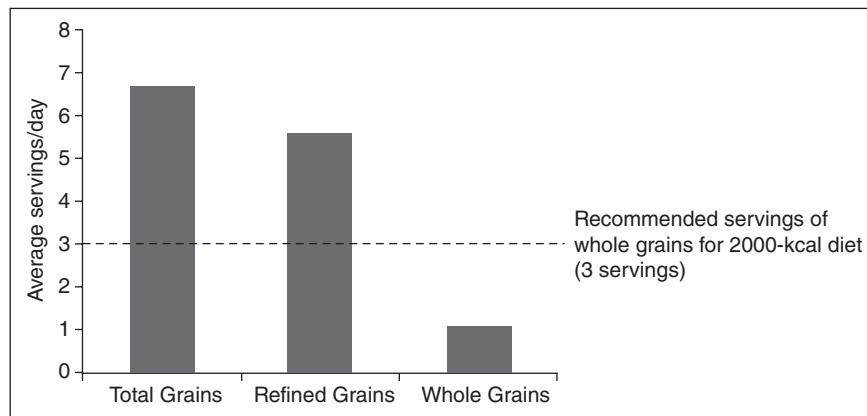

While the 2010 DGAC acknowledged that some studies show an association between added sugars from sugar-sweetened beverages and weight gain, they concluded it was not possible to determine if the relationship was due specifically to added sugars or just a result of increased caloric consumption. Furthermore, additional calories from added sugars are not different from calories from other sources in the diet. The DGAC recommended reducing intake of added sugars from multiple sources as a strategy to reduce caloric intake in the US population (DGAC, 2010).

### **Whole-Grain Recommendations**

In continuation of the 2005 Dietary Guidelines recommendation to increase whole-grain servings to three per day at the expense of refined grains (USDA, 2005), the 2010 DGAC reviewed literature published since June 2004 examining the relationship of whole-grain intake to cardiovascular disease, type 2 diabetes and body weight (DGAC, 2010). What constitutes a whole grain as opposed to a refined grain? Whole grains consist of the entire kernel or seed of the grain, which consists of three components: the bran layer (which contains most of the fiber), the endosperm (which is primarily starch), and the germ (which contains some fat and other nutrients). When whole grains are refined, most of the bran and germ are lost, leaving the endosperm. Refined grains are then enriched with thiamin, riboflavin, iron, and niacin, fortified with folic acid, and are called “enriched grains.” Whole grains do not have to be intact in the food product to be called “whole grains” but they do have to have the same ratio of bran to endosperm to germ as they had in the intact kernel. Based on the new data that they reviewed, they concluded (DGAC, 2010):

A moderate body of evidence from large prospective cohort studies shows that whole-grain intake, which includes cereal fiber, protects against cardiovascular disease. Limited evidence shows that consumption of whole grains is associated with a reduced incidence of type 2 diabetes in large prospective cohort studies. Moderate evidence shows that intake of whole grains and grain fiber is associated with lower body weight.

Considering that most Americans are consuming large amounts of predominantly refined grains (Lin and Yen, 2007), the recommendation was made to replace refined grains with fiber-rich whole grains in the diet. An

**FIG. 7.3** Typical US consumption of total, whole and refined grains based on USDA report on grain consumption (Gibson, 2008). For someone consuming 2000 kcal/day, the 2005 dietary guidelines recommended six total servings of grain per day with at least half of these servings from whole grains. The typical US consumer is eating more grains than recommended, and the majority of those servings are from refined grains.

emphasis was placed on fiber-rich whole grains since not all whole grains or whole-grain foods are high in fiber. For example, brown rice and corn are both whole grains; yet a typical half-cup serving of either contains less than 2 g of fiber. Also foods made from these whole grains, such as rice cakes or corn chips, are also often low in fiber. While there is evidence that whole grains, independent of fiber, have beneficial effects on health, the DGAC acknowledged that when studies on the bran and or/germ components of grain were included with the whole-grain evidence, the scientific support for the health benefit (e.g. CVD) became stronger.

### Current Intakes

According to statistics from the FAO/WHO (1998), carbohydrate consumption worldwide ranges from 40% to 80% of energy intake. Most industrialized countries fall at the bottom of this range, whereas underdeveloped countries fall closer to the top of the range. Approximately 50% of carbohydrates consumed are in the form of starch, but this proportion is higher in countries where starches and grains are staple food items. Industrialized nations have shown an increase in sugar intake to 20% to 25% of calories from sugars, and a substantial portion of these calories are from added sugars such as corn syrups and sucrose. In the US, 13% of the population currently consumes more than 25% of their calories from added sugars (Marriott *et al.*, 2010).

Whole-grain consumption varies worldwide. Food consumption data from the USDA indicates that most Americans only consume around one serving of whole grains per day and only 7% of the population meets the recommended three servings per day (Lin and Yen, 2007). Most Americans are consuming more than the recommended amounts of total grains, indicating overconsumption of refined grains (Figure 7.3). Studies in Scandinavian populations show consumption of whole-grain foods to be almost four times the amount consumed in the United States (Lang and Jebb, 2003).

## Carbohydrates in Chronic Disease

### Energy Balance and Obesity

While the evidence is limited, a number of epidemiological studies have shown an increased intake of added sugars to be associated with an increase in overall energy intake and body weight (DGAC, 2010). Several studies have estimated that consumption of sugar-sweetened beverages in adults adds approximately 200–275 excess calories per day (Reid *et al.*, 2007; Stookey *et al.*, 2007; Duffey *et al.*, 2010). However, when compared with other sources of energy (e.g. fat), calories from added sugars are no more likely to cause weight gain (Vartanian *et al.*, 2007; Gibson, 2008). Since non-diet soft drinks are the largest source of added sugars in the US diet and consumption has increased (Block, 2004), much of the recent research has focused on

this area. Vartanian *et al.* (2007) conducted a systematic review and meta-analysis of 88 studies that investigated the effect of sweetened-beverage consumption on energy intake and body weight. While the size of the effect was small, there was a significant relationship between added sugars and energy intake and body weight. Alternatively, a recent review by Ruxton *et al.* (2010) concluded that there is no relationship between added sugar intake and BMI. Many of the discrepancies in these different reports are due to differences in how the reviews were conducted as well as differences in the methods used to measure intake and body weight in the studies. Despite limited evidence, the DGAC recommended that reduction of added sugars from all sources in the diet is advisable to control caloric intake (DGAC, 2010).

Recently, more attention has become focused on different sources of added sugars in the diet (e.g. HFCS, sucrose, fructose, glucose, etc.). A recent workshop reviewed the science in this area and determined key areas that need further investigation. Research was presented and there was scientific agreement that the metabolic effects of HFCS and sucrose are similar. However, it was determined that more science is needed to directly compare the effects of fructose with those of other sweeteners with regard to energy metabolism and chronic disease endpoints. As fructose is metabolized differently from glucose, some research suggests fructose may contribute more than other sweeteners to weight gain or other chronic diseases, such as type 2 diabetes, but more research is needed directly comparing the different monosaccharides (Murphy, 2009).

A few short-term studies have linked low glycemic index diets to weight loss, but longer term controlled studies show no difference in weight loss compared with other calorically restricted diets (e.g. low-fat diets) or high glycemic index diets (DGAC, 2010). Based on these data, the DGAC concluded that there is “strong and consistent evidence that glycemic index and/or glycemic load are not associated with body weight and do not lead to greater weight loss or better weight maintenance” (DGAC, 2010).

The impact of carbohydrates on satiety has also been investigated as a means of controlling energy intake. The glucostatic theory, introduced in the 1950s, suggested that blood glucose levels impacted appetite. When blood glucose levels were high, feelings of satiety were increased and when blood glucose dropped, this triggered feelings of hunger. It has been shown that consuming carbohy-

drates prior to a meal does increase satiety and decrease caloric intake at the next meal. However, this same effect can be seen when protein or fat is given prior to a meal, independent of the glycemic effect. Furthermore, comparisons of high and low glycemic index foods showed no differences in satiety, energy intake, or weight loss (DGAC, 2010).

### **Diabetes and Insulin Sensitivity**

Diabetes is a disorder of carbohydrate metabolism characterized primarily by hyperglycemia resulting from ineffective uptake of glucose by tissues. Type 1 diabetes is an autoimmune disease that typically occurs early in life and results in total loss of insulin production, whereas type 2 diabetes develops over time as tissues develop a resistance to insulin, and insulin release from the pancreas slowly diminishes. As carbohydrates have the greatest effect on blood glucose of all macronutrients, their role in the development of diabetes has been closely examined. Evidence from prospective studies with follow-up periods as long as 16 years have shown no relationship between the amount of carbohydrate in the diet and the development of diabetes. However, recent studies have evaluated the intake of added sugars, particularly from sugar-sweetened beverages, on the incidence of type 2 diabetes and found mixed results. Some studies looking specifically at sugar-sweetened beverages have found a positive relationship to intake and the development of type 2 diabetes (Schulze *et al.*, 2004; Ruxton *et al.*, 2010). However, studies evaluating overall sugar intake as well as intake of overall carbohydrate and refined grains found no association with type 2 diabetes (Meyer *et al.*, 2000; Janket *et al.*, 2003). In most studies the positive association between sugar intake and diabetes is attenuated when overall energy intake is accounted for, suggesting that it is the excess calories provided by the added sugar intake that may be the primary contributor.

Whole grains and dietary fiber, particularly cereal fiber, have been shown in a number of epidemiological studies to be inversely associated with the risk of type 2 diabetes (de Munter *et al.*, 2007). In fact, it appears that the risk reduction due to whole grains may be attributed, in part, to the fiber or bran content of the whole grain (de Munter *et al.*, 2007). One systematic review of six different epidemiological studies, totaling 286 125 people, found that increasing intake of whole grains by two servings per day resulted in a 21% decrease in risk for type 2 diabetes (de Munter *et al.*, 2007).

A number of recent prospective studies have shown mixed results as to an association of glycemic index with type 2 diabetes (DGAC, 2010). Whereas several have shown a positive association of glycemic index and incidence of type 2 diabetes (Schulz *et al.*, 2006; Villegas *et al.*, 2007; Halton *et al.*, 2008), the same number of studies show no association or a negative association (Stevens *et al.*, 2002; Hodge *et al.*, 2004; Barclay *et al.*, 2007; Mosdøl *et al.*, 2007; Sahyoun *et al.*, 2008). Similarly, glycemic load has shown an inconsistent association with the incidence of type 2 diabetes.

### **Cardiovascular Disease and Blood Lipids**

Several epidemiological studies have found a consistent relationship between increased intake of whole grains and reduced risk of cardiovascular disease (CVD) (DGAC, 2010). Additionally, when studies on added bran/germ are included, these inverse relationships are strengthened, suggesting that the fiber content of the whole grain may play an important role in CVD prevention. However, there may be additional bioactive components in whole grain that may act synergistically with the fiber to contribute to the prevention of CVD (Liu *et al.*, 1999; De Moura *et al.*, 2009). The primary mechanisms by which whole grains have been shown to influence CVD is through lowering of blood lipids and decreasing blood pressure. Additional biomarkers of enhanced antioxidant protection and decreases in inflammation have also been suggested as part of the protective mechanism of whole grains against CVD, but have not been confirmed (Brownlee *et al.*, 2010, DGAC, 2010).

There have been no well-established associations between sugar intake and CVD; however, some prospective studies have shown a positive association between sugar-sweetened beverage intake and certain markers for CVD (Malik *et al.*, 2010). Most of these studies report increased incidence of hypertension and hypertriglyceridemia with increasing intakes of sugar-sweetened beverages. Only one study has found a positive association between sugar-sweetened beverage intake and coronary heart disease in women, but adjustment for energy intake attenuated these associations, indicating a contribution of increased energy intake with elevated sugar intake (Fung *et al.*, 2009).

### **Cancer**

Carbohydrate intake has not been shown to be strongly linked to cancer incidence, with the exception of colorectal

cancer. Generally, diets high in refined carbohydrates and sugars appear to increase the risk of colon cancer whereas diets high in whole grains appear to be protective (USDA, 2005). Numerous studies in the past 5 years have evaluated the association of glycemic index and cancers of the stomach, ovary, breast, pancreas, and colon. A review of this literature by the 2010 DGAC found that “evidence for an association . . . is overwhelmingly negative” (DGAC, 2010).

### **Future Directions**

A tremendous amount of scientific research and many regulatory changes have occurred in the past decade in the area of carbohydrates’ impact on health. Yet there remain areas where research and regulatory clarification are needed. A critical area is establishing a universally accepted definition for whole grains. There is currently inconsistency in how whole-grain foods are defined, which makes it difficult to assess the true effect of whole grains on health when different studies use different inclusion criteria for what constitutes a whole-grain food. Furthermore, an acceptable definition for whole grains would also help consumer understanding and assist them in meeting the dietary recommendations. Future research should also examine the role of other bioactive components (phenolics, etc.) in whole grains beyond just the fiber portion that may be contributing to some of the health benefits seen with whole grains. Additionally, much recent research has focused on liquid calories, such as sugar-sweetened beverages, and the variety of beverages on the market has vastly increased in recent years. The 2010 DGAC recognized that the methods for reporting liquid calories in epidemiological studies should be better developed in order to accurately determine the contribution of carbohydrate sweeteners to energy intake and health endpoints. An important issue to resolve is the substitution of carbohydrates for saturated fats and whether or not that substitution results in an improved blood lipid profile and subsequent decreased risk of coronary heart disease. There has also been a rapid rise in high-throughput technologies, such as metabolomics, that may lead to the discovery of new biomarkers of health and/or disease and a better indication of how carbohydrates may impact disease and metabolic pathways that may lead to disease.

## DIETARY FIBER

IAN T. JOHNSON, PhD

*Institute of Food Research, Norwich, UK*

### Summary

Dietary fiber is a collective term for the many carbohydrate polymers that escape hydrolysis by human digestive enzymes, enter the large bowel and contribute to fecal bulk, either directly or after fermentation by gut bacteria. The presence of dietary fiber within the partially digested intraluminal food matrix modifies gastrointestinal function at every stage of the digestive process, but the physiological effects of the different components of the fiber complex vary, depending upon their physical properties and their chemical interactions within the gut lumen. By modifying the rate and site of nutrient absorption, and by increasing fecal mass and delivering fermentation products to the circulation, the various components of the dietary fiber complex can modify human metabolism to a degree which is of major significance for health. Dietary fiber contributes to the maintenance of normal bowel function, and epidemiological evidence suggests that high intakes are associated with reduced incidences of various dyslipidemias, with type 2 diabetes and coronary heart disease, and with several abnormalities of the metabolic syndrome, which predisposes to these major pathologies. In spite of recommendations by public health bodies to consume higher levels of fiber, average intakes remain low in most industrialized countries. There is a continuing need for research to clarify the mechanisms of action of fiber of most relevance to human alimentary and metabolic health, and to facilitate increased levels of fiber intake at all ages, both by public health initiatives and through the development of novel sources and products.

### Introduction

Early physicians were well aware that human bowel movements were influenced by the foods eaten, and knew that some constituents of the diet remained undigested in the alimentary tract. Hippocrates, in the fourth century BC, is said to have recommended the consumption of breads made from unrefined flour. During the nineteenth century

in the USA, the brothers J.H. and W.K. Kellogg developed food products based on the perceived benefits of whole-grain cereals, but the formal scientific investigation of the various different sources of carbohydrates in the human diet really began with the work of McCance and Lawrence, who first quantified what they termed the “unavailable carbohydrate” component of plant foods, by which they meant those carbohydrate polymers that, unlike starch,

cannot be hydrolyzed by human digestive enzymes (McCance and Lawrence, 1929). The modern concept of “dietary fiber” emerged in the early 1970s, when two colonial medical officers, Denis Burkitt and Hugh Trowell, building on ideas and observations by Cleave (1974), Walker (1949), and others, popularized the hypothesis that many chronic non-infectious diseases of Western society were caused by consumption of diets that lacked adequate quantities of polysaccharides derived from the cell walls of plants used as human foods (Burkitt and Trowell, 1975). This hypothesis was focused initially on the physiology and health of the alimentary tract, but it was soon broadened in scope to include mechanisms related to the prevention of other metabolic and systemic disorders. In the last 35 years much epidemiological research has been carried out to test the fiber hypothesis at the population level, and an immense amount of experimental work has been done to explore the physiological properties and metabolic effects of fiber in humans and animal models. This chapter is concerned with the definition, composition and analysis of dietary fiber, with its physiological effects, both within and beyond the alimentary tract, and with our current understanding of its importance for the maintenance of human health. The use of dietary fiber in the treatment of disease is discussed only where it is relevant to these overall objectives.

## The Definition, Composition, and Analysis of Dietary Fiber

“Dietary fiber” is a collective term for various carbohydrates that escape digestion in the human small intestine. This concept seems simple enough, and yet its unexpected complexities have delayed the development of an agreed formal definition of dietary fiber for over 40 years. The term was probably first used by Hipsley, in an early paper on toxemia of pregnancy (Hipsley, 1953), but both the concept of dietary fiber and its broader implications became more widely recognized with papers by Painter and Burkitt on the causes of diverticular disease (Painter and Burkitt, 1971), and by Trowell, on dietary fiber and ischemic heart disease (Trowell, 1972b). In his paper, Trowell defined dietary fiber simply as “that portion of food which is derived from cellular walls of plants which are digested very poorly by human beings” but a growing awareness of the chemistry of plant cell walls prompted the development of a more precise definition published by

Trowell and colleagues in 1976: “The sum of the lignin and the plant polysaccharides that are not digested by the endogenous secretions of the mammalian digestive tract (Trowell *et al.*, 1976).

Apart from starch, which is the principal storage polysaccharide in plants used as human foods, plant polysaccharides function as the mechanical, supportive elements of tissues and cell walls. They vary considerably in composition and structure, both between plant varieties, and between tissues within the same plant, but they consist mainly of polymers of glucose, galactose, arabinose, xylose, and uronic acids. Cellulose is a linear polymer of beta-linked glucose molecules. Individual polymers, which attain molecular weights of a million Daltons or more, aggregate by means of hydrogen bonding to form cellulose fibrils. A typical, relatively thin, plant cell wall from the undifferentiated parenchyma cells of fruits and vegetables is composed of cellulose fibrils within a matrix of water-soluble polymers of galactose and arabinose and various branching xylose polymers. In supporting tissues, the mechanical strength of the cells is increased by the deposition of additional cellulose and matrix polysaccharides, and in vascular tissues the cell walls are toughened by deposition of a highly complex phenolic compound, lignin. In cereals and other seeds, which provide a very high proportion of the carbohydrates in human diets, the outer polysaccharide layers, forming the bran in cereals, are often thickened and strengthened by lignin and other complex polyphenolic substances. A simplified illustration of the distribution of non-starch polysaccharides and starch granules within the main tissues of a grain of wheat is given in Figure 8.1.

The physical properties of the various polysaccharides differ widely, but they all consist of polymers of beta-linked saccharides, completely resistant to hydrolysis by human digestive enzymes. A summary of the major components of dietary fiber and their sources in the human diet is given in Table 8.1. Lignin, which is a branching polymer of phenyl propane units rather than a polysaccharide, is included in most definitions of dietary fiber, largely because of the difficulty of separating it from cell-wall polysaccharides during analysis. It contributes relatively little to the total mass of fiber in foods, but its presence is very important because of its effects on the physical properties of the polysaccharides with which it is associated.

The development of analytical methods for fiber in foods soon drew attention to the fact that a significant

**FIG. 8.1** The distribution of the major non-starch polysaccharides, and starch granules, within the major tissues of a typical wheat grain. Adapted from Waldron and Selvendran (1990).

**TABLE 8.1** Major sources and components of dietary fibre in the human diet

Food source	Non-starch polysaccharides	Associated substances
Cereal grains	Cellulose, branched arabinoxylans, xyloglucans, beta-glucans, glucomannans	Lignin, phenolic esters
Leguminous seeds	Cellulose, xyloglucans, mannans, galactomannans, pectic substances	Oligosaccharides
Vegetables and fruits	Cellulose, xyloglucans, pectic polysaccharides	Lignin, suberin, glycoproteins
Manufactured foods	Galactomannan gums (guar, locust bean), beta-glucans, pectins, alginates, carageenans, modified cellulose gums (carboxymethyl cellulose, methyl cellulose)	

proportion of dietary starch resists hydrolysis by pancreatic amylase. Subsequent research has confirmed that some starch escapes digestion in the small intestine and enters the colon together with intact cell-wall polysaccharides. Starch is chemically quite distinct from cell-wall polysaccharides because the two glucose polymers of which it is composed, amylose and amylopectin, both contain only alpha linkages, which are rapidly and completely hydrolysed by human digestive enzymes. In practice, however, the digestion of starch in the human small intestine is often incomplete (Asp *et al.*, 1996). Englyst and Cummings (1988) developed a technique for the complete removal of starch from the cell-wall polysaccharides during analysis, and recommended that dietary fiber should always be defined as *non-starch polysaccharides* (NSP), with *resistant starch* quantified and reported sepa-

rately. An alternative view is that, since the behavior of resistant starch in the alimentary tract is physiologically similar to that of cell-wall polysaccharides, it should be regarded as dietary fiber and included in the definition (Asp, 1987).

The task of defining dietary fiber became increasingly complex during the 1980s with the widespread use of isolated and purified non-starch polysaccharides, both as research tools and later as food constituents. For example, the galactomannan polymers, guar gum, locust bean gum, and carob bean gum, are storage polysaccharides from leguminous seeds that have long been used in small quantities as thickening agents in foods. Though very different in their physical properties from the structural polysaccharides of plant cell walls, these water-soluble and often viscous polysaccharides also remain undigested in the

small intestine, and can exert important effects on digestive physiology. Another group of carbohydrates that have grown in importance as food constituents since the concept of dietary fiber was first proposed are the beta-linked oligosaccharides with chain lengths of three or more saccharide units. These include natural food constituents such as inulin, and purified or synthetic galactose and fructose oligosaccharides used to stimulate the growth of beneficial bacteria in the colonic microflora (prebiotics). Again, since these carbohydrates resist digestion in the small intestine and are readily fermented by the colonic microflora, many argue that they should be included in the general definition of dietary fiber (Flamm *et al.*, 2001), whereas others have maintained that they should be excluded because of their low molecular weight and general lack of similarity to the structural polysaccharides of plant cell walls (Englyst *et al.*, 2007).

Recent definitions of dietary fiber have been designed to take account of the full range of carbohydrates that resist human digestive enzymes and exert beneficial physiological effects. The definition published by the Institute of Medicine of the National Academy of Sciences of the USA makes a distinction between *dietary fiber*, defined as “non-digestible carbohydrates and lignin that are intrinsic and intact in plants” and *functional fiber*, which consists of isolated, non-digestible carbohydrate components that have beneficial physiological effects in humans (Institute of Medicine, 2005). Oligosaccharides, whether from natural or synthetic sources, are excluded from the first category but can be included in the second. Under this scheme, *total dietary fiber* is defined as the sum of dietary and functional fiber. A scientific panel of the European Food Safety Authority published a statement on dietary fiber in 2007, in which it noted that in practice no analytical technique was available to distinguish between dietary fiber and functional fiber when they occur as a mixture in food products, and recommended a simple definition of dietary fiber as “all carbohydrates occurring in foods that are non-digestible in the human small intestine” (European Food Safety Agency, 2007). In 2009 the Commission on Nutrition and Foods for Special Dietary Uses of the Codex Alimentarius Commission, which is the food regulation arm of the World Health Organization, adopted a new definition of dietary fiber for the guidance of national governments when formulating their own legislation. The definition (FAO/WHO Food Standards Programme Codex Committee on Methods of Analysis and Sampling, 2010) is as follows:

Dietary fibre means carbohydrate polymers with ten or more monomeric units, which are not hydrolysed by the endogenous enzymes in the small intestine of humans and belong to the following categories:

- Edible carbohydrate polymers naturally occurring in the food as consumed,
- Carbohydrate polymers, which have been obtained from food raw material by physical, enzymatic or chemical means and which have been shown to have a physiological effect of benefit to health as demonstrated by generally accepted scientific evidence to competent authorities,
- Synthetic carbohydrate polymers which have been shown to have a physiological effect of benefit to health as demonstrated by generally accepted scientific evidence to competent authorities.

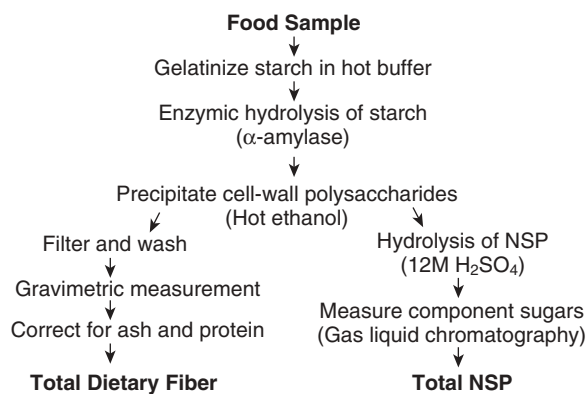

This definition does include both resistant starch and purified polysaccharide supplements, but it excludes all oligosaccharides with degrees of polymerization (DP) between 3 and 9. However, a pragmatic footnote to the definition states that a “decision on whether to include carbohydrates from three to nine monomeric units should be left to national authorities.”

### **The Analysis of Dietary Fiber in Foods**

Clearly the definition of fiber and the design of analytical methods to quantify it in foods are closely related problems. The earliest methods for fiber analysis were developed to measure the indigestible fraction of animal feeds (Goering and Van Soest, 1970). Among such methods, the neutral detergent fiber technique has been applied most frequently to human foods (Van Soest *et al.*, 1991), but it suffers from the disadvantage that soluble polysaccharides, including pectin, are not included in the analysis. To overcome this and similar problems, Southgate developed a method for the analysis of unavailable carbohydrates in foods (Southgate, 1969), based on enzymatic hydrolysis of polysaccharides and analysis of the liberated sugars by colorimetry, and this was used to determine the values in the fourth edition of the official UK food tables, *The Composition of Foods*, published in 1978 (Paul and Southgate, 1978). This approach was refined by Englyst and colleagues (Englyst *et al.*, 1982), who used carbohydrate analysis by gas liquid chromatography (GLC) to obtain a more definitive analysis of the residual non-starch polysaccharides (NSP) after the removal of starch. This definition of dietary fiber, which is much narrower than the more recent definitions described above, was used in

later editions of the UK food tables. Asp *et al.* (1983) and Prosky *et al.* (1984) published methods that relied on gravimetric analysis (i.e. by weight) of residual undigested carbohydrates, after enzymatic hydrolysis and correction for protein and ash. This approach formed the basis for the Association of Official Analytical Chemists (AOAC) method (Prosky *et al.*, 1988) for total dietary fiber (TDF). Standardized versions of the AOAC method are used in the USA, and have now become widely accepted and officially endorsed for routine use elsewhere (FAO, 2010). Variants of both the NSP and TDF methods also support the analysis of *soluble fiber* as a separate component of the total figure. However, the validity of this distinction is problematic because solubility in water is, without other information, a poor predictor of physiological activity, and it is usually not known whether the fraction defined as soluble fiber *in vitro* is actually solubilized in the gut lumen during digestion of foods. A report on carbohydrates published by FAO/WHO in 1998 suggested that the distinction between insoluble and soluble fiber should be phased out (FAO, 1998), but the terminology is still widely used, both in food tables and research papers.

The essential characteristics of the two principal approaches to dietary fiber analysis are summarized in Figure 8.2. In practice, methods based on gravimetric determination of fiber are faster and less expensive than those requiring analysis of sugars, and so are better suited to commercial applications. The TDF method gives higher analytical values than the NSP method, largely because of the inclusion of resistant starch (Tables 8.2, 8.3, and 8.4).

**FIG. 8.2** A summary of the essential steps in both the gravimetric (total dietary fiber) and non-starch polysaccharide approaches to dietary fiber analysis.

**TABLE 8.2** Values for dietary fiber from some representative foods, measured as NSP and as total dietary fiber

Food source	Non-starch polysaccharide (Englyst method)	Total dietary fiber (AOAC method)
Wholemeal bread	5.0	7.0
Brown bread	3.5	5.0
White bread	2.1	2.9
Green vegetables	2.7	3.3
Fresh fruit	1.4	1.9
Potatoes	1.9	2.4

Data from Food Standards Agency (2002).

**TABLE 8.3** Values for dietary fiber from some cereal products, measured as total NSP, insoluble NSP, and soluble NSP

Food source	Non-starch polysaccharides (g/100g fresh weight)		
	Total NSP	Insoluble NSP	Soluble NSP
Wholemeal bread	4.8	3.2	1.6
Brown bread	3.6	2.5	1.1
White bread	1.5	0.6	0.9
Cornflakes	0.9	0.5	0.4
Crunchy oat cereal	6.0	2.7	3.3

Data from Englyst *et al.* (1989).

**TABLE 8.4** Values for dietary fiber from some fruits, vegetables, and nuts, measured as total NSP, insoluble NSP, and soluble NSP

Food source	Non-starch polysaccharides (g/100g fresh weight)		
	Total NSP	Insoluble NSP	Soluble NSP
Apples	1.7	1.0	0.7
Oranges	2.1	0.7	1.4
Bananas	1.1	0.4	0.7
Tomatoes	1.1	0.7	0.4
Brussels sprouts	4.8	2.3	2.5
Runner beans	2.3	1.4	0.9
Celery	1.3	0.7	0.6
Potatoes	1.1	0.5	0.6
Brazil nuts	4.3	3.0	1.3
Walnuts	3.5	2.0	1.5
Peanuts	6.2	4.3	1.9

Data from Englyst *et al.* (1989).

This is consistent with the broad definitions of dietary fiber now recommended by the Codex Alimentarius Commission and other bodies, but, when reading the physiological or epidemiological literature, it is important to consider how any quoted fiber values have been determined. In any case a single gravimetric measurement of residual carbohydrates of unknown composition cannot predict the physiological effects of any particular food. The NSP method, when combined with a full analysis of carbohydrates by gas liquid chromatography, is more technically demanding and expensive, but gives much more information about the individual polysaccharide components of a food sample, and is therefore more suitable for research on the physiological effects of dietary fiber. Most of the techniques recommended by the Codex Alimentarius Commission for analysis of fiber are AOAC methods for TDF, but the NSP method is also included in recognition of its importance for research purposes (FAO, 2010).

### Physiological Effects of Dietary Fiber

During digestion, food is conveyed progressively through the alimentary organs while undergoing a tightly regulated sequence of physical changes and chemical reactions. The presence of intact carbohydrate polymers within the partially digested intraluminal matrix modifies this process at every stage, but the physiological effects of the different constituents of the fiber complex depend upon their physical properties, their chemical interactions with other food components and digestive secretions, and their susceptibility to bacterial fermentation in the large intestine.

#### Oropharyngeal Effects

The earliest stages of digestion begin with the addition of saliva, which is both a lubricant and a source of salivary amylase, and the mechanical disruption of food during mastication. Raw or lightly processed plant foods usually contain relatively high levels of cell-wall polysaccharides, and often retain much of the three-dimensional cellular structure of the original plant tissue. The presence of intact cell-wall polysaccharides tends to inhibit the physical disruption of food before it reaches the stomach, and thus can inhibit the rate of starch digestion at a very early stage. Hard foods need to be chewed more thoroughly than soft ones, and there is evidence from animal studies that the physical properties of foods consumed during early life influence craniofacial development. It is not clear whether consumption of foods rich in dietary fiber has develop-

mental consequences for human infants, but, at the other end of life, poor dentition among the elderly has been shown to be associated with low intakes of dietary fiber and it has been suggested that this increases the risk of gastrointestinal disease (Moynihan *et al.*, 1994).

#### Gastric Effects

The transit of food through the digestive tract is delayed in the stomach, where residual food fragments are further degraded by vigorous muscular activity in the presence of hydrochloric acid and proteolytic enzymes. The rate of gastric emptying is partly regulated by particle size, and so the prolonged disruption and dispersion of intractable food particles can delay the digestive process significantly. For example, it has been shown that coarse but not finely dispersed wheat bran slows gastric emptying in humans (Vincent *et al.*, 1995), and the rate at which the starch is digested and absorbed from cubes of cooked potato has been shown to be much slower when they are swallowed whole than when they are chewed normally (Read *et al.*, 1986). Thus simple physical factors can limit the rate at which glucose from carbohydrate foods enters the circulation (Bjorck *et al.*, 1994) but it is important to emphasize that these potentially important effects, though related to the retention of intact cell walls within food, cannot be predicted from single analytical values for dietary fiber.

#### Small Intestinal Effects

After the physical disruption of food particles and the partial hydrolysis of macromolecules in the stomach, the semi-liquid products of the gastric phase of digestion are released at intervals into the duodenum. Starch, proteins, and triglycerides are further hydrolyzed to oligomers by pancreatic enzymes in the upper jejunal lumen. The final stages of digestion occur at the mucosal surface in the presence of the brush-border hydrolases of the epithelial cells, through which the newly released monosaccharides, fatty acids, peptides, and amino acids, together with water and electrolytes, are absorbed into the circulation. The peristaltic waves of the small intestinal musculature and the rhythmic contractions of the villi ensure that the partially digested chyme is well stirred. In adults, the first residual polysaccharides from a meal containing dietary fiber enter the cecum approximately 4.5 h after ingestion. Soluble polysaccharides, such as guar gum and beta-glucan from oats, have the property of forming extremely viscous solutions in water at low concentrations. Test meals containing such polysaccharides can delay gastric emptying

and increase the resistance to peristaltic flow in the small intestine, thereby increasing mouth-to-cecum transit time. On the other hand, coarse insoluble wheat bran, but not finely ground bran, has been reported to accelerate small intestinal transit (Vincent *et al.*, 1995).

The functional significance of dietary fiber in the small intestine lies mainly in its ability to slow the rate of glucose absorption, and thus to modify the metabolic response to a meal. Much of the research to explore the effects of fiber on glucose absorption and metabolism has been done by measuring the glycemic index (GI), either of naturally fiber-rich foods, or of liquid or solid test-meals to which dietary fiber has been added as a supplement. The GI of a food is defined as the incremental area under the blood glucose response curve after consumption of a standardized sample, expressed as a percentage of the response to an equivalent amount of carbohydrate consumed as glucose (Jenkins *et al.*, 1981). Studies on dietary fiber are usually conducted using healthy individuals who have fasted overnight. The technique has undergone a number of methodological refinements in recent years, and it has been shown that, when carefully controlled, the method gives consistent results, which allow foods to be classified according to GI (Wolever *et al.*, 2008). Complex carbohydrates rich in fiber tend to have glycemic indices below 100%, indicating that the rate of glucose absorption is lower than that from pure glucose, but the mechanism of action differs for different types of fiber. In the case of cell walls that remain intact in the small intestine, their presence will impede the access of pancreatic amylase to starch, thus slowing the release of glucose, and often enabling a significant fraction of ingested starch to reach the colon. This is particularly important in the case of certain beans and other leguminous seeds, which have been shown to retain much of their cellular integrity during digestion (Wursch *et al.*, 1986). In general, wheat bran and other insoluble types of fiber have little effect on glucose metabolism when added to test meals of glucose or starch, whereas soluble polysaccharides that form viscous solutions in the stomach and small intestine delay the absorption of glucose (Jenkins and Jenkins, 1985). Their primary mechanism of action appears to be to increase the viscosity of the fluid layer adjacent to the epithelial cells at the mucosal surface. To sustain a high rate of influx, the concentration of glucose and other actively transported substrates must be maintained within the boundary layer, either by convective mixing, or by the much slower process of diffusion. If the physical stirring effects of gut motility

are inhibited by a high viscosity, then the effect is to increase the resistance of the boundary layer and slow the overall rate of transport (Johnson and Gee, 1981). A similar mechanism inhibits the uptake of cholesterol (Gee *et al.*, 1983), and probably also the re-absorption of bile salts in the distal ileum.

Apart from the effects of fiber on macronutrient transport and metabolism, there has been much interest in the possibility that both the polysaccharides and complex phenolic components of cell walls interact with and bind ionized substances such as mineral micronutrients in the stomach and small intestinal contents, thereby reducing their availability for absorption (Torre *et al.*, 1991). Intraluminal binding of heavy metals and organic carcinogens might be a valuable protective mechanism against toxicity, but binding of micronutrients could seriously compromise nutritional status. Interactions of this type can be shown to occur *in vitro*, and studies with animals and humans suggest that charged polysaccharides such as pectin can bind inorganic cations in the small intestinal lumen and displace them into the colon under experimental conditions, but there is little objective evidence that dietary fiber *per se* has much of an adverse effect on mineral metabolism in humans. However, phytate (myo-inositol hexaphosphate), which is an organic compound often present in close association with the cell-wall polysaccharides of unprocessed legume seeds, oats, and other cereals, does exert potent binding effects on minerals, and has been shown to significantly reduce the availability of magnesium, zinc, and calcium for absorption in humans (Hurrell *et al.*, 2003). Phytate levels in foods can be reduced by the activity of endogenous phytase enzymes in plant tissue, or by hydrolysis with exogenous phytase enzymes. Such measures may be used to process foods for consumption by populations at risk of mineral deficiency (Troesch *et al.*, 2009).

### **Metabolic Effects of Dietary Fiber**

Long-term supplementation with the viscous polysaccharide guar gum improves control of blood glucose in patients with non-insulin-dependent diabetes mellitus (Groop *et al.*, 1993), and similar effects can be achieved using diets designed to provide a low glycemic index (Jenkins *et al.*, 2008). The glycemic response to carbohydrate ingestion is the major determinant of insulin secretion. Glucose uptake also regulates the release of the incretins, glucagon-like peptide 1 (GLP-1) and gastric inhibitory peptide (GIP), which act to amplify the release

of insulin by the pancreatic beta cells, reduce secretion of glucagon by pancreatic alpha cells, and inhibit the motility of the upper gastrointestinal tract. There is evidence that the presence of dietary fiber in foods modulates this system, but neither the mechanisms of action nor the consequences are fully understood. For example, the release of insulin, GLP-1, and GIP has been shown to be lower after ingestion of rye bread than after an equivalent test-meal of white bread, but the effect was apparently attributable to differences in the physical structure of the bread, rather than to the level of dietary fiber (Juntunen *et al.*, 2002). In another study, concerned with soluble dietary fiber, the addition of the viscous polysaccharide beta-glucan from oats to a test-beverage was shown to suppress the absorption of glucose, and to inhibit the release of insulin, cholecystokinin, GLP-1, and peptide YY (PYY). In this example, the importance of the viscosity of the polysaccharide was confirmed by the fact that the effect was abolished by hydrolysis of the beta-glucan, although the total fiber content of the beverage was unchanged (Juvonen *et al.*, 2009).

The distal small intestine is richly endowed with endocrine cells that secrete regulatory peptides including enteroglucagon, GLP-1, and PYY into the circulation in response to intraluminal signals. Soluble, viscous types of dietary fiber can modulate the secretion of these hormones, probably by slowing the absorption of glucose and lipid in the duodenum and thereby increasing their concentrations in the distal intestine, where they can interact with mucosal endocrine cells. In one study, human volunteers consumed varying doses of oat beta-glucan, incorporated into a cereal product. There was evidence of a dose-related increase in plasma PYY levels after meals containing 4–6 g of beta-glucan compared with a control meal (Beck *et al.*, 2009). The significance of such endocrine effects lies in the regulatory role of PYY and other gut peptides in relation to gut motility and appetite. PYY in particular is implicated in the control of food intake in experimental animals but its precise role in humans is unclear (Neary and Batterham, 2009).

Lipid metabolism is also modified by dietary fiber consumption in humans, but again the mechanisms are not well understood. The effects on cholesterol metabolism are of particular interest because of its role in the etiology of coronary heart disease, which is discussed in more detail below. It is well established that soluble polysaccharides, including oat beta-glucan, guar gum, and pectin, exert hypocholesterolemic effects in humans. Brown *et al.*

(1999) undertook a meta-analysis of randomized, controlled intervention trials and concluded that the soluble polysaccharides most commonly used in intervention studies all modified plasma cholesterol levels to a similar though limited extent, amounting in the case of oat beta-glucans to a reduction of about 0.13 mmol/L total cholesterol for every 3 g soluble fiber consumed per day. This is a relatively modest reduction, but one that would be potentially significant for those with total plasma cholesterol levels close to the generally recognized desirable level of 5.2 mmol/L. The most probable mechanism is that the viscosity of these polysaccharides in the distal small intestine inhibits bile-salt reabsorption, thus increasing fecal bile losses. To compensate for this, hepatic bile salt synthesis increases, and draws upon the plasma cholesterol pool. In experimental trials, various types of dietary fiber have been shown also to modify the lipid composition of chylomicrons entering the circulation from the small intestine after fatty test-meals (Cara *et al.*, 1992) but the metabolic significance of these effects in free-living humans consuming mixed diets is not clear.

### Colorectal Effects

After their passage through the small intestine, all of the components of dietary fiber enter the proximal colon via the ileocecal valve. In contrast to the upper alimentary tract of healthy human beings, where a number of physiological adaptations ensure that bacterial numbers are kept to a minimum, the colon and rectum are adapted to facilitate colonization by bacteria. Humans do not possess the enlarged cecum typical of herbivores, but the proximal colon does contain around 200 g of bacteria, dietary residues, mucus, and other intestinal secretions, in a semi-liquid state that favors fermentation. Estimates differ as to the number of different bacterial species present in the human colon, but it is one of the richest bacterial ecosystems known. The largest single groups present are Gram-negative anaerobes of the genus *Bacteroides*, and Gram-positive organisms including bifidobacteria, eubacteria, lactobacilli, and clostridia. A full understanding of this complexity has been difficult to achieve because a large proportion of the species present cannot be cultured *in vitro* using classical methods, but new genomic techniques are rapidly transforming this situation (Streit and Schmitz, 2004).

The gut microflora and their human host exist in a symbiotic relationship that has evolved over the millennia like any other aspect of human biology. Unlike the endog-

enous digestive enzymes, which only hydrolyze the alpha linkages of dietary carbohydrates, the gut microflora expresses a diverse array of enzymes capable of degrading most of the components of the plant cell wall. The advantage to the host lies in the ability of the bacteria to break down the residual oligo- and polysaccharides of the dietary fiber complex to the short-chain fatty acids acetate, propionate and butyrate, some of which can be reabsorbed and utilized as a source of metabolic energy. Propionate is metabolized in the liver, whereas acetate enters the circulation and is used as an energy source by various peripheral tissues. The colorectal epithelial cells are adapted to utilize butyrate as their primary source of energy (Roediger, 1980). Although there is no doubt that the human body derives energy from the fermentation of dietary fiber, the precise contribution to total energy needs is difficult to quantify. Dietary energy values are usually calculated using energy conversion factors, applied separately to the protein, fat, and carbohydrate components, and summed to give a total value for the food or diet. The commonly used conversion factor for carbohydrate, based on the empirical work of Atwater (Atwater and Benedict, 1902) is 16.7 kJ/g (4 kcal/g), and assumes that all the carbohydrate is absorbed and metabolized as glucose. If dietary fiber is included in the total carbohydrate content of a food or diet, then the energy content will be overestimated, whereas if it is assumed to contribute zero energy, and is subtracted from total carbohydrates, the energy content will be underestimated (Livesey, 1995). Both non-starch polysaccharides and the various types of resistant starch that occur in foods of plant origin differ significantly in their susceptibility to fermentation, but this is difficult to account for, particularly if only a gravimetric analysis of fiber, with no separate determination of individual polysaccharides, is available. In practice, a figure of 8.4 kJ/g (2.0 kcal/g) is considered a realistic approximation for the energy value of fiber derived from mixed diets (Livesey, 1992) and this figure has been endorsed by the Food and Agriculture Organization of the United Nations (FAO, 2002). It is, however, important to be aware that this is only an approximation, and that the capacity to derive energy from fermentation of carbohydrate differs between individuals, presumably because of differences in the composition of the colonic microflora and the transit time of feces through the colon (Wisker and Feldheim, 1990). A further complication is that high levels of fiber in the diet have been shown to decrease the metabolizable energy available from fat and protein (Baer *et al.*, 1997).

Although most of the bacteria of the human colon exploit carbohydrates, not all can degrade polysaccharides directly, and many are adapted to utilize the initial degradation products of other bacterial species in the community. The amount of fermentable carbohydrates reaching the human colon each day has proven difficult to quantify, but it is clear that it differs considerably between individuals and populations because of the great variation in human diets (Stephen *et al.*, 1995). A minimum quantity of around 20 g can be deduced from estimates of total dietary fiber intake in Western populations consuming mainly refined carbohydrates (Cust *et al.*, 2009). Estimates of resistant-starch intake range up to 30–40 g for the populations of developing countries (Stephen *et al.*, 1995), but these are based largely on the estimation of resistant starch by *in vitro* techniques. Using an isotope tracer method in human volunteers, Wang *et al.* (2008) observed that as much as 25% of the starch in some unrefined cereal foods escaped hydrolysis in the small intestine. Thus upper limits in excess of 50 g of fermentable carbohydrate reaching the human colon seem feasible for populations such as those of rural and urban South Africa that consume diets based largely on maize porridge (Ahmed *et al.*, 2000).

Much remains to be discovered about gut bacteria, but, whatever the significance of the gut microflora for the overall metabolic health of human beings turns out to be, there is no doubt of its importance for the proper maintenance of normal bowel function. Nor is there any doubt that the quantity and types of dietary fiber consumed are major determinants of the bulk and the frequency of passage of stool (Stephen *et al.*, 1986). The magnitude of this laxative effect of fiber depends upon the types of polysaccharides consumed. At one extreme are the soluble cell-wall polysaccharides such as pectin, which are readily fermented by bacteria, and at the other are the lignified plant tissues such as wheat bran, which are resistant to bacterial enzymes, and tend to remain at least partially intact in the feces. All components of dietary fiber increase fecal bulk to some extent, but the size of this laxative effect differs markedly between food sources (Table 8.5). The more than five-fold difference in the fecal bulking capacity of wheat bran compared with pectin reflects the fact that, whereas the increment in stool mass caused by wheat bran depends mainly on water retention by the intact bran within the fecal matrix, that caused by fermentable polysaccharides such as pectin is due mainly to increased bacterial cell mass (Stephen and Cummings, 1980). In this as in other physiological effects of fiber, the fecal bulking effect

**TABLE 8.5** Mean and range of increased fecal output measured in response to different types of dietary fiber fed to human volunteers

Fiber type or food source	Increase in fecal weight (g/g fiber eaten)
Wheat bran	7.2 (3.0–14.4)
Fruits and vegetables	6.0 (1.4–19.6)
Oats	3.4 (1–5.5)
Legumes	1.5 (0.3–3.1)
Pectin	1.3 (0–3.6)

Data from Elia and Cummings (2007).

of a food cannot, without other information, be predicted from a simple analysis of its total dietary fiber content.

The composition of the residual carbohydrates reaching the colon determines not only the quantity but to some extent also the composition of the bacterial microflora that lives upon it. In health, an individual's gut microflora remains relatively stable over long periods of time. Most types of dietary fiber seem to stimulate a general increase in microbial numbers, with little effect on the relative proportions of different bacterial species present. However, certain oligosaccharides provide a selective stimulus for the growth of species of bifidobacteria, which are thought to be beneficial to health, and this is the basis for the supplementation of diets with galactose or fructose oligosaccharides, or *prebiotics* as they have come to be known (Gibson and Roberfroid, 1995).

Although fermentation tends to reduce the laxative effect of a polysaccharide, the fermentation products do have other very important effects in the colon. Besides providing metabolic energy for the colorectal epithelial cells (Roediger, 1980), butyrate causes differentiation of tumor cells, suppresses cell division, and induces programmed cell death (apoptosis). All of these phenomena have been studied extensively *in vitro*. If the same effects occur in the intact human gut, they may have the beneficial effect of eliminating precancerous cells from the epithelial population (Johnson, 2001), but this remains to be established. The physiological effects of butyrate observed *in vitro* appear to be mediated via the inhibition of the histone deacetylases, a group of enzymes that modify the protein structure of chromosomes and thus regulate gene transcription. These effects are consistent with an anticarcinogenic role for butyrate, but it is not yet clear to what extent they also occur in the intact human intestine.

Although, as mentioned previously, inhibition of nutrient absorption by viscous fiber can initially inhibit the release of GLP-1, butyrate, and acetate derived from fermentation of carbohydrate in the colon can stimulate the release of GLP-1 and PYY by colonic mucosal endocrine cells, and this may provide another mechanism influencing human metabolism. It has been suggested that GLP-1 derived from this source may increase insulin sensitivity in humans, but there is a need for further studies with human subjects to fully evaluate the physiological importance of this mechanism (Freeland and Wolever, 2010). Research continues on the importance of butyrate and other short-chain fatty acids derived from fermentation of dietary fiber for human health.

The other major breakdown products of carbohydrate fermentation are hydrogen, methane, and carbon dioxide, which together comprise flatus gas. Excess gas production may cause distension and pain in some individuals, especially if using supplements such as guar gum (Bianchi and Capurso, 2002), or if they attempt to increase their fiber consumption too abruptly. In many cases, however, extreme flatus is probably caused more by fermentation of oligosaccharides such as stachyose and verbascose, which are found principally in legume seeds, rather than by fermentation of long-chain polysaccharides from the cell wall (Suarez *et al.*, 1999).

## Dietary Fiber in the Management and Prevention of Disease

The founders of the dietary fiber hypothesis believed that the populations of Western industrialized societies had become chronically malnourished because of a deficiency of dietary fiber from complex carbohydrate foods, and that the inability of humans to adapt successfully to such a diet accounted for the prevalence of a variety of gastrointestinal and metabolic diseases. As Burkitt put it, "We have so changed our environmental cogs that they no longer engage harmoniously with our genetic constitution which cannot be changed" (Kritchevsky and Bonfield, 1997). This general paradigm of the maladaptation of populations in developed societies to many aspects of modern lifestyles continues to evolve and to gain credence among biomedical scientists, but the precise role of dietary fiber in this context remains uncertain. In this section the evidence for the importance of fiber as a determinant of the major types of non-infectious diseases will be briefly reviewed.

### **Diabetes and the Metabolic Syndrome**

Interest in the possibility that a deficiency of fiber might play a role in the etiology of type 2 diabetes began very early in the development of the dietary fiber hypothesis, with the work of Trowell and others (Trowell, 1972a). As we have seen, the rate of delivery of glucose from the gut to the circulation is modified by the presence of intact cell walls, and by certain soluble polysaccharides dispersed in the small intestinal lumen. Epidemiological research published in recent years supports at least some of the early theoretical arguments for the benefits of dietary fiber, and provides strong evidence that the physiological effects revealed under experimental conditions do have important consequences at the population level, even if the mechanisms underlying these effects are unclear. It has become increasingly clear that type 2 diabetes is often preceded by a combination of clinical abnormalities associated with obesity, collectively termed the *metabolic syndrome* (Zimmet *et al.*, 1999), involving impaired glucose tolerance due to insulin resistance, raised plasma LDL cholesterol, raised blood pressure, and signs of increased low-grade systemic inflammation. Remarkably, there is growing evidence that consumption of dietary fiber is associated with protection against all of these abnormalities.

Salmerón and colleagues conducted prospective studies to investigate the relationship between the glycemic index and dietary fiber content of the habitual diets of men (Salmerón *et al.*, 1997a) and women (Salmerón *et al.*, 1997b) and their risk of developing type 2 diabetes during 6 years of follow-up. In both sexes there was an adverse effect of dietary glycemic index and a protective effect of cereal fiber intake. The combined effect of high glycemic index and low intake of cereal fiber more than doubled the risk of disease. More recently, de Munter *et al.* (2007) evaluated the intake of whole grain, bran, and cereal germ in a cohort of 161 737 healthy American women participating in the Nurses' Health Studies I and II, and identified 6486 cases of type 2 diabetes over 12–19 years of follow-up. After adjustment for confounders and for body mass index (BMI), the relative risks for development of type 2 diabetes in the highest consumers of whole grain were 0.75 (95% CI 0.68–0.83) and 0.86 (95% CI 0.72–1.02) in the NHS 1 and 2 cohorts, respectively. The protective effect was similar for cereal bran, but was not significant for cereal germ. Combining these data in a meta-analysis with four other previously published studies, the authors concluded that an increment in whole-grain consumption of two 16 g servings of whole-grain constitu-

ents per day was associated with a 21% (95% CI 13%–28%) decrease in risk of type 2 diabetes. It should be noted of course that “whole grain” contains many constituents other than dietary fiber, and that the correlation with bran intake is consistent with, but does not prove, a direct protective effect of cell-wall polysaccharides.

In a recent prospective study Sluijs and colleagues examined the relationship between carbohydrate consumption and risk of diabetes in 37 846 Dutch members of the European Prospective Investigation of Cancer and Nutrition (EPIC) cohort (Sluijs *et al.*, 2010). The food intake data were used to calculate total carbohydrate, total starch, glycemic index (GI), and glycemic load (the product of carbohydrate intake and average GI). After 10 years of follow-up, 915 cases of type 2 diabetes were identified. Total carbohydrate intake, starch, and glycemic load were all positively correlated with risk of diabetes, but there was an inverse association with total dietary fiber intake (hazard ratio = 0.92; 95% CI: 0.85, 0.99).

Overall, epidemiological data support the concept that diets rich in refined carbohydrate, having a high GI and low content of dietary fiber, carry an increased risk of type 2 diabetes, and conversely that a high intake of fiber is protective. One paradox that remains to be resolved, however, is that whereas it is viscous soluble fiber that attenuates glucose absorption and the insulin response most effectively in acute experimental studies, epidemiological data indicate that habitual consumption of insoluble cereal fiber is most strongly associated with a reduced risk of type 2 diabetes (Schulze *et al.*, 2007). Perhaps, in the context of epidemiological studies, dietary fiber intake merely acts as a surrogate marker for some other protective component or characteristic of the diet. There are, however, experimental data to show that even a short-term intervention with insoluble dietary fiber supplements can improve insulin sensitivity in overweight subjects (Weickert *et al.*, 2006), an effect which, given the nature of the dietary fiber used, seems likely to be independent of any direct effects on glucose absorption in the small intestine.

One interesting possibility is that, at the population level, dietary fiber intake may be acting through a reduction in low-grade systemic inflammation, which is itself a risk factor for type 2 diabetes (Kolb and Mandrup-Poulsen, 2010). Direct evidence for this hypothesis comes from studies on the relationship between fiber consumption and C-reactive protein (CRP) in humans. CRP is a blood-borne protein synthesized in the liver in response to a variety of pathologies ranging from infections to the

chronic inflammatory changes associated with abdominal obesity. CRP has a specific functional role in the immune response to infections, and it is widely used as a clinical marker of general inflammatory status. A chronic elevation of CRP is a risk factor for diabetes and cardiovascular disease. Epidemiological studies reveal an inverse relationship between dietary fiber intake and serum CRP levels in the general population. For example, Ajani *et al.* (2004) used data from the National Health and Nutrition Examination Survey 1999–2000 (NHANES) to show that in the USA the odds ratio for having an abnormally high CRP level (>3.0 mg/L) was 0.49 (95% CI 0.37–0.65) for the highest quintile of fiber intake compared with the lowest. In the Finnish Diabetes Prevention Study, Herder *et al.* (2009) showed that of the various aspects of lifestyle investigated, dietary fiber intake and physical activity both independently predicted a reduction in CRP after correction for weight loss. Confidence in a causal relationship between fiber intake and CRP is strengthened by intervention studies with fiber. In a systematic review of the literature, North *et al.* (2009) identified six out of seven intervention trials with fiber, at daily doses of 3.3–7.8 g/MJ energy, in which statistically significant reductions in CRP concentrations of 25–54% were observed. However, the mechanisms by which dietary fiber modifies systemic inflammation are not known, and at the present time it is difficult to separate them from a relationship between fiber intake and body weight.

### Obesity

In general, epidemiological studies tend to support the hypothesis that dietary fiber intake is inversely associated with body-mass index (BMI) in adults, but experimental evidence for a causal relationship remains ambiguous. Population studies have shown that the average daily intake of dietary fiber by individuals with BMI in the normal range is significantly lower than that of overweight and clinically obese subjects (Alfieri *et al.*, 1995; van de Vijver *et al.*, 2009), but this does not necessarily indicate that fiber consumption has any direct influence on body weight gain. The use of prospective studies to explore the issue of causation has been partly successful. Koh-Banerjee *et al.* (2004) studied dietary intake and self-reported weight gain over an 8-year period in 27 082 American men aged 40–75 years. Multivariate analyses indicated a statistically significant inverse association between whole-grain intake and weight gain, such that for every 40-g/day incre-

ment in whole-grain intake, weight gain was 0.49 kg lower. A reduction in weight gain associated independently with the presence of cereal bran in the diet was identified, such that, for every 20 g/day increase in intake, weight gain was reduced by 0.36 kg. The authors therefore concluded that the effects of whole grain on body weight were due both to dietary fiber and to other unidentified constituents of cereal grains. Liu (2003) studied whole-grain and dietary fiber intake in a large cohort of American women enrolled in the Nurses' Health Study and came to similar conclusions. In contrast, a study of a large Danish cohort failed to identify any relationship between weight gain and fiber intake after adjustment for covariates (Iqbal *et al.*, 2006).

Intervention studies designed to test the hypothesis that increased intakes of dietary fiber lead directly to weight loss in humans have produced mixed findings. In a review of published research, Howarth *et al.* (2001) concluded that, in most intervention studies in which energy intakes were maintained constant, an increased intake of either soluble or insoluble fiber led to an increase in postprandial satiety, which would favor weight loss. In studies where energy intake was uncontrolled, an average consumption of an additional 4 g/day fiber was associated with a reduction in energy intake, and a reduction in body weight of 1.9 kg over 3.8 months. Nevertheless, intervention studies with well-defined supplements of soluble dietary fiber, the type which has been shown to exert the most potent effects on gastric emptying and satiety, have not always been successful. Howarth *et al.* (2003) studied the effects of 27-g supplements containing either pectin and beta-glucan, which are soluble, fermentable, non-starch polysaccharides, or methyl cellulose, a soluble but non-fermentable polysaccharide, given to 11 men and women for 3 weeks. They observed no significant effects on energy intake, body weight or body fat. Pittler and Ernst (2001) conducted a meta-analysis of intervention studies with the soluble, viscous, and fermentable polysaccharide guar gum and concluded that, on the basis of the 11 trials identified as suitable for detailed statistical analysis, there was no overall evidence of an effect on weight loss in humans. They noted also that a significant number of unpleasant gastrointestinal side-effects were associated with regular intake of guar gum supplements at the levels used in such studies.

Overall, the epidemiological evidence shows that the consumption of relatively fiber-rich diets in Western coun-

tries is associated with lower BMI in adults, but it is unclear whether this can be attributed to any direct effect of dietary fiber on energy intake or metabolism. Dietary fiber, and foods containing high levels of dietary fiber, have a lower energy density and are often bulkier than refined carbohydrate foods. This may tend to promote satiety at relatively low levels of energy intake, so the general concept that a high intake of fiber is associated with greater postprandial satiety seems plausible. However, in view of the complexity of self-selected human diets and the difficulty of correcting for all the variables involved, this general hypothesis is very difficult to test (Elia and Cummings, 2007). At any rate it has proven difficult to consistently demonstrate direct effects of dietary fiber on appetite control in humans under experimental conditions.

### **Hypertension**

Several randomized controlled-intervention trials have explored the hypothesis that supplementation with dietary fiber is an effective means of reducing blood pressure in humans. Two independent meta-analyses have explored this issue and have concluded that dietary fiber supplements are effective as a means of reducing blood pressure in hypertensive and non-hypertensive subjects. Whelton *et al.* (2005) estimated that, overall, fiber supplementation was associated with a significant reduction of  $-1.65$  mm Hg (95% confidence interval  $-2.70$  to  $-0.61$ ) in diastolic blood pressure, and a non-significant reduction of  $-1.15$  mm Hg (95% confidence interval  $-2.68$  to  $0.39$ ) in systolic blood pressure. Streppel *et al.* (2005) concluded that an average dose of 11.5 g dietary fiber per day reduced systolic blood pressure by  $-1.13$  mm Hg (95% confidence interval  $-2.49$  to  $0.23$ ) and diastolic blood pressure by  $-1.26$  mm Hg (95% confidence interval  $-2.04$  to  $-0.48$ ). The effects were greater in older hypertensive subjects and in studies with longer duration, but the mechanism of action remains largely unexplored. Although these reductions in blood pressure seem modest, they should be seen in the context of estimates that a reduction of just 2.0 mm Hg in the average systolic blood pressure of the US population would lead to reductions in annual mortality from coronary heart disease and stroke of 4% and 6% respectively (Stamler *et al.*, 1989).

### **Cardiovascular Disease**

The ability of dietary fiber to modify, under experimental conditions, several of the metabolic factors linked to car-

diovascular physiology in humans has encouraged a sustained interest in the possibility that fiber-rich diets may reduce the risk of coronary heart disease (CHD). In most of the large-scale prospective studies that have addressed the issue, good evidence for a protective effect has been obtained. Pereira and colleagues pooled the data from 10 such studies in a systematic analysis (Pereira *et al.*, 2004) that included 91 058 men and 245 186 women, among whom a total of 5249 incident cases of CHD and 2011 deaths occurred during the years of follow-up. In each of the studies analysed, dietary intakes were measured using questionnaires, and intakes of total fiber and fiber from cereals, fruits, and vegetables were estimated. After correction for confounding factors, each 10-g increment in total dietary fiber intake was found to be associated with a 14% reduction in risk of coronary events, and a 27% reduction in risk of death from CHD. Cereal fiber and fruit fiber were protective to similar extents, but there was apparently no protective effect of fiber from vegetables. The findings of this large-scale study of pooled data are generally consistent with those of other smaller studies, including a more recent Japanese cohort (Eshak *et al.*, 2010) in which those in the highest quintiles for consumption of dietary fiber from cereals and fruits were all at lower risk of death from cardiovascular disease compared with those in the lowest quintiles. The protective effects of cereal fiber against death from CHD seem to extend to patients who are already at increased risk of cardiovascular disease because of established type 2 diabetes. In a prospective study of 7822 diabetic women in the USA, identified within the Nurses' Health Study, He *et al.* (2010) explored the relationship between whole-grain consumption and death from CHD. When participants with the highest versus the lowest quintiles of intakes of whole grain, cereal fiber, bran, and germ were compared, the highest consumers experienced up to 31% lower mortality from all causes. After adjustment for confounders, a statistically significant protective effect of bran intake against both all-cause and CHD mortality was confirmed.

The consistent evidence from cohort studies supporting a protective effect of dietary fiber against CHD is impressive, but when interpreting such data one must remain aware that correlations do not prove causality. Dietary fiber intake is difficult to measure with precision at the population level, intakes may alter over the years of follow-up, and fiber may simply be acting as a marker for other

dietary or environmental factors with which it is associated. Statistical corrections for such confounding factors are difficult to achieve, and it is particularly hard to assess whether there are real differences in the effectiveness of fiber from different dietary sources. Ideally a randomized intervention trial should be used to test the hypothesis that dietary fiber protects against CHD, but in practice such experiments are extremely difficult and when attempted they have been inconclusive. One approach to the problem is to measure recurrence of infarction in patients who have already been treated for a cardiac event. An example is the Diet and Reinfarction Trial (DART), in which a group of 2033 men with a history of CHD were randomly allocated to receive either no advice on diet, or advice targeted to dietary intake of fish, dietary lipids or cereal fiber. After 2 years the compliance with advice to consume more cereal fiber was good in that the mean daily intake in those men given advice was 15 g compared with 9 g in those given no advice, but there was no reduction in risk of coronary reinfarction (Burr, 2007). The only conclusion to be drawn is that, assuming that the epidemiology is correct and dietary fiber does indeed protect against CHD, the protective mechanisms probably act over a long period of time and begin well before the pathology has become fully established.

### **Constipation and Associated Disorders**

It is well established that dietary fiber increases fecal frequency and bulk in healthy volunteers, and so it is natural to conclude that it is likely to be of value as a treatment for the symptoms and complications of constipation. According to widely accepted clinical criteria, constipation can be regarded as a pathological condition in patients who regularly experience fewer than three bowel movements per week, where this is coupled with hard stools, a sense of incomplete evacuation or excessive straining (Drossman, 2006). Such patients are usually advised to increase their consumption of dietary fiber, and may be prescribed pharmaceutical preparations based on isphagula husk derived from the seeds of *Plantago psyllium* (Lennard-Jones, 1993), which has been shown to improve symptoms significantly (Fenn *et al.*, 1986). Epidemiological evidence supports the conclusion that a higher intake of dietary fiber from self-selected diets is associated with a reduced incidence of constipation in the general population (Dukas *et al.*, 2003) but the field is in need of further randomized intervention trials to identify the most effective types of fiber and their mechanisms of action.

Diverticular disease is a common condition in which small protrusions called diverticulae bulge through the muscular wall of the colon at sites of penetration by blood vessels. It is much more common in Western populations than in the rural African populations first studied by Burkitt and colleagues, and is strongly associated with increasing age. It was one of the first disorders to be attributed to a chronic deficiency of fiber in the diet (Painter and Burkitt, 1971), and it has long been thought to be caused by the increased intracolonic pressure associated with constipation. There is good epidemiological evidence to support the hypothesis that a high intake of dietary fiber protects against diverticular disease in the male population of the USA (Aldoori *et al.*, 1998), but there appears to be little evidence that increased consumption of dietary fiber is of any value in the management of established disease (Tursi and Papagrigroriadis, 2009).

### **Irritable Bowel Syndrome**

The term “irritable bowel syndrome” (IBS) is applied to a common functional bowel disorder with a variable set of symptoms, the most characteristic of which is abdominal pain in association with changes in bowel habit for which no organic cause can be found. The condition is common in Europe and North America, where the prevalence may be about 10% of the adult population. However, there is some uncertainty about this figure as diagnostic criteria vary between studies and at least half of those who report the recognized symptoms never seek advice from health-care providers (Hungin *et al.*, 2005). Both the colicky pain of IBS, and the frequent occurrence of constipation, suggest a motility disorder, but there is no convincing evidence that IBS is fiber deficiency disease, and the causes of the condition are unknown. Nevertheless, many general practitioners/family physicians give dietary advice for the management of the condition, and increased consumption of dietary fiber from high-fiber foods or from supplements is frequently prescribed although the clinical basis for this is not well established.

Various types of dietary fiber have been used in the management of IBS but the most common have been wheat bran, which, as we have seen, is insoluble and poorly fermentable, but with good laxative properties, and isphagula, which is largely soluble, and partially fermentable. Isphagula, though commonly used as a bulk laxative in hospital settings and as an ingredient of functional foods, is of course not found in traditional diets. In a systematic review Bijkerk *et al.* (2004) analyzed 17 randomized con-

trolled trials and concluded that there was evidence for a statistically significant beneficial effect of dietary fiber on the global symptoms of IBS, particularly in patients with constipation, but no evidence for relief from pain. The beneficial effects were confined to soluble fiber. Wheat bran had no significant beneficial effects, and in some studies was found to worsen symptoms slightly, an effect that has been noted before (Lewis and Whorwell, 1998). In a more recent analysis of placebo-controlled intervention trials, Ford *et al.* (2008) concluded that ispaghula was significantly more effective than placebo, whereas wheat bran was not. These conclusions have now been confirmed in a further randomized placebo-controlled trial (Bijkerk *et al.*, 2009).

### **Cancers of the Alimentary Tract and Other Sites**

The mechanism for the supposedly protective effects of dietary fiber against colorectal cancer proposed by Burkitt was a largely mechanical one, based on the laxative properties of undigested polysaccharides. Burkitt observed that the normal bowel habit of rural Africans consuming traditional diets was very different from that observed in the United Kingdom and other industrialized countries. He proposed that the normal bowel habit for human beings was frequent passage of soft bulky stools, and that Western dietary patterns led to chronic constipation and hence prolonged exposure of the colon to carcinogens in the faecal stream. As we have seen, high intakes of dietary fiber do lead to bulkier stools and more frequent defecation. An influential paper by Cummings and colleagues (Cummings *et al.*, 1992) provided evidence for an inverse relationship between fecal weight and the incidence of colorectal cancer across many population groups, but we cannot be certain that these correlations reflect a causal mechanism.

Much has been learned about the etiology of colorectal cancer in the years since the development of the fiber hypothesis. The disease is now known to result from multiple mutations and long-term modifications of gene expression in developing colorectal epithelial cells, leading to the progressive disruption of normal cellular proliferation and differentiation. These changes occur over decades and are thought to be caused partly by mutagens in the fecal stream, coupled with metabolic risk factors related to obesity, insulin sensitivity, and physical activity (Johnson and Lund, 2007). Thus, apart from the bulking and laxative effects of fiber, it may exert protective effects by reducing the risk of obesity, insulin resistance, and other aspects

of the metabolic syndrome. Another possibility is that the supply of butyrate in the fecal stream, which, as mentioned previously, regulates the proliferation, differentiation, and apoptosis of colorectal epithelial cells, may be sub-optimal in Western diets because they lack sufficient fermentable carbohydrate to support the production of butyrate in sufficient quantities to maintain epithelial homeostasis (Scharlau *et al.*, 2009).

It is something of a paradox that although our understanding of the potential mechanisms by which fiber may reduce the risk of colorectal cancer has deepened in the years since the hypothesis was formulated, the epidemiological evidence to support the hypothesis has weakened. For example, in a large prospective study of 88 757 middle-aged North American women, Fuchs *et al.* (1999) observed no protective effects of fiber. Similarly, Pietinen *et al.* (1999) and Terry *et al.* (2001) failed to detect any protective effect of fiber intake in prospective trials with Finnish men and Swedish women, respectively. In contrast, the results of the very large European Prospective Investigation of Cancer and Nutrition (EPIC) project have been much more positive. EPIC was designed to overcome the limitations of prospective studies conducted with relatively small population groups consuming similar diets. The cohort of 519 978 individuals was drawn from several geographically and culturally distinct European countries, and so encompassed a very broad range of fiber intakes from varying sources. Bingham *et al.* (2003) estimated that the relative risk of colorectal cancer for the highest quintile of fiber intake (mean 35 g/day) versus the lowest (mean 15 g/day) was 0.58 (95% CI 0.41–0.85). In a subsequent analysis based on an increased number of cases, these results were confirmed (Bingham, 2006). The authors concluded that in the EPIC cohort there was a significant reduction in colorectal cancer of approximately 9% for each quintile increase in fiber ( $p < 0.001$ ), and the possibility that the protective effects might have been due to the confounding effects of folate intake from plant foods was tested and eliminated (Bingham, 2006). The EPIC study also provided evidence that the increased risk of colorectal cancer associated with red-meat consumption was substantially reduced in subjects who also consumed relatively large amounts of dietary fiber, though no mechanism for this interactive effect was identified.

Systematic reviews, in which the results of large cohort studies are pooled in order to maximize the numbers of subjects studied, substantially increase the statistical power of the overall analysis. Park *et al.* (2005) pooled 13 cohort

studies to give a total of 725 628 participants and 8081 cases, although the analysis did not include the EPIC study. The analysis revealed a statistically significant reduction in risk of 16% when the highest quintile of fiber consumption was compared with the lowest, but this difference was reduced to only 6%, and ceased to be statistically significant, when the data were adjusted for a range of other risk factors. There was no overall evidence of a dose–response relationship, although the 11% of the total population who consumed less than 10 g of fiber per day were found to be at significantly greater risk than the remaining population. The most recent systematic review of dietary fiber and colorectal cancer was that of the World Cancer Research Fund in 2007 (World Cancer Research Fund/American Institute for Cancer Research, 2007) based on a formal meta-analysis of eight studies including EPIC. The results did indicate a dose-dependent protective effect, with a reduction in risk of about 10% for each increment in fiber intake of 10 g per day. The overall judgment of the panel was that foods containing dietary fiber “probably protect against colon cancer,” though confounding effects due to other risk factors could not be entirely excluded.

Colorectal cancer develops from adenomatous polyps, which are relatively common precancerous lesions of the colorectal mucosa. Removal of small precancerous polyps at endoscopy is a routine preventative measure, and there have been a number of intervention trials in which supplementation with dietary fiber of various types has been given after polypectomy, with the aim of reducing the risk of polyp recurrence. None of these studies has produced unequivocal evidence for a protective effect of fiber supplementation, although there is some evidence that men may benefit more than women, and that this may have masked a small protective effect in some studies (Jacobs *et al.*, 2006). It is also arguable that, being focused on middle-aged individuals with an already established vulnerability to colorectal cancer, such studies only address a narrow window of time, late in the adenoma–carcinoma sequence, and that they do not rule out a greater protective effect of high dietary fiber consumption extending over a lifetime.

### Adverse Effects of Dietary Fiber

There are few well authenticated adverse effects of dietary fiber in humans. Although it is often stated that increased

intakes of dietary fiber may lead to abdominal discomfort or flatulence, the effect appears to be mild and short-lived in most individuals. Well-controlled studies with fermentable fructose polysaccharides (Bruhwylter *et al.*, 2008) or resistant maltodextrins (Storey *et al.*, 2007) have suggested that only relatively mild symptoms are reported by healthy volunteers. The possible adverse effects of high-fiber diets on mineral status have been mentioned previously, but are thought to be almost entirely due to phytate, rather than to the polysaccharides with which it is closely associated in some foods. There are occasional reports of intestinal obstruction due to abnormally high intakes of wheat bran; these are usually associated with pre-existing intestinal abnormalities, but occasional reports suggest it is possible to consume enough bran to cause obstruction in an otherwise normal intestine (Harries *et al.*, 1998). Oesophageal obstruction due to consumption of other types of dietary fiber, such as guar gum marketed in the form of “weight-loss pills” is also occasionally reported (Seidner *et al.*, 1990).

One interesting argument against the widening of the definition of dietary fiber to include rapidly fermented polysaccharides and oligosaccharides has been advanced by Goodlad and Englyst, who have suggested that although the supply of butyrate from slowly fermented cell-wall polysaccharides may be beneficial, a very high production of butyrate from rapidly fermented substrates might enhance mucosal cell proliferation in the colon to an extent that could promote rather than inhibit the development of cancer (Goodlad and Englyst, 2001). This argument is supported to some extent by studies with experimental animals, but there is no evidence that fermentable carbohydrate poses such a threat to humans.

### Future Directions

Leaving aside the many problems of definition and measurement, the essential idea shared by all the founders of the dietary fiber hypothesis was that the quantity of fiber consumed by the populations of prosperous industrialized societies was much too low. It is a striking fact that, after four decades of research, debate, publicity, and campaigning by public health bodies, much the same can be said today. In 2002, the US National Academy of Sciences Institute of Medicine published Dietary Reference Intakes (Institute of Medicine, 2002) for total dietary fiber in the

USA. The *adequate intake* (AI) for healthy individuals older than 12 months was estimated to be 14 g/1000 kcal/day, which equates to about 38 g/day for an adult man in mid-life and 25 g/day for a woman. In contrast, the actual average intake of dietary fiber was estimated to be 15 g/day for American adults. In the United Kingdom the recommended intake of dietary fiber (defined as NSP) set by the Department of Health is 18 g/day (DoH, 1991), which is equivalent to about 24 g of fiber measured by the AOAC method. In contrast, according to the National Diet and Nutrition Survey, in 2003 the estimated daily intake of fiber by adults was only 15.2 g/day for men and 12.6 g/day for women (Henderson *et al.*, 2003). Higher average intakes of dietary fiber intake do occur in some European countries, but across most of the industrialized world there is a general tendency for fiber intakes to fall significantly below recommended levels (Buttriss and Stokes, 2008). It is probably inevitable that Western diets rich in manufactured foods, dairy products, and meat, will tend to be low in fiber from fruits, vegetables, and lightly processed cereal foods. To achieve the recommended levels of fiber intake, consumers will need to rely on fiber-enriched manufactured foods or on supplements of various kinds. According to the Codex Alimentarius recommendations, a product qualifies as a source of fiber if it contains 3 g/100 g, and it can be described as high in fiber if it contains 6 g/100 g or more (FAO, 2010). The creation of palatable food products that meet or exceed these criteria is something of a challenge, and food technologists will increasingly make use of novel carbohydrate polymers. However, the requirement to go beyond the simple analytical value for fiber, and demonstrate that such novel carbohydrate polymers “have physiological effect of benefit to health”, as the Codex Alimentarius definition of dietary fiber requires, poses an even greater challenge. The growing evidence from epidemiological studies showing that a high fiber intake is associated with a reduced risk of several components of the metabolic syndrome is particularly relevant in an industrialized world where obesity and its co-morbidities are of growing concern. There is therefore a continuing need for experimental studies to explore in greater detail the physiological mechanisms whereby dietary fiber interacts with human metabolism beyond the alimentary tract, and to determine which of the many novel components of dietary fiber now available in the human food chain are of most benefit to human health.

## LIPIDS: ABSORPTION AND TRANSPORT

ALICE H. LICHTENSTEIN<sup>1</sup>, DSc AND PETER J.H. JONES<sup>2</sup>, PhD

<sup>1</sup>Tufts University, Boston, Massachusetts, USA

<sup>2</sup>University of Manitoba, Winnipeg, Manitoba, Canada

### Summary

Because of the hydrophobic nature of lipids, dietary fat is handled differently than protein or carbohydrate with respect to digestion and absorption. Dietary fats are broken down throughout the gastrointestinal system. A unique group of enzymes and cofactors allows this process to proceed in an efficient manner. Elegant systems operate to digest lipid, and to ferry it from the gastrointestinal tract through the unstirred water layer into the enterocyte. Within the enterocyte, complex lipids are resynthesized and packaged into lipoprotein particles for release into the lymph system for subsequent metabolism by peripheral tissue. Once in the body, the apolar nature of lipids necessitates multiple complex transport systems that are unique relative to protein and carbohydrate. Through the coordination of numerous factors, including plasma enzymes and cofactors, cell surface receptors, and intracellular trafficking molecules dietary lipids are ultimately delivered to their targeted sites.

### Introduction

Lipid has long been recognized as an important dietary component. Dietary lipid (fat) is a critical source of metabolic energy, a substrate for the synthesis of metabolically active compounds (essential fatty acids) and regulator of gene expression, and serves as a carrier for other nutrients such as the fat-soluble vitamins A, D, E, and K and vitamin precursors in both the gastrointestinal tract and plasma. The bioavailability of dietary lipid-soluble compounds is dependent on fat absorption. With the exception of essential fatty acids, phytosterols, and fat-soluble vitamins, humans have the capacity to synthesize lipids from carbohydrate and protein. In the body, lipid serves as a critical component of cell membranes, as structural moieties of

lipoprotein particles, as a precursor for bioactive compounds involved in a wide range of biological functions, and in some cases a regulator of gene expression.

### Chemistry

#### **Fatty Acids**

Fatty acids are composed of a hydrocarbon (acyl) chain with a methyl and carboxyl group at either end. Most fatty acids have an even number of carbon atoms that are arranged in a straight chain. The majority of dietary fatty acids range in chain length from 4 to 22 carbons (Table 9.1). Although by no means the most metabolically active, fatty acids with 16 and 18 carbons comprise the

**TABLE 9.1** Common fatty acids found in foods and in the body

Code	Common name	Formula
<i>Saturated</i>		
4:0	butyric acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>2</sub> COOH
6:0	caproic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>4</sub> COOH
8:0	caprylic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>6</sub> COOH
10:0	capric acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>8</sub> COOH
12:0	lauric acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>10</sub> COOH
14:0	myristic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>12</sub> COOH
16:0	palmitic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>14</sub> COOH
18:0	stearic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>16</sub> COOH
<i>Monounsaturated</i>		
16:1n-7 <i>cis</i>	palmitoleic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>5</sub> CH=(c)CH(CH <sub>2</sub> ) <sub>7</sub> COOH <sup>a</sup>
18:1n-9 <i>cis</i>	oleic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>7</sub> CH=(c)CH(CH <sub>2</sub> ) <sub>7</sub> COOH
18:1n-9 <i>trans</i>	elaidic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>7</sub> CH=(t)CH(CH <sub>2</sub> ) <sub>7</sub> COOH
<i>Polyunsaturated</i>		
18:2n-6,9 all <i>cis</i>	linoleic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>4</sub> CH=(c)CHCH <sub>2</sub> CH=(c)CH(CH <sub>2</sub> ) <sub>7</sub> COOH
18:3n-3,6,9 all <i>cis</i>	α-linolenic acid	CH <sub>3</sub> CH <sub>2</sub> CH=(c)CHCH <sub>2</sub> CH=(c)CHCH <sub>2</sub> CH =(c)CH(CH <sub>2</sub> ) <sub>7</sub> COOH
18:3n-6,9,12 all <i>cis</i>	γ-linolenic acid	CH <sub>3</sub> (CH <sub>2</sub> ) <sub>4</sub> CH=(c)CHCH <sub>2</sub> CH=(c)CHCH <sub>2</sub> CH =(c)CH(CH <sub>2</sub> ) <sub>4</sub> COOH

20:5n-3,6,9,12,15 all <i>cis</i>	eicosapentaenoic acid	CH <sub>3</sub> (CH <sub>2</sub> CH=(c)CH) <sub>5</sub> (CH <sub>2</sub> ) <sub>3</sub> COOH
22:6n-3,6,9,12,15,18 all <i>cis</i>	docosahexaenoic acid	CH <sub>3</sub> (CH <sub>2</sub> CH=(c)CH) <sub>6</sub> (CH <sub>2</sub> ) <sub>2</sub> COOH

<sup>a</sup>c, *cis*; t, *trans*.

bulk of fatty acids in both the diet and the human body. Individual fatty acids are distinguished from each by chain length, degree of saturation, and double-bond number, conformation, and location. A fatty acid with no double bonds is termed saturated; with a single double bond is termed monounsaturated; and with two or more double bonds is termed polyunsaturated (Figure 9.1A). The double bonds within unsaturated fatty acids can appear in the more common *cis* configuration, with hydrogen atoms on the same side of the carbon atoms, or in the *trans* configuration, with hydrogen atoms on opposite sides of the carbon atoms (Figure 9.1B). Most double bonds occur in a non-conjugated sequence; a carbon atom with single carbon-carbon bonds separates the carbons forming the double bonds. Some occur in the conjugated form: no intervening carbon separates the carbons forming the double bonds (Figure 9.1C). Double-bond number, position, and conformation allow fatty acids to occur as multiple isomers (same number of carbon, hydrogen, and oxygen atoms, yet different structure).

Geometric isomers of fatty acids result from differences in the conformation (spatial orientation) of the double bond(s). The presence of a *cis* relative to a *trans* double bond results in a greater bend or kink in the acyl chain. This kink impedes the fatty acids from aligning or close packing with neighboring lipids, thereby altering the physical properties of the fat. The presence of a *trans* double bond reduces the internal rotational mobility of carbon atoms and makes them less reactive to chemical change than a *cis* double bond.

Positional isomers of fatty acids are defined by differences in the location of double bonds within the acyl chain. These differences result in small alterations to the physical properties of the fatty acid and large changes in the metabolic fate of the fatty acid. The most common distinction among positional isomers is the location of the first double bond from the methyl end of the acyl chain. Fatty acids in which the first double bond occurs three carbons from the methyl end are designated as omega-3 fatty acids, denoted as ω-3 or n-3 fatty acids. Fatty acids in which the first double bond occurs six carbons from the

**FIG. 9.1** (A) Examples of fatty acids: a saturated fatty acid (stearic acid), a monounsaturated fatty acid containing a *cis* double bond (oleic acid), and a polyunsaturated fatty acid containing a *trans* double bond (linoleic acid). (B) Conformational difference between *cis* (oleic acid) and *trans* (elaidic acid) double bond containing fatty acids. (C) Structures of c9t11-conjugated linoleic acid (CLA) and linoleic acid (18:2[n-6]). Adapted from Belury (2002).

methyl end are termed  $\omega$ -6 or *n*-6 fatty acids (Leonard *et al.*, 2004; Dupont, 2005).

Fatty acid isomers with conjugated double bonds tend to be more reactive chemically than non-conjugated double bonds (Breitillon *et al.*, 1999). Although there is considerable speculation regarding their role in disease progression, the current state of knowledge is insufficient to make any firm conclusion (Plourde *et al.*, 2008).

Enzymes that metabolize fatty acids distinguish among isomers. The metabolic products are different and can have at times opposing biological effects (Wijendran and Hayes, 2004). For example, omega-3 polyunsaturated fatty acids result in eicosanoids that have vasodilatory properties whereas omega-6 polyunsaturated fatty acids result in eicosanoids that have vasoconstrictor properties.

### **Triacylglycerols**

Triacylglycerols, commonly referred to as triglycerides, are composed of three fatty acids esterified to a glycerol molecule. Each position of the three carbons comprising the glycerol molecule allows for a stereochemically distinct fatty acid bond position; sn-1, sn-2, and sn-3. The fatty acid moieties of the triacylglycerol molecule account for ~90% of its weight, depending on the length of the constituent fatty acids. The physical form of a triacylglycerol is determined by the fatty acids esterified to the glycerol moiety on the basis of chain length; number, position, and conformation of the double bonds; and the stereochemical position of each fatty acid. In vivo, triacylglycerol serves as a storage form of energy and a substrate reservoir for synthesis of bioactive compounds.

### **Phospholipids**

A phospholipid is composed of two fatty acids esterified to a glycerol molecule and one polar head group attached via a phosphate linkage. Phospholipid molecules are amphipathic. The fatty acids confer hydrophobic properties and the polar head group confers hydrophilic properties. Long-chain fatty acids are preferentially esterified to the sn-2 position of glycerol. The most predominant polar head groups include choline, serine, inositol, and ethanolamine.

In vivo, due to their amphipathic nature, phospholipids serve as the structural components of cellular membranes and lipoprotein particles. The fluidity of cell membranes is determined, in part, by the fatty acid profile of the constituent phospholipids. Membrane phospholipid serves as a reservoir of fatty acids necessary

for the synthesis of bioactive compounds. For example, cell-membrane-associated phosphatidylinositol is the predominant source of arachidonic acid. Arachidonic acid is a substrate for cyclooxygenase and 5-lipoxygenase, resulting in the formation of prostaglandins. Additionally, phosphatidylinositol-derived compounds, inositol triphosphate and diacylglycerol, play important roles in cell signal transduction.

### **Cholesterol and Cholesteryl Ester**

Cholesterol is an amphipathic molecule that is composed of a steroid nucleus and a branched hydrocarbon tail. Its presence in the food supply is for the most part restricted to fats of animal origin. It is found in two forms, either unesterified or esterified to a fatty acid at carbon number 3. Unesterified cholesterol is a component of cell membranes, and, along with the phospholipid fatty acid profile, modifies fluidity (Jaureguiberry *et al.*, 2010). Intracellularly, unesterified cholesterol mediates cholesterol homeostasis in three ways (Lillis *et al.*, 2008). Unesterified cholesterol inhibits 3-hydroxy 3-methylglutaryl CoA (HMG CoA) reductase activity, the rate-limiting enzyme in de novo cholesterol biosynthesis. Unesterified cholesterol increases acyl CoA cholesterol acyltransferase (ACAT) activity, the intracellular enzyme that esterifies unesterified cholesterol thereby lowering intracellular concentrations. Lastly, unesterified cholesterol decreases the synthesis of low-density lipoprotein (LDL) cell surface receptors, thereby diminishing the uptake of additional cholesterol from plasma. These three factors protect against excess intracellular cholesterol accumulation, particularly important because a high concentration of intracellular unesterified cholesterol is cytotoxic due to the formation of micelles which have detergent properties.

Esterified cholesterol is less polar than free cholesterol. As a consequence, whereas free cholesterol is localized on the surface, cholesteryl ester is sequestered in the core of lipoprotein particles. The majority of cholesterol in plasma, two-thirds, is carried on LDL. In plasma, cholesteryl ester is formed as a result of lecithin cholesterol acyltransferase (LCAT) activity. Intracellularly, cholesteryl ester is formed as a result of ACAT activity and is stored in lipid droplets (Chang *et al.*, 1997; Buhman *et al.*, 2000; Rudel *et al.*, 2001). Cholesteryl ester forms the core of atherosclerotic plaques (Degirolamo *et al.*, 2009). Long-chain saturated fatty acids have been reported to suppress LDL receptor activity (Knopp, 2000).

FIG. 9.2 Diagram of absorption.

### Plant Sterols

Fats derived from plant materials contain phytosterols, compounds structurally related to cholesterol, commonly referred to as plant sterols. Cholesterol and phytosterols differ chemically with regard to their side-chain configuration and steroid-ring bonding patterns. The most common dietary phytosterols are  $\beta$ -sitosterol, campesterol, and stigmasterol (Abumweis *et al.*, 2008; Demonty *et al.*, 2009). In contrast to cholesterol, phytosterols are poorly absorbed and levels in plasma tend to be low. Because of their ability to displace cholesterol from intestinal micelles, phytosterols can reduce the absorption efficiency of cholesterol, lowering circulating LDL levels.

### Digestion

Typical intakes of dietary fat range from 25% to 35% of energy. For a 2000-calorie diet this represents 56 to 78 g of fat and for a 3000-calorie diet 83–117 g of fat. In contrast to dietary carbohydrate and protein, fat does not interface with the aqueous milieu of the gastrointestinal tract, so a different system exists to accommodate the unique challenges posed for the digestion and absorption of dietary fat.

### Triacylglycerols

#### Mouth, Esophagus, and Stomach

Fat digestion begins at the point of entry, the oral cavity where salivation and mastication occur (Figure 9.2). Lingual lipase, released from the von Ebner (serous) glands of the tongue along with saliva, can cause the release of small amounts of fatty acids from triacylglycerol (Lohse *et al.*, 1997; Kawai and Fushiki, 2003). Lingual lipase cleaves the sn-3 position of the triacylglycerol molecule, with higher efficiency towards shorter-chain fatty acids. For this reason the impact is thought to be greater in infants due to their high intake of milk fat, which contains a high proportion of short-chain fatty acids. When active, lingual lipase activity continues as food travels through the esophagus and into the stomach. In the stomach, gastric lipase is released from the gastric mucosa (Canaan *et al.*, 1999a; Pafumi *et al.*, 2002; Mu and Hoy, 2004). This enzyme cleaves triacylglycerol at the sn-3 position. It has been estimated that 10–30% of fat hydrolysis occurs prior to the masticated bolus of food entering the small intestine (Mu and Hoy, 2004). The increased pH of the intestine on entry of the food bolus decreases the activity of the lingual and gastric lipases.

## Intestine

The majority of triacylglycerol digestion and absorption occurs in the small intestine (Mu and Hoy, 2004). This process is co-dependent on pancreatic lipase and liver-derived bile salts. Bile is secreted from the gall bladder or directly from the liver in response to the presence of fat in the duodenum. Bile, *per se*, is composed of bile salts, phospholipid and cholesterol. The major function of bile is to emulsify the intestinal contents, referred to as chyme. Emulsification serves to increase the surface area of the hydrophilic mass. Bile salts have a steroid nucleus and an aliphatic side chain conjugated in an amide bond with taurine or glycine (Canaan *et al.*, 1999b; Chiang, 2004). Bile acids are synthesized from cholesterol in the liver. The rate-limiting enzyme in this process is 7 $\alpha$ -hydroxylase (Davis *et al.*, 2002; Hofmann, 2009). The hydroxyl and ionized sulfonate or carboxylate groups of the conjugate make bile salts water soluble. The primary bile salts are cholate and chenodeoxycholate (tri- and dihydroxy bile salts, respectively) which are synthesized directly from cholesterol. The secondary bile salts, deoxycholate and lithocholate, are synthesized from primary bile salts (cholate and chenodeoxycholate, respectively) by bacteria normally present in the intestinal microflora. Secondary bile salts can be further modified by hepatocytes or bacteria. The products are sulfated esters of lithocholate and ursodezylcholate.

The entry of fat into the duodenum, in addition to stimulating the contraction of the gall bladder, causes cholecystokinin secretion and the release of pancreatic lipase and colipase. The amount of fat habitually entering the duodenum regulates gene expression of pancreatic lipase. In the intestine pancreatic lipase is responsible for the majority of the triacylglycerol hydrolysis (Canaan *et al.*, 1999a,b; Whitcomb and Lowe, 2007). Pancreatic lipase hydrolyzes the sn-1 and sn-3 positions of triglyceride. The sn-2 (middle) position of glycerol is resistant to hydrolysis by lipases. Pancreatic lipase is inhibited by bile salts via displacement from the lipid droplet. Colipase, synthesized by the pancreas, binds pancreatic lipase and facilitates the enzyme's adhesion to the lipid droplets (Aloulou *et al.*, 2006; Whitcomb and Lowe, 2007). The hydrolytic products of triacylglycerol (2-monoacylglycerol and free fatty acids), along with bile salts, phospholipids, cholesterol, and other fat-soluble substances, form micelles in the small intestine. Micelles form when the critical micellar concentration of bile, about 2 mM, is reached. The presence of monoacylglycerol increases the capacity of the micelle to

accommodate free fatty acids and cholesterol. Deficits in the availability of an adequate amount of pancreatic lipase or bile acids can result in steatorrhea (presence of undigested fat in the stool).

## Phospholipid

The majority of the phospholipid in the small intestine is derived from bile with a smaller component coming from the diet. Phospholipase A<sub>2</sub>, a pancreatic enzyme secreted in bile, mediates phospholipid digestion. This enzyme hydrolyzes the ester bond at the sn-2 position of the phospholipid, resulting in a free fatty acid and lysophosphoglyceride. These products are incorporated into micelles for subsequent absorption.

## Cholesterol and Cholesteryl Ester

Both bile and, to a lesser and more variable extent, diet and sloughed intestinal cells contribute cholesterol to the contents of the small intestine (Nordskog *et al.*, 2001). Cholesterol originating from bile and intestinal cells is present in the free form. Cholesterol originating from the diet occurs as free cholesterol and cholesteryl ester. Prior to absorption, cholesteryl ester hydrolase hydrolyzes cholesteryl ester to free cholesterol and a fatty acid.

## Absorption

### Triacylglycerol

The efficiency of triacylglycerol absorption is approximately 95% in adults and 85–90% in infants, and is similar over a wide range of the total fat intakes. Fatty acids with 12 or more carbon atoms are absorbed into the lymphatic system as chylomicrons (see later section headed "Intestinal particles"). Fatty acids with 10 or fewer carbon atoms, sometimes referred to as short- and medium-chain fatty acids, are absorbed directly into the portal circulation.

Absorption of micellar components into intestinal mucosal cells is dependent on the penetration of micelles across the unstirred water layer that separates the intestinal contents from the brush border of the small intestine (Nordskog *et al.*, 2001; Iqbal and Hussain, 2009) (Figure 9.3). Under normal circumstances micellar components exist in dynamic equilibrium with the surrounding environment and spontaneously exchange among micellar particles. This process is facilitated by the peristaltic action of the small intestine. Micelles traverse the unstirred water layer because of their relatively small size (30–100 Å) and

**FIG. 9.3** Fat absorption from the small intestine. VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; LCAT, lecithin cholesterol acyltransferase; ACAT, acyl coenzyme A cholesterol acyltransferase.

hydrophilic nature, due to the presence of bile salts and phospholipid. Since the concentration of the components in the unstirred water layer and intracellularly is lower than in the surrounding environment, the products of hydrolysis flow down the concentration gradient; hence, the mechanism of absorption is passive diffusion. This net loss of micellar constituents results in a shift in the distribution of hydrolytic products from micelles in the intestinal lumen to micelles in the unstirred water layer, and from the unstirred water layer to intestinal cells.

Micellar bile salts are recycled with high efficiency, being reabsorbed in both the small intestine and colon, and resecreted via bile in the duodenum. Bile salts are absorbed independently by both passive and active mechanisms. Passive absorption of unconjugated bile salts occurs along the entire length of the small intestine and colon. Active absorption occurs in the ileum and involves a brush-border membrane receptor, cytosolic bile acid-binding protein, and basolateral anion-exchange proteins. Approximately 97–98% of bile acids are absorbed (Chiang, 2004; Keating and Keely, 2009). Interfering with the reabsorption of bile acids forces the liver to use cholesterol for the synthesis. This cause/effect relationship has been exploited for treatment of hypercholesterolemic patients with bile acid sequestrants and plant sterols, specifically intended to interfere with this process.

Short-chain fatty acids are absorbed directly into the portal circulation and transported bound to albumin via the peripheral circulation rather than undergoing incorporation into chylomicrons as occurs for longer-chain fatty acids. The majority of short-chain fatty acids are either oxidized directly as energy sources or converted to other metabolites within the hepatocyte (White *et al.*, 1999). As such, short-chain fatty acids have been identified as possessing greater thermogenic action than longer-chain fatty acids.

### Phospholipid

The products of phospholipid digestion, free fatty acid and lysophosphoglyceride, are incorporated into intestinal micelles and absorbed by a process similar to that described for the hydrolytic products of triacylglycerol.

### Cholesterol and Cholesteryl Ester

The efficiency of free and esterified cholesterol absorption is similar, approximately 40–60%. Free cholesterol and the free fatty acids resulting from the hydrolysis of cholesteryl esters are incorporated into intestinal micelles. Absorption efficiency is regulated by the balance between the incorporation of cholesterol into a newly synthesized chylomicron particle and trafficking of cholesterol out of the enterocyte

back into the small intestine (Sehayek, 2003; Wilund *et al.*, 2004). These processes are regulated by ATP-binding cassette (ABC) G5 and G8 transporters and Niemann-Pick C1-Like 1 (NPC1L1) (Altmann *et al.*, 2004; Davis *et al.*, 2004; Wang *et al.*, 2004; Rudkowska and Jones, 2008).

### Plant Sterols and Sterol Esters

The efficiency of plant sterol absorption is relatively low, approximately 1–10% depending on the specific plant sterol, and somewhat lower for the saturated form of the compounds, stanols (Katan *et al.*, 2003). The poor efficiency of absorption is attributed to multiple factors. These include the activity of the ATP-binding cassette proteins G5 and G8 that transport plant sterols but not cholesterol out of the enterocyte (Sehayek, 2003), the low solubility of the sterols in micelles, and the inability of the intestinal cell to re-esterify the sterols once absorbed (Field and Mathur, 1983). Despite their poor solubility in micelles, plant sterols interfere with cholesterol's incorporation into the intestinal particles, diminishing cholesterol absorption efficiency (Meijer *et al.*, 2003; Sudhop *et al.*, 2003; Talati *et al.*, 2010). Lower rates of cholesterol absorption result in, on average, a 10% reduction in plasma LDL cholesterol concentrations in most individuals (Talati *et al.*, 2010).

### Transport and Metabolism

Lipid is transported out of the intestine and in plasma in the form of lipoprotein particles. A common feature of lipoprotein particles is their structure. The core of the spherical particle is composed primarily of apolar components: triacylglycerol and cholesteryl ester. The surface of the particle is composed of the more polar constituents: a

phospholipid monolayer, apolipoproteins, and free cholesterol (Babin and Gibbons, 2009). Fat-soluble vitamins are sequestered in the core of the chylomicron particle.

### Intestinal Particles

Chylomicrons are intestinally derived lipoprotein particles formed and secreted after the ingestion of fat. Their main function is to provide a mechanism whereby dietary triacylglycerol, cholesterol, and other fat-soluble compounds are carried from the site of absorption (intestine) to other parts of the body for subsequent uptake and metabolism or storage (Redgrave, 2004; Williams *et al.*, 2004).

The first step in the formation of chylomicron particles is the resynthesis of triacylglycerol and phospholipids from fatty acids, and glycerol, sn-2 monoacylglycerides, or lysophospholipids, respectively (Gordon *et al.*, 1994; White *et al.*, 2004). This process occurs on the smooth endoplasmic reticulum. The fatty acid composition of the chylomicron triacylglycerol reflects the fatty acid composition of the diet (Hussain, 2000). A large proportion of the cholesterol that enters the enterocyte is re-esterified, a reaction catalyzed by ACAT, prior to incorporation into the chylomicron particle (Chang *et al.*, 1997; Buhman *et al.*, 2000; Rudel *et al.*, 2001). The re-esterification processes are facilitated by fatty acid-binding protein (Joyce *et al.*, 1999). Chylomicron particles are the largest of all the lipoprotein subclasses (Joyce *et al.*, 1999) (Table 9.2).

In humans, the distinguishing apolipoprotein of intestinally derived lipoprotein particles is apolipoprotein (apo) B-48, in contrast to the distinguishing apolipoprotein of hepatically derived particles, apo B-100. Apo B-48 is a large hydrophobic protein synthesized on the rough endoplasmic reticulum. It results from mRNA editing and is approximately 48% of the molecular weight of apo B-100. Once released into the circulation, additional

**TABLE 9.2** Characteristics of lipoproteins

apolipoproteins are added to the surface of chylomicron particles include apo A-I, apo A-IV, apo A-II, apo C, and apo E (Brown, 2007). It has been suggested that the release of apo A-IV is stimulated by dietary fat and has a role in the regulation of upper gut function and satiety (Tso and Liu, 2004). It has further been suggested that apo A-IV may be involved in the long-term regulation of food intake and that chronic ingestion of a high-fat diet blunts the intestinal apo A-IV response to dietary fat and hence predisposes to obesity (Tso and Liu, 2004).

Chylomicrons are assembled from apo B-48 and triacylglycerol accumulated in the smooth endoplasmic reticulum. Microsomal triacylglycerol transfer protein (MTP) is responsible for transporting and inserting the triacylglycerol into the nascent chylomicron core as the particle is then transferred into the lumen of the endoplasmic reticulum (White *et al.*, 1998). Some data suggest that small apo B-48-containing particles fuse with large, independently formed triacylglycerol apo B-48 free particles prior to secretion (Mu and Hoy, 2004; Kindel *et al.*, 2010). Carbohydrate is added to the nascent chylomicron particle just before release from the Golgi apparatus by exocytosis from the cell.

Chylomicrons are released from enterocytes into the lymph before being channeled from the thoracic duct to the subclavian vein. Some of the apolipoproteins associated with chylomicron particles are acquired by transfer after the lipoprotein is released into the bloodstream. Once in circulation, the triacylglycerol component of chylomicron particles is hydrolyzed by lipoprotein lipase. During this process, apolipoproteins are transferred to other lipoprotein particles. Lipoprotein lipase is synthesized in adipose tissue, heart, and skeletal muscle, and migrates to the capillaries where it functions to hydrolyze triglyceride (Merkel *et al.*, 2002; Stein and Stein, 2003). Apo C-II is a critical cofactor for the reaction whereas apo C-I and apo C-III inhibit the reaction (Shachter, 2001; Merkel *et al.*, 2002; Saito *et al.*, 2004). The hydrolysis of chylomicron triacylglycerol in the circulation accounts for the delivery of fatty acids from the gastrointestinal system to peripheral tissue for oxidation, metabolism, and storage. Chylomicron particles depleted of the triacylglycerol component are taken up by the liver via either the LDL receptor or LDL-receptor-like protein receptor (Cooper, 1997; Havel, 2000). The components of chylomicron particles are either used by the liver directly or are incorporated into newly synthesized hepatically derived lipoprotein particles.

### **Lipoprotein Particles**

#### **Very-low-density (VLDL) and Intermediate-density (IDL) Lipoproteins**

VLDL are hepatically derived particles that mediate the transport of fat from the liver to peripheral tissue (Frost and Havel, 1998; Karpe, 1999). The triacylglycerol in VLDL is synthesized from fatty acids derived from de novo lipogenesis (using monosaccharides as substrate), cytoplasmic triacylglycerol, lipoproteins taken up directly by the liver, and exogenous free fatty acids. The major apolipoprotein in VLDL is apo B-100 (Tessari *et al.*, 2009). Apo B-100 is synthesized on the rough endoplasmic reticulum and transferred to the Golgi apparatus where, with the involvement of MTP, it is incorporated into the nascent VLDL particle. Inadequate triacylglycerol or the absence of MTP results in internal degradation of apo B-100 (Olofsson *et al.*, 2007). This degradation is facilitated by the association of nascent apo B with a cytosolic chaperone protein, heat shock protein 70 (Ginsberg, 1997). In plasma, VLDL also contains apo E and apo C, which are either present at the time of secretion or acquired once in the circulation (Frost and Havel, 1998; Karpe, 1999). The lipid components of VLDL particles are similar to those of chylomicrons; however, the relative proportion of triacylglycerol is less (Table 9.2). This results in smaller, denser particles. Once in circulation, the initial stages of VLDL metabolism are similar to that of chylomicron metabolism. Lipoprotein lipase hydrolyzes the core triacylglycerol (Choi *et al.*, 2002; Cilingiroglu and Ballantyne, 2004). The resulting fatty acids are taken up by cells locally and are oxidized for energy, used for the synthesis of structural components (phospholipid) or bioactive compounds (leukotrienes, thromboxanes), or stored (triacylglycerol). Triacylglycerol-depleted particles, VLDL remnants, can either be taken up directly by receptor-mediated mechanisms in the liver or remain in circulation and be progressively depleted of triacylglycerol. The delipidation of VLDL results in the progressive shift in the composition of the lipoprotein particle from one defined as VLDL to IDL and eventually LDL (Choi *et al.*, 2002; Cilingiroglu and Ballantyne, 2004). This process is facilitated not only by lipoprotein lipase, but also by hepatic lipase (Choi *et al.*, 2002; Zambon *et al.*, 2003; Cilingiroglu and Ballantyne, 2004). This second lipase has the capacity to hydrolyze both triacylglycerol and phospholipid, and is localized to the liver. The progressive depletion of triacylglycerol from the lipoprotein particle results in a marked increase in the relative proportion of cholesterol. In circu-

lation, as VLDL is depleted of triacylglycerol, all apolipoproteins with the exception of apo B-100 are transferred to other lipoprotein particles. The ultimate product is LDL, a cholesterol-rich particle containing only a single copy of apo B-100.

### Low-density Lipoprotein

LDL particles can be taken up by an apolipoprotein-mediated (LDL receptor family) or scavenger receptor (Van Berkel *et al.*, 2000; Linton and Fazio, 2001). Several LDL receptor family members exist including the LDL receptor itself, LDL receptor-related protein (LRP), apo E receptor 2 protein, multiple epidermal growth factor-containing protein 7, VLDL receptor, LRP1B, megalin, LRP 5, and LRP 6 (May *et al.*, 2007; Lillis *et al.*, 2008; Goldstein and Brown, 2009). LDL receptors predominate in tissues such as liver, smooth muscle cells, fibroblasts, central nervous system neurons and astrocytes, epithelial cells of the gastrointestinal tract, testis Leydig cells, ovarian granulosa cells, and kidney dendritic interstitial cells (Moestrup *et al.*, 1992). Whereas the LDL receptor mediates the uptake of apo B-100 or apo E-containing lipoproteins, other members of the LDL receptor family recognize multiple apolipoproteins, proteases, and protease/inhibitor complexes, and additional signaling molecules as well as playing other diverse biological roles (Bajari *et al.*, 2005). Once LDL particles are taken up by the cell, they dissociate from the receptor which in turn allows the receptor to be recycled. The LDL particle then fuses with a lysosome and is subsequently degraded. This step is critical for whole-body cholesterol homeostasis because the cholesterol taken up from circulation and released from the lysosome has three distinct effects as discussed earlier in the “Cholesterol and cholesteryl ester” section. Alternatively, LDL can be taken up by a scavenger receptor on macrophages in various tissues. Scavenger receptors predominate in macrophages. This system predominates after LDL particles are modified or oxidized as they circulate in plasma (Van Berkel *et al.*, 2000; Linton and Fazio, 2001). Whereas the LDL receptor-mediated uptake is rate limited by the ability of unesterified cholesterol to inhibit the synthesis of new receptors, scavenger receptor uptake is proportional to circulating LDL cholesterol concentrations.

### Lipoprotein(a) (Lp[a])

Lipoprotein(a) (Lp[a]) contains an LDL-like particle and a single copy of apo(a), covalently bounded to apoB on the LDL-like particle. Blood Lp(a) concentrations are

highly heritable and affected by the apo(a) gene (LPA) located on chromosome 6q26-27. Apo(a) proteins comprise a family of proteins differing in size. The size of apo(a) is determined by the number of kringle IV repeats incorporated into the protein as a function of the LPA gene size polymorphism [KIV-2 VNTR]. Although the precise function of Lp(a) remains to be established, high blood Lp(a) concentrations are associated with increased coronary heart disease and stroke risk (Tziomalos *et al.*, 2009; Spence, 2010).

### High-density Lipoprotein (HDL)

HDL particles are derived from the liver and intestine. In addition, during delipidation of chylomicrons in the periphery, excess phospholipid and apolipoproteins from the surface of these particles serve as a source of HDL (Merkel *et al.*, 2002). The primary role of HDL particles is to participate in “reverse cholesterol transport” by shuttling cholesterol from the peripheral tissues to the liver for excretion, metabolism, or storage (Meagher, 2004; Morgan *et al.*, 2004). An integral part of this process is scavenger receptor (SR)-B1. This hepatic HDL receptor selectively takes up the cholesteryl ester component of HDL, thus enabling HDL to continually pick up additional cholesterol from peripheral tissue and shuttle it to the liver (Tall, 1998; Marcil *et al.*, 2004).

HDL is a heterogeneous group of particles that differ in both the apolipoprotein composition and size. All HDL particles contain apo A-I. Additional apolipoproteins (apo) associated with HDL can include apo A-II, A-IV, and Cs (Brown, 2007). HDL particles appear to protect other lipoproteins from oxidative modification. This activity appears to be related to the presence of apo A-I, paraoxonase, and platelet-activating factor acetylhydrolase (Ji *et al.*, 1999; Navab *et al.*, 2004, 2007). Plasma HDL levels are inversely related to triglyceride and risk of developing cardiovascular disease (Taskinen, 2003; Szapary and Rader, 2004).

Tangier disease is an autosomal recessive disorder characterized by the virtual absence of HDL cholesterol. HDL-mediated cholesterol efflux, and intracellular lipid trafficking and turnover, are abnormal in fibroblasts from Tangier patients. The genetic defect encoding for a member of the ATP-binding cassette transporter family has been identified in these individuals (Burris *et al.*, 2002; Oram, 2002; Kolovou *et al.*, 2006). The ABC transporter is integral to the process of reverse cholesterol transport. Individuals with a mutation in the ABC transporter have

very low levels of HDL cholesterol and develop premature atherosclerosis.

In addition to delipidation, lipoproteins are altered while in circulation (Borggreve *et al.*, 2003; Miller *et al.*, 2003; Wirtz, 2006; Masson *et al.*, 2009). This includes both exchange and modification of lipoprotein constituents. LCAT esterifies free cholesterol on the surface of HDL particles. Apo A-I serves as a co-factor and HDL-associated phosphatidylcholine as the source of fatty acid (Miller *et al.*, 2003; Masson *et al.*, 2009). The formation of cholesteryl ester and its subsequent migration to the core of the HDL particle creates an environment receptive to the addition of more free cholesterol from peripheral tissue and ensures that the cholesterol already on the HDL particle does not transfer back to peripheral tissue. Cholesterol ester transfer protein (CETP) facilitates the exchange of cholesteryl ester from HDL to VLDL or chylomicrons for triacylglycerol (Borggreve *et al.*, 2003; Masson *et al.*, 2009). Phospholipid transfer protein activity results in HDL remodeling through the exchange of phospholipid (Wirtz, 2006). These processes enhance reverse cholesterol transport.

## Future Directions

Several areas of lipid nutrition exist at the forefront of research. First, lipid cellular regulators have been identified recently that affect processes including fat synthesis and breakdown. In particular, a group of ethanolamides has been identified as being derived through a series of enzymatic steps from dietary fatty acids in the intestinal cells. Oleoylethanolamide, derived from oleic acid, appears to suppress fat synthesis as well as perhaps to affect appetite (Capasso and Izzo, 2008). Another future area of discovery involves transesterified fats. Repositioning the three fatty acids configured across a glycerol molecule can profoundly alter the manner by which that triacylglycerol is absorbed and metabolized (Berry, 2009). Further research is required to fully define how transesterified triacylglycerol impacts on processes of lipid digestion and utilization.

Another area of current research focus involves the genetic modification of plants to produce vegetable oils with non-traditional fatty acid profiles. For example, plant-based oils enriched in stearidonic or docosahexaenoic acid through genetic enhancement are now available for dietary consumption (Damude and Kinney, 2007). Similarly, fats enriched in oleic acid which function well as substitutes for *trans* fats are available to the food indus-

try. The health effects of such oils need to be more precisely defined.

## LIPIDS: CELLULAR METABOLISM

PETER J.H. JONES<sup>1</sup>, PhD AND ANDREA A. PAPAMANDJARIS<sup>2</sup>, PhD

<sup>1</sup>University of Manitoba, Winnipeg, Manitoba, Canada

<sup>2</sup>Nestlé Inc., North York, Ontario, Canada

### Summary

The biology and essentiality of fatty acids and other lipids have been well established. Similarly, structural roles for and cellular pathways of lipids have been clearly defined. Given the diversity of fatty acids across edible oils, the role of dietary fatty acid selection in subsequent cellular structure–function and its downstream implications for disease risk reduction are being increasingly recognized. Recently, focus has shifted to the development of functional foods that incorporate essential fatty acids and other lipids to offer added health benefits to consumers. Overall, research suggests that dietary lipid selection plays a central role in the prevention and development of several important chronic diseases.

### Introduction

The objective of this chapter is to provide a general overview of dietary control of lipid metabolism, emphasizing cellular regulatory processes and dietary fatty acid requirements. The discovery of the importance of lipids in healthy nutrition has been a process spanning the twentieth century. Before the 1920s, it was believed that fat did not play an essential dietary role if sufficient vitamins and minerals were in the diet. However, in 1927, Evans and Burr demonstrated that animals fed semi-purified, fat-free diets had impaired growth and reproductive failure (Evans and Burr, 1927). This demonstration that fat was required for health led these authors to postulate that fat contained a new essential substance, which they called vitamin F. Subsequently, Burr and Burr (1929) documented the

nutritional essentiality of a specific essential component of fat, linoleic acid (C18:2n-6). In the absence of this nutrient, symptoms developed, including scaliness of the skin, water retention, impaired fertility, and growth retardation (Evans and Burr, 1927; Burr and Burr, 1929, 1930). Thus, the concept of “essential” fatty acids was introduced to represent those dietary fatty acids required by mammals that are not synthesized *in vivo*.

Fatty acids are classified as essential based on the position of the first double bond from the methyl end of the acyl chain. Mammals do not possess enzymes that are able to synthesize double bonds at the n-6 and n-3 positions of the carbon chain of a fatty acid. Therefore, humans must obtain the essential fatty acids, linoleic acid and  $\alpha$ -linolenic acid (C18:3n-3), and their chain-elongated derivatives, from dietary sources. Specific amounts of

essential fatty acids required for optimal growth and development are provided later in this chapter.

Identification of the dietary importance of essential fatty acids in humans followed discovery of their importance in animals. Beginning in 1958, studies in infants using skim-milk-based, fat-free diets demonstrated a requirement for essential fatty acids in humans when the introduction of linoleic acid into the diet alleviated skin symptoms (Hansen *et al.*, 1958). In human adults, the use of fat-free parenteral solutions containing only glucose, amino acids, and micronutrients resulted in clinical fatty acid deficiency, which was reversed by the inclusion of linoleic acid in the solution. In the 1970s, dietary deficiency of n-3 fatty acids was linked to abnormal electroretinographic recordings in animals (Futterman *et al.*, 1971; Wheeler *et al.*, 1975). A human n-3 fatty acid requirement was demonstrated in 1982, when deficiency symptoms, including neuropathy, were linked to a parenteral solution deficient in n-3 fatty acids in a young girl (Holman *et al.*, 1982). Symptoms were reversed with the addition of n-3 fatty acids to the solution.

Recent essential fatty acid research has focused on the importance of the dietary ratio of linoleic acid to  $\alpha$ -linolenic acid, particularly as it is related to the development of disease (Stanley *et al.*, 2007; Simopoulos, 2009; Harris, 2010). Characterization of dietary needs of individual long-chain polyunsaturated fatty acids, arachidonic acid (ARA) (C20:4n-6), docosahexaenoic acid (DHA) (C22:6n-3), and eicosapentaenoic acid (EPA) (C20:5n-3), is also under investigation, notably in infant populations (Koletzko *et al.*, 2008; Ramakrishnan *et al.*, 2009; Makrides *et al.*, 2010). Additionally, the evolutionary importance of DHA in human brain development has been stressed (Cunnane and Crawford, 2003).

Recent studies show that some polyunsaturated fatty acids play a role in regulating gene expression involved in lipid and energy metabolism.  $\alpha$ -Linolenic acid regulates transcription factors such as peroxisome proliferator-activated receptors (PPARs). These transcription factors are important in modulating the expression of genes controlling both systemic and tissue-specific lipid homeostasis and membrane composition (Sampath and Ntambi, 2005).

In addition to their important roles in membrane phospholipids and as energy sources, polyunsaturated fatty acids are required in the formation of metabolic regulators called eicosanoids. Eicosanoids, as a class of diverse components, function in cardiovascular, pulmo-

nary, immune, secretory, and regulatory systems. The discovery of the unique properties of eicosanoids dates back to the 1930s, when the effect of seminal fluid on the relaxation of the uterus was documented. After further research, Von Euler (1967) characterized the active lipid-soluble compound, naming it prostaglandin. In the 1960s, prostaglandin E1 and prostaglandin F1a were isolated from sheep prostate glands (Bergstrom and Sjoval, 1960a,b). Characterization of other prostaglandins followed (Baker, 1990). The biologically active compounds derived from 20-carbon unsaturated fatty acids were classified as eicosanoids in 1979 (Baker, 1990). The effects and mechanisms of eicosanoids in health and disease represent the focus of active, ongoing investigation. These and additional aspects of essential fatty acid research are leading to a better understanding of their role in human nutrition and health.

## Dietary Sources of Lipids

Lipids are found in a variety of foods (Table 10.1; see also Table 9.1 in Chapter 9, “Lipids: Absorption and Transport,” for fatty acid formulas). Butter is a source of short-chain fatty acids. Medium-chain fatty acids are found in coconut oil. Meat contains longer-chain saturates and monounsaturates, whereas vegetable oils are major dietary sources of essential fatty acids and other unsaturated fatty acids. The fatty acid profile of vegetable oils varies widely, and therefore different oils have different proportions of linoleic acid and  $\alpha$ -linolenic acid. Safflower, sunflower, corn, and soybean oils are high in linoleic acid, yet, of these, only soybean oil is a significant source of  $\alpha$ -linolenic acid. Flaxseed, linseed, and canola oils are also high in  $\alpha$ -linolenic acid but relatively low in linoleic acid. Olive and canola oils have a higher content of monounsaturated oleic acid. Consequently, the consumption of specific vegetable oils as a sole dietary fat source can lead to a deficiency of essential fatty acids. Long-chain polyenoic fatty acids, products of intracellular elongation and desaturation of essential fatty acids, are not present in vegetable oils but are found in some animal products, as well as algae. Particularly, high-fat fish and marine mammals contain larger amounts of long-chain n-3 fatty acids, EPA and DHA. The longer-chain n-6 fatty acids, such as arachidonic acid, are found in foods of animal origin, including organ meats. Smaller quantities of very long chain fatty acids (VLCFAs) and alcohols (more than 24 carbons) are found in plant-derived foods. Cholesterol is found only in

**TABLE 10.1** Average triacylglycerol fatty acid composition of various foods and oils

Food	Average fat %	Total <sup>a</sup>	Average fatty acid composition (%)					
			Saturated			Mono- and polyunsaturated		
			16:00	18:00	18:1n-9	18:2n-6	18:3n-3	20:4n-6

Note: The percentages given are approximations because climate, species, fodder composition, etc., cause great variations. Trace, 1% detected.

–, Non-detectable amount.

<sup>a</sup>The balance of saturated fatty acids is formed by fatty acids with chain length 12 (butter 14%) and chain lengths of 12 and 14 (butter 16%, coconut and palm kernel 65–70%).

<sup>b</sup>–4% of C20:0 and C22:0; groundnuts from Argentina have relatively low C18:1 and high C18:2 concentrations.

<sup>c</sup>Also contains 18:3n-6.

<sup>d</sup>Menhaden herring oil has 11% C20:5n-3 and 9% C22:6n-3, but Norwegian herring oil has 13% C20:1n-9, 21% C22:1n-11, 7% C20:5n-3, and 7% C22:6n-3. Depending on fishing grounds, mackerel oil is similar to menhaden or to Norwegian/North Sea herring.

<sup>e</sup>Contrary to new rapeseed varieties like canola and low erucic acid rapeseed (LEAR), old varieties of rapeseed oil as well as mustard seed oil have 10% C20:1n-9 and 30–50% C22:1n-9.

<sup>f</sup>Safflower seed oil with the reverse C18:1/18:2 composition is also available.

products of animal origin, while phytosterols (or plant sterols) occur in plant oils.

Recently, focus has shifted to the development of functional foods that incorporate essential fatty acids and other lipids to offer added healthful benefits to consumers. Examples include bakery products made with flaxseed oil, eggs containing marine n-3 fatty acids, and spreads incorporating phytosterols, or their saturated derivatives, phytostanols. Additionally, foods that require oil during preparation are currently made with vegetable-based oils, such as high-oleic vegetable oils, rather than with oils that are animal-based, thereby decreasing the amount of saturated and/or trans fats incorporated in the diet.

## Cellular Roles of Lipids

Lipid constituents are required for a diverse array of cellular processes, including structure, function, and energy-related roles. Polyenoic fatty acids provide the hydrophobic moiety of phospholipids, which are critical for membrane structure and serve as precursors for eicosanoids, which regulate cellular activity. Fatty acids also play a pivotal role in providing fuel for adenosine triphosphate (ATP) and reducing equivalents and in generating body heat. Fat contains more than twice the energy per gram (9 kcal/g) as does carbohydrate or protein (4 kcal/g), which explains why humans preferentially store fat as the primary energy reservoir. Dietary lipids are also a source of lipid-soluble vitamins and sterols. Although not essential in the diet, cholesterol is needed as an integral component of membranes to increase their fluidity. Cholesterol is also converted to bile salts through hepatic hydroxylation and conjugation. Bile salts are required for normal digestion and absorption of dietary lipids. Additionally, cholesterol serves as a precursor for steroid-based hormone systems, including sex and adrenocorticoid hormones. Cholesterol, as 7-dehydrocholesterol, exists as the precursor of vitamin D, formed at the skin surface through the action of ultraviolet irradiation. Approximately 50 mg of cholesterol is converted to steroid hormones daily.

To ensure normal cellular function, an elaborate system of control regulates lipid biosynthesis, oxidation, and intracellular trafficking. This homeostatic regulatory system ensures that pathways of lipid anabolism and catabolism mesh with those of other macronutrients. Dominating this regulatory system is the ability of dietary lipid selection to modulate several key metabolic pathways. For example, the fatty acid composition of the diet

alters the composition of membrane phospholipids, which in turn changes membrane functions. Similarly, the blend of dietary fatty acids substantially alters adipose tissue fatty acid profiles (Field *et al.*, 1985). Dietary fatty acid selection also modulates cellular synthesis of regulatory eicosanoids, influencing a series of physiological responses. Similarly, alterations in cholesterol or phytosterol intake modulate cholesterol synthesis, absorption, and subsequent metabolism. Consequently, the metabolism of fatty acids, sterols, and their derivatives responds to manipulation in dietary lipid intakes in many important ways. To appreciate the link between dietary lipid consumption and disease risk modification, it is important to individually consider the fundamental processes of cellular lipid metabolism.

## Lipid Biosynthesis

### Fatty Acid Synthesis

Fatty acids are synthesized *de novo* from acetyl coenzyme A (CoA) in the extramitochondrial space by a group of enzymes classified as fatty acid synthetases. The synthesis of fatty acids is governed by the enzyme acetyl CoA carboxylase, which converts acetyl CoA to malonyl CoA. A series of malonyl CoA units are added to the growing fatty acid chain to culminate in the formation of palmitic acid (C16:0). From this point, more complex fatty acids can be formed through elongation and desaturation; however, humans do not possess the enzymes capable of inserting points of unsaturation at sites below the n-7 carbon, making the n-6 and the n-3 fatty acids essential (see Chapter 9, "Lipids: Absorption and Transport," for a discussion of nomenclature). Desaturase enzymes are membrane bound and occur in the endoplasmic reticulum of several tissues. Desaturases are specific for the position of the double bond in the carbon chain and require electrons supplied by nicotinamide adenine dinucleotide (NADH) or nicotinamide adenine dinucleotide phosphate (NADPH), which are catalyzed by cytochrome b5.

Longer-chain fatty acids are synthesized from C16:0, C18:0, C18:2n-6, and C18:3n-3 by alternating desaturation and elongation. The synthesis of C20:4n-6 from C18:2n-6 and of C20:5n-3 from C18:3n-3 is achieved through D6 desaturation followed by elongation and D5 desaturation (Figure 10.1). The synthesis of C22:6n-3 from C20:5n-3 occurs through elongation, desaturation, and partial  $\alpha$ -oxidation (Catalá, 2010). It was recently demonstrated that fatty acid elongation need not

**FIG. 10.1** Interconversions of non-essential and essential fatty acids. EFA, essential fatty acid.

commence with 18-carbon precursors. To meet n-6 fatty acid requirements, it is possible to use C16:2n-6, derived from plant materials, in place of linoleic acid, thereby effectively reducing the requirement for the latter fatty acid (Cunnane, 2003). The extent to which this pathway contributes substantially to in vivo linoleic acid levels remains to be assessed.

The synthesis of longer-chain fatty acids has been shown to be regulated by the  $\Delta 6$  desaturase enzyme, which in turn is influenced by hormones and dietary constituents. The  $\Delta 6$  desaturase preferentially targets the most highly unsaturated fatty acid; the preferential desaturation order is therefore C18:3n-3 > C18:2n-6 > C18:1n-9. As such, the competitive nature of the fatty acid desaturation and elongation among the three classes of fatty acids (Figure 10.1) has nutritional implications. The consumption of diets rich in n-6 fatty acids can result in suppression of the elongation and desaturation of C18:3n-3 to C20:5n-3 and C22:6n-3. An example of this situation is infant formulas, in which high ratios of C18:2n-6 to C18:3n-3 potentially depress the production of important n-3 poly-

enoic fatty acids required for the developing nervous system. Alternatively, changing prostaglandin profiles through elevated intakes of n-3 fatty acids such as EPA and DHA from fish and fish oils can decrease the clotting capacity of blood. Hormonal shifts may also perturb desaturase activity: insulin increases, but glucagon and epinephrine decrease, desaturase enzyme activity (El-Badry *et al.*, 2007).

Reversal of the elongation and desaturation process may also occur intracellularly. Very long chain and long chain n-3 and n-6 fatty acids may undergo shortening and saturation through retroconversion to other, shorter, fatty acids (Mebarek *et al.*, 2009). This process occurs in peroxisomes and is probably necessary for some, if not all, of the endogenous synthesis of DHA in animals (Catalá, 2010).

### **Cholesterol Biosynthesis**

Cholesterol is synthesized in almost all human tissues in a process that possesses more than 20 steps; indeed, the pathway is one of the longest of any lipid produced intracellularly. Humans likely once relied extensively on

endogenously produced cholesterol for cellular requirements, as ancestral daily dietary intakes have been estimated at as low as 50 mg. However, today, most people consume diets in which the dietary intake of cholesterol and fat is increased such that cholesterologenesis is less relied on to serve cellular cholesterol needs. Unlike animals, humans appear to synthesize most cholesterol in extrahepatic tissues. The total body pool of cholesterol is estimated to be 75 g. Of the 1200 mg cholesterol turned over daily, 300 to 500 mg is absorbed from the diet, and de novo synthesis accounts for 700 to 900 mg (Dietschy, 1984). How synthesis is coordinated across tissues remains to be defined.

As with fatty acids, the process of cholesterol synthesis begins with acetyl CoA generated through the oxidative decarboxylation of pyruvate or the oxidation of fatty acids. In the initial phase of the pathway, acetyl CoA molecules combine to form mevalonic acid. The final enzyme of this initial phase, hydroxymethylglutaryl (HMG) CoA reductase, is considered to be rate limiting in the overall cascade of cholesterologenesis and has been studied widely in relation to pathway control. In fact, statin drugs, currently the most widespread pharmacological intervention to lower cholesterol levels, work through inhibition of HMG CoA reductase. The later phase of cholesterol biosynthesis involves steps of phosphorylation, isomerization, and conversion to geranyl-B and farnesyl-pyrophosphate, which in turn form squalene (Figure 10.2). From the squalene stage, loss of three methyl groups, side-chain saturation, and bond rearrangement result in the formation of cholesterol.

Diet modulates cholesterol biosynthesis in several ways. Curiously, it is a common misconception that high levels of dietary cholesterol increase circulating levels of cholesterol; however, total and low-density lipoprotein (LDL) cholesterol levels as well as cholesterol biosynthesis are minimally affected by even sizable increases in dietary cholesterol concentration (Jones *et al.*, 1996; Greene *et al.*, 2005). Conversely, qualitative dietary fat intake more substantially perturbs the rate of cholesterol biosynthesis and circulating lipid levels. In particular, dietary polyunsaturated fat intake enhances (Jones, 1997), whereas trans fatty acid intake suppresses (Matthan *et al.*, 2000), cholesterol biosynthesis. Despite this observed effect of trans fatty acids on cholesterol synthesis, overall these fats lower HDL and raise LDL cholesterol levels (Mozaffarian *et al.*, 2006). Increasing the number of meals consumed per day, while holding total caloric intake constant, has also been shown to reduce cholesterol biosynthesis rates (Jones, 1997). Of the dietary factors capable of modifying cholesterol syn-

FIG. 10.2 Stages of cholesterol biosynthesis.

thesis, energy restriction has the greatest effect. Humans who fast for 24 hours exhibit complete cessation of cholesterol biosynthesis (Jones, 1997). How synthesis responds to more minor energy imbalances has not been examined; however, substantial suppression of human de novo cholesterologenesis has been demonstrated with even modest levels of energy restriction and weight loss (Di Buono *et al.*, 1999).

### Fatty Acid Oxidation

Fatty acid oxidation generates acetyl CoA and occurs through  $\beta$ -oxidation, predominantly in mitochondria. During this process, the fatty acyl chain undergoes cyclical degradation through four stages, including dehydrogenation (removal of hydrogen), hydration (addition of water), dehydrogenation, and cleavage. At points of unsaturation within the acyl chain, the initial dehydration step does not take place. The four-stage oxidation process is repeated until the fatty acid is completely degraded to acetyl CoA, as shown by the absence of chain-shortened n-3 or n-6 fatty acids within cells or in the bloodstream. Fatty acids containing 18 carbons or fewer enter the mitochondria as fatty acyl CoA through transport by carnitine. Short- and medium-chain fatty acids do not require the presence of the carnitine shuttle to enter the mitochondria for oxidation.

Beta-oxidation also occurs in peroxisomes through a similar, but not identical, process that is tailored to the oxidation of long-chain fatty acids with more than 18 carbons. Also, the initial desaturation reaction in peroxisomal oxidation occurs via a fatty acyl CoA oxidase, whereas an acyl CoA dehydrogenase is the first enzyme in the mitochondrial pathway. Last, peroxisomal  $\beta$ -oxidation is not tightly linked to the electron transfer chain. Thus, in peroxisomes, electrons produced during the initial stage of oxidation transfer directly to molecular oxygen. This oxygen generates hydrogen peroxide that is degraded to water by catalase. The energy produced in the second oxidation step is conserved in the form of the high energy level electrons of NADH. Without  $\beta$ -oxidation in peroxisomes, abnormal accumulation of VLCFAs will ensue in plasma and different tissues, leading to peroxisomal disorders such as Zellweger syndrome (ZS) and adrenoleukodystrophy (Fidaleo, 2010).

Evidence is emerging that the rate of fatty acid oxidation is not identical across all chain lengths and degrees of unsaturation, but exhibits structural specificity. For decades it has been suggested that short- and medium-chain saturated fatty acids undergo more rapid combustion for energy compared with long-chain fatty acids, probably because of the preferential transport of the former linked to albumin through the portal circulation and the lack of need for carnitine to enter the mitochondria (Papamandjaris *et al.*, 1998).

In addition, the notion that more highly unsaturated long-chain fatty acids are preferentially oxidized has also received some support (DeLany *et al.*, 2000), although this concept is paradoxical given the essentiality of these highly unsaturated polyunsaturated fatty acids. Intriguingly, carbon from oxidized linoleic and  $\alpha$ -linolenic acid is extensively recycled into de novo synthesis of long-chain fatty acids and cholesterol. This pathway is particularly evident in the brain during early development (Cunnane *et al.*, 2003), but is quantitatively important even when intake of these parent polyunsaturates is severely deficient (Cunnane *et al.*, 2006).

In addition to the effect exerted by the type of fatty acid consumed, variations in the metabolic state also influence the rate of fat oxidation. Conditions such as fasting and exercise at moderate intensity result in increased lipolysis and oxidation (Achten and Jeukendurp, 2004; Solomon *et al.*, 2008). With respect to substrates and hormones, raised glucose and insulin levels suppress fatty acid oxidation (Wolfe, 1998).

## Eicosanoid Production and Regulation

Structurally, as oxygenated 20-carbon derivatives from the n-3 and n-6 family of fatty acids, eicosanoid members include prostaglandins, thromboxanes, leukotrienes, hydroxy acids, and lipoxins. The production of specific categories of eicosanoids is governed by fast-acting and rapidly inactivated enzyme systems. Whereas prostaglandins and thromboxanes are generated via cyclooxygenase (COX) enzymes, leukotrienes, hydroxy acids, and lipoxins are produced through the action of lipoxygenase (LOX) enzymes. Major pathways for eicosanoid synthesis are depicted in Figure 10.3. The process begins with the action of phospholipase A2 on cell-membrane phospholipids, splitting off fatty acids from the sn-2 position of the molecule. All membrane phospholipid species serve as substrates in the cleavage process; the resultant cleaved fatty acids serve directly as substrates for eicosanoid production via the cyclooxygenase and lipoxygenase enzyme cascades. With respect to the n-6 series, cleaved arachidonic acid is transformed to prostaglandins by prostaglandin H synthase-1 (PGHSB1) and prostaglandin H synthase-2 (PGHSB2). These enzymes catalyze the conversion of arachidonic acid to prostaglandin G2 (PGG2) via a cyclooxygenase reaction, and then the reduction of PGG2 to PGH2 via a peroxidase reaction. This latter intermediate then undergoes rapid conversion to other active forms of prostaglandins, thromboxanes, or prostacyclins. As an alternative pathway, arachidonic acid undergoes oxidation via a series of LOX enzymes to form a series of active eicosanoids. The 5-LOX pathway generates leukotrienes B4, C4, and D4 (LTB4, LTC4, and LTD4), which are believed to serve as mediators in the immune response. The 12-LOX pathway generates 12-L-hydroxyeicosatetraenoic acid (12-HETE) and 12-hydroperoxyeicosatetraenoic acid (12-HPETE), which are also involved in the inflammatory response. The action of a third LOX reaction pathway, 15-LOX, results in the formation of 15-hydroeicosatetraenoic acid (15-HETE), which possesses anti-inflammatory actions and may inhibit the activities of both 5-LOX and 12-LOX. Thus, several eicosanoid subtypes may be generated from arachidonic acid intracellularly.

Eicosanoids are also derived from the n-3 series of fatty acids cleaved from membrane phospholipids. Eicosanoids derived from n-3 fatty acids evoke less-active responses than do those of the corresponding n-6 eicosanoids. Thus, PGE3 formed from EPA possesses less inflammatory action than does PGE2 formed from arachidonic acid.

FIG. 10.3 Synthesis of major eicosanoids from n-6 and n-3 fatty acids.

Similarly, LTB<sub>5</sub> derived from EPA is less active in the proinflammatory response than is LTB<sub>4</sub>, which is produced from arachidonic acid. On these bases, the two classes of eicosanoids compete, evoking opposing biological actions.

Dietary fatty acid composition has been shown to play an important role in eicosanoid-mediated function. The consumption of diets high in n-3-rich fats produces higher levels of n-3 fatty acids in phospholipids. These fatty acids, when cleaved from phospholipids, compete with arachidonic acid for incorporation into eicosanoids. The enhanced bleeding times observed in Inuit populations who consume higher levels of n-3 fatty-acid-containing fish reflect the shift from n-6- to n-3-based eicosanoid formation. PGI<sub>3</sub>, produced from EPA, has anti-aggregatory action. The prolonged bleeding times in individuals consuming high amounts of n-3 fatty-acid-containing marine-based foods are believed to be mediated through such anti-aggregatory action of n-3-based eicosanoids. Conversely, eicosanoid overproduction from arachidonic acid, a result of diets poor in n-3 fatty acids, may result in a number of disorders associated with the inflammatory and immune systems, including thrombosis, arthritis, lupus, and cancer (see section on dietary fatty acids and disease risk). For instance, arthritic patients appear to benefit from increasing their intake of fish oil (Calder, 2009a), likely to be due to the inhibition by n-3 fatty acids of the production of the proinflammatory eicosanoids LTB<sub>4</sub> and PGE<sub>2</sub>. The demonstration that dietary fatty acid selection may modulate physiological function through eicosanoid generation underscores the impor-

ance of food selection in the prevention and treatment of disease.

## Dietary Requirements for Fatty Acids

The USDA recommends 20–35% of the daily food intake should come from fat. Currently, dietary recommendations for omega-3 fatty acids are 1.6 g/day for men and 1.1 g/day for women, whereas omega-6 fatty acids recommendations are 17 g/day for men and 12 g/day for women (Institute of Medicine 2002/2005). These values were established based on the levels of fatty acids required to prevent or alleviate essential fatty acid deficiency. Deficiency symptoms were documented when patients were fed total parenteral nutrition solutions devoid of essential fatty acids in the 1960s. Skin irritations that developed during fat-free diets were alleviated when patients were fed solutions containing linoleic acid (Hansen *et al.*, 1958). Recent evidence indicates that pure linoleate deficiency, in contrast to general unsaturated fatty acid deficiency categorized previously, can be reversed with as little as 2% of dietary energy fed as linoleic acid in the rat (Cunnane, 2003). For  $\alpha$ -linolenic acid, classification of deficiency symptoms has been difficult, since related deficiencies are more subtle than those found with linoleic acid. Also, pure deficiencies are hard to induce because symptoms may remain absent in the presence of DHA.

Based on essential fatty acid metabolism, an indicator for essential fatty acid deficiency is the triene-to-tetraene ratio, which assesses the ratio of C20:3n-9 to C20:4n-6. The triene, C20:3n-9, is the product of the desaturation

of C18:1n-9 to C20:3n-9 (Figure 10.1). Because of the affinity of the D6 desaturase for essential fatty acids more than 16 carbons in length, triene concentrations increase only during essential fatty acid deficiency, when C16:0 and C18:1n-9 are the major substrates available. A triene-to-tetraene ratio above 0.4 indicates essential fatty acid deficiency. However, the ratio is not specific to deficiency of linoleic or  $\alpha$ -linolenic acid. To assess for  $\alpha$ -linolenic deficiency, the ratio of DPA (n-6) to DHA can be a valuable index, because the absence of n-3 fatty acids results in the increased formation of n-6 elongation and desaturation products.

As the roles of essential fatty acids and their products in the achievement and maintenance of optimal health are further elucidated through research, dietary recommendations may be set on the basis of health promotion rather than on the avoidance of deficiency. An example is the recognition of the contribution of the ratio of linoleic acid to  $\alpha$ -linolenic acid in the diet to a healthy essential fatty acid profile. The competitive desaturation of n-3, n-6, and n-9 fatty acids by D6 desaturase is of major significance consistent with this rationale. If  $\alpha$ -linolenic acid is lacking in the diet or if there is a large amount of linoleic acid present, EPA production will become elevated and little or no DHA will be produced. If both essential fatty acids are lacking, C20:3n-9 will accumulate. Inhibition of arachidonic acid and DHA production achieved through high levels of linoleic acid or essential fatty acid deficiency may be undesirable, based on the metabolic functions of these compounds and their roles in disease onset and progression (see below).

Beginning in the 1920s, the levels of linoleic acid in the Western diet have been increasing and the levels of  $\alpha$ -linolenic acid have been decreasing (Uauy *et al.*, 1999; Simopoulos, 2009). Estimates of the current ratio of linoleic to  $\alpha$ -linolenic acid in North America range from 9.8:1 to 15:1 to 30:1 (Kris-Etherton *et al.*, 2000; Simopoulos, 2008). A ratio of 2:1 to 5:1 is currently recommended (Holman, 1998; Kris-Etherton *et al.*, 2000; Simopoulos, 2008), with the World Health Organization (WHO, 1994) recommended level at 5:1 to 10:1. Achieving this recommended ratio would require a reversal in the trend of fatty acid consumption, with the inclusion of greater amounts of n-3 fatty acids from plant and marine oils in tandem with the consumption of lower amounts of n-6 fatty acids from seed oil in the diet. The consequences of the long-term consumption of a high ratio of n-6 to n-3 fatty acids are being studied and will

provide further insight into healthy dietary essential fatty acid levels. At present, arachidonic acid and DHA are not considered essential to a healthy adult diet, unless the capacity for desaturation and elongation of essential fatty acids is compromised.

Dietary essential fatty acid requirements in infants are being widely investigated, because there might be a need to provide not only essential fatty acids, but arachidonic acid and DHA as well. Preterm infants, depending on age at birth, may not receive an intrauterine supply of arachidonic acid and DHA (Lapillonne and Jensen, 2009) and, if formula fed, may not receive arachidonic acid and DHA, but only 18-carbon essential fatty acids. Recently, conventional infant formulas have been produced that contain added DHA and ARA. DHA and ARA are often added at levels concurrent with the WHO (1994) guidelines, which are based on international levels of DHA and ARA in breast milk (Innis, 2007). Because both brain and retina have high levels of DHA, it has been hypothesized that DHA in breast milk may confer a developmental advantage to both term and preterm infants, as has been reported with breast feeding (Lucas *et al.*, 1994; Michaelsen *et al.*, 2009). These findings have been somewhat supported by the results of clinical intervention studies, in which direct supplementation of formula with n-3 fatty acids resulted in improvements in development-associated parameters (Neuringer *et al.*, 2000; Uauy *et al.*, 2003; Fleith and Clandinin, 2005). Without the inclusion of arachidonic acid and DHA, there may not be sufficient capacity to convert essential fatty acids into arachidonic acid and, more specifically, into DHA to meet requirements for brain and visual function (Cunnane, *et al.*, 2000). Results in preterm infants have demonstrated evidence that DHA supplementation may affect visual acuity and development (Lapillonne *et al.*, 2000; Uauy *et al.*, 2000; Agostoni, 2008; Henriksen *et al.*, 2008), but not all studies show positive benefits (Simmer and Patole, 2004). A recent review of the clinical trials published to date in preterm infants has concluded that the long-term benefits of DHA and ARA formula supplementation have yet to be demonstrated (Simmer *et al.*, 2008b). For infants born at term, research has demonstrated that formula supplementation with DHA may (Larque *et al.*, 2002; Hoffman *et al.*, 2003, 2009; Birch *et al.*, 2005, 2010; Eilander *et al.*, 2007) or may not (Simmer *et al.*, 2008a; Beyerlein *et al.*, 2010) affect development, and that any effect may disappear over time (Agostoni *et al.*, 1995, 1997). No differences were reported in age-appropriate tests of receptive and expres-

sive language, IQ, visual or motor function, or visual acuity in infants at 39 months who had either been breast-fed or formula-fed with formula that either did or did not contain DHA and ARA (Uauy *et al.*, 2003). Continued research in this area in both term and preterm infants using well-controlled studies with large sample sizes will address the long-term and short-term effects of DHA and arachidonic acid supplementation on visual and cognitive development.

## Dietary Fatty Acids and Disease Risk

Scientists and the general public alike are interested in the importance of comparative fatty acid selection in relation to health and longevity. Consensus is beginning to emerge concerning the role of qualitative fat intake in the management of disease risk. For certain diseases common to Western civilization, the evidence for reducing risk by adopting certain fat intake profiles is compelling; for other diseases, the link remains speculative. This rapidly progressing field will undoubtedly see further development as research advances our knowledge. Quantitative fat intake is undergoing renewed scrutiny as scientists debate the percentage of daily energy from fat that is necessary for optimal health.

Current recommendations relating to quantitative fat intake call for a reduction in total fat and saturated fat intakes (National Cholesterol Education Program, 2002; Lichtenstein *et al.*, 2006; Hall, 2009). The basis for such recommendations comes from epidemiological evidence indicating that body weight is positively correlated with quantitative fat and not carbohydrate intake (Astrup, 2005; Acheson, 2010). Additionally, research has shown that increasing the fat content of a diet promotes fat storage in adipose tissue rather than fat oxidation (Jequier, 1993; Fernández-Quintela *et al.*, 2007) (see Chapters 45, 61, 62, and 68). However, not all evidence establishes a link between quantitative fat intake and obesity. Willett (1998) demonstrated that a decrease in dietary fat as a percentage of energy has not resulted in a decrease in overweight and obesity. Indeed, there is insufficient evidence to link percentage energy from dietary fat with obesity (Astrup, 2005). It may be more effective to focus on qualitative fat consumption – notably, decreased saturated fat and increased unsaturated fat – combined with recommendations to restrict energy intakes (Lichtenstein, 2003; Purnell, 2009). Such an approach would acknowledge the overall importance of the metabolic actions of all

### BOX 10.1 Diseases influenced by qualitative polyunsaturated fatty acid intake in humans

Essential fatty acid deficiency during development  
Autoimmune disorders, including lupus and nephropathy  
Type 2 diabetes  
Inflammatory bowel disease  
Breast, colon, and prostate cancers  
Rheumatoid arthritis

fatty acids in the diet, which is an increasing area of focus in fatty acid research. This approach would also recognize the link between percent fat and energy density, and the influence on total caloric intake (French and Robinson, 2003; Prentice and Jebb, 2003).

Box 10.1 lists diseases linked to the relationship between polyunsaturated and other fatty acids in the diet. Of these disorders, coronary heart disease is the most strongly linked to qualitative fat intake. Although it has been well established that consumption of n-9 and n-6 fatty acids favorably reduces circulating levels of total cholesterol and LDL cholesterol, n-3 fatty acids recently have been the focus of much attention (Lichtenstein, 2003; McCowen and Bistrrian, 2005; Erkkilä *et al.*, 2008; Harris *et al.*, 2008; Wall *et al.*, 2010). The surprisingly low cardiovascular mortality rate in Native Alaskans consuming traditional diets high in EPA and DHA alerted researchers to the fact that, in the presence of elevated total fat intakes, n-3 fatty acids are effective in reducing disease risk. The influence of fish oils on cardiovascular disease risk is multifactorial. Fish oils reduce very-low-density-lipoprotein (VLDL) secretion, lower triacylglycerol transport, and may enhance VLDL clearance (McEwen *et al.*, 2010). The net effect often is a reduction of circulating triacylglycerol levels. For LDL cholesterol, the data are clearer for n-9 and n-6 fatty acids, as the consumption of these fats results in unequivocal depression of circulating levels. However, for n-3 fatty acids, the data are more controversial; evidence indicates that LDL cholesterol may increase marginally in humans fed fish oil. Similarly, *in vitro* plasma lipid oxidizability is enhanced in animals fed fish oil. The consumption of diets high in n-6 fatty acids generally results in the suppression of HDL cholesterol levels, whereas n-9 fatty acid intake

does not affect values. Studies of the effects on blood lipids of n-3-containing fish oils suggest that HDL cholesterol levels are maintained or elevated with fish-oil consumption.

The action of n-3 fatty acids in reducing coronary heart disease risk is not related solely to effects on circulating lipids. Fish-oil-derived fatty acids may also increase endothelium-dependent dilatation of arteries, which is thought to be beneficial in risk reduction for atherosclerosis. Moreover, polyenoic n-3 fatty acids are receiving considerable attention as potential anti-inflammatory agents (Calder, 2004; Flickinger and Huth, 2004; Singer *et al.*, 2008). In vitro studies comparing the action of various long-chain polyunsaturated fatty acids on endothelial tissue activation as assessed by surface enzyme immunoassay or flow cytometry found no effect. However, a progressive increase in the inhibition of cytokine-induced expression of adhesion molecules was observed with increasing degrees of fatty acid unsaturation from monounsaturated fatty acids to polyenoic n-3 fatty acids. Endothelial activation was most highly inhibited with n-3 versus n-6 or n-9 fatty acids.

In addition, the beneficial effects of dietary n-3 fatty acids on coronary heart disease risk are thought to be mediated via the prevention of arrhythmias, particularly ventricular tachycardia and fibrillation, as well as by favorable modulation of prostaglandin and leukotriene production to reduce thrombogenesis (Gerber *et al.*, 2000; Renaud, 2001). It can be surmised that dietary fat selection consistent with maximal reduction in cardiovascular disease risk would result in lower levels of saturated fats and higher intakes of EPA and DHA from fish oil. Based on current knowledge, this approach would be appropriate for both primary and secondary disease prevention.

A second critical health issue regarding the selection of dietary fatty acids is the need for adequate intakes of essential fatty acids during fetal development and shortly following birth. As noted above, polyenoic unsaturated fatty acids are important components of neural structure membrane phospholipids. Major phospholipid classes in brain and retina contain high levels of DHA. DHA is considered a conditionally essential nutrient for adequate growth in humans (Saldanha *et al.*, 2009). Prolonged absence of dietary n-6 or n-3 fatty acids results in depressed levels of phospholipid polyenoic fatty acids. Of particular interest is the definition of what constitutes adequate dietary n-3 fatty acid levels; neural tissue DHA levels fall to one-fifth the normal amount in animals deprived of n-3

fats (Neuringer *et al.*, 1986). In addition to structural changes, n-3 fatty acid deficiency also results in pronounced behavioral changes. In rhesus monkeys, perinatal n-3 deficiency resulted in functional changes in offspring including reduced vision, electroretinogram irregularities, polydipsia, and possibly cognition disturbances (Reisbick *et al.*, 1996). Although the behavioral changes in animals deprived of n-3 fatty acids may be due directly to impaired neural cell function, secondary neurotransmitter-related effects arise from n-3 fatty acid deficiency. In rats deficient in n-3 fatty acids, behavioral disturbances were shown to be associated with changes in dopaminergic neurotransmission in the nucleus accumbens region of the brain (Zimmer *et al.*, 2000).

By extension, a critical issue relating to human health is the quantity and composition of n-3 fatty acids in infant formulas. Probably because of reduced levels of polyenoic long-chain fatty acids in infant formulas compared with human breast milk, formula-fed infants have lower levels of DHA in the brain (Makrides *et al.*, 1994). Although earlier formulas had notoriously imbalanced ratios of n-3 to n-6 fatty acids, the use of soybean oil has markedly improved this ratio in modern formulas. However, the n-3 fatty acids are provided largely as  $\alpha$ -linolenic acid, which may not be fully converted to DHA by developing infants. Current debate focuses on whether infant formula would benefit from direct supplementation with highly polyunsaturated fatty acids of both the n-6 and the n-3 classes. Manufacturing processes presently add specific antioxidants to reduce the possibility of oxidative damage, which allows the routine addition of long-chain polyunsaturated fatty acids. Results at this time remain equivocal, but continued study with reliable sources of DHA and ARA, such as single-cell oils and standardized developmental tests, should permit the establishment of consensus in the near future.

The relationship between dietary fat composition and inflammatory bowel disease is increasingly recognized (Calder, 2009b; Uchiyama *et al.*, 2010). Although it has been proposed that olive oil and oils containing n-6 fatty acids are potentially beneficial, most interest is centered on the use of dietary fish oil to improve remission rates of Crohn's disease and to suppress the symptoms and histological appearance of ulcerative colitis. Results from recent studies are not unequivocal; however, evidence suggests that the consumption of n-3 fatty acids, particularly as fish oil, improves the clinical management of inflammatory bowel disease (Turner *et al.*, 2007). The likely reason is

that n-3 fatty acids suppress LTB<sub>4</sub> and thromboxane A<sub>2</sub>, both of which are derived from arachidonic acid and are associated with mucosal inflammation.

The role of dietary fat composition in cancer risk remains controversial. It has been demonstrated that the effects of specific fatty acids on mammary carcinogenesis vary in both in vitro and in vivo animal models, with stimulatory effects observed for linoleic acid compared with saturated fatty acids (Rose *et al.*, 1995; Rose, 1997). Mechanistically, cyclooxygenase and lipoxygenase products derived from n-6 fatty acids may stimulate the growth factors and oncogenes that are responsible for the increased carcinogenesis. Alternatively, the inhibition of calcium mobilization, which is linked to cell signaling and cell proliferation, may be affected by the presence of higher cellular concentrations of EPA and DHA (Calviello *et al.*, 2000). The link with n-6 fatty acid consumption and prostate cancer remains weak. Mounting evidence does, however, suggest a beneficial role of n-3 fatty acids compared with other fats in the suppression of breast and prostate cancers (Rose *et al.*, 1995; Judé *et al.*, 2006; Berquin *et al.*, 2008; Giacosa and Rondanelli, 2008; Hurst *et al.*, 2010; Shaikh *et al.*, 2010).

Evidence linking the consumption of n-3 fatty acids with reduced severity of arthritic symptoms remains controversial despite reported improvements in the incidence of tender joints and joint stiffness in a meta-analysis of studies reporting n-3 fatty acid supplement use (Hurst *et al.*, 2010). The effect probably involves altered eicosanoid metabolism and interleukin-1 levels. In general, patients are advised to consume 3–6 g/day of n-3 fatty acids to achieve benefits against arthritis, although further confirmation of this association is needed.

Several studies raise the possibility that certain dietary fatty acids can lower the risks of developing type 2 diabetes mellitus (T2DM). Research has shown that increasing the amounts of dietary n-3 long-chain polyunsaturated fatty acids may reduce T2DM as these fatty acids are linked to cell membrane function, enzyme activity, and gene expression, all of which influence glucose metabolism (Risérus *et al.*, 2009). Also, increased intake of omega-3 fatty acids has been shown to increase insulin sensitivity, reduce circulatory TG levels, and increase HDL concentrations. In addition, fatty acids are now linked to reducing adiposity and lipid accumulation in the visceral area (Fruchart, 2009). These actions not only reduce the progression in T2DM but also decrease the risks of obesity and cardiovascular disease.

A model demonstrating the possible effects of different levels of essential fatty acids and long-chain polyunsaturated fatty acids on the disease states discussed above is illustrated in Figure 10.4 (Okuyama *et al.*, 1996; Uauy *et al.*, 1999; Steinberg, 2007; Simopoulos, 2008). The model demonstrates the interrelated manner in which various dietary lipid components interact to influence disease outcome, and highlights the heterogeneity of dietary lipid constituents. It also points out potential beneficial actions of increasing the ratio of n-3 to n-6 fatty acid intake; however, the possible risk of increasing peroxidative status with the elevation in degree of unsaturation of the fat consumed must also be considered.

Overall, research suggests that dietary lipid selection plays a central role in the prevention and development of several important chronic diseases (McCowen and Bistrrian, 2005). An emerging conclusion is that the ratio of linoleic acid to  $\alpha$ -linolenic acid may be of importance in the etiology of several of these conditions. Evidence suggests that a lower ratio may be protective. Given the present high ratio of 18:2n-6 to 18:3n-3 in the Western-style diet (Simopoulos, 2008), dietary recommendations to include greater amounts of n-3 fatty acids may be valuable in preventing disease (Holman, 1998; Uauy *et al.*, 1999; Harris, 2006; Simopoulos, 2008; Calder, 2009a). However, safety issues related to increased n-3 fatty acid intakes also need to be fully explored, because it cannot be ruled out that peroxidative status increases along with the degree of unsaturation of dietary fat (Catalá, 2010). Future well-controlled clinical trials are necessary to clearly elucidate the effects of qualitative fatty acid intake in relation to disease risk.

## Future Directions

### **Resolvins and Protectins: Novel Lipid Mediators**

Eicosanoids derived from 20-carbon PUFAs provide a pivotal link between the dietary balance of n-6 and n-3 PUFAs and their association with the progression of inflammatory diseases. Recently, novel lipid mediators have been identified that actively induce the resolution of acute inflammation, termed resolvins (resolution phase interaction products) and protectins (Serhan *et al.*, 2008). These proresolution products are synthesized from the oxygenation of EPA and DHA. A series of reactions via the 5-LOX pathway produces the EPA E-series resolvins (RvE1, RvE2) and DHA D-series resolvins (RvD1 through

**FIG. 10.4** Interaction among dietary lipid components, metabolic systems, and disease/health outcomes.

RvD6), as well as neuroprotectin D1 (Serhan *et al.*, 2008). Since DHA is highly concentrated in neurological tissue, protectins comprise the DHA metabolites docosatrienes and the D-series resolvins and are specifically associated with neuroprotective and anti-inflammatory effects (Serhan, 2005). Resolvins and protectins act locally to reduce PMN infiltration and proinflammatory gene expression, block inflammatory cytokines such as TNF- $\alpha$  and IL-1, and induce macrophage uptake of apoptotic cells. Although preliminary *in vitro* studies have been conducted with isolated human cells, future studies are needed to investigate the *in vivo* functions of resolvins and protectins and their role in amelioration of chronic disease.

### PPARs

Peroxisome proliferator-activated receptors (PPARs), which include the isoforms PPAR $\alpha$ , PPAR $\gamma$ , and PPAR $\delta$ , are a group of ligand-regulated nuclear transcription factors regulating the expression of genes involved in lipid and lipoprotein metabolism, inflammation, and vascular function (Fruchart, 2009). EPA and DHA have a high affinity for PPARs, therefore current research is focusing on the metabolic effects associated with regulation of

transcription factors by PUFAs and implications in chronic disease.

## VITAMIN A

NOEL W. SOLOMONS, MD

*Center for Studies of Sensory Impairment, Guatemala City, Guatemala*

### Summary

Vitamin A is a fat-soluble compound essential for functions of the retinal pigments for vision, intercellular communication via the connexin mechanisms, and regulation of nuclear transcription via nuclear receptor coupling related to cellular growth and differentiation. Its actions include retinoid analogs' anti-proliferative action against proliferative disorders, and a putative enhancement of the biological availability of dietary iron. The vitamin can be obtained from foods of animal origin, such as organ meats, fish oil, dairy products, in the preformed vitamin (retinoid) form, and from plant-origin foods, such as orange, yellow, and green vegetables and fruits, as provitamin A (carotene). The latter is enzymatically oxidized to yield the active vitamin, although a number of intestinal, dietary, and genetic factors influence the efficiency of bioconversion of provitamin A to the active form. The limited intake of vitamin A sources, absorptive disorders of the intestines, and inflammatory diseases are common predisposing conditions for deficiency. The manifestations of vitamin A deficiency include functional and anatomic ocular degeneration, diverse changes in epithelial tissues, immune deficits, and excessive mortality from childhood diseases. The hepatic concentration of vitamin A is a true reflection of nutritional status. The ideal diagnostic biomarker for assessing vitamin A status of individuals has yet to be devised. Circulating retinol concentration has severe limitations for reflecting vitamin A status of an individual and cannot be easily interpreted in a survey context to assess the vitamin A status of a population. When adequate vitamin A cannot be provided from the diet, periodic vitamin supplementation and food fortification constitute common public health intervention strategies. Home fortification of complementary foods and enriching provitamin A content in plants (biofortification) are recently developed approaches in the area of fortification. Vitamin A supplementation has diverse applications in clinical medicine from treating severe clinical deficiency to supporting recovery from measles and protein energy malnutrition. Excess intakes of preformed vitamin A can produce congenital malformations and possibly thinning of the bones. Severe overdoses of preformed vitamin A damage the liver and nervous system, with potentially lethal consequences.

## Introduction

McCollum and his co-workers recognized vitamin A as the first of the vitamins in 1913. By 1929, Moore had shown that oxidation of the carotenoid family (provitamin A compounds) could be oxidized to yield the retinoid forms of the vitamin. Vitamin A deficiency is a public health problem. The highest specific prevalence rates of hypovitaminosis A are seen in southern Asia and sub-Saharan Africa among pregnant women and young children (Ramakrishnan, 2002). Specifically, it has been estimated that approximately 127 million preschool children have vitamin A deficiency at any time, and 4.4 million have some stage of xerophthalmia (West, 2002). Annually, over 6 million women in developing countries develop night blindness during pregnancy. Vitamin A and other retinoids have important health-related actions beyond a nutritional role.

## Nomenclature and Chemical Properties

The term “vitamin A” refers to a subgroup of retinoids that possess the biological activity of all-*trans*-retinol. Retinol has a molecular weight of 286.5 kDa. Retinoids typically have four isoprenoid units joined head to tail, and contain five conjugated carbon–carbon double bonds. Figure 11.1 provides the molecular structures for selected retinoid and carotenoid compounds. The numbering system for the carbons of retinol is illustrated in Figure 11.1A (American Institute of Nutrition, 1990). Retinol can be reversibly oxidized to retinal (Figure 11.1B), which exhibits all of the biological activities of retinol, or further oxidized to retinoic acid (Figure 11.1C). Exogenous retinoic acid is insufficient for vision and reproduction. The form of vitamin A involved in vision is 11-*cis*-retinal (Figure 11.1D), whereas the primary storage form is retinyl palmitate (Figure 11.1E) (Blomhoff *et al.*, 1994). Beyond

**FIG. 11.1** Vitamin A. (A) All-*trans*-retinol; (B) all-*trans*-retinal; (C) all-*trans*-retinoic acid; (D) 11-*cis*-retinal; (E) retinyl esters, mainly retinyl palmitate; (F) all-*trans* β-carotene; (G) trimethyl methoxyphenol retinoic acid (etrin, acitretin); (H) lycopene.

their nutritional function, skin disorders, and some cancers are therapeutic targets of retinoids (Dawson and Okamura, 1990). Acitretin (Figure 11.1F) is one example of a less toxic, highly active, synthetic retinoid. The term “provitamin A” is given to several carotenoids, the archetype of which, B-carotene (Figure 11.1G), has a molecular weight of 536.9 kDa and can be cleaved to yield active retinoids. An unsubstituted  $\beta$ -ionone ring is necessary for this function. Lycopene, by contrast (Figure 11.1H), is an example of a carotene that lacks the properties to be a provitamin A compound. Although more than 700 carotenoids have been isolated from natural sources, only about 50 possess vitamin A activity.

Retinoids and carotenoids are susceptible to oxidation and isomerization when exposed to light, oxygen, reactive metals, and thermal effects. Both are insoluble in water but soluble to varying degrees in most organic solvents. Under ideal storage conditions, both retinoids and carotenoids will remain stable for long periods in serum, tissue, or crystalline forms (Comstock *et al.*, 1993).

## Analytical Methods

The conjugated polyene structures of these compounds give them unique light absorption spectra and high molar absorptivities, producing characteristic ultraviolet or visible absorption spectra, constituting physical properties useful for its analysis (Furr, 2004). The absorption maxima and molar extinction coefficients in ethanol are 325 nm ( $\sim 52\,480$ ) for all-*trans*-retinol, 381 nm ( $\sim 43\,400$ ) for all-*trans*-retinal, and 350 nm ( $\sim 45\,200$ ) for all-*trans*-retinoic acid. Retinol fluoresces at 470 nm when excited with UV light at 325 nm. Its ability to form a blue color with Lewis acids in anhydrous chloroform has been used as the basis of quantitation for decades.  $\beta$ -Carotene, with nine conjugated double bonds, absorbs maximally in petroleum ether at 450 nm ( $\sim 138\,900$ ).

The historical approach to quantifying retinoids and carotenoids using their absorption or fluorescence properties has given way in recent years to reverse-phase high-performance liquid chromatography (HPLC) (Furr, 2004). Reverse-phase HPLC (C18 column) followed by visible detection for carotenoids (approximately 450 nm) or UV detection for retinoids is the most common method of analysis. In many cases, *cis-trans* isomers can be better separated using normal-phase HPLC (silica or alumina columns). During sample preparation and analysis, samples should be protected from heat, light, and oxidizing sub-

stances. Other techniques, such as gas chromatography (GC) and mass spectroscopy (coupled with GC and HPLC), immunoassays, supercritical fluid chromatography, and capillary electrophoresis, have proven useful in certain applications (Furr, 2004). To analyze serum retinol, the retinol binding protein (RBP) is denatured with alcohol or acetonitrile to release the retinol for organic-solvent extraction prior to analysis.

Relevant in pathology and in food composition analysis is the fact that vitamin A in tissues is stored as retinyl esters, predominantly retinyl palmitate. Although retinyl esters can be extracted directly into organic solvents, cellular proteins are usually precipitated prior to hydrolysis of the esters to release free retinol. Guidance for the analysis of provitamin A compounds in foods by both traditional open-column and advanced HPLC techniques has been published (Rodriguez-Amaya, 1999; Blake, 2007).

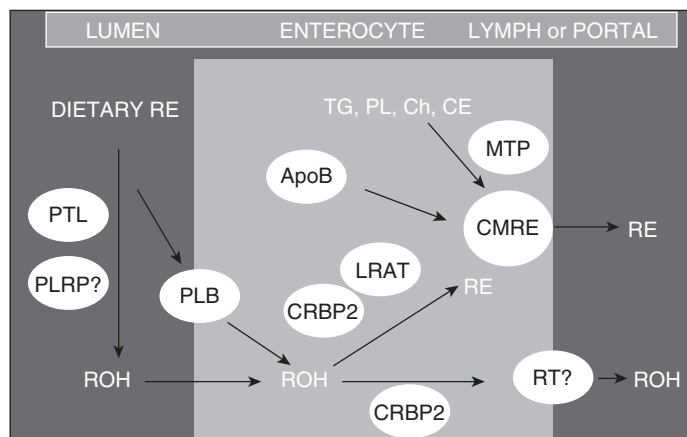

## Intestinal Absorption of Preformed Vitamin A and Provitamin A

The first requirement for a nutrient to nourish is for it to be absorbed. Host vitamin nutriture depends on the sequence of digestion of vitamin A source foods, uptake of preformed vitamin A or carotenoids into intestinal cells, and its handling within the enterocyte.

### *Mechanisms of Absorption*

Accessing vitamin A may begin with food matrix factors, dissociated by chewing and gastric action. In green leafy vegetables, carotenes are embedded in chloroplasts, whereas they form part of chromoplasts in orange fruits, vegetables, and tubers of hue (West *et al.*, 2002). Thereafter, as dietary lipids, digestion is fundamental for access of carotenes and vitamin A. This includes the constellation of actions by bile salts and pancreatic lipases within an appropriate pH milieu, in conjunction with forming mixed micelles within the intestinal lumen. In foods such as dairy items, and especially some fatty fruits, the carotenoids are dispersed and emulsified in an oily milieu within the foods. Not unlike other nutrients in their absorption, provitamin A carotenes are more efficiently converted to the active vitamin at lower oral intakes (Novotny *et al.*, 2010).

Once taken up into enterocytes, an intracellular transport system for vitamin A, not dissimilar to that in peripheral tissue cells (see below), is mediated by a complement of cellular transport proteins. Cellular mechanisms of vitamin A absorption have been reviewed by Harrison

**FIG. 11.2** Overview of digestion and absorption of vitamin A. Dietary retinyl esters (REs) are hydrolyzed in the lumen by the pancreatic enzyme pancreatic triglyceride lipase (PTL) and intestinal brush-border enzyme phospholipase B (PLB). Studies of the carboxylester lipase (CEL) knockout mouse suggested that CEL is not involved in dietary RE digestion. The possible roles of the pancreatic lipase-related proteins (PLRPs) 1 and 2 and other enzymes require further investigation. Unesterified retinol (ROH) is taken up by the enterocyte, perhaps facilitated by an as-yet-unidentified retinol transporter. Once in the cell, retinol is complexed with cellular RBP type 2 (CRBP2), and the complex serves as substrate for re-esterification of the retinol by the enzyme lecithin retinol acyltransferase (LRAT). The REs are then incorporated into chylomicrons, intestinal lipoproteins containing other dietary lipids such as triglycerides (TGs), phospholipids (PLs), cholesterol (Ch), cholesteryl esters (CEs), and apolipoprotein B (ApoB). The incorporation of some of the lipids is dependent on the activity of microsomal triglyceride-transfer protein (MTP). Chylomicrons containing newly absorbed retinyl esters (CMREs) are then secreted into the lymph. Unesterified retinol is also absorbed into the portal circulation and its efflux from the basolateral cell membrane may also be facilitated by retinol transporter (RT) proteins. Reproduced with permission from Harrison (2005).

*et al.* (2005). The particular routes of transport and roles of transporters are illustrated diagrammatically in Figure 11.2 (Harrison, 2005).

As to provitamin A carotenes, options include being passed intact into the lymphatic circulation, cleaved and converted into a retinoid, metabolized to an inactive species, or retained intact until the cell is desquamated. The history of discovery and the mechanisms of bio-conversion of provitamin A to the active (retinoid) form of the vitamin have been reviewed (Krinsky *et al.*, 1993; Yuem and Russell, 2002; Lietz *et al.*, 2010). The conventional mechanism for conversion of  $\beta$ -carotene to retinaldehyde involves oxygen-mediated oxidative cleavage in the center of the molecule by the intestinal enzyme, carotene monoxygenase 1 (CMO1, EC 1.13.11.21, formerly the 15,15' monoxygenase enzyme); this central cleavage leads to the formation of up to two retinal molecules from each carotenoid moiety. The enzyme has been

cloned (Lindqvist and Andersson, 2002). Early on, peroxisome proliferator-activated receptor- $\alpha$  (PPAR- $\alpha$ ) was thought to be a transcriptional regulator in the expression of this monoxygenase (Boulanger *et al.*, 2003), but later a role for PPAR- $\gamma$  in the expression of CMO1 was confirmed (Gong *et al.*, 2006). Understanding of a more complex and elaborated scenario for the regulation of the intestinal handling of provitamin A  $\beta$ -carotene has advanced importantly over the past 5 years, as recently reviewed by von Lintig (2010). In addition to CMO1, a membrane protein, scavenger receptor class B type 1 (SR-B1), is involved as part of a negative feedback homeostatic regulation mechanism. More than through retinoid receptor or PPAR transcription factors, the intestine-specific transcription factor, ISX, suppresses both SR-B1 and CMO1 in an independent fashion. When sufficient dietary vitamin A is available, it exerts a suppressive effect on the further oxidative cleavage of  $\beta$ -carotene to avoid

vitamin A production in excess of nutritional needs (von Lintig, 2010).

Eccentric cleavage of  $\beta$ -carotene also occurs, with the conversion of  $\beta$ -carotene into  $\beta$ -apo-carotenals and eventually retinoids. This is not exclusively related to spontaneous oxidation, and it has been found to be present in at least four mammalian species by enzymatic action (carotene monooxygenase 2 or CMO2) (Biesalski *et al.*, 2007).

### **Considerations of Bioavailability and Bioconversion of Provitamin A**

It is the consensus of experts in the field that provitamin A carotenoids are an important contributor to the vitamin A nutrition of the world's population (Grune *et al.*, 2010). A series of factors influence the yield of vitamin A derived from provitamin A carotenoids, both those extrinsic to the body (i.e. diets that provide vitamin A) and those intrinsic to the host (i.e. the consequence of one's digestive and absorptive capacities). These factors can enhance or inhibit the uptake of vitamin A or provitamin A and the conversion of the latter into the active vitamin. This topic has been comprehensively reviewed (Grune *et al.*, 2010).

#### **Extrinsic Factors**

Our understanding of the dietary factors influencing the efficacy of conversion of provitamin A in foods has been aided by rapid advances in isotope tracer techniques and mathematical modeling (van Lieshout *et al.*, 2003; Furr *et al.*, 2005). It is known that the yield of vitamin A from carrots, for example, is generally low, and highly variable depending on the preparation: juiced, puréed, grated, or cooked (Edwards *et al.*, 2002; Thurmann *et al.*, 2002). When the provitamin A is in leaves or pulp of plants, the bioefficacy is well below 6:1 in relation to active vitamin A (Haskell *et al.*, 2004; Tang *et al.*, 2005) in both marginal and replete subjects. Pectin also interferes with dietary carotene utilization, but not non-starch polysaccharides. Weight-control drugs, which induce fat malabsorption, do not affect vitamin A status, but plant sterols consumed for cholesterol lowering can interfere with  $\beta$ -carotene uptake.

As carotenes dispersed and emulsified in fat or oil approach the biological efficacy of preformed vitamin A itself (West *et al.*, 2002), the amount of dietary fat accompanying vitamin A and provitamin A in meals is an enhancing factor. The presence of fat ensures the absorption of preformed vitamin A, but a minimum of 3–5 g is required to enhance the uptake of provitamin A for bio-

conversion (Ribaya-Mercado, 2002). In two situations in Asia in which fat intake is habitually low, addition of fat to the diet resulted in improvement in circulating levels of retinol (Alam *et al.*, 2010) or increased body stores of the vitamin (Maramag *et al.*, 2010). Nagao (2004) also suggests that lipids modulate the action of CMO1.

#### **Intrinsic Factors**

The intrinsic factors for intestinal uptake begin with the nutritional demand of the organism for vitamin A, by which the intestine homeostatically regulates the conversion of provitamin A carotenoids to vitamin A. That is, in the healthy individual, it depends upon the underlying adequacy of vitamin A status. Individuals who are replete have a low bioconversion drive (Hickenbottom *et al.*, 2002), and aging may reduce the efficiency of the conversion further (Wang *et al.*, 2004). The physical health of the alimentary tract is an additional factor for both preformed and provitamin A, insofar as fat maldigestion or injury or malfunction of the intestinal cells impairs the release of the constituents from the food and their transport out of the intestinal lumen.

#### **Genetic Factors**

Suspicion regarding heterogeneity and an adaptation of the efficiency of bioconversion has existed for decades (Solomons and Bulux, 1994). Evidence to that effect has appeared more recently. Two variant allelic polymorphisms exist for the CMO1 carotene-splitting enzyme: A379V and R267S (Leung *et al.*, 2009). With respect to the non-mutant genotypes, the A379V variant reduces carotene bioconversion efficiency by 32% and the combination of both variant alleles produces a 69% reduction. Comparisons across populations show Europeans to have higher frequencies of the variant alleles, and hence less efficiency of provitamin A conversion than Asian and African groups, suggesting a selection for greater production of vitamin A in areas historically more dependent on plant sources in the diet.

#### **Post-intestinal (Systemic) Bioconversion of Provitamin A Carotenenes**

Enzymes capable of oxidative cleavage of carotenes, both in a central and eccentric manner, have long been identified in extra-intestinal peripheral tissues including liver, lungs, and kidney (Wyss *et al.*, 2001; Leung *et al.*, 2009). Wyss *et al.* (2001) noted that "beta-carotene 15,15'-dioxygenase is also expressed in epithelial structures, where

it serves to provide the tissue-specific vitamin A supply,” and Lindqvist and Andersson (2004) stated that “the finding that the enzyme is expressed in all epithelia examined thus far leads us to suggest that BCMO1 may be important for local synthesis of vitamin A, constituting a back-up pathway of vitamin A synthesis during times of insufficient dietary intake of vitamin A.” To date, however, no firm quantitative estimate of extra-intestinal enzymatic bioconversion of provitamin A of nutritional importance has been made.

## Metabolism of Preformed Vitamin A and Provitamin A

The appropriate fate of an absorbed nutrient is to become inserted into the sites of its essential physiological or structural roles or to be maintained in a storage reserve until needed.

### Storage and Transport

At any given time, the majority of the body’s vitamin A, up to 90%, is in storage, with the remainder in active sites in peripheral tissues and undertaking vitamin A-dependent functions.

### Cellular Uptake and Intracellular Metabolism

As shown in the entero- and hepatocyte metabolic schemes in Figure 11.3 (Napoli, 2000), the chemical actors are RBP from the circulation, cellular RBPs (CRBP I and CRBP II), cellular retinoic acid binding proteins (CRABP I and CRABP II), the retinaldehyde dehydrogenase type 2 (RALDH-2) and other enzymes, the retinoic acid receptors (RARs), and the retinoid X receptors (RXRs). Since the composition of those schemata, cytochrome P450 must be added to the scene. The RARs are primed for activation by retinoic acid and its analogs, whereas the RXRs are receptors for the vitamin A metabolite 9-*cis* retinoic acid (Glass *et al.*, 1997; Rowe, 1997; Troen *et al.*, 1999). It has also been noted by Biesalski and Nohr (2004) that under certain circumstances and in selected tissues, such as buccal mucosa and vaginal epithelium, retinyl ester forms can be taken up directly by cells for nutritional purposes.

The transport of retinoids intracellularly is the purview of the cellular retinol-binding proteins. Retinol first encounters the CRBP class of transport proteins to carry retinol to either esterifying or oxidizing enzymes (Troen *et al.*, 1999). Metabolic transformation of the step of all-

*trans* RA to 4-hydroxylated RA appears to be primarily catalyzed by the cytochrome P450 (Gidlof *et al.*, 2006; Heise *et al.*, 2006). After oxidation to the aldehyde, and further on to an acid, the CRABP class assumes a relevant regulatory role as well (Rowe, 1997; Napoli, 2000). These intracellular binding proteins show high specificity and affinity for specific retinoids, and seem to control retinoid metabolism both qualitatively and quantitatively. On the former side, they protect retinoids from non-specific interactions, and, on the quantitative side, they have been stated to “chaperone” access of metabolic enzymes to retinoids (Napoli, 1999).

### Hepatic Storage

The storage organ for vitamin A is the liver, with 80% of the body’s vitamin in the liver, and 50–80% of that located in the fat-storing stellate cells (Senoo *et al.*, 2010). Newly absorbed retinyl esters are packaged in chylomicra, circulated through the mesenteric lymph to the systemic circulation and eventually taken up by the liver (hepatocyte) cells (Napoli, 2000), as shown in Figure 11.3. Its uptake by the liver follows the normal metabolism and degradation of chylomicra to their remnants. Aging greatly retards the clearance rate of retinyl esters from the circulation.

### Circulatory Transport

Transport of vitamin A to peripheral tissues occurs primarily by way of a shuttle of recently absorbed vitamin from the liver to the tissues as part of the retinol–RBP–transthyretin (TTR) complex. Within the hepatocyte, retinol forms a complex with RBP, a 183-amino acid residue, 21-23-kDa peptide, and accumulates in the endoplasmic reticulum until retinol for transport becomes available (Gaetani *et al.*, 2002); this in turn joins a binding site on TTR after secretion into the circulation. Stability of RBP’s binding to retinol is enhanced by complexing with TTR, increasing the binding affinity of RBP for retinol (Zanotti and Berni, 2004). This undergoes further complexing with the 55-kDa homotetramer TTR to prevent glomerular filtration and urinary excretion of the smaller RBP (Raghu and Sivakumar, 2004).

In states of vitamin A sufficiency, RBP synthesis and accumulation are modest, and little if any newly absorbed vitamin moves out of the liver. In states of vitamin A deficiency, hepatic RBP builds up in the hepatocyte. Consumption of a vitamin A-rich meal translates into a major release of RBP-bound retinol to feed deprived

**FIG. 11.3** A model of retinol metabolism and retinoic acid (RA) biosynthesis that integrates cumulative data of interactions between cellular retinol-binding protein (CRBP) and CRBP (II) and enzymes that catalyze retinol metabolism. Top panel: Dietary carotenoids undergo central cleavage into retinal, which binds to CRBP (II). A microsomal retinal reductase recognizes retinal bound with CRBP (II) and converts it into retinol. Dietary retinyl esters (RE) undergo hydrolysis into retinol, which bind to CRBP (II). Lecithin retinol acyltransferase (LRAT) recognizes the complex CRBP (II)-retinol and synthesizes RE. CRBP(II) prevents oxidation of retinol and retinol, optimizing RE formation. Chylomicrons incorporate and deliver RE to the liver as chylomicron remnants formed after hydrolysis of triacylglycerol (TAG). Bottom panel: Chylomicron remnants deliver RE to the liver, where lysosomes engulf them and an acidic hydrolase releases retinol to bind with CRBP. The holo-CRBP formed serves as substrate for retinol esterification catalyzed by LRAT. A neutral bile salt-independent RE hydrolase (bsiREH) catalyzes RE mobilization. Apo-CRBP controls retinol metabolism by inhibiting LRAT and increasing the rate of hydrolysis via the bsiREH. Holo-CRBP also serves as substrate for retinol formation, catalyzed by retinol dehydrogenase (RoDH). Retinal dehydrogenase (RALDH) isozymes catalyze the irreversible and possibly rate-determining conversion of retinal into RA. Absence of CRBP potentially allow numerous enzymes access to retinol, in addition to LRAT and RoDH, including perhaps medium-chain alcohol dehydrogenases, cytochromes P-450 (CY), oxidoreductases, etc. Reactive oxygen species, nucleophiles and other intracellular reactive molecules also would have access to retinol in the absence of CRBP. The enhanced access of enzymes and reactive smaller molecular species would accelerate retinol metabolism and RE depletion. Reproduced with permission from Napoli (2000).

peripheral tissues. This is the biological basis for the relative dose–response test (Loerch *et al.*, 1979).

### Transplacental Transport

Given the essential role of retinoids in cell proliferation and differentiation and the teratogenic role of retinol and its analogs, the width of the gaps in knowledge concerning the transplacental transport of vitamin A and the dearth of research interest are astounding. What appears to be most likely is that RBP-free retinol diffuses across the intravillous spaces to be captured by RBP of fetal amnio-chorionic membrane origin (Artacho *et al.*, 1993). Two scenarios have been proposed for the enigma of vitamin A nutrition of the fetus: (1) that the vitamin A is derived from the 15 mL of amniotic fluid swallowed daily in utero; or (2) that it derives from the placenta as an extra-intestinal site of bioconversion of  $\beta$ -carotene to the active vitamin (Dimenstein *et al.*, 1996).

### Secretory Transport in Lactation

The vitamin A supplied by lactation is adequate to supply all of the needs of the growing infant through the first 6 months of life (Dewey *et al.*, 2004). In a multinational collaborative study involving developed and transitional nations (Australia, Canada, China, Chile, Japan, Mexico, the Philippines, and the United Kingdom), milk retinol levels were generally adequate, but varied two-fold across countries (Canfield *et al.*, 2003). Nevertheless, experience from dairy sciences and laboratory animals provides an inference for the mechanisms by which vitamin A is mobilized to the mammary glands for milk secretion. Rodent (Valentine and Tanumihardjo, 2005) and piglet (Akohoue *et al.*, 2006) studies suggest that recently absorbed vitamin A is preferentially delivered to the milk, as compared with that stored in the liver. The human literature is inconsistent, however, as to the determinance of the specific intake of vitamin A from meals on milk content of the vitamin (Olafsdottir *et al.*, 2001; Menses *et al.*, 2004; Menses and Trugo, 2005). Even more inconsistency about diet's determinance comes from reports on the degree to which high-dose oral supplements of retinyl palmitate to lactating mothers improve vitamin A concentrations or augment circulating retinol in the offspring (Oliveira-Menegozzo and Bergamaschi, 2010).

Findings related to carotenoids as a source of infant vitamin A were even more interesting. Overall, provitamin A species constituted 50% of total milk carotenoids. In

the aforementioned multinational study (Canfield *et al.*, 2003), total carotenoids were highest in Japanese milk samples and lowest in the Philippines, whereas  $\beta$ -carotene content was highest in Chile and lowest in the Philippines. In Brazilian mothers, the plasma-to-milk ratio for  $\beta$ -carotene was 17:1, with modest mutual association (Menses and Trugo, 2005). Observations comparing carotenoid patterns in colostrum and mature milk may provide some inferential insights into the distribution of provitamin A to human milk. In colostrum, the carotenoid pattern resembled that in LDL lipoproteins, whereas at 19 days (mature milk) it reflected that in HDL, suggesting that the transfer of carotenoids to milk involves different lipoproteins at different specific times of lactation (Schweigert *et al.*, 2004).

### Excretion

The primary excretion route for vitamin A metabolites from the body is in the bile. In rodent models (Skare and DeLuca, 1983; Hicks *et al.*, 1984), vitamin A is excreted with a fixed concentration in bile, with net losses depending on biliary volume. With increased hepatic stores, output increases in a responsive manner (Skare and DeLuca, 1983). The fractional loss of vitamin A in the urine is minuscule under usual circumstances. Eclampsia, acute renal failure, multiple myeloma, and febrile infections, however, are pathological situations producing excessive urinary losses. An estimated 20–40% of a child's liver reserve can be lost in the urine during a severe diarrheal episode (Mittra *et al.*, 2002).

## Physiology of Vitamin A: Functions and Actions

The late Professor James A. Olson defined the “function” of a food constituent as “an essential role played by the nutrient in growth, development, and maturation”; by contrast, he defined “actions” as “demonstrable effects in various biologic systems that may or may not have general physiologic significance” (Olson, 1998).

### Physiological Functions of Vitamin A

Some form of retinoid is involved in the functions of every cell in the body. Vision, intercellular communication, mucin production, embryogenesis, cell growth, and cell differentiation are prominent among the gamut of functions related to vitamin A.

### Retinal Isomer and Visual Pigments in the Visual Cycle

The classical function for which vitamin A is known is in the visual cycle. The vitamin A metabolite retinaldehyde (retinal) is an active component of the visual pigments in the rods and cones of the retina. For dim-light (scotopic) vision with the dark-adapted eye, the cycle involves the regeneration of the rhodopsin pigment, with the insertion of 11-*cis*-retinal. Low-intensity photons produce the cleavage of the pigment–retinoid complex, liberating dissociated all-*trans*-retinal, and exciting neural transmission, as originally described by George Wald (1968). The regeneration of the retinol from the aldehyde form was the primary feature, and the molecular biology of this visual pathway has subsequently been elucidated. For high-resolution, color (photopic) vision in daylight, the retinal cones of the retinal epithelium are involved in a similar, although less well understood, photon-activated excitation and neural signal transmission. The regeneration of 11-*cis*-retinal via all-*trans*-retinol to 11-*cis*-retinal has been shown to be distinct in the photopic vision cycle (Wolf, 2004).

### Retinoids and Intercellular Communication

One of the macro-level functions for the integrity and function of tissues is the communication among adjacent cells. This can occur by various signaling mechanisms, the best understood of which is the connexin 36 mechanism at so-called “gap junctions” across the intercellular space. All-*trans*-retinal and retinoic acid have been shown to be potent inhibitors of connexin-36-mediated gap junctional communication (Pulukuri and Sitaramayya, 2004). On the other hand, within the cell nucleus, retinoic acid induces adhesion proteins and membrane complexes necessary for cell-to-cell adhesion and communication among hepatocytes (Ara *et al.*, 2004).

### Mechanism of Action as a Nuclear Hormone

The functions, metabolism, and relationship to their nuclear receptors of natural retinoids have been reviewed (Ziouzenkova and Plutzky, 2008; Rochette-Egly and Germain, 2009; Lefebvre *et al.*, 2010; Amman *et al.*, 2011). Much of the wide variety of functions of vitamin A enumerated earlier are derived from a complex retinoid signaling pathway system in which various isometric forms of retinoic acid act as nuclear hormones (Evans, 2005). These include all-*trans*-retinoic acid and 9-*cis*-retinoic acid as the principal players, with additional participation by

13-*cis*-retinoic acid. As alluded to below, a wide array of synthetic retinoid analogs can also participate in the signaling system in pharmacological situations.

The retinoids act as transcription factors, modulating and regulating either the activation or repression of messenger RNA formation in cell nuclei (Lefebvre *et al.*, 2010). This is effected by their serving as binding ligands in nuclear receptor complexes. The basic elements of the genetic signaling system are the nuclear receptors. The receptors for retinoic acid (RAR) and its 9-*cis* isomer (RXR) each have three subtypes (alpha, beta, and gamma). RARs can bind and respond to both retinoic acid and its isomer, whereas RXRs are specific for an isometric form (9-*cis*-retinoic acid). The receptors act through either dimerization to form homodimers (RAR–RAR, RXR–RXR) or heterodimers (RAR–RXR) with the various permutations of the Greek-letter subtypes. Cooperative binding to hormone response elements coordinates the regulation of target genes by RXR ligands. The transcription regulation, moreover, can involve further heterodimer formation between the RXR receptor and either thyroid hormone receptor or the peroxisome proliferator-activated receptor-gamma (PPAR- $\gamma$ ) (Higgins and Depaoli, 2010).

The best-known roles of the retinoid receptor system involve the regulation of the division and differentiation of cells. Signals involving the RXR reduce cellular proliferation and enhance programmed cell death (apoptosis) (Nohara *et al.*, 2009). The pivotal action of intracellular retinoid regulatory roles via RAR in cellular differentiation involves influencing the cell cycle proteins (Chen and Ross, 2004).

An alternative mechanism for influencing genetic expression involves epigenetic regulation at the level of conformation of the chromatin backbone of the helical nucleic acid strands of DNA. Mammalian reflections of the uncoupling of histone acetylation in the HIV1 virus are postulated (Kiefer *et al.*, 2004). Interestingly, the alcohol form, retinol, has been shown possibly to have epigenetic potential in modifying the chromatin conformation of a zinc-finger domain of the gene for serine/threonine kinase expression (Hoyos *et al.*, 2005).

Up-regulated expression of mRNA for mucin proteins of the conjunctiva and the respiratory tract by retinoic acid is a classical example of signaling related to intracellular protein synthesis (Hori *et al.*, 2004). The retinoid signaling system is central to embryogenesis such as of the brachial arches (Mark *et al.*, 2004) and the alveolar membrane of the lungs (Maden and Hind, 2004).

Retinoic acid, circulating in nanomolar concentrations in blood, accounts for the majority of the supply for the brain and liver, but is also locally produced in other tissues (Ross, 2004). Beyond the serial oxidation of retinol is the intracorporeal bioconversion of carotenoids as a potential source of retinoids at the tissue and cellular level (Tang *et al.*, 2003).

### **Actions of Vitamin A**

Outside of the evolutionary functions of vitamin A for the metabolism in normal health, vitamin A exhibits a series of actions that assist in the correction of various pathological conditions.

#### **Antiproliferative Action**

The ability of vitamin A and its isomeric forms to promote terminal differentiation, inhibit proliferation, and promote apoptosis comes into play in neoplasia. High-dose retinoids have shown anti-neoplastic activity *in vitro* in a diverse array of cancer cell lines as discussed below (Dawson and Zhang, 2002; Abu *et al.*, 2005; Evans, 2005).

#### **Improved Iron Uptake from Meals**

Iron is a vitally essential but generally poorly bioavailable dietary trace element. There are a series of conflicting observations related to enhancement of the biological availability of iron. Vitamin A, including provitamin A forms, improved iron absorption, presumably by nullifying the interference of phytates (Layrisse *et al.*, 1997, 1998; Garcia-Casal *et al.*, 1998). Swiss investigators examined iron absorption efficiency from iron-fortified maize porridge in vitamin A-deficient African children in the presence or absence of retinyl palmitate, and found no enhancement (Davidsson *et al.*, 2003). Since the settings and systems used in Venezuela and Africa are so different, the final word on this potential dietary action of vitamin A is not yet established.

### **Manifestations and Consequences of Vitamin A Deficiency and Variation in Vitamin A Nutriture**

Deficiency of vitamin A is associated with clinical and functional manifestations. However, apparent variations of vitamin A status within the range that would be considered adequate also can influence human health and modulate physiological function.

#### **Ocular Manifestations**

Xerophthalmia (literally, dryness of the eye) is the hallmark clinical feature of clinical vitamin A deficiency. It has been classified by stages according to specific ocular manifestations. Stage XN, the earliest stage, involves night blindness due to impaired dark adaptation. Stage X1A is conjunctival xerosis due to reduction in goblet cell mucus, followed by stage X1B, which is manifested by Bitot's spots, foamy excrescences on the temporal surface of the conjunctiva. Corneal xerosis constitutes the advancing stages, with X2 being simple drying of the cornea, with involvement of less than (X3A) or more than (X3B) one-third of the corneal surface with ulceration or corneal liquefaction, respectively. Past involvement leaves a corneal scar (XS), and a globe destroyed by advanced keratomalacia is xerophthalmic fundus.

#### **Other Epithelial Dysfunction Syndromes**

Other epithelial tissues are affected by vitamin A deficiency. Thickening of the hair follicles (follicular hyperkeratosis) is a cutaneous manifestation of vitamin A deficiency. The reduction in mucin production in mucous membranes from the adenopharyngeal passages, bronchial and pulmonary tissue to the digestive tract, produces symptomatic distress and susceptibility to microbial invasion. Overt esophagitis is a recently recognized consequence of the mucosal alterations of impaired vitamin A status (Herring *et al.*, 2010).

#### **Excessive Mortality Rates**

The pioneering epidemiological observations of Sommer *et al.* (1983) in the Ache region of Indonesia in the 1980s first informed us that marginal vitamin A status was associated with excessive mortality from childhood infections. This was confirmed first by a vitamin A intervention study in the same population (Sommer *et al.*, 1986) and then by meta-analyses across six sites (Beaton *et al.*, 1993). Additional confirmatory intervention studies continue to emerge, including a 22% mortality reduction in newborn infants in southern India (Rahmathullah *et al.*, 2003) and a 46% reduction in HIV-infected children in Uganda (Semba *et al.*, 2005).

In developed countries, sudden infant death syndrome (SIDS) may bear some relationship to differential vitamin A status. Observations from Sweden suggested a high association between SIDS and infants not being given vitamin A supplements during the first year of life (Alm *et al.*, 2003).

### **Excess Infectious Morbidity**

Although deaths from childhood infectious diseases are more common in low-income societies, and immune defense deficiencies result from marginal vitamin A deficiency, little evidence for reduced *incidence* (new occurrences) of infectious episodes has been gleaned from community intervention trials. The odds ratio was 1.08 for the effect of prophylactic vitamin A supplementation on acute respiratory infections in a meta-analysis (Grotto *et al.*, 2003), whereas a comparable analysis for efficacy also showed no efficacy (Brown and Roberts, 2004). Supplementation was effective to prevent cough among HIV-infected children in Uganda (Semba *et al.*, 2005). The prevention of diarrhea is another domain in which meta-analyses revealed no efficacy (Grotto *et al.*, 2003). In the situation of HIV, however, reductions in the incidence of acute and chronic diarrhea (Semba *et al.*, 2005) have been noted. As tentative resolution of this apparent mortality–morbidity paradox, it is postulated that the specific intensity and lethality of infections is aggravated in the child with marginal vitamin A status.

### **Hematological Support**

Observational studies have documented an independent association of vitamin A status with hematological adequacy (Kafwembe, 2001; Gamble *et al.*, 2004; Osório *et al.*, 2004) beyond any direct action of meal vitamin A to enhance iron absorption. Historically, vitamin A interventions were shown to improve hemoglobin or hematocrits in a multiply deficient, anemic population. Semba and Bloem (2002) propose several metabolic mechanisms whereby modulation of vitamin A exposure and status could influence red cell biology: stimulating progenitor cells, promoting resistance to infection, and mobilization of iron to the erythron. Basic research provides evidence for retinoids regulating hematopoiesis from the yolk sac stage in the embryo to the fetal liver production in utero to the bone marrow (Oren *et al.*, 2003).

Not only is the erythropoietic line of bone marrow proliferation related to vitamin A, but platelet production is also influenced by retinoid biology. Japanese oncologists observed increased thrombocytosis and thrombopoietin levels in patients treated with all-*trans*-retinoic acid for acute promyelocytic leukemia. In subsequent *in vitro* studies in bone marrow stromal cell culture, all-*trans*-retinoic acid triples thrombopoietin mRNA expression (Kinjo *et al.*, 2004).

### **Miscellaneous Considerations**

Endemic vitamin A deficiency and controlled observations of responses to vitamin A supplementation interventions have received so much interest in observational and intervention studies that commentary on consequences that do not appear to be part of the hypovitaminosis A context may not receive specific attention. Two situations of benefits from vitamin A unrelated to initial deficiency are of interest. For instance, in the situation of HIV-infected preschoolers, vitamin A supplementation to non-deficient women improved postnatal growth of children in Tanzania (Villamor *et al.*, 2005), while direct child supplementation improved growth in the same milieu (Villamor *et al.*, 2002). A curious, but potentially important, recent observation in hemodialysis patients is that a lower circulating retinol level is an independent predictor of overall cardiovascular mortality in this population (Kalousová *et al.*, 2010).

## **Causes of Variation in Vitamin A Status and the Epidemiology of Vitamin A Deficiency**

Secondary vitamin A deficiency can arise in any situation or clinical condition or illness in which there is reduced absorption, increased excretion, enhanced destruction, impaired utilization, or exaggerated requirement for the nutrient.

### **Conditions Predisposing to Impaired Vitamin A Status**

A standard list of predisposing causes of vitamin A deficiency has been recognized for decades. These include a myriad of situations of low intake and reduced bioconvertibility of dietary vitamin A, along with poor intestinal absorption, impaired utilization of the vitamin, and its increased destruction or wastage. Recent concerns focus on impairment in vitamin A nutriture in novel conditions or emergent or re-emergent diseases. These include: bariatric surgical procedures for weight loss (Slater *et al.*, 2004; Mason *et al.*, 2005), pancreaticoduodenostomy ablation surgery for malignancies (Armstrong *et al.*, 2005), peritoneal dialysis (Aguilera *et al.*, 2002), hematopoietic stem cell transplant (High *et al.*, 2002), acute respiratory syndromes (Schmidt *et al.*, 2004), pulmonary tuberculosis (van Lettow *et al.*, 2004), cigarette smoking (Tiboni *et al.*, 2004), HIV/AIDS (Visser *et al.*, 2003; Vorster *et al.*, 2004), and asthma (Arora *et al.*, 2002).

## Population Epidemiology of Hypovitaminosis A

The current estimates of hypovitaminosis A on a worldwide basis suggest that it is the second most common micronutrient deficiency. Singh and West (2004) estimate that 23% of children between the ages of 5 and 15 years in Southeast Asian nations have deficient vitamin A status. In a nationally representative sample of Mexico (Villalpando *et al.*, 2003), low retinol levels were found in a quarter of the sample, with highest rates in indigenous communities in the southern part of the country. Diverse, contemporary surveys have identified a prevalence of impaired vitamin A status in Inuit and First Nation newborns (Dallaire *et al.*, 2003), Israeli Bedouin toddlers (Coles *et al.*, 2004), black toddlers in the Western Cape of South Africa (Oelofse *et al.*, 2002), nomadic herder women in Chad (Zinsstag *et al.*, 2002), and pregnant urban women in Nigeria (Ajose *et al.*, 2004). Risk factors found variously across sites of hypovitaminosis A endemicity were male gender (Semba *et al.*, 2004), young age of children (Villalpando *et al.*, 2003; Semba *et al.*, 2004), low body-mass index (BMI) (Villalpando *et al.*, 2003), stunting (Semba *et al.*, 2004), familial xerophthalmia history (Semba *et al.*, 2004), history of maternal diarrhea (Semba *et al.*, 2004), the nutritional quality of pastoralists' milk (Zinsstag *et al.*, 2002), and warm seasons (Semba *et al.*, 2004).

## Nutrient Requirements and Recommended Intakes for Dietary Vitamin A

### Quantitative Expression of Dietary Vitamin A Activity

Units of expression of vitamin A in foods and pharmaceutical preparations have a tortuous history, and present confusion to consumers and professionals alike. Historically, we have international units (IU) from early food science literature, retinol equivalents (RE), adopted by a Food and Agriculture Organization of the United Nations/World Health Organization (FAO/WHO) panel in 1967 (FAO/WHO, 1967), and retinol *activity* equivalents (RAE), created by the US Institute of Medicine for the 2001 *Dietary Reference Intakes* (Institute of Medicine, 2001). Certain measures can be taken to promote harmonization and reduce inconsistencies.

The IU expression can be found in food composition tables, and is still widely used in medicinal contexts. The

conversion relationship is 1 IU = 3.3 RE (1 RE = 0.3 IU), which is valid only for preformed vitamin A. Where *preformed* vitamin A in foods or supplements are concerned, RE and RAE are completely interchangeable. Interconversions involving the IU and provitamin A are universally invalid, and expression of dietary vitamin A in mixed diets in RE or RAE will grossly overestimate true vitamin content.

The RE is related to vitamin A compounds in gravimetric units in the following manner:

- 1 RE = 1 µg of retinol
- 1 RE = 6 µg of all-*trans* β-carotene
- 1 RE = 12 µg of other provitamin A carotenes

The equivalency definitions for RAEs provided in the DRI (Institute of Medicine, 2001) were:

- 1 RAE = 1 µg of retinol
- 1 RAE = 2 µg of all-*trans* β-carotene as supplement
- 1 RAE = 12 µg of all-*trans* β-carotene in food matrix
- 1 RAE = 24 µg of other provitamin A carotenes in food matrix

The aforementioned considerations regarding the inferior conversion for carotenes in the plant matrices and the superior bioconversion of isolated carotenes in an oily matrix, reviewed above, guided the creation of the RAE. For clarification, the “other” provitamin A carotenes include the stereoisomers of β-carotene, as well as compounds such as α-carotene and β-cryptoxanthin. Moreover, it must be clarified that, implicitly, 4 µg of other provitamin A carotenoids alone or in oil could also be equivalent to 1 RAE. What still may be unresolved within the RAE convention is an appropriate value for carotenes that are free of plant matrices but in a relatively modest fatty milieu. This would apply to provitamin A in milk and most cheeses, as well as in eggs.

### Estimated Human Requirements and Recommended Dietary Intakes

For planning and evaluation, it is important to have estimates of the daily requirements of vitamin A. The recommendable intakes for vitamin A from both the 2001 DRIs for the United States and Canada (Institute of Medicine, 2001) and the 2004 WHO and Food and Nutrition Organization *Human Vitamin and Mineral Requirements* (FAO/WHO, 2004) are outlined in Table 11.1. The former are based, when possible, around estimated average requirements (EAR) for relevant age

**TABLE 11.1** Recommendations for Daily Intake of vitamin A from the US Institute of Medicine and the World Health Organization

Population	United Nations System (WHO/FAO)		United States and Canada dietary reference intakes	
	Recalculated estimated average requirements <sup>a</sup>	Recommended nutrient intake	Estimated average requirement	Recommended dietary allowance
	RE/day		RAE/day	
0–6 months	–	375	–	400 AI
7–12 months	–	400	–	500 AI
0–1 years	290	400	–	–
1–3 years	320	450	210	300
4–6 years	320	450	–	–
4–8 years	–	–	275	400
7–9 years	360	500	–	–
9–13 years	–	–	445 <sup>b</sup> ; 420 <sup>c</sup>	600
10–18 years	430	600	–	–
14–18 years males	–	–	630	900
14–18 years females	–	–	485	700
Adult males	430	600	625	900
Adult females	360	500	500	750
Pregnant	570	800	550	770
Lactating	610	850	900	1300

AI, adequate intake; RE, retinol equivalents; RAE, retinol activity equivalents.

<sup>a</sup>Using modeling provided on p. 292 of Allen *et al.* (2006) and rounded off to the nearest zero. They can only be applied after 1 year of age.

<sup>b</sup>Males.

<sup>c</sup>Females.

groups, sexes, and physiological status. When individual recommended nutrient intakes are considered, for an intake level of reference to assure upwards of a 90% probability of covering the requirement of vitamin A for a healthy individual, the DRI calculates a recommended dietary allowance (RDA) and the United Nations (UN) agencies provide a recommended nutrient intake (RNI). Returning to the EARs, their primary purpose is to allow for probabilistic estimates for the prevalence of individuals at risk in a *population* (Murphy and Poos, 2002). EARs were not originally part of the UN system at the time of its publication in 2004 (FAO/WHO, 2004), but a WHO document on food fortification (Allen *et al.*, 2006) provides for a back-calculated modeling of these population means.

The discrepancy between the units of dietary vitamin A activity, RAE for the DRI (Institute of Medicine, 2001) and RE for the UN system (FAO/WHO, 2004), compli-

cates the discussion of recommended intakes of vitamin A for an international forum. Nevertheless, there is a certain degree of correspondence in the estimates for protective intakes, RNI, and RDA for vitamin A between the two options in Table 11.1. The recommended intakes of the UN system agencies are slightly lower for infancy, higher for childhood, and lower again for adolescence and adulthood. The major discrepancy between the two panels of recommendations relates to the disproportion in estimated requirements for lactation.

## Food Sources and Dietary Intakes of Vitamin A

The richest animal sources of vitamin A in the human diet are fish liver oils, liver, other organ meats, cream, butter, and fortified milks. Certain tropical fatty fruits are the richest sources of provitamin A.

### **Estimates of Average Dietary Intake and Adequacy of Vitamin Consumption**

There is a large dietetic and nutritional literature on vitamin A intakes by different populations. Nevertheless, differences in dietary methodology, use of different food compositions and different units of measurement, and variation in expression (median vs. mean), with different ways of adjusting and modeling are among the challenges to its synthesis and comparison. For instance, the RAE unit is not fully accepted or used outside of the US and Canada, and little if any survey results using the RAE have been published in the decade since its creation. One survey, denominated in RAE, was published for *pregnant* Mexican-American women in 2005 by Harley *et al.* For the US-born subjects in the survey (Harley *et al.*, 2005), the vitamin A intake from foods and beverages was 1035 RAE, but this rose to 2156 RAE when prenatal vitamin supplement content was included in the summation. Surprisingly these totals were about 300 RAE lower than corresponding Mexican-born subjects in the same study, whose higher intakes related exclusively to additional consumption of the vitamin on the dietary side.

Erwin *et al.* (2004) disaggregated the mean contribution of preformed vitamin A to the sex-combined representative samples of United States adults from the era of 1999–2000. Still estimated in RE, the average preformed vitamin A was 1484 RE, and with an estimated contribution from provitamin A in plants of 450 RE, and a total of 1934 RE; insofar as the use of the RE expression tends to overvalue the contribution of carotene sources, equivalency in RAE would be somewhat lower, at 225 RE, for a revised combination in the Erwin *et al.* (2004) data of 1610 RE. This is far greater than estimates for European populations, with the RE-based average intake of the vitamin from foods in surveys estimated at 900 RE (Goldbohm *et al.*, 1998) for Dutch women and 549 RE for British women (Henderson *et al.*, 2003). Across a broad selection of the data in surveys and convenience samples in low-income societies of the tropical regions, women's estimated intakes, expressed in RE, are on the order of that for the British sample or lower.

Children are theoretically the most vulnerable segment of society for ill effects from hypovitaminosis A. Clearly, central tendencies of juveniles' intake of the vitamin from the era in which the contribution of provitamin A was overvalued by two-fold, were much higher in Europe (Serra-Majem *et al.*, 2001; Sichert-Hellert *et al.*, 2001a;

Watt *et al.*, 2001) than on the Indian subcontinent (Venkaiah *et al.*, 2002).

With respect to adequacy of intakes, preformed vitamin A levels were above the EAR in adult women of all ethnic groups in small towns of the contemporary rural south of the United States (Lewis *et al.*, 2003) and generally among pregnant Mexican-American women (Harley *et al.*, 2005). From studies in selected European adult samples, over 10% of the Spanish population was shown to be consuming less than two-thirds of the referent standard for vitamin A intake (Aranceta *et al.*, 2001); among Portuguese elderly, 78% of men and 73% of women had intakes below the lowest European recommended dietary intake levels (Martins *et al.*, 2002).

### **Dietary Sources of Vitamin A**

The comparative aspects for the contribution of different foods and beverages to vitamin A intake is relatively less susceptible to the vagaries that confound quantitative estimates. Dietary sources from two representative national survey samples, for the United States and The Netherlands, are available. Sixty-seven percent of cumulative intake of vitamin A in the US diet, as calculated in RE, comprised, in descending order: carrots, organ meats, ready-to-eat cereals, cheese, margarine, tomatoes, and eggs (Cotton *et al.*, 2004). Carrots constitute 27% of all estimated intake. Comparable data for The Netherlands, also in RE but organized by food groups, found 91% of all vitamin A consumed came from meats (35%), fats and oils (24%), vegetables (16%), and dairy foods (16%) (Goldbohm *et al.*, 1998).

Among Inuits of Canada, the livers of seals, caribou, and fish provide half of the vitamin A, and market foods provide the other half (Egeland *et al.*, 2004). It has been estimated that fortified dairy products can contribute 39% of the RDA in three standard portions in Spain (Herrero *et al.*, 2002). In central Java, where 83% of pregnant women consumed less than 700 RE in the first trimester of pregnancy, plant sources contributed 64% to 79% of total vitamin A (Persson *et al.*, 2002). As noted above, dietary supplements make an important contribution to vitamin A intake. Through interval nationally representative surveys in the United States from 1987 to 1992 to 2000, the use of dietary supplements has increased steadily from 23.2% to 23.7% to 33.9% across the successive time points (Millen *et al.*, 2004). Supplement use is credited with reducing the number of adults consuming substand-

ard amounts of vitamin A by Irish adults from 20% to 5% (Kiely *et al.*, 2001).

With respect to juvenile populations, German children and adolescents received 50–65% of reference intake needs of vitamin A from non-fortified foods in their diets, and an additional 10–20% from fortified foods (Sichert-Hellert *et al.*, 2001a, b). This cohort had shown a 5–15% increase in the amount of the vitamin obtained from fortified beverages during the previous 15-year period (Sichert-Hellert *et al.*, 2001b). On the island of Guam in the South Pacific, fruit drinks, milk, and fortified cereals contributed most of the vitamin A in Guamanian children, the median vitamin A intake was 76% of the age-appropriate RDA (Pobocic and Richer, 2002). For the children living on the mainland of the United States, however, concern has been expressed that excessive sweetened drink consumption is associated with displacement of milk from children's diets, higher daily energy intake, and greater weight gain (Mrdjenovic and Levitsky, 2003).

Human milk can be a relatively important source of vitamin A, even beyond the first year of life. According to a study in Kenya, breast milk supplies more vitamin A than the complementary foods that replace it, making it an “irreplaceable source of fat and vitamin A” (Onyango *et al.*, 2002). The role of supplements as the source of vitamin A for juvenile populations is now beginning to emerge, even in the first two years of life. Among a cohort followed from infants to toddlers in the US state of Iowa, 32% were consuming vitamin A-containing supplements 40–60% of days by the age of 24 months (Eichenberger-Gilmore *et al.*, 2005).

### **Factors Affecting Vitamin A Consumption**

The influence of cultural, behavioral, and physical factors on vitamin A intake has been studied in various adult populations. In a study among pregnant women in the United States, Mexican-born women consumed more vitamin A than US-born Mexican-American women during pregnancy (Cotton *et al.*, 2004). Edentulous US white elderly consumed less vitamin A and carotene than peers with adequate dentition, although no gradient was seen in African-American contemporaries compared in an analogous manner related to mastication capacity. Smoking behavior – smokers, ex-smokers, or never smokers – had no effect on vitamin A intake in Greater Chicago residents (Dyer *et al.*, 2003). In an analysis of US Department of Agriculture (USDA) survey data, estimated vitamin A

intakes were highest in those who derived the greatest portion of energy from carbohydrates (Bowman and Spence, 2002). Meals containing traditional native foods provide more vitamin A than non-traditional commodities among indigenous populations of the Arctic of Canada (Kuhnlein *et al.*, 2004).

In children, adequacy of vitamin A intakes decreases with age (Serra-Majem *et al.*, 2001; Lytle *et al.*, 2002). Moreover, a gender gap emerges and widens over time, with boys' relative intakes better maintained than those of girls (Lytle *et al.*, 2002). Ethnicity joins sex as a factor among US children, with the Continuing Survey of Food Intakes showing that being black or being a female child of any race conferred the highest risk of consuming less than two-thirds of the RDA for vitamin A (Ganji *et al.*, 2003).

A predictor of a preschool child's not meeting the RNI in the northern regions of the United Kingdom was being the son or daughter of a manual laborer (Thane *et al.*, 2004). In the metro Manila area, schoolchildren of higher socioeconomic status consumed more vitamin A than those of low socioeconomic status (Florentino *et al.*, 2002). In British youth, low intake was inverse to dairy food consumption (Thane *et al.*, 2004). Finally, consuming a more “Mediterranean” diet did not influence the relative adequacy of vitamin A intake (Serra-Majem *et al.*, 2003).

### **Diagnostic Assessment of Vitamin A Nutriture**

The Biomarkers of Nutrition for Development (BOND) project is giving impetus to the re-examination of diagnostic assessment of nutritional status by pointing out some obvious discrepancies and weaknesses in the current application and interpretation of nutritional biomarkers (Raiten *et al.*, 2011). After a period of dormancy and reliance on established conventions, renewed emphasis on evidence-based decision making and expanding technological and logistic capacity to measure nutrients and metabolites in the clinic and in populations have provided incentives for more objective, transparent, and robust documentation and analysis.

The BOND biomarker paradigm is divided into three levels of interest for any nutrient: (1) magnitude of exposure to the nutrient; (2) nutrient (nutritional) status; and (3) functional consequences of exposure. It seeks primarily

material (chemical) markers, with less tangible (behavioral) indicators as a second level of marker. It recognizes for a nutrient such as vitamin A that health and policy issues revolve around how much of the nutrient is actually offered and consumed. Since there is no stoichiometric relationship between consumption with uptake, retention, and utilization, the first level of quantifying exposure is somewhat discrete from nutrient status; the latter refers to the amount of the nutrient within stores and functional pathways. Finally, insofar as nutrients have functions and actions, as discussed earlier, the third element of the paradigm looks for concrete measures of functional consequence attributable to a given degree of nutrient exposure. In general terms, all three of the aforementioned elements can refer to individuals (a specific diagnosis), or to groups of individuals (as prevalence and rates).

A virtual plethora of diagnostic options are displayed in Table 11.2. The key to rational selection depends, in part, on whether the application is for individuals in a clinical context or for a population for epidemiological and public health purposes. In the former, it is our interest to get an accurate measurement for the individual patient to

diagnose the underlying disease or take a decision for supplement therapy. When it comes to a population, the issue is the risk of a substantial number of individuals having suboptimal vitamin A status to merit a collective or targeted intervention program. In general, the limits on diagnostic methods for clinical practice derive from the day-to-day variation or distortion by clinical conditions, which combine to create imprecision in reflecting the underlying status of an individual, or both. The limits on assessment testing at the public health and population level derive from constraints of cost, convenience, acceptability, and ethical application in otherwise healthy persons.

**Evolution of Vitamin A Assessment**

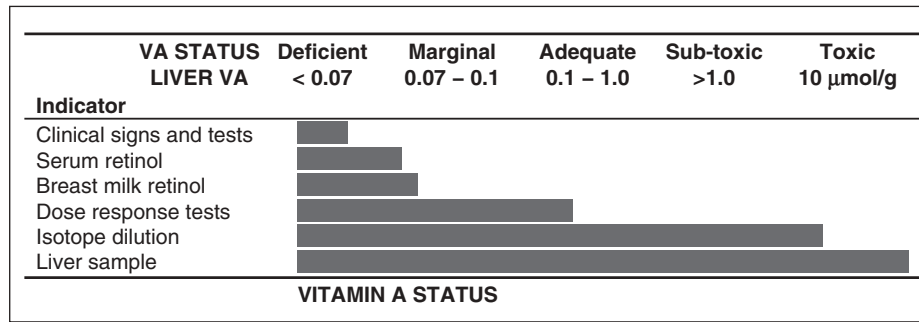

It was the emergence of interest in vitamin A and childhood mortality (Sommer *et al.*, 1983), in which pre-clinical (“marginal”) vitamin A deficiency was a risk factor, that stimulated creation of assessment tools. In 1993, in a guideline book from the International Vitamin A Consultative Group, Underwood and Olson (1993) set forth its mission: to provide tools for “assessing the regional distribution and magnitude of vitamin A deficiency.” It covered 13 assessment areas, 10 of which would be firmly considered biomarkers. This was followed, in 1996, by a largely derivative official WHO publication (WHO, 1996) which claimed to provide “principles governing the use of biological indicators for vitamin A deficiency (VAD) surveillance [providing] the rationale behind each indicator and its limitations and cut-off points for interpretation in terms of public health significance.” Almost a decade later, Tanumihardjo (2004) comments, in published proceedings: “having many choices of vitamin A assessment methods, laboratory sophistication and resources available will usually dictate which methods are chosen.” As part of the BOND, she has updated her consideration: “biomarkers of vitamin A status are still needed for the near future in order to more specifically identify populations at risk for vitamin A deficiency and to evaluate the effectiveness of different interventions or programs” (Tanumihardjo, 2011).

**TABLE 11.2** Clinical assessment of vitamin A status and estimation of population risk of vitamin A deficiency

Dietary intake assessment	Test type
Biological fluid markers	Circulating retinol Retinol binding protein (RBP) RBP/transthyretin (TTR) ratio Breast-milk retinol
Isotope dilution tests	Deuterated retinol dilution test (DRD)
Tissue biopsy markers	Invasive: -Hepatic biopsy assay Non-invasive: -Buccal cell vitamin A
Functional tests	Invasive: -Relative dose–response (RDR) -Modified RDR -30-day RDR Mildly invasive: -Conjunctival impression -Cytology Non-invasive: -Dark adaptation tests -Self-reported night blindness

**Gold Standards of Vitamin A Status for Reference to Biomarkers**

A chemical rendering of a cadaver postmortem is the most definitive gold standard, but of little clinical relevance. Since 80% of vitamin stores are in the liver, chemical analysis of a percutaneous liver biopsy is the second best approximation (Figures 11.4 and 11.5), and reflection of

**FIG. 11.4** The horizontal axis represents a continuum of hepatic vitamin A concentrations in  $\mu\text{mol/g}$ , with corresponding division into range bands categorizing specific states of vitamin A status. For each of the six approaches (one clinical method and five biomarkers), the range of liver concentration in which an abnormal result can provide diagnostic validity is represented by the horizontal solid bars in each row. Reproduced with permission from Tanumihardjo (2011).

**FIG. 11.5** The relationship of the modified relative-dose–response value to liver retinol concentration in piglets. Below  $17\mu\text{g/g}$  liver, the MRDR value is invariably positive, i.e.  $>0.060$ ; between  $17$  and  $29\mu\text{g/g}$ , the response is split; and above  $29\mu\text{g/g}$  liver, the MRDR value is usually  $<0.060$ . Reproduced with permission from Tanumihardjo (2011).

hepatic stores is the metric of other biomarkers (WHO, 1996; Tanumihardjo, 2004, 2011). Underwood and Olson (1993) consider  $1.05\mu\text{mol}$  of vitamin A per gram of liver tissue (equivalent to  $30\mu\text{g/g}$  in gravimetric units) the lower threshold for normal vitamin A status. The safest

surrogate “gold standard” method for assessment of total body vitamin A is deuterated-retinol, stable-isotopic dilution technique (Tang *et al.*, 2002; Ribaya-Mercado *et al.*, 2003, 2004a,b); it reflects hepatic vitamin A levels across the entire spectrum from depletion to intoxication (Figure 11.4).

### **Biomarkers for Patient Management in Clinical Practice**

If vitamin A status is severely deficient, clinical acumen in the physical examination may provide suspicion of hypovitaminosis A. In general, the majority of the screening tests listed in Table 11.2 are not relevant to hospital or clinic practice. Only the circulating retinol for routine application and the tissue biopsy for extraordinary use are of major interest. With respect to the former, however, for clinical assessment retinol has a series of recognized limitations. It is often low in situations of deficiency. It can be falsely normal in the situation of recent ingestion of preformed vitamin, dehydration, or hyperproteinemia, or falsely low with hypoproteinemia, infection, inflammatory states, obesity, hormonal replacement, or oral contraception. It has been suggested that only circulating concentrations  $<10\mu\text{g/dL}$  ( $0.35\mu\text{mol}$ ) have any robust diagnostic significance for vitamin A inadequacy (Underwood and Olson, 1993), but it is probably more prudent to be guided by the established limits of normality for circulating retinol in the clinical laboratory of record. A lower-than (or higher-than) limit result should guide the practitioner to pursue the implications for differential diagnosis in an individual case.

### ***Biomarkers for Population Assessment in Surveys and Epidemiology***

In the era of concern surrounding “marginal” vitamin A deficiency and the populations in which it is endemic, the relevance of biomarkers relates to action for public health (Underwood and Olson, 1993; WHO, 1996; Tanumihardjo, 2004, 2011). Among the selected biomarkers listed in Table 11.2, those with the lowest degree of invasiveness, complexity, and cost are the initial candidates for application in the field survey setting. According to the recent review by Tanumihardjo (2011), only four biomarkers (serum retinol, breast-milk retinol, dose–response tests, isotope dilution) have been cross-calibrated with grades of liver vitamin A concentration, and only the first three are appropriate for the field assessment for marginal vitamin A status of a population. Serum retinol and breast-milk retinol would both be susceptible to distortion by inflammation and infection, which are prevalent in low-income populations; they would be limited as monitoring indices for improvement in response to interventions by not bridging from the marginal to the adequate band of hepatic vitamin stores.

The family of dose–response tests, the relative dose response (RDR) (Stephensen *et al.*, 2002; Verhoef and West, 2005) and the modified RDR (Tanumihardjo and Olson, 1988; Tanumihardjo *et al.*, 1990a,b) merit special attention because of their putative ability to respond across a wider range of vitamin A status and through the range of the spectrum most relevant to public health (Figure 11.4). Both are based on the same physiological principle, namely that apo-RBP builds up in the liver during vitamin A deprivation; hence, an acute dosing with oral retinol leads to an exaggerated export of vitamin A. This response can be tracked as a quantitative post-dose elevation in retinol concentrations in the standard RDR, which requires two serial blood samples at a 5-hour interval (Verhoef and West, 2005), or an increment in a variant vitamin A isomer (3,4-didehydroretinol) in the modified RDR, which requires only a single (4-hour post-dose) blood sampling (Tanumihardjo *et al.*, 1990b; Tanumihardjo, 2011). The sensitivity and specificity of the modified RDR (MRDR) in relation to the 30  $\mu\text{g/g}$  (1.05  $\mu\text{mol/g}$ ) hepatic vitamin A concentration, posited as the cutoff for marginal versus adequate vitamin A status (Underwood and Olson, 1993) are illustrated by original work by Tanumihardjo (2011) in Figure 11.5. A normal MRDR ratio value of  $<0.06$  was seen in all but one instance of

liver vitamin A in the adequate range, for a virtually 100% diagnostic specificity to detect vitamin A-adequate individuals. Abnormal ratios begin to appear below the critical liver value, but the test is only 100% sensitive for a deficient classification at liver vitamin A concentrations less than 18  $\mu\text{g/g}$  (0.63  $\mu\text{mol/g}$ ). For applications, such as to exclude populations from interventions and to monitor improvement (correction) of vitamin A status to adequate, the MRDR is a minimally invasive biomarker of exceptional promise.

We should not neglect or discard, however, the other creative – and even less invasive and certainly less expensive – assessment tools that came out of the test-generating brainstorming of the 1980s and 1990s. Among these are ocular-response tests (Wondmikun, 2002; Taren *et al.*, 2004), conjunctival histology (Courtright *et al.*, 2002), buccal sampling (Sobeck *et al.*, 2002), and others, which are yet to be calibrated with hepatic stores. However, by cross-calibrating the rates of test-result abnormalities in a population known to meet the objective threshold for intervention, one might develop population-based criteria for the diagnosis of hypovitaminosis A endemicity. The caveats are two-fold: (1) selecting appropriate criteria for normal and abnormal rating of the tests, and (2) making any feasible adjustments for ethnic, environmental or other confounders of test response. As it is the population itself that is the target of policy action and programmatic intervention, the status of the collective – rather than the individuals within it – would seem to be a viable viewpoint for the interpretation of screening biomarkers for vitamin A. The BOND process (Raiten *et al.*, 2011) must grapple with a subtle conceptual issue of whether population assessment inherently needs to be based on measurement of the *prevalence* of individuals with truly marginal vitamin A stores in a population of interest or merely on an index of the *rate* of abnormal screening test occurrences.

### ***Assessment for Vitamin A Excess***

The concern for exposure and status assessment does not only reside at the lower end and the center of the vitamin A continuum. The upper end of individual status or collective exposure can produce adverse consequences on unborn fetuses and on overly exposed individuals. Early in the course of toxic exposure, circulating levels of retinol may rise above 300  $\mu\text{g/dL}$  (10.5  $\mu\text{mol}$ ), in association with elevations of fasting retinyl esters (Underwood and Olson,

1993). When severe hypervitaminosis A is suspected on clinical grounds, a liver biopsy is medically justified.

The risk of damage to the developing fetus is based on dietary intake criteria (Institute of Medicine, 2001). In the absence of any imminent prospects for a salivary, urinary or fecal metabolite as a biomarker for individuals' chronic exposure, mathematical modeling, using data on food selection, food preformed vitamin A content, and extent of fortification (Dary, 2006), is likely to offer the best promise for identifying community risk and taking remedial action at the public education or food regulation levels or both.

## Vitamin A Interventions in Preventive Medicine and Public Health

As part of the global call to action, the UN Special Session on Children in 2002 set as one of its goals the elimination of vitamin A deficiency and its consequences by the year 2010. The strategy to achieve this goal is to ensure that young children living in areas where the intake of vitamin A is inadequate receive the vitamin through a combination of breastfeeding, dietary improvement, food fortification, and supplementation.

### General Health Interventions

A healthy individual is better able to absorb, retain, and utilize vitamin A than an impaired host. Sanitation and hygienic measures that reduce diarrhea and control intestinal parasites optimize the intestinal health and the capacity to take up the vitamin from the diet. As inflammation and fevers provoke urinary wastage of the vitamin, prevention of febrile episodes would limit the loss of vitamin A. Routine immunizations and control of systemic parasites can act to limit catabolic losses of micronutrients including vitamin A.

### Food-Choice Approaches

Dietary diversification is the most fundamental and sustainable format to prevent hypovitaminosis A and has recently been acclaimed as the ideal approach (Latham, 2010). It is based on increasing the selection and consumption of foods rich in dietary vitamin A activity to bring the habitual consumption into the range of recommended intakes. Constraints in culture, cuisine, and household

economics, however, often interfere with achieving adequate intakes in low-income societies. To succeed with dietary approaches, strategies appropriate to the endogenous possibilities and limitations of the settings must be devised.

Preformed vitamin A is the more utilizable form. In Bangladesh, the consumption of small indigenous fish is widespread and promotes adequacy of intake (Roos *et al.*, 2003a,b). In Kenya, the addition of milk or meat to the school snack (a vegetable stew) improved overall vitamin A intake (Murphy *et al.*, 2003). When animal source foods can be made affordable and directed to vulnerable segments of the population, they constitute the most potent underpinning for a food-based strategy.

Plant sources of vitamin A are considerably more problematic as strategies for ensuring adequacy given the bioconversion issues of plant matrices. Nevertheless, home-gardening interventions in South Africa (Faber *et al.*, 2002a) and Thailand (Schipani *et al.*, 2002) were shown to support better vitamin A status. Varieties of bananas, extraordinarily rich in provitamin A carotenes, are cultivated throughout the Micronesian islands of the Pacific and have been recommended as a complement for that region (Englberger *et al.*, 2003). To enhance the bioefficacy of mango's provitamin A, its consumption with fat has been advanced in Gambia (Drammeh *et al.*, 2002).

A number of oil-bearing fruits with high contents of vitamin A are available but underutilized. Gac fruit (*Momordica cochinchinensis*) from Vietnam (Vuong and King, 2003) and aguaje or buriti fruit (*Mauritia vinifera* Mart) from the Amazon valley (Mariath *et al.*, 1989) are the two tropical fatty fruits with the highest specific concentrations of provitamin A. Derivatives of the palm fruit (*Elaeis* spp.), such as red palm oil, are in third place, containing in excess of 50 mg of mixed provitamin A per 100 g of oil (Nagendran *et al.*, 2000). Intervention trials in India (Sivan *et al.*, 2002; Radhika *et al.*, 2003) and Burkina Faso (Zagre *et al.*, 2003) demonstrate the efficacy of cooking with red palm oil to improve vitamin A status. Tailored shortenings (Benade, 2003) or dishes of local cuisine (Solomons and Orozco, 2003) prepared with red palm oil represent the most highly developed approaches to dietary fortification with derivatives of oil-bearing fruits. With the caveat of potential health risks from certain saturated fatty acid patterns, the provitamin A in oil matrices optimizes the nutritional potential for the carotenes. (Institute of Medicine, 2001).

### **Food Fortification with Vitamin A and Provitamin A**

The addition of vitamin A to foods began in the 1930s with the enrichment of margarine so that it supported vitamin nutrition in a manner similar to natural butter. Homogenized milk, with its lower butterfat content, is also enriched with vitamin A, as is skim and low-fat milk and their powdered forms. Beginning in the 1970s, the idea of fortifying foods that were never natural sources of vitamin A emerged into public-health thinking (Dary and Mora, 2002; Mora, 2003). This has been expanded and developed, and an overview and guideline for food fortification with micronutrients serve as a contemporary guide to understanding and effecting this strategy (Allen *et al.*, 2006).

For the selection of the vehicle for mass fortification, it is important that the item reach those segments most at risk, which would include those with the lowest incomes and the young and the pregnant and lactating within that class (Allen *et al.*, 2002). Two food items, sugar and cooking oil, are currently leading in the context of public-health fortification of staple foods. Sugar is fortified with retinyl palmitate in four of the five republics of Central America, as well as in Zambia. A survey showed that 89% of Ugandan households consumed sugar during any given week, making this sweetener a feasible vehicle in that African country as well (Kawuma, 2002). Oil is the other potentially useful vehicle. A pilot fortification of coconut oil in the Philippines made it the leading single source of the vitamin, providing one-third of dietary vitamin A and improved retinol status in the population (Candelária *et al.*, 2005). Salt may soon become a third staple food vehicle because a triple-fortification strategy involving microencapsulation, which adds vitamin A to table salt without displacing iodine and iron, has been developed (Zimmermann *et al.*, 2004).

A variation on the theme of fortification is that of specific products. At the public health level, vitamin A fortification can also be targeted to a specific segment of the population, as shown in a low-cost complementary food for infants and toddlers that was pilot tested in South Africa (Oelofse *et al.*, 2003). Outside of public health programs, industrial fortification of commercial foods has growing prominence; this has been termed “market-driven” fortification (Allen *et al.*, 2006; Dary, 2006). Breakfast cereals and fruit-flavored drinks are among the commercial items offered with additional vitamin A. Although this approach adds more vitamin A to national food supplies,

critics suggest that vitamin A in commercial foods does not reach the vulnerable sectors due to cost, but may expose the more affluent consumers to additional and unneeded preformed vitamin (Dary, 2006).

### **Home Fortification and Its Variants**

The accompanying with or mixing of micronutrient preparations with the non-breast-milk component of the weanling’s diet, termed home fortification, is a promising modality for combating deficiencies in later infancy and in the toddler years (Nestel *et al.*, 2003). Home fortification of complementary diets originally arose as a response to anemia, but multiple micronutrients, including vitamin A, are added to each of the common formats: micronutrient lipid spreads (Briend, 2001; Adu-Afarwuah *et al.*, 2008), nutrient mix in sachets (Sprinkles™, MixMe™) (Lundeen *et al.*, 2010), and crushable food-based tablets (foodLETs) (Smuts *et al.*, 2003, 2005). Although each of the options for home fortification has been demonstrated as effective to decrease anemia, only the foodLETs have been explicitly analyzed for their effects on hypovitaminosis A. In a randomized, four-regimen, multi-center study in Peru, South Africa, Indonesia, and Vietnam (Smuts *et al.*, 2005), 6 months of daily or weekly supplementation with a multinutrient foodLET preparation significantly reduced the prevalence of retinol values of  $<0.7 \mu\text{mol/L}$  ( $<20 \mu\text{g/dL}$ ), without any effects with the placebo or iron-only regimens. An analogous approach, but for schoolchildren, has been adopted in India; fortifying a school meal for Himalayan children over an 8-month school year with 75% of RDA for vitamin A improved circulating vitamin A concentration (Osei *et al.*, 2010).

### **Biofortification of the Food Supply**

Biofortification is an example of a food-based approach to improving vitamin A status in which food sources are modified to include greater than usual contents of dietary vitamin A. It has generally been applied to foods of vegetable origin, in which the provitamin A content is enhanced by genetic means, either cross-breeding hybridization or genetic modification (Welch, 2005). Vegetables such as carrots (Mills *et al.*, 2008), roots and tubers such as potatoes (Diretto *et al.*, 2010), sweet potatoes (Low *et al.*, 2007; Failla *et al.*, 2009), cassava (Thakkar *et al.*, 2007; Welsch *et al.*, 2010), and staple grains such as maize (Naqvi *et al.*, 2009; Vallabhaneni *et al.*, 2009; Yan *et al.*, 2010) and rice (Beyer, 2010) are among the examples of foods biofortified with provitamin A. Some are enriched spon-

taneously or through traditional hybridization cross-breeding (Low *et al.*, 2007; Thakkar *et al.*, 2007; Mills *et al.*, 2008; Failla *et al.*, 2009; Diretto *et al.*, 2010; Yan *et al.*, 2010), whereas others are genetically modified by gene insertion (Naqvi *et al.*, 2009; Vallabhaneni *et al.*, 2009; Beyer, 2010; Diretto *et al.*, 2010; Welsch *et al.*, 2010). Another genetically modified plant identified for potential contribution of provitamin A is golden mustard (*Brassica juncea*) (Chow *et al.*, 2010); oil extracted from mustard seed has wide distribution and has had a profound impact against hypovitaminosis A in India.

One might first consider enhancing the carotene content of fruits and vegetables. We have hybrid carrots as a beginning (Mills *et al.*, 2008). Carrot provitamin A is not of high bioavailability, the consumption frequency is occasional, and the amount consumed is limited. It is really in the main staple crops relied upon by low-income populations, such as maize and rice, in which hopes for biofortification's public-health role have been invested (Nestel *et al.*, 2006; Hotz and McClafferty, 2007). These two grains, along with cassava, potatoes, and sweet potatoes, cover much of the caloric needs of developing countries.

It was widely speculated that provitamin A would be poorly available to provide active vitamin from the matrices of staple crops. In stark contrast to predictions, at least with newer varieties of golden rice, ingenious studies with cultivars isotopically labelled hydroponically revealed a carotene-to-retinol conversion factor in healthy adults of ~4:1 (Tang *et al.*, 2009). Similarly, with carotene-rich natural hybrids of orange-flesh sweet potatoes, field trials in East Africa showed significant increases in serum retinol with the supplemented diets (Low *et al.*, 2007).

In the final analysis, the acceptability by the public of a yellow or orange hue in normally white-fleshed foods, such as rice, cassava, potatoes or cauliflower, or even of pigmented plants of a deeper hue, such as maize and sweet potato, remains to be assessed in large-scale consumer trials. The other acceptability (and safety) issue emerges as with any edible genetically modified organism, especially in developing countries. There is greater skepticism in governments and civil society in tropical societies, and the concerns for human health and environmental safety of consuming and cultivating these plants have yet to be entirely allayed.

### **Vitamin A Supplementation Interventions**

Since the pioneering field trial by Sommer *et al.* (1986), a myriad of vitamin A supplementation trials for prophylaxis against adverse health outcomes have been conducted.

With their ongoing evaluation and meta-analyses, the recommendations for target populations and schedules of public-health vitamin A supplementation for prophylaxis against endemic hypovitaminosis A continue in flux.

### **Current Prophylactic Vitamin A Supplementation Recommendations**

Over the years, recommendations have been based on one or a number of studies, transient evidence for routine, prophylactic administration to all of the groups listed in Table 11.3, and programs sanctioned by the WHO, Centers for Disease Control and Prevention, or the International Vitamin A Consultative Group, alone or in conjunction. On August 11, 2011, however, a revised and updated, target-group-specific set of guidelines from the WHO were disseminated: <http://www.who.int/nutrition/publications/micronutrients/guidelines>; these were the product of Cochrane-style systematic reviews, assessed by a panel of experts specific to the population groups. These contemporary guidelines are summarized in the second column of Table 11.3. Prophylactic "high-dose" oral supplementation of vitamin A is routinely recommended only for 6- to 59-month-old children, with the caveat that supplementation of pregnant women can be recommended where evidence of maternal night blindness is found. Delivery of these periodic doses is linked to the immunization schedules for infants and children.

Caution in supplementation is warranted in areas of high endemicity of HIV, as vitamin A supplementation to seropositive mothers has demonstrated adverse effects on the health and viral progression of mothers and offspring (Mehta *et al.*, 2007). As noted, earlier recommendations for neonatal dosing have been largely abandoned. In fact, in the setting of Guinea Bissau in West Africa, adverse health effects and excess mortality occur in female low- and normal-birth-weight neonates, but it is safe for newborn boys (Benn *et al.*, 2010). In the specific instance of HIV-infected infants, however, the delivery of an age-appropriate supplement dosage (~50 000 IU) of vitamin A to infants of HIV-positive mothers within 2 days of birth improved survival (Sommer, 2005; Humphreys *et al.*, 2010).

### **Programmatic and Pragmatic Challenges to the Delivery of Vitamin A Supplements**

After a brisk take-off in the early 1990s, the worldwide effort to maintain dosing every 6 months with age-appropriate, high-dose vitamin A has subsequently run

**TABLE 11.3** World Health Organization Guidelines on Vitamin A supplementation (2011)

Population category	Guideline for vitamin A supplementation
Neonates	The WHO does not recommend vitamin A supplementation for neonates as a public health intervention.
Infants 1–5 months of age	The WHO does not recommend vitamin A supplementation for infants 1–5 months of age as a public health intervention. Mothers should continue to be encouraged to exclusively breastfeed infants for the first 6 months to achieve optimal growth, health, and development.
Infants and children 6–59 months of age	The WHO recommends high-dose vitamin A supplementation every 4–6 months for infants and children 6–59 months of age, as a public health intervention to reduce child morbidity and mortality.
Pregnant women	The WHO does not recommend vitamin A supplementation during pregnancy as part of routine antenatal care. However, in areas where there is a severe public health problem of vitamin A deficiency, the WHO recommends giving vitamin A supplementation during pregnancy for the prevention of night blindness.
Postpartum women	The WHO does not recommend vitamin A supplementation for postpartum women as a public health intervention for the prevention of maternal and infant morbidity and mortality.
During pregnancy for reducing the risk of mother-to-child transmission of HIV	Currently the WHO does not recommend vitamin A supplementation in HIV-positive women as a public health intervention for the prevention of mother-to-child transmission of HIV.

The WHO standard for “high-dose” vitamin A supplementation refers to an oral dose of 100 000 IU (30 303 RE) for 6- to 12-month-old infants and 200 000 IU (60 606 RE) from 1 year onward, including in adults. These are also the age-specific dosages for specific therapeutic indications for oral vitamin A supplementation. Modified from guidelines on routine immunization from the World Health Organization. (Available at: <http://www.who.int/nutrition/publications/micronutrients/guidelines/en/index.html>.)

into obstacles. It was forced to move from campaign-style vaccination campaigns, associated with polio eradication, to the more routine, health-post-based schedules, which are far less universal across populations. It has also been shown in Indonesia (Pangaribuan *et al.*, 2004), the Philippines (Choi *et al.*, 2005), and Bangladesh (Semba *et al.*, 2010) that poorer (and theoretically more vulnerable) target families were less likely to have access to the vitamin A distribution system.

The safety reputation of the measure came under assault as the result of a highly publicized incident in Assam State, India, in 2002, in which excessive doses of a vitamin A syrup allegedly produced inadvertent lethal overdose during a regional campaign (Kapil, 2002). However, the emergent concern has shifted to the dependency issues of a medically controlled and health-sector-linked measure. Latham (2010) has argued that the only sustainable approach to coverage of the vitamin A needs of infants and young children will be a food-based strategy; the insistence

on maintaining high-dose prophylaxis in policy circles is seen as deferring a serious and concerted effort to transfer the burden of protection to an improved vitamin A content of complementary food and home diets of the children (and mothers) at risk of hypovitaminosis A in the world’s low-income societies.

## Vitamin A in Clinical Medicine and Therapeutics

### *Uses for Vitamin A and Provitamin A*

Vitamin A supplements of both high and lower doses have been studied, and therapeutic supplementation is potentially indicated in a number of conditions and explicitly recommended in others.

### **Xerophthalmia**

Xerophthalmia is a medical emergency. An immediate administration of 200 000 IU (60 606 RE) of vitamin A

is indicated, followed by a second dose on the following day, to respond to the danger of rapid deterioration of the ocular tissues.

### Measles

Vaccination has dramatically reduced the worldwide incidence of this viral exanthem. Complications from measles are more common in vitamin A-deficient populations (Perry and Halsey, 2004). First indicated as efficacious intervention trials in hospitalized children with measles complications in Africa, systematic reviews confirmed that intra-infection supplementation with vitamin A is effective in reducing measles mortality (D'Souza and D'Souza, 2004; Sudfeld *et al.*, 2010). Two consecutive day's worth of age-appropriate "high doses", as established for prophylactic administration by the WHO (Table 11.3, footnotes), is indicated.

### Clinical Protein-Energy Malnutrition

The severe, endemic protein-energy malnutrition had been in decline in recent decades, resulting in a loss of the clinical acumen to manage sporadic cases. Recent famines, natural disasters, civil conflicts, and refugee situations, however, have produced a recrudescence in clinical protein-energy malnutrition. It has long been appreciated that multiple micronutrient deficiencies, including that of vitamin A, are common in these patients. The WHO initiative to improve care for protein-energy malnutrition (Ashworth *et al.*, 2004) includes a provision to administer high-dose vitamin A, with the same "high-dose" dosage as shown in the footnotes of Table 11.3.

### Vitamin A Supplementation Indications in Other Diseases and Conditions

Aside from the three major public-health situations discussed above, evidence for efficacy of vitamin A supplementation has been reported in at least six areas of note (Box 11.1). Multiple therapeutic trials have shown that daily administration of retinyl palmitate slows the progression of the ocular defect in patients with retinitis pigmentosa (Hartong *et al.*, 2006). Vitamin A cycles from retinal pigment epithelia to photoreceptors of the neural retina with the conversion of all-*trans*-retinol to 11-*cis*-retinal. Gene mutations in these pathways explain a series of retinal dystrophies (Thompson and Gal, 2003).

Complications associated with premature birth are another vitamin A-responsive condition. Because hepatic vitamin A stores are laid down in late gestation, babies

#### BOX 11.1 Additional situations in which evidence for efficacy of vitamin A supplementation has been reported

Retinitis pigmentosa  
Complications associated with premature birth  
Malaria  
Tuberculosis  
Radiation proctitis  
Prevention of malignant transformation of hydatidiform moles

born before term are notably deficient in vitamin A (Mactier and Weaver, 2005). Moreover, lung prematurity or bronchopulmonary dysplasia, a common affliction of the small preterm infant, is more frequent the lower the circulating retinol concentration (Spears *et al.*, 2004). Vitamin A has been found to up-regulate genes necessary for fetal lung growth and increase surfactant production in animal models. A major multicenter collaborative randomized clinical trial of thrice-weekly doses of 5000 IU (1515 RAE) of intramuscular retinyl palmitate over the first 4 weeks of life in extremely low-birth-weight infants (under 1000 g), was conducted in US neonatal intensive care units in the 1990s (Tyson *et al.*, 1999); it demonstrated a slight, but significant, 11% reduction in the combined outcomes of death or chronic lung disease at 36 weeks. Darlow and Graham (2007), in their systematic review, comment:

Supplementing very low birthweight infants with vitamin A is associated with a reduction in death or oxygen requirement at one month of age and oxygen requirement among survivors at 36 weeks postmenstrual age, with this latter outcome being confined to infants with birthweight less than 1000 g.

With respect to infections, vitamin A supplementation has shown beneficial effects in malaria and tuberculosis. Vitamin A administration has had a positive effect on malaria by reducing the severity of attacks. Shankar *et al.* (1999) demonstrated reduced morbidity from this parasitosis in an area of hyperendemicity of *Plasmodium falciparum* malaria in Papua New Guinea, with periodic high-dose vitamin A supplementation. Serghides and Kain (2002) speculate that the mechanism could lie in enhancing protozoal clearance by phagocytic cells and in suppressing the tumor necrosis factor-alpha response. It

also decreases C-reactive protein (Cusick *et al.*, 2005). Moreover, vitamin A supplementation ameliorated the adverse effect on growth of malaria-infected children in Tanzania (Sazawal *et al.*, 2006). With respect to tuberculosis, a double-blind, placebo-controlled study of vitamin A and zinc supplementation in persons with tuberculosis was conducted in central Java in Indonesia (Karyadi *et al.*, 2002). A daily regimen of 5000 IU (1515 RAE) and 15 mg zinc in patients with tuberculosis under treatment produced earlier sputum clearance and radiographic resolution. The authors recommended this micronutrient combination as an adjunctive therapy for tuberculosis.

In several applications in oncology, vitamin A supplementation has a role. In proctitis due to pelvic field radiotherapy, preliminary encouraging findings in a randomized clinical trial using 10 000 IU (3030 RAE) of retinyl palmitate for 90 days in oncology patients reduced rectal symptoms 6 months post-radiation (Ehrenpreis *et al.*, 2005). A preliminary observation in Indonesia of a five-fold reduction in the malignant transformation of hydatidiform moles (non-viable conceptuses giving rise to vesicular placenta, occurring in one in 100 pregnancies) with short-term daily supplementation with 200 000 IU of vitamin A has been reported (Andrijono and Muhilal, 2010).

Well conducted studies have also tested supplementation and found it to be ineffective. Clinical trials with vitamin A supplementation during episodes of acute diarrhea have shown mixed and selective results, generally with no greater efficacy for reducing disease severity than placebo (Biswas *et al.*, 1994; Bhandari *et al.*, 1997; Andreozzi *et al.*, 2006). Such is also the case for reducing the vaginal shedding of herpes simplex virus in HIV infection (Baeten *et al.*, 2004).

## Uses for Retinoids

Retinoic acid and various isomers and synthetic analogs are being used in pharmacological dosages for an increasing number of therapeutic purposes.

### Severe Acne Vulgaris

Both topical and systematic administration of retinoids have been successfully applied to the treatment of severe cases of acne vulgaris. Retinoids act to lyse the micro-comedo before they develop into full-blown comedones (Chivot, 2003). Both all-*trans*-retinoic acid (tretinoin) and

13-*cis*-retinoic acid (isotretinoin) have successful track records in acne therapy.

### Malignancies

Retinoids have also found application in therapy of both solid tumors and hematological malignancies. They are used to treat cancer, in part because of their ability to induce differentiation and arrest proliferation (Bushue and Wan, 2010; Tang and Gudas, 2011). It also inhibits angiogenesis, depriving tissues of new vasculature (Siddikuzzaman *et al.*, 2010).

It was first observed that long-term remissions of chronic myelogenous leukemia could be induced by systemic application of all-*trans*-retinoic acid (ATRA), and later its efficacy in chronic promyelocytic leukemia was also shown. In both dyscrasias, the retinoid induces terminal differentiation of the myeloid cells (Oren *et al.*, 2003). It is also effective in the treatment of Wilms' tumors (Johanning and Piyathilake, 2003). Also among the human tumors for which ATRA has shown therapeutic value are: Kaposi's sarcoma, head and neck squamous cell carcinoma, ovarian carcinoma, bladder cancer, and neuroblastoma (Siddikuzzaman *et al.*, 2010). Rapid metabolism and resistance are problems such that combination therapy with drugs such as DNA methyltransferase and histone deacetylase inhibitors, which regulate the epigenome, are required (Tang and Gudas, 2011).

### Adjunctive Therapy in Hepatitis C Treatment

Insight into a potential advance in adjunctive interferon-1 therapy for hepatitis C virus comes from in vitro studies with 9-*cis*-retinoic acid on hepatic cells. The retinoid increases expression of the IFN-1 receptors, enhancing the antiviral effect of the drug (Hamamoto *et al.*, 2003).

## Adverse and Toxic Consequences of Exposures to Vitamin A and Retinoids

By virtue of their chemical nature and persistence in the body, exposure to retinoids has recognized adverse consequences, and even toxic effects, which can prove lethal under certain conditions (Fenaux *et al.*, 2001, 2007). In conjunction with the considerations of nutritional adequacy, at least two organizations have offered systematic advice regarding tolerable upper intake levels (ULs) for habitual daily dietary intakes of preformed vitamin A: (1) the Food and Nutrition Board of the US Institute of

**TABLE 11.4** Summary of estimated tolerable upper intake levels for average daily consumption of preformed vitamin A supplementation with vitamin A

Population group	Estimated tolerable upper level (micrograms <sup>a</sup> )
<i>EU Commission Scientific Committee on Food<sup>b</sup></i>	
1–3 years	800
4–6 years	1100
7–10 years	1500
11–14 years	2000
15–17 years	2600
Adults	3000
Older adults	No finding
<i>Dietary reference intakes<sup>c</sup></i>	
0–1 years	600
1–3 years	600
4–8 years	900
9–13 years	1700
14–18 years	2800
Adults	3000
Pregnant women	3000
Lactating women	3000

<sup>a</sup>Assumes micrograms of preformed vitamin A.

<sup>b</sup>Data from European Union Commission, Scientific Committee on Food, Task-Force on Upper Levels for Vitamins and Minerals (2002).

<sup>c</sup>Data from Institute of Medicine (2001).

Medicine (Institute of Medicine, 2001); and (2) a panel of the European Union on Food (European Union Commission, 2002). The respective estimates of tolerable levels are shown in Table 11.4. They are largely homologous, indicating that habitual intake of 3000 µg of preformed vitamin A is the consensus UL.

## Systemic Toxicity of Vitamin A

A hepatic concentration of over 300 mg/g of vitamin A is considered excessive, and could be associated with clinical toxicity manifestations. In fulminant overdoses of vitamin A, signs include severe skin rash, headache, double vision, and coma due to pseudotumor cerebri, resulting in rapid demise (Khasru *et al.*, 2007). In more chronic, but massive overdoses, hepatic fibrosis and ascites and skin lesions share the syndrome with central nervous system disturbances. More recently recognized toxic manifestations include bone-marrow suppression in an infant with hypervitaminosis A (Perrotta *et al.*, 2002) and hypercalcemia in

an adult consuming commercial enteral formula for a prolonged period (Bhalia *et al.*, 2005).

In an interesting observation at the interface of pharmacology and toxicology, Myhre *et al.* (2003) reported that oil-based vitamin A and liver have one-tenth the toxic potential as water-miscible, emulsified, and solid forms of retinol supplements. In recent years, two prospective studies in healthy adult volunteers have compared daily consumption of oil-based retinyl ester supplements at dosages of 25 000 IU (7575 RAE), 50 000 IU (15 152 RAE), and 75 000 IU (23 727 RAE) for periods of 12 months (Alberts *et al.*, 2004) and 16 months (Sedjo *et al.*, 2004) with this latter dose representing 7.5 times the UL. No evidence of toxicity or adverse consequences was detected over the respective intervals.

With a public health perspective, Allen and Haskell (2002) have examined the supplementation regimens current in 2002, and conclude that, on a single-dose or periodic basis, the schedules for high-dose supplements were safe for infants, children, and postpartum women. Although some exceeded the daily UL on a prorated basis, none would surpass the no-observed-adverse-effect level.

## Systemic Toxicity of Retinoic Acid and Isomers

Since the advent of high-dose treatment with systemic retinoic acid for leukemia and other malignant conditions, a condition known as “retinoic acid syndrome” has been recognized. It is characterized by weight gain, episodes of hypotension, acute renal failure, unexplained fever, and respiratory distress associated with interstitial pulmonary infiltrates and pleural and pericardial effusions seen on chest X-rays (Larson and Tallman, 2003). High doses of retinoid analogs can increase intracranial pressure as well (Friedman, 2005).

## Teratogenesis

Congenital birth defects can be induced by vitamin A deficiency and excess. The UL of vitamin A (Institute of Medicine, 2001) is based on increased risk of teratogenesis, which is estimated to begin with habitual intakes of preformed vitamin A in excess of 10 000 IU (3030 RAE). The damage occurs in the embryogenic phase within days of conception. The manifestations of excess vitamin A include a spectrum of malformations including ocular, pulmonary, cardiovascular, and urogenital defects (Lefebvre *et al.*, 2010). These same birth defects can arise when systemic doses of the retinoid analogs are administered in

dermatological practice to treat acne (Miller *et al.*, 1998). Provisional evidence suggests, however, that the topical use of these analogs in early pregnancy presents minimal to no risk of teratogenesis (Loureiro *et al.*, 2005).

### **Other Adverse Consequences**

Interest has arisen regarding adverse consequences of vitamin A interaction with HIV infections, bone mineralization, cardiovascular risk, and repletion of iodine-deficient populations.

### **Interaction with HIV infection**

A series of adverse effects of vitamin A in the maternal–infant dyad with maternal HIV infection have been identified (Mehta *et al.*, 2007). Subclinical mastitis, common among HIV-infected women, was exacerbated in its incidence when vitamin A supplements were given to seropositive Tanzanian lactating women (Arsenault *et al.*, 2010).

### **Bone Demineralization and Osteoporotic Fracture Risk**

One of the areas of most recent toxicological concern is that of an adverse effect of vitamin A on bone mineralization and structural integrity. Spontaneous bone fractures are a common manifestation from vitamin A overfeeding in animals (Genaro and Martini, 2004), and it is well established that vitamin A stimulates bone resorption and inhibits bone formation (Kawahara *et al.*, 2006). A concern for humans arose from a study in Swedish women (Melhus *et al.*, 1998), in which an inverse association was reported between consumption of preformed vitamin A intake and bone mineral density in a cross-sectional analysis, with adverse effect arising for habitual daily vitamin A intakes above 1500 µg equivalents, one-half the UL level (Institute of Medicine, 2001). Subsequently, numerous publications based on estimated preformed vitamin A intake or circulating retinol showed inconsistent results (Crandall, 2004; Ribaya-Mercado and Blumberg, 2007; Morgan *et al.*, 2009). Of important note is that intakes of provitamin A carotenes are in no way suspected of adverse effects on bone mineralization. Also, with respect to vitamin A analog retinoids and bone loss, a survey from the nationwide registry of Denmark failed to show any association between fractures at any site and retinoid therapy histories (Vestergaard *et al.*, 2010).

The public-health importance of this constellation of observations has yet to be defined. A prudent interim

conclusion comes from Crandall (2004), however: “It is not yet possible to set a specific level of retinol intake above which bone health is compromised. Pending further investigation, Vit A supplements should not be used with the express goal of improving bone health.”

### **Future Directions**

The future of vitamin A may involve a return to basics and to revisiting issues addressed in previous decades. An emerging notion is that the conventional application of biomarkers to assessment of vitamin A status has not been providing guidance for policy decisions. The BOND effort along with a forthcoming World Health Organization reissuing of guidance needs to rationalize the way in which biomarkers are used in assessment, while preserving the features of low-cost, non-invasive nature and subject-friendliness. The recent re-evaluation of interpretation of biomarkers calls for the setting aside of conventional approaches to assessment of vitamin A status and points out the need to become more circumscriptive and attentive to the BOND process and the WHO reassessment.

Another legacy of the 1980s, the population-wide supplementation with high-dose retinyl palmitate, has come under scrutiny as permanent programs. Detractors feel that reliance on supplementation focuses on only one of many micronutrients that may be problematic, and deters a serious mobilization in developing food-based approaches (Allen *et al.*, 2006). To replace supplementation, any food-based approaches must cover the foods consumed by the most vulnerable sub-segment of the population, children under 5 years. Addition of vitamin A to the diet through voluntary fortification of commercial foods is expanding (Allen *et al.*, 2006); however, contribution of such foods to the diets of young children in the poorest of communities is questionable. For the more affluent consumers of such products, however, the ability to add retinyl palmitate to commercial processed foods, as well as public health programs, raises safety issues about excess vitamin A exposure as a prominent health concern. For vulnerable populations, biofortification and carotene fortification present potential intervention opportunities. Plant sources of provitamin A and added carotenes have absolute safety, but variable efficacy, depending on food-matrix factors and accompanying fat. Moreover, newly acquired insights into polymorphisms in the enzymes governing bioconversion of provitamin A sources (Allen *et al.*, 2006) may guide public health authorities in selection of populations in

which plant-source intervention might hold greater or lesser promise.

## CAROTENOIDS

BRIAN L. LINDSHIELD, PhD

*Kansas State University, Manhattan, Kansas, USA*

### Summary

Carotenoids are 40-carbon fat-soluble compounds. Many carotenoids are pigmented; the six main carotenoids consumed and found in the body are:  $\beta$ -carotene,  $\alpha$ -carotene,  $\beta$ -cryptoxanthin, lutein, zeaxanthin, and lycopene.  $\beta$ -Carotene,  $\alpha$ -carotene, and  $\beta$ -cryptoxanthin are provitamin A carotenoids, meaning they can be cleaved to form retinal primarily by the carotenoid cleavage enzyme carotenoid monoxygenase 1 (CMO1). Retinol activity equivalents (RAEs) were established by the Dietary Reference Intakes Committee to estimate the vitamin A contribution of provitamin A carotenoids. Evidence suggests that the second carotenoid cleavage enzyme carotenoid monoxygenase 2 (CMO2) cleaves non-provitamin A carotenoids. A number of factors influence carotenoid bioavailability and bioconversion, which are summarized by the mnemonic "SLAMENGI" (Species, Linkage, Amount, Matrix, Effectors, Nutrient status, Genetic factors, Host-related factors, and Interactions). The relationship between carotenoids and chronic diseases has been and remains an active area of investigation. Three of the most researched areas are  $\beta$ -carotene and lung cancer, lycopene and prostate cancer, and lutein/zeaxanthin and macular degeneration. Golden rice, genetically modified to produce  $\beta$ -carotene, was designed to combat vitamin A deficiency in countries that consume rice as a staple food. Despite being developed over a decade ago it continues to face regulatory hurdles in making it to market.

### Introduction

Carotenoids are non-polar, 40-carbon poly-isoprenoid compounds found throughout nature. Of the approximately 600 known carotenoids, only 40 are typically ingested by humans and of these only 20 are commonly found in human tissues (Young *et al.*, 2004). The six main carotenoids found in the diet, blood, and tissues are:  $\beta$ -carotene,  $\alpha$ -carotene,  $\beta$ -cryptoxanthin, lutein, zeaxanthin,

and lycopene. The latter carotenoid, lycopene, is the predominant carotenoid found in the diet and blood in the United States (Holden *et al.*, 1999) (Table 12.1 and Figure 12.1). Carotenoids are classified in two ways: first, based on whether or not the carotenoid is capable of being converted to vitamin A (provitamin A activity), and secondly on structural differences and polarity. Oxygenated carotenoids are known as xanthophylls, while hydrocarbon carotenoids are known as carotenes.

**Table 12.1** Color, xanthophyll/carotene classification, retinol conversion factors, US mean serum and intake levels, and good food sources of selected carotenoids.

Carotenoid	Color	Xanthophyll or Carotene	RE	RAE	US mean serum levels <sup>a</sup>		US mean intake from foods <sup>a</sup>		Good food sources <sup>b</sup>
					M	F	M	F	
					$\mu\text{g/dL}$		$\text{mg/d}$		
Lycopene	Red	Carotene	–	–	26.4	23.9	11.27	6.71	Tomatoes, watermelon, guava, pink grapefruit
$\beta$ -Carotene	Yellow-orange	Carotene	6	12	14.6	18.4	2.22	1.87	Carrots, sweet potatoes, pumpkin, spinach, apricots
$\alpha$ -Carotene	Light yellow	Carotene	12	24	3.8	4.4	0.44	0.36	Carrots, pumpkin
$\beta$ -Cryptoxanthin	Orange	Xanthophyll	12	24	8.6	8.1	0.13	0.10	Sweet red peppers, tangerines, papaya, persimmons
Lutein	Yellow	Xanthophyll	–	–	20.1 <sup>c</sup>	18.2 <sup>c</sup>	2.11	1.86	Kale, spinach, corn, collard greens, broccoli, eggs
Zeaxanthin	Yellow	Xanthophyll	–	–	–	–	–	–	Not consumed in significant quantities
Canthaxanthin	Red-orange	Xanthophyll	–	–	–	–	–	–	Not consumed in significant quantities
Astaxanthin	Red	Xanthophyll	–	–	–	–	–	–	Not consumed in significant quantities

RE, retinol equivalent; RAE, retinol activity equivalent; M, male; F, female.

<sup>a</sup>US mean serum levels and food intakes were calculated using the values for the 19–30 and 30–51 age groups (DRI 2000, DRI 2001).

<sup>b</sup>Foods from: Holden *et al.* (1999).

<sup>c</sup>Serum and intake levels are the sum of lutein and zeaxanthin.

Carotenoid structures contain multiple conjugated double bonds that are responsible for their ability to efficiently scavenge free radicals (and thus serve as antioxidants) and to absorb light in the visible region. This absorption causes them to reflect their respective colors. Differences in the number of double bonds result in carotenoids ranging from colorless (owing to an insufficient number of conjugated double bonds) to bright red (Deming *et al.*, 2001) (Figure 12.1 and Table 12.1). This unsaturated structure also causes carotenoids to be labile to oxygen, light, and heat.

In plants, carotenoids are part of the light-harvesting complex that captures light for photosynthesis. Carotenoids are also found in bacteria, yeasts, molds, bird feathers, and

crustaceans; however, mammals do not synthesize carotenoids and must obtain them from their diet. The carotenoids astaxanthin, lutein, and zeaxanthin are commonly used as animal feed supplements. Astaxanthin is responsible for the pink color of salmon, while lutein and zeaxanthin are used in poultry to increase the yellow pigmentation of egg yolks (Table 12.1 and Figure 12.1).

In this chapter, the factors that influence carotenoid bioavailability (how much carotenoid is actually absorbed) and bioconversion (how much carotenoid is converted to vitamin A) will be initially addressed, followed by a discussion of the conversion of provitamin A carotenoids. The transport and accumulation of carotenoids, factors affecting circulating serum levels, deficiency, and toxicity will

**FIG. 12.1** All-*trans* structures of common carotenoids.

Note: Narrow arrow on  $\beta$ -carotene indicates 15,15' CMO1 central cleavage site; wide arrow on  $\beta$ -carotene indicates 9',10' CMO2 eccentric cleavage site.

next be reviewed. The carotenoid cleavage enzymes will then be discussed, followed by sections on  $\beta$ -carotene and lung cancer, lycopene and prostate cancer, lutein/zeaxanthin and macular degeneration and cataract formation, carotenoids and skin, and carotenoids and cardiovascular disease. Finally, future directions of carotenoid research will be suggested.

## Bioavailability and Bioconversion

A number of factors influence the absorption of carotenoids and conversion of provitamin A carotenoids to vitamin A. To help remember these factors, the mnemonic “SLAMENGHI” (for Species, Linkage, Amount, Matrix, Effectors, Nutrient status, Genetic factors, Host-related factors, and Interactions) was coined by Clive West and colleagues (Castenmiller and West, 1998). The major SLAMENGHI factors impacting carotenoid bioavailability and bioconversion to vitamin A are addressed below.

### Species

Among carotenoids, xanthophylls are generally more readily absorbed than carotenes. This is believed to be

because the more hydrophilic nature of xanthophylls allows them to be incorporated into the outer portion of lipid micelles in the gastrointestinal tract (Yeum and Russell, 2002). Carotenoids are normally found in nature in the all-*trans* form; however, they are easily isomerized to form *cis* isomers following exposure to heat and/or light. The relative absorption of *cis* isomers apparently differs between carotenoids. For example, absorption is decreased for  $\beta$ -carotene *cis* isomers, whereas uptake is increased for lycopene *cis* isomers compared with their respective all-*trans* forms (Castenmiller and West, 1998).

### Molecular Linkage

In many fruits and vegetables, the hydroxyl groups of xanthophylls are esterified to fatty acids. Before esterified xanthophylls can be absorbed, the fatty acids must be cleaved to form free xanthophylls in the gastrointestinal tract. Xanthophyll ester hydrolysis appears to be an efficient process because the absorption of lutein and  $\beta$ -cryptoxanthin esters is similar to that of the free carotenoid forms (Breithaupt *et al.*, 2003; Chung *et al.*, 2004), while the uptake of zeaxanthin esters may actually be greater than that of free forms of this carotenoid (Breithaupt *et al.*, 2004).

**Matrix**

The context, or matrix, in which carotenoids are provided appears to be the greatest factor affecting their bioavailability. For example, orange fruits such as papaya, mango, squash, and pumpkin yield twice as much vitamin A activity and four-fold higher serum  $\beta$ -carotene levels than green leafy vegetables and carrots (Boileau and Erdman, 2004). The difference between these fruits and vegetables is that in these fruits the carotenoids are found dissolved in oil droplets, whereas in vegetables they are sequestered as crystals, bound in chloroplasts, or associated with macromolecules such as fiber or protein. It is difficult for crystalline or bound carotenoids to become solubilized in micelles in the gastrointestinal tract, thus hindering their absorption. Mild heating and food processing increase the bioavailability of carotenoids by disrupting plant cell walls, binding proteins, and organelles, thus freeing carotenoids for uptake. In addition, because there is no matrix inhibiting their release, carotenoids provided in oil (e.g. red palm oil), or commercially available water-soluble beadlets, have superior bioavailability compared with fruits or vegetables (Boileau and Erdman, 2004). In rats, however, lycopene from tomato powder was more bioavailable than water-soluble beadlets (Canene-Adams *et al.*, 2007).

**Effectors**

There are many effectors of carotenoid absorption. Fat intake, like a modest amount of salad dressing on a salad, increases carotenoid uptake by facilitating the formation of mixed micelles. Mixed micelles are needed for lipid-soluble carotenoids to cross the unstirred water layer for uptake into enterocytes. Fiber, olestra, plant sterol, and stanol esters are dietary compounds that decrease the absorption of carotenoids. When provided at high levels, the consumption of one carotenoid can decrease carotenoid absorption. This most likely occurs because carotenoids share similar uptake and transport pathways (Yeum and Russell, 2002). In contrast, cosupplementation with other antioxidants may actually increase the bioavailability of carotenoids. Antioxidants, such as vitamins C and E, may increase the stability of the carotenoids in the gastrointestinal tract and thereby facilitate their absorption (Tanumihardjo *et al.*, 2005).

**Nutrient Status of Host**

Higher vitamin A status is believed to decrease carotenoid bioconversion (Yeum and Russell, 2002), whereas low vitamin A status increases the conversion to vitamin A to help meet the body's needs. In addition, protein deficiency

decreases the level of the carotenoid central cleavage enzyme in rats (Barua, 2004; Tang and Russell, 2004). Furthermore, because the central cleavage enzyme requires ferrous iron as a cofactor, iron status also is likely important to its activity (von Lintig *et al.*, 2005).

**Host-Related Factors**

Atrophic gastritis, a common condition of aging that results in insufficient gastric acid secretion, decreases carotenoid uptake by disturbing the formation and absorption of mixed micelles (Yeum and Russell, 2002). Parasitic infections, which are prevalent in vitamin A deficient populations, can also have a dramatic negative effect on carotenoid absorption (Barua, 2004).

**Carotenoid Retinol Equivalents and Retinol Activity Equivalents**

In 1989, the Food and Nutrition Board of the National Academies of Science established the conversion value of 2  $\mu\text{g}$  of purified all-*trans*- $\beta$ -carotene from supplements to be one retinol equivalent (RE = 1  $\mu\text{g}$  all-*trans*-retinol). Because of decreased bioavailability, 3  $\mu\text{g}$  of dietary all-*trans*- $\beta$ -carotene from food was considered to be equivalent to 1  $\mu\text{g}$  of purified all-*trans*- $\beta$ -carotene in oil. Thus, 6  $\mu\text{g}$  of dietary all-*trans*- $\beta$ -carotene was equivalent to 1 RE. Other dietary provitamin A carotenoids (mainly  $\alpha$ -carotene and  $\beta$ -cryptoxanthin) were believed to have half the vitamin A activity of dietary all-*trans*- $\beta$ -carotene and set at 12  $\mu\text{g}$  = 1 RE (Table 12.1). However, in 2001 the Food and Nutrition Board revised these conversion values based on human trials revealing that the bioavailability of all-*trans*- $\beta$ -carotene from foods was half of what was originally believed. To help alleviate the confusion in making the changes, a new term was coined: "retinol activity equivalent" (RAE = 1  $\mu\text{g}$  all-*trans*-retinol). The RAE ratios of conversion for purified all-*trans*- $\beta$ -carotene in oil, dietary all-*trans*- $\beta$ -carotene, and other dietary provitamin A carotenoids were set at 2:1, 12:1, and 24:1, respectively (Table 12.1) (Institute of Medicine, 2001). However, recent work in Mongolian gerbils suggests that the bioconversion of dietary provitamin A carotenoids may be more efficient than the RAE ratios (Howe and Tanumihardjo, 2006; Davis *et al.*, 2008; Howe *et al.*, 2009; Arscott *et al.*, 2010; Ejoh *et al.*, 2010). A recent study found evidence suggesting that the relative bioavailability of  $\beta$ -cryptoxanthin and  $\alpha$ -carotene is greater than that of  $\beta$ -carotene, a fact that would partly explain the more efficient bioconversion (Burri *et al.*, 2010).

## Transport and Accumulation

In the lumen of the small intestine, carotenoids are first incorporated into mixed micelles, which facilitate their absorption through an unresolved mechanism(s). Evidence suggests that carotenoids are absorbed by simple diffusion and transporters such as scavenger receptor class B type I (SR-BI) (Nagao, 2009). Following absorption, carotenoids are incorporated primarily into chylomicrons and released into the lymph before entering general circulation. Carotenoids may be partially taken up by peripheral tissues before chylomicron remnants are taken up by the liver (Deming *et al.*, 2001). In the liver, carotenoids are repackaged into very-low-density lipoproteins (VLDL) and secreted back into the blood.

Carotenoids are not equally distributed among lipoproteins; the hydrophobic carotenes are found predominantly in low-density lipoproteins (LDL), while the more hydrophilic xanthophylls tend to be found in higher amounts in high-density lipoproteins (HDL) (Furr and Clark, 2004). The uptake of carotenoids also varies between tissues. Table 12.2 gives the concentrations of the six major carotenoids in selected human tissues. Quantitatively, carotenoids are highest in the liver and adipose; however, carotenoid concentrations are highest in the liver, adrenal, and reproductive tissues (such as the prostate). The reason for this differential accumulation is not known, but it has been hypothesized that the differential uptake is a result of either high levels of LDL receptors in these tissues or specific carotenoid-binding proteins and/or transporters that have not yet been identified (Deming *et al.*, 2001). Recently lutein keto-carotenoid metabolites were found to accumulate at higher levels than lutein in the liver and fat, suggesting they are actively metabolized in the body

(Yonekura *et al.*, 2011). Similar metabolites of lutein and zeaxanthin accumulated at high levels in CMO2 knockout mice (Amengual *et al.*, 2011). It remains to be seen what the functions of these metabolites are and whether  $\beta$ -cryptoxanthin forms similar metabolite(s).

## Factors Affecting Circulating Levels

Body composition is a major factor that affects the circulating levels of carotenoids. A number of studies have reported an inverse association between body mass index (BMI) and plasma carotenoid concentrations. Further dissection of this association suggests that carotenoid plasma concentrations are inversely related not only to fat mass, but also to lean body mass. This indicates that non-fat tissues, such as muscle, may also serve as a reservoir for carotenoids (Furr and Clark, 2004). Accordingly, people with anorexia nervosa have very high levels of plasma carotenoids, most likely due to high levels of mobilization in this catabolic condition (Curran-Celentano and Erdman, 1993).

In general, circulating carotenoid levels are correlated with serum triglyceride and cholesterol levels. There are reported increases in serum levels as people age, which could be related to the upward shift in the serum lipid profile of older adults. In females, the concentrations of different carotenoids peak at different points of the menstrual cycle. The reason or significance is not known, but in men there also appears to be an inverse interaction between androgens and lycopene (Furr and Clark, 2004). Smoking is associated with lower carotenoid levels, presumably owing to an increase in oxidative stress, and alcohol intake has been shown to be inversely related to  $\beta$ -carotene levels. However, both smoking and alcohol

**TABLE 12.2** Carotenoid concentrations in selected human tissues

intake are also associated with reduced dietary intakes of carotenoids. It is not clear whether diet or metabolic differences are responsible for these decreased serum carotenoid levels (Institute of Medicine, 2000).

## Toxicity and Deficiency

Unlike vitamin A, there are no deficiencies or toxicities for carotenoids *per se*. Low levels of carotenoids may increase people's risk for developing certain chronic diseases, but no classical deficiencies have been described. High intakes of  $\beta$ -carotene and lycopene can lead to carotenoderma and lycopenderma, respectively. Carotenoderma is a condition that results in a yellowing of the skin due to accumulation of high levels of  $\beta$ -carotene. This disorder has been reported in subjects consuming large amounts of foods such as carrots or supplementing with 30 mg  $\beta$ -carotene per day or more for long periods of time. Carotenoderma does not result in discoloring of the ocular sclera as occurs in jaundice, thus allowing carotenoderma to be distinguished from this malady. Similarly, lycopenderma results from high intakes of tomatoes or lycopene and causes the skin to become orange (Institute of Medicine, 2000). Both of these conditions reverse days or weeks after reducing carotenoid intake. Two examples of adverse effects of high-dose carotenoid supplementation that are discussed below are  $\beta$ -carotene and lung cancer risk in smokers, and canthaxanthin-induced retinopathy in the eye.

## Carotenoid-Cleavage Enzymes

The small intestine and selected other tissues contain high levels of the two main carotenoid-cleavage enzymes, carotenoid monooxygenase 1 (CMO1) and carotenoid monooxygenase 2 (CMO2). Both of these enzymes are capable of cleaving provitamin A carotenoids to form different retinoids. CMO1 primarily catalyzes the central cleavage of the 15,15'  $\beta$ -carotene bond to form two retinal molecules (Figure 12.1), along with cleavage of the other provitamin A carotenoids. Characterization of a human mutation and studies with CMO1 knockout mice have found increased  $\beta$ -carotene levels and decreased vitamin A levels, as expected given its function (Hessel *et al.*, 2007; Lindqvist *et al.*, 2007). In addition, dyslipidemia, increased risk of obesity, and steatosis have been reported in CMO1 knockout mice, suggesting alterations in lipid metabolism (Hessel *et al.*, 2007). However, another study in CMO1

knockout mice failed to find these lipid alterations (Lindshield *et al.*, 2008). Two common CMO1 single nucleotide polymorphisms (SNPs) have been identified that decrease  $\beta$ -carotene cleavage in women (Leung *et al.*, 2009), meaning they are less efficient at converting  $\beta$ -carotene to retinal. It does not appear that CMO1 cleaves non-provitamin A carotenoids to any great extent.

CMO2 catalyzes the eccentric cleavage of the 9',10'  $\beta$ -carotene bond that subsequently can be shortened to one retinoic acid molecule by a mechanism similar to  $\beta$ -oxidation of fatty acids (Figure 12.1). Unlike CMO1, evidence suggests that CMO2 cleaves non-provitamin A carotenoids. For lycopene this evidence includes the following:

- *E. coli* engineered to express CMO2 and produce lycopene experience a color shift compared with *E. coli* producing lycopene alone (Kiefer *et al.*, 2001);
- ferret CMO2 in insect cells cleave lycopene *cis* isomers, but not all-*trans* lycopene (Hu *et al.*, 2006);
- CMO1 knockout mice that have increased expression of CMO2 exhibit altered tissue lycopene biodistribution (Lindshield *et al.*, 2008);
- CMO2 knockout mice have increased serum and tissue lycopene levels (Ford *et al.*, 2010).

In addition, ferret CMO2 *in vitro* has been shown to preferentially cleave zeaxanthin and lutein (Mein *et al.*, 2011), and CMO2 knockout mice have been shown to accumulate 3,3'-didehydrozeaxanthin and 3-dihydrolutein, derivatives of zeaxanthin and lutein, respectively. In addition to cleavage alterations in accumulation of xanthophylls, mitochondrial dysfunction and increased oxidative stress were reported in CMO2 knockout mice fed lutein or zeaxanthin (Amengual *et al.*, 2011).

Table 12.3 shows the relative tissue levels of CMO1 in mice and humans and CMO2 expression in mice. The expression varies between tissues, and the two different carotenoid cleavage enzymes are not always expressed in the same tissue. The significance of this differential tissue expression is under investigation.

## Health and Disease States Related to Carotenoids

### $\beta$ -Carotene and Lung Cancer

Lung cancer is the leading fatal cancer in both men and women in the United States, with the main risk factor being smoking (American Cancer Society, 2010). In the

<sup>c</sup>Lindqvist and Andersson (2002) and Yan *et al.* (2001);

<sup>d</sup>Lindqvist and Andersson (2004).

early 1990s, there was strong epidemiological evidence indicating an inverse association between consumption of  $\beta$ -carotene-rich fruits and vegetables and lung cancer risk. Thus two large randomized placebo-controlled trials were undertaken to determine whether high-dose  $\beta$ -carotene supplementation could decrease lung cancer incidence in high-risk populations. These two studies infamously found that  $\beta$ -carotene supplementation increased lung cancer risk (Lindshield and Erdman, 2010). A recent systematic review and meta-analysis found that high-dose  $\beta$ -carotene supplementation (20–30 mg/day) is associated with an increased risk of lung cancer in smokers and asbestos workers (Druesne-Pecollo *et al.*, 2010). However, lower-dose  $\beta$ -carotene supplementation and dietary  $\beta$ -carotene are more protective than detrimental to lung cancer development (Gallicchio *et al.*, 2008; Druesne-Pecollo *et al.*, 2010).

These dose-dependent effects of  $\beta$ -carotene have also been found in smoking ferrets, an appropriate animal model used because they metabolize and accumulate  $\beta$ -carotene in a manner similar to humans (Lee *et al.*, 1999). The mechanism through which high-dose  $\beta$ -carotene has these deleterious effects in smokers has not been elucidated, but a number of mechanisms have been suggested such as an increased oxidative stress, altered retinoic acid signaling, and cytochrome P450 induction (Goralczyk, 2009). These mechanisms have been found *in vitro* and in some animal models, but not in human samples from those who developed lung cancer in the  $\beta$ -carotene clinical trials (Liu *et al.*, 2009; Wright *et al.*, 2010).

Accordingly, with the evidence discussed above, after reviewing the evidence the American Institute for Cancer Research (AICR) panel determined “that foods containing carotenoids probably protect against lung

cancer” and that the evidence was convincing “that  $\beta$ -carotene supplements cause lung cancer in current smokers” (AICR, 2007).

### **Lycopene and Prostate Cancer**

The prostate is the most frequent site of cancer in males in the United States, estimated to account for nearly one-third of all diagnosed cases in 2010 (American Cancer Society, 2010). In 1995, the Health Professional Follow-up Study, a prospective male cohort in the United States, found that lycopene intake, as well as the consumption of raw tomatoes, tomato sauce, and pizza, were all significantly associated with a decreased risk of prostate cancer (Giovannucci *et al.*, 1995). As reviewed recently (Lindshield and Erdman, 2010), along with publications since that review (Karppli *et al.*, 2009; Beilby *et al.*, 2010; Kristal *et al.*, 2010), epidemiological evidence when considered as a whole suggests a moderate decrease in prostate cancer risk with increased dietary tomato/lycopene consumption and/or serum levels. A number of small clinical trials/intervention studies have been reviewed recently (Lindshield and Erdman, 2010). When considered with those published since or not included in that review (Barber *et al.*, 2006; Schwenke *et al.*, 2009), these suggest that there may be some benefit of tomato/lycopene consumption for men with prostate cancer. However, larger, longer, better-designed studies are needed to determine whether tomato/lycopene conclusively improves outcomes for men with prostate cancer (Haseen *et al.*, 2009). No intervention study has looked at whether lycopene or tomato consumption can prevent the development of prostate cancer.

Why the association between lycopene and prostate cancer? For reasons that are still not understood, lycopene preferentially accumulates in the prostate. In this tissue, the androgens testosterone and dihydrotestosterone play an important role in stimulating proliferation and the development of prostate cancer. There appears to be an interaction between androgens and lycopene levels, such that castration of male rats leads to a two-fold increase in hepatic lycopene, an effect that is normalized by testosterone replacement (Boileau *et al.*, 2001). In addition, some animal studies have found that lycopene reduces the expression of androgen-signaling genes (Wertz, 2009); however, other animal studies have failed to find evidence of these alterations (Lindshield *et al.*, 2010). There are a variety of other proposed mechanisms (Wertz, 2009); evidence however suggests that antioxidant action is unlikely

to be the primary mechanism of action (Erdman *et al.*, 2009).

A common question is whether lycopene is responsible for the inverse association between tomato consumption and prostate cancer, or if there are other compounds in tomatoes that may also have anti-cancer action. This is a question that is hard to address in human studies or epidemiology, but animal studies recently reviewed (Lindshield and Erdman, 2010), and one published since (Lindshield *et al.*, 2010), suggest that lycopene is not as efficacious as the whole tomato. It should, however, be noted that a recent animal study found lycopene to be superior to the tomato-paste diet in decreasing the incidence of prostate cancer (Konijeti *et al.*, 2010).

In 2004 the FDA was petitioned to create a health claim for tomatoes, lycopene, and prostate cancer. After reviewing the evidence the FDA issued the following qualified health claim (Kavanaugh *et al.*, 2007) for tomatoes and prostate cancer: “very limited and preliminary scientific research suggests that eating one-half to one cup of tomatoes and/or tomato sauce a week may reduce the risk of prostate cancer.” For lycopene and prostate cancer, the FDA concluded “that there was no credible evidence to support lycopene consumption, either as a food ingredient, a component of food, or as a dietary supplement, and any of the cancers evaluated in the studies” (Kavanaugh *et al.*, 2007). In contrast, the American Institute for Cancer Research (AICR) panel, which considered more studies than the FDA, concluded that “foods containing lycopene (particularly tomato products) probably protect against prostate cancer,” while not assigning an evidence ranking to consumption of lycopene alone (AICR, 2007).

### **Lutein/Zeaxanthin and Macular Degeneration**

In the United States and Europe, age-related macular degeneration (AMD) is the leading cause of blindness in people aged 60 or older (Barker, 2010). AMD is characterized by the formation of druzens, oxidized lipids and proteins that can lead to the separation of photoreceptor cells from their nutrient and oxygen source (Bernstein, 2009). Photoreceptor cell death follows, leading to permanent vision loss.

The retina, which is located at the back of the human eye, contains a depression known as the fovea, on which light is focused after entering the lens (Figure 12.2). This region contains a high concentration of color-sensitive cones that afford humans our clearest, sharpest vision. The fovea is in the center of the macula lutea, which is Latin

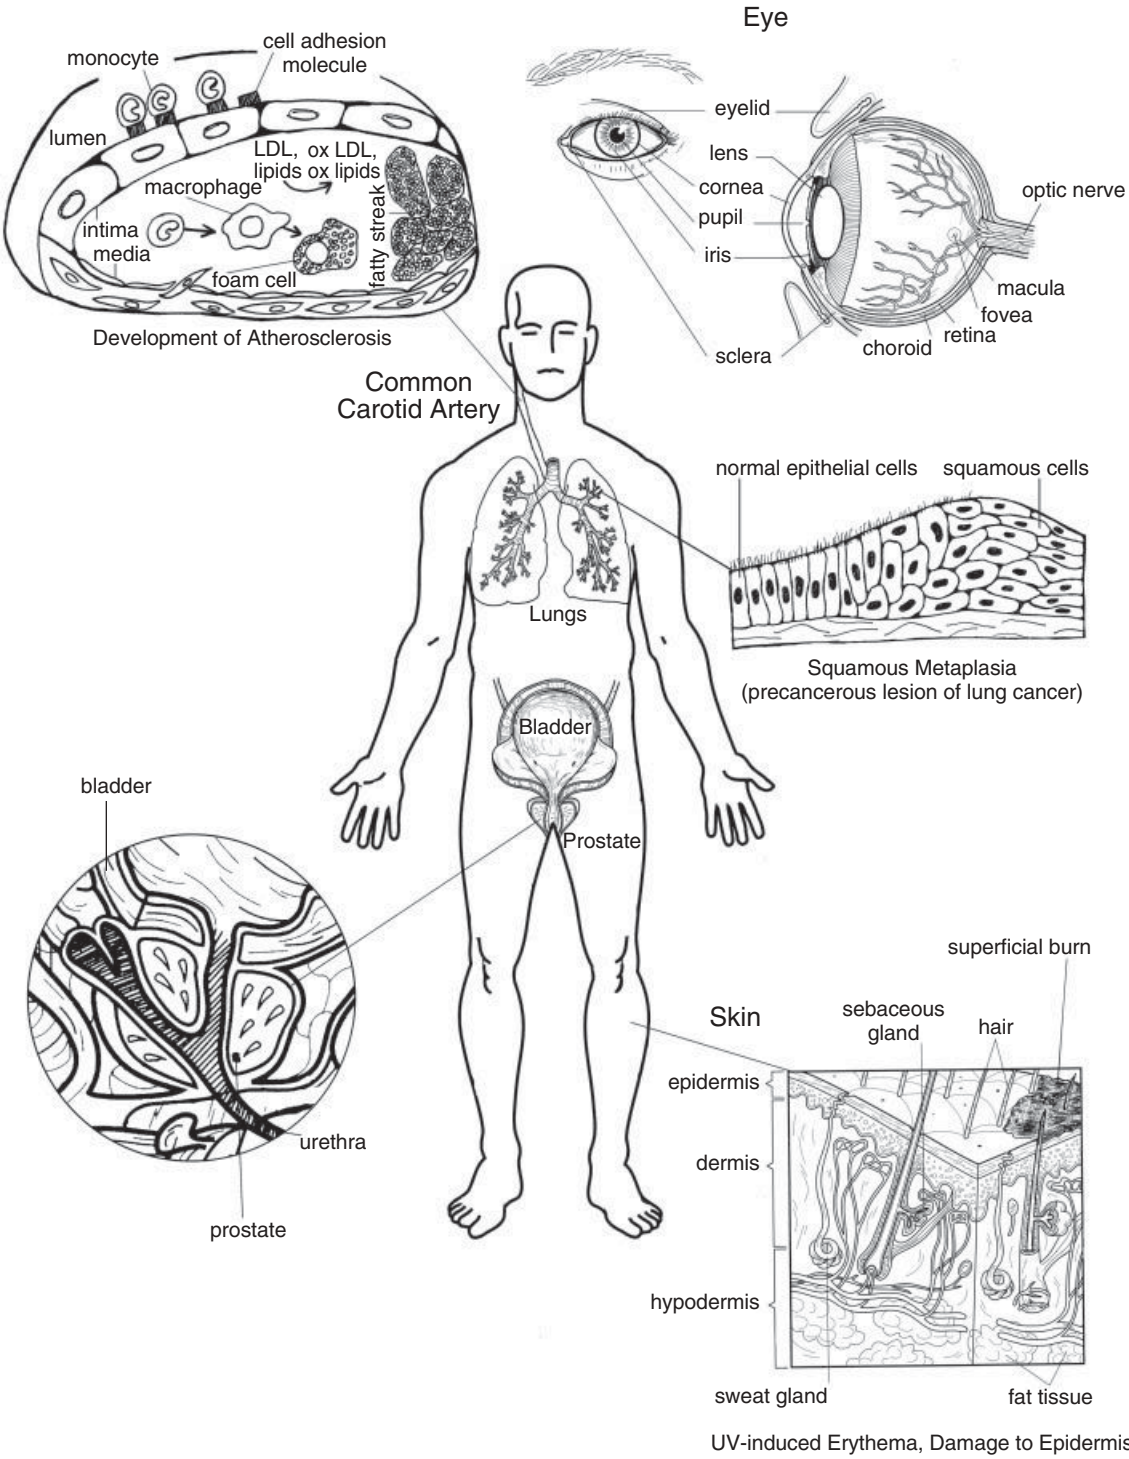

FIG. 12.2 Health and disease states related to carotenoids. ox, oxidized.

for “yellow spot.” This yellow color is the result of large amounts of lutein and zeaxanthin in this area, collectively referred to as the macular pigment. The levels of carotenoids in this macula lutea are by far the highest found in the body. Lutein and zeaxanthin concentrations vary throughout the retina. In the central fovea, zeaxanthin and its isomer meso-zeaxanthin are each found in equal concentrations to lutein; however, with increasing distance from the fovea the concentration of lutein increases, making lutein the predominant carotenoid in the peripheral regions of the retina (Bhosale *et al.*, 2009).

Meso-zeaxanthin is not found in the diet to any great extent. Instead it is believed to be formed from a double-bond shift of lutein in the central fovea (Figure 12.1) (Johnson *et al.*, 2005). How this occurs is unknown, but glutathione S-transferase Pi isoform is a zeaxanthin-binding protein found in high levels in the macula near the fovea, and at lower levels elsewhere in the retina. Glutathione S-transferases have been shown to catalyze reactions similar to the double-bond shift from lutein to meso-zeaxanthin, so it is possible that this protein may be enzymatically involved in this transformation (Bhosale *et al.*, 2004). A lutein-binding protein has been identified from the human peripheral retina that is believed to be a member of the steroidogenic acute regulatory (StAR) family of proteins. The location of these binding proteins in the retina corresponds to the distribution of the carotenoids (Bhosale *et al.*, 2009).

The connection between lutein, zeaxanthin, and AMD is that autopsied retinas from individuals with AMD have decreased macular pigment levels in comparison with non-diseased retinas. The macular pigment is believed to be protective in two ways: by absorbing blue light, and by acting as an antioxidant (Bernstein, 2009). Monkeys raised on a carotenoid-free diet lack macular pigment and form druzen, mimicking the early stages of AMD (Landrum and Bone, 2004). Epidemiologic studies, as well as feeding and supplementation studies, suggest that macular pigment levels can be increased by lutein and zeaxanthin intake (Barker, 2010).

Some, but not all, epidemiologic studies have found that both intake and serum lutein and zeaxanthin levels are associated with reduced risk of AMD (Barker, 2010). To determine whether supplementation with lutein and zeaxanthin, along with omega-3 fatty acids, can prevent the development of advanced AMD, the Age-Related Eye Disease Study 2 (AREDS2) is currently underway. AREDS2 is a randomized clinical trial that completed

enrollment in June 2008. The subjects will be followed for 5–6 years, so results are expected in 2013–2014 (AREDS2, 2010).

In addition to AMD, lutein and zeaxanthin intake/blood levels have been associated with decreased cataract incidence. Lutein and zeaxanthin are the only detectable carotenoids present in the lens, albeit at much lower levels than in the retina. Cataracts are believed to be caused by photo-induced oxidation and precipitation of lens proteins. It is believed that lutein and zeaxanthin lower the risk of cataract formation by preventing the oxidation of proteins, which ultimately leads to the development of this condition (Barker, 2010). AREDS2 is looking at cataract formation as an outcome; its results should give the strongest evidence to date on whether lutein and zeaxanthin are efficacious in preventing this condition (AREDS2, 2010).

### **Skin**

Excess sunlight can lead to ultraviolet (UV)-induced erythema, a reddening of the skin more commonly referred to as sunburn. There is evidence to suggest that carotenoids can provide modest skin protection. Studies suggest that at least 10 weeks of supplementation is needed before benefits can be expected; for example, a recent meta-analysis found that  $\beta$ -carotene supplementation for at least 10 weeks is associated with a significant decrease in sunburn (Kopcke and Krutmann, 2008). It is also important to note that beneficial interactions occur between carotenoids, and probably other dietary components such as flavonoids, meaning diets rich in these compounds will likely provide better protection against UV-induced skin damage than the individual compounds alone (Stahl and Sies, 2007; Shapira, 2010).

The red-orange carotenoid canthaxanthin is marketed at high doses as a natural tanning pill because it accumulates in the fat pads below the skin, giving skin a bronze color. However, the high-dose long-term supplementation needed to sustain skin's tanned color may lead to the development of canthaxanthin-induced retinopathy, a condition in which canthaxanthin crystals form in the retina. Luckily this condition is reversible and does not result in vision loss (Goralczyk *et al.*, 2000; Sujak, 2009).

### **Cardiovascular Disease**

Epidemiological studies have supported the relationship between carotenoid-rich foods and decreased risk of developing cardiovascular disease. There are a number of potential mechanisms through which carotenoid consumption

may maintain endothelial function and prevent atherosclerosis. The most commonly cited is through the antioxidant action of carotenoids, which would then decrease lipid and LDL oxidation. The oxidation of lipids and LDL increases their uptake by macrophages. After macrophages accumulate high levels of these lipids, they become what are known as foam cells. Foam cells aggregate to form the fibrous plaque that leads to the development of fatty streaks and ultimately atherosclerosis (Figure 12.2). Research indicating that carotenoids act as antioxidants in this manner to prevent cardiovascular disease is, however, limited (Erdman *et al.*, 2009; Riccioni, 2009).

## Future Directions

To date,  $\beta$ -carotene has been the primary carotenoid studied, but far less is known about other carotenoids commonly found in human diets and tissues. This includes potential cleavage of non-provitamin A carotenoids by CMO2. If carotenoids are cleaved, products that are produced and whether they are bioactive are questions of great interest. We coined the term “lycopenoids” to refer to potential lycopene metabolites produced by CMO2 that we hypothesize are metabolically active like retinoids (Lindshield *et al.*, 2007). Similar hypotheses can be made for other non-provitamin A carotenoids; however, very little is known in this area. The role of the carotenoid cleavage enzymes CMO1 and CMO2 in lipid metabolism still remains to be elucidated. The results thus far suggest that the enzymes have other metabolic functions besides cleaving carotenoids. The role of CMO1 and CMO2 SNPs in carotenoid and potentially lipid metabolism also remains to be investigated.

Reasons for varying carotenoid concentrations in different tissues are not clear, with the exception of the accumulation of lutein and zeaxanthin in the eye. For example, it is not known why lycopene preferentially accumulates in the prostate compared to its precursor carotenoids, phytoene, phytofluene, and  $\zeta$ -carotene, which are remarkably similar in structure (Campbell *et al.*, 2007). Factors that regulate carotenoid storage in tissues and/or degradation still need to be elucidated. Identifying factors that influence the levels of carotenoids in tissues is likely to help us to begin to understand the role of individual carotenoids in tissues, and potentially, roles in health and disease prevention.

The genetic modification of plants to increase their carotenoid level is also an active area in research. Golden

rice, which is genetically engineered to accumulate  $\beta$ -carotene, was produced to help combat vitamin A deficiency in developing countries. However, the levels of  $\beta$ -carotene in the rice were believed to be too low to realistically ameliorate this condition. In response to this concern, a corn-derived enzyme was inserted that increased the production of  $\beta$ -carotene 20-fold in golden rice 2. This new  $\beta$ -carotene concentration is closer to a range that may be relevant to preventing vitamin A deficiency (Grusak, 2005; Paine *et al.*, 2005). Recently it was shown that the  $\beta$ -carotene in golden rice 2 is bioavailable and it will probably reach the market in 2012 after more than a decade clearing regulatory hurdles (Tang *et al.*, 2009; Potrykus, 2010). It remains to be seen whether golden rice 2 will finally make it to intended populations and be accepted for growing and consumption.

## VITAMIN D

ANTHONY W. NORMAN, PhD AND HELEN L. HENRY, PhD

*University of California, Riverside, California, USA*

### Summary

It is established that the classical biological actions of the nutritionally important vitamin D in mediating calcium homeostasis are supported by a complex vitamin D endocrine system which coordinates the metabolism of vitamin D<sub>3</sub> into 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> and 24R,25(OH)<sub>2</sub>D<sub>3</sub>. The biologically inert vitamin D<sub>3</sub> must be converted to its daughter steroid hormone, 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, which acts in partnership with the vitamin D receptor (VDR) to mediate both genomic and rapid responses. Our updated understanding of the vitamin D endocrine system includes many more target tissues than simply the calcium-homeostasis-related intestine, bone, kidney, and parathyroid gland. It is now accepted that five previously unrecognized physiological systems respond to 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> working with VDR. These include the heart and cardiovascular system, the immune system (both innate and adaptive), muscle, pancreas, and metabolic homeostasis, and the brain. Vitamin D nutritionists and scientists in many countries agree that about half of elderly Western Europeans and North Americans and probably two-thirds of the rest of the world are not receiving enough vitamin D to maintain healthy bone. It is also agreed that the best marker of an individual's vitamin D nutritional status is the level of the serum 25(OH)D. A level of 25(OH)D of <20 ng/mL (50 nmol/L) reflects a state of vitamin D insufficiency or worse. A circulating level of 25(OH)D >30 ng/mL or 75 nmol/L is reflective of a vitamin D sufficient state. Given its recently recognized importance in important physiological systems, the fact that so many people throughout the world have much lower 25(OH)D levels is a public health challenge of major proportions.

### Introduction

#### **Background**

Vitamin D is essential for life in higher animals. Classically it has been shown to be one of the most important biological regulators of calcium homeostasis. It has been established that these biological effects are only achieved as a consequence of the metabolism of vitamin D into a family of daughter metabolites, including the two

key kidney-produced metabolites, 1 $\alpha$ ,25(OH)<sub>2</sub>-vitamin D<sub>3</sub> [1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>] and 24R,25(OH)<sub>2</sub>-vitamin D<sub>3</sub> [24R,25(OH)<sub>2</sub>D<sub>3</sub>] (see Figure 13.2). 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> is considered to be a steroid hormone and there is evidence that 24R,25(OH)<sub>2</sub>D<sub>3</sub> may also act as a steroid hormone (Feldman *et al.*, 2005).

Since the 1980s it has become increasingly apparent that 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, in addition to its role in calcium homeostasis, plays an important role in differentiation and

proliferation of a wide variety of cells and tissues not primarily related to mineral metabolism; these include cells of the hematopoietic system, keratinocytes, and cells secreting parathyroid hormone and insulin. In addition, many types of cancer cells, including breast and prostate cancer cells, possess the vitamin D receptor (VDR) and therefore are targets of  $1\alpha,25(\text{OH})_2\text{D}_3$  action. And in the last decade, it has become clear that five new physiological roles for  $1\alpha,25(\text{OH})_2\text{D}_3$  have been added to its list of responsibilities.

The purpose of this chapter is to provide a succinct overview of our current understanding of the important nutritional substance vitamin D, the mechanisms by which its biologically active metabolite, the steroid hormone  $1\alpha,25(\text{OH})_2\text{D}_3$ , mediates biological responses, and its role in several important human diseases. In addition, the nutritional aspects of vitamin D are presented from the perspective that there is widespread vitamin D deficiency in all countries of the world.

### Historical Review

The first scientific description of rickets, the hallmark of vitamin D deficiency, was provided by Dr Daniel Whistler in 1645 and Professor Francis Glisson in 1650 (Norman, 1979). The major breakthrough in understanding the causative factors of rickets was the development of nutrition as an experimental science, followed by the appreciation of the existence of vitamins more than two centuries later. Although vitamin D, through a historical accident, was originally classified as a vitamin, it is now known that the “D-vitamin” is produced in the skin and it is widely accepted that its biologically active form is a steroid hormone. In 1919–1920 Sir Edward Mellanby, working with dogs raised exclusively in the absence of sunlight or ultraviolet light, devised a diet which allowed him to unequivocally establish that rickets was caused by a deficiency of a trace component in the diet. In 1921 he wrote, “The action of fats in rickets is due to a vitamin or accessory food factor which they contain, probably identical with the fat-soluble vitamin.” Furthermore he established that cod-liver oil was an excellent antirachitic agent, leading to the classification of the antirachitic factor as a vitamin (Norman, 1979).

The chemical structures of the D vitamins were determined in the 1930s in the laboratory of Professor A. Windaus at the University of Göttingen. Vitamin  $\text{D}_2$ , produced by ultraviolet irradiation of the plant/yeast steroid ergosterol, was chemically characterized in 1932

(Norman, 1979). Vitamin  $\text{D}_3$ , the form that is produced in the skin of vertebrate animals, was not chemically characterized until 1936 when it was shown to result from the ultraviolet irradiation of 7-dehydrocholesterol (Norman, 1979). Virtually simultaneously, the elusive antirachitic component of cod-liver oil was shown to be identical to the newly characterized vitamin  $\text{D}_3$  (Norman, 1979). These results clearly established that the antirachitic substance vitamin D was chemically a steroid, more specifically a seco-steroid (see below).

The modern era of vitamin D began in the interval of 1965–1970 with the discovery (Haussler *et al.*, 1968) and chemical characterization of  $1\alpha,25(\text{OH})_2\text{D}_3$  (Norman *et al.*, 1971) and its nuclear receptor, the VDR (Haussler and Norman, 1969).

### Chemistry of Vitamin D

The structures of vitamin  $\text{D}_3$  (cholecalciferol) and its provitamin, 7-dehydrocholesterol, are presented in Figure 13.1. Vitamin D is a generic term and indicates a molecule of the general structure shown for rings A, B, C, and D with differing side-chain structures. The ring structure is derived from the cyclopentanoperhydrophenanthrene ring structure for steroids but with the 9,10 carbon–carbon bond of ring B broken, as indicated by the inclusion of “9,10-seco” in the official nomenclature. A discussion of the conformational shapes attainable by vitamin D is given in the legend to Figure 13.1.

Vitamin D (synonym calciferol) is named according to the revised rules of IUPAC (the International Union of Pure and Applied Chemists: IUPAC, 1960). Because it is derived from a steroid, vitamin D retains its numbering from the parent compound cholesterol (see Figure 13.1). Asymmetric centers are designated by using the R,S notation (Norman and Litwack, 1987); the configurations of the double bonds are indicated as E (*trans*) and Z (*cis*). Thus the official name of vitamin  $\text{D}_3$  is 9,10-seco(5Z,7E)-5,7,10(19)cholestatriene-3 $\beta$ -ol. Vitamin  $\text{D}_2$  differs from  $\text{D}_3$  by virtue of the presence of a 22,23 double bond and a 24-methyl group in the side chain. The official name of vitamin  $\text{D}_2$  is 9,10-seco(5Z,7E)-5,7,10(19),22-ergostatetraene-3 $\beta$ -ol. From 1940 until about 1960, vitamin  $\text{D}_2$  was used as the food supplement to supply vitamin D activity, but since the 1970s, in the United States, vitamin  $\text{D}_3$  has been the form of calciferol that is routinely used for food supplementation (Norman, 1979).

**FIG. 13.1** Chemistry and irradiation pathway for production of vitamin D<sub>3</sub>. The provitamin 7-dehydrocholesterol (in the skin), which is characterized by the presence in the B ring of a Δ<sup>5,7</sup> conjugated double-bond system, when exposed to ultraviolet light is converted to the seco B previtamin D<sub>3</sub> steroid when the 9,10 carbon-carbon bond has been broken. Then the previtamin D<sub>3</sub>, in a process independent of ultraviolet light, thermally isomerizes to the “vitamin” form, which is characterized by a Δ<sup>5,6,7,8,10,19</sup> conjugated triple bond system.

The extreme conformational flexibility potential of all vitamin D metabolites is illustrated in the inset box for the principal metabolite, 1α,25(OH)<sub>2</sub>D<sub>3</sub>. Each of the arrows indicates carbon-carbon single bonds present (in the side chain, the seco B ring, and the A ring) that have complete 360° rotational freedom. This results, for the various vitamin D molecules, in the generation in solution and in biological systems of a multitude of different shapes (Bouillon *et al.*, 1995). The main portion of the figure also illustrates the two principal conformations of the molecule that result as a consequence of rotation about the 6,7 carbon single bond of the seco B ring. These are the 6-s-*cis* conformer (the steroid-like shape) and the 6-s-*trans* conformer (the extended shape).

Vitamin D<sub>3</sub> is produced photochemically in the epidermis of most higher animals from the provitamin D, 7-dehydrocholesterol, by the action of sunlight or artificial ultraviolet light. The conjugated double bond system in ring B (see Figure 13.1) allows the absorption of light quanta in the UV range 280–310 nm to initiate a complex series of transformations of the provitamin into vitamin D<sub>3</sub> (Figure 13.1). Thus it is important to appreciate that, as long as the animal (or human) has access to adequate sunlight on a regular basis, vitamin D<sub>3</sub> can be endog-

enously produced and there may be no need for a dietary requirement for this “vitamin”.

## Physiology and Biochemistry of Vitamin D

### Vitamin D Endocrine System

Vitamin D<sub>3</sub> itself is not known to have any intrinsic biological activity but must be metabolized, first to 25(OH)D<sub>3</sub> in the liver and then to 1α,25(OH)<sub>2</sub>D<sub>3</sub> and/or

$24R,25(OH)_2D_3$  by the kidney. Altogether, some 37 vitamin  $D_3$  metabolites have been isolated and chemically characterized (Bouillon *et al.*, 1995).

The elements of the vitamin D endocrine system (Bouillon *et al.*, 1995) include the following:

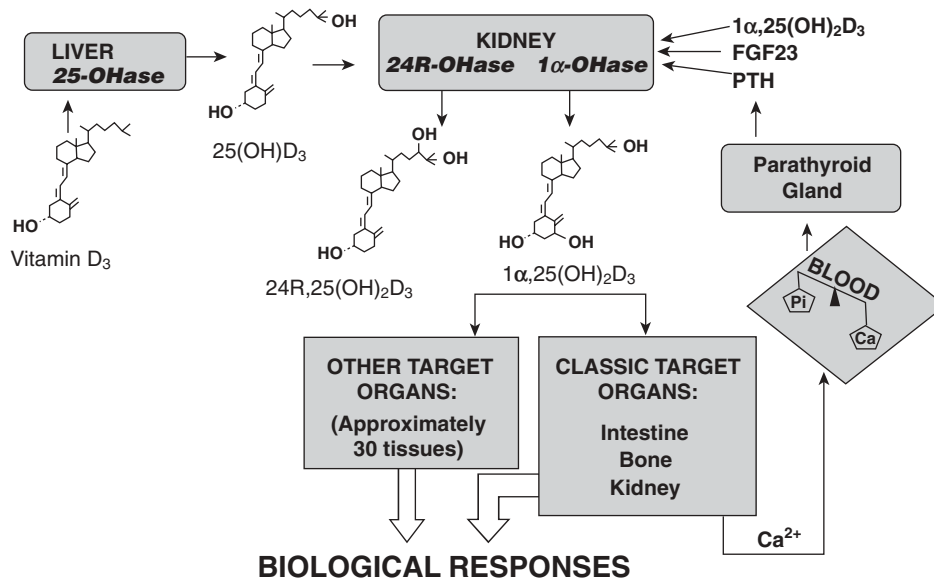

- the photoconversion of 7-dehydrocholesterol to vitamin  $D_3$  in the skin or dietary intake of vitamin  $D_3$  (Figure 13.1);
- metabolism of vitamin  $D_3$  by the liver to  $25(OH)D_3$  which is the major form of vitamin D circulating in the blood (Figure 13.2);
- conversion of  $25(OH)D_3$  by the kidney (functioning as an endocrine gland) to produce the two principal dihydroxylated metabolites,  $1\alpha,25(OH)_2D_3$  and  $24R,25(OH)_2D_3$ ;
- systemic transport of the dihydroxylated metabolites  $24R,25(OH)_2D_3$  and  $1\alpha,25(OH)_2D_3$  to distal target organs (Figure 13.2);

- binding of the dihydroxylated metabolites, particularly  $1,25(OH)_2D_3$ , to the vitamin D receptor (VDR) in the target organs followed by the subsequent generation of appropriate biological responses (Figure 13.3).

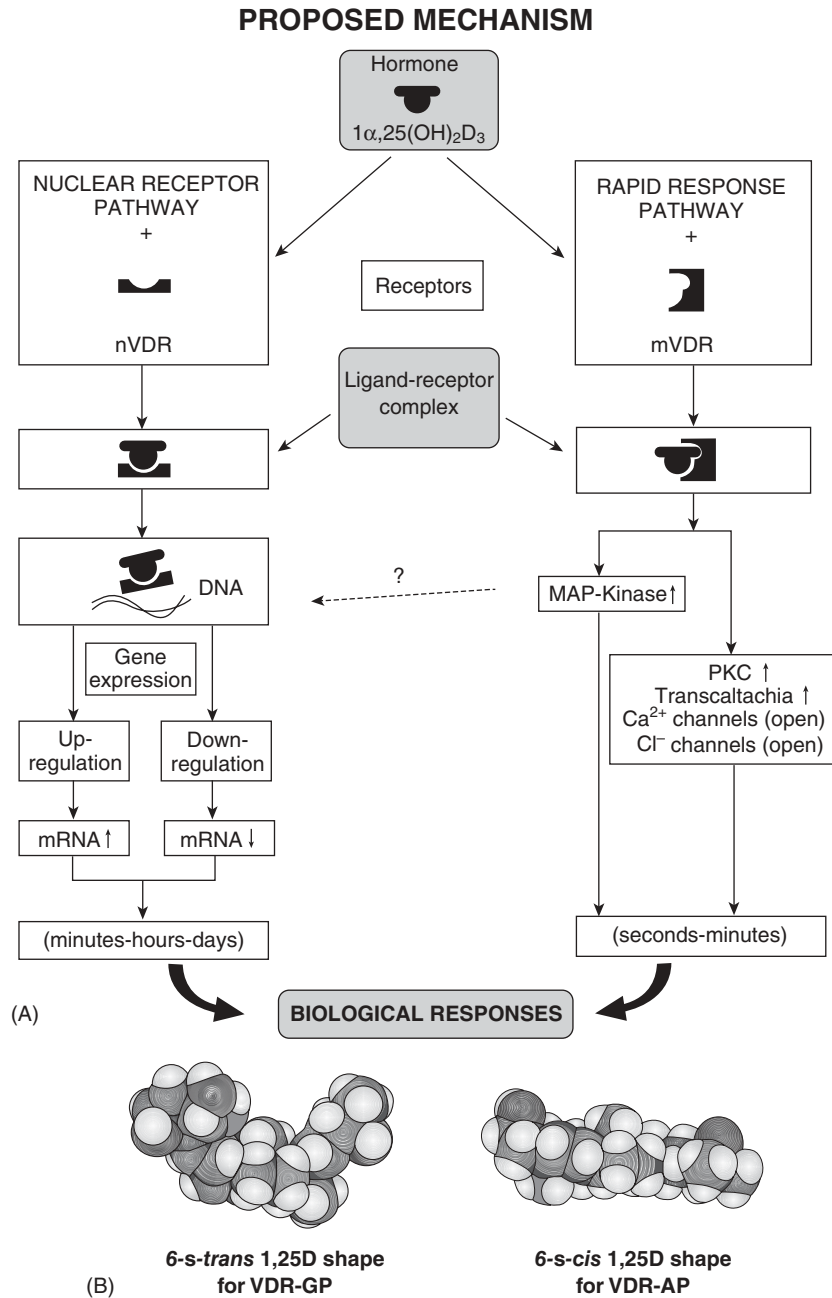

An additional key component in the operation of the vitamin D endocrine system is the plasma vitamin D binding protein (DBP) which carries vitamin  $D_3$  and all its metabolites to their sites of metabolism and various target organs (Laing and Cooke, 2005).

### Vitamin D Metabolism

The three enzymes responsible for the conversion of vitamin  $D_3$  into its two key metabolites (Figure 13.2) are the hepatic vitamin  $D_3$ -25-hydroxylase (Feldman *et al.*, 2005) and the two kidney enzymes, the  $25(OH)D_3$ - $1\alpha$ -hydroxylase (Henry, 2005) and the  $25(OH)D_3$ - $24R$ -hydroxylase (Feldman *et al.*, 2005). All three enzymes have

**FIG. 13.2** Elements of the vitamin D endocrine system. The biologically inactive vitamin D is first hydroxylated at C-25 on the side chain in the liver to form  $25(OH)D_3$ , the principal circulating member of vitamin D steroids.  $25(OH)D_3$  serves as the substrate for one of two hydroxylases in the kidney to result in either  $24R,25(OH)_2D_3$  or  $1\alpha,25(OH)_2D_3$ , the predominant biologically active steroid-hormone form of the parent vitamin. The regulation of these two hydroxylases is exerted by parathyroid hormone, which reflects serum calcium levels; the steroid hormone  $1\alpha,25(OH)_2D_3$  itself; and FGF23 as a feedback regulator representing blood phosphate levels. The biological actions of the two dihydroxylated metabolites of vitamin D are represented in general form here and described in the text.

**FIG. 13.3** Model to describe how  $1\alpha,25(\text{OH})_2\text{D}_3$  generates biological responses. (A) Biological responses to  $1\alpha,25(\text{OH})_2\text{D}_3$  occur as a consequence of different shapes of the conformationally flexible  $1\alpha,25(\text{OH})_2\text{D}_3$  interacting with two ligand binding domains (a VDR-GP, genomic pocket, and a VDR-AP, alternative pocket) on the classic vitamin D receptor (VDR). In the genomic pathway, occupancy of the VDR-GP by a 6-s-trans-shaped  $1\alpha,25(\text{OH})_2\text{D}_3$  that is localized to the nucleus of the cell (top of the hat icon) leads to up- or down-regulation of genes subject to hormone regulation. In the rapid response pathway, occupancy of the VDR-AP, which is localized to the cell membrane/caveolae by a (6-s-cis) shape (half-hat icon) of  $1\alpha,25(\text{OH})_2\text{D}_3$ , can produce a variety of rapid responses which depend upon the cell type. These can include activation of protein kinase C (PKC), opening of voltage-gated  $\text{Ca}^{2+}$  or  $\text{Cl}^-$  channels, or activation of MAP-kinase which are linked to the generation of biological response(s). (B) The 6-s-trans and 6-s-cis space-filling molecular shapes of  $1\alpha,25(\text{OH})_2\text{D}_3$  are shown.

been demonstrated to be cytochrome P-450 mixed-function oxidases (Henry, 2000). Both renal enzymes are localized in mitochondria of the proximal tubules of the kidney. The genes for all three cytochrome P-450 molecules have been cloned (Feldman *et al.*, 2005). The specific sites of mutations of the 25(OH)D<sub>3</sub>-1 $\alpha$ -hydroxylase which result in vitamin D-resistant rickets type I (VDRR-I) have been identified (Kitanaka *et al.*, 1998).

A crucial point of regulation of the vitamin D endocrine system occurs through the stringent control of the activity of the renal 25(OH)D<sub>3</sub>-1 $\alpha$ -hydroxylase (1 $\alpha$ -hydroxylase) so that the production of the hormone 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> can be modulated according to the calcium and other endocrine needs of the organism (Henry, 2005). It is well known that the chief determinant of kidney 1 $\alpha$ -hydroxylase activity is the vitamin D status of the animal whereby the activity is elevated in vitamin D deficiency and muted by vitamin D depletion. This is accomplished by 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> itself, which down-regulates its own production in a tight negative feedback loop. Parathyroid hormone (PTH), secreted in response to low serum-calcium levels, stimulates the renal production of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> so that it can contribute to normalizing blood calcium (Henry *et al.*, 1992). The other endocrine factor that contributes to maintaining the balance between calcium and phosphate in the blood through modulation of vitamin D metabolism is fibroblast growth factor 23 (FGF23) which is secreted by bone cells in response to elevated serum phosphate levels and down-regulates 1 $\alpha$ -hydroxylase activity in the kidney.

The 25(OH)D<sub>3</sub>-24R-hydroxylase in the kidney produces circulating 24R,25(OH)<sub>2</sub>D<sub>3</sub>, whose biological significance is discussed below (Norman and Henry, 2003). In the kidney the 24R-hydroxylase is sensitive to vitamin D status (i.e. circulating 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> levels) and is also subject to regulation by parathyroid hormone. An equally important function of the 24R-hydroxylase, which occurs in the vast majority if not all target cells of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, is the inactivation and degradation of this steroid hormone. In target cells exposed to 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, the 24R-hydroxylase is rapidly increased from virtually undetectable levels to those several orders of magnitude higher. The enzyme not only catalyzes the formation of 1 $\alpha$ ,24R,25(OH)<sub>3</sub>D<sub>3</sub> but also subsequent oxidation steps on the side chain, resulting in the inactive catabolite, 1 $\alpha$ (OH)-23-OH-24,25,26,27-tetranor-vitamin D<sub>3</sub>. Thus, the 24-hydroxylase can be considered to have two functions depending on its location: production of circulating

24R,25(OH)<sub>2</sub>D<sub>3</sub> in the kidney and inactivating 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> in target cells throughout the body (Henry, 2001).

### **Mechanisms of Action of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>**

The steroid hormone 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, as well as many other steroid hormones (e.g. estradiol, progesterone, testosterone, cortisol, aldosterone), generates biological responses both by regulation of gene transcription (the classic genomic responses) and through the rapid activation of signal transduction pathways at or near the plasma membrane. These are referred to as either rapid or non-genotropic responses (Mizwicki *et al.*, 2004; Norman *et al.*, 2004).

The genomic responses to 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> result from its stereospecific interaction with its nuclear receptor, VDR (see Figure 13.3). VDR is a protein of 50 kDa which binds 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> with high affinity ( $K_d \approx 0.5$  nM). 25(OH)D<sub>3</sub> and 1 $\alpha$ (OH)D<sub>3</sub> only bind 0.1–0.3% as well as 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> and the parent vitamin D does not bind to the VDR at all. As is the case for all nuclear steroid hormone receptors, the primary amino acid sequence of the VDR consists of five functional domains: nuclear localization (A/B), DNA binding (the C domain), heterodimerization, ligand binding (the E domain) and transcriptional activation (F) (Pike and Shevde, 2005). A detailed discussion of the VDR and its participation in the regulation of gene transcription is available (Whitfield *et al.*, 2005).

The receptors for all classic steroid hormones and the nuclear receptors for 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, retinoic acid, and thyroid hormone are members of the same superfamily (Mangelsdorf *et al.*, 1995); accordingly there is substantial conservation of their amino acid sequences, particularly in the DNA binding domains. Although there is considerably less conservation of amino acid sequence in the ligand binding domains (LBDs) of the nuclear receptors, X-ray crystallographic studies of many of these LBDs show the same overall secondary and tertiary structures (Weatherman *et al.*, 1999). These LBD structures, including that of the VDR, consist of 12  $\alpha$ -helices arranged to create a three-layer sandwich that completely encompasses the ligand 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> in a hydrophobic core.

Nuclear-receptor-mediated regulation of gene transcription is exquisitely dependent upon the structural relationship between the unoccupied receptor, which is, in general, transcriptionally inactive, and its cognate ligand. Formation of the ligand–receptor complex results in conformational

**FIG. 13.4** Model of  $1\alpha,25(\text{OH})_2\text{D}_3$  and VDR activation of transcription. The VDR after binding its cognate ligand  $1\alpha,25(\text{OH})_2\text{D}_3$  forms a heterodimer with RXR. This heterodimer complex then interacts with the appropriate VDRE on the promoter of genes (in specific target cells) which are destined to be up- or down-regulated. The heterodimer–DNA complex then recruits necessary coactivator proteins, TATA, TBP, TFIIB and other proteins to generate a competent transcriptional complex capable of modulating mRNA production. A detailed discussion is given by Whitfield *et al.* (2005).

changes in the receptor protein, allowing it to interact with the transcriptional machinery. A detailed understanding of the complementarity of the ligand shape with that of the interior surface of the nuclear VDR receptor ligand binding domain is the key to understanding the structural basis of its formation of heterodimers and interactions with coactivators (see Figure 13.4). Such an understanding is also fundamental to designing new drug forms of the steroid hormones, including  $1\alpha,25(\text{OH})_2\text{D}_3$ .

Mice in which the gene for the VDR has been deleted or rendered non-functional (VDR-KO) by targeted disruption of the DNA encoding the first or second zinc finger of the DNA-binding domain of the VDR (Bula *et al.*, 2005) display the phenotype of vitamin D-dependent rickets type II (VDDR-II). Except for the alopecia that appears at about 7 weeks, most of the features of this phenotype can be “rescued” by feeding the mice a diet high in calcium and lactose. Additionally, in spite of the widespread tissue distribution of the VDR,

these animals are phenotypically normal at birth. These results suggest that there is biological redundancy with respect to many of the functions of the VDR. Interestingly, VDR knockout (KO) mice have an impaired insulin secretory capacity (Zeitz *et al.*, 2003) which may presage involvement of vitamin D nutritional status with glucose homeostasis.

The “rapid” or non-genomic responses to  $1\alpha,25(\text{OH})_2\text{D}_3$  are mediated through its interaction with the classic VDR that is associated with caveolae present in the plasma membrane of a variety of cells (Huhtakangas *et al.*, 2004). For example, studies with VDR KO mice demonstrated that rapid modulation of osteoblast ion channel responses by  $1\alpha,25(\text{OH})_2\text{D}_3$  requires the presence of a functional vitamin D nuclear/caveolae receptor (Zanello and Norman, 2004).

Rapid responses stimulated by  $1\alpha,25(\text{OH})_2\text{D}_3$  or 6-*s-cis* locked analogs of  $1\alpha,25(\text{OH})_2\text{D}_3$  (see below) acting through the VDR include the following: rapid stimulation

by  $1\alpha,25(\text{OH})_2\text{D}_3$  of intestinal  $\text{Ca}^{2+}$  absorption (transcaltachia) (Norman *et al.*, 1993); opening of voltage-gated  $\text{Ca}^{2+}$  and  $\text{Cl}^-$  (Zanello and Norman, 2007) RM channels; store-operated  $\text{Ca}^{2+}$  influx in skeletal muscle cells as modulated by phospholipase C, protein kinase C, and tyrosine kinases (Vazquez *et al.*, 1998); activation of protein kinase C (PKC) (Schwartz *et al.*, 2002); and inhibition of activation of apoptosis in osteoblasts mediated by rapid activation of Src, phosphatidylinositol 3'-kinase and JNK kinases (Vertino *et al.*, 2005).

Careful study using structural analogs of  $1,25(\text{OH})_2\text{D}_3$  has shown that the genomic and non-genomic responses to this conformationally flexible steroid hormone have different requirements for ligand structure (Mizwicki *et al.*, 2004, 2010). The results indicate that the classic nuclear VDR can orchestrate both genomic and nongenomic responses (see Figure 13.3A). A plausible mechanism by which it could carry out these two disparate functions is that specific structural features of the VDR permit differently shaped ligands (see Figure 13.3B) to activate different classes of biological responses via either the VDR-GP (genomic pocket) or the VDR-AP (alternative pocket).

For example, a key consideration is the position of rotation about the 6,7 single carbon-carbon bond which can either be in the 6-*s-cis* or 6-*s-trans* orientation (see Figure 13.1). The preferred shape of the ligand for VDR, determined from the X-ray crystal structure of the VDR-GP receptor occupied with ligand, is a 6-*s-trans*-shaped bowl with the A-ring 30° above the plane of the C/D rings. In contrast, structure-function studies of rapid non-genomic actions of  $1,25(\text{OH})_2\text{D}_3$  and its analogs show that the VDR-AP prefers its ligand to have a 6-*s-cis* shape (Mizwicki and Norman, 2009).

### **Biological Properties of $24\text{R},25(\text{OH})_2\text{D}_3$**

In comparison with  $1\alpha,25(\text{OH})_2\text{D}_3$ , the biological actions of  $24\text{R},25(\text{OH})_2\text{D}_3$  have been relatively less studied. One key question that has attracted attention is whether  $1\alpha,25(\text{OH})_2\text{D}_3$  acting alone can generate *all* the biological responses that are attributed to the parent vitamin  $\text{D}_3$  or whether, for some responses, a second vitamin  $\text{D}_3$  metabolite may be required. Evidence has been presented to support the view that the combined presence of  $1\alpha,25(\text{OH})_2\text{D}_3$  and  $24\text{R},25(\text{OH})_2\text{D}_3$  is required to generate the complete spectrum of biological responses attributable to the parent vitamin  $\text{D}_3$  (Norman *et al.*, 1980). The key experiments demonstrated that, when hens were raised

from hatching to sexual maturity with  $1\alpha,25(\text{OH})_2\text{D}_3$  as their sole source of vitamin D, fertile eggs appear to develop normally but failed to hatch. However, when the hens received a combination of  $1\alpha,25(\text{OH})_2\text{D}_3$  and  $24\text{R},25(\text{OH})_2\text{D}_3$ , hatchability equivalent to that with hens given vitamin  $\text{D}_3$  was obtained (Henry and Norman, 1978; Norman *et al.*, 1983).

Evidence of a biological role for  $24\text{R},25(\text{OH})_2\text{D}_3$  in the fracture-healing process has also been obtained using a chicken model system (Seo *et al.*, 1997). Recent studies in mice deficient in the 24R-hydroxylase have extended the evidence for a role for  $24\text{R},25(\text{OH})_2\text{D}_3$  in fracture healing to a mammalian system by demonstrating delayed callus mineralization in these mice relative to wild-type control animals (St-Arnaud, 2010).

## **Disease States in Man Related to Vitamin D**

### **Newly Recognized Vitamin D Target Organs and Their Associated Diseases**

Over the past several decades it has emerged that the vitamin D endocrine system is not restricted to calcium homeostasis and that at least 38 tissues express the VDR (Norman and Bouillon, 2010). In just the last 10 years, several lines of investigation have resulted in striking new insights into the new responsibilities of vitamin D. The following approaches were employed:

- (a) studies of the cellular and molecular effects of  $1\alpha,25(\text{OH})_2\text{D}_3$  in a wide range of cell types (Norman, 2006);
- (b) experimental studies in VDR KO mouse models (Bouillon *et al.*, 2006);
- (c) several large observational epidemiological studies in subjects with variable degrees of vitamin D status (Thacher and Clarke, 2011).

Figure 13.5 summarizes the newly expanded vitamin D endocrine systems. The five new physiological systems known to be influenced by vitamin D are the immune system (both innate and adaptive), the pancreas and glucose and fat metabolism, and the heart-cardiovascular, muscle, and brain systems. Examples of documented biological responses are provided for each new system, except for the brain, as well as disease states that have been found to be associated with vitamin D deficiency (see Figure 13.5 legend). A more detailed presentation and discussion are provided by Norman and Bouillon (2010).

**FIG. 13.5** Vitamin D contributions to good health. The three columns on the right-hand side summarize (a) the six physiological systems that are dependent upon a proper vitamin D nutritional status; (b) biological responses mediated by  $1\alpha,25(\text{OH})_2\text{D}_3$ , in collaboration with its VDR; and (c) disease states associated with vitamin D deficiency. These six systems are dependent upon the availability of the essential vitamin  $\text{D}_3$ , and its subsequent metabolism to  $25(\text{OH})\text{D}_3$  and then to the steroid hormone,  $1\alpha,25(\text{OH})_2\text{D}_3$ . The inset table (lower left) summarizes the serum  $25(\text{OH})\text{D}$  concentrations that define the spectrum of vitamin D nutritional states. These range from severe D deficiency to vitamin D sufficiency and then to levels of  $25(\text{OH})\text{D}$  that are associated with a risk of toxicity. Selected literature citations for disease states that have been found to have some association with vitamin D deficiency for each new system (except for the brain) are as follows: innate immune system, Williams *et al.* (2008) and Talat *et al.* (2010); adaptive immune system – inflammation, Munger *et al.* (2006); pancreas – metabolic syndrome, adiposity, Pittas *et al.* (2007) and Ochs-Balcom *et al.* (2011); heart – cardiovascular, Shea *et al.* (2008) and Bouillon (2009); and muscle, Bischoff-Ferrari (2009). There are also associations between low levels of serum  $25(\text{OH})\text{D}$  (20 ng/mL or 50 nmol/mL) and a higher incidence of digestive system cancers (Giovannucci *et al.*, 2006; Garland *et al.*, 2007).

### Traditional Vitamin D Deficiency Diseases (Rickets, Osteomalacia, Osteoporosis)

The classic deficiency state of vitamin D, due to either its absence from the diet or inadequate exposure to sunlight, is the bone disease termed rickets in children or osteomalacia in adults; the clinical features depend upon

the age of onset. Rickets includes deformity of the bones, especially in the knees, wrists, and ankles, as well as changes in the costochondral joint functions, sometimes referred to as the rachitic rosary. If rickets develops in the first 6 months, infants may suffer from convulsions or develop tetany due to a low blood calcium level

(usually  $<7$  mg/100 mL), but may have only minor skeletal changes. After 6 months, bone pain as well as tetany are likely to be present. Since osteomalacia occurs in adulthood after growth and development of the skeleton are complete, its main symptoms are muscular weakness and bone pain with little bone deformity (Norman and Litwack, 1987).

The differences between osteomalacia and osteoporosis are subtle but important. Osteomalacia arises from a problem in the bone-building process, whereas osteoporosis arises from a weakening of mature bone via a general loss of bone calcium from the ongoing daily process of bone remodeling.

Osteoporosis is the most common generalized disorder of bone; it is estimated that in the US over 30 million people, 80% of whom are female, have some form of osteoporosis. Chronic vitamin D deficiency in the elderly ( $>70$  years) can result in an imbalance in the remodeling rate of bone and exacerbate the bone loss.

## Nutritional Aspects of Vitamin D

### *Vitamin D Deficiency*

Vitamin D nutritionists and scientists in many countries agree that about half of elderly Western Europeans and North Americans and probably two-thirds of the rest of the world are not receiving enough vitamin D to maintain healthy bone and that this is a major public health issue (Norman *et al.*, 2007; Henry *et al.*, 2010). It is possible that there are as many as 1 billion people in the world who are vitamin D deficient. Given the emerging data supporting a worldwide pandemic of vitamin D deficiency (Norman *et al.*, 2007), this represents an enormous challenge to the nutrition and health agencies of the world's nations.

Substantial proportions of the population of the US and of Canada are exposed to suboptimal levels of sunlight, particularly during winter months (Webb and Holick, 1988). Under these conditions vitamin D becomes a true vitamin, which dictates that it must be supplied in the diet on a regular basis. One report (Vieth *et al.*, 2001) suggests that winter-time vitamin D insufficiency is common in young Canadian women, and makes the observation that the levels of vitamin D in food did not prevent the deficiency. Other reports document the widespread deficiency of vitamin D in all regions and on all continents of the world (Lips, 2007). These observations have led to the question as to whether the optimal requirement of vitamin

D should be much higher than what is officially recommended (Vieth, 2004).

The nutritional availability of vitamin D is particularly important in both the newborn and young child and in the elderly. Deprivation of sunlight through seasonal variation (winter) (Harris and Dawson-Hughes, 1998), skin pigmentation in Africans (Thacher *et al.*, 1999) or African-Americans (Kreiter *et al.*, 2000), or certain cultural groups or clothing habits such as those of Muslims (Mawer *et al.*, 1986), all can lead to the onset of clinical rickets or osteomalacia, characterized by low serum 25(OH)D<sub>3</sub> levels. If the clothing covers the nursing infant as well, she or he will be at risk for rickets if the mother is vitamin D deficient.

When vitamin D deficiency is encountered in the clinical setting (e.g. older or sick individuals; newborn infants), the physician naturally will want to provide replacement or supplemental vitamin D; this could be in the form of either vitamin D<sub>3</sub> or vitamin D<sub>2</sub>. It has been taught for the last seven decades that in humans vitamin D<sub>3</sub> and vitamin D<sub>2</sub> are equally biologically efficacious. However, with the realization that the serum 25(OH)D clinical assay provides the best assessment of vitamin D status (see Figure 13.5, inset table), it became appropriate to determine whether vitamin D<sub>2</sub> is as effective in elevating serum 25(OH)D levels in humans as vitamin D<sub>3</sub>. Four studies in humans have compared the relative abilities of vitamin D<sub>2</sub> and vitamin D<sub>3</sub> to elevate serum 25(OH)D. Three studies (Trang *et al.*, 1998; Armas *et al.*, 2004; Heaney *et al.*, 2011) reported that vitamin D<sub>3</sub> is significantly more effective than vitamin D<sub>2</sub>, but there was one report (Holick *et al.*, 2008) that, for a dose of 1000 IU/day, vitamin D<sub>3</sub> and vitamin D<sub>2</sub> were equivalent.

Unfortunately, for patients who have a poor vitamin D status, there are currently no high-dose vitamin D<sub>3</sub> formulations approved by the USA FDA for clinical use. Similarly no drug formulations of 25(OH)D<sub>3</sub> are approved in the USA.

### **Recommended Dietary Reference Intake (DRI) of Vitamin D**

The former dietary reference intake (DRI: average daily requirements) allowance of vitamin D recommended in 1997 by an Institute of Medicine (IOM) special committee was 200 IU/day (5 μg/day) for infants, children, and adult males and females (including during pregnancy and lactation) up to age 51. The adequate intake level was set

at 400 IU/day (10 µg) for males and females aged 51–70 and at 600 IU/day (15 µg) for ages > 70 (Institute of Medicine, 1997).

These 1997 DRI guidelines were updated on November 30, 2010, by a newly convened IOM Expert Committee of 13 members (Institute of Medicine, 2011). The US and Canadian governments asked the IOM committee to assess the current data on health outcomes associated with vitamin D and calcium. For vitamin D the recommended dietary allowance is now 600 IU/day for ages 1–70 years, regardless of pregnancy or lactation, and 800 IU/day for ages > 70. For infants (0–12 months), the RDA is 800 IU/day.

## Vitamin D: Safety, Serum 25(OH)D Levels, and Toxicity

### Safety

The 1997 IOM committee set the tolerable upper level intake (TULI) at 1000 IU/day for infants and 2000 IU/day for all other age groups. The 2010 IOM committee raised the TULI to 4000 IU/day for individuals of 9 years or older. The TULI dose for infants 0–6 months is 1000 IU/day, 1500 IU/day for infants 6–12 months, 2500 IU/day for ages 1–3 years, and 3000 IU/day for ages 4–8 years. Others have argued, based on the absence of toxicity in a number of human clinical trials, that the TULI should be 10 000 IU/day (Hathcock, 2007).

### 25(OH)D Levels

The Institute of Medicine (IOM) committee has emphasized that, although a serum 25(OH)D level of 20 ng/mL is adequate to ensure good bone health, there is not enough evidence to make any recommendations with respect to non-skeletal benefits. Both of the authors of this chapter as well as many other scientists in the vitamin D field (Norman *et al.*, 2007; Henry *et al.*, 2010) believe that there are at least four new physiological systems (the immune system, the pancreas and metabolic homeostasis, heart and cardiovascular system, and muscle) in which there is a clear and strong positive association between serum 25(OH)D levels (dependent on vitamin D intake) and optimal function that is contributory to good health (Figure 13.5, right-hand column). Support for the fifth biological system, the brain, is just now emerging.

The inset table in Figure 13.5 provides alternative guidelines concerning serum 25(OH)D levels as a measure of relative vitamin D nutritional status. It lists six categories:

severe D deficiency; vitamin D deficiency; vitamin D insufficiency; marginal vitamin D status; vitamin D sufficiency; and risk for toxicity. The serum 25(OH)D levels that define the first three categories, severe D deficiency, vitamin D deficiency, and vitamin D insufficiency, are also endorsed by the IOM committee. In deviation from the IOM committee, we and many other scientists in the field believe that the range of 20–30 µg/mL is a state of marginal vitamin D status and that, to insure an adequate response by the calcium homeostatic system as well as the four new biological systems, it is essential to have achieved a state of “*vitamin D sufficiency*”; that is, a serum 25(OH)D concentration in the range of 30–60 ng/mL (75–150 nmol/L). Heaney and Holick (2011) have enunciated a “rule of thumb” that states that, for vitamin D intake, each additional increment of 100 IU/day will raise serum 25(OH)D by about 1 ng/mL (2.5 nmol/L). Thus a daily dose of vitamin D of 3000 IU should elevate the serum 25(OH)D to 30 ng/day.

In support of safety concerns for 25(OH)D levels in the 50–70 ng/mL (125–175 nmol/L) interval, it is known that outdoor construction workers and lifeguards routinely have serum 25(OH)D levels in the summer in the range of 50–65 ng/mL (125–160 nmol/L) without adverse consequences (Barger-Lux and Heaney, 2002).

### Toxicity

Excessive amounts of vitamin D are not normally available from the usual dietary sources and thus reports of vitamin D intoxication are rare. However, there is always the possibility that vitamin D intoxication may occur in individuals who are taking excessive amounts of supplemental vitamins. One report describes vitamin D intoxication occurring from drinking milk that had been fortified with inappropriately high amounts of vitamin D<sub>3</sub> (5.1 mg or 230 000 IU/L levels per liter) (Jacobus *et al.*, 1992). This resulted in an average serum 25(OH)D level of 300 ng/mL or 750 nmol/L in eight subjects, seven of whom had hypercalcemia levels that are associated with vitamin D intoxication.

Symptoms of vitamin D intoxication include hypercalcemia, hypercalciuria, anorexia, nausea, vomiting, thirst, polyuria, muscular weakness, joint pains, diffuse demineralization of bones, and general disorientation. If the condition is allowed to go unchecked, it will likely be fatal. The extent of vitamin D toxicity has been shown in some instances to be related to the level of dietary intake of calcium (Beckman *et al.*, 1995).

## Future Directions

### **New Ideas about Vitamin D Intake Levels**

There is emerging evidence that a state of vitamin D sufficiency can contribute to longevity of life. One example was reported in hemodialysis patients (Wolf *et al.*, 2008). A second example reported that low serum 25(OH)D levels (<17 ng/mL or 42 nmol/L) were associated with a higher rate of mortality (Melamed *et al.*, 2008). Finally, 25(OH)D deficiency has been found to be associated with hypertension, obesity, glucose intolerance, and the metabolic syndrome, which may be responsible, at least in part, for its association with increased cardiovascular mortality rate (Michos and Blumenthal, 2007).

Will the D-responsive physiological systems data be derived from evidence-based medicine (randomized clinical trials in the appropriate target populations) or via observational approaches? An important concern is what are the frequency and severity of vitamin D toxicity when vitamin D supplementation is implemented in a very large population of many millions of people over a lifetime?

### **Policy: Food Supplementation versus Daily Intake**

Under the right circumstances, sunlight UVB exposure can generate significant amounts of vitamin D. But since sunlight exposure can also result in skin cancer as well as non-lethal skin damage, the use of UVB as source of vitamin D is not encouraged. Given that the 2009 world population was 6.8 billion (Wright, 2010), then approximately one-third of the world's citizens (2.3 billion) live between 40°N and 90°N, where, for a significant portion of the year, levels of UVB are limited and there is a risk of vitamin D deficiency.

Given the worldwide pandemic of vitamin D insufficiency, a major goal for the health and nutritional agencies of each of the world's countries is to elucidate the severity of the vitamin D deficiency for each ethnic group and document their dietary practices. This may facilitate the decision as to whether food fortification or individual supplementation is the best approach. This is a complex public health and policy matter that is beyond the scope of this presentation.

In the US, the FDA has approved fortification of milk and milk products, breakfast cereal, orange juice, pastas, infant formulas, and margarines. In developing-world countries there are no reliable sources of vitamin D-enriched food.

### **Suggestions for Further Reading**

The interested reader is referred to five articles in the recent scientific literature which provide differing perspectives and more detailed elaboration. These include the following:

- VDR and  $1\alpha,25(\text{OH})_2\text{D}_3$  mediated genomic and rapid responses (Mizwicki *et al.*, 2010);
- Vitamin D nutritional policy (Norman and Bouillon, 2010);
- Use of vitamin D deficient mice to make new observations (Bouillon *et al.*, 2006);
- 25(OH)D levels and the risk of mortality in the general population (Melamed *et al.*, 2008);
- Vitamin D and human health – lessons from vitamin D receptor null mice (Bouillon *et al.*, 2008).

## VITAMIN E

MARET G. TRABER, PhD

*Oregon State University, Corvallis, Oregon, USA*

### Summary

$\alpha$ -Tocopherol acts as a peroxy and alkoxy radical scavenger in lipid environments, and thus halts lipid peroxidation in lipoproteins and membranes. Nervous tissues in humans are particularly susceptible to vitamin E deficiency, resulting in a progressive peripheral sensory neuropathy. A growing body of evidence suggests that it is not only free-radical-mediated reactions, but also inflammatory responses, that play major roles in chronic diseases such as heart disease, diabetes, and neurodegenerative diseases. Epidemiologic studies suggest that chronic disease risk can be reduced by a lifetime of consuming higher dietary vitamin E intakes. However, more than 90% of Americans consume less than 40% of the 15 mg (22 IU)  $\alpha$ -tocopherol recommended daily by the Food and Nutrition Board. Is the usual 6 mg consumed sufficient? The evidence-based data necessary to answer this question are currently unavailable. The Women's Health Study, a 10-year prevention trial in normal, healthy women, found that 600 IU vitamin E every other day decreased overall cardiovascular mortality by 24%, and in women over 65 by 49%. In contrast, randomized clinical trials of vitamin E therapeutic benefit in the treatment of heart disease were overly optimistic in their expectation that a vitamin could reverse poor dietary habits and a sedentary lifestyle, as well as provide benefits beyond those of pharmaceutical agents in treating heart disease. Thus, nearly 100 years after the discovery of vitamin E, we are still searching for the answer to the question, why is  $\alpha$ -tocopherol required by humans?

### Introduction

Vitamin E is unique in human nutrition because its major, if not sole, function is that of an antioxidant and it is thus unlike most vitamins that are co-factors or have specific metabolic functions (Traber and Atkinson, 2007). Consequently, vitamin E deficiency symptoms in target

tissues are dependent not only upon vitamin E concentrations, but also on the degree of oxidative stress and the level of other antioxidants and antioxidant enzymes (Macevilly and Muller, 1996). Potentially, nerve degeneration caused by lipid peroxidation could be reversed by adequate vitamin E (Butterfield *et al.*, 2010). This chapter will describe vitamin E structures and antioxidant proper-

ties; distribution in food; lipoprotein transport, delivery to tissues, and metabolism; and safety and its role in chronic disease prevention.

## Definitions, Structures, Antioxidant Activity

Vitamin E is the collective name for molecules synthesized by plants that exhibit the antioxidant activity of  $\alpha$ -tocopherol. Vitamin E was discovered in 1922 when it was found that  $\alpha$ -tocopherol was required by pregnant rats to prevent the resorption of fetuses (Evans and Bishop, 1922). At least eight different molecules (tocopherols and tocotrienols) have  $\alpha$ -tocopherol antioxidant activity (Institute of Medicine, 2000). These forms vary in the number of methyl groups on the chromanol ring: trimethyl ( $\alpha$ -), dimethyl ( $\beta$ - or  $\gamma$ -), and monomethyl ( $\delta$ -). The tocopherols have a chromanol ring with a phytyl side chain, while the tocotrienols have an unsaturated side chain.

### Vitamin E Form Required by Humans: $\alpha$ -Tocopherol

$\alpha$ -Tocopherol, as synthesized by plants, is *RRR*- $\alpha$ -tocopherol (Institute of Medicine, 2000). This nomenclature means that the chiral carbons are in the *R*-conformation at positions 2, 4' and 8'. Unlike most other vitamins, commercially, chemically synthesized  $\alpha$ -tocopherol is not identical to the naturally occurring form. Synthetic  $\alpha$ -tocopherol is called *all-rac*- $\alpha$ -tocopherol (*all racemic*, or *dl*) and contains an equal mixture of eight different stereoisomers (*RRR*, *RSR*, *RRS*, *RSS*, *SRR*, *SSR*, *SRS*, *SSS*), which differ in the stereochemistry of the side chain. Thus, all of the stereoisomers have equal in vitro antioxidant but differing biologic activities. Recent efforts have been published describing the purification using chiral columns that allow separation of *2R*- and *2S*- $\alpha$ -tocopherol from the racemic product (Netscher, 2007). Enzymatic methods for *RRR*- $\alpha$ -tocopherol synthesis have been described (Nozawa *et al.*, 2000), but these are not in commercial production.

The 2 position of  $\alpha$ -tocopherol (the junction of the ring and side chain) is critical for  $\alpha$ -tocopherol biologic activity. Only *2R*- $\alpha$ -tocopherol forms meet human vitamin E requirements (Institute of Medicine, 2000). *SRR*- $\alpha$ -tocopherol is prototypic of the *2S*-forms and has been used to study synthetic vitamin E kinetics.

Vitamin E supplements often contain esters of  $\alpha$ -tocopherol, such as  $\alpha$ -tocopheryl acetate, succinate, or nicotinate. The ester form prevents the oxidation of vitamin E and prolongs its shelf life. Following oral administration, these esters are readily hydrolyzed and  $\alpha$ -tocopherol (unesterified form) is absorbed (Cheeseman *et al.*, 1995).

### Antioxidant Activity

Vitamin E, a potent peroxy radical scavenger, is a chain-breaking antioxidant that prevents the propagation of free radicals in membranes and in plasma lipoproteins (Traber and Atkinson, 2007). When peroxy radicals ( $\text{ROO}\cdot$ ) are formed, these react 1000 times faster with vitamin E (Vit E-OH) than with polyunsaturated fatty acids (PUFA, or RH in Figure 14.1) (Buettner, 1993). The hydroxyl group of tocopherol reacts with the peroxy radical to form the corresponding hydroperoxide and the tocopheroxyl radical (Vit E-O $\cdot$ ):

In the presence of vitamin E:

In the absence of vitamin E:

The tocopheroxyl radical (Vit E-O $\cdot$ ) reacts with vitamin C (or other hydrogen donors, AH), thereby oxidizing the latter and returning vitamin E to its reduced state.

This phenomenon has led to the idea of “vitamin E recycling”, where the antioxidant function of oxidized vitamin E is continuously restored by other antioxidants. This “antioxidant network” depends upon the supply of aqueous antioxidants and the metabolic activity of cells. It should be noted that free metals, such as iron or copper, can reinitiate lipid peroxidation by reaction with ROOH to form an alkoxyl radical. Additionally, if other antioxidants are not present, Vit E-O $\cdot$  can reinitiate lipid peroxidation (Thomas and Stocker, 2000).

The interaction of vitamins E and C has been demonstrated in humans under oxidative stress. Specifically, cigarette smokers with the lowest plasma ascorbic acid concentrations had the fastest vitamin E disappearance rates (Bruno *et al.*, 2005). Furthermore, when cigarette smokers were supplemented with vitamin C, their vitamin

**FIG. 14.1** Vitamin E antioxidant activity. When peroxy radicals (ROO•) are formed, these react 1000 times faster with vitamin E (Vit E-OH) than with PUFA (RH); thus, membranes and lipoproteins are protected from the chain reaction of lipid peroxidation by vitamin E. The hydroxyl group of tocopherol reacts with the peroxy radical to form the corresponding hydroperoxide (ROOH) and the tocopheroxyl radical (Vit E-O). The tocopheroxyl radical reacts with vitamin C (or other hydrogen donors, AH), thereby oxidizing the latter and returning vitamin E to its reduced state. It should be noted that free metals, such as iron or copper, can reinitiate lipid peroxidation by reaction with ROOH to form an alkoxyl radical. Additionally, if other antioxidants are not present, Vit E-O• can reinitiate lipid peroxidation (Thomas and Stocker, 2000).

E disappearance rates returned to levels seen in normal subjects (Bruno *et al.*, 2006a). Additionally, studies in rodents have shown that a combined vitamin E and C deficiency causes devastating neurologic damage in guinea pigs (Burk *et al.*, 2006) and increases the severity of atherosclerosis in susceptible mice unable to synthesize vitamin C (Babaev *et al.*, 2010).

Since the tocopheroxyl radical can be reduced back to tocopherol by ascorbate or other reducing agents, oxidized tocopherols are usually not found *in vivo*. Biologically relevant oxidation products formed from  $\alpha$ -tocopherol include 4a,5-epoxy- and 7,8-epoxy-8a(hydroperoxy)-tocopherones and their respective hydrolysis products, 2,3-epoxy-tocopherol quinone and 5,6-epoxy- $\alpha$ -tocopherol quinone (Liebler *et al.*, 1996). However, these products are formed during *in vitro* oxidation; their importance *in vivo* is unknown (Brigelius-Flohé and Traber, 1999).

The search for a specific vitamin E function has continued since its discovery. Various authors have claimed “non-antioxidant” functions, or various signaling functions. It

is likely, however, that all of the observations concerning the *in vivo* mechanism of action of  $\alpha$ -tocopherol, as a vitamin, result from its role as a lipid-soluble antioxidant (Traber and Atkinson, 2007). The importance of this function is to maintain the integrity of long-chain polyunsaturated fatty acids in the membranes of cells and thus maintain their bioactivity. Thus, these bioactive lipids are important signaling molecules, and changes in their amounts, or in their loss due to oxidation, are the key cellular events to which cells respond, not the amount or oxidation state of  $\alpha$ -tocopherol (Traber and Atkinson, 2007). This premise was elegantly tested using the comparison of  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol in the protection against glutamate-induced neurotoxicity *in vitro*. Saito *et al.* (2010) demonstrated that, when both tocopherols were delivered to cells in similar concentrations,  $\alpha$ -tocopherol was a better antioxidant and protected against the oxidative stress induced by glutamate.

Various authors have also used esters of  $\alpha$ -tocopherol to deliver vitamin E to cells in culture and study gene regulation. This approach has shown that  $\alpha$ -tocopheryl

succinate (Neuzil *et al.*, 2001; Yu *et al.*, 2003; Li *et al.*, 2010; Saito *et al.*, 2010; Wang *et al.*, 2010), or other non-hydrolyzable analogues such as  $\alpha$ -tocopherol ether-linked acetic acid (Tiwary *et al.*, 2010), may be potent anti-cancer agents. However, these are not vitamin E functions, but functions of  $\alpha$ -tocopheryl esters. Careful reading of protocols to ascertain that  $\alpha$ -tocopheryl succinate, not tocopherol, was used, and ensuring that the concentrations used are high relative to those achieved in vivo are necessary to avoid misleading conclusions.

## Content of Foods

$\gamma$ -Tocopherol is the most abundant tocopherol found in the US diet (Eitenmiller and Lee, 2004). However,  $\alpha$ -tocopherol, not  $\gamma$ -tocopherol, and specifically only the 2*R*-forms of  $\alpha$ -tocopherol, were defined by the Food and Nutrition Board to meet human vitamin E requirements (Institute of Medicine, 2000). Only 8% of men and 2% of women in the United States had dietary vitamin E intakes (Maras *et al.*, 2004) that met the 2000 estimated

average requirement (EAR, 12 mg  $\alpha$ -tocopherol/day) (Institute of Medicine, 2000). Moreover, most individuals obtain dietary vitamin E from high-energy, high-fat foods that are not particularly  $\alpha$ -tocopherol-rich (Maras *et al.*, 2004). Some examples of vitamin E food sources are shown in Table 14.1. It is therefore not surprising that the USDA's Dietary Guidance 2010, in an effort to limit fat intakes, does not try to optimize vitamin E intakes (<http://www.cnpp.usda.gov/DGAs2010-DGACReport.htm>, August 27, 2010).

## Dietary Reference Intakes

### **Recommended Dietary Allowance for $\alpha$ -Tocopherol**

In 2000, the Food and Nutrition Board published the Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium and the Carotenoids (Institute of Medicine, 2000). The recommended dietary allowances (RDAs) represent the daily  $\alpha$ -tocopherol intakes required to ensure adequate nutrition in 95–97.5% of the population and are

**TABLE 14.2** Criteria and dietary reference intake values for vitamin E by life-stage group<sup>a</sup>

Life-stage group	Criterion	EAR <sup>b</sup> (mg/day)	RDA <sup>c</sup> (mg/day)	AI <sup>d</sup> (mg/day)	UL <sup>e</sup> (mg/day)
<i>Premature infants</i>					21
0–6 months	Average vitamin E intake from human milk			4	
7–12 months	Extrapolation from 0 to 6 months AI			5	
1–3 years	Extrapolation from adult EAR	5	6		200
4–8 years	Extrapolation from adult EAR	6	7		300
9–13 years	Extrapolation from adult EAR	9	11		600
14–18 years	Extrapolation from adult EAR	12	15		800
>18 years	Intakes sufficient to prevent hydrogen peroxide-induced erythrocyte hemolysis in vitro	12	15		1000
<i>Pregnancy</i>					
≤18 years	Adolescent EAR	12	15		800
19–50 years	Adult EAR	12	15		1000
<i>Lactation</i>					
≤18 years	Adolescent EAR plus average amount of vitamin E secreted in human milk	16	19		800
19–50 years	Adolescent EAR plus average amount of vitamin E secreted in human milk	16	19		1000

<sup>a</sup>Adapted from Institute of Medicine (2000).

<sup>b</sup>EAR, estimated average requirement. The intake that meets the estimated nutrient needs of half the individuals in a group.

<sup>c</sup>RDA, recommended dietary allowance. The intake that meets the nutrient needs of almost all (97–98%) individuals in a group.

<sup>d</sup>AI, adequate intake. The observed average or experimentally determined intake by a defined population or subgroup that appears to sustain a defined nutritional status. For healthy infants receiving human milk, the AI is the mean intake.

<sup>e</sup>UL, tolerable upper intake level. The highest level of daily nutrient intake that is likely to pose no risk of adverse health effects in almost all individuals.

an overestimation of the level needed for most people in any given age or gender group (Institute of Medicine, 2000): see Table 14.2.

The vitamin E requirement is based on the observation that only supplements containing  $\alpha$ -tocopherol have been shown to reverse vitamin E deficiency symptoms in humans. The  $\alpha$ -tocopherol amounts were based primarily on the amounts necessary to correct abnormal erythrocyte hemolysis in physically healthy subjects who had consumed experimental vitamin E-deficient diets for 5 to 7 years (Institute of Medicine, 2000). Serum concentrations (in response to known supplemental vitamin E intakes) that prevented in vitro peroxide-induced erythrocyte hemolysis were used to determine the EAR. Supplements

containing either *RRR*- or *all rac*- $\alpha$ -tocopherol were used to reverse vitamin E abnormal erythrocyte hemolysis; therefore, correction factors were developed to convert IU to milligrams of *2R*- $\alpha$ -tocopherol.

The factors to convert IU to milligrams are 0.45 times the IU for *all rac*- and 0.67 times the IU for *RRR*- $\alpha$ -tocopherol (see Table 6.1 in Institute of Medicine, 2000). For example, if a vitamin E supplement is labeled 400 IU *dl*- $\alpha$ -tocopheryl acetate, then 400 times 0.45 equals 180 mg *2R*- $\alpha$ -tocopherol, but if it is labeled 400 IU *d*- $\alpha$ -tocopheryl acetate, then 400 times 0.67 equals 268 mg *2R*- $\alpha$ -tocopherol. These conversions are used only to estimate intakes relative to the RDA; different conversion factors are used to assess intakes relative to the upper limit

(UL). For labeling, the vitamin E daily value (DV) is 30 IU, which is based on a Daily Reference Value established in FDA regulations 21 CFR 101.9(c)(9) (Food and Drug Administration, 2009).

The amount of vitamin E to be recommended for daily consumption is controversial, and various organizations have proposed different values. For example, the FAO (Food and Agriculture Organization of the United Nations, 2004) found as follows:

At present, data are not sufficient to formulate recommendations for vitamin E intake for different age groups except for infancy... Thus a human-milk-fed infant consuming 850 ml would have an intake of 2.7 mg  $\alpha$ -TE ( $\alpha$ -tocopherol equivalents). It seems reasonable that formula milk should not contain less than 0.3 mg  $\alpha$ -TE/100 ml of reconstituted feed and not less than 0.4 mg  $\alpha$ -TE/g PUFA.

Note that this unit of  $\alpha$ -TE takes into account that the various forms of vitamin E in the diet have different biological activities that are based on the rat fetal resorption assay. This assay has been called into question because the placenta and uterus express the  $\alpha$ -tocopherol transfer protein and therefore suggest that  $\alpha$ -tocopherol is required by the fetoplacental unit (Kaempf-Rotzoll *et al.*, 2002, 2003; Muller-Schmehl *et al.*, 2004; Rotzoll *et al.*, 2008).

### Safety and Upper Limits

The recommendation by the Food and Nutrition Board is that the UL for any supplements containing  $\alpha$ -tocopherol is 1000 mg for adults (Institute of Medicine, 2000). Reports of adverse effects of vitamin E supplements in humans are sufficiently rare that data from multi-year studies in rats fed high dietary vitamin E levels were used to set the ULs (Institute of Medicine, 2000). No UL was set for infants as food was recommended as the only vitamin E source for infants. However, a UL of 21 mg/day was suggested for premature infants with birth weights of 1.5 kg, based on the adult UL. The ULs are also shown in Table 14.2.

The UL was set only for vitamin E supplements, not for food, because it is almost impossible to consume 1000 mg  $\alpha$ -tocopherol from foods daily for prolonged periods of time. The UL was defined for both 2*R*- and 2*S*- $\alpha$ -tocopherols because all of the stereoisomeric forms in *all rac*- $\alpha$ -tocopherol are absorbed and delivered to the liver. The appropriate conversion factors are different from those above for *all rac*- $\alpha$ -tocopherol. The factors to convert IU to milligrams are 0.9 times the IU for *all rac*- and 0.67 times the IU for *RRR*- $\alpha$ -tocopherol. The UL amounts

given in IU are 1100 IU for *all rac*- and 1500 IU for *RRR*- $\alpha$ -tocopherol. The UL for *RRR*- $\alpha$ -tocopherol is apparently higher because each capsule of *RRR*- $\alpha$ -tocopherol contains fewer milligrams of  $\alpha$ -tocopherol than does one containing *all rac*- $\alpha$ -tocopherol.

The UK established an Expert Group on Vitamins and Minerals which in 2003 reported their evaluation of the toxicity data for vitamin E (Expert Group on Vitamins and Minerals, 2003). They recommended that the Safe Upper Level supplemental for daily consumption over a lifetime should be 800 IU (540 mg *d*- $\alpha$ -tocopherol equivalents per day), which they estimated is equivalent to 9.0 mg/kg body weight per day in a 60-kg adult. Note that, as of October 1, 2010, the responsibility for nutrition policy transferred from the Food Standards Agency to the Department of Health in England and to the Assembly Government in Wales (web accessed Jan 6, 2011, <http://www.food.gov.uk/healthiereating/>).

A review of the literature on vitamin E safety has been published (Hathcock *et al.*, 2005). However, reports from three clinical trials have suggested adverse vitamin E effects in humans under special circumstances (Biesalski *et al.*, 2010). One study was a 3-year double-blind trial of antioxidants (vitamins E and C,  $\beta$ -carotene, and selenium) in 160 subjects on simvastatin-niacin therapy (Brown *et al.*, 2001). In subjects taking antioxidants, there was less benefit of the drugs in raising HDL cholesterol than was expected and there was an increase in clinical endpoints (arteriographic evidence of coronary stenosis, or the occurrence of a first cardiovascular event [death, myocardial infarction, stroke, or revascularization]) (Brown *et al.*, 2001). The Women's Angiographic Vitamin and Estrogen (WAVE) trial was a randomized, double-blind trial of 423 postmenopausal women with at least one coronary stenosis at baseline coronary angiography. In the postmenopausal women on hormone replacement therapy, all-cause mortality was increased in women assigned to antioxidant vitamins compared with placebo (HR, 2.8; 95% CI, 1.1–7.2;  $p = 0.047$ ) (Waters *et al.*, 2002). Finally, the HopeToo trial suggested that patients at high risk for coronary heart disease taking vitamin E were at increased risk of left-ventricular dysfunction (Lonn *et al.*, 2005). Interestingly, none of these trials had the same adverse effect of vitamin E. Moreover, a meta-analysis evaluating the relationship of vitamin E supplements with all-cause mortality did not associate any adverse effects with a vitamin E-specific mechanism (Miller *et al.*, 2005). Studies using the meta-analysis approach to evaluating clinical trials have reached very dramatically different conclusions ranging from

increased risk of mortality to virtually no risk from antioxidant supplements (Miller *et al.*, 2005; Bjelakovic *et al.*, 2007; Berry *et al.*, 2009; Biesalski *et al.*, 2010). In fact, the use of randomized clinical trials to assess nutrient benefits has been called into question given the fact that the known adverse effect of a nutrient in humans results from its deficiency and that subjects in the placebo group do not consume inadequate intakes (Blumberg *et al.*, 2010). Biesalski *et al.* (2010) evaluated benefit as well as harm, and suggested that a risk/benefit ratio be used to evaluate vitamin E effects.

Another potential source of the adverse effects seen in clinical trials is that the patients who are studied are likely consuming a variety of pharmaceutical agents. In general, interactions between nutrients and xenobiotic metabolism has not been taken into account, and there is the possibility that the nutrients are consumed with drugs (Traber, 2004). Potentially, an increase in vitamin E metabolism in response to supplements could alter xenobiotic metabolism and disposition, thereby decreasing the efficacy of pharmaceutical agents. However, when vitamin E supplements were given to patients taking statin drugs that are metabolized by cytochrome P450 3A (CYP3A), no effect on cholesterol levels was observed (Leonard *et al.*, 2007). In contrast,  $\gamma$ -tocopherol levels increased when a statin drug was administered (Werba *et al.*, 2007), suggesting that tocopherol levels may be influenced by xenobiotic metabolism in humans.

High vitamin E intakes are associated with an increased tendency to bleed (Institute of Medicine, 2000). It is not known if increased bleeding is a result of decreased platelet aggregation caused by an inhibition of protein kinase C by  $\alpha$ -tocopherol (Freedman *et al.*, 2000), some other platelet-related mechanism (Steiner and Anastasi, 1976; Steiner, 1981), or decreased clotting due to vitamin K and E interactions (Glynn *et al.*, 2007) causing abnormal blood clotting (Institute of Medicine, 2000). Importantly, in the Women's Health Study, vitamin E supplements (600 IU every other day for 10 years) decreased incidence of thromboembolism (Glynn *et al.*, 2007). Thus, there may be a benefit from vitamin E supplements, as well as harm, by altering blood clotting.

## Biological Activities of the Tocopherols

### Intestinal Absorption

All vitamin E forms are absorbed along with fats into intestinal cells and incorporated in chylomicrons for secre-

tion into lymph (Traber, 1999). The major steps from micellar uptake, to enterocyte trafficking and incorporation into chylomicrons, are largely unknown. Along with other transporters, Niemann-Pick C1-like 1 (NPC1L1) facilitates cholesterol absorption into the enterocyte (Hui *et al.*, 2008). Similarly, vitamin E absorption is facilitated by NPC1L1 (Narushima *et al.*, 2008), but the exact mechanisms for its transfer across the intestinal mucosa remain undiscovered.

Fat malabsorption syndromes (e.g. cholestatic liver disease) and genetic abnormalities in either lipoprotein synthesis (e.g. abetalipoproteinemia) or the  $\alpha$ -tocopherol transfer protein (e.g. ataxia with vitamin E deficiency, AVED) result in vitamin E malabsorption or abnormally low plasma  $\alpha$ -tocopherol transport, respectively (Traber, 1999).

Vitamin E absorption from supplements is poor when the supplement is consumed without fat, as was observed when vitamin E pills were consumed without food (Leonard *et al.*, 2004). Moreover vitamin E bioavailability is highly influenced by prandial status (Iuliano *et al.*, 2001). Indeed, studies using apples fortified with deuterium-labeled vitamin E demonstrated that vitamin E absorption increased as the fat in the meal increased (Bruno *et al.*, 2006b). Depending on the fat content of the meal, the bioavailability of vitamin E that occurs naturally in foods, that is present as a food fortificant, or is consumed as a supplement may be different.

### Lipoprotein Transport

Unlike other fat-soluble vitamins that have specific plasma transport proteins, vitamin E is transported non-specifically in all of the plasma lipoproteins (Figure 14.2). Once chylomicron remnants containing dietary vitamin E reach the liver, only one form of vitamin E,  $\alpha$ -tocopherol, is preferentially secreted by the liver into the plasma in very-low density lipoproteins (VLDL) (Traber, 1999). In the circulation, VLDL are delipidated to form LDL. During this process, vitamin E is transferred to HDL, which can transfer vitamin E to all of the circulating lipoproteins (Traber, 1999). Thus, the liver, not the intestine, discriminates between tocopherols. All lipoproteins transport vitamin E, and all mechanisms for delivery of lipids from lipoproteins to tissues (e.g. receptors) deliver vitamin E along with the lipoprotein contents. This phenomenon was demonstrated in a porcine blood-brain barrier model where both the SR-B1 receptor and lipoprotein lipase were demonstrated to deliver  $\alpha$ -tocopherol to cells (Goti *et al.*, 2002).

**FIG. 14.2** Determinants of vitamin E biologic activity. The various dietary forms of vitamin E are absorbed by the intestine and secreted in chylomicrons. During chylomicron catabolism some vitamin E is transferred to circulating lipoproteins; the remainder is delivered to the liver. The liver  $\alpha$ -TTP selects  $\alpha$ -tocopherol for re-secretion into the plasma, while "excess"  $\alpha$ -tocopherol and other dietary vitamin E forms are metabolized and excreted as CEHCs. Thus, metabolism is a major determinant of plasma vitamin E concentrations.

All forms of vitamin E are absorbed and transported by chylomicrons and are delivered to the tissues. Thus, forms in addition to  $\alpha$ -tocopherol can be detected in tissues (Burton *et al.*, 1998). However, it should be noted that metabolism and excretion of non- $\alpha$ -tocopherol forms result in their relatively rapid removal from the body. This rapid excretion was demonstrated in  $\alpha$ -tocotrienol-fed rats (Patel *et al.*, 2006) and in increased metabolism of deuterium-labeled  $\gamma$ -tocopherol in humans (Leonard *et al.*, 2005b). Moreover, sesame oil, which interferes with the metabolism of  $\gamma$ -tocopherol, slowed plasma  $\gamma$ -tocopherol disappearance (Frank *et al.*, 2008). These findings emphasize that the body prefers  $\alpha$ -tocopherol despite the presence of other non- $\alpha$ -tocopherol forms in the diet.

### **$\alpha$ -Tocopherol Transfer Protein**

The liver preferentially secretes  $\alpha$ -tocopherol into plasma under the control of the hepatic  $\alpha$ -tocopherol transfer protein ( $\alpha$ -TTP), as shown in patients with genetic

$\alpha$ -TTP defects (Traber *et al.*, 1990b, 1993) and in  $\alpha$ -TTP null mice (Terasawa *et al.*, 2000).

Liver  $\alpha$ -TTP has been isolated, its cDNA sequences have been reported and  $\alpha$ -TTP crystallized, and the  $\alpha$ -tocopherol binding pocket has been identified (Meier *et al.*, 2003; Min *et al.*, 2003). Interestingly, the pocket causes  $\alpha$ -tocopherol to fold such that the 2-position is critical for the fit into the pocket. This preference of  $\alpha$ -TTP for the 2R- $\alpha$ -tocopherol stereoisomers is the basis for the statement that only 2R- $\alpha$ -tocopherols (RRR, RSR, RSS, RRS) meet the human requirement for vitamin E (Institute of Medicine, 2000).

$\alpha$ -TTP belongs to a family of hydrophobic ligand-binding proteins that have a *cis*-retinal binding motif sequence (CRAL\_TRIO). All of these can bind  $\alpha$ -tocopherol, but only  $\alpha$ -TTP appears to have sufficient affinity to be a physiological mediator of its transport (Panagabko *et al.*, 2003). The selective transfer of  $\alpha$ -tocopherol is hypothetically responsible for the *in vivo*  $\alpha$ -TTP action enriching nascent VLDL secreted with

*RRR*- $\alpha$ -tocopherol (Traber *et al.*, 1990a). However, when tested directly,  $\alpha$ -TTP-mediated  $\alpha$ -tocopherol secretion was not coupled with VLDL secretion (Arita *et al.*, 1997). Studies to elucidate the mechanism by which  $\alpha$ -TTP facilitates  $\alpha$ -tocopherol secretion into plasma have used fluorescent  $\alpha$ -tocopherol analogs to follow trafficking (West *et al.*, 2010) and assessment of ligand binding by native and naturally occurring human mutations in  $\alpha$ -TTP (Morley *et al.*, 2008). Thus far the mechanisms by which  $\alpha$ -TTP delivers  $\alpha$ -tocopherol to the plasma remain unclear and are under investigation.

### Plasma Vitamin E Kinetics

A kinetic model of vitamin E transport in plasma has been described (Traber *et al.*, 1994). In normal subjects, the fractional disappearance rates of *RRR*- $\alpha$ -tocopherol ( $0.4 \pm 0.1$  pools per day) were significantly ( $p < 0.01$ ) slower than for *SRR*- $\alpha$ -tocopherol ( $1.2 \pm 0.6$ ). The apparent half-life of *RRR*- $\alpha$ -tocopherol was about 48 hours, whereas *SRR*- $\alpha$ -tocopherol had a half-life of approximately 13 hours (Traber *et al.*, 1994).

Vitamin E kinetics of  $\alpha$ - and  $\gamma$ -tocopherols have also been studied (Leonard *et al.*, 2005b). Plasma  $\gamma$ -tocopherol exponential disappearance rates ( $1.39 \pm 0.44$  pools per day) were triple those of  $\alpha$ -tocopherol ( $0.33 \pm 0.11$ ,  $p < 0.001$ ). The  $\gamma$ -tocopherol half-lives were  $13 \pm 4$  hours compared with  $57 \pm 19$  hours for  $\alpha$ -tocopherol. Thus, *RRR*- $\alpha$ -tocopherol remains in the plasma around four times longer than does *SRR*- $\alpha$ -tocopherol or  $\gamma$ -tocopherol. The similarity in the disappearance rates for  $\gamma$ -tocopherol and *SRR*- $\alpha$ -tocopherol strongly support the idea that forms of vitamin E that are not actively re-secreted by  $\alpha$ -TTP into the plasma are excreted or metabolized.

### Biliary Excretion

Vitamin E is not accumulated in the liver to “toxic” levels, suggesting that excretion and metabolism are important in preventing adverse effects of vitamin E excess. However, the regulation of hepatic vitamin E concentrations has not been extensively studied.  $\alpha$ -Tocopherol is excreted into bile via multi-drug resistance gene 2 (MDR2, ABC B4, or p-glycoprotein) (Mustacich *et al.*, 1998), an ATP-binding cassette transporter that also facilitates biliary phospholipid excretion.

The ATP-binding cassette transporter (ABCA1) mediates the  $\alpha$ -tocopherol efflux from cells to HDL, similarly to “cholesterol reverse transport” (Oram *et al.*, 2001).

HDL has been shown to deliver  $\alpha$ -tocopherol to the liver via scavenger receptor-BI (SR-BI) (Mardones *et al.*, 2001). In SR-BI-null compared with wild-type mice, plasma  $\alpha$ -tocopherol concentrations increased, biliary  $\alpha$ -tocopherol decreased but liver  $\alpha$ -tocopherol was unchanged (Mardones *et al.*, 2002); therefore, it appears that SR-BI-mediated hepatic  $\alpha$ -tocopherol uptake is coupled to its biliary excretion (Mardones *et al.*, 2002). Importantly, SR-BI protein is increased in vitamin E-deficient rats, suggesting that the liver can increase SR-BI to increase hepatic  $\alpha$ -tocopherol delivery (Witt *et al.*, 2000). Under normal conditions,  $\alpha$ -tocopherol transport via HDL to the liver would allow uptake of  $\alpha$ -tocopherol into a liver pool destined for excretion in bile or perhaps metabolism.

### Vitamin E Metabolism

Vitamin E metabolites ( $\alpha$ -CEHC and  $\gamma$ -CEHC [carboxyethyl hydroxychromans]) are derived from  $\alpha$ - and  $\gamma$ -tocopherol (as well as from  $\alpha$ - and  $\gamma$ -tocotrienols), respectively, and have been detected in urine, bile, and plasma (Brigelius-Flohé and Traber, 1999), and from liver homogenates (Leonard *et al.*, 2005a). When equimolar amounts of labeled tocopherols ( $\sim 50$  mg each  $d_6$ - $\alpha$ - and  $d_2$ - $\gamma$ -tocopheryl acetates) were administered to normal humans (Leonard *et al.*, 2005b), plasma  $d_6$ - $\alpha$ -CEHC concentrations were below levels of detection for all subjects at all time points. Rates of plasma  $\gamma$ -CEHC and  $\gamma$ -tocopherol disappearance were not different from each other and were much faster than  $\alpha$ -tocopherol disappearance (Leonard *et al.*, 2005b). These studies confirm that vitamin E metabolism is important in discriminating between various tocopherols and tocotrienols and is thus a key regulator of vitamin E bioavailability.

Vitamin E metabolism is mediated by cytochrome P450s (CYPs), in that the tocopherols or tocotrienols are initially  $\omega$ -oxidized by CYPs, then following  $\beta$ -oxidation are conjugated with sulfate or glucuronide and excreted in urine or bile (Brigelius-Flohé and Traber, 1999). CYP4F2 has been demonstrated to be the major P450 enzyme involved in the  $\omega$ -oxidation of vitamin E (Sontag and Parker, 2002, 2007). However, there is cross-talk between the P450 enzymes, and CYP3A may also play a role when liver vitamin E concentrations are particularly high (Traber, 2010). The subsequent  $\beta$ -oxidation of the metabolite has been localized to the mitochondria (Mustacich *et al.*, 2010). Sulfation may be an important

early step in intracellular trafficking to guide vitamin E metabolism, or at least  $\gamma$ -tocopherol metabolism. Sulfated- $\gamma$ -CEHC is the major CEHC conjugate both in rats and in human cells in culture, and sulfated intermediates were found between 13'-OH- $\gamma$ -tocopherol and  $\gamma$ -CEHC (Jiang *et al.*, 2007; Freiser and Jiang, 2009a,b). Intermediates of  $\gamma$ -tocopherol metabolism, including 9-COOH, 11-COOH, 13-COOH, and 13-OH- $\gamma$ -tocopherol, have been identified using a novel mass spectrometric approach (Yang *et al.*, 2010).

Because of their rapid metabolism, orally administered  $\gamma$ -tocopherol or tocotrienols are not very effective at raising their own plasma and tissue concentrations (Khanna *et al.*, 2005; Patel *et al.*, 2006). In humans, Wiser *et al.* (2008) used a  $\gamma$ -tocopherol-rich preparation (containing 623 mg  $\gamma$ -tocopherol, 61.1 mg  $\alpha$ -tocopherol, 11.1 mg  $\beta$ -tocopherol, and 231 mg of d- $\delta$ -tocopherol per capsule). Taken daily for 2 weeks this preparation raised plasma  $\gamma$ -tocopherol concentrations to nearly those of  $\alpha$ -tocopherol, but, within 1 week of stopping the dosing,  $\gamma$ -tocopherol concentrations returned to baseline. Therefore, to take advantage of the possibility that  $\gamma$ -tocopherol could scavenge reactive nitrogen species, nebulized tocopherols have been used in lung studies (Hamahata *et al.*, 2008).

## Deficiency

Although rare, overt vitamin E deficiency occurs in humans as a result of genetic abnormalities in  $\alpha$ -TTP or lipoprotein synthesis and as a result of various fat malabsorption syndromes (Traber, 1999). Vitamin E deficiency occurs secondary to fat malabsorption because vitamin E absorption requires biliary and pancreatic secretions (Traber, 1999).

The large-caliber myelinated axons in peripheral sensory nerves are the predominant target tissue in vitamin E deficiency in humans. A progressive peripheral neuropathy is observed with a dying back of the large-caliber axons in the sensory neurons (Sokol, 1993). In deficient humans, axonal degeneration rather than demyelination is the primary sensory nerve abnormality (Traber *et al.*, 1987; Sokol *et al.*, 1988). Thus, the axons degenerate first, then demyelination occurs.

Genetic defects in  $\alpha$ -TTP are associated with a characteristic syndrome, ataxia with vitamin E deficiency, AVED (Ben Hamida, C. *et al.*, 1993; Ben Hamida, M. *et al.*, 1993; Doerflinger *et al.*, 1995; Ouahchi *et al.*, 1995). The

ataxia observed in these patients has also been mimicked in  $\alpha$ -TTP-null mice (Yokota *et al.*, 2001).

AVED patients have extraordinarily low plasma vitamin E concentrations (as low as 1/100 of normal), but if they are given vitamin E supplements, plasma concentrations reach normal within hours (Sokol *et al.*, 1988). A dose of 800–1200 mg/day is usually sufficient to prevent further deterioration of neurologic function, and in some cases improvements have been noted (Sokol, 1993; Gabsi *et al.*, 2001). Post-mortem analysis of an AVED patient demonstrated that vitamin E supplementation did allow brain vitamin E accumulation and prevention of Purkinje cell loss (Yokota *et al.*, 2000). If supplementation is halted, plasma vitamin E concentrations fall within days to deficient levels. The biochemical defect in AVED patients, shown using deuterated tocopherols, demonstrated that hepatic  $\alpha$ -TTP is required to maintain plasma  $RRR$ - $\alpha$ -tocopherol concentrations (Traber *et al.*, 1990b, 1993) via secretion in VLDL. Over 20 mutations have been identified in patients with AVED (Di Donato *et al.*, 2010).

## Chronic Disease Protection and Public Health Implications

Given that vitamin E deficiency is very rare and that the vitamin E intakes of most Americans are very much less than their estimated requirements, the question arises as to whether the dietary  $\alpha$ -tocopherol recommendations are too high. Conversely, given the potential for adverse effects, is there benefit to vitamin E supplements? The questions would be easier to answer if there were specific metabolic pathways that required vitamin E such that a marginal deficiency could be defined. Certainly, signaling pathways and specific genes have been identified that are altered by low or high  $\alpha$ -tocopherol concentrations (Azzi *et al.*, 2004), but there is no consensus concerning such “molecular” effects and they are difficult to separate from changes in oxidative stress-dependent mechanisms (Saito *et al.*, 2010). One area of particular importance is that of impaired immune function in the elderly, which can be improved with vitamin E supplementation (Meydani *et al.*, 2004). Again, it is not clear if the elderly are an example of long-term sub-optimal intakes of vitamin E that allow increased oxidative stress to alter T-cell function. Similarly, aged patients with eye disease (macular degeneration) were benefited by a supplement cocktail that

included vitamin E (Age-Related Eye Disease Study Research Group, 2001). Eyes are an extension of the nervous system, and vitamin E is particularly necessary for the maintenance of normal nerve function. It is therefore interesting that vitamin E supplements were associated with a decreased risk of amyotrophic lateral sclerosis (Ascherio *et al.*, 2005) and that supplements have been reported to delay progression of Alzheimer disease (Sano *et al.*, 1997). However, meta-analysis of vitamin E intervention trials in Alzheimer disease have not found a benefit of vitamin E supplements in prevention of the onset of the disease (Isaac *et al.*, 2008).

Oxidative stress increases plasma vitamin E disappearance in endurance exercise (Mastaloudis *et al.*, 2001) and in cigarette smokers (Bruno *et al.*, 2005). Thus, increased oxidative stress might increase chronic disease risk; however, measures of oxidative stress are frequently not obtained. Vitamin E supplements have decreased heart-attack risk in subjects with demonstrably inadequate antioxidant protection. For example, haptoglobin 2-2 genotype results in a dysfunctional protein and causes increased oxidation by free heme (Levy *et al.*, 2010). In a placebo-controlled study carried out in diabetics who have the haptoglobin 2-2 genotype, daily vitamin E supplementation (400 IU) reduced cardiovascular events (Milman *et al.*, 2008). Additionally, haptoglobin 2-2 genotype subjects are more susceptible to vitamin C deficiency as a result of impaired haptoglobin antioxidant function (Cahill and El-Sohemy, 2010). The lower vitamin C status may also increase vitamin E depletion (Bruno *et al.*, 2005, 2006a).

Taken together these findings suggest that long-term sub-optimal vitamin E intakes will indeed allow the accumulation of oxidative damage. Certainly, it is generally agreed that chronic diseases are associated with increased, accumulated, oxidative damage (Institute of Medicine, 2000). What remains an open question is whether vitamin E supplements in excess of daily requirements will decrease the risk of chronic disease. Although many vitamin E supplementation studies carried out in patients with various kinds of chronic diseases have failed to show benefit, these studies have largely attempted to reverse existing disease. The question as to whether increased oxidative stress as a result of suboptimal vitamin E intakes increases the risk of chronic disease has not yet been answered. However, a follow-up study of the Alpha-Tocopherol Beta-Carotene Cancer Prevention trial showed (Wright *et al.*, 2006) that men in the

higher quintiles of serum  $\alpha$ -tocopherol had significantly lower risks of total and cause-specific mortality than did those in the lowest quintile (relative risk [RR] = 0.82 [95% CI: 0.78, 0.86] for total mortality and 0.79 [0.72, 0.86], 0.81 [0.75, 0.88], and 0.70 [0.63, 0.79] for deaths due to cancer, cardiovascular disease, and other causes, respectively; P for trend for all <0.0001).

Importantly, these benefits were found for those subjects consuming 12 mg  $\alpha$ -tocopherol daily, a level equivalent to the vitamin E EAR (Institute of Medicine, 2000).

## Future Directions

Oxidative stress in humans more rapidly depletes plasma vitamin E (Bruno *et al.*, 2005, 2006a) and sufficient vitamin C intake counters the accelerated vitamin E depletion (Bruno *et al.*, 2006a). In response to oxidative stressors, vitamin E can decrease biomarkers of lipid peroxidation, is itself sacrificed, and requires optimal vitamin C status to function most effectively. Thus, adequate vitamin E intakes are clearly needed, but what is adequate, and for what function, have yet to be defined. Studies are needed to define why humans require vitamin E and how much they need. Vitamin E kinetic studies will allow determination of key measures of vitamin E status including fractional absorption, rates of delivery to tissues, and whole-body efflux. Hypothetically, the delivery of  $\alpha$ -tocopherol to the target tissues will be increased if ascorbic acid is limiting, or if oxidative stress is high in those tissues.

Additionally, we are learning that there are certain genetic abnormalities that lead to increased vitamin E requirements. It is becoming increasingly apparent that each individual's "nutrigenomic biome" may have important consequences for nutrient requirements. Personalized nutrition will require the recognition of factors that alter needs. A biomarker for vitamin E status has yet to be defined; moreover, we do not have any specific indicators of vitamin E function that might be altered in health or disease.

## VITAMIN K

GUYLAINE FERLAND, PhD

*Université de Montréal, Montréal, Québec, Canada*

### Summary

Historically discovered for its role in blood coagulation, vitamin K is emerging as a vitamin of wide-ranging physiological implications. Whether through the vitamin K-dependent protein family or specific K vitamers, vitamin K is now known to be involved in bone and cardiovascular metabolism, cell proliferation, brain function, and energy metabolism. In this chapter we will go over the most recent scientific literature relating to vitamin K and point to ongoing and future research efforts.

### Introduction

The history of vitamin K dates back to 1929 when, as part of his work on sterol metabolism, Henrik Dam observed that chicks fed fat-free diets developed subcutaneous hemorrhages and anemia. Further work by Dam determined that the antihemorrhagic substance was fat soluble and occurred in extracts of liver and various plant tissues. In 1935 Dam named this new substance vitamin K. By 1939 the two naturally occurring forms of the vitamin – vitamin K<sub>1</sub> and vitamin K<sub>2</sub> – had been isolated from alfalfa and putrefied fish meal, respectively (Suttie, 2009). In 1941 the first vitamin K antagonist was discovered when a new substance identified in spoiled sweet clover hay had been reported to cause hemorrhagic disease in cattle in the US and western Canada in the 1920s. This substance, 3,3'-methyl-bis-(4-hydroxycoumarin), later became known as dicoumarol. In the period after the discovery

of dicoumarol, several derivatives of coumarin were synthesized for use as clinical agents in anticoagulant therapy. One of these, warfarin (3-[*a*-acetylbenzyl]-4-hydroxycoumarin), has been used successfully as a clinical agent since 1941. Access to vitamin K antagonists eventually helped specify the role of vitamin K in blood coagulation and proved to be invaluable to vitamin K research in general.

Although the bleeding condition reported by Dam was originally associated with decreased prothrombin (Factor II) activity, it was later established that three other coagulation proteins (factors VII, IX, and X) were also depressed in vitamin K deficiency states. For many years this participation in blood coagulation was assumed to be the sole physiological role for vitamin K. However, the discovery in the early 1970s of  $\gamma$ -carboxyglutamic acid (Gla), a new amino acid common to all vitamin K proteins, later led to the discovery of additional vitamin K-dependent proteins

**FIG. 15.1** Chemical structures of phylloquinone, the menaquinones, MK-4, and menadione.

not involved in hemostasis, and greatly contributed to our present understanding of the action of vitamin K at the molecular level. To this day, the participation of vitamin K in Gla synthesis remains the only well defined function of this vitamin (Berkner and Runge, 2004).

## Chemistry and Nomenclature

Compounds with vitamin K activity have a common 2-methyl-1,4-naphthoquinone ring but differ in the structure at the 3-position. Vitamin K occurs naturally in two forms. Phylloquinone (2-methyl-3-phytyl-1,4-naphthoquinone; also referred to as vitamin K<sub>1</sub>), is synthesized in plants and represents the main source of dietary vitamin K in Western countries (Institute of Medicine, 2001). Menaquinones (2-methyl-1,4-naphthoquinones; also referred to as vitamin K<sub>2</sub>), are produced by bacteria and form a family of compounds with unsaturated isoprenyl side chains of varying length at the 3 position. The predominant forms of the menaquinone series contain 6–10 isoprenoid units, but menaquinones containing up to 13 units have been isolated (Suttie, 1995). One of the

menaquinones, MK-4, is not a common product of bacterial synthesis but is synthesized from phylloquinone with menadione as an intermediate (see later in this chapter). The parent structure of all K vitamins, 2-methyl-1,4-naphthoquinone, also called menadione or vitamin K<sub>3</sub>, does not occur in nature but can be alkylated to MK-4 in avian and mammalian tissues. This synthetic form has been used as a source of vitamin K in a wide range of animal feeds (Suttie, 2009). The different K vitamers are illustrated in Figure 15.1.

Current methods to assess vitamin K in plasma, biological tissues, and foods are based on high performance liquid chromatography (HPLC). Vitamin K is first extracted from matrices with organic solvents, then by solid phase chromatography, before being selectively isolated by HPLC. Quantitation is usually achieved using fluorescence detection, and procedures enabling simultaneous determination of phylloquinone and the menaquinones have been developed and applied reliably (Davidson and Sadowski, 1997; Wang *et al.*, 2004). Methods combining chromatographic and mass spectrometry techniques have also been developed and used in studies involving labeled

phylloquinone (Ducros *et al.*, 2010). A vitamin K external quality assurance scheme (KEQAS) was recently established to assist in the harmonization of phylloquinone analysis among laboratories worldwide and to improve the comparability of clinical and nutritional studies (Card *et al.*, 2009). Finally, a method using HPLC was recently published for the measurement of menadiol in urine (Al Rajabi *et al.*, 2010).

## Absorption, Transport, Turnover, and Storage

### Absorption/Bioavailability

Vitamin K is absorbed from the proximal intestine into the lymphatic system by a process that requires the presence of bile and pancreatic juices (Shearer *et al.*, 1974). Consequently, conditions interfering with these functions or associated with fat malabsorption will impair vitamin K absorption (Savage and Lindenbaum, 1983). In healthy adults, absorption of phylloquinone has been estimated to be ~80% when administered in its free form, but decreases significantly when it is absorbed from foods (Shearer *et al.*, 1974). When investigated using the area under an absorption curve, absorption of phylloquinone from spinach was found to be 4–17% that of phylloquinone from a suspension or a tablet (Gijssbers *et al.*, 1996; Garber *et al.*, 1999). A similar estimate was recently reported for phylloquinone from kale using compartmental modelling (Novotny *et al.*, 2010). Phylloquinone absorption from vegetables can be improved when consumed with fat (Gijssbers *et al.*, 1996) but absorption efficiency remains lower than when phylloquinone is being consumed in an oil form (Booth *et al.*, 2002). Moreover, a recent study that used stable isotope methodology suggests that absorption of phylloquinone is influenced by meal components (Jones *et al.*, 2009). Data for the menaquinones are more limited but when MK-4 was administered with butter (Gijssbers *et al.*, 1996) and MK-7 as part of the Japanese food natto (Schurgers and Vermeer, 2000), the bioavailability of these two vitamers was higher than that of phylloquinone from spinach.

### Transport and Cellular Uptake

Absorbed phylloquinone is incorporated into chylomicrons and transported to the liver, where it is cleared from chylomicron remnants through an apolipoprotein E (apoE) receptor. Unlike other fat-soluble vitamins, vitamin K has no known carrier protein. In the circulation, phylloquinone is principally carried in triacylglycerol-rich lipoproteins (TGRLP; >50%) with each of the LDL and HDL fractions accounting for ~15% of the circulating vitamers (Lamon-Fava *et al.*, 1998; Erkkila *et al.*, 2004). This likely explains the strong positive correlation observed between circulating phylloquinone and triacylglycerols in various studies (Sadowski *et al.*, 1989; Azharuddin *et al.*, 2007). Data on the lipoprotein distribution of ingested menaquinones is more limited. In a comparative study that involved the administration of equimolar amounts of phylloquinone, MK-4 and MK-9, the menaquinones were associated with both the TGRLP and LDL fractions while MK-4 was also observed in the HDL fraction (Schurgers and Vermeer, 2002). This study also highlighted a much longer half-life time in the circulation for MK-9 compared with phylloquinone, a finding also observed for MK-7 (Schurgers *et al.*, 2007). Compared to the other fat-soluble vitamins, phylloquinone circulates in blood in very small concentrations, and a normal range of 0.25–2.7 nmol/L has been published by Sadowski *et al.* (1989). Fasting plasma phylloquinone has been linked to the genetic polymorphism of apolipoprotein E (apoE); however, results have been inconsistent, differing in healthy subjects and certain groups of patients (Kohlmeier *et al.*, 1995; Yan *et al.*, 2005). Normal ranges for menaquinones are not yet available. Uptake of phylloquinone into tissues including bone is deemed to be via clearance of chylomicron remnants by apoE. Furthermore, internalization of phylloquinone in osteoblasts appears to vary according to apoE genotype (Newman *et al.*, 2002). Cellular uptake of menaquinones has not been investigated specifically, but it was recently suggested that long-chain menaquinones could enter osteoblasts via the LDL receptor in light of their close association with this lipoprotein fraction (Shearer and Newman, 2008).

Older studies that used pharmacological dosage protocols showed phylloquinone to be rapidly metabolized with about 20% being excreted in the urine and 40–50% excreted in the feces via the bile. Urinary vitamin K metabolites consist mainly of glucuronide conjugates of derivatives in which the phytyl side chain has been oxidized and cleaved. Biliary metabolites have not been clearly identified. A method for measuring two major urinary metabolites of phylloquinone, 5C- and 7C-aglycones, by HPLC with electrochemical detection in the redox mode, has been published (Harrington *et al.*, 2005) and used successfully in metabolic studies (Harrington *et al.*, 2010).

### Catabolism and Turnover

Older studies that used pharmacological dosage protocols showed phylloquinone to be rapidly metabolized with about 20% being excreted in the urine and 40–50% excreted in the feces via the bile. Urinary vitamin K metabolites consist mainly of glucuronide conjugates of derivatives in which the phytyl side chain has been oxidized and cleaved. Biliary metabolites have not been clearly identified. A method for measuring two major urinary metabolites of phylloquinone, 5C- and 7C-aglycones, by HPLC with electrochemical detection in the redox mode, has been published (Harrington *et al.*, 2005) and used successfully in metabolic studies (Harrington *et al.*, 2010).

When consumed in physiological amounts, postprandial plasma phylloquinone concentration peaks after about 6 hours, returning to baseline by 24 hours (Erkkila *et al.*, 2004). This is in contrast to the long-chain menaquinones which remain in the circulation for much longer periods when ingested in similar quantities (up to 72 hours in the case of MK-7; Schurgers and Vermeer, 2000). Studies on the clearance kinetics of phylloquinone following an intravenous dose have been conducted using various approaches and point to a biphasic disappearance profile comprised of a rapid phase with a half-life of ~0.3 hour and a slower phase with a half-life of ~2.5 hours (Shearer *et al.*, 1974; Jones *et al.*, 2008). Other studies have reported slower clearance rates (Olson *et al.*, 2002; Novotny *et al.*, 2010) suggesting that other body pools of vitamin K, e.g. adipose tissue or bone, could turn over much more slowly. A detailed review of vitamin K metabolism has been published (Shearer and Newman, 2008).

#### **Tissue Stores and Biosynthesis of MK-4**

As the site of synthesis of the coagulation proteins, liver has traditionally been considered the main storage organ and consists of around 90% menaquinones, with MK-10 and MK-11 being particularly abundant, and 10% phylloquinone (Suttie, 2009). However, phylloquinone and the menaquinones are also present in extrahepatic tissues. In post-mortem specimens, phylloquinone concentrations in heart and pancreas were found to be comparable to that in liver while those in lung, kidney, and brain were much lower. Menaquinone-4 is also widely distributed and is present in tissues in variable amounts. In brain and kidney, for instance, MK-4 concentrations largely exceed those of phylloquinone whereas, in the pancreas, MK-4 and phylloquinone are present in comparable amounts (Thijssen and Drittij-Reijnders, 1996). Vitamin K is also present in bone, phylloquinone predominating over the menaquinones (MK-4 through MK-8) (Shearer and Newman, 2008).

The presence of MK-4 in tissues has been the object of investigation for over 50 years. It is only recently, however, that the origin of this menaquinone has been elucidated. It is now well established that MK-4, which is not a common product of bacterial synthesis, is synthesized from phylloquinone with menadione as an intermediate (Thijssen *et al.*, 2006). In a series of studies conducted in mice, data suggest that MK-4 in cerebra could originate from two sources: (1) phylloquinone following the release of menadione in the intestine and subsequent prenylation of menadione in the cerebra, and (2) cleavage of phylloquinone and generation of menadione within the target cells followed by prenylation (Okano *et al.*, 2008).

Very recently, this team established that the human UbiA prenyltransferase domain-containing protein 1 (UBIAD1) enzyme is responsible for MK-4 biosynthesis. This enzyme, which is located in the endoplasmic reticulum, was found to be expressed in several tissues in mice (Nakagawa *et al.*, 2010).

## **Biochemical and Physiological Function**

### **Vitamin K-dependent Carboxylation**

Over 40 years after its discovery, vitamin K was shown to act as a cofactor in the post-translational synthesis of Glu from glutamic acid (Glu) residues contained in precursor proteins.  $\gamma$ -Carboxyglutamic acid is common to all vitamin K-dependent proteins (VKDP) and increases the affinity of these proteins for calcium (Berkner and Runge, 2004). As illustrated in Figure 15.2, the  $\gamma$ -carboxylation of glutamate residues is catalyzed by a microsomal enzyme called  $\gamma$ -glutamyl carboxylase (GGCX) located at the luminal surface of the endoplasmic reticulum in a reaction that requires the reduced form of vitamin K, hydroquinone, as well as carbon dioxide and oxygen. It is currently believed that the vitamin K hydroquinone and oxygen react to form a strong base capable of abstracting a proton from the  $\gamma$ -carbon of the Glu residue to form a carbanion intermediate, which then undergoes carboxylation to yield a Glu residue (Dowd *et al.*, 1995). The carboxylase hence uses the energy of vitamin K hydroquinone oxygenation to convert Glu residues to Glu residues in the VKDPs. Carboxylation of the Glu residues is accomplished by a processive mechanism and is facilitated by a carboxylase recognition signal propeptide that tethers the Glu residues to the enzyme (reviewed in Berkner, 2008).

Once formed, vitamin K 2,3-epoxide is recycled to its quinone and hydroquinone forms in successive reactions catalyzed by a vitamin K oxidoreductase (VKOR). Activity of VKOR is dependent on dithiol cofactors and is inhibited by 4-hydroxycoumarin derivatives such as warfarin. The blocking action of coumarin-type drugs towards this enzyme forms the basis of their pharmacological action as anticoagulants. However, at least in the liver, reduction of the vitamin K quinone to hydroquinone is also possible by a NAD(P)H-dependent quinone reductase that is insensitive to coumarin drugs, but cannot reduce vitamin K epoxide to the quinone form. This enzyme operates at high tissue concentrations of vitamin K and can therefore

**FIG. 15.2** The vitamin K cycle. GGCX refers to the  $\gamma$ -glutamyl carboxylase and VKOR to the vitamin K oxidoreductase enzymes, respectively. X-(SH)<sub>2</sub> and X-S<sub>2</sub> denote reduced and oxidized dithiols, respectively. The dithiol-dependent reductases are inhibited by coumarin-type drugs such as warfarin whereas the NAD(P)H-dependent reductase is not.

support carboxylation of the hepatic VKDP in the presence of coumarins (reviewed in Berkner and Runge, 2004; Suttie, 2009). Collectively, these reactions make up the vitamin K cycle (Figure 15.2).

In the absence of vitamin K or in the presence of vitamin K antagonists, carboxylation of precursor proteins is incomplete and proteins are secreted in plasma in various undercarboxylated forms. These proteins, referred to as PIVKAs (protein induced by vitamin K absence or antagonism), lack biological activity and have been used to assess vitamin K nutritional status. Specific antibodies for the undercarboxylated forms of prothrombin, osteocalcin, and matrix Gla protein have been developed and their presence in blood and tissues is usually interpreted as reflecting a suboptimal VK status (see below).

## Vitamin K-dependent Proteins

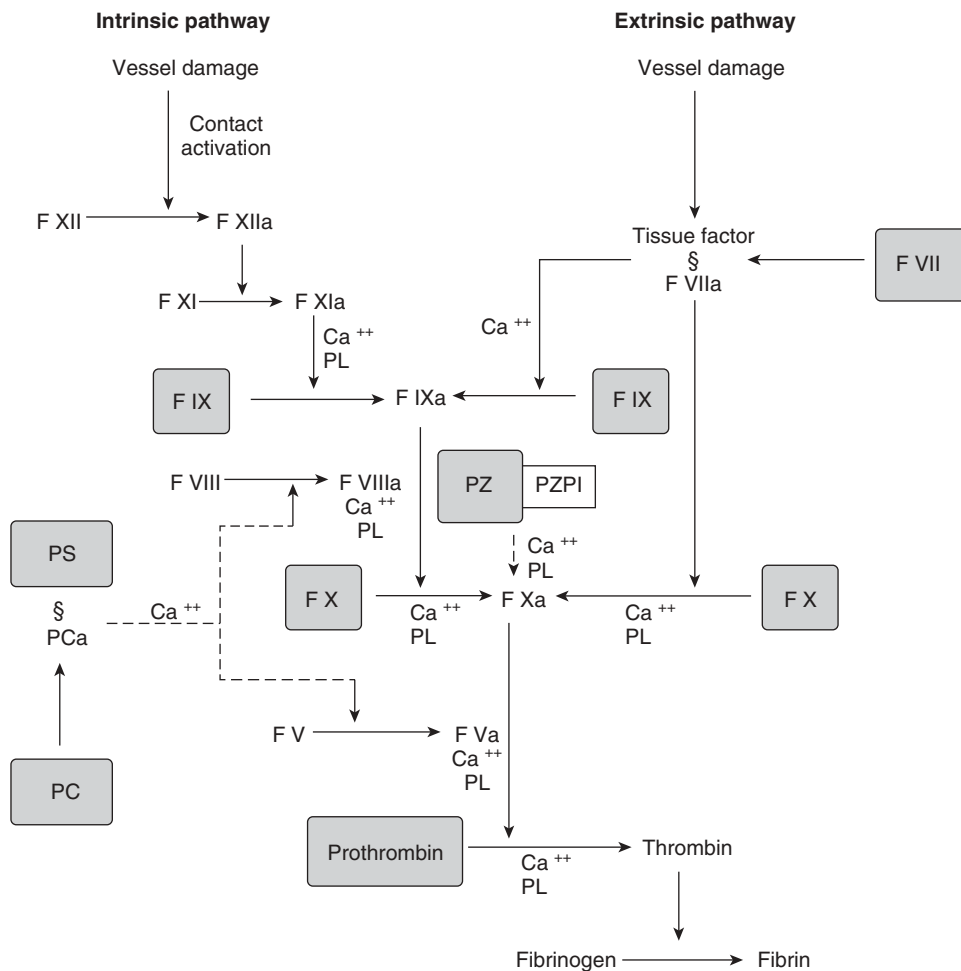

Although gamma-carboxyglutamic acid residues have been detected in both vertebrate and invertebrate species, only proteins of mammalian origin will be discussed here.

### Blood Coagulation Proteins

There are seven vitamin K-dependent proteins involved in blood coagulation, namely prothrombin (factor II), factors VII, IX and X, protein C, protein S, and protein Z. All the vitamin K-dependent coagulation proteins (46 000–80 000 Da) are synthesized in the liver and contain between 10 and 12 Gla residues. The Gla residues enable Ca<sup>2+</sup>-mediated binding of the proteins to the negatively charged phospholipid surfaces provided by blood platelets and

endothelial cells at the site of injury. With the exception of proteins S and Z, Gla-containing blood proteins are zymogen forms of serine proteases and have considerable structural homology. Prothrombin was among the proteins associated with the coagulation cascade as described in the middle of the 19th century. The identification of factors VII, IX, and X came much later (1950s) through the study of patients with hereditary bleeding tendencies, and proteins C, S, and Z were discovered in the mid-1970s (Davie, 2003; Suttie, 2009). Prothrombin and factors VII, IX, and X represent the classical vitamin K-dependent plasma clotting factors and participate in the cascade resulting in the

formation of a fibrin clot. A key element in the formation of fibrin is the generation of thrombin from prothrombin by activated factor X. Vitamin K-dependent factors VII and IX activate factor X by the extrinsic and intrinsic pathways, respectively. In contrast, proteins C, S, and Z are inhibitors of the procoagulant system. Protein C exerts its inhibitory activity by inactivating factors Va and VIIIa and enhances fibrinolysis with protein S as a cofactor, and protein Z serves as a cofactor for the inhibition of factor Xa by protein Z-dependent protease inhibitor (Berkner and Runge, 2004). An abbreviated diagram of the coagulation cascade is presented in Figure 15.3.

**FIG. 15.3** The coagulation cascade. Factors and proteins in boxes are vitamin K-dependent. Numbered factors are abbreviated as F VII, F IX, etc. PC and PS denote protein C and protein S, respectively. Active proteins are represented as "a". PZPI, protein Z-dependent protease inhibitor; PL, phospholipid. Procoagulant reactions are shown as solid lines whereas inhibition reactions are shown as dotted lines.

In addition to their hemostatic action at the cell surface, many of the coagulation proteins are now known to also possess cell signaling activity and influence a wide range of cellular events. Hence, through its interaction with protease-activated receptors (PARs), thrombin has been shown to promote platelet aggregation and to be involved in such phenomena as tumor growth and metastasis, angiogenesis, atherosclerosis and inflammation, survival of glial cells, neurons and myoblasts, and chemotaxis of neutrophils and monocytes (Sokolova and Reiser, 2008; Chen and Dorling, 2009). When complexed to tissue factor, factors VII and Xa activate PAR-1 and PAR-2 receptors and participate in pro-inflammatory cell signaling (Levi and Van der Poll, 2010). In contrast, protein C (PC) and its activated form (APC) have been shown to possess anti-inflammatory and anti-apoptotic properties through mechanisms that appear to involve interactions with the endothelial PC receptor (EPCR) and PAR-1 in the membrane. Clinically, alterations in the PC system have been linked to conditions such as sepsis, asthma, inflammatory bowel disease, atherosclerosis, and lung and heart inflammation (Danese *et al.*, 2010). In contrast to the other VK-dependent blood factors, which are principally associated with the liver, protein S (PS) is synthesized by different cell types (e.g. megakaryocytes, endothelial and vascular smooth muscle cells [VSMCs], and osteoblasts) and has been found in many extrahepatic tissues including brain, testes, spleen, heart, endothelium, and bone. Like the parent vitamin K-dependent protein, Gas6 (cf. later in this chapter), protein S is a ligand for the receptor tyrosine kinases Axl, Sky, and Mer, and is involved in important cell functions. Specifically, protein S has been shown to possess anti-inflammatory activity, to mediate phagocytosis of apoptotic cells, to be a potent mitogen for VSMCs, and to confer neuronal protection (Hafizi and Dahlback, 2006).

### **Bone Proteins**

There are three Gla proteins in bone, namely osteocalcin, matrix Gla protein, and protein S, although two recently discovered VKDP (Gla-rich protein and periostin, cf. below) could probably also be included in this category. Osteocalcin, also known as bone Gla protein, is synthesized in osteoblasts and odontoblasts, and accounts for 15–20% of the non-collagenous bone protein in most vertebrate species. Osteocalcin (OC) has a molecular weight of ~5.7 kDa and three Gla residues, which allow binding to hydroxyapatite crystals in bone. Synthesis of OC by osteoblasts is stimulated by the active metabolite

of vitamin D, 1,25(OH)<sub>2</sub>D<sub>3</sub>. About 20% of the newly synthesized protein is released into the circulation and is used as a measure of bone formation. In states of dietary restriction or following treatment with vitamin K antagonists, partially carboxylated osteocalcin (ucOC) appears in the circulation. Despite the interest osteocalcin has raised since its discovery, its physiological function remains elusive. Reports have shown that rats rendered OC deficient following treatment with warfarin exhibit excessive bone mineralization and premature closure of the growth plate (Price, 1988) and that mice lacking the osteocalcin gene exhibit a phenotype characterized by increased bone mass and improved functional qualities (Ducy *et al.*, 1996). Collectively, these data suggest a role for OC as a negative regulator of bone formation. The second vitamin K-dependent bone protein to be discovered, matrix Gla protein (MGP), has a molecular weight of ~9.6 kDa and contains five Gla residues. In contrast to osteocalcin, which is exclusively associated with mineralized tissues, MGP is expressed in many soft tissues and cell types including vascular smooth muscle cells, although the protein itself only accumulates in calcified tissues. The physiological function of MGP as an inhibitor of calcification was established when mice lacking the gene coding for MGP showed calcification of their arteries that led to hemorrhagic death due to vessel rupture within 2 months (Luo *et al.*, 1997). A similar phenotype, i.e. calcification of the arteries and of the aortic valves, was subsequently observed, although to a lesser degree of severity, in MGP-depleted rats treated with warfarin (Price *et al.*, 1998). Although the mechanism of action for MGP remains to be fully elucidated (Proudfoot and Shanahan, 2006), the protein has been shown to bind calcium ions and inhibit crystal growth (Roy and Nishimoto, 2002), and to modulate the action of bone morphometric protein type 2 (Zebboudj *et al.*, 2003) and type 4 (Yao *et al.*, 2006). Finally, protein S is also present in bone. The protein has been shown to be synthesized and secreted by osteoblasts (Maillard *et al.*, 1992) and to enhance the bone-resorbing activity of mature osteoclasts, an action that appears to be related to its ability to bind tyrosine kinase receptors (Nakamura *et al.*, 1998).

### **Other VKDPs**

#### **Gas6**

Discovered in 1993, Gas6, thus named after it was found to be the product of the growth-arrest-specific gene 6, is a high molecular weight protein (75 kDa) that contains

11–12 Gla residues. It has a structure similar to that of protein S (44% amino acid homology) and is expressed in numerous tissues (Manfioletti *et al.*, 1993). Gas6 binds and activates the receptor tyrosine kinases of the TAM family (Tyro3, Axl, and Mer), a property that is dependent on Gla residues. Since its discovery, Gas6 has been involved in a wide range of cellular processes that include cell differentiation, proliferation and activation, cell adhesion and chemotaxis, phagocytosis, and protection against apoptosis. Physiologically, Gas6 has been involved in the nervous system and the retina, in platelet metabolism and hemostasis, in vascular calcification, and in osteogenic differentiation and osteoclast function. In light of these actions, Gas6 has been linked to conditions such as inflammation, thrombotic events, atherosclerosis, glomerular kidney disease, and cancer. The multiple actions of Gas6 have recently been reviewed (Bellido-Martín and de Frutos, 2008; Benzacour, 2008; Tjwa *et al.*, 2009).

### Transmembrane Gla Proteins

Among the other VKDPs that have been identified are those of the transmembrane Gla family (TMG), which comprises four proteins: proline-rich Gla proteins 1 and 2 (PRPG1, PRPG2; Kulman *et al.*, 1997) and transmembrane Gla proteins 3 and 4 (TMG3 and TMG4; Kulman *et al.*, 2001). In contrast to the previously discussed VKDPs, these are not secreted but rather are single-pass integral membrane proteins. Like Gas6, however, the TGMs have a wide tissue distribution. Their functions *in vivo* are presently unclear but their chemical conformations suggest that they could be involved in cell transduction and have broad physiological activities.

### Gla-rich Protein

In 2008, a new Gla-rich protein (GRP) was isolated from calcified cartilage. This 10.2-kDa protein contains 16 Gla residues, which is the highest proportion of Glas reported among the VKDPs (Viegas *et al.*, 2008). It is widely distributed but its expression is highest in cartilage with chondrocytes, chondroblasts, osteoblasts, and osteocytes expressing the protein. In a recent report, GRP was found to accumulate in pathological calcification (Viegas *et al.*, 2009). Although the exact function of GRP is presently unknown, it could regulate extracellular calcium.

### Periostin

Associated with the extracellular matrix known to promote cell migration and angiogenesis, periostin was recently

identified as a VKDP (Coutu *et al.*, 2008). Specifically, it was shown to be secreted by mesenchymal stromal cells and to be present in mineralized bone nodules. In addition to its known functions, periostin could have a role in extracellular matrix mineralization.

### Transthyretin

A protein known for its association with thyroid hormones and retinol-binding protein, transthyretin was recently found to contain a Gla residue (Ruggeberg *et al.*, 2008). The role of this vitamin K-dependent modification is presently unknown. A summary of the VKDPs and their functions is given in Table 15.1.

## Vitamin K and Health

### Bone Health

The discovery of osteocalcin and the evidence that the glutamic acid residues it contained needed to be carboxylated for its function in bone soon fostered interest in the role of vitamin K nutrition in bone health. Numerous observational studies have been conducted over the years, opening the way to randomized control trials of vitamin K supplementation which have just recently become available. In observational studies, high phyloquinone intakes have been associated with lower risk of hip fracture in most studies in contrast to the relationship between phyloquinone intake and bone mineral density (BMD) which has been more variable. Reports from Japan have pointed to higher BMD and lower risk of hip fracture in individuals with a high consumption of the MK-7-rich food, natto. When investigated with respect to vitamin K nutritional status, increased levels of the ucOC, reflective of a low status, have been associated with increased risk of hip fracture in the elderly and lower BMD in both adults and children. However, and as reviewed in detail by Gundberg *et al.* (1998), the methodology for the estimation of ucOC is subject to numerous sources of variation, and, without proper standardization of the assay, ucOC values may not be reliable.

Associations between plasma phyloquinone, the menaquinones, and bone health have been more variable. These studies have recently been reviewed (Shea and Booth, 2008; Booth, 2009). One caveat of dietary associations is that they make it difficult to discern the specific role of vitamin K from those of other nutrients in the diet. Diets rich in vitamin K also tend to be rich in fruits and vegetables which in themselves are beneficial to

**TABLE 15.1** Summary of the vitamin K-dependent proteins and their functions

Protein category	Physiological functions	
Blood coagulation	Hemostasis	Cell Signaling-Related Actions
Prothrombin	Procoagulant	<i>Thrombin</i>
Factor VII	Procoagulant	Platelet aggregation
		Tumor growth and metastasis
		Angiogenesis
		Atherosclerosis and inflammation
		Cell survival
		Chemotaxis
Factor IX	Procoagulant	<i>FVII-FIX-tissue factor complex</i>
Factor X	Procoagulant	Pro-inflammatory action
Protein C	Anticoagulant	<i>Protein C</i>
Protein S	Anticoagulant	Anti-inflammatory action
		Anti-apoptotic actions
Protein Z	Anticoagulant	<i>Protein S</i>
		Anti-inflammatory and anti-apoptotic actions
		Phagocytosis of apoptotic cells
		Mitogenesis (VSMC)
		Neuronal protection
Bone		
Osteocalcin	Negative regulator of bone formation	
	Endocrine function	
Matrix Gla protein	Inhibitor of calcification*	
Protein S	Undetermined	
Others		
Gas6	Cell differentiation, proliferation, adhesion, and chemotaxis	
	Phagocytosis and protection from apoptosis	
TMGs	Undetermined	
Gla rich protein	Undetermined	
Periostin	Cell migration and angiogenesis	
Transthyretin	Ligand for thyroid hormones and retinol-binding protein	

TMG, transmembrane Gla; VSMC, vascular smooth muscle cells.

\*This role as calcification inhibitor applies to soft tissues as well as bone.

bone health (Tucker, 2009). Our recent access to large randomized control trials of vitamin K supplementation have been helpful in this regard. Data from five trials of phylloquinone (Braam *et al.*, 2003; Bolton-Smith *et al.*, 2007; Booth *et al.*, 2008; Cheung *et al.*, 2008; Binkley *et al.*, 2009) and four trials (one open label) of MK-4 (Shiraki *et al.*, 2000; Knapen *et al.*, 2007; Binkley *et al.*, 2009; Inoue *et al.*, 2009) of 1–3 years' duration are now available. Studies were mostly conducted in postmenopausal women (with or without osteoporosis) and included dosages ranging from 200 µg/day to 5 mg/day for phylloquinone and 45 mg/day for MK-4. In most studies calcium and vitamin D were also provided with the K vitamers. As

summarized in recent reviews (Booth, 2009; Iwamoto *et al.*, 2009), supplementation protocols led to increased circulating vitamers, decreased levels of ucOC and little or no change in bone resorption markers. With respect to bone outcomes, supplementation had little impact on BMD when assessed at the hip or other anatomical sites, with only one trial reporting increased BMD at the ultra-distal radius following 2-year supplementation with 200 µg/day phylloquinone (no effects were observed at the femoral neck and mid-radius) (Bolton-Smith *et al.*, 2007). In another trial, women who had been supplemented with 5 mg phylloquinone for 2 years presented fewer clinical fractures. As pointed out by the authors, however, this

result should be viewed with caution as the study had not been powered to examine fractures and their numbers were small (Cheung *et al.*, 2008). Results from a recent large MK-4 trial are also at odds with previous smaller studies. In the two trials that included their assessment, MK-4 supplementation had no effect on bone resorption markers. Furthermore, impact on bone was in general limited with one trial reporting improved bone mineral content and femoral neck width, but no effect on BMD (Knapen *et al.*, 2007), and another trial reporting, in post-hoc analysis, a lower incidence of vertebral fractures in patients with at least five vertebral fractures, but not in the whole group ( $n \approx 2000$ ) (Inoue *et al.*, 2009). None of the other trials reported any benefit from high phylloquinone or MK-4 intakes on bone. Clearly, results from these well-designed trials do not support the conclusions of previous observational studies and those of the smaller phylloquinone and MK-4 supplementation trials (Cockayne *et al.*, 2006). However, the role of vitamin K in bone is complex, and research needs to be pursued. In vitro studies have shown MK-4 to be a potent agonist of the steroid and xenobiotic nuclear receptor and to regulate the transcription of various bone-related genes including those of the extracellular matrix involved in collagen accumulation (reviewed in Horie-Inoue and Inoue, 2008). Finally, because individuals on warfarin therapy are by definition in states of chronic vitamin K deficiency, bone status in these patients has been investigated. A meta-analysis conducted some years ago associated warfarin treatment with a modest reduction in BMD at the radius but not at other sites (Caraballo *et al.*, 1999a). Studies of warfarin treatment and risk of fractures have also been discordant, some reporting negative impact (Caraballo *et al.*, 1999b) or no impact (Woo *et al.*, 2008) on bone fractures. Warfarin is used for a wide range of clinical entities and this may explain the inconsistencies of the current literature.

### **Cardiovascular Health**

In addition to the animal work described earlier, evidence for a role of vitamin K in calcification came with reports from genetic diseases. Individuals suffering from Keutel syndrome, a disorder characterized by abnormal cartilage calcification, have been shown to possess mutations of the MGP gene that result in non-functional MGP (Munroe *et al.*, 1999). Similarly, patients presenting with pseudoxanthoma elasticum, a multi-system disorder characterized by dystrophic mineralization of soft connective tissues, had a lower concentration of total MGP

compared with healthy controls (Hendig *et al.*, 2008). Immunohistochemical studies comparing normal and atherosclerotic human tissues showed MGP to be constitutively expressed in the vessel wall during calcification and in atherosclerotic plaque (Erkkila and Booth, 2008). However, the association between circulating MGP and calcification has been inconsistent. In one study, total MGP was inversely correlated with the severity of coronary artery calcification (Jono *et al.*, 2004) whereas it was positively associated with risk factors for atherosclerosis but not with coronary artery disease in another study (O'Donnell *et al.*, 2006). Assays targeting the inactive uncarboxylated form of MGP (ucMGP) have recently been developed (Schurgers *et al.*, 2005, 2010); however, reports using these assays have been difficult to interpret due to the different specificity of the antibodies. Whether circulating level of ucMGP is a useful surrogate marker of the calcification process requires further investigation. Furthermore, although the role of vitamin K in cardiovascular health has thus far been assumed to be through MGP, it must be kept in mind that other VKDPs, i.e. Gas6, GRP, and periostin, have been associated with the calcification process. Future studies should include these proteins as well.

The influence of dietary vitamin K in cardiovascular health has also been investigated through epidemiological studies. In the majority of cases, phylloquinone intakes have not been associated with cardiovascular disease (CVD) after adjustments for other risk factors. In contrast, high menaquinone intakes have been linked to reduced incidence of CVD and coronary calcification in three studies (reviewed in Erkkila and Booth, 2008; Booth, 2009; Rees *et al.*, 2010). The lack of association between phylloquinone intake and CVD is not surprising given that a high phylloquinone intake has been associated with a heart-healthy dietary pattern (Braam *et al.*, 2004a). The reported association between menaquinone intake and CVD is certainly interesting but will need to be replicated in future studies as issues have been raised regarding the relative validity of the food frequency questionnaires (FFQ) used in these studies. In contrast to phylloquinone (Presse *et al.*, 2009), no FFQ have been specifically validated for the menaquinones. Furthermore, because menaquinones are found in the diet in low amounts except for MK-7 in the Japanese diet, circulating MKs are usually at the limit of detection of current assessment methods. In light of this and as we aspire to better understand the impact of dietary MKs in cardiovascular health, future

studies should include state-of-the-art diet assessment tools. Two randomized control trials aimed at assessing the effect of phylloquinone on vascular health have been conducted to date. Supplementation with 1 mg of phylloquinone plus vitamin D and a mineral cocktail for 3 years improved the elastic and compliance properties of the common carotid artery in a group of postmenopausal women (Braam *et al.*, 2004b). More recently, supplementing older men and women with 500 µg of phylloquinone along with a multivitamin for 3 years slowed the progression of coronary artery calcification (CAC). In this study, the beneficial effect of phylloquinone on CAC was independent of changes in serum MGP (Shea *et al.*, 2009a). Additional intervention studies, notably trials of menaquinone supplementation, are warranted before it can be determined whether dietary vitamin K influences cardiovascular health in a clinically significant manner. Finally, there has been limited investigation of the impact of warfarin treatment on vascular calcification. Available cross-sectional studies have reported warfarin treatment to be associated with aortic valve (Koos *et al.*, 2009) and extra-coronary arterial (Rennenberg *et al.*, 2010) calcification. In contrast, warfarin exposure has not been associated with extent of coronary calcification in patients without apparent coronary heart disease participating in the Warfarin and Coronary Calcification Study (Villines *et al.*, 2009). Here also, large prospective studies are needed to determine whether warfarin treatment has a significant clinical impact on vascular health (Danziger, 2008).

## Emerging Functions for Vitamin K

### **Sphingolipid Synthesis**

Vitamin K is involved in the synthesis of sphingolipids, a group of complex lipids present in brain cell membranes and which possess important cell signaling properties. Administration of the vitamin K antagonist warfarin to growing rats has been shown to reduce brain sphingolipids and perturb key synthetic enzymes (reviewed in Denisova and Booth, 2005). MK-4, which represents >98% of total vitamin K in rat brain, is present in significantly higher concentrations in myelinated regions of the brain and is strongly correlated to the sphingolipids, sulfatides, sphingomyelin, and gangliosides (Carrié *et al.*, 2004). In a recent report, changes in sphingolipid profile were associated with cognitive deficits in old rats (Carrié *et al.*, 2011). Whether vitamin K through its action in sphingolipid metabolism has a role in neurodegenerative diseases such

as Alzheimer's disease (Presse *et al.*, 2008) remains to be determined.

### **Inflammation**

Menaquinone-4 has been shown to limit the production of interleukin-6 (IL-6) and of prostaglandins *in vitro*, and to limit inflammation in models of encephalomyelitis. Similarly, phylloquinone has been reported to suppress lipopolysaccharide-induced inflammation in the rat (reviewed in Shearer and Newman, 2008). Furthermore, recent epidemiological cohort studies have reported that a high vitamin K nutritional status is associated with lower levels of the proinflammatory markers IL-6, intracellular adhesion molecule-1, tumor necrosis factor receptor 2, and C-reactive protein (reviewed in Booth, 2009). The role of vitamin K in the inflammation process is a topic of much research interest.

### **Endocrine Function**

Menaquinone-4 is present in pancreatic juices (Thomas *et al.*, 2004), and studies conducted over 20 years ago have suggested that both phylloquinone and MK-4 could have a protective role against insulin resistance (reviewed in Booth, 2009). More recently, high phylloquinone intakes were reported to have beneficial effects on insulin resistance in healthy men and women, as determined by the homeostasis model assessment of insulin resistance (HOMA-IR) (Yoshida *et al.*, 2008a,b). It has been suggested that the VKDP osteocalcin could act as a hormone. In a series of reports, osteocalcin, notably its undercarboxylated form (ucOC), was shown to regulate glucose metabolism and fat mass in a transgenic mouse model (Lee *et al.*, 2007; Ferron *et al.*, 2008). The fact that only ucOC was associated with the endocrine effect of osteocalcin in these studies was not confirmed in recent epidemiologic cohort studies where the protective effect of a high phylloquinone intake on insulin resistance was associated with the carboxylated form of osteocalcin (Shea *et al.*, 2009b). Research aimed at elucidating the mechanisms of action of vitamin K in energy metabolism is ongoing.

### **Anti-cancer Effect**

Numerous *in vitro* and a few *in vivo* studies have suggested anti-carcinogenic effects for vitamin K, notably for MK-4. This protective role of vitamin K has been linked to its ability to influence cell differentiation and induce apoptosis (reviewed in Shearer and Newman, 2008). Recently, intakes of menaquinones, but not of phylloquinone, were

associated with reduced risk of cancer and mortality in the large EPIC-Heidelberg study (Nimptsch *et al.*, 2008, 2010). As for the other actions of vitamin K, its anti-cancer potential will have to be investigated in rigorous intervention trials.

## Deficiency

Clinically significant vitamin K deficiency is associated with an increase in prothrombin time and, in severe cases, bleeding. However, overt vitamin K deficiency is uncommon in adults and has mainly been associated with gastrointestinal disorders associated with fat malabsorption (e.g. bile-duct obstruction, inflammatory bowel disease, chronic pancreatitis, cystic fibrosis) and liver disease (Savage and Lindenbaum, 1983). Hospitalized patients with low food intake or poor nutritional status may also be at increased risk of vitamin K deficiency, especially if treated with antibiotics or other drugs interfering with vitamin K metabolism. Although bleeding episodes in antibiotic-treated patients have often been attributed to an acquired vitamin K deficiency resulting from a suppression of menaquinone-synthesizing organisms in the gut, data to substantiate this hypothesis are lacking. Furthermore, interpretation of these reports has generally been complicated by the possibility of general malnutrition in the patients under investigation (Institute of Medicine, 2001). However, newborn infants are a clinical population with a well established risk for vitamin K deficiency. Factors contributing to the condition are poor placental transfer, low concentrations of plasma clotting factors due to hepatic immaturity, and low vitamin K content of breast milk. Individually or in concert, these factors increase the risk of bleeding in infants in the first weeks of life, a condition known as vitamin K deficiency bleeding (VKDB) (Shearer, 2009). Because VKDB can be effectively prevented by administration of vitamin K, the American Academy of Pediatrics recommends that phyloquinone be given to all newborns as a single, intramuscular dose of 0.5–1 mg within 6 hours of birth (American Academy of Pediatrics Committee on Fetus and Newborn, 2003). Similarly, the WHO/FAO recommends that all breast-fed babies receive vitamin K supplementation at birth according to nationally approved guidelines, vitamin K formulations and prophylactic regimes differing from country to country (WHO/FAO, 2004). In preterm infants, a bolus of 0.2 mg (or 0.3 mg/kg) appears to be sufficient to protect during the neonatal period (Clarke,

2010). Reports in the early 1990s of an increased risk of leukemia and other forms of cancer in children who had received vitamin K intramuscularly at birth were not corroborated in subsequent studies, confirming the innocuousness of this prophylactic measure.

High doses of vitamin E have been shown to interfere with vitamin K and precipitate deficiency states, especially in subjects with low vitamin K status. In a study, 12 weeks' supplementation with 1000 IU *RRR*- $\alpha$ -tocopherol per day increased PIVKA-prothrombin (PIVKA-II) levels in adults not receiving oral anticoagulant therapy. In contrast, neither plasma phyloquinone nor ucOC was significantly affected by the supplementation regimen (Booth *et al.*, 2004). Although the clinical significance of the PIVKA-II changes observed in this study warrants further investigation, this study shows that high-dose vitamin E supplementation has the potential to interfere with vitamin K status. The interaction between vitamin K and E has recently been reviewed (Traber, 2008).

Patients treated with coumarin drugs undergo a particular drug–nutrient interaction as warfarin blocks the vitamin K cycle by inhibiting vitamin K epoxide reductase activity. In light of this tight coupling, alteration in vitamin K intake will influence warfarin efficacy, as has been reported on numerous occasions. The Institute of Medicine recommends that once the dose of warfarin has been established, individuals can avoid any complications resulting from variations in vitamin K intake by continuing to follow their normal dietary patterns (Institute of Medicine, 2001). However, recent studies have shown that anticoagulated patients who have low dietary intake of vitamin K are more likely to present unstable anticoagulation (Rombouts *et al.*, 2010). In fact a growing number of reports indicate beneficial effects of high intakes of vitamin K with respect to anticoagulation control (Kim *et al.*, 2010), and supplementing patients with small amounts of phyloquinone has also been shown to be beneficial (Sconce *et al.*, 2007). In a recent report, high usual dietary vitamin K intake was found to be associated with low relative variability in vitamin K intake, a finding that could partly explain the beneficial effect of high dietary vitamin K intake on anticoagulant therapy (Presse *et al.*, 2011).

## Requirements

The Food and Nutrition Board of the National Academy of Sciences updated the recommendations for vitamin K

in 2001 (Institute of Medicine, 2001). The recommended adequate intake (AI) for vitamin K is 120 µg/day for men and 90 µg/day for females. The AI for children during the first 6 months of life is 2 µg/day and from 7 to 12 months is 2.5 µg/day. AIs for children are 30 µg/day for ages 1–3 years, 55 µg/day for ages 4–8 years, 60 µg/day for ages 9–13 years, and 75 µg/day for ages 14–18 years. The recommendations for pregnancy and lactation are the same as for non-pregnant females of similar age (90 µg/day). No Tolerable Intake Level for vitamin K has been established.

In the United Kingdom, an amount of 1 µg of phylloquinone per kilogram body weight per day is being used as the official guideline for vitamin K and is based on the estimated average daily requirement for its role in blood clotting (Department of Health, 1991). This amount is also used by the WHO/FAO as part of their recommended nutrient intakes (RNI). Values for respective categories are: infants 0–6 months 5 µg/day, an intake that cannot be met by infants who are exclusively breast-fed; infants 7–12 months 10 µg/day; children 1–3 years 15 µg/day; children 4–6 years 20 µg/day; children 7–9 years 25 µg/day; adolescents 10–18 years 35–55 µg/day; adult females >19 years 55 µg/day; adult males >19 years 65 µg/day. The recommendations for pregnancy and lactation are the same as for non-pregnant females of similar age (55 µg/day) (WHO/FAO, 2004).

## Sources and Dietary Intakes of Vitamin K

The application of high performance liquid chromatography analysis to vitamin K and the development of relatively straightforward assay procedures have enabled analysis of a large number of foods in the last decade in both the US and in Europe. Vitamin K is found in a limited number of foods, with the green leafy vegetables contributing 40–50% of total intake, followed by certain oils. Mixed dishes were reported to contribute 15% of total intake by virtue of the oils added to the foods. Vegetables such as Swiss chard, spinach, and kale contain in excess of 300 µg phylloquinone/100 g, while broccoli, brussels sprouts, and cabbage contain between 100 and 200 µg phylloquinone/100 g (Booth and Suttie, 1998). The phylloquinone content of oils is variable, soybean and canola oils being the richest sources (100 and 200 µg/100 g), followed by olive oil whose content is slightly lower (50–100 µg/100 g). Oils derived from corn and sunflower seeds are not good sources of phylloquinone, with a content of

<10 µg/100 g. Hydrogenation of plant oils to form solid shortenings results in some conversion of phylloquinone to 2',3'-dihydrophylloquinone. This form of the vitamin is most prevalent in margarines and prepared foods and has been reported to contribute 15–30% of total phylloquinone intakes in the United States. The bioavailability and the relative biological activity of dihydrophylloquinone were shown to be lower than those of phylloquinone (Booth *et al.*, 2001). The menaquinones are not widely distributed in commonly consumed foods but can be found in animal-based foods (chicken, meats, etc.) and some cheeses (Schurgers and Vermeer, 2000; Elder *et al.*, 2006). Natto, a traditional Japanese dish made of fermented soybeans, is an excellent source of MK-7 (Kamao *et al.*, 2007).

The availability of reliable data on the vitamin K content of foods has now made it possible to obtain reasonable estimates of the dietary phylloquinone intake of the North American, European, and Asian populations. The results of a number of studies on phylloquinone intake have been summarized by Booth and Suttie (1998). These data are somewhat variable but indicate a mean phylloquinone intake of about 150 µg/day for older (>55 years) and 80 µg/day for younger men and women. Reported phylloquinone intakes in the UK and Ireland are comparable to these, albeit slightly lower, while those in The Netherlands and in China are higher (reviewed in Shearer and Newman, 2008). Intake and sources of phylloquinone from British children have also been published (Prynne *et al.*, 2005). Dietary intake data for the menaquinones are more limited but available data suggest that their contribution to total vitamin K intake does not exceed 10% (Schurgers and Vermeer, 2000).

## Toxicity

No toxicity for the natural form of vitamins K<sub>1</sub> and K<sub>2</sub> has been documented even when large amounts are administered (Institute of Medicine, 2001). However, synthetic menadione has been shown to produce hemolytic anemia, hyperbilirubinemia, and kernicterus when administered in amounts of more than 5 mg/day to infants. Consequently, menadione is no longer used as a therapeutic agent.

## Future Directions

Significant ground has been covered since the discovery of vitamin K. From a nutrient assumed to be strictly involved in blood coagulation, this vitamin has become a nutrient

of many physiological systems. The family of the vitamin K-dependent proteins now comprises proteins involved in bone remodeling, calcification processes, endocrine function, and cell-signaling events. Still, many aspects of vitamin K metabolism remain to be specified. For instance, although recent clinical trials do not appear to support a role for dietary vitamin K in bone health, research into the underlying action of vitamin K in bone should be pursued. Similarly, the role of vitamin K in cardiovascular health needs to be further investigated using randomized clinical trials to determine whether vitamin K nutriture has the potential to significantly influence cardiovascular risks. Finally, research efforts should focus on the emerging actions of the various K vitamers, i.e. sphingolipid metabolism, inflammation, endocrine function and anti-cancer effects, as they could have important public health impact. In light of this research agenda, the vitamin K field will continue to be an exciting one in the years to come.

## VITAMIN C

CAROL S. JOHNSTON, PhD, RD

*Arizona State University, Phoenix, Arizona, USA*

### Summary

Vitamin C is a potent reducing agent/antioxidant in animal species and land plants. Humans rely on vitamin C for the activity of enzymes involved in collagen, carnitine, and norepinephrine synthesis, and vitamin C status may impact physiological health, including risk for infections, cardiovascular disease, and cancer. The recommended daily intake for vitamin C is 90 mg/day for adult men and 75 mg/day for adult women, and the tolerable upper limit is 2000 mg/day. Supplemental vitamin C should not replace high intakes of fruits and vegetables, but may offer health benefits under certain circumstances for some individuals. Low intakes of fresh fruits and vegetables, either by choice or due to scarcity, increase the risk for scurvy, a concern for isolated populations, refugees, cancer patients, the critically ill, and the elderly. Smokers, individuals with diabetes, and adult men living alone are also at risk for suboptimal vitamin C status; in developed countries, current vitamin C deficiency rates range from 8% to 19%. Individuals with a history of renal stone formation or conditions associated with iron overload should use caution when supplementing vitamin C.

### Introduction

Long before vitamin C was utilized as a cofactor for enzymes in mammalian systems, it was a ubiquitous constituent of plants. The presence of duplicative biosynthetic pathways for vitamin C in algae and land plants suggests an important role for vitamin C in the evolutionary success of higher plants (Wolucka and Van Montagu, 2007). In the animal kingdom, invertebrates and teleost fish, the dominant fishes in oceans and fresh water, cannot manufacture vitamin C; however, primitive fish, amphibians, and reptiles produce vitamin C as do most mammals.

The extremely stressful conditions associated with terrestrial life, including high oxygen tension, desiccation by dry air, and hot sun, may have necessitated selection pressure for species capable of vitamin C synthesis (Chatterjee, 1973). However, several divergent lines of mammals (bats, guinea pigs, non-human primates, and man) lost the ability to synthesize vitamin C due to the absence of the terminal enzyme of the ascorbic acid synthetic pathway. Yet, vitamin C-dependent species possess a marked increase in both copper and zinc superoxide dismutases compared with the vitamin C-synthesizing amphibians, reptiles, and mammals, thereby maintaining

a strong defense system against oxygen toxicity (Nandi *et al.*, 1997).

Chatterjee (1973) calculated that the rate of vitamin C synthesis in small mammals ranged from 150 mg/kg body weight/day in rats to nearly 275 mg/kg body weight/day in rabbits and mice. In these species, the body pool of vitamin C ranged from 30 to 100 mg/kg and blood vitamin C concentrations varied from 0.5 to 1.0 mg/dL (28–57  $\mu\text{mol/L}$ ) (Dash *et al.*, 1984). In contrast, vitamin C-dependent humans consume only about 1 mg of vitamin C/kg body weight/day and maintain a body pool of vitamin C near 20 mg/kg and a plasma vitamin C concentration near 0.5–0.7 mg/dL (28–40  $\mu\text{mol/L}$ ) (Bluck *et al.*, 1996). Also, the half-life for vitamin C in humans (range: 14–40 days) appears to be orders of magnitude above that for rats or guinea pigs (3–6 days) (Blanchard, 1991). However, direct interspecies comparisons for ascorbate body-pool size and turnover are probably invalid owing to confounding related to variability in dosage level, baseline vitamin C status, stress level of subject, and/or analytical methods (Levine, 1986). Although incapable of manufacturing vitamin C, humans are particularly adept at conserving the vitamin since adequate plasma concentrations are maintained at lower intakes of vitamin C (~1 mg/kg per day) as compared with other vitamin C-dependent species (3–6 mg/kg per day) (Tillotson and O'Connor, 1980).

In guinea pigs and rats, as well as in primates, there is considerable conversion of vitamin C to carbon dioxide. Over 65% of an injected dose was excreted as carbon dioxide within 10 days in guinea pigs, with 20% of the dose catabolized to carbon dioxide within the first 24 hours (Burns *et al.*, 1951). In humans, this respiratory pathway seems insignificant since less than 5% of an injected dose appeared as carbon dioxide after a 10-day period. The principal route of excretion of vitamin C and its metabolites in humans is through the urine, mainly as oxalate and unmetabolized ascorbic acid. In 10 days, about 40% of an injected dose of ascorbic acid is excreted in the urine in humans compared with only 10% in guinea pigs (Hellman and Burns, 1958).

## Chemistry and Metabolism

Vitamin C was first isolated from the adrenal glands of cows in 1928 and termed “hexuronic acid” by the Hungarian scientist, Albert Szent-Györgyi. By 1932 the antiscorbutic property of hexuronic acid was established

FIG. 16.1 Oxidation of ascorbic acid.

independently by Szent-Györgyi and C.G. King of the University of Pittsburgh, and the compound was renamed “ascorbic acid.” Chemist Norman Haworth, in Birmingham, England, working in collaboration with Szent-Györgyi, elucidated the structure of ascorbic acid in 1933. Both men received a Nobel Prize in 1937 for their work leading to the discovery and structure of vitamin C.

Vitamin C is a redox-active system comprising L-ascorbic acid, the free radical monodehydro-L-ascorbic acid (AFR), and oxidized ascorbate or dehydro-L-ascorbic acid (DHA) (Figure 16.1). The ascorbate radical/ascorbate thermodynamic couple, the one-electron reduction potential, is below that of most physiological redox systems. Hence, ascorbic acid is a primary nonenzymatic antioxidant for many reactive compounds *in vivo*, including the  $\alpha$ -tocopherol free radical, the glutathione radical, peroxyl radicals, the hydroxyl free radical, the superoxide radical, and the urate free radical (Buettner and Jurkiewicz, 1993). AFR can be detected directly by electron spin resonance spectroscopy and is a useful measure of radical formation in biological systems and plasma (Stefansson *et al.*, 2008).

Ascorbic acid is a six-carbon, water-soluble (33 g/100  $\text{cm}^3$  at 20°C)  $\gamma$ -lactone (MW 176.14). Its acidic nature results from the ionization of the enolic OH on C-3 ( $\text{p}K_a$  4.25) at neutral pH. Liquid chromatography–electrochemical detection methods are considered the most sensitive and

precise systems for measuring ascorbic acid in biological samples. Currently, DHA cannot be detected directly in these systems and is measured indirectly by subtraction after its pre- or post-column reduction to ascorbic acid (Li and Franke, 2009). Ascorbic acid degrades rapidly in extracted plasma; hence, samples must be carefully handled and rapidly preserved and frozen. Procedures vary dependent on preservatives used. Plasma samples preserved with trichloroacetic acid should be collected in EDTA tubes and supernatants frozen at  $-70^{\circ}\text{C}$  within 1.5 hours of collection (Salminen and Alfthan, 2008). This preparation and storage preserves the ascorbic acid for up to 10 years. If meta-phosphoric acid is the precipitant, heparin vacutainers should be used, and the samples should be analyzed within 80 days (Karlsen *et al.*, 2007).

A simple and rapid enzymatic procedure using ascorbate oxidase and o-phenylenediamine was automated for use in clinical settings and correlated well with standard chromatographic analyses (Ihara *et al.*, 2000). A colorimetric procedure utilizing the reducing properties of ascorbic acid was also shown to provide plasma ascorbic acid results comparable to those from HPLC analyses (Chung *et al.*, 2001). Schaus *et al.* (1986) demonstrated that total ascorbic acid (ascorbate + DHA) analyses of isolated leukocytes using the 2,4-dinitrophenylhydrazine colorimetric method yielded results comparable to those from HPLC methodology.

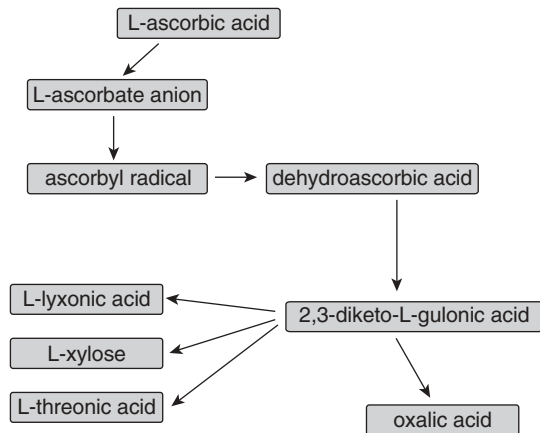

In all plant species tested, ascorbic acid is synthesized from GDP-D-mannose in the L-galactose pathway; in mammals the vitamin is synthesized from L-gulonate in the hexuronic acid pathway of the liver or kidney. In the vitamin C-dependent mammals, a genetic lesion inhibits the synthesis of L-gulonolactone oxidase, the terminal enzyme for ascorbic acid synthesis, and L-gulonate is processed via the pentose pathway to re-enter carbohydrate metabolism (Linster and Van Schaftingen, 2006).

Ascorbic acid is transported into cells via the sodium-dependent transporter SVCT1, located on epithelial cells; the sodium and  $\text{Ca}^{2+}/\text{Mg}^{2+}$ -dependent transporter SVCT2, widely distributed in metabolically active and specialized tissues, including brain, eye, placenta, osteoblast cells, adrenals, and endothelial tissues, transports ascorbic acid into metabolically active tissue cells (Godoy *et al.*, 2007). Hence, SVCT2 likely regulates ascorbic acid metabolism in tissues while SVCT1 regulates whole-body homeostasis. Oxidative stressors increase SVCT2 mRNA expression, whereas aging decreases SVCT1 mRNA expression (Rivas *et al.*, 2008).

Genetic variation in the gene that codes for the ascorbic acid transporter SVCT1, *SLC23A1*, has been associated with variations in circulating ascorbic acid concentrations in large population studies (Cahill and El-Sohemy, 2009; Timpson *et al.*, 2010). Also, glutathione S-transferase genotypes have been associated with risk for serum vitamin C deficiency, but only for individuals whose diets were marginal in vitamin C (Cahill *et al.*, 2009). These results demonstrate the important roles that this transport system plays in vitamin C homeostasis. Genetic variations in the SVCT2 transporter are associated with risk for cancer (Wright *et al.*, 2009) and preterm delivery (Erichsen *et al.*, 2006) indicating an important role for this transporter in vitamin C functionality.

In its metabolic roles, ascorbic acid is converted to AFR in blood and tissues. This radical does not contribute to free radical chain reactions *in vivo* since it is rapidly recycled to ascorbic acid via NADPH-dependent reduction by thioredoxin reductases or by microsomal or mitochondrial oxidoreductases which are present in all cell types (Kennett and Kuchel, 2006). At sites of marked oxidant stress, the dismutation of two molecules of AFR to DHA and ascorbic acid likely occurs. Although DHA undergoes irreversible hydrolysis with a half-life of less than 2 minutes, nearby cells can bind DHA via specific facilitative glucose transporter isoforms: GLUT1 (ubiquitous distribution), GLUT3 (largely confined to neuronal tissues), and GLUT4 (largely confined to muscle and adipose tissues) (Corti *et al.*, 2010). This uptake of DHA via glucose transporters by many cell types, followed by the immediate two-electron reduction of DHA to ascorbic acid by several mechanisms (glutathione-dependent systems or NADPH-dependent systems mediated by thioredoxin reductase or by  $3\alpha$ -hydroxysteroid dehydrogenase), suggests an efficient system for the recycling and salvaging of vitamin C at sites of high oxidative stress (Nualart *et al.*, 2003).

Possibly this “bystander effect” would increase the intracellular antioxidant defense capacity of targeted tissues when the need is greatest. Yet, under normal physiologic conditions, DHA concentrations would be low and the circulating glucose would successfully compete with DHA for the GLUT transporters minimizing this recycling pathway (Corti *et al.*, 2010). Moreover, research in SVCT2 knockout mice clearly demonstrates that this recycling pathway is not sufficient in the absence of direct ascorbic acid transfer into cells. In mutant mice lacking SVCT2 as a result of allele deletion, respiratory failure and severe

**FIG. 16.2** Catabolism of ascorbic acid.

cerebral hemorrhaging occurred immediately after birth, indicating the vital role of ascorbic acid transport via SVCT2 (Sotiriou *et al.*, 2002).

If not recycled to ascorbate, DHA is irreversibly delactonized to 2,3-diketogulonic acid, and its further degradation to oxalic acid likely represents the major catabolic pathway of vitamin C in nonsupplementing individuals. Other possible catabolic products of vitamin C include L-threonic acid, L-xylic acid, L-lyxonic acid, and L-xylose (Figure 16.2). In a carefully conducted vitamin C depletion–repletion pharmacokinetic study in seven healthy in-patient volunteers, the bioavailability of an orally administered dose of ascorbic acid ranged from 100% at 200 mg, 73% at 500 mg, and 49% at 1250 mg (Levine *et al.*, 1996). At these same doses, the fraction of ascorbic acid excreted unmetabolized after 24 hours was approximately 50%, and at steady state (once plasma ascorbic acid reached a plateau) the 24-hour oxalate excretion was approximately 30, 35, and 40 mg.

In subjects administered intravenous ascorbic acid (1.5 g/kg or approximately 100 g), within 6 hours, about 80% of the administered dose was excreted unmetabolized and <0.5% of the administered dose was excreted as oxalic acid (80 mg oxalic acid) (Robitaille *et al.*, 2009). In healthy adults, oxalate excretion averages about 25 mg/day, and normal oxalate excretion is considered to be less than 40 mg/day. Thus, practitioners utilizing high-dose intravenous vitamin C therapy need to recognize the possibility of hyperoxaluria.

## Biochemical Functions

As a cofactor for mixed function oxidases, vitamin C participates in the synthesis of various macromolecules including collagen, carnitine, and norepinephrine. In these reactions, vitamin C promotes enzyme activity by maintaining metal ions in the reduced form. In collagen and carnitine syntheses,  $\alpha$ -ketoglutarate-dependent dioxygenases incorporate one atom of oxygen into succinate and one into the oxidized product of the substrate in the presence of ferrous iron. Three ascorbate-dependent dioxygenases are required for the synthesis of collagen (prolyl 4-hydroxylase, prolyl 3-hydroxylase, and lysyl-hydroxylase), and two are involved in carnitine biosynthesis (6-N-trimethyl-L-lysine hydroxylase and  $\gamma$ -butyrobetaine hydroxylase). Many of the symptoms of the vitamin C deficiency disease scurvy are attributed to weakened collagenous structures and insufficient tissue carnitine: fatigue and lassitude, bleeding and gum deterioration, impaired wound healing, and epiphyseal and metaphyseal plate lesions in bone. Oral vitamin C repletion (10–15 mg/kg/day) results in rapid resolution of the hemorrhagic and bone abnormalities in scurvy (Karthiga *et al.*, 2008; Vitale *et al.*, 2009).

Hughes *et al.* (1980) first postulated that reduced muscle carnitine was responsible for the marked fatigue characteristic of vitamin C depletion and early scurvy. Carnitine is necessary for the transport of long-chain fatty acids into the mitochondrial matrix for oxidation, and plays an important role in energy metabolism. Individuals with myopathies associated with primary carnitine deficiency report muscle weakness and fatigability (Vielhaber *et al.*, 2004); however, to date, muscle carnitine analyses in human scurvy have not been conducted. In cultured guinea-pig hepatocytes, supplemental vitamin C resulted in enhanced carnitine synthesis and the stimulation of beta-oxidation (Ha *et al.*, 1994).

Vitamin C is also considered to be the predominant reductant for two copper-dependent enzymes: dopamine  $\beta$ -hydroxylase (used in the synthesis of norepinephrine from dopamine in the adrenal medulla) and peptidylglycine  $\alpha$ -amidating monooxygenase (used in the amidation, and therefore activation, of various hormones and neurotransmitters) (Bornstein *et al.*, 2003; Bousquet-Moore *et al.*, 2010). A role for vitamin C in these reactions may explain the high concentrations of vitamin C in the adrenal and pituitary glands, 30–40 mg/100 g versus 10–15 mg/100 g in most other tissues. Given the roles of

norepinephrine in the regulation of arousal and adaptation to stressors, and the fact that peptidylglycine  $\alpha$ -amidating monooxygenase controls the production of more than one half of all neuropeptides, the involvement of vitamin C in these synthetic pathways suggests an important yet largely unexplored role of this nutrient in neuroendocrine biology.

Although the impact of ascorbic acid in cell culture media is difficult to interpret (Osiecki *et al.*, 2010), recent investigations utilizing cDNA microarray analysis showed that vitamin C affects gene expression in human skin fibroblasts (increasing expression of DNA replication and repair genes) and in rat CNS precursor cells (increasing expression of pro-collagen type 1 alpha 2, transferrin, tyrosine hydroxylase, and interferon alpha-inducible protein) (Yu *et al.*, 2004; Duarte *et al.*, 2009). Vitamin C-induced cell differentiation is a novel molecular mechanism of vitamin C and suggests an important role for vitamin C in intracellular signaling cascades. Other work demonstrates a facilitator role for vitamin C in the reprogramming of somatic cells to pluripotent stem cells, possibly by increasing the activity of epigenetic regulating factors such as histone demethylases (Esteban *et al.*, 2010).

## Physiological Functions

Supplemental vitamin C has been demonstrated to enhance immune parameters in certain patient populations, including neutrophil activation in sepsis and Chediak-Higashi syndrome, natural killer cell activity in thalassemia, and improved neutrophil motility in furunculosis (Weening *et al.*, 1981; Vohra *et al.*, 1990; Levy *et al.*, 1996; Atasever *et al.*, 2006). However, these are isolated reports amid many that show no benefit, and a definitive role for vitamin C in immunoresponsiveness has not been established. As an effective scavenger of reactive oxygen species, vitamin C may minimize the oxidative stress associated with the respiratory burst of activated phagocytic leukocytes, thereby functioning to control the inflammation and tissue damage associated with immune responses (Wintergerst *et al.*, 2006). *In vitro*, vitamin C directly inhibited NF- $\kappa$ B activation and selectively inhibited inflammatory cytokine production in monocytes, suggesting a possible antioxidant-independent effect of vitamin C in controlling inflammatory responses (Bowie and O'Neill, 2000; Härtel *et al.*, 2004).

The addition of ascorbic acid to virally infected cultured cells reduced virus multiplication, but this antiviral activity was related specifically to ascorbic acid-derived oxidation

products including dehydroascorbic acid and hydroxyl radicals (Furuya *et al.*, 2008). Topical application of ascorbic acid in patients with herpes simplex virus infections decreased the duration of the lesions and viral shedding (Hamuy and Berman, 1998), and intravenous ascorbic acid in the treatment of herpetic neuralgia resulted in immediate remission of the neuropathic pain and remission of the cutaneous lesions within 10 days in two patients (Schencking *et al.*, 2010). In a randomized clinical trial, intravenous administration of ascorbic acid for 1 week reduced spontaneous pain in postherpetic neuralgia patients as compared with the saline control, but ascorbate therapy did not improve brush-evoked mechanical pain in these patients (Chen *et al.*, 2009). In patients recovering from wrist fractures, oral vitamin C dosing (200–1500 mg/day) reduced the occurrence of complex regional pain syndrome for up to 350 days (Zollinger *et al.*, 2007). These reports suggest a possible role for vitamin C therapy in pain management.

Serum vitamin C was inversely related to seroprevalence of *Helicobacter pylori* in a large, population-based US sample (Simon *et al.*, 2003). In a randomized, controlled trial ( $n = 312$  patients with *H. pylori* infection), the addition of vitamin C (500 mg/day) to the standard *H. pylori* treatment regimen significantly improved the *H. pylori* eradication rate by nearly 60% (from 49% to 78%) (Zojaji *et al.*, 2009). Others have also noted beneficial effects of supplemental vitamin C in combination with *H. pylori* eradication regimens in randomized clinical trials (Kaboli *et al.*, 2009; Sezikli *et al.*, 2009). However, these improvements in eradication rates may be related to reductions in antibiotic resistance, differences in genetic composition, and/or geographical localization, and not to a direct antiviral effect of vitamin C (Filik, 2010).

The role of supplemental vitamin C in combating the common cold has long been debated, and although the majority of randomized clinical trials show no effect of vitamin C for reducing the incidence or duration of colds in the general population, there are some notable exceptions. A meta-analysis of 30 controlled trials concluded that vitamin C supplementation reduced the incidence of colds in people under stressful conditions such as severe physical activity or cold environments but not in normal, unstressed people (Douglas *et al.*, 2007). A 5-year randomized, double-blinded, placebo-controlled trial demonstrated that vitamin C supplementation (500 mg/day) reduced the frequency of colds by 20%, and reduced the risk of suffering more than two cold episodes over a 3-year

period by 66% compared with the placebo treatment (50 mg vitamin C/day) (Sasazuki *et al.*, 2006).

In a randomized controlled trial, vitamin C (1500 mg/day for 2 weeks) protected against exercise-induced airway narrowing in patients with asthma, possibly due to reductions in the proinflammatory eicosanoids related to bronchoconstriction (Tecklenburg *et al.*, 2007). Also, supplementation with 250 mg of vitamin C/day for 6 weeks significantly reduced (by 50%) monocyte ICAM-1 mRNA expression in healthy male subjects (Rayment *et al.*, 2003); ICAM-1 is an adhesion molecule associated with the airway hyperresponsiveness that is characteristic of the common cold, allergic asthma, and seasonal allergic rhinitis. Low vitamin C status has also been associated with risk of lung infections, particularly pneumonia (Hemilä and Louhiala, 2007).

Current evidence suggests possible roles of vitamin C in the promotion of vascular health beyond its role as a general antioxidant (Frikke-Schmidt and Lykkesfeldt, 2009). In coronary heart disease (CHD) oxidative stress reduces intracellular concentrations of the vasodilator nitric oxide (NO) and elevates vascular cell adhesion molecules and proinflammatory substances. Vitamin C stimulates endothelial NO synthesis by attenuating the oxidative degradation of tetrahydrobiopterin, an essential cofactor for endothelial NO synthase (Kim *et al.*, 2006). Additionally, vitamin C reduced plasma concentrations of the cell adhesion molecule P selectin and the inflammatory cytokine, IL-6, a mediator of local inflammation and vascular dysfunction (Tahir *et al.*, 2005; Böhm *et al.*, 2007). Vitamin C administration has been shown to reverse endothelial dysfunction in patients with hypertension, diabetes, and stable angina (Anderson *et al.*, 2006; Holowatz and Kenney, 2007) and to reverse ischemia-reperfusion-induced endothelial dysfunction in healthy subjects, subjects with peripheral arterial disease, and smokers (de Sousa *et al.*, 2005; Pleiner *et al.*, 2008).

Although several large randomized clinical trials did not show clear benefits of supplemental vitamin C for reducing risk of CHD or for improving clinical symptoms in patient populations (Hasnain and Mooradian, 2004; Willcox *et al.*, 2008), other evidence suggests that vitamin C regimens may have clinical value. In a randomized controlled trial, vitamin C (500 mg/day) reduced restenosis 26% and increased the minimal lumen diameter 30% in patients recovering from coronary angioplasty (Tomoda *et al.*, 1996). Pooled analyses from several clinical trials ( $n = 156\,949$ ) revealed that subjects who took >700 mg

vitamin C daily had a significant 25% lower risk for CHD compared with subjects who did not take supplemental vitamin C, a finding that remained significant after adjustment for healthy lifestyles (Knekt *et al.*, 2004). However, in the subjects that did not supplement vitamin C, dietary vitamin C was not related to CHD risk. In a 5-year prospective study of 1605 randomly selected men (42–60 years), those with vitamin C deficiency at baseline (plasma vitamin C <0.2 mg/dL) were at significantly increased risk of myocardial infarction after controlling for confounding variables (Nyyssonen *et al.*, 1997). For patients receiving cardiac catheterization treatment, a low plasma vitamin C concentration predicted the presence of an unstable coronary syndrome as indicated by atherosclerotic lesion activity (Vita *et al.*, 1998).

Many large prospective trials show modest, inverse relationships between vitamin C status and cancer incidence and/or mortality, particularly in men; and, recent meta-analyses suggest that vitamin C may possibly protect against lung, breast, and esophageal cancers (Cho *et al.*, 2006; Kubo and Corley, 2007). Yet, short-term prospective intervention trials did not demonstrate an anti-cancer role for supplemental vitamin C (120 mg/day for 5 years on the incidence of esophageal, stomach, or colon cancers or 500 mg/day for 8 years on the incidence of prostate or total cancer in men) (Blot *et al.*, 1993; Gaziano *et al.*, 2009). However, the progression of *H. pylori* infection to gastric dysplasia or gastric cancer was reduced by 80% in individuals with adequate serum vitamin C status (>0.55 mg/dL) compared with those who had below-adequate status (You *et al.*, 2000).

Although investigations show that vitamin C reduces DNA and protein oxidative damage *in vivo*, providing plausible mechanisms for an anti-cancer effect of vitamin C, current interest is focused on the efficacy of high-dose vitamin C injection therapy as a cancer treatment (Frei and Lawson, 2008). At pharmaceutical concentrations in biological systems, vitamin C acts as a pro-oxidant generating H<sub>2</sub>O<sub>2</sub> that directly destroys cancer cells but not normal cells. Although case studies report success with high-dose intravenous vitamin C therapy (Padayatty *et al.*, 2006), a phase I clinical trial in 24 patients with advanced cancers did not demonstrate an objective anti-cancer response with intravenous vitamin C (0.4 to 1.5 g/kg fixed dosages three times weekly) in any patient (Hoffer *et al.*, 2008). Vitamin C may also promote anti-cancer effects by inhibiting cancer metastases although the mechanism of this effect is not known (Pollard *et al.*, 2010).

For the many pathological conditions associated with oxidative stress and reactive radicals, including cataract, macular degeneration, Alzheimer's disease, and rheumatoid arthritis, the total antioxidant capacity of tissues is an important preventive measure. Vitamin C regenerates vitamin E as well as antioxidant polyphenols and acts in synergy with these antioxidants, and with glutathione and selenium, to promote maximal antioxidant protection (Cuddihy *et al.*, 2008; Iglesias *et al.*, 2009).

High intakes of vitamin C have been related to higher bone mineral density in older adults (Sahni *et al.*, 2008). Recent research suggested that vitamin C has cofactor roles in several transcription and enzymatic reactions that regulate osteoblast differentiation (Gabbay *et al.*, 2010). Vitamin C status is also inversely related to adiposity in adults (Johnston *et al.*, 2007). Plausibly, obesity-induced inflammation may accelerate the metabolism of vitamin C *in vivo*, reducing plasma concentrations of the vitamin; however, some evidence has shown that vitamin C promotes locomotive behaviors and lipolytic responses in cafeteria-diet-fed rats (García-Díaz *et al.*, 2009) and inhibited gene expression linked to obesity onset (García-Díaz *et al.*, 2007).

Non-heme iron absorption from test meals is enhanced two- to threefold in the presence of 25 to 70 mg of vitamin C, a consequence of the ascorbate-induced reduction of ferric iron to ferrous iron, the form less likely to bind phytates. Recent evidence suggests that vitamin C also promotes duodenal ferric reductase activity in iron-deficient subjects but not in iron-replete subjects (Atanasova *et al.*, 2005). In animal models, vitamin C deficiency reduces the activity of hepatic cholesterol 7  $\alpha$ -hydroxylase, affecting the catabolism of cholesterol to bile acids and the risk for gall-bladder disease, and reduces serum uric acid via a uricosuric effect. Prospective trials in adult populations have demonstrated protective effects of vitamin C for reducing risk for gallstones and for gout (Choi *et al.*, 2009; Walcher *et al.*, 2009).

## Deficient and Marginal Status

Functional measures of vitamin C status are not currently available, and vitamin C concentrations in plasma or leukocytes are used to determine vitamin C status. Leukocyte concentrations are difficult to measure and interpret; hence, the measurement of plasma vitamin C is the most widely applied test for vitamin C status. Plasma concentrations  $<0.2$  mg/dL (11  $\mu$ mol/L) indicate vitamin C defi-

ciency, and concentrations between 0.2 and 0.5 mg/dL (11 and 28  $\mu$ mol/L) represent marginal vitamin C status, defined as moderate risk for developing vitamin C deficiency due to inadequate tissue stores. Intakes at the recommended level, 75–90 mg/day, are associated with plasma vitamin C concentrations near 0.8 mg/dL (45  $\mu$ mol/L), and tissue saturation is achieved at intakes from 100 to 200 mg/day, corresponding to plasma concentrations near 1.0 mg/dL (about 60  $\mu$ mol/L) (Levine *et al.*, 1996).

Subcutaneous and intramuscular hemorrhages, leg edema, neuropathy, and cerebral hemorrhage characterize scurvy, the vitamin C deficiency disease, and these symptoms are generally attributed to weakened collagenous structures. If untreated, the condition is ultimately fatal. Throughout the course of civilization, scurvy has plagued whole populations without access to fresh fruits and vegetables. Scurvy continues to be observed in developed nations, particularly among alcoholics, institutionalized elderly, men who live alone, and individuals who consume restrictive diets. Patients complain of lassitude, weakness, and general malaise, and seek medical advice following the appearance of a skin rash, lower extremity edema, and bone pain.

Data from the second National Health and Nutrition Examination Survey (NHANES II) conducted in the US from 1976 to 1980 indicated that the prevalence of vitamin C deficiency ranged from 0.1% in children (3–5 years) to 3% in females (25–44 years) and 7% in males (45–64 years) (Fulwood *et al.*, 1982). The prevalence of marginal vitamin C status ranged from 17% in adult females to 24% in adult males. In the most recent NHANES data analyses (2003–2004), vitamin C deficiency rates ranged from 8 to 11% for women and men (20–39 years and 20–59 years, respectively) (Schleicher *et al.*, 2009). Marginal vitamin C prevalence rates for adults have remained fairly stable over the past 25 years (20–23%) (Hampl *et al.*, 2004). Vitamin C deficiency rates for Canadian and low-income European citizens have also been reported recently (14% and 19% respectively) (Mosdól *et al.*, 2008; Cahill *et al.*, 2009).

## Dietary Requirements

In 2000 the Panel on Dietary Antioxidants and Related Compounds of the Institute of Medicine, a part of the United States National Academies, released the Dietary Reference Intakes (DRI) for vitamin C (Table 16.1)

**TABLE 16.1** Daily vitamin C recommendations for age and gender groups by various health agencies

Age (gender) group	Vitamin C/day (mg)			
	RDA IOM	RNI WHO/FAO	RNI UK	RDA NIHN
0–6 months	40 <sup>a</sup>	25	25	40 <sup>b</sup>
7–12 months	50 <sup>a</sup>	30	25	40 <sup>b</sup>
1–3 years	15	30	30	40–45
4–8 years	25	30–35	30	45–70
9–13 years (boys)	45	35–40	30–35	70–100
14–17 years (boys)	75	40	35–40	100
9–13 years (girls)	45	35–40	30–35	70–100
14–17 years (girls)	65	40	35–40	100
19+ years (men)	90	45	40	100
19+ years (women)	75	45	40	100
14–18 years (pregnant)	80	55	50	110
19–50 years (pregnant)	85	55	50	110
14–18 years (lactating)	115	70	70	150
19–50 years (lactating)	120	70	70	150

RDA, recommended dietary allowance; RNI, reference nutrient intake; IOM, Institute of Medicine of the United States National Academies; WHO/FAO, World Health Organization/Food and Agricultural Organization of the United Nations; UK, United Kingdom; NIHN, National Institute of Health and Nutrition, Japan.

<sup>a</sup>Estimated average requirement.

<sup>b</sup>Adequate intake.

(Institute of Medicine, 2000). For adult men, the estimated average requirement (EAR) for vitamin C, the level of intake that is estimated to meet the requirements of half the healthy individuals in a life stage and gender group, was set at 75 mg/day to maintain near-maximal tissue concentrations of vitamin C and provide antioxidant protection. The estimated requirement for adult women, 60 mg/day, was extrapolated based on body weight differences from the EAR for men.

The RDAs were calculated as 120% of the EAR, and are believed to cover the needs of 97–98% of individuals in a group (90 and 75 mg/day for adult men and women, respectively). Older age groups (>50 years) have decreased lean body mass compared with their younger counterparts; however, the DRIs for older men and women were not decreased from that for younger adults because oxidative stress, which causes higher vitamin C needs, increases with age. Smokers should consume an additional 35 mg of vitamin C daily, totaling 125 mg/day for adult men and 110 mg/day for adult women, due to increased oxidative stress.

Higher vitamin C intakes were recommended for pregnant and lactating women to offset losses from maternal

body pools (Table 16.1). RDAs for children ranged from 15 to 25 mg/day for younger children and from 45 to 75 mg/day for preadolescents and adolescents. Since there were no functional criteria for vitamin C status in infants, the recommended intakes of vitamin C at this age level were based on adequate intakes (AI), reflecting the vitamin C ingestion of mainly breast-fed infants (Table 16.1).

The World Health Organization and Food and Agriculture Organization of the United Nations (WHO/FAO, 2002) set the recommended nutrient intake for vitamin C at 45 mg/day for all adults and elderly individuals including smokers, a value estimated to achieve 50% tissue saturation in 97.5% of this population. Pregnant and lactating women require an additional 10 and 20 mg daily; recommended intakes were arbitrarily set at 25 mg/day for infants, gradually rising to 40 mg/day for adolescents (Table 16.1). The United Kingdom's Food Standards Agency recommended vitamin C intakes of 40 mg/day for adults and 50 and 70 mg/day for pregnant and lactating women respectively (COMA, 1991). The Ministry of Health, Labour and Welfare of Japan set the dietary reference intakes for vitamin C at 40 mg/day for infants and children up to 2 years of age; the recommendation

gradually rises to 80 mg/day for children 10–11 years of age and to 100 mg daily for all age categories 12 years and older (Sasaki, 2008). For pregnant and lactating women, the recommendations are 110 and 150 mg daily (Table 16.1).

High doses of vitamin C (as high as 2 g/day) are well tolerated by healthy individuals. Based strictly on reports of gastrointestinal disturbances, a tolerable upper intake level for vitamin C was set at 2000 mg/day for adults by the Institute of Medicine (2000). The upper intake level represents a dosage level that with high probability is tolerated biologically and provides guidance to individuals using dietary supplements. Claims that high-dose vitamin C regimens may lead to rebound scurvy, the iron-catalyzed oxidation of ascorbic acid, red blood cell hemolysis, and vitamin B<sub>12</sub> deficiency do not withstand scientific scrutiny.

Because dietary vitamin C may enhance mealtime iron absorption, high-dose vitamin C regimens may aggravate conditions associated with increased iron absorption and storage, notably hemochromatosis. About 0.5% and 10% of the US population are homozygous and heterozygous, respectively, for the hemochromatosis *HFE* gene mutation. The addition of vitamin C fortified orange juice to a test meal did increase non-heme iron absorption in homozygous patients compared with controls (Lynch *et al.*, 1989), but increased iron absorption was not observed in patients heterozygous for the *HFE* gene mutation (Hunt and Zeng, 2004). Analyses of NHANES data from 1976 to 1980 showed that women with the highest serum vitamin C concentrations (>2.1 mg/dL or 116 μmol/L) had a twofold increased prevalence of elevated serum ferritin levels (Simon and Hudes, 1999).

Vitamin C supplementation may also have adverse effects on thalassemia major, an iron-overload disease characterized by impaired globin chain synthesis. Cases are usually diagnosed in the first year of life, and blood transfusions are often required for survival. In the absence of chelation therapy, iron accumulation in parenchymal tissues is associated with progressive dysfunction of the heart, liver, and endocrine glands. Vitamin C supplementation by patients may mobilize iron stores, creating iron-overloaded plasma and risk for increased oxidative stress (Diav-Citrin *et al.*, 1999). Vitamin C supplementation in these patients should be coordinated with chelation therapy.

High-dose vitamin C regimens increase urinary excretion of oxalic acid and uric acid, constituents of renal

calculi, and, theoretically, may promote the formation of kidney stones. Epidemiologic investigations have reported mixed results regarding a direct association between vitamin C supplementation and stone incidence. In one large prospective trial (51 529 men), the annual number of additional incidental kidney stones was 0.84 per 1000 for those consuming >90 mg vitamin C daily (Taylor *et al.*, 2004).

## Future Directions

Research into the contribution of vitamin C deficiency to morbidity and mortality is needed since 8–19% of North American and European citizens fall into this category. Diet–gene interactions are important considerations for trials examining associations between vitamin C intake and disease risk. Also, because it is inexpensive and relatively non-toxic, continued investigation of the potential benefits of supplemental vitamin C should be pursued.

## THIAMIN

LUCIEN BETTENDORFF, PhD

*University of Liège – GIGA-Neurosciences, Liège, Belgium*

### Summary

Thiamin (vitamin B<sub>1</sub>) was the first vitamin to be characterized and from its discovery originated the vitamin concept. Thiamin deficiency mainly affects the nervous system and causes two classical diseases, beriberi (a polyneuritic syndrome) and Wernicke–Korsakoff syndrome (anterograde amnesia resulting from brain lesions in alcoholics). Thiamin transport across cell membranes requires specific carriers. As this process is slow, various lipid-soluble thiamin precursors with better bioavailability have been developed. In the cytosol, thiamin is pyrophosphorylated to thiamin diphosphate (ThDP), an indispensable cofactor in cell energy metabolism. Therefore, thiamin deficiency causes decreased cofactor function, leading to neuronal death. In addition, the non-cofactor roles of the triphosphorylated derivatives thiamin triphosphate and adenosine thiamin triphosphate may play a part in metabolic regulation and may contribute to the pathology of thiamin-deficiency-induced brain lesions. Current research interest is focused on the metabolism and role of thiamin derivatives (especially in catalysis by ThDP-dependent enzymes) and the biochemical and pathophysiological mechanisms by which thiamin deficiency induces specific brain lesions and may be implicated in other disorders such as Alzheimer's disease and diabetes.

### Introduction

Thiamin (thiamine, Figure 17.1A) is a water-soluble vitamin of the B group (vitamin B<sub>1</sub>, aneurin). Most bacteria, fungi, and plants are able to synthesize thiamin *de novo*, whereas animals solely rely on exogenous sources. Nutritional thiamin deficiency leads to beriberi, a polyneuritic syndrome. Beriberi used to be a major public health problem in East Asia, especially in the nineteenth century, because the population in these countries relied

heavily on polished rice (poor in thiamin) as staple food. A rare cardiovascular form of beriberi (wet beriberi, shoshin beriberi) leading to congestive heart failure is also sometimes observed. Another, relatively common form of thiamin deficiency, Wernicke–Korsakoff syndrome, affects the central nervous system and is generally associated with chronic alcoholism.

Free thiamin has no known physiological role, but thiamin diphosphate (ThDP, Figure 17.1A), formerly called thiamin pyrophosphate or cocarboxylase, is an

**FIG. 17.1** Structure of thiamin derivatives. A, Natural derivatives; B, formation of the catalytic ylide intermediate; C, tricyclic fluorescent thiochromes.

essential cofactor in cell energy metabolism. As is the case for thiamin, several other B vitamins such as riboflavin (B<sub>2</sub>), niacin (B<sub>3</sub>), and pantothenic acid (B<sub>5</sub>) are also precursors of cofactors required for mitochondrial energy production (Depeint *et al.*, 2006). In addition to ThDP, two other phosphorylated derivatives, thiamin monophosphate (ThMP) and thiamin triphosphate (ThTP), have been known for many years (Makarchikov *et al.*, 2003). More recently, adenylated thiamin derivatives, adenosine thiamin triphosphate (AThTP) and adenosine thiamin diphosphate have been described (Bettendorff *et al.*, 2007; Frédéricich *et al.*, 2009). The biological roles of derivatives other than ThDP are still unclear, especially in eukaryotic organisms.

## The Discovery of Vitamins: Thiamin and the Biochemical Lesion

The discovery of thiamin is a well-known story (Carpenter, 2000) from which originated the concept of vitamins and other food accessory factors. Beriberi was described in Chinese medical texts as early as 4000 years ago. The first description of beriberi in Japan appeared in the ninth century, but its relationship with diet was not suspected until the end of the nineteenth century. In 1884, a Japanese navy surgeon, Kanehiro Takaki, noticed that sailors were protected from beriberi when their diet was supplemented with condensed milk, bread, and meat in addition to the basic food consisting of polished rice (Takaki, 1885). In

1890, the Dutch physician, Christiaan Eijkman, working at the Laboratory of Bacteriology and Pathology in Batavia (now Djakarta), made the significant observation that fowl, when fed on polished rice, soon died from paralysis. Their peripheral nerves revealed histological signs of degeneration analogous to those described in human beriberi (Eijkman, 1990). In chickens, the early symptoms could be reversed by switching to whole rice.

Gerrit Grijns, Eijkman's successor in Batavia, correctly recognized that polyneuritis was caused by the lack of an essential substance virtually absent in the endosperm but present in the husk of the rice (Grijns, 1901). At the same time, the vitamin concept started to be developed by the English biochemist Frederick Hopkins, who first postulated that food must contain, in addition to the well-known fundamental components, i.e. proteins, sugars, and fats, "accessory factors" that, although present in only low amounts, are none the less indispensable for the normal functioning of the organism. The anti-beriberi factor had been called "vitamine" because it contained an amino group, but the final e was dropped when it was recognized that not all accessory factors were amines. It took many years to isolate the anti-beriberi factor, which was finally obtained in pure crystals by B.C.P. Jansen and W.F. Donath in 1926, also in Batavia (Jansen and Donath, 1926). The American chemist R.R. Williams determined its structure in 1934 and synthesized the vitamin for the first time (Williams and Cline, 1936). It was first called "aneurin" for *anti-neuritic vitamin* but later it was internationally agreed that it should be named "thiamin" for "sulfur-containing vitamin"; however, its exact properties and role remained unknown.

The first clues concerning the fundamental role of thiamin in carbohydrate metabolism were provided by the classical studies carried out from 1929 to 1940 by Peters and associates, using the thiamin-deficient pigeon as a model. The deficient birds (fed on polished rice) show a typical head retraction behavior called opisthotonos. Remarkably, thiamin administration at an early stage of the deficiency allows a complete recovery within 30 minutes. As no morphological brain lesions were observed before or after thiamin treatment, these observations led to the concept of "biochemical lesion."

What is the nature of this biochemical lesion? In 1937, Lohman and Schuster demonstrated that ThDP was an indispensable cofactor for the oxidative decarboxylation of pyruvate, an end product of glycolysis. It was subsequently

demonstrated that ThDP is also a cofactor for the oxidative decarboxylation of 2-oxoglutarate, another 2-oxo acid. Between 1950 and 1960, Breslow and coworkers investigated the mechanism by which the thiamin moiety of ThDP catalyzes the decarboxylation of pyruvate in the reaction catalyzed by yeast pyruvate decarboxylase (Breslow, 1958). The same mechanism is involved in the first step of oxidative decarboxylation of 2-oxo acids by mitochondrial pyruvate and oxoglutarate dehydrogenase complexes. These studies revealed that ThDP exerts its function by proton substitution on the carbon in position 2 of the thiazolium ring (Figure 17.1B).

## Chemical Properties of Thiamin and Thiamin Phosphate Derivatives

Thiamin (3-[(4-amino-2-methyl-5-pyrimidinyl)methyl]-5-(2-hydroxyethyl)-4-methylthiazole) contains a pyrimidine and a thiazole moiety linked through a methylene bridge. Whereas the pyrimidine ring is found in many natural compounds, such as the pyrimidine nucleotides, thiamin is the only coenzyme of the primary metabolism containing a thiazole ring. Thiamin, generally available as the double chloride salt ( $C_{12}H_{17}N_4OSCl \cdot HCl$ , molecular weight 337.28), is highly soluble in water, but poorly soluble in alcohol and other organic solvents. Thiamin is therefore unable to diffuse through lipid membranes and its uptake by living cells requires specific transporters. As this carrier-mediated transport is relatively slow, lipid-soluble thiamin precursors with higher bioavailability have been synthesized. The properties of these compounds will be discussed later in this chapter.

Thiamin is highly reactive and may undergo various transformations in the presence of  $OH^-$  and other nucleophilic agents (thiazolium ring opening, Figure 17.1B) or oxidizers (thiochrome formation, Figure 17.1C). Thiamin is stable at acid pH (2–4) and unstable at alkaline pH and high temperatures. While the  $N_{1'}$  and  $N_{3'}$  have a basic character and can be protonated, the primary amine  $C_{4'}$ - $NH_2$  is never protonated. Phosphorylated derivatives with phosphoanhydride bonds (in particular ThDP and ThTP) are spontaneously hydrolyzed to ThMP in aqueous solutions, especially at high or low pH. At physiological temperatures and pH, ThDP is stable for several hours.

The biosynthesis of thiamin occurs in most prokaryotes, plants, and fungi. During this complex process, phosphorylated thiazolium and pyrimidinium moieties are

synthesized separately and then assembled to yield ThMP (Jurgenson *et al.*, 2009). In enterobacteria, ThMP is phosphorylated to ThDP by a ThMP kinase, whereas in eukaryotic organisms ThMP is dephosphorylated and thiamin is pyrophosphorylated to ThDP by the enzyme thiamin pyrophosphokinase (EC 2.7.6.2). In most cell types, the cofactor ThDP is the major thiamin compound ( $\geq 80\%$  of total thiamin). Free thiamin and other phosphorylated derivatives are found in variable amounts (Makarchikov *et al.*, 2003; Frédérich *et al.*, 2009; Gangolf *et al.*, 2010a).

### Determination of Thiamin in Biological Samples and Food Preparations

Many different methods have been described for the determination of thiamin derivatives (Kawasaki, 1992). In most cases, detection involves transformation of thiamin derivatives to the corresponding tricyclic thiochrome derivative (Figure 17.1C). Quantitative derivatization is obtained after oxidation (e.g. with potassium ferricyanide or bromocyanogen) in highly alkaline medium. Thiochrome derivatives are highly fluorescent at pH  $>8$  with an excitation maximum around 370 nm and an emission maximum at 433 nm.

Thin-layer chromatography, electrophoresis, and low pressure liquid chromatography were used until the 1970s for the separation of thiamin derivatives, but since then HPLC has become the method of choice for the separation and quantification of thiamin derivatives in tissue samples, food or pharmaceutical preparations. Most methods rely on reversed-phase columns with or without ion-pairing agents (Kawasaki, 1992; Fayol, 1997). They are based on either a precolumn or a postcolumn derivatization procedure. According to our experience, precolumn procedures are preferable for several reasons. First, thiochromes, because of their lack of a positive charge on the thiazole ring and their tricyclic structure, have a more hydrophobic character (resulting in better chromatographic parameters) than the corresponding thiamin compounds. Second, postcolumn derivatization implies the presence of a reaction coil introducing additional void volumes responsible for decreased resolution. However, thiochromes are only fluorescent at alkaline pH, conditions under which silica-based columns are unstable. This drawback can be avoided by the use of postcolumn derivatization. Alternatively, stationary phases resistant to alkaline pH, such as polystyrene-divinylbenzene resins, can be used (Bettendorff

*et al.*, 1991). Most of these methods are highly sensitive, and amounts as low as several femtomoles can be detected, allowing the detection of thiamin or its derivatives at nanomolar concentrations.

### Nutritional Requirements and Toxicity

Thiamin is found in most foods, but whole grains, meat, fish, and yeast are particularly rich sources for this vitamin, containing approximately 3 mg/kg of wet weight (Davis and Icke, 1983). Vegetables contain two to three times less thiamin than meat per unit weight. Thiamin is stable on storage, but it should be emphasized that food processing may have an impact on the final thiamin content. Thiamin is heat-labile, and procedures such as overcooking, pasteurization of milk or heating of canned food may result in considerable loss of the vitamin.

For that reason, many processed foodstuffs such as cereals, bread, dairy products, and infant formulas are enriched with thiamin along with other vitamins such as niacin, riboflavin or folic acid. The recommended dietary allowance (RDA) is 1.2 mg/day for adult males and 1.1 mg/day for adult females. The RDA is increased to 1.4 mg/day during pregnancy and even 1.5 mg/day for lactating women. In children, the RDA increases with age and is 0.5, 0.6, and 0.9 mg/day respectively for 1–3, 4–8, and 9–13 years of age.

Thiamin supplementation is advisable for alcohol abusers and is sometimes suggested for elderly people as both might have decreased intestinal thiamin absorption. High thiamin intake (100 mg/day orally or intravenously) is needed in some rare conditions such as Wernicke's encephalopathy and in some rare genetic diseases, e.g. thiamin-responsive megaloblastic anemia or thiamin-responsive maple syrup urine disease. In these cases, thiamin derivatives with higher bioavailability than thiamin may be of advantage (benfotiamine, sulbutiamine or fursultiamine, see below).

Therapeutic doses generally range between 10 and 100 mg/day. For instance, cardiovascular beriberi is treated with 100 mg thiamin intravenously for several days. Note that intravenous thiamin administration should precede intravenous glucose administration as glucose may worsen thiamin deficiency. Indeed, it has been consistently observed that thiamin requirement, in contrast to that of other vitamins, increases when carbohydrate intake is high. This might be linked to the role of the cofactor ThDP in glucose catabolism. A recent study suggested an

instability of enzyme-bound ThDP during the catalytic reactions (McCourt *et al.*, 2006). Therefore, increased glucose uptake would result in increased flux through ThDP-dependent enzymes and in increased breakdown of ThDP, worsening the thiamin status.

Oral intake of large doses generally has no adverse effects. However, intravenous administration of large doses (125 mg/kg in mice) can lead to respiratory depression and neuromuscular blockade. In dogs, blood thiamin levels of 10 µg/100 ml (300 µmol/L) are invariably fatal (Davis and Icke, 1983). In humans, allergic reactions (anaphylactic shock) are a rare complication of intravenous thiamin administration.

## Thiamin Transport and Homeostasis

### Intestinal Absorption

Thiamin homeostasis is maintained by balancing intestinal uptake and renal loss. Thiamin phosphate esters taken up from the food are hydrolyzed to thiamin or ThMP by intestinal alkaline phosphatase and transported across the brush-border membrane to the portal system. At low concentration (<1 µM), thiamin is absorbed through an active process, while at high intraluminal concentration a passive process seems to prevail. As a result, a larger proportion of small doses of thiamin is absorbed when its concentration is low.

The high-affinity transport process ( $K_m = 0.1\text{--}1\ \mu\text{M}$ ) across the brush-border membrane of the enterocyte involves an electroneutral thiamin/H<sup>+</sup> antiport and is thus facilitated by an outwardly directed H<sup>+</sup> gradient (Casirola *et al.*, 1988).

Therefore, the pH gradient (more alkaline in the intestinal lumen) is probably the driving force for intestinal thiamin transport. Chronic ethanol consumption was shown to decrease intestinal thiamin transport (Balaghi and Neal, 1977; Gastaldi *et al.*, 1989; Subramanya *et al.*, 2010). Furthermore, enterocyte thiamin transport seems to be affected by age. Aging is associated with decreased affinity and increased rate of high-affinity thiamin transport, while low-affinity transport is decreased (Gastaldi *et al.*, 1992).

### Transport and Distribution of Thiamin Derivatives in Other Tissues

In most cell types, as in enterocytes, there is a dual, active high-affinity and passive low-affinity thiamin uptake mechanism. For active transport, different mechanisms

have been shown to exist: a pH dependence similar to that observed in enterocytes has been demonstrated in human-derived liver cells (Said *et al.*, 2002), rat renal brush-border membrane (Gastaldi *et al.*, 2000), and human-derived renal epithelial cells (Ashokkumar *et al.*, 2006). However, a Na<sup>+</sup>-thiamin cotransport mechanism has been suggested in hepatocytes (Lumeng *et al.*, 1979; Yoshioka, 1984). Intracellular thiamin pyrophosphorylation, subsequent uptake of ThDP by mitochondria and binding to apoenzymes are additional factors favoring the intracellular accumulation of thiamin derivatives.

In rats, only 1.5% of total thiamin is found in the brain, while 22% is found in the liver (Balaghi and Pearson, 1966; Ishii *et al.*, 1979; Sanemori *et al.*, 1980). However, during thiamin deficiency, thiamin levels decrease less steeply in the brain than in the liver (De Caro *et al.*, 1961; Balaghi and Pearson, 1966). Administration of high doses of thiamin (or thiamin precursors with a higher bioavailability) leads to a marked increase in total thiamin in the blood and in the liver, but not in the brain (see below). These results can be explained if the rate of thiamin transport across the blood-brain barrier is low compared with the rate of uptake by hepatocytes. As many studies use different units, it is difficult to compare the relative rates of transport in various preparations. There is no doubt, however, that the administration of radioactively labeled thiamin in rats leads to a much more rapid and higher accumulation of radioactivity in the blood and the liver than in the brain (Rindi *et al.*, 1980). This is in agreement with the observation that thiamin is not actively transported across the blood-brain barrier (Greenwood *et al.*, 1982, 1986), except maybe in the choroid plexus (Spector and Johanson, 2007). In brain cells, thiamin is probably not exchanged for H<sup>+</sup> nor cotransported with Na<sup>+</sup>. Rather, the driving force for thiamin uptake appears to be its pyrophosphorylation to ThDP and subsequent strong binding to apoenzymes such as transketolase and oxoglutarate dehydrogenase complex (Bettendorff and Wins, 1994). Active accumulation of ThDP by mitochondria is another possibility (see below).

Net thiamin accumulation by the brain is also influenced by efflux of thiamin through the blood-brain barrier (Lockman *et al.*, 2003), an efflux considerably increased by trans-stimulation. Thiamin efflux was also stimulated by extracellular thiamin in cultured rat neuroblastoma cells, possibly by a self-exchange mechanism (Bettendorff, 1995). Such a trans-stimulation of thiamin efflux would limit excess thiamin uptake by the brain. It has been

shown by different groups that, even in the presence of blood thiamin levels several orders of magnitude above control, brain thiamin content hardly changed whereas levels in liver and erythrocytes greatly increased (Sanemori and Kawasaki, 1982; Bettendorff *et al.*, 1990; Volvert *et al.*, 2008).

In conclusion, the emerging picture is that thiamin entering the bloodstream is mostly captured and phosphorylated by the liver (which is the main organ storing the vitamin) and, to a lesser extent, by erythrocytes which act as a thiamin buffer. In contrast, thiamin levels in the brain are highly regulated to minimize variations in thiamin and thiamin phosphate levels: regulatory mechanisms control both the influx and efflux of thiamin. Similar considerations hold for other vitamins (Spector and Johanson, 2007). Thus, vitamins B<sub>3</sub> (niacin) and B<sub>6</sub> (pyridoxine/pyridoxal) enter the brain through high-affinity transporters, whereas pantothenic acid and biotin enter through active transport. Homeostatic mechanisms tend to keep plasma levels and, even more, brain levels constant.

### Thiamin Excretion

Excess thiamin and some of its metabolites (2-methyl-4-amino-5-pyrimidine carboxylic acid and 4-methyl-thiazole-5-acetic acid) are excreted in the urine. Urinary thiamin excretion is decreased during fasting (Fukuwatari *et al.*, 2010). Human urine thiamin concentrations are ~0.5 µg/ml or 1.5 µM (Roser *et al.*, 1978). In the rat, after intraperitoneal administration of <sup>14</sup>C-pyrimidine-labeled thiamin, ~30% of the vitamin taken up is eliminated by urinary excretion and 13% in the feces (Pearson *et al.*, 1966). However, only ~6% of the excreted radioactivity was genuine thiamin, the rest being found in at least 22 degradation products (Neal and Pearson, 1964). Probably most of these are products of detoxification enzymes present in liver and kidney. None of these enzymes is known to be specific for thiamin.

### Thiamin Transport Proteins

Thiamin-responsive megaloblastic anemia is accompanied by diabetes mellitus and sensorineural deafness. Patients affected by this genetic disease lack the high-affinity thiamin transporter in erythrocytes (Poggi *et al.*, 1984; Rindi *et al.*, 1992, 1994; Stagg *et al.*, 1999). As the low-affinity thiamin transporter is still present, the patients respond, at least partly, to high doses of thiamin. The gene location was restricted to the chromosomal 1q23.3 region, and the identification of the genes in this region led to the

identification of a new gene (*SLC19A2* for solute carrier family 19 member 2) homologous to *SLC19A1* encoding the reduced folate carrier protein (RFC-1) (Fleming *et al.*, 1999). In humans it is highly expressed in skeletal muscle, heart, and placenta, but in mice the highest expression is observed in liver, kidney, and brain, with practically no expression in skeletal muscle (Fleming *et al.*, 2001; Oishi *et al.*, 2001). As these tissues are not affected in the patients and they have normal plasma thiamin levels (Oishi *et al.*, 2002), it is plausible that alternative routes for transporting thiamin are present in many cells except in tissues affected in thiamin-responsive megaloblastic anemia, i.e. bone marrow (where blood cells are formed), beta cells of the islets of Langerhans and inner-ear cells. The identity of alternative transporters is still unclear but it has been shown that RFC-1 is able to transport ThMP and ThDP but not thiamin (Zhao *et al.*, 2001, 2002). While ThDP is not physiologically encountered in extracellular media, ThMP is present in plasma and cerebrospinal fluid and therefore RFC-1 may be an alternative route for cells to capture thiamin. The choroid plexus, which plays an important role in brain thiamin homeostasis, accumulates the vitamin by an active process and releases thiamin and ThMP on the apical (CSF) side (Spector and Johanson, 2007). RFC-1 is highly expressed on the apical side of the choroid plexus (Wang *et al.*, 2001) and may thus be responsible for the release of ThMP into the CSF.

A third member of the same gene family, *SLC19A3*, located on chromosome 2q37, encodes a 55.6-kDa protein with 56% similarity to RFC-1 and 64% identity to ThTR1 (Eudy *et al.*, 2000). ThTR2, the *SLC19A3* gene product, was shown to transport thiamin (Rajgopal *et al.*, 2001), with a very high apparent affinity for thiamin ( $K_m = 27 \pm 8$  nM) (Said *et al.*, 2004). In contrast, ThTR1 has a  $K_m$  of  $2.5 \pm 0.6$  µM (Dutta *et al.*, 1999).

ThTR2 is rather ubiquitously expressed, with the highest levels in placenta, liver, kidney, and heart, which might explain why these tissues are spared in thiamin-responsive megaloblastic anemia. Furthermore, its expression is low in bone marrow. ThTR2 is expressed along the whole length of the human digestive tract, with the highest expression in the proximal part (duodenal and jejunal areas), which has the highest capacity of the intestine to absorb thiamin (Rindi and Ferrari, 1977; Laforenza *et al.*, 1997). Nevertheless the transporter is also present on colonocytes where it might play a role in the absorption of thiamin produced by the microflora of the large intestine (Said *et al.*, 2001). Differentiation of intestinal

epithelial cells is associated with an up-regulation of thiamin transport, in a process involving transcriptional regulation of both the *SLC19A2* and *SLC19A3* genes (Nabokina *et al.*, 2005; Reidling and Said, 2005).

That mutations in *SLC19A2* are indeed responsible for thiamin-responsive megaloblastic anemia was shown by targeted disruption of the gene in mice (Oishi *et al.*, 2002). These mice exhibited the hallmarks of the disease: megaloblastosis, diabetes, and sensorineural deafness when put on a thiamin-deficient diet (Oishi *et al.*, 2002). The fact that gene disruption alone does not cause these symptoms suggests that differences in thiamin metabolism and in tissue distribution of thiamin transporters exist between humans and mice, as was indeed shown for *SLC19A3* (Eudy *et al.*, 2000). An intriguing point is that recent results suggest that mutations in *SLC19A3* are responsible for biotin-responsive basal ganglia disease (Zeng *et al.*, 2005), a rare recessive disorder with onset in childhood and with brain-specific pathology involving bilateral lesions of the caudate nucleus and the putamen. At an early stage the disease is associated with subacute encephalopathy, progressing to acute encephalopathy. These symptoms are reversed by high doses of biotin (vitamin B<sub>7</sub>). Many transporters have overlapping substrate specificity, as illustrated by the case of RFC-1, able, for instance, to transport reduced folate, ThMP, and ThDP. Therefore, the hypothesis that ThTR2 might transport biotin was very appealing. However, it was shown (Subramanian *et al.*, 2006) that the mutations identified in *SLC19A3* in patients with biotin-responsive basal ganglia disease inhibit the thiamin transport capacity of ThTR2 but that the normal as well as the mutated proteins were all unable to transport biotin.

### **Thiamin Diphosphate Synthesis and Transport into Mitochondria**

In animal cells, thiamin transported into the cells is rapidly phosphorylated to ThDP according to the reaction: thiamin + ATP  $\rightleftharpoons$  ThDP + AMP, catalyzed by thiamin pyrophosphokinase. The equilibrium of this reaction is far towards the reactants (Peterson *et al.*, 1975). However, inside the cells the equilibrium is shifted to the right because of the binding of ThDP to cytosolic transketolase and transport into mitochondria.

A mitochondrial ThDP transporter (*SLC25A19*) was recently characterized in yeast (Marobbio *et al.*, 2002) and in animals (Lindhurst *et al.*, 2006). Mutations in *SLC25A19* cause Amish lethal microcephaly, an autosomal

recessive disease characterized by extreme microcephaly, severe 2-oxoglutarate aciduria, and fatal outcome within the first year. *SLC25A19* seems to act as an antiporter, exchanging extramitochondrial ThDP against intramitochondrial nucleotides. The concentration of free ThDP is probably higher in the mitochondrial matrix than in the cytosol, but the exact mechanism of active ThDP transport – if any – in mitochondria remains unclear.

### **Tissue Content and Metabolism of Thiamin Phosphate Derivatives**

Thiamin phosphate derivatives are found in all organisms. In most cases the cofactor ThDP is the major thiamin compound. In most animal cells, ThDP represents 70 to 90% of total thiamin, and in the brain most of it is bound to apoenzymes. However, free ThDP is more concentrated in hepatocytes, enterocytes, and skeletal muscle fibers. ThDP is synthesized from thiamin and ATP in the cytosol (see above) and is hydrolyzed by thiamin diphosphatases yielding ThMP, which can be hydrolyzed to thiamin. Several enzymes have been reported to hydrolyze ThDP, but all thiamin diphosphatases studied so far also hydrolyze nucleoside diphosphates. Likewise, no hydrolase has been found to be specific for ThMP, which may be hydrolyzed by alkaline phosphatases, acid phosphatases or an ecto-5'-nucleotidase. ThMP and free thiamin generally amount to less than 15% of total thiamin in animal cells. The triphosphorylated derivative, ThTP, is generally a minor compound (less than 1% of total thiamin), but it is found in most organisms, including humans (Makarchikov *et al.*, 2003; Gangolf *et al.*, 2010a). In *E. coli*, ThTP is transiently synthesized when the bacteria are switched from an amino acid rich medium to one that is amino acid poor, suggesting that it might be a signal involved in the adaptation to amino acid starvation (Lakaye *et al.*, 2004). In animal tissues, ThTP is consistently found in nervous tissue and skeletal muscle. At least two kinds of enzymes have been shown to hydrolyze ThTP. A soluble 25-kDa thiamin triphosphatase (EC 3.6.1.28) has been characterized at the molecular level (Lakaye *et al.*, 2002; Song *et al.*, 2008). It is very specific for ThTP and relatively ubiquitously expressed in mammalian tissues, and in the brain it seems mainly localized in neurons (Czerniecki *et al.*, 2004). A membrane-bound thiamin triphosphatase has been described in animal tissues, but this enzyme has never been purified and its specificity remains to be demonstrated (Barchi and Braun, 1972; Bettendorff *et al.*,

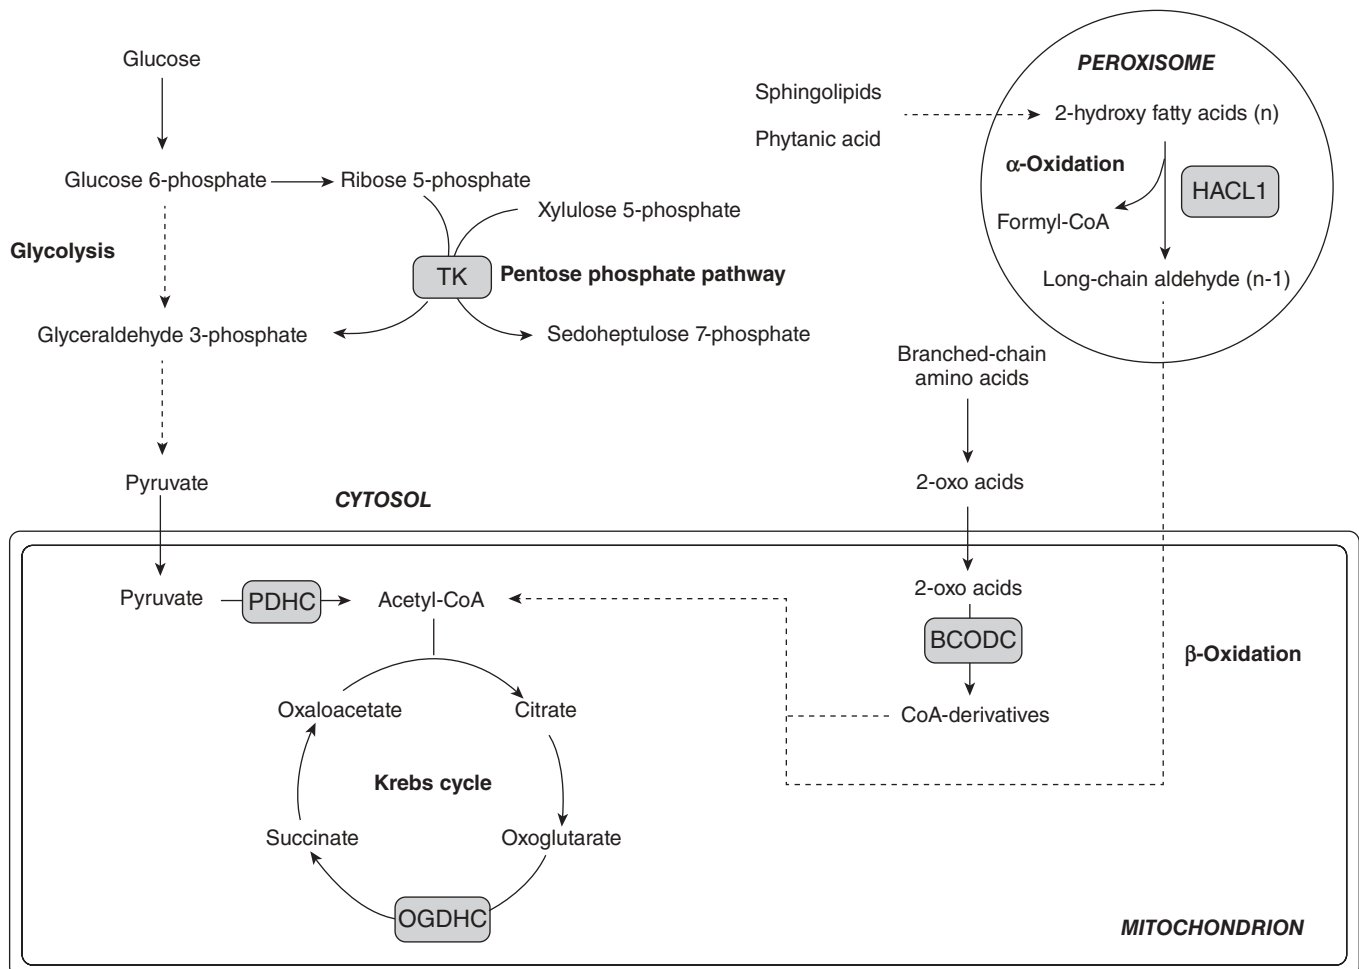

1987, 1988). The mechanism of ThTP synthesis is controversial. Adenylate kinase 1 (EC 2.7.4.3) may synthesize ThTP according to the reaction  $\text{ThDP} + \text{ADP} \rightleftharpoons \text{ThTP} + \text{AMP}$  (Shikata *et al.*, 1989a,b; Gigliobianco *et al.*, 2008), but the rate of this reaction is six to seven orders of magnitude lower than the natural reaction  $2 \text{ADP} \rightleftharpoons \text{ATP} + \text{AMP}$ . Nevertheless, this enzyme may be responsible for the accumulation of cytosolic ThTP in tissues, such as skeletal muscle, where AK1 activity is particularly high. In brain, ThTP is localized in mitochondria and might be synthesized by a chemiosmotic mechanism resembling that of ATP synthesis (Gangolf *et al.*, 2010b).

A<sub>Th</sub>TP was only recently discovered in *E. coli*, where it accumulates during acute energy stress (Bettendorff *et al.*,

2007; Gigliobianco *et al.*, 2010). It might be synthesized by a ThDP adenylyl transferase (Makarchikov *et al.*, 2007). It is found in the roots of plants and in animal cells, but we have no indication as to its potential roles. The diphosphate analog, adenosine thiamin diphosphate, was found in low amounts in bacteria and rodent liver (Frédérich *et al.*, 2009).

## Cofactor Role of Thiamin Diphosphate

Vitamins of the B group or their derivatives are essential cofactors in many basic enzyme-catalyzed reactions. In the case of thiamin, ThDP is the cofactor of several enzymes involved in key metabolic pathways (Figure 17.2). ThDP

**FIG. 17.2** Thiamin diphosphate-dependent enzymes in mammalian cells. TK, transketolase; PDHC, pyruvate dehydrogenase complex; OGDHC, oxoglutarate dehydrogenase complex; BCODC, branched-chain 2-oxo acid dehydrogenase; HAACL1, 2-hydroxyacyl-CoA lyase.

bound to apoenzymes is considered the “slow turnover ThDP pool” (Bettendorff, 1994a; Bettendorff *et al.*, 1994), although the stability of the different coenzyme–apoenzyme complexes varies: ThDP dissociates faster from pyruvate dehydrogenase than from oxoglutarate dehydrogenase complex and transketolase. It can be estimated that, in brain cells or neuroblastoma cells, the slow ThDP pool represents 90–95% of the total cellular ThDP and has a turnover of 6–20 hours. For the smaller pool, the turnover is of the order of 1–3 hours. In other cell types such as hepatocytes or red blood cells, the free cytosolic ThDP pool may be much more important, particularly after administration of thiamin.

### **ThDP-Dependent Enzymes and Their Roles**

In mammalian cells, ThDP is a cofactor for the cytosolic transketolase (EC 2.2.1.1), and in mitochondria ThDP is the cofactor of E1 subunits of pyruvate dehydrogenase complex (EC 1.2.4.1), oxoglutarate dehydrogenase complex (EC 1.2.4.2), and branched-chain 2-oxo acid (EC 1.2.4.4) dehydrogenase. More recently, 2-hydroxyacyl-CoA lyase (EC 4.1.-.-) has been described in peroxisomes where it is involved in the degradation of 3-methyl-branched-chain and 2-hydroxy long-chain fatty acids (Foulon *et al.*, 1999).

In yeast, pyruvate decarboxylase (EC 4.1.1.1), catalyzing the non-oxidative decarboxylation of pyruvate to acetaldehyde, is the committed step in alcoholic fermentation. It is a key reaction involved in the production of beer, wine, and other alcoholic beverages.

Pyruvate and oxoglutarate dehydrogenase complexes are essential for mitochondrial oxidative metabolism, which, especially in neurons, is crucial for survival. Mutations in pyruvate dehydrogenase (among other enzymes involved in mitochondrial energy metabolism) have been associated with subacute necrotizing encephalomyelopathy (Leigh’s disease) (Barnerias *et al.*, 2010), a rare heterogeneous neurodegenerative disorder of early childhood characterized by focal, symmetric necrotic brain lesions, leading to death generally before the age of 5. Administration of thiamin in these patients may at best delay but will not prevent the fatal outcome. Oxoglutarate dehydrogenase complex is the rate-limiting enzyme of the Krebs cycle in the brain. Its activity is decreased in the brains of patients with Alzheimer’s disease (Mastrogiacomo *et al.*, 1996b).

Transketolase is cytosolic and is a key enzyme in the pentose phosphate pathway, a major source of NADPH for reductive biosynthesis (of fatty acids, for instance) and

of ribose (nucleic acid synthesis). It has been suggested that carriers of variants with decreased affinity for ThDP might have a predisposition for Wernicke–Korsakoff’s syndrome, but no mutations were found in the coding sequence in Wernicke–Korsakoff compared with non Wernicke–Korsakoff individuals (Mukherjee *et al.*, 1987; McCool *et al.*, 1993; Alexander-Kaufman and Harper, 2009). In humans, three isoforms of the enzyme have been described: transketolase, transketolase-like 1, and transketolase-like 2 (Coy *et al.*, 1996, 2005; Xu *et al.*, 2009). Transketolase-like 1 expression is up-regulated in various forms of cancer, and specific inhibitors of transketolase-like 1 (antithiamins) might have antitumor effects (Cascante *et al.*, 2000).

Branched-chain 2-oxo acid dehydrogenase complex plays a central role in the degradation of the branched-chain amino acids leucine, isoleucine, and valine. Deficiency of this activity due to mutations leads to the accumulation of toxic 2-oxo acid products leading to maple syrup urine disease, also called branched-chain ketoaciduria. This autosomal recessive metabolic disorder is characterized by a maple-syrup-like odor of the urine of affected children. If untreated, severe brain damage will rapidly lead to coma and death. The patients must observe a strict diet, poor in the three incriminated amino acids. As they are essential amino acids, they must be present in minimal amounts in the daily ration so their levels have to be carefully adjusted on an individual basis. The patients may respond to administration of high-dose thiamin when the E1 component of the branched chain 2-oxo acid dehydrogenase complex is affected.

2-Hydroxyacyl-CoA lyase was the first ThDP-dependent enzyme to be discovered in peroxisomes (Foulon *et al.*, 1999). In liver it is involved in the degradation of 3-methyl-branched fatty acids, essentially phytanic acid (3,7,11,15-tetramethyl hexadecanoic acid) present in human diet as a degradation product of chlorophyll. Accumulation of phytanic acid in blood and tissues leads to Refsum’s disease, an autosomal, recessive, and progressive metabolic disorder presenting neurologic damage, cerebellar degeneration, and peripheral neuropathy.

Several other ThDP-dependent enzymes have been described in prokaryotes, but they will not be discussed here.

### **Mechanism of ThDP-Dependent Catalysis**

In all ThDP-catalyzed enzymatic reactions, ThDP catalyzes the cleavage or the formation of a C–C bond immediately adjacent to a carbonyl group ( $\alpha$ -cleavage or

$\alpha$ -condensation) such as in the decarboxylation of 2-oxo acids (Eq. 1, 2-oxo acid dehydrogenases, pyruvate decarboxylase and 2-hydroxyacyl-CoA lyase) or the cleavage of  $\alpha$ -hydroxyketones (Eq. 2, transketolase):

As there is no simple acid–base-catalyzed mechanism for such reactions, a special catalyst is required. The catalytic action of ThDP is linked to the ability of its thiazolium ring to form an ylide (carbanion) intermediate (Figure 17.1B) by deprotonation of the thiazolium C-2 and attack of the resulting carbanion on a substrate carbonyl. The diphosphate group plays no role in catalysis itself and is only required for tight binding of ThDP to the apoenzymes. The anionic carbon of the thiazolium ring readily reacts with substrates by addition to the carbonyl group, forming a covalent adduct undergoing cleavage that ultimately leads to the formation of acetyl-CoA in the case of oxidative decarboxylation of pyruvate.

### Non-Cofactor Roles of Thiamin Phosphate Derivatives in Animals

Non-cofactor roles of thiamin or its phosphorylated derivatives have been postulated since the 1940s (Bettendorff, 1994b). Such hypotheses take root in the well-known particular sensitivity of the nervous system to thiamin deficiency and to more specific observations, e.g. that electrical stimulation of isolated nerves leads to a release of thiamin, probably as a consequence of the dephosphorylation of ThDP and ThTP. This result has sometimes been interpreted as consumption of ThTP during nerve activity, for instance for protein phosphorylation. ThTP has indeed been shown to be able to phosphorylate proteins in the electric organ of *Torpedo marmorata* or rodent brain (Nghiem *et al.*, 2000). Furthermore, ThTP activated a high-conductance chloride channel, possibly by a phosphorylation-dependent mechanism (Bettendorff *et al.*, 1993). However, the physiological significance of these events remains to be established. The recent observation that ThTP is synthesized in brain but not in liver mitochondria suggests that this compound might play a role in neuronal energy metabolism (Gangolf *et al.*,

2010b). Several studies showed complex effects of free thiamin on the neuromuscular junction (Eder *et al.*, 1976; Romanenko, 1990), but in all cases relatively high concentrations (>0.1 mM) were required, casting doubt on the physiological significance of these data. Adenylated thiamin derivatives also exist in animals in small quantities (Bettendorff *et al.*, 2007; Frédéricich *et al.*, 2009). Therefore, it appears that thiamin biochemistry is more complex than that of other B vitamins. The existence of mono-, di-, and triphosphates is more reminiscent of nucleotides than of vitamins.

### Diseases Specifically Related to Thiamin Deficiency

#### Assessment of Thiamin Status in Humans

As discussed above, HPLC is the method of choice for the determination of thiamin in body fluids. The most direct measure is the determination of ThDP in blood samples (Korner *et al.*, 2009). This method is direct, rapid, suitable for pediatric diagnostics, highly sensitive, and easy to standardize. However, such methods are generally not routinely available in most medical laboratories. The erythrocyte transketolase activity assay is a widely used method to assess thiamin status in humans. It is based on the increased activity of erythrocyte transketolase after addition of ThDP. An abnormally large ThDP effect can be interpreted as a low saturation of transketolase by the cofactor, as a consequence of thiamin deficiency. A good correlation is obtained between direct erythrocyte ThDP determination and the ThDP effect. The latter is, however, an indirect determination of the thiamin status that can be influenced by factors other than thiamin deficiency and it is less sensitive.

#### Dry and Wet Beriberi

Beriberi is the typical manifestation of alimentary thiamin deficiency. It was a major health problem in Eastern and Southern Asia during the nineteenth century as polished rice had become the staple food in these countries. Such chronic deficiency (unrelated to alcohol abuse) most often results in dry beriberi, characterized by symmetrical peripheral neuritis. The condition, which mainly affects the lower limbs, results in weakness in the legs and cramps, followed at later stages by hyperesthesia and deep muscle pain. If not treated it may lead to death, but administration of thiamin results in a rapid cure. Wet (shoshin) beriberi is a rarer form of the disease with a difficult

diagnostic, ultimately leading to fatal congestive heart failure. It is characterized by edema, pulmonary hypertension, and lactic acidosis. The improvement can be rapid and spectacular after treatment with thiamin. Just like the nervous system, the heart muscle relies heavily on oxidative metabolism, which explains its high sensitivity to thiamin deficiency.

### **Wernicke–Korsakoff Syndrome**

In developed countries, beriberi is now virtually nonexistent, but thiamin deficiency related to chronic alcohol abuse leads to a severe impairment of brain function known as Wernicke–Korsakoff syndrome. This remains the third most common cause of dementia after Alzheimer's disease and vascular dementia, contributing to between 10 and 24% of all cases of dementia (Victor *et al.*, 1989; Butterworth, 2003; Harper, 2009; Kopelman *et al.*, 2009). It seems that alcohol interferes with intestinal thiamin absorption, in particular by reducing the expression of ThTR1 in the intestine (Subramanya *et al.*, 2010). An impairment of phosphorylation of thiamin to ThDP has also been suggested (Rindi *et al.*, 1986; Laforenza *et al.*, 1990).

The clinical features of Wernicke's encephalopathy (which is the first acute stage of the syndrome) include ophthalmoplegia, global confusional state, and ataxia. Korsakoff's psychosis appears as a consequence of chronic thiamin deficiency in the alcoholic patient, often after several episodes of Wernicke's encephalopathy. Clinical features are anterograde amnesia, disorientation, confabulation, and learning defects, probably arising from irreversible diencephalic lesions. Administration of thiamin at an early stage of Wernicke's encephalopathy leads to rapid improvement, but if high doses of thiamin are not administered early enough, there are irreversible sequelae such as residual ataxia and horizontal nystagmus, deficits in learning, memory loss, and personality changes, which are hallmarks of Korsakoff's psychosis. This is linked to irreversible brain lesions that are rather specific, affecting the thalamus, the mammillary bodies, and sometimes the cerebellum, the cerebral cortex being largely spared. The lesions probably arise from decreased 2-oxoglutarate dehydrogenase activity impairing energy metabolism in endothelial cells and neurons (Heroux and Butterworth, 1995). Neuronal loss actually results from a combination of several factors, including excitotoxicity, inflammation and oxidative stress (Hazell and Butterworth, 2009). The reason for the selective vulnerability of certain brain

regions remains largely unknown and is a subject of active investigation. A recent hypothesis links the origin of the lesions to an impairment of the blood cerebrospinal fluid barrier at the level of the choroid plexus (Nixon *et al.*, 2008).

Not all alcoholics develop Wernicke–Korsakoff syndrome, and environmental and genetic factors may also play a role. Some variants of transketolase (Alexander-Kaufman and Harper, 2009) and ThTR1 (Guerrini *et al.*, 2005) have been associated with Wernicke–Korsakoff syndrome, but it remains to be proven that there is a causal relationship. Furthermore, while Wernicke–Korsakoff syndrome is most often associated with alcoholism, it can also occur as a result of general malnutrition after gastrectomy (Shimomura *et al.*, 1998), in patients with fast-growing hematologic malignant tumors (van Zaanen and van der Lelie, 1992), in drug abusers, and in AIDS patients (Butterworth *et al.*, 1991). Rare cases of accidental thiamin deficiency may also occur, such as an episode of encephalopathy in infants in Israel in 2003, caused by a defective soy-based formula (Fattal-Valevski *et al.*, 2005).

### **Subclinical Thiamin Deficiency**

Subclinical thiamin deficiency in humans is probably more widespread in developed countries than initially thought, especially in elderly people (Smidt *et al.*, 1991; Chen *et al.*, 1996; Thurman and Mooradian, 1997; Wilkinson *et al.*, 1997; Vognar and Stoukides, 2009), as well as in some risk groups such as infants, and pregnant and lactating women (Butterworth, 1987). Maternal thiamin deficiency may be a problem in displaced populations, as a result either of insufficient thiamin intake or of the consumption of thiaminase-containing food (McGready *et al.*, 2001). Low circulating thiamin levels were also observed in patients with Alzheimer's disease (Gold *et al.*, 1995; Molina *et al.*, 2002) and ThDP levels are decreased in postmortem brains of patients with Alzheimer's disease (Heroux *et al.*, 1996; Mastrogiacomo *et al.*, 1996a) and frontal lobe degeneration of the non-Alzheimer's type (Bettendorff *et al.*, 1997). It is important to emphasize that circulating and brain thiamin levels are much lower in humans than in rodents (Bettendorff *et al.*, 1996; Gangolf *et al.*, 2010a). This might be one reason why humans are more prone to thiamin deficiency than rodents and most other animals. It has also been reported that loop diuretic therapy in patients with heart failure results in increased renal thiamin loss and these patients are therefore at a higher risk of developing thiamin deficiency (Sica, 2007).

### Nutritional, Alcohol-Related, and Genetically Induced Thiamin Deficiencies Are Symptomatically Distinct

It is worth commenting on the various forms of thiamin-deficiency-related diseases. While purely nutritional thiamin deficiency mainly leads to peripheral symptoms such as polyneuritis (dry beriberi) or congestive heart failure (wet beriberi), alcohol-induced thiamin deficiency mainly affects the central nervous system (Wernicke–Korsakoff syndrome) although polyneuritis is also present in many cases. This may suggest that alcohol toxicity may contribute to the symptoms observed, as discussed by some authors (Harper, 1998). On the other hand, deficiency in thiamin transport due to mutations in ThTR1 (*SLC19A2*) leads to the peripheral symptoms (though unrelated to beriberi) in thiamin-responsive megaloblastic anemia: anemia, diabetes, and deafness. This suggests that the main transporter in the brain is ThTR2. Indeed, patients with known loss-of-function mutations in ThTR2 suffer from brain lesions and respond to thiamin administration (Kono *et al.*, 2009). However, some mutations in ThTR2 lead to a lethal familial form of encephalopathy as a result of necrosis of the basal ganglia (Vlasova *et al.*, 2005; Zeng *et al.*, 2005; Debs *et al.*, 2010). Strangely, this disease responds to biotin administration, or sometimes to a combination of biotin and thiamin, though biotin is not transported by ThTR2. ThTR2-knockout mice have reduced intestinal thiamin uptake and are relatively normal, but die at age of 1 year of unknown causes (but not from brain lesions) (Reidling *et al.*, 2010). This does not seem to be due to compensation by ThTR1 but could be the result of a different expression pattern of thiamin transporters in humans compared with mice. Finally, the fact that ThDP deficiency in mitochondria plays a key role in thiamin deficiency-induced brain lesions is illustrated by the extremely severe phenotype observed in mutation of the mitochondrial ThDP transporter *SLC25A19* (Amish lethal microcephaly, see above) (Lindhurst *et al.*, 2006).

### Thiamin Precursors and Lipid-Soluble Thiamin Compounds

Unlike other B-vitamins, oral administration of thiamin does not lead to significantly increased plasma vitamin levels (Davis and Icke, 1983), probably because intestinal thiamin absorption is a relatively slow process, especially in humans. This probably contributes to the fact that

**FIG. 17.3** Thiamin precursors with high bioavailability. Note the thioester bond in benfotiamine as compared with the disulfide bridge in the other compounds, as well as the phosphate group making this molecule lipid insoluble. Note that in contrast to the other three molecules, sulbutiamine is a symmetric dimer. Modified from Volvert *et al.* (2008).

marginal thiamin deficiency in humans is more common than initially thought. In order to overcome this problem, several thiamin precursors with higher bioavailability were developed (Figure 17.3).

In the 1950s, M. Fujiwara and colleagues in Tokyo discovered that a thiamin derivative with high bioavailability was formed in crushed garlic (*Allium sativum*) bulbs through the action of a plant enzyme on thiamin and alliin (diallyl thiosulphinate) (Fujiwara *et al.*, 1954). They

named this compound allithiamin, which they later identified as thiamin allyl disulfide. Other synthetic thiamin disulfides such as sulbutiamine (O-isobutylthiamin disulfide) and fursultiamine (thiamin tetrahydrofurfuryl disulfide) were developed. All have a higher bioavailability than thiamin, probably because their hydrophobic character means that they easily cross intestinal membranes and no transporter is required. In the bloodstream, these disulfide compounds are easily reduced to thiamin in the presence of cysteine or glutathione. Intraperitoneal administration of sulbutiamine in rats leads to a significant increase in the levels of thiamin phosphate esters in the brain and it has a documented effect on the central nervous system as a psychotropic drug (Bizot *et al.*, 2005). Fursultiamine improves energy metabolism and physical performance during physical fatigue loading in rats (Nozaki *et al.*, 2009). Central nervous effects of fursultiamine are less well documented but it was suggested to have beneficial effects on speech, behavior and sleep in autistic children (Lonsdale *et al.*, 2002).

Benfotiamine (S-benzoylthiamin O-monophosphate), another synthetic thiamin precursor, is being extensively studied. In contrast to the lipophilic thiamin disulfides, benfotiamine, a thioester, because of its hydrophilic phosphoryl group is not lipid-soluble. In contrast, it dissolves in aqueous solvents at slightly alkaline pH. To be absorbed, benfotiamine must be dephosphorylated to S-benzoylthiamin by ecto-alkaline phosphatases present in the intestinal mucosa (Volvert *et al.*, 2008). The more lipophilic S-benzoylthiamin may then cross the brush-border membrane. It can be hydrolyzed to thiamin by thioesterases present in the liver. The different modes of transport and degradation of these three compounds probably explain their different effects, though all raise blood thiamin levels well above those obtained by administration of an equivalent dose of thiamin. Benfotiamine mainly acts on peripheral tissues through increase in transketolase activity and thus is effective in preventing diabetic complications such as retinopathy (Hammes *et al.*, 2003). However, benfotiamine is unable to significantly raise thiamin phosphate levels in the rodent brain, which probably explains why, until recently, it had no documented central nervous system effects. However, very recently, benfotiamine was shown to improve cognitive functions and to dramatically decrease amyloid plaques and neurofibrillary tangles in a mouse model of Alzheimer's disease (Pan *et al.*, 2010).

## Antithiamins

Several synthetic thiamin antagonists have been developed. The most potent is pyriethiamin, a highly competitive inhibitor of thiamin transport and thiamin pyrophosphokinase. Other analogs such as oxythiamin, amprolium, and the chemically unrelated diuretic amiloride also inhibit thiamin transport (Bettendorff and Wins, 1994). While pyriethiamin has an affinity comparable to that of thiamin ( $K_{m,app} < 1 \mu\text{M}$ ) for thiamin pyrophosphokinase, oxythiamin has a 1000 times lower affinity. Both compounds may be pyrophosphorylated by thiamin pyrophosphokinase. Oxythiamin diphosphate is a potent inhibitor of thiamin-dependent enzymes, whereas pyriethiamin diphosphate is not. Pyriethiamin, in combination with a thiamin-deficient diet, is used in rodents as a model of Wernicke–Korsakoff syndrome (Desjardins and Butterworth, 2005). Indeed, nutritional deprivation of thiamin alone takes at least 4 weeks in rats before thiamin deficiency symptoms develop. Administration of pyriethiamin in addition to thiamin deprivation reduces the delay to about 10 days. Pyriethiamin, in contrast to oxythiamin, crosses the blood–brain barrier, and the lesions observed closely resemble those in human Wernicke–Korsakoff syndrome. In contrast, oxythiamin-treated animals have no neurological symptoms, but suffer weight loss, anorexia, and cardiac enlargement, probably as a result of inhibition of ThDP-dependent enzymes by oxythiamin diphosphate.

Sulfites, added as preservatives to food, cleave the vitamin at the level of the methylene bridge yielding separate pyrimidine and thiazole moieties, and cases of thiamin deficiency in dogs due to feeding on sulfite-preserved meat have been described (Singh *et al.*, 2005). Earlier studies had suggested that 3,4-dihydroxycinnamic acid (caffeic acid) and similar substances had an antithiamin activity, but this was later disproved (Horman and Brambilla, 1982).

Some foodstuffs may contain thiaminases (thiamin-destroying) enzymes. Some fish (carp, eel, Baltic herring or catfish, for instance) and shellfish may contain thermolabile thiaminase I, a pyrimidine transferase (EC 2.5.1.2). This is also the case for some ferns (*Pteris aquilina*), which, when consumed by grazing cattle or horses, may result in severe thiamin deficiency. Thiaminase is destroyed by cooking, but consumption of raw food containing thiaminase may cause beriberi in humans. Another thiaminase found in microorganisms, thiaminase II (EC 3.5.99.2),

catalyzes the hydrolysis of thiamin in separate pyrimidine and thiazole moieties. Recent results suggest that this enzyme may be involved in thiamin salvage, rather than a thiamin degradation pathway (Jenkins *et al.*, 2007). Indeed, thiamin degradation in the soil leads to the formation of aminopyrimidine, and thiaminase II catalyzes the conversion of aminopyrimidine to hydroxypyrimidine, a building block for the biosynthesis of thiamin by some bacteria.

## Future Directions

Thiamin was the first vitamin characterized and from its discovery the concept of vitamins originated. Nearly a century later, many questions remain. Several phosphorylated thiamin derivatives exist in practically all cell types, but only the cofactor role of ThDP has been clearly demonstrated and extensively studied. Future work should be devoted to the study of the biological roles of all phosphorylated derivatives, as compounds other than ThDP, in particular the triphosphates, might also participate in the symptoms observed during thiamin deficiency. Though we have learned a lot concerning the effects of thiamin deficiency on cell survival, many questions remain open. In particular, we must clarify the mechanism leading to selective vulnerability of certain brain regions to thiamin deficiency, but also the possible beneficial effects of benfotiamine in diabetes and Alzheimer's disease open exciting new fields in thiamin research.

## RIBOFLAVIN

DONALD B. MCCORMICK, PhD

*Emory University, Atlanta, Georgia, USA*

### Summary

Riboflavin (vitamin B<sub>2</sub>) is the principal flavin among a larger group of natural substituted isoalloxazines that can be biosynthesized by many bacteria, yeasts, and higher plants. However, most animals cannot make riboflavin and it must be supplied by dietary intake either as the free vitamin or as flavocoenzymes that are hydrolyzed in the gut to release the vitamin. After both specific and facilitated uptake, as well as passive diffusion into cells, the vitamin is largely converted by kinase- and synthetase-catalyzed reactions to the coenzymes, flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), which operate in numerous enzymatic oxidation–reduction catalyses. Two among many such enzyme systems are FAD-dependent glutathione reductase and FMN-dependent pyridoxine (pyridoxamine) phosphate oxidase, both useful as erythrocyte biochemical indicators of riboflavin nutritional status in humans. Less frequently encountered are enzymes that have flavocoenzymes covalently attached to the polypeptide backbone, such as the mammalian mitochondrial 8 $\alpha$ -S-cysteinyl-FAD of monoamine oxidase and the 8 $\alpha$ -N<sup>3</sup>-histidyl-FAD of dehydrogenases for succinate and sarcosine.

Riboflavin has a wide distribution in foodstuffs, and is present at especially high levels in kidney, liver, cheese, eggs, and milk, where it is largely bound in coenzymes that can be hydrolyzed in the gut to release the free vitamin. Limited solubility of riboflavin precludes tissue overload and potential toxicity. Specific and saturable absorption mechanisms for the vitamin occur at cellular level, and the transport by albumin and more tightly bound immunoglobulins follows in the blood plasma of mammals. A significant fraction of the vitamin and derived flavin products are excreted in urine and secreted in milk by humans and other mammals. The diverse degradative products from flavin that are excreted in the urine reflect hydrolytic and oxidative processes including tissue mixed-function oxidation of methyl groups of the free flavin and ribityl side-chain cleavage that is largely the result of microfloral activity in the gut and exposure of skin to light.

Causes for nutritional deficiency are ascribed not only to inadequate intake but also, less frequently, to impairment in metabolic disposition. There is an expansion of our knowledge of genetic defects in the formation of functional flavoproteins such as reflect mitochondrial electron transfer and  $\beta$ -oxidation of fatty acyl-CoAs. Some of these relatively rare diseases benefit from supplementation, but normal individuals receive ample vitamin by eating a variety of foods, some already fortified with riboflavin.

## Introduction

Riboflavin is so named because it has a ribose-like part of its structure and is yellow (Latin, *flavus*); it was historically designated as the second vitamin in the B-complex of water-soluble vitamins so it is also called vitamin B<sub>2</sub>. Much of the early history of this vitamin has been detailed in volume series such as that edited by Sebrell and Harris during the 1940s, and has been summarized in more recent book chapters (McCormick, 1988; Combs, 1998). Most of the methods for isolation or syntheses, characterization, and quantitation of flavin systems have been collated in the series on *Vitamins and Coenzymes* that was edited by McCormick *et al.* (1970–1997). The ongoing discovery of new flavins, the proteins they associate with, and the diverse oxidation–reduction (redox) reactions in which they participate have been periodically enlarged upon in volumes resulting from symposia held every three years since 1960; a recent (sixteenth) volume of such proceedings was published in 2008 (Frago *et al.*, 2008a). Augmentation of this largely biochemical information can be found in recent papers on flavoprotein systems (see Gadda, 2010). Relatively current reviews that include brief coverage of the history of riboflavin and coenzymes, including chemistry and properties, are to be found in books dealing with all the vitamins required by humans (McCormick, 2006; Rivlin, 2007). The present chapter provides an update on this vitamin since the preceding editions of *Present Knowledge in Nutrition* (McCormick, 1990; Rivlin, 2006).

## Natural Flavins

All known natural flavins but one (5-deazaflavin) are isoalloxazines, which are 10-substituted derivatives of alloxazine, the parent tricyclic ring system, with nitrogens in positions 1, 3, and 5. The variations in structures of naturally occurring flavins, with a dashed line between atoms in positions 1 and 5 to allow for oxidized (quinoid), half-reduced (semiquinoid or radical), and fully reduced (hydroquinoid) forms, are summarized in Figure 18.1. Approximately 35 different flavoquinones have been isolated from natural sources.

Riboflavin (7,8-dimethyl-10-[1'-D-ribyl]isoalloxazine) is a yellow fluorescent compound that is widely distributed throughout the plant and animal kingdoms. Studies with bacteria and fungi, particularly *Ashbya gossypii* and *Eremothecium ashbyii*, which can biosynthesize

rather large quantities of riboflavin, have revealed a pathway from guanosine triphosphate (GTP). Most of the intermediates and enzymes involved were characterized over the past half-century; however, continuing work has provided more molecular details (Bacher *et al.*, 2000, 2001). Recent examination of the crystal structure of a bifunctional enzyme from *Bacillus subtilis* revealed an N-terminal deaminase domain belonging to the cytidine deaminase superfamily and a C-terminal reductase domain similar to that found in dihydrofolate reductase (Chen *et al.*, 2006). The two reductases involved in riboflavin and folate biosyntheses probably evolved from an ancestral gene and remind us of the similar initial steps in the pathways that result in isoalloxazine and pterin systems, both of which originate from GTP and require cyclohydrolases. Dismutation of 6,7-dimethyl-8-ribityllumazine yields diastereomeric pentacyclic intermediates in archaeal (*Methanococcus jannaschii*) and non-archaeal (*Escherichia coli*) riboflavin synthases that yield 5-amino-6-ribitylamino-2,4(1H,3H)-pyrimidinedione and riboflavin (Illarionov *et al.*, 2005). Though most flavins derive from further actions upon riboflavin, at least two, namely roseoflavin with an 8-dimethylamino function produced by *Streptomyces davawensis* and coenzyme F<sub>420</sub> with a 5-carba-5-deaza nucleus formed in *Methanobacterium* sp., must arise in variations of the usual biosynthetic pathway. Structures of these native flavins, with substituents noted in respect to Figure 18.1, are summarized in Table 18.1. Higher organisms, notably the human and other mammals, cannot biosynthesize the isoalloxazine system; therefore, riboflavin is a water-soluble vitamin (i.e. a required nutrient) for such species.

**FIG. 18.1** Generalized structure for flavins and derivatives that occur naturally. Particular substituents are given in the text and tables that refer to diverse types.

## Flavocoenzyme Types and Functions

The major coenzyme forms of riboflavin function as prosthetic groups of numerous holoenzymes that catalyze diverse and often essential one- and two-electron redox reactions. The five physiologically relevant redox forms have been structurally detailed in an earlier review (McCormick, 1988). Flavin mononucleotide (FMN, also named riboflavin 5'-phosphate) may account for as much as 10% of the total flavin in diverse cells, and the more frequently encountered flavin adenine dinucleotide (FAD) comprises nearly 90%. Moreover, a small but significant fraction of both coenzymes (5–10% of FAD) occurs in some organelles and organisms as forms altered at positions 6, 8, or 8 $\alpha$ . Structures of the coenzyme-level flavins with substituents noted in respect to Figure 18.1 are summarized in Table 18.2.

Sources for the coenzyme-level flavins were summarized in a previous review (Merrill *et al.*, 1981a). Briefly, however, it can be noted that the 6-hydroxy derivatives of both FMN and FAD may arise from oxidative turnover of the predominant natural coenzymes during function. The

6-S-cysteinyl-FMN, 8-hydroxy flavins, and 8 $\alpha$ -O-tyrosyl-FAD have been found in certain bacterial systems, but the 8 $\alpha$ -S-cysteinyl- and both 8 $\alpha$ -N<sup>1</sup>- and N<sup>3</sup>-histidyl-FAD forms are found in several lower and higher organisms. Berberine bridge enzyme, a plant enzyme involved in alkaloid biosynthesis, was isolated from the California poppy (*Eschscholzia californica*), expressed at a higher level in the methylotropic yeast (*Pisichia pastoris*), and found to contain an FAD linked in the 8 $\alpha$ -position to a histidyl residue and in the 6-position to a cysteinyl thiol function (Winkler *et al.*, 2006). The bi-covalently attached FAD has the highest redox potential so far known for any flavoprotein and may predispose the enzyme for a hydride ion transfer from substrate (Winkler *et al.*, 2007). Examination of the crystal structure of berberine bridge enzyme and such mutants as lack one of the linkages to FAD revealed that both linkages are involved in increasing redox potential and fine-tuning the active-site geometry for optimal substrate binding (Winkler *et al.*, 2009). The covalent attachment of FAD via an 8 $\alpha$ -linkage to a cysteinyl residue in mitochondrial monoamine oxidase (both A and B types) and such linkage to the N<sup>3</sup> of an imidazole of histidyl residues in mitochondrial succinate and sarcosine dehydrogenases are important examples in our bodies. The N<sup>1</sup>-histidyl linkage occurs, among other places, in L-gulonolactone oxidase, which allows certain animals, e.g. rats, to biosynthesize L-ascorbic acid.

**TABLE 18.1** Native flavins formed by microorganisms

Name	Substituent				
	A	B	C	D	E
Riboflavin	1'-D-ribityl	CH <sub>3</sub>	CH <sub>3</sub>	H	N
Roseoflavin	1'-D-ribityl	(CH <sub>3</sub> ) <sub>2</sub> N	CH <sub>3</sub>	H	N
5-Deazaflavin	1'-D-ribityl	HO	H	H	CH

## Absorption, Transport, and Uptake

Methods to assess the bioavailability of riboflavin from foods continue to be improved. As determined by

**TABLE 18.2** Flavocoenzymes found with flavoenzymes

Name	Substituent				
	A	B	C	D	E
FMN	1'-D-ribityl-5'-phosphate	CH <sub>3</sub>	CH <sub>3</sub>	H	N

stable-isotope labels and kinetic modeling (Dainty *et al.*, 2007), a large fraction of newly absorbed riboflavin in the human is removed by the liver on “first pass” so that appearance in plasma underestimates bioavailability from foodstuffs. Urinary monitoring suggests that riboflavin from spinach is as bioavailable as it is from milk. After ingestion of diverse natural flavins, most of which occur as coenzymes and traces of flavinyl peptides, release occurs by non-specific hydrolytic activities in the gastrointestinal tract. Earlier investigations on general aspects of absorption in humans were updated by studies with sections of gut (Daniel *et al.*, 1983) and isolated cells (Hegazy and Schwenk, 1983) from other mammals. The vitamin is primarily absorbed in the human in the proximal small intestine by a saturable uptake that is rapid and proportional to dose before leveling off in adults at about 25 mg of riboflavin (Zempleni *et al.*, 1996a). Bile salts appear to facilitate uptake, and a modest amount of the vitamin circulates via the enterohepatic system. Active transport at lower concentrations may be Na<sup>+</sup> dependent and involve phosphorylation. However, a recently studied Na<sup>+</sup>-independent transport protein that is pH sensitive may also contribute in jejunal and ileal regions (Yamamoto *et al.*, 2009). Most recently human riboflavin transporters (hRFTs) have been identified and found to be expressed differentially in various tissues (Fujimura *et al.*, 2010; Yao *et al.*, 2010). The mRNAs for both hRFT 1 and 2 are strongly expressed in the small intestine, whereas hRFT 3 is expressed in the brain. As reported earlier, intestinal absorption seems to be affected by aging, fiber intake, antacids, and uremic conditions (McCormick, 1990). Metabolic trapping by conversion to coenzymes generally occurs before release of the vitamin to circulation by pyrophosphatase and phosphatase activities.

Transport of flavin by blood plasma is known to involve both loose association with albumin and tight associations with some globulins. Among the latter, immunoglobulins were identified as the major binding proteins for riboflavin in serum from normal humans (Merrill *et al.*, 1981b; Innis *et al.*, 1985) and from patients with certain types of cancer (Innis *et al.*, 1986; Zhu *et al.*, 2006). By use of flavinyl-affinity chromatography, different immunoglobulin subclasses, namely IgG, IgM, and IgA, were isolated and shown to have both  $\kappa$  and  $\lambda$  light chains (Merrill *et al.*, 1987). Papain cleavage of the immunoglobulins yielded Fab fragments that still bound riboflavin. Hence, at least a portion of the antigenic binding site may be involved. In this connection it is interesting to note that riboflavin

antibodies were elicited in response to haptenic challenges (Barber *et al.*, 1987).

Some riboflavin-binding proteins are pregnancy specific, including the classic case of the estrogen-induced egg white protein. This subject has been reviewed both in particular (Kozik, 1985; White and Merrill, 1988) and as part of past general reviews of riboflavin (McCormick, 1990, 2006). Examples include binding proteins from pregnant cows, rats, bonnet monkeys, and humans. These proteins appear similar to the avian riboflavin-binding protein because their epitopes are recognized by monoclonal antibodies to the chicken riboflavin-binding protein. They are essential for fetal development because immunization of animals with the avian protein or injection of antibodies against the avian protein terminates pregnancy in rats, mice, and the bonnet monkey. Fetal degeneration accompanies lowering of FAD levels in the fetus. The exact cause of the effect on level of flavocoenzyme is not known, but an interaction between chick liver flavokinase and riboflavin-binding protein has been demonstrated (Kozik, 1985; White and Merrill, 1988; McCormick, 1990, 2006). Placental transfer of riboflavin seems to involve binding proteins that help vector the vitamin and enhance supply to the fetus. In perfused human placenta, differential rates of uptake were noted at maternal and fetal surfaces (McCormick, 2006). There are differences in riboflavin concentrations in maternal and cord blood in the human, carrier proteins were isolated from both, and a flavin-containing placental protein was isolated (McCormick, 2006).

Uptake processes for flavins by mammalian cells have some characteristics in common, but there are both qualitative and quantitative differences among different cell types (Bowman *et al.*, 1989; McCormick, 1990, 2006). Hepatocytes exhibit an initial rapid and specific intake followed by slower passive diffusion of the vitamin, which becomes metabolically trapped by flavokinase-catalyzed phosphorylation (Aw *et al.*, 1983). The uptake process is relatively insensitive to both Na<sup>+</sup> and ouabain and probably reflects a facilitated, carrier-mediated system. A riboflavin-binding protein has been reported to occur in the plasma membrane of rat liver cells (Nokubo *et al.*, 1989). With proximal tubular epithelial cells from rat kidney, the faster facilitated phase of flavin uptake exhibits Na<sup>+</sup> dependence (like small intestine but unlike liver) but is insensitive to ouabain (like liver but unlike small intestine) (Bowers-Komro and McCormick, 1987). An ATP requirement reflects, as for other cells, the trapping of

**FIG. 18.2** Interconversions of flavin and flavocoenzymes.

riboflavin by phosphorylation, a process that can be impeded by other flavin substrates or inhibitors of flavokinase.

## Coenzyme Formations and Interconversions

Knowledge on the way in which flavins are interconverted to coenzymatic forms is summarized in Figure 18.2.

As noted in a summary on this subject (McCormick *et al.*, 1987), relatively homogeneous preparations of flavokinase (now also called riboflavin kinase) were obtained first from rat liver (Merrill and McCormick, 1980), then from mung beans (Sobhanaditya and Appaji Rao, 1981) and more recently from a bacterium (Manstein and Pai, 1986). Though not identical in molecular properties, the mammalian (28 000 MW) and plant (30 000–35 000 MW) kinases cannot further catalyze formation of FAD from FMN, whereas the bacterial enzyme (38 000 MW) is both a flavokinase and an FAD synthetase. This type of dual-functional enzyme is found in many prokaryotes wherein the N-terminal and C-terminal domains are related to nucleotidyl transferase and riboflavin kinases, respectively (Frago *et al.*, 2008b). The FAD synthetase from liver is a larger enzyme (100 000 MW dimer) but cannot function as a flavokinase (Oka and McCormick, 1987). Seemingly in all cases,  $Zn^{2+}$  is preferred for kinase activity and  $Mg^{2+}$  for synthetase activity. The phylogenetic differences among flavokinases and FAD synthetases located in the cytosol are interesting and may have a bearing on the controls that can modulate levels of flavocoenzyme formed in higher organisms with separate but probably interactive enzymes. The kinetics of substrate and product interactions with the kinase/synthetase system of rat liver has been discerned (Yamada *et al.*, 1990). FAD as an inhibitory end-product may regulate its own formation. There is significant endocrine control of mammalian

flavocoenzyme level, most especially as involves thyroid-hormone induced increase in biosynthesis (Rivlin, 2001). Increase in triiodothyronine in rats leads to an increase in a more active form of liver flavokinase and a concomitant decrease in a less active form (Lee and McCormick, 1985). Recent work suggests that tumor necrosis factor, through activation of flavokinase, enhances the incorporation of FAD in NADPH oxidases (Yazdanpanah *et al.*, 2009).

The non-specific hydrolytic enzymes that break down FMN and FAD have been observed in extracts from numerous sources (McCormick, 1975). Mammalian phosphatases that can hydrolyze FMN to riboflavin and inorganic phosphate not only include those with somewhat acidic pH optima (McCormick and Russell, 1962), such as those located in lysosomes, but also include those with alkaline optima (Akiyama *et al.*, 1982), such as in the intestinal brush border. FAD pyrophosphatases from both liver and intestine are optimal at alkaline pH. There are age-related decreases in the hydrolytic activities for both FMN and FAD in liver (Lee and McCormick, 1983). It has been found recently that a C-terminal flavokinase homolog in plants (*Arabidopsis thaliana*) is fused with an FMN hydrolase (Sandoval and Roje, 2005). Subcellular localization of these and the FAD synthetase activities within plastids has also been delineated (Sandoval *et al.*, 2008).

The means by which subsequent modifications of flavocoenzymes occur is not yet completely understood. However, it is certain that FMN and more commonly FAD are preformed before fractions of these coenzymes are covalently attached to specific apoenzymes. Studies on incorporation of  $^{14}C$ -riboflavin into covalently bound FAD of enzymes from rat liver mitochondria indicate that formation of FAD preceded attachment (Yagi *et al.*, 1976; Addison and McCormick, 1978; Sato *et al.*, 1984). The fact that certain synthetic  $8\alpha$ -substituted riboflavins (e.g. S-cysteinyl or  $N^3$ -histidyl derivatives) were not converted by flavokinase to the corresponding FMN analog (Merrill and McCormick, 1979, 1980) and that synthetic  $8\alpha$ -imidazole-FMN is not a substrate for the FAD synthetase (Bowers-Komro *et al.*, 1989) would also argue against covalent linkage of FAD to the peptide in such systems as are in monoamine oxidase or succinate dehydrogenase until after FAD is formed.

Work with cell-free synthesis of 6-hydroxy-D-nicotine oxidase from *Arthrobacter oxidans*, an enzyme with an  $8\alpha$ - $N^3$ -histidyl-FAD, has established that intact FAD is incorporated into nascent polypeptide chains during

ribosomal translation (Hamm and Decker, 1978, 1980). This has been extended to the similarly linked FAD within bacterial succinate and fumarate dehydrogenases (Brandsch and Bichler, 1985, 1986). The apoenzyme of the hydroxynicotinase could be transformed into holoenzyme in the presence of FAD, ATP, phosphoenolpyruvate, and pyruvate kinase (Brandsch and Bichler, 1987). This indicates that flavinylation is enzyme catalyzed and may proceed through a phospho-intermediate. A protein fraction in the mitochondrial matrix has been reported to stimulate flavination of dimethylglycine dehydrogenase (Brizio *et al.*, 2000).

### Catabolism, Excretion, and Secretion

Certain bacteria of the genus *Pseudomonas* can extensively degrade both the ring system (Tsai and Stadtman, 1971) and side chains (Yanagita and Forster, 1956; Yang and McCormick, 1967) of flavins, but mammals are more limited in their abilities to catabolize the vitamin (McCormick, 1975; McCormick *et al.*, 1984, 1987). The diversity of flavin-derived products in mammalian urine, however, reflects metabolic events that occur in gastrointestinal microbes as well as in the somatic cells and additionally is augmented by photochemical events that occur at the dermal level. These diverse compounds and their interconnections are summarized in Figure 18.3.

Cleavage of the side chain at position 10 seems mainly if not entirely attributable to intestinal microflora and light. Action of the former on riboflavin was shown to lead to partial fragmentation to form the 10-formylmethylflavin found in urine from ruminants (Owen and West, 1971a) which can interconvert this product with the 10-hydroxyethylflavin formed as a result of pyridine-nucleotide-dependent dehydrogenase in tissues (Owen and West, 1971b). The 10-hydroxymethylflavin is also found in urine from rats (Chastain and McCormick, 1987a) and humans (Chastain and McCormick, 1987b). Lumichrome-level compounds not only may result from complete removal of the side chain by microflora, which can be decreased by antibiotic administration (Yang and McCormick, 1978; Chastain and McCormick, 1987a), but may also accompany lumiflavin as a photoproduct from action of light on flavin within the dermal tissue (Yang and McCormick, 1978; Chastain and McCormick, 1987a,b). A significant fraction of fecal radioactivity obtained from rats administered [2-<sup>14</sup>C]riboflavin was also found to be chloroform soluble and at the level of lumi-

chrome (Yang and McCormick, 1978). A portion of the formylmethylflavin can also be oxidized by alimentary bacteria of the ruminant and human to form the 10-carboxymethylflavin (West and Owen, 1973).

No enzymatic activity able to lead to such chain-shortened products has been identified within tissues (Oka and McCormick, 1985). Rather, those catabolites of riboflavin that primarily derive from oxidations within tissue are the 7- and 8-hydroxymethylriboflavins (7 $\alpha$ - and 8 $\alpha$ -hydroxyriboflavins) found especially in human urine (Ohkawa *et al.*, 1983a; Chastain and McCormick, 1987b). The 7 $\alpha$ -compound is also the main catabolite to appear in plasma of humans administered the vitamin orally (Zempleni *et al.*, 1996b). The 7- and 8-carboxyllumichromes occur in considerable amounts in rat urine (Ohkawa *et al.*, 1983b; Chastain and McCormick, 1987a). These methyl oxidized products reflect microsomal mixed-function oxidase activity (Ohkawa *et al.*, 1983c). Other flavin catabolites include those from 8 $\alpha$ -(amino acid)riboflavins released from covalently bonded FAD (Chia *et al.*, 1978). An 8 $\alpha$ -sulfonylriboflavin found in human urine may derive from the 8 $\alpha$ -cysteinyl-FAD of monoamine oxidase (Chastain and McCormick, 1987b). A peptide ester of riboflavin has also been found in human urine (Chastain and McCormick, 1988). We can account for > 95% of flavins excreted in human urine. For normal adults eating varied diets, riboflavin comprises about two-thirds; 7-hydroxymethylriboflavin, 10–15%; a few to several percent of the 8-hydroxymethyl- and 8 $\alpha$ -sulfonylriboflavins occur; there are lesser amounts of riboflavinyl peptide ester and such side-chain-altered flavins as the 10-hydroxyethyl and 10-formylmethyl compounds; and only traces of carboxymethylflavins and lumiflavin. It has been reported that such compounds as boric acid and chlorpromazine increase urinary excretion of riboflavin (Rivlin, 2006).

Secretion of flavins into milk has been reviewed (McCormick, 2006). As with urinary flavins, output reflects dietary status of the mother. In milk from cows (Roughead and McCormick, 1990a) and from humans (Roughead and McCormick, 1990b), the flavin in highest concentration other than the free vitamin is FAD, which can account for more than one-third of total flavin. Much of this is hydrolyzed during pasteurization. Fairly significant quantities of the 10-(2'-hydroxyethyl)flavin are notable, because this catabolite has antivitaminic activities as reflected in competitive inhibition of both cellular uptake (Aw *et al.*, 1983) and subsequent flavokinase-catalyzed phosphorylation of

**FIG. 18.3** Catabolism and photodegradation of riboflavin reflected by urinary products from mammals.

riboflavin (McCormick, 1962). Hence, this catabolite subtracts modestly from the biologic activity of the milk. Several percent of both 7- and 8-hydroxymethylriboflavins are also present, with more of the former. Smaller amounts of other catabolites, including the 10-formylmethylflavin and lumichrome, account for most of the rest (Roughhead and McCormick 1990a,b).

There are other metabolic derivatives of flavin known to occur naturally. Among these are glycosides (Whitby, 1971) and a cyclic phosphodiester (Tachibana, 1967) of the ribityl side chain, and even schizoflavins (Tachibana and Murakami, 1980) that derive from oxidations at the 5'-hydroxymethyl terminus (Kekelidze *et al.*, 1994; Chen and McCormick, 1997a,b). A riboflavinyl 5'-malonate has

been obtained from *Avena coleoptiles* (Ghisla *et al.*, 1984). However, these compounds are generally associated with bacterial, fungal, or plant organisms and are not normally of consequence to the human. The riboflavinyl  $\alpha$ -D-glucoside was reported in rat urine (Ohkawa *et al.*, 1983d) and its uptake and metabolism have been studied in rat liver cells (Joseph and McCormick, 1995).

## Status and Deficiency

Human riboflavin requirements, biochemical indicators for these, and factors affecting the requirements have been covered in earlier reviews (Sauberlich, 1984; Bates, 1987) and were summarized in a report by the Institute of Medicine (1998). The current RDAs for adults are 1.1 mg for women and 1.3 mg for men. The median intake from foods in the US, especially including supplements, is considerably higher than requirements. As previously listed (Ensminger *et al.*, 1994; Rivlin, 2007), foods especially rich in bioavailable riboflavin are yeast, kidney, liver, cheese, eggs, and milk. Green vegetables are reasonably good sources. Natural grains and cereals are relatively poor sources, but fortification and enrichment have led to a considerable increase in intake of riboflavin from these food items. The mean intake of the vitamin by the US population is well above the estimated requirements. There are many who take over-the-counter supplements of micronutrients, which are commonly pills and drinks that contain riboflavin as well as other vitamins and trace essential elements; however, few gain from such misguided practice, especially as concerns riboflavin which has limited absorption (McCormick, 2010). Among factors affecting the requirement are bioavailability (~95% of food flavin), nutrient–nutrient interactions, and perhaps energy intake and physical activity. There is also some increase in urinary flavin loss with the use of such drugs as chlorpromazine and in the accidental drinking of boric acid solutions (Rivlin, 2006).

Biochemical indicators for estimating riboflavin requirements and determining status include assays of red cell and urinary flavin (both enhanced by HPLC and fluorometry) and the erythrocyte assays of glutathione reductase ( $\pm$  FAD) and pyridoxine (pyridoxamine) phosphate ( $\pm$  FMN). Although widely used, the erythrocyte glutathione reductase assay using freshly lysed red cells (Sauberlich *et al.*, 1972; McCormick and Green, 1999) has known limitations. The test cannot be used in persons with glucose-6-phosphate dehydrogenase deficiency, which

occurs in about 10% of African-Americans, because of an increased avidity in the glutathione reductase for FAD in this disease (Nichols, 1981). A study of mutations in the glutathione reductase gene among Saudi Arabians showed that both genetic causes and deficiency can lead to a decrease in the reductase (Warsy and El-Hazmi, 1999). Moreover, in vitro treatment of blood with inosine and adenine elevates activity coefficients (Trout, 1989). In a study of piglets, the erythrocyte glutathione reductase activity coefficient was not significantly correlated with either total vitamin B<sub>2</sub> metabolites in the circulation or liver, which may suggest that it is not useful as a status determinant in this species (Giguère *et al.*, 2002). However, the erythrocyte reductase activity coefficient increased and liver flavins concomitantly decreased during induction of riboflavin deficiency in the rat (Yates *et al.*, 2001). More recently used is the FMN-dependent pyridoxine (pyridoxamine) phosphate oxidase assay which is unaffected by differences in glucose-6-phosphate status. The oxidase is an interface between riboflavin and vitamin B<sub>6</sub> (McCormick, 1989). The oxidase was shown to require FMN as coenzyme with the pure liver apoenzyme (Kazarinoff and McCormick, 1975). Its sensitivity to riboflavin status was then demonstrated with rats (Rasmussen *et al.*, 1979, 1980). Extension of this oxidase assay as an indicator for flavin status in the human was forthcoming (Mushtaq *et al.*, 2009). A low oxidase activity due to a red cell deficiency of FMN, confirmed by response to oral riboflavin, was reported in the majority of subjects with glucose-6-phosphate dehydrogenase deficiency (Powers and Bates, 1985; Anderson *et al.*, 1987). Such cases seem to have an accelerated conversion of FMN to FAD so that glutathione reductase is saturated. This contrasts with heterozygous  $\beta$ -thalassemia, where there is an inherited slow red-cell conversion of riboflavin to FMN, a decrease in subsequent FAD, and a high stimulation of the glutathione reductase by extraneous FAD (Anderson *et al.*, 1984, 1987).

Clinical signs of deficiency (ariboflavinosis) have been reviewed (Wilson, 1983; Institute of Medicine, 1998; Rivlin, 2006). In all animals there is retardation of growth. Additional effects include loss of hair, disturbances of the skin, etc. In humans, symptoms include sore throat; hyperemia and edema of the pharyngeal and oral mucous membranes; cheilosis; angular stomatitis; glossitis (magenta tongue); seborrheic dermatitis; and normochromic, normocytic anemia associated with pure red cell cytoplasia of the bone marrow. Because riboflavin deficiency is most

often accompanied by deficiency of other B-complex vitamins, some of the symptoms described may reflect such complications. In general where there are populations that receive too little food, such as in parts of Africa, one still finds deficiency of riboflavin and other vitamins. However, there have also been reports of poor riboflavin status in European groups that do not show overt clinical signs of riboflavin deficiency, but reflect a possible biochemically detected subclinical deficiency. One recent example is the high activity coefficient of erythrocyte glutathione reductase measured in a group of young Irish women (Powers *et al.*, 2011).

There has been an expansion in our knowledge of those inborn errors of metabolism that are the result of genetic defects in formation of functional flavoproteins (Bartlett, 1983; Gregersen, 1985; Vianey-Liaud *et al.*, 1987). Some involve enzymes of mitochondrial general electron transfer, as in amyotrophic lateral sclerosis (Lin *et al.*, 2009) and a myopathic form of coenzyme Q10 deficiency (Gempel *et al.*, 2007), whereas others are associated with  $\beta$ -oxidation of fatty acyl-CoA (Chioang *et al.*, 2007; Henriques *et al.*, 2009). In most cases, therapeutic levels of riboflavin have a beneficial effect.

Other diseases also affect riboflavin status, as previously noted (McCormick, 1990). Some effects arise as a result of treatment, e.g. dialysis required with chronic renal failure or phototherapy in the potentially kernicteric infant. In these cases supplements are warranted. Supplementation also may be reasonable with the use of certain drugs, including antimalarials, some of which are flavin analogs (Cowden *et al.*, 1988). In this latter connection, it is interesting that a relative riboflavin deficiency confers some protection against plasmodial infection in humans (Thumham *et al.*, 1983).

## Future Directions

Some points that still require further investigation were raised in the last edition of *Present Knowledge in Nutrition* (Rivlin, 2006). However, it seems clear that studies at the molecular to cellular levels can reveal more. The relative sensitivity of the numerous flavin-dependent enzymes needs to be better defined and the criticality of their formation understood. Ultimately clinical symptoms are a reflection of these parameters. Ideally one should know which systems are most affected by limitation of flavoenzyme availability, whether due to impaired intake of vitamin, formation of coenzymes, or improper holoen-

zyme formation and function. Clearly both biochemical and genetic approaches will continue to be useful for a more complete nutritional understanding. Certain too is the need to expand our knowledge on how age, gender, and disease interplay with the need for riboflavin.

### Suggestions for Further Reading

As has been pointed out in the Introduction, several earlier volumes contain more information concerning the history of discovery of riboflavin and its natural forms, and details of the isolation and chemistry of these, and there is an ever-expanding literature on the biological actions of the myriad related flavins. In particular, there are three volume series that can be perused by any who are looking for a fuller account of how we accrued our present level of understanding in this area:

*Present Knowledge in Nutrition*, editions from the first to the current (10th) published by the International Life Sciences Institute.

*Modern Nutrition in Health and Disease*, editions from first to current (10th) published by Lippincott Williams & Wilkins.

*Vitamins and Coenzymes*, 12 volumes intermittent from Vol. 18 to Vol. 282 spanning 1970–1997 in the *Methods in Enzymology* series published by Academic Press.

### Summary

The niacin deficiency disease pellagra was the most devastating nutritional disease in modern American history. Even today, after enrichment of refined foods, niacin deficiencies may occur through poor food habits. Niacin is transformed to the essential pyridine nucleotides nicotinamide adenine dinucleotide (NAD[P]). Used by at least 470 proteins, these are involved in more reactions than any other vitamin-derived molecule. Nicotinic acid may also activate the GPR109 receptors, which mediate many of the dyslipidemia-correcting activities. An active area of therapeutic research involves increased nicotinamide adenine dinucleotide (NAD) working through sirtuin activation to provide benefit in many disease settings. The development of poly(ADP)-ribose polymerase inhibitors to simultaneously preserve NAD levels while decreasing genomic stability is also an area of great interest, particularly in cancer research. Nicotinic acid, nicotinamide, nicotinamide riboside, tryptophan, and the more recently considered nicotinamide mononucleotide all possess distinguishable characteristics as NAD precursors that continue to be examined. Other nutrients affecting NAD metabolism have potential as combinatorial modifiers of niacin status. These include glutamine, thiamin, and others required for completion of the de novo pathway from tryptophan: ascorbate, riboflavin, and pyridoxal phosphate. Further study of NAD metabolism will excite scientists and clinicians, and will lead to improved health.

### Introduction

Niacin deficiency was first described by Casal in 1762 in Europe as a condition characterized by extreme weakness and crusty skin (Carpenter, 1981). Accordingly, Casal coined the disease “pellagra,” meaning angry skin. Just over 100 years later, pellagra would reach epidemic proportions in the southern United States due to the invention and distribution of industrial-scale milling devices in the 1870s. Suddenly the first refined foods, white flour

and rice, became available to the American masses. Thereafter pellagra and beriberi became pervasive depending on the variety of individual diets. Pellagra exerted many effects on psychiatric health and was the leading cause of death in mental hospitals in 1907. By the 1920s, pellagra had become the most severe deficiency disease in the history of the United States. Over 120 000 people died from pellagra epidemics in the US during the first two decades of the twentieth century (Etheridge, 1972; Carpenter, 1981).

**FIG. 19.1** Forms of vitamin B<sub>3</sub>. Various dietary precursors can support the formation of the essential molecule, nicotinamide adenine dinucleotide (NAD). The cofactors required to convert each vitamin B<sub>3</sub> precursor to NAD are shown. PRPP, 5-phosphoryl-ribose-1-pyrophosphate; Q, glutamine.

Pellagra was finally understood in the 1930s thanks in large part to the work of the epidemiologist Dr Joseph Goldberger. Initially Dr Goldberger's hypothesis that pellagra was a dietary deficiency disease was rejected in favor of corn toxins or poor sanitation. Elvjeham identified the pellagra-preventing factor in 1937 as the molecule nicotinic acid. First a dietary-deficiency dog model that caused tongue discoloration was created. Then, a rice-polishing component that prevented tongue discoloration was isolated and named the pellagra-preventing factor. The government established legally mandated standards of niacin enrichment of flour in 1942. Niacin refers to the chemical nicotinic acid, while niacinamide refers to the chemical nicotinamide. However, niacin is commonly used to refer to either form. This is unfortunate because there are significant physiological differences between niacin and niacinamide.

Doctors who witnessed pellagrous dementia noticed many similarities to schizophrenia and theorized that schizophrenics might have a genetic disorder that required far greater levels of niacin. Experiments performed in the 1950s revealed that administration of gram quantities of niacin to schizophrenic patients frequently exerted therapeutic benefits with no adverse reaction (Hoffer *et al.*, 1957). However, this approach remains controversial today. This may be due, in part, to the fact that schizophrenia could enter a stage of irreversible change that is no longer responsive to chemical approaches. These same researchers discovered that high-dose nicotinic acid, but not nicotinamide, effectively lowered blood cholesterol (Altschul *et al.*, 1955). Today, high-dose niacin is a more effective elevator of the high-density lipoprotein ("good" cholesterol) than any pharmaceutical. This approach also lowers triglycerides, and very-low-density lipoprotein ("bad" cholesterol). Amazingly, high-dose niacin will also raise cholesterol for individuals with abnormally low cholesterol. Administration of high doses of the various alternative nicotinamide adenine dinucleotide (NAD) precursors nicotinic acid/niacin, nicotinamide/niacinamide, and/or nicotinamide riboside remains an ongoing area of clinical research.

## Niacin Structure and Nomenclature

Niacin, which commonly refers to nicotinic acid or nicotinamide, is vitamin B<sub>3</sub>. Nicotinic acid has many effects that differ from nicotinamide due to the presence of a ketone body receptor, which also recognizes nicotinic acid and mediates the flush response. Niacin is also known as nicotinic acid or pyridine-3-carboxylic acid, while niacinamide is also known as nicotinamide or pyridine-3-carboxamide. Together nicotinic acid and nicotinamide are vitamin B<sub>3</sub>. Vitamin B<sub>3</sub> is defined as the dietary precursors to nicotinamide adenine dinucleotide, other than the amino acid tryptophan. Most recently, a third form of vitamin B<sub>3</sub>, nicotinamide riboside, was discovered (Bieganowski and Brenner, 2004). Structures for the three molecules are shown in Figure 19.1.

## Assessment and Maintenance of Niacin Nutriture

### Biochemical Determination of Niacin Status

Biochemical assessment of niacin status is ideally determined by measuring tissue NAD levels (Jacobson

*et al.*, 1999; Shah *et al.*, 2005). Alternatively, measures of the urinary metabolites N'-methylnicotinamide and 2-pyridone are frequently used as indirect indicators of niacin status (McCormick and Greene, 1999). Measures of 41 nM/mL human blood are increased by approximately fourfold after supplementation, while consumption of a low-niacin diet causes a decrease of about 50% in whole blood NAD (Jacobson *et al.*, 1999). Another frequently used measure is the niacin number, which is a ratio of NAD to NADP in whole blood (Fu *et al.*, 1989; Jacobson and Jacobson, 1997). As NADP levels are relatively stable during niacin deficiency whereas NAD declines (Tang *et al.*, 2008), this ratio is a convenient measure of niacin status. Analysis of over 1000 women in 1980s Sweden using this technique surprisingly revealed that 15–20% of modern-day populations in developed countries may have significant niacin deficiency (Jacobson, 1993).

“Niacin” is a term that refers to direct vitamin precursors for NAD formation whereas “niacin equivalents” takes into consideration the non-vitamin NAD precursor, tryptophan. The conversion factor for the endogenous transformation of tryptophan to NAD is approximately 60 mg of tryptophan per 1 mg of NAD. Thus ingestion of 60 mg of tryptophan counts as 1 niacin equivalent (NE). The tryptophan content of protein is approximately 1%. Thus, a diet of approximately 100 g of protein would presumably result in approximately 16 mg of niacin, thus meeting the recommended daily allowance for NAD without inclusion of the vitamin forms of niacin.

### Daily Recommended Intake and Food Sources

Recommended dietary allowances (RDA) originated during World War II as minimal standards for food relief, and have continued to evolve. The RDA represents the amount of vitamin necessary to meet the needs of 97.5% of the population. Restricting niacin intake to 50% of RDA decreases NAD by 70% within 5 weeks, while nicotinamide adenine dinucleotide phosphate (NADP) levels remain constant (Fu *et al.*, 1989). These decreased NAD levels precede pellagra symptoms and are frequently seen in carcinoid syndrome patients (Shah *et al.*, 2005). Most significantly, more niacin is needed during pregnancy and lactation (Table 19.1) (Otten *et al.*, 2006). Since tryptophan can also be converted to nicotinic acid mononucleotide (Figure 19.2), but with 1/60th the efficiency of nicotinic acid, 60 mg of tryptophan is considered 1 niacin equivalent.

**Table 19.1** Recommended dietary allowance (RDA) values for niacin across the lifespan

Population group	NE/day <sup>a</sup>
Infants	
0–0.5 years	2
0.5–1.0 years	4
Children	
1–3 years	6
4–8 years	8
9–13 years	12
Males	
≥14	16
Females	
≥14	14
Pregnant	18
Lactating	17

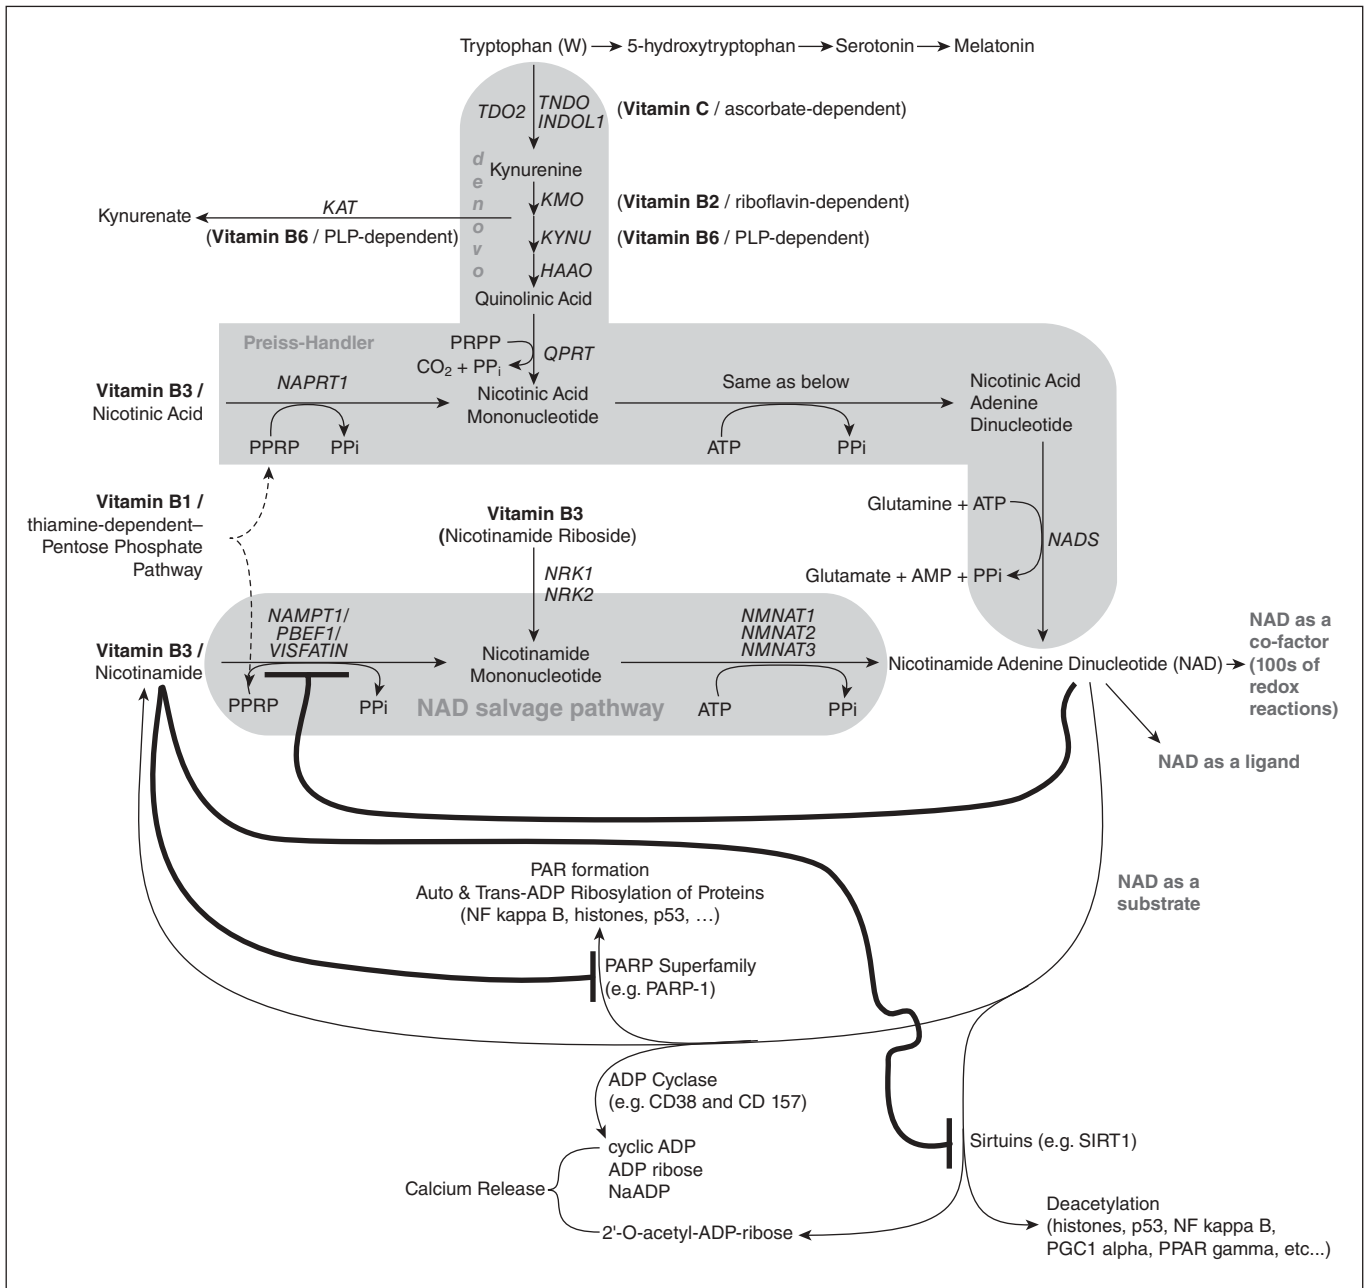

<sup>a</sup>NE (niacin equivalents) = mg niacin + 1/60 mg tryptophan. Reproduced with permission from Otten *et al.* (2006).

**TABLE 19.2** Food sources of preformed niacin

Food source	Amount of niacin
Dairy	0.2 mg per 1 cup whole milk 0.05 mg per 1 egg
Meats (per 3oz, 85 g)	14 mg beef liver 10–11 mg tuna, halibut, swordfish 7 mg rainbow trout 2–6 mg beef, lamb, pork, poultry, other fish
Cereals and grain products	2–10 mg per 1 cup ready-to-eat cereal 3 mg per cup barley or rice, cooked 3–4 mg per 4-in (3-oz/85-g) bagel 2 mg per 2-oz/56-g hard roll 2 mg per cup noodles or pasta
Vegetables (per cup)	4 mg canned tomato product 3 mg mushrooms 2 mg corn 2 mg potatoes 0.5 mg of mustard greens
Other	4 mg per oz (28g) peanuts

Data from USDA/ARS (2005) USDA National Nutrient Standard Database, Release 18. USDA/ARS, Washington, DC. Retrieved December 23, 2005, from [www.ars.usda.gov/ba/bhnrc/ndl](http://www.ars.usda.gov/ba/bhnrc/ndl).

The simple but essential niacin pyridine molecules are first made in plants and thereafter distributed in the food chain (Table 19.2) (USDA/ARS, 2005). For example, niacin can be synthesized in grasses, which are ingested by cows. Then bacteria can synthesize more niacin. Ultimately

**FIG. 19.2** Pathways forming and utilizing NAD. The three biosynthetic pathways, including the de novo, Preiss-Handler, and salvage pathways, are followed with grey shading. Vitamin B<sub>2</sub> (riboflavin), vitamin B<sub>6</sub> (pyridoxyl phosphate), and vitamin C (ascorbate) are all required for completion of the NAD de novo pathway starting from tryptophan. Otherwise, vitamin B<sub>1</sub> (thiamin) is required for synthesis of phosphoribosyl pyrophosphate (PRPP) in the pentose phosphate pathway. The uses of NAD as a co-factor, ligand, or substrate are shown to the right. Gene names are in italics.

the vitamin can be transmitted through milk or meat consumption to people.

## Physiological Functions of NAD

Molecular biologists use gene deletion to determine gene function. We can consider similar loss of function analysis for determining nutrient function. More significantly, however, we are able to readily perform pharmacological complementary rescue of loss of function symptoms by administering the vitamin molecule. Experiments involving vitamin deficiencies can only be performed on humans for brief periods (Fu *et al.*, 1989); however, we can still learn from the history of pellagra and through experimentally controllable animal models of niacin deficiency.

### Dietary Deficiency Disease

The three classic “Ds” of pellagra include diarrhea, dermatitis, and dementia, which occur in unpredictable orders and combinations, depending perhaps on genetics, lifestyle or infectious conditions. These are followed ultimately by death of the patient if the diet is not improved. Pellagrous dermatitis has a characteristic appearance on parts of the body that is triggered by exposure to sunlight, heat, or mild trauma, such as the face, neck, hands, feet, and elbows. These lesions are typically bilaterally symmetric about the head. Accordingly they were first termed “Casal’s necklace.” Mental symptoms include irritability, headaches, sleeplessness, loss of memory, and emotional instability. Women were more suicidal, while men were more violent during the pellagra epidemics. Pellagra-like symptoms are also caused by chronic alcoholism, carcinoid syndrome (Shah *et al.*, 2005), and some drugs such as the anti-tuberculosis medicine isoniazid or chemotherapeutics (Dreizen *et al.*, 1990).

### Niacin-Responsive Genetic Disorders

Ultimately niacin is converted to NAD, which is used in more reactions than any other vitamin-derived cofactor. Over 400 proteins use NAD for chemical reactions. Ultimately amino acid polymorphisms residing within cofactor binding domains result in decreased binding affinity with associated decreased enzyme kinetics (increased  $K_m$ ). There are known examples where administration of vitamin co-factor supplements can rescue the symptoms arising from decreased enzyme efficiency due to these mutations (Ames *et al.*, 2002). Known niacin-responsive genetic diseases include mutations in either the

neutral amino acid transporter encoded by the SLC6A19 gene, the aldehyde dehydrogenase encoded by ALDH2, or the glucose-6-phosphate-1-dehydrogenase gene. Mutations causing a loss of SLC6A19 function result in Hartnup disease, which resembles pellagra and leads to death unless treated early. This occurs due to an inability to transport tryptophan into cells. Symptoms are rescued via the administration of niacin, thus supporting the vital importance of tryptophan as a NAD precursor (Nozaki *et al.*, 2001). Up to one-third of all known enzyme-encoding gene mutations may result in decreased enzyme efficiency due to altered binding affinity for the cofactor (Ames *et al.*, 2002). Given that there are more NAD-binding proteins than any other cofactor and most have never been examined, it is expected that many more undiscovered mutations are in fact responsive to administration of high doses of NAD precursors.

## NAD Metabolism

Humans cannot specifically synthesize nicotinic acid or nicotinamide endogenously. Rather we depend on plants and microorganisms to introduce these chemicals into the food chain. NAD is essential to all forms of life, and humans convert various sources of niacin to NAD by distinct metabolic pathways.

### Pathways to and from NAD

The NAD precursors (nicotinic acid/niacin, nicotinamide/niacinamide, nicotinamide riboside, or tryptophan) follow separate pathways to generate NAD within the cell, but all of these pathways ultimately require the one enzyme, nicotinamide mononucleotide phosphoribosyltransferase (NMNAT). There are three different NMNAT isoforms (encoded by *NMNAT1*, *NMNAT2*, and *NMNAT3*) expressed in distinguishable subcellular locations. Over-expression of any of these enzymes dramatically increases cell viability when challenged by otherwise lethal stress in general through maintaining vital NAD concentrations (Sasaki *et al.*, 2006; Feng *et al.*, 2010; Gilley and Coleman, 2010; Mayer *et al.*, 2010; Yan *et al.*, 2010). In this section we review the NAD-producing pathways as shown in Figure 19.2.

Nicotinamide produced by NAD glycohydrolases is recycled back to NAD via the *NAD salvage pathway* (Figure 19.2). The first enzyme, nicotinamide phosphoribosyltransferase, is rate-limiting in controlling NAD synthesis (Revollo *et al.*, 2004). Changes in NMNAT levels become

more important in controlling NAD production during times of stress, which are known to highly induce expression of NAMPT. Increases in the efficiency of the NAD salvage pathway have been repeatedly shown to provide greater protection against otherwise lethal shocks in a wide variety of cell types.

Nicotinic acid is converted to NAD via the *Preiss-Handler pathway* starting with nicotinic acid phosphoribosyltransferase (encoded by the *NPT1* gene). This enzyme is not inhibited by nicotinamide, whereas the equivalent mononucleotide-generating enzyme for nicotinamide (encoded by the *NAMPT* gene) is inhibited. Accordingly, high doses of nicotinic acid are known to increase the amount of NAD within cells to a greater level than does nicotinamide. Whether this greater increase in intracellular NAD is part of the reason for nicotinic acid's superior performance in preventing atherosclerosis is not very clear. Next, nicotinic acid mononucleotide is converted to nicotinic acid adenine dinucleotide via NMNAT, which requires ATP. Lastly glutamine is used by NAD synthase to replace the acid with the amide to produce NAD.

Lastly, nicotinamide riboside was discovered in 2004 to be a third form of vitamin B<sub>3</sub> (Bieganowski and Brenner, 2004). By contrast, nicotinic acid and nicotinamide were discovered and have been studied for over 60 years to date. Nicotinamide riboside is converted to NAD by a simple two-step pathway starting with a reaction catalyzed by nicotinamide riboside kinase (Figure 19.2). Less is known about nicotinamide riboside, but it is present in milk. None the less, experiments to date indicate that nicotinamide riboside boosts NAD levels, activates Sir2, and extends replicative lifespan in yeast, thus supporting the high likelihood that there will be positive therapeutic benefits in humans (Belenky *et al.*, 2007). Nicotinamide riboside is distinguished in vertebrate development for serving essential pathways in muscular development (Goody *et al.*, 2010).

The *de novo* pathway of NAD synthesis starts with tryptophan. Requiring over seven chemical reactions, this is the longest NAD biosynthetic pathway. One intermediate, 2-amino-3-carboxymuconate-6-semialdehyde (ACMS), has to accumulate and degrade nonenzymatically to allow the pathway to be completed. The enzyme that degrades ACMS towards acetyl CoA lowers the efficiency of tryptophan to niacin conversion (Fukuwatari *et al.*, 2002), likely explaining the individual and interspecies variation that is observed. Tryptophan has two distinctly essential characteristics. It is required for the

biosynthesis of NAD starting from endogenous sources, and tryptophan is found at the lowest concentrations of any amino acid under basal conditions. The importance of tryptophan as a precursor to NAD is particularly evident with Hartnup disease, which arises from a mutation in a transporter that is required to assist delivery of tryptophan into the cell. Hartnup disease presents with many symptoms that resemble pellagra, most of which are rescuable by administration of preformed niacin or niacinamide (Oakley and Wallace, 1994; Symula *et al.*, 1997; Patel and Prabhu, 2008). The NAD *de novo* pathway also requires riboflavin (vitamin B<sub>2</sub>), pyridoxyl phosphate (vitamin B<sub>6</sub>), ascorbate (vitamin C), and glutamine in order to go to completion to NAD (Figure 19.2). Much of the tryptophan to NAD conversion occurs via the hepatic tryptophan dioxygenase (TDO) catalyzed pathway. However, the *de novo* pathway is highly regulated by the immune system in specific cell types as well. Interferon gamma activates the rate-limiting enzyme indoleamine-2,3-dioxygenase (IDO) which is required for interferon's biological activities. The intermediates in this NAD synthetic pathway such as kynurenine and kynurenate have significant physiological roles. IDO is also expressed in endothelial cells, which are vulnerable to excessive immune-cell depletion of plasma tryptophan (Niinisalo *et al.*, 2010). Persistent activation of IDO is seen in many autoimmune diseases and cancer, where decreased serum tryptophan is a common diagnostic indicator of poor prognosis. Complementary administration of high doses of NAD precursors have been repeatedly shown to rescue these pathogenic processes in animal models as well as in examined clinical cases (Penberthy, 2007).

## NAD-utilizing Proteins

NAD participates in more reactions than any other vitamin-derived molecule. At least 470 proteins use NAD(P(H)), see supplementary Table, NAD-Utilizing Proteins ([http://web.me.com/wtpenber/NAD-Utilizing\\_Enzymes/1.html](http://web.me.com/wtpenber/NAD-Utilizing_Enzymes/1.html)). NAD functions in hundreds of redox reactions as a *cofactor*; tens of reactions as a *substrate*, and single-digit numbers of proteins use NAD as a *ligand*. More and more proteins are being discovered by biochemists to be directly involved in NAD(P(H))-connected activities at the biochemical level. The importance of NAD concentrations in regulating these various processes is a perennial area of vibrant clinical research interest.

### **NAD as a Cofactor in Redox Reactions**

In general, redox enzymes use NAD(H) for catabolic reactions and NADP(H) more commonly for anabolic (biosynthetic) reactions. For example, NADPH serves as an important reducing agent for the synthesis of lipids and steroids, while NAD<sup>+</sup> is required to oxidize substrates in the Krebs cycle.

Both NAD and NADP serve essential bioenergetic functions in the intracellular respiratory chain of all cells. NAD assists in the stepwise transfer of electrons from various energy substrates to the cytochromes. NADH usually donates its electrons to a flavin coenzyme in the mitochondrial electron transport chain responsible for ATP production. Reducing equivalents are carried to the mitochondria by the malate–aspartate or the glycerol phosphate–dihydroxyacetone shuttles. The approximately 57 different cytochrome P450 monooxygenase proteins are used by humans for a wide variety of metabolic processes including synthesis and degradation of: drugs, xenobiotics, prostaglandins, leukotrienes, retinoic acid, vitamin D, cholesterol, bile, and steroids (Nebert and Russell, 2002). Pyridine nucleotides and flavocoenzymes funnel reducing equivalents to the mitochondrial respiratory chain.

### **NAD as a Substrate and NAD Depletion**

Four categorical enzymes play conditionally dominant roles in controlling NAD levels. These enzymes respond to DNA damage, immune activation, and other stimuli. This section covers aspects of these NAD concentration-controlling enzymes: poly(ADP-ribose) polymerase (PARPs 1–18), NAD-dependent deacetylases (sirtuins 1–7), ADP cyclases (CD38 and CD157), and indoleamine 2,3-dioxygenases (IDO). The first three categorical enzymes produce nicotinamide as a side product that is recycled back to NAD via the salvage pathway as shown in Figure 19.2.

PARP1 and PARP2 NAD-consuming activities are highly activated by any kind of DNA damage (Schraufstatter *et al.*, 1986). These enzymes use NAD to produce the anionic polymer poly(ADP)ribose. Also they transfer ADP-ribose directly to histones and other proteins including p53, NF kappa B, and other important proteins. There are up to 18 different ADP-ribose transferring enzymes identified, based on genome sequencing. The degree of PARP activation is directly proportional to the degree of DNA damage. This response serves a critical function in stopping cell division after the DNA is damaged, thus

minimizing rogue cancer cell expansion and enabling DNA repair. However, hyperactivation of PARP1 leads to severe depletion of intracellular NAD and ATP. This results in uncontrolled necrotic cell death. In fact PARP inhibition prevents a wide variety of otherwise lethal shocks in mammals, but it does come with a slightly increased likelihood for tumor formation (Shall and de Murcia, 2000).

We cannot change our genetic makeup significantly during our lifetime, but epigenetics are very responsive to nutritional status. Increased NAD levels can activate SIRT1, which alters chromatin structure through histone deacetylation. SIRT1 activation has been attracting interest as it is thought to be the mechanism underlying the lifespan extension associated with caloric restriction. While other histone deacetylases only possess constitutive activity, the sirtuins are activated by increases in NAD concentrations. This NAD-dependent activation of sirtuin HDAC activity is thus quite unique because we can alter our NAD levels to ultimately alter chromatin structure. However, NAD-dependent PARP1 activity also tends to relax chromatin structure, and the combination of these two influences of niacin status on chromatin structure has not been properly investigated (Kirkland, 2009a).

Activated NAD-dependent sirtuins deacetylate histones, p53, NF kappa B, and many other important proteins. Sirtuins can negatively regulate PARP activity by deacetylation (Gupta *et al.*, 2008). A tremendous amount of investment has been devoted to sirtuin research owing in large part to the excitement surrounding SIRT1-dependent caloric restriction-mediated lifespan extension (Howitz *et al.*, 2003). Animal models have revealed that sirtuin activation is beneficial for treatment of diabetes (Ramsey *et al.*, 2008) and neurodegeneration (Araki *et al.*, 2004; Qin *et al.*, 2006).

The ADP cyclase enzyme CD38 uses NAD as a substrate to generate known mediators of intracellular calcium release (De Flora *et al.*, 2004). This mechanism is required for chemotaxis of many types of immune cells. The CD38-deficient mouse has persistent elevated NAD levels and increased energy, and does not become obese even when fed a high-fat diet (Barbosa *et al.*, 2007). However, CD38-deficient mice are more susceptible to infections (Partida-Sanchez *et al.*, 2007). CD38 levels and activity are chiefly regulated at the transcriptional level. Tumor necrosis factor-alpha (TNF-alpha) especially increases CD38 expression. CD157 is another NAD-dependent ADP cyclase that has important but less studied functions.

CD38 is highly expressed in the brain, where its potential neurological role is an active area of research (Young and Kirkland, 2008).

Indoleamine 2,3-dioxygenase (IDO) is highly regulated by the immune responses (Mellor and Munn, 2004). IDO plays significant roles by decreasing available plasma tryptophan concentrations and potentially controlling NAD concentrations, similar to Hartnup disease. Tryptophan is present at the lowest concentrations of all amino acids under basal conditions, and it is used for the NAD biosynthesis *de novo* pathway. During pregnancy IDO is highly expressed in the trophoblasts surrounding the developing fetus. This starves local immune cells, thus conferring fetal immunotolerance and preventing rejection of the foreign fetus by the immune system. During infections and in autoimmune disease, IDO is highly activated by interferons in specific professional antigen-presenting immune cells (dendritic cells, macrophages, and B cells). Activation of IDO also exerts antibacterial and antiviral activities, particularly intracellularly. IDO is frequently persistently activated in autoimmune disease and cancer (Uyttenhove *et al.*, 2003). Persistent or acute excessive activation of IDO during autoimmune disease or cancer weakens neighboring cells due to exceedingly low serum tryptophan levels. Accordingly high doses of vitamin B<sub>3</sub> have been shown to complement many effects of this deficiency of *de novo* NAD precursor tryptophan, thus relieving many of the pellagra-like symptoms similar to the effects seen in Hartnup disease (Penberthy, 2007).

### **NAD as a Ligand**

NAD binds to the receptors P2Y1 (colonic cells) or P2Y11 (in monocytes and granulocytes) to function as a neurotransmitter (Mutafova-Yambolieva *et al.*, 2007; Klein *et al.*, 2009). NAD functions as an inhibitory neurotransmitter inhibiting colonic muscle contraction. This causes an increase in intracellular calcium. Some of these NAD effects are ultimately due to associations between the P2Y receptors and other G-protein coupled receptors.

### **Physiological Concentrations of NAD Precursors**

Baseline sera concentrations of nicotinic acid are in the low nanomolar range, while nicotinamide concentrations are somewhat higher and more responsive to normal dietary intakes. Treatment of dyslipidemia, pharmacological administration of 3–5 g/day of nicotinic acid, elevates

serum levels of nicotinic acid above 10 μM. Peak concentrations vary up to 240 μM depending on whether immediate-release niacin or timed-release niacin is used (Kirkland, 2009b). This high concentration exerts many therapeutically desirable effects for preventing cardiovascular disease, including raising HDL while lowering triglycerides, LDL, and VLDL. By contrast, high doses of nicotinamide do not exert these effects on blood lipids.

Nicotinic acid mediates some of these beneficial effects on the lipid profile via the nicotinic acid high affinity (100 nM equilibrium binding) G-protein coupled receptors, GPR109a and GPR109b (Gille *et al.*, 2008). Nicotinamide does not bind to these receptors, and the binding by nicotinic acid appears to represent an unphysiological binding to receptors meant to respond to high circulating ketone bodies. Nicotinic acid–GPR109 signaling causes a flush response: vasodilation, reddening of the skin, alterations in temperature, and sometimes itching. The flush response occurs with as little as 35 mg of nicotinic acid and is considered unpleasant by most individuals, but it is not associated with any known tissue injury. The nicotinic acid-mediated flush is linked to beneficial effects in the correction of dyslipidemia, whereas nicotinamide does not exert these beneficial effects on lipid profiles.

### **Niacin and Disease**

The questions as to which is the most effective NAD precursor in pharmacological use and which diseases are most responsive to these treatments are among the most exciting in molecular therapeutic clinical research today. We therefore briefly review here what happens to concentrations of NAD, tryptophan, poly(ADP)ribose, and other relevant molecules over the course of pathogenesis for several diseases.

#### **Pharmacological Niacin**

Gram-level quantities of standard/immediate release or prescription sustained release niacin have been used with large populations of hyperlipidemic patients with only rare adverse events. Sustained release niacin, however, has resulted in chemical hepatitis (Carlson, 2005; Guyton and Bays, 2007). Other rare side-effects include cystoid macular edema. Inositol hexanicotinate has also been prescribed as a form of niacin (“flush free”); however, there is evidence that the nicotinic acid is poorly released from the inositol and that correction of dyslipidemia is less effective.

### Cardiovascular Disease

More people ultimately die due to cardiovascular events than as a result of any other disease. High-dose niacin is well known as one of the most effective agents preventing atherosclerosis-related strokes and heart attacks (Carlson, 2005). Niacin increases HDL (the good cholesterol) levels more than any other pharmaceutical, while simultaneously decreasing cholesterol, VLDL, and triglycerides in otherwise dyslipidemic individuals. A 15-year follow-up to a cohort receiving 3 g niacin per day showed a 15% reduction in mortality (Canner *et al.*, 1986). Similar reductions in mortality were seen in patients with previous myocardial infarctions (Carlson and Rosenhamer, 1988). The book *The Eight-Week Cure for Cholesterol* written by a medical journalist described his struggle to treat severe dyslipidemia using niacin (Kowalski, 2001).

The mechanism of action of niacin in correcting dyslipidemia is a perennial cardiovascular research question. The high-affinity nicotinic acid G-protein-coupled receptors GPR109a and GPR109b serve primary roles in the niacin dyslipidemia-correcting mechanism of action. These are highly expressed in adipose tissue, but also in neutrophils, professional antigen presenting cells (dendritic cells, macrophages, and B cells), intestine, retina, and other areas within the central nervous system. In adipocytes nicotinic acid signaling through GPR109 causes a decrease in cyclic AMP levels, which decreases hormone-sensitive lipase (Karpe and Frayn, 2004). In other cells a wide variety of prostaglandins are produced at high levels, mediating potentially beneficial effects including increased peripheral circulation. The endogenously produced prostaglandin PGJ<sub>2</sub> most potently activates PPAR gamma and other PPARs similar to the diabetes and dyslipidemia drugs, thiazolidinediones and clofibrate, respectively. NAD working through sirtuin-PPAR pathways is also potentially involved in positive lipid-correcting activities. Still other nicotinic acid associated pathways, including regulation of membrane-bound ATP synthases and diacylglycerol acyltransferase, are potentially involved in the myriad of high-dose niacin/nicotinic acid benefits (Kamanna and Kashyap, 2008).

### Cancer

While the death rate for cardiovascular disease has dropped by over 60% over the past 50 years, that for cancer has been disappointingly unchanged by comparison, having decreased by merely 5% adjusted for age and population (Kolata, 2009). Cancer is initiated by unrepaired DNA

damage. Under healthy conditions, cells with too much DNA damage commit apoptosis. NAD plays significant roles in controlling both genomic stability and the cell death process. Moreover, later in the progression of cancer disease, NAD can become a dominant theme in metabolic chemotherapy.

The rate of NAD turnover in cancerous transformed cells is much higher than that of normal cells. This is due to an increased demand for NAD in glycolysis and also the increased PARP1/2 activity associated with genomic instability. Cancer cells have a far greater essential requirement for glycolysis than for oxidative phosphorylation as a means of generating ATP. Tumor cells typically perform glycolysis at a 30 times greater rate than that of normal cells (Ganapathy *et al.*, 2009). Moreover the rate of entry of glucose into cancer cells is also 20 to 30 times greater than into untransformed cells in order to supply essential levels of glucose. Oxygen-independent glycolytic ATP production requires regeneration of NAD by lactate dehydrogenase. Interestingly, clinical pellagra may be observed during chemotherapy (Dreizen *et al.*, 1990).

Today, chemotherapeutics are being developed to decrease NAD via inhibition of NAMPT and/or IDO (Yang *et al.*, 2010). Other interesting areas of niacin cancer research include the observation that GPR109a can function as a tumor suppressor in the colon (Thangaraju *et al.*, 2009). Whether administration of niacin can help in colon cancer is unknown. However, niacin is well known to provide therapeutic benefit in the related ectodermal skin cancer models (Gensler *et al.*, 1999; Jacobson *et al.*, 1999; Benavente *et al.*, 2009).

### Neurodegenerative Disease

As excitable energy-demanding tissues, neural cells (neurons and glia) have distinct metabolic NAD-dependent requirements. Similar to tumor cells, neurons are very dependent on glycolysis as a source of ATP generation. Oxidizing glucose in glycolysis and the pentose phosphate pathway, with low mitochondrial activity, decreases oxidant stress in these sensitive tissues. Glial cells function as support cells to neurons, synthesizing cholesterol and lactate, which are both delivered to neurons. Increases in baseline NAD or NAD salvage pathway efficiency are well known to prevent otherwise lethal stress-induced neurodegeneration in cells and animal models. Thus, we must understand what happens to NAD levels in the diseases of neurodegeneration: dementia/Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD),

amyotrophic lateral sclerosis, multiple sclerosis, and even schizophrenia. Alzheimer's disease is the most common form of dementia recognized today. This is followed by vascular dementia. The NAD-deficiency disease pellagra is characterized by dementia, where niacin is one of the rare molecules known to prevent a form of dementia while also providing many therapeutic vascular benefits.

Diseases defined by the formation of insoluble protein plaques include AD (amyloid protein; tauopathies), HD (huntingtin protein), and PD ( $\alpha$ -synuclein; Lewy bodies). While surgery and stem cells may hold promise for the future, currently these latter diseases are irreversible after a certain point in disease progression. Primary emphasis is placed on prevention or stay of progression. An increase in dietary niacin from 15 mg to 40 mg/day has been correlated with a 70% decrease in the likelihood of Alzheimer's disease, in a study examining 6158 patients over 65 years of age (Morris *et al.*, 2004). NAD, potentially through activation of SIRT1, can reduce amyloid precursor protein processing to plaques in transgenic mouse models of AD (Qin *et al.*, 2006). Studies show that high apolipoprotein A-1 (apoA-1) decreases AD risk (Scarmeas, 2007), and high-dose niacin is effective in raising apoA-1 containing HDL, suggesting that this might be effective in delaying the progression of brain injury. Meanwhile, high ApoE is associated with increased risk of AD (Corder *et al.*, 1993, 1994) and is found in the chylomicrons, VLDL and LDL particles. ApoE mutations can cause familial AD and dyslipidemia. ApoE-deficient mice are used as a model of dyslipidemia, where administration of niacin is able to correct the elevations in cholesterol and triglycerides but not the decrease in HDL unless cholesteryl ester transfer protein is over-expressed (van der Hoorn *et al.*, 2008). More research is needed to understand how niacin nutrition and pharmacological use relate to the frequency of AD, ApoE, and vascular dementia as well as how best to incorporate niacin into treatments. Parkinson's disease occurs due to a deficiency of dopamine-producing neurons in the substantia nigra part of the midbrain. The mechanisms of Parkinson's disease are poorly understood; however, excessive methyl-nicotinamide (MN) has been proposed to be part of the cause of PD pathogenesis (Ying, 2007). Urinary MN is elevated in Parkinson's disease. Since this is the metabolic byproduct of niacin metabolism, this suggests that NAD metabolism is somehow involved. By contrast, administration of NADH has been tested on PD patients and found to stimulate increased dopamine production. Future work will be required to

understand the role in brain metabolism of various NAD precursors and metabolites.

Multiple sclerosis (MS) is the most commonly diagnosed disease of the central nervous system. Animal models of MS have revealed that NAD precursors can prevent the onset and damage of MS pathogenesis. Poly (ADP-ribose) (PAR) formation increases at sites of pathogenesis, where preservation of NAD levels is key to maintaining health (reviewed by Penberthy and Tsunoda, 2009).

Other ongoing areas of neurobiology research involve the slow Wallerian degeneration (*Wld<sup>Δ</sup>*) mouse, which is remarkably resilient to stress-induced neuronal cell death. Razor excision of wild-type neurons leads to degeneration in less than 24 hours. Remarkably, *Wld<sup>Δ</sup>* mouse neurons survive for up to 2 weeks and are still capable of depolarization (Adalbert *et al.*, 2005). The gene mediating this effect includes the NAD biosynthetic enzyme, nicotinamide adenine mononucleotide adenylyl transferase-1 (Ube4b/NMNAT1) (Mack *et al.*, 2001). Follow-up research has determined that increased expression of NMNAT1, NMNAT2, or NMNAT3 is extremely neuroprotective and that NAD itself can exert a similar survival effect (Araki *et al.*, 2004; Sasaki *et al.*, 2009; Gilley and Coleman, 2010; Yan *et al.*, 2010). NAD-mediated neuroprotection may be mediated by increased sirtuin activity (Araki *et al.*, 2004), but NAD-chaperone survival activities have also been observed for NMNAT (Zhai *et al.*, 2008).

### Autoimmune Disease

Some autoimmune diseases, listed from more to less common include hypothyroiditis, rheumatoid arthritis, hyperthyroiditis, type 1 diabetes, systemic lupus erythematosus, myocarditis, multiple sclerosis, and inflammatory bowel disease. Autoimmune diseases commonly arise from an undesirable clonal expansion of autoreactive T cells. One of the best-understood mechanisms for controlling this expansion involves starving the T cells of tryptophan by interaction with tryptophan-hoarding professional antigen-presenting cells (dendritic cells, macrophages, B cells, and microglia [Mellor and Munn, 2004]). IDO is frequently activated in autoimmune diseases as the immune system works to control this undesirable expansion. This ultimately contributes to depletion of extracellular tryptophan where low tryptophan levels are characteristic and correlate highly with a poor prognosis (Schrocksnadel *et al.*, 2006). This activated immune system may also activate PARP-1, which additively contributes to NAD depletion. Ultimately, the complementary administration

of NAD precursors to this situation makes sense and has been repeatedly shown to prevent onset of pathogenesis or even to cure the disease in many animal models of disease as well as in some clinical examples (Penberthy, 2007).

## Future Directions

There is much that remains to be determined in niacin research. The impact of low and high niacin status on basic energy metabolism is poorly appreciated and is a logical area in which to apply cutting-edge techniques in metabolomics. The use of NAD as a substrate in the formation of poly, mono, and cyclic ADP-ribose, as well as in support of sirtuin activities, suggests that there are complex interactions between intermediary metabolism and control through ADP-ribosylation reactions. It is clear that ADP-ribosyltransferases, sirtuins, and metabolic families of enzymes all play important roles in cancer and in autoimmune and neurodegenerative diseases, with much still to be learned. With the benefits of inhibiting ADP-ribose metabolism under certain conditions (ischemia-reperfusion, treatment of certain cancers), and the risks of doing so at other times, clinical management of ADP-ribose metabolism is in its infancy. Given the extremely large number of niacin-dependent proteins in metabolism, cataloging polymorphisms and individual variation in niacin requirements is another long-term goal.

## VITAMIN B<sub>6</sub>

VANESSA R. DA SILVA<sup>1</sup>, PhD, KATELYN A. RUSSELL<sup>2</sup>, BS, AND  
JESSE F. GREGORY III<sup>2</sup>, PhD

<sup>1</sup>University of Georgia, Athens, Georgia, USA

<sup>2</sup>University of Florida, Gainesville, Florida, USA

### Summary

Vitamin B<sub>6</sub> is a family of related compounds comprised of pyridoxine (PN), pyridoxal (PL), and pyridoxamine (PM), along with their phosphate esters and glucosides. The primary vitamin B<sub>6</sub> coenzymic form, pyridoxal 5'-phosphate, is an obligatory cofactor in over 140 enzymatic reactions primarily in the metabolism of amino acids but also in reactions of carbohydrates and lipids. Vitamin B<sub>6</sub> also plays a vital role in one-carbon metabolism, facilitating cellular methylation processes, methionine recycling, regulation of homocysteine, and synthesis of cysteine. Recent findings indicate that marginal vitamin B<sub>6</sub> status remains a concern in human nutrition, at least in segments of the population. The consequence of marginal vitamin B<sub>6</sub> status is unclear but serves as cause for concern in view of associations between low vitamin B<sub>6</sub> status, risk of cardiovascular disease and stroke, and certain cancers. This chapter provides an overview of vitamin B<sub>6</sub> bioavailability, metabolism and metabolic function, nutritional status and assessment, and roles in human health and disease.

### Introduction

#### **Background, Chemistry, Sources, and Bioavailability**

Evidence of the existence of an unknown water-soluble factor later termed vitamin B<sub>6</sub> first emerged in the late 1920s, and its purification, identification, and synthesis followed quickly thereafter in the 1930s (for historical review, see Gyorgy, 1956). Identification of pyridoxal (PL) and pyridoxamine (PM) as natural forms of the vitamin, and the recognition of a phosphorylated form of PL, eventually identified as pyridoxal 5'-phosphate, followed in the 1940s (for review, see Snell, 1990). Much of this work

evolved from bioassays involving the growth of rats and the prevention of a characteristic skin condition termed acrodynia (Beaton *et al.*, 1952; Gyorgy, 1956) and the use of vitamin B<sub>6</sub>-dependent bacteria (Snell, 1990). We are indebted to these early researchers for their biochemical ingenuity, insight, and experimental skills in an era when modern analytical tools were lacking.

Vitamin B<sub>6</sub> is the term for the family of water-soluble vitamin species with the basic structure of 2-methyl,3-hydroxy,5-hydroxymethyl-pyridines (Figure 20.1). Through its coenzymatic function in processes including amino acid metabolism, one-carbon metabolism and nucleotide synthesis, neurotransmitter metabolism,

**FIG. 20.1** Chemical forms of vitamin B<sub>6</sub>. R = -H for non-phosphorylated pyridoxine, pyridoxal, and pyridoxamine, and R = -PO<sub>3</sub>H for their 5'-phosphates.

heme synthesis, gluconeogenesis, and glycogenolysis, vitamin B<sub>6</sub> affects nearly all aspects of metabolic function and cellular homeostasis. The various forms differ with respect to the nature of the C-4 substituent which defines pyridoxal (PL, aldehyde, -CHO), pyridoxine (PN, alcohol, -CH<sub>2</sub>OH), and pyridoxamine (PM, amine, -CH<sub>2</sub>NH<sub>2</sub>). Further variation among the constituents of this family exists through the ability of PN, PM, and PL to exist as a phosphate ester (designated PLP, PNP, and PMP for pyridoxal 5'-phosphate, pyridoxine 5'-phosphate, and pyridoxamine 5'-phosphate, respectively) or with pyridoxine as a glucoside derivative (PNG). 4-Pyridoxic acid (4-PA) is the primary catabolic product. Pyridoxine (PN), as the HCl salt, is the synthetic form used in food fortification and dietary supplements, mainly for reasons of its superior stability.

The ability of PLP (and PL to a lesser extent) to condense with the uncharged amino group of amines and amino acids to form Schiff base (aldimine) and related complexes is well known and, indeed, serves as the basis for the coenzyme function of vitamin B<sub>6</sub>. This reactivity with amines and aldehydes also accounts for the observed non-enzymatic interconversions between PLP and/or PL with PMP and/or PM during food processing (Gregory, 2007). In addition, PLP is very sensitive to photochemical oxidation, forming 4-pyridoxic acid phosphate, and other vitamin B<sub>6</sub> species also exhibit some photochemical insta-

bility. Consequently, care must be taken to minimize light exposure in vitamin B<sub>6</sub> analysis and other research procedures. The greater reactivity of PLP toward amines is due to the presence of the phosphate group which prevents the formation of an internal hemiacetal bridge between the C-5 hydroxymethyl group and the C-4 aldehyde, as occurs readily in PL. PL and PLP also can undergo reductive binding to the ε-amino groups of protein lysyl side chains to form ε-pyridoxyllysine during the thermal processing of food. This complexed form of the vitamin is enigmatic as it is not detected in common vitamin B<sub>6</sub> assays, and it exhibits partial vitamin B<sub>6</sub> activity but also competes with other vitamin B<sub>6</sub> species for cellular uptake (Gregory, 1997).

Vitamin B<sub>6</sub> is widely distributed in foods of plant and animal origin. Muscle-derived foods including beef, pork, chicken, and fish are good sources, and organ meats are particularly rich in vitamin B<sub>6</sub>. The distribution of vitamin B<sub>6</sub> in plants is rather enigmatic, although certain generalizations can be made as follows. Whole grains are good sources of vitamin B<sub>6</sub>, as are bananas and, to a lesser extent, potatoes. Whereas whole-wheat flour is a good source of the vitamin, white flour is low (which reflects the relative lack of vitamin B<sub>6</sub> in the endosperm). The presence of glycosylated forms of PN in plants, particularly as PNG, complicates their nutritional evaluation. This is because dietary PNG exhibits only about 50% bioavailability in

humans and it also exerts weak antagonistic effects on the utilization of non-glycosylated PN (Nakano *et al.*, 1997; Gregory, 1998). The content of PNG in plant foods varies widely, ranging, for example, from 5% in bananas to 75% in carrots as a fraction of total vitamin B<sub>6</sub>. The overall bioavailability of vitamin B<sub>6</sub> in a mixed diet has been reported to be approximately 75% (Tarr *et al.*, 1981). In spite of the potential for lower bioavailability of vitamin B<sub>6</sub> in certain plant foods due to the presence of PNG and potential effects of fiber and cellular structure, there is little evidence that vegetarians with sufficiently varied diet and good total intake of the vitamin would be particularly at risk of insufficient vitamin B<sub>6</sub> status (Shultz and Leklem, 1987). However, individuals with marginal intake of total vitamin B<sub>6</sub> would be more prone to reduced nutritional status due to this incomplete bioavailability.

Whereas sources of vitamin B<sub>6</sub> in the US diet are distributed over a wide range of foods, breakfast cereals fortified with PN constitute an important source. Various fortified sports bars, meal-replacement products, and beverages also constitute major sources of vitamin B<sub>6</sub> intake in many individuals. Unlike thiamin, niacin, riboflavin,

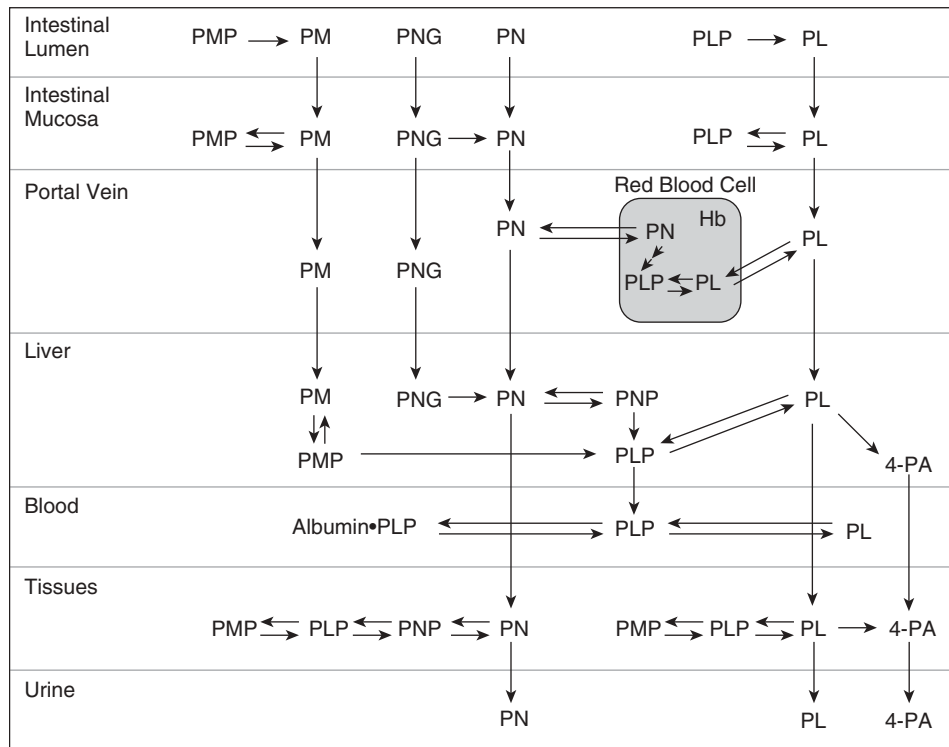

and folic acid, PN is not added to enriched flour and other enriched grain products.

## Vitamin B<sub>6</sub> Disposition and Metabolic Function

The *in vivo* disposition of vitamin B<sub>6</sub> is summarized in Figure 20.2, which was adapted from McCormick (2006).

### Uptake

Intestinal absorption of vitamin B<sub>6</sub> from dietary sources occurs both in the small intestine and from bacterial production in the large intestine. Uptake of dietary vitamin B<sub>6</sub> occurs primarily in the jejunum, with rate of absorption varying according to the B<sub>6</sub> species present (Hamm *et al.*, 1979; Mehansho *et al.*, 1979; Buss *et al.*, 1980). Glycosylated forms of vitamin B<sub>6</sub> found in plant foods are hydrolyzed partially by brush-border lactase-phlorizin hydrolase (Mackey *et al.*, 2004) prior to absorption. Some absorption of intact PNG also occurs, after which it may be partially hydrolyzed by  $\beta$ -glucosidase apparently in the kidney or excreted in the urine (Ink *et al.*, 1986; Gregory

**FIG. 20.2** *In vivo* disposition of ingested forms of vitamin B<sub>6</sub>. PL, pyridoxal; PM, pyridoxamine; PN, pyridoxine; PLP, PMP, PNP, their respective phosphorylated forms; PNG, pyridoxine  $\beta$ -D-glucoside; 4-PA, 4-pyridoxic acid. Hb, hemoglobin.

*et al.*, 1991; Nakano *et al.*, 1997). PMP and PLP usually are major vitamin B<sub>6</sub> species in animal products and also exist in lesser proportions in plant-derived foods. All such phosphorylated vitamers require dephosphorylation by alkaline phosphatase and other phosphatases prior to absorption. Kinetics reported in many studies are consistent with intestinal absorption of PL, PM, and PN by simple, non-saturable diffusion. However, evidence exists for carrier-mediated intestinal absorption of the vitamin, with rate of transport both pH dependent and saturable (Kozik and McCormick, 1984; Said *et al.*, 2008). Vitamin B<sub>6</sub> synthesized by the microflora in the human colon may be a secondary exogenous source available for absorption. Studies with mouse and human colonic cells have provided evidence of colonic absorption of vitamin B<sub>6</sub> (Said *et al.*, 2008). While the contribution of bacterially produced vitamin B<sub>6</sub> to overall nutritional status warrants further investigation, dietary intake certainly constitutes the major source of vitamin B<sub>6</sub> nutrition.

Phosphorylation catalyzed by pyridoxal kinase in the enterocytes provides metabolic trapping of the newly absorbed PL, PM, and PN (Mehansho *et al.*, 1979). The negative charge provided by the phosphate moiety hinders diffusion of the vitamin across the cell membrane and promotes protein binding. PNP, PMP, and PLP are dephosphorylated before crossing the basolateral membrane and entering portal circulation (Mehansho *et al.*, 1979). Uptake by the liver is facilitated by metabolic trapping.

The liver is at the core of vitamin B<sub>6</sub> metabolism. Whereas most tissues can phosphorylate PL, PN, and PM, the liver is the site where the various species of vitamin B<sub>6</sub> undergo interconversion to form PLP. The latter serves as the primary coenzymatic form of vitamin B<sub>6</sub> and is the major form of the vitamin in the body (Johansson *et al.*, 1974; Merrill *et al.*, 1984; Coburn *et al.*, 1988a). Upon absorption to the liver, the non-phosphorylated forms of vitamin B<sub>6</sub> are first phosphorylated by pyridoxal kinase, which uses zinc and ATP as cofactor and phosphoryl donor (Merrill *et al.*, 1984). Hepatic activity of pyridoxal kinase is ten-fold that of the phosphatase, therefore phosphorylated species of vitamin B<sub>6</sub> predominate (Merrill *et al.*, 1984). Binding of PLP to high-abundance PLP-dependent enzymes such as serine-hydroxymethyltransferase, aminotransferases and glycogen phosphorylase also renders PLP less accessible to phosphatases for dephosphorylation. The formation of PLP by oxidation of PNP and PMP occurs by the action of the

flavin mononucleotide-dependent pyridoxine (pyridoxamine) phosphate oxidase (PNP–PMP oxidase) (Kazarinoff and McCormick, 1975; McCormick and Chen, 1999).

### Transport

Vitamin B<sub>6</sub> is carried to organs and tissues primarily in plasma. There the main form is PLP and to a lesser extent PL, which are bound to albumin (Lumeng *et al.*, 1974a). In erythrocytes, PLP and PL are bound to hemoglobin (Mehansho and Henderson, 1980; Coburn *et al.*, 1988b). Tissue uptake of circulating plasma PLP requires prior removal of the 5'-phosphate group, whereas plasma PL is immediately available. The importance of alkaline phosphatase in vitamin B<sub>6</sub> metabolism is evident in the transport as well as in the initial absorption of the vitamin. Prior to uptake by tissue or transfer between cell compartments, membrane phosphatase converts PLP to PL (Van Hoof and de Broe, 1994). Metabolic trapping by phosphorylation, as seen in the enterocyte, is repeated in tissues in order to retain the vitamin.

### Vitamin B<sub>6</sub> Metabolism and Role as a Coenzyme

The largest body pool of vitamin B<sub>6</sub> is in skeletal muscle, which constitutes 70–80% of the whole-body vitamin B<sub>6</sub> mainly as PLP associated with glycogen phosphorylase (Krebs and Fischer, 1964; Coburn, 1990). An analysis of the vitamin B<sub>6</sub> content of human muscle via biopsy estimated the total body pool in adult humans to be ~1000 μmol (~170 mg) (Coburn *et al.*, 1988a). Muscle concentration of vitamin B<sub>6</sub> has been found to be quite resilient to effects of dietary restriction and even supplementation, whereas plasma vitamin B<sub>6</sub> showed marked changes under the same conditions (Coburn *et al.*, 1991). Studies in rats have shown that muscle PLP concentration and glycogen phosphorylase activity decreased in response to a caloric deficit but not to dietary depletion of vitamin B<sub>6</sub> (Black *et al.*, 1978), but functional consequences of these findings are unclear.

The PLP molecule readily condenses with free amino groups of proteins and small molecules to form a Schiff base. As the coenzyme for aminotransferases and most other PLP-dependent enzymes, the pyridine ring and the C-4 carbonyl group enable PLP to facilitate many reactions involving amino acid substrates. In the absence of substrate, PLP is bound to an ε-amino group of a specific lysine residue. In the case of aminotransferases, the binding

of the incoming substrate amino acid to the enzyme-PLP complex allows migration of the PLP to yield a new Schiff base with the amino acid. Subsequent shifting of charge in this complex allows bond labilization at the  $\alpha$ -carbon, with hydrolysis of the complex to release the keto acid product and concurrent generation of PMP. Schiff base formation of an alternate keto acid leads to an analogous process of charge transfer, bond labilization, and transfer of the NH<sub>2</sub> group from PMP (i.e. originally from the first substrate amino acid) to the keto acid to generate a new amino acid. See Figure 20.3 for a depiction of the mechanism by which the Schiff base formation labilizes the  $\alpha$ -carbon bond of an amino acid.

Whereas this reactivity of PLP with lysyl residues of PLP-dependent enzymes and the  $\alpha$ -amino groups of their substrates accounts for the primary coenzymatic mechanism of PLP, its ability to form such Schiff bases indiscriminately when present at higher concentrations probably explains why an over-accumulation of cellular PLP would have adverse effects. The body minimizes the risk of

detrimental levels of PLP when vitamin B<sub>6</sub> intake is high by the combined action of phosphatases and oxidases. The strong inhibition of PNP–PMP oxidase by its product, PLP, retards accumulation of the latter (Merrill *et al.*, 1978). Dephosphorylation of the phosphorylated forms also contributes to cellular homeostasis of PLP by promoting vitamin B<sub>6</sub> turnover, through enhanced conversion of PL to a biologically inactive form, 4-pyridoxic acid (4-PA), with a carboxyl group at the 4'-carbon (Huff and Perlzweig, 1944). This irreversible conversion is known to occur in the liver, and has not been well examined in other tissues. Perfusion studies with isolated rat kidney have suggested that the kidney may also be a site of 4-PA production (Hamm *et al.*, 1980). 4-PA, the major vitamin B<sub>6</sub> catabolite, is then excreted in the urine.

PLP-dependent processes are involved either directly or indirectly in almost all phases of metabolism. Many processes in amino acid interconversion and catabolism involve PLP-dependent enzymes. Aside from playing important roles in amino acid metabolism, the formation of  $\alpha$ -keto

**FIG. 20.3** Mechanism of bond labilization via Schiff-base formation in PLP-dependent transamination reactions.

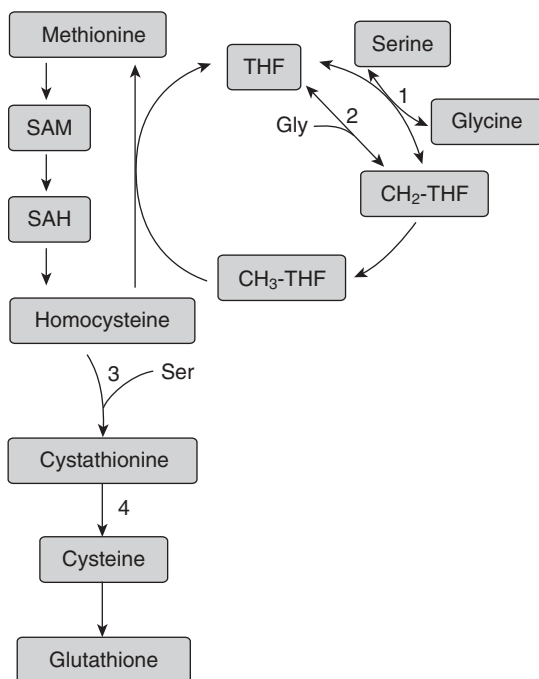

acids constitutes an important anapleurotic process generating and interconverting metabolic intermediates. An indirect role of PLP in the metabolism of n-3 and n-6 fatty acids can be inferred from reported changes in fatty acid profiles during vitamin B<sub>6</sub> deficiency (Tsuge *et al.*, 2000); however, the biochemical mechanism is unknown.

Another important role of PLP-dependent enzymes is in the area of one-carbon metabolism which constitutes a collection of reactions in the folate cycle and methionine cycle that generate methyl groups (as S-adenosylmethionine), facilitate methionine recycling, and regulate homocysteine concentration, incorporate one-carbon units in thymidylate and purine synthesis, and provide synthesis of cysteine. Figure 20.4 illustrates the PLP-dependent reactions in the one-carbon pathway. Serine hydroxymethyltransferase (SHMT) isoforms exist

in both cytoplasm and mitochondria and catalyze the reversible reaction: glycine + 5,10-methylenetetrahydrofolate  $\leftrightarrow$  serine + tetrahydrofolate. These reactions mediate vital components of cellular one-carbon metabolism by allowing the interconversion of serine and glycine as well as providing a means of supplying the folate one-carbon pool by generating 5,10-methylenetetrahydrofolate. The mitochondrial glycine cleavage system is a four-enzyme complex containing a PLP-dependent glycine decarboxylase. This glycine cleavage process has been shown to yield at least 20 times as much 5,10-methylenetetrahydrofolate as needed for methylation demands and to maintain glycine cleavage flux that far exceeds the rate of SHMT-catalyzed processes (Lamers *et al.*, 2009b). Stable isotopic tracer studies conducted before and after vitamin B<sub>6</sub> restriction in humans showed the resiliency of these critical processes in maintaining one-carbon metabolism (Davis *et al.*, 2005, 2006; Lamers *et al.*, 2009b).

PLP also serves as the coenzyme for both components of the transsulfuration pathway, which is responsible for the catabolism of homocysteine and the synthesis of cysteine. The first step, cystathionine  $\beta$ -synthase (CBS), exhibits allosteric stimulation by S-adenosylmethionine (SAM), and exhibits little change in activity as a result of moderate vitamin B<sub>6</sub> deficiency. The second enzyme, cystathionine  $\gamma$ -lyase (CGL), catalyzes the cleavage of cystathionine to form cysteine and  $\alpha$ -aminobutyrate. CGL exhibits much greater susceptibility to loss of its PLP coenzyme during vitamin B<sub>6</sub> deficiency. Unexpectedly, cysteine production and cysteine concentration in tissue and plasma are maintained over a wide range of suboptimal levels of vitamin B<sub>6</sub> nutriture (Davis *et al.*, 2006; Lima *et al.*, 2006; Nijhout *et al.*, 2009) apparently because the greatly elevated cystathionine concentration tends to maintain CGL flux (Davis *et al.*, 2006).

### One-Carbon Metabolism

## Assessment of Vitamin B<sub>6</sub> Nutritional Status

### Methods

Vitamin B<sub>6</sub> nutritional status can be measured by either direct or indirect methods. The most commonly used direct criterion is plasma PLP concentration, which is typically measured by the tyrosine decarboxylase assay or by HPLC. Plasma PLP has been shown to correlate well with tissue stores in rats (Lui *et al.*, 1985) and serves as a reasonable indicator of long-term vitamin B<sub>6</sub> nutritional status.

In spite of its widespread utility, plasma PLP may be influenced by factors other than vitamin B<sub>6</sub> intake that complicate its interpretation as a status indicator. These factors include pregnancy (Lumeng *et al.*, 1974b), age (Lee and Leklem, 1985), exercise (Manore *et al.*, 1987), sex (Manore *et al.*, 1989; Morris *et al.*, 2008), inflammation (Morris *et al.*, 2010), smoking (Ulvik *et al.*, 2010), and alcohol intake (Lumeng and Li, 1974). Whereas rigorous assessment of vitamin B<sub>6</sub> status is best accomplished when using an alternative indicator to accompany plasma PLP measurement, in practice such efforts are duplicative and rarely performed. Regardless, the complexity of plasma PLP data should be recognized.

Other direct measures of vitamin B<sub>6</sub> status include total plasma vitamin B<sub>6</sub>, erythrocyte PLP, urinary 4-pyridoxic acid (4-PA), and total urinary vitamin B<sub>6</sub> excretion, all of which have been used widely in previous nutritional evaluations. Approximately 50% of total vitamin B<sub>6</sub> intake is excreted as urinary 4-PA. The measurement of urinary 4-PA as a nutritional status indicator is limited because it is influenced by both vitamin B<sub>6</sub> tissue stores and short-term dietary intake. Whereas assessments using urinary 4-PA generally involve burdensome complete 24-h urine collections, the validity of assays based on a 4-PA/creatinine ratio in untimed urine collections has been reported and may alleviate this issue (Schuster *et al.*, 1984). The value of plasma 4-PA measurements in vitamin B<sub>6</sub> status assessment requires further evaluation.

Indirect methods of vitamin B<sub>6</sub> status evaluate concentrations of metabolites or the activity of PLP-dependent enzymes. Before plasma PLP became the preferred method of vitamin B<sub>6</sub> status assessment, the tryptophan load test was widely used as a functional indicator of vitamin B<sub>6</sub> status (Leklem, 1990). The activity of kynureninase, a PLP-dependent enzyme involved in the catabolism of tryptophan, is decreased in vitamin B<sub>6</sub> deficiency, altering the flux of the pathway (Yess *et al.*, 1964). Following a 2-g oral bolus of tryptophan, metabolites can be measured in the urine. In vitamin B<sub>6</sub> deficiency, the urinary excretion of xanthurenic acid and other tryptophan metabolites is increased (Yess *et al.*, 1964). However, the tryptophan load test is not a highly specific measure of vitamin B<sub>6</sub> status as tryptophan metabolism can be affected by various factors including certain drugs.

The methionine load test, which involves a 3-g oral methionine load (Ubbink *et al.*, 1996), is similar to the tryptophan load test in that it measures the functioning of a vitamin B<sub>6</sub>-dependent pathway. In effect, the methionine

load test evaluates the balance of homocysteine production from the bolus of methionine versus the capacity for its metabolic clearance (Selhub, 1999). Under the conditions of this procedure, homocysteine remethylation is suppressed while homocysteine production is extensive. Thus, the methionine load test as applied to vitamin B<sub>6</sub> status assessment is a functional evaluation of the transsulfuration pathway of homocysteine catabolism. As stated above, both cystathionine  $\beta$ -synthase and cystathionine  $\gamma$ -lyase are PLP-dependent, with the latter highly subject to effects of inadequate vitamin B<sub>6</sub> status (Davis *et al.*, 2006; Lima *et al.*, 2006). In contrast to the utility of post-methionine-load plasma homocysteine as a diagnostic criterion of vitamin B<sub>6</sub> status, fasting plasma homocysteine is only weakly related to vitamin B<sub>6</sub> status (Selhub, 1999). Fasting plasma cystathionine also can be used as a functional biomarker of vitamin B<sub>6</sub> nutritional insufficiency. In vitamin B<sub>6</sub> deficiency, rat liver cystathionine and human plasma cystathionine exhibit elevation over a wide range of vitamin B<sub>6</sub> deficiency states ranging from marginal to severe (e.g. Stabler *et al.*, 1997; Davis *et al.*, 2006; Lima *et al.*, 2006). Further investigation and standardization of the use of cystathionine as a nutritional index is required. Elevation of plasma glycine also commonly occurs in vitamin B<sub>6</sub> deficiency but to a lesser extent than that of cystathionine.

Erythrocyte alanine aminotransferase (EALT) and aspartic aminotransferase (EAST) activity and stimulation can also be used to measure vitamin B<sub>6</sub> status indirectly. Coenzyme stimulation is the increase in enzyme activity following the addition of PLP *in vitro*, as vitamin B<sub>6</sub> deficiency increases the proportion of apoenzyme to holoenzyme in the erythrocyte. EALT and EAST are viewed as indicators of long-term vitamin B<sub>6</sub> status (Leklem, 1990). In principle one would expect that these coenzyme stimulation assays would correlate closely with erythrocyte PLP concentration.

### Deficiency

Vitamin B<sub>6</sub> deficiency can contribute to adverse health effects because of the many metabolic roles played by PLP. Overt vitamin B<sub>6</sub> deficiency is rare in developed countries, but includes clinical manifestations such as microcytic anemia, convulsions, and dermatitis. PLP is a cofactor for  $\delta$ -aminolevulinate synthase, the rate-limiting enzyme in heme biosynthesis. In vitamin B<sub>6</sub> deficiency, heme synthesis is depressed, which limits hemoglobin synthesis and leads to the production of smaller than normal red blood

cells and a condition known as microcytic anemia (Verloop and Rademaker, 1960). PLP also is involved in the synthesis of neurotransmitters, such as  $\delta$ -aminobutyric acid and serotonin. Depressed neurotransmitter levels have been observed in vitamin B<sub>6</sub>-deficient animals (Paulose *et al.*, 1988). PLP's role in neurotransmitter production may explain the seizures observed in infants fed vitamin B<sub>6</sub>-deficient formula; administration of PN alleviated the problem (Nelson, 1956). The risk of all such disorders associated with vitamin B<sub>6</sub> deficiency would undoubtedly be affected by the vitamin B<sub>6</sub> intake relative to the requirement, the rate of depletion if associated with an abrupt change in intake, and the duration and extent of a chronic deficiency.

Vitamin B<sub>6</sub> deficiency can be caused by inadequate intake, impaired absorption, and inefficient conversion of absorbed forms of the vitamin to PLP (Merrill *et al.*, 1984). Certain drugs, such as isoniazid (Cilliers *et al.*, 2010), phenelzine (Stewart *et al.*, 1984), dopamine (Weir *et al.*, 1991), and gentamicin (Weir *et al.*, 1990), bind to the carbonyl group of PLP or PL and can induce functional vitamin B<sub>6</sub> deficiency. Theophylline, an asthma drug, inhibits PL kinase, which interferes with PLP synthesis (Ubbink *et al.*, 1990). The effect of oral contraceptives on vitamin B<sub>6</sub> status has been debated (Miller *et al.*, 1975; Leklem, 1986; Miller, 1986), but several studies report significantly lower plasma PLP concentration in oral contraceptive users compared with non-users (Lumeng *et al.*, 1974b; Lussana *et al.*, 2003; Morris *et al.*, 2008).

More relevant in developed countries is the issue of marginal vitamin B<sub>6</sub> status, which often is viewed as that associated with the range of plasma PLP concentration of 20–30 nmol/L. Though not accompanied by clinical symptoms of deficiency, marginal status may increase risk for chronic diseases such as cancer and cardiovascular disease. Studies involving controlled depletion of healthy adults frequently show changes in plasma amino acids, specifically mild elevation of glycine and a doubling of cystathionine concentration (Davis *et al.*, 2006; Lamers *et al.*, 2009b), and alterations in glutathione synthesis in certain individuals (Lamers *et al.*, 2009a). Whereas this level of deficiency yields little or no elevation in fasting plasma homocysteine, a transient postprandial rise in homocysteine could occur. The relationship between these metabolic changes and disease processes remains unclear.

Abnormal electroencephalographic patterns were observed in women consuming a controlled diet providing

less than 0.05 mg of vitamin B<sub>6</sub> per day having mean plasma PLP of 9.8 nmol/L (Kretsch *et al.*, 1991). Therefore, plasma PLP concentrations of at least 10 nmol/L are suggested as a lower limit of nutritional adequacy based on this physiological criterion.

### Toxicity

Pyridoxine supplements of over 500 mg/day have been reported to cause sensory neuropathy (Berger *et al.*, 1992). In order to minimize this risk, the tolerable upper limit for vitamin B<sub>6</sub> has been set at 100 mg/day for adults (Institute of Medicine, 1998). This range far exceeds the formulation of typical multivitamin supplements that provide 2 mg/daily dose.

Several types of genetic disorders are vitamin B<sub>6</sub>-responsive, and therapeutic vitamin B<sub>6</sub> supplementation is used in their management. These conditions include inborn errors that affect enzymes involved in the interconversion of vitamin B<sub>6</sub> isoforms, reduce absorption of vitamin B<sub>6</sub>, or affect PLP-dependent enzymes; for example, pyridoxine-responsive anemia, cystathioninuria, and homocysteinuria (Clayton, 2006). Furthermore, certain inborn errors result in the generation of metabolites that inactivate PLP. Similar high doses of pyridoxine have been used therapeutically in pyridoxine-responsive disorders with few reports of toxic effects, although health-care professionals should be cognizant of risks of toxicity (Clayton, 2006).

### Requirements

Many controlled dietary studies and observational investigations have concluded that vitamin B<sub>6</sub> intake and dietary protein intake (Miller *et al.*, 1985; Hansen *et al.*, 1996) are the most significant determinants of plasma PLP concentration. Plasma PLP concentrations appear to increase 12 nmol/L for every 1 mg/day increase in vitamin B<sub>6</sub> intake (Morris *et al.*, 2008), whereas high protein intake lowers plasma PLP concentrations (Pannemans *et al.*, 1994; Hansen *et al.*, 1996). Extensive literature exists regarding the relationship between vitamin B<sub>6</sub> intake and various other indices of vitamin B<sub>6</sub> status such as urinary total vitamin B<sub>6</sub>, urinary 4-PA, EALT and EAST activity and PLP stimulation, plasma total vitamin B<sub>6</sub>, plasma 4-PA, plasma PLP, and the methionine and tryptophan load tests. However, none of these provides the truly functional information from a biochemical or physiological basis on which to base the absolute requirement. As mentioned earlier, the observation of altered electroencephalographic

patterns in a vitamin B<sub>6</sub> depletion study that induced plasma PLP ~10 nmol/L provides evidence of a functional inadequacy in this very low and undoubtedly inadequate range.

As reviewed previously (Institute of Medicine, 1998), many studies have shown that plasma PLP values in the range of 20–30 nmol/L are common and have not been associated with obvious health effects. Leklem (1990) recommended that 30 nmol/L plasma PLP be viewed as indicative of the lower end of the normal range of vitamin B<sub>6</sub> status, and the range of 20–30 nmol/L has been considered as marginal deficiency (Leklem, 1999; Gregory, 2001). The Institute of Medicine used a cutoff of 20 nmol/L on which to base the estimated average requirement (EAR) and commented that even this conservative criterion may overestimate the actual requirement for half of the population on the basis of health maintenance (Institute of Medicine, 1998). In spite of this conservative view on which the current RDA is based, the dilemma remains how to define the requirement in the absence of obvious causal relationships between vitamin B<sub>6</sub> and health. The revision of an RDA based on a 30 nmol/L plasma PLP cutoff would provide greater assurance of adequacy as indicated by the biochemical effects of marginal status and growing associations between marginal vitamin B<sub>6</sub> status and chronic disease. The current recommended dietary allowances (RDA) for vitamin B<sub>6</sub> across the lifespan are given in Table 20.1.

Recent NHANES data estimate average vitamin B<sub>6</sub> intake in the US to be 1.86 mg/day for non-users of dietary supplements and 1.94 mg/day for supplement users

(Morris *et al.*, 2008). Relative to the vitamin B<sub>6</sub> RDA of 1.3 mg/day for adults, this suggests adequate intake by most of the population, with the exception of lower percentiles. However, measurement of plasma PLP revealed concentrations <20 nmol/L in all subgroups examined, which suggests that the current RDA may be insufficient. These data also showed at-risk populations, such as the elderly, blacks, and oral contraceptive users, that may require above 3–4.9 mg/day to maintain adequate plasma PLP concentrations (Morris *et al.*, 2008). The reason for the large discrepancy between these observations and those based on controlled dietary studies has not been determined.

### Vitamin B<sub>6</sub> in Health and Disease

The lower ranges of vitamin B<sub>6</sub> intake, especially among women, are well below recommended levels, and this marginal range is associated with increased risk of cardiovascular disease, stroke, and venous thrombosis. These lower ranges also have been associated recently with incidence of certain cancers. At present the key word is association: the mechanistic connections (if any) between low vitamin B<sub>6</sub> status and chronic disease remain to be determined.

Chronically inadequate vitamin B<sub>6</sub> nutritional status has been associated with aberrant one-carbon metabolism and health. Suboptimal vitamin B<sub>6</sub> nutriture was first associated with vascular disease in monkeys (Rinehart and Greenberg, 1949), a relationship confirmed in human epidemiological studies. Verhoef *et al.* (1996) reported that the frequency of myocardial infarction was negatively associated with both folate and vitamin B<sub>6</sub> nutriture. Rimm *et al.* (1998) confirmed these findings in the Nurses' Health Study. Women in the highest quintile of B<sub>6</sub>, folate, or folate plus B<sub>6</sub> intake had less coronary heart disease than those in the lowest quintile of each intake category. An Italian study (Friso *et al.*, 2004) also reported an independent association of low plasma PLP concentration with coronary artery disease risk. Dalery *et al.* (1995) described the results of large trials examining plasma PLP concentration and risk of vascular disease. Even in healthy control subjects, low folate or B<sub>6</sub> status increased the risk of vascular disease, and risk of vascular disease in low vitamin B<sub>6</sub> status was independent of plasma homocysteine concentration. Kelly *et al.* observed that low vitamin B<sub>6</sub> status (plasma PLP <30 nmol/L) was associated with more than a two-fold increase in risk of stroke or transient ischemic attack (Kelly *et al.*, 2003, 2004) independent of folate

**TABLE 20.1** Current recommended dietary allowances for vitamin B<sub>6</sub>

Life stage and age		Amount (mg/day)	
		Female	Male
Infants	0–5 months	0.1	0.1
	6–11 months	0.3	0.3
Children	1–3 years	0.5	0.5
	4–6 years	0.6	0.6
	7–9 years	1.0	1.0
	10–18 years	1.2	1.3
Adults	19–50 years	1.3	1.3
	>50 years	1.5	1.7
Pregnancy		1.9	
Lactation		2.0	

status or plasma total homocysteine (tHcy). Further, a prospective study has shown that people with plasma PLP <23.3 nmol/L had 1.8-fold higher recurrent risk of venous thromboembolism than those with PLP >23.3 nmol/L (Hron *et al.*, 2007). In spite of the strength of these associations, acute supplementation trials with mixed folic acid, vitamin B<sub>12</sub> and vitamin B<sub>6</sub> (e.g. Albert *et al.*, 2008; Hankey *et al.*, 2010) or pyridoxine alone compared with mixed vitamins (e.g. Ebbing *et al.*, 2008, 2010) for *secondary* prevention (i.e. preventing *recurrence* of cardiovascular disease) have yielded largely negative results.

The mechanism by which low vitamin B<sub>6</sub> intake is associated with risk of vascular disease is not known. Since vitamin B<sub>6</sub> deficiency has little tendency to raise fasting plasma total homocysteine and primarily yields an elevation following a methionine load, low B<sub>6</sub> nutriture may lead to repeated transient mild hyperhomocysteinemia following meal consumption.

Several reports of associations between elevated plasma C-reactive protein (CRP) and low vitamin B<sub>6</sub> status have raised the hypothesis that systemic inflammation is prone to occur during vitamin B<sub>6</sub> deficiency or contributes to low B<sub>6</sub> status (Friso *et al.*, 2001; Morris *et al.*, 2010). The mechanism behind this association is unclear because controlled dietary restriction of vitamin B<sub>6</sub> in healthy adults does not cause a change in CRP (Davis *et al.*, 2006). In light of the reports of a relationship between CRP, vascular disease, and low vitamin B<sub>6</sub> status in observational studies such as NHANES (Morris *et al.*, 2010), it appears that vitamin B<sub>6</sub> deficiency alone is not an inflammatory condition, but the deficiency may predispose an individual to the effects of other inflammatory processes. Alternatively, inflammation may lead to tissue-specific deficiency (Chiang *et al.*, 2005) by altering vitamin B<sub>6</sub> cellular metabolism, turnover or transport. Altered glutathione metabolism (Lima *et al.*, 2006; Lamers *et al.*, 2009a) may be one such metabolic connection between impaired vitamin B<sub>6</sub> status and inflammatory response. These questions indicate the need for a more thorough understanding of the metabolic changes occurring in low vitamin B<sub>6</sub> status, inflammatory conditions, and disease risk.

A linkage between vitamin B<sub>6</sub> status and certain aspects of cancer risk has also been reported. For example, a meta-analysis evaluated prospective studies and found a significant inverse relationship between plasma PLP concentration and colorectal cancer risk (Larsson *et al.*, 2010). In this study, the evidence was less conclusive regarding vitamin B<sub>6</sub> intake and risk, possibly as a result of greater uncer-

tainty in assessing vitamin B<sub>6</sub> consumption patterns. Risk of lung cancer also has been shown to be inversely associated with plasma PLP concentration (Johansson *et al.*, 2010). Little consistent evidence of other connections between vitamin B<sub>6</sub> and cancer has been reported, and further investigation is needed.

## Future Directions

Vitamin B<sub>6</sub> is a family of related compounds consisting of pyridoxine, pyridoxal, pyridoxamine, and their 5'-phosphates. Fruits and vegetables also contain pyridoxine β-D-glucoside in variable and often substantial amounts. The development of more complete food composition tables would improve dietary assessment by accounting for differences in bioavailability among various dietary forms of the vitamin.

The development of a better understanding of the linkage between vitamin B<sub>6</sub> nutritional status and disease susceptibility is an important need. Smaller scale controlled mechanistic studies examining connections of metabolic patterns, dietary intake, genetics, and in vivo kinetics may help in the development of diagnostic tools and biomarkers for use in larger population studies.

Understanding vitamin B<sub>6</sub> nutrition on a personalized level will be important in assessing optimal intakes and consequences of deficiency. For example, how do genetic and nutritional factors interact to define an individual's health and susceptibility to chronic disease?

Further characterization of the interaction of inflammatory processes and vitamin B<sub>6</sub> status may be an important key in understanding optimal nutrition and in interpreting biomarkers such as plasma PLP and CRP.

It is also important to determine the role of vitamin supplementation and food fortification in human health, specifically with respect to primary prevention of cardiovascular and other forms of chronic disease.

## FOLATE

LYNN B. BAILEY<sup>1</sup>, PhD AND MARIE A. CAUDILL<sup>2</sup>, PhD, RD

<sup>1</sup>*University of Georgia, Athens, Georgia, USA*

<sup>2</sup>*Cornell University, Ithaca, New York, USA*

### Summary

Key metabolic reactions involving the transfer and acceptance of one-carbon entities are dependent on folate consumed as polyglutamyl food folate or as monoglutamyl synthetic folic acid in fortified foods or supplements. Intestinal absorption of folate vitamers involves deconjugation, if in the polyglutamyl form, followed by absorption of the monoglutamate form primarily by the proton-coupled folate transporter (PCFT). Circulating folate is free or bound to proteins prior to cellular uptake by specific transporters. Intracellular folate is converted to a series of coenzymes whose functions include the acceptance and donation of one-carbon (1-C) entities critical to nucleotide and amino acid synthesis as well as numerous regulatory and structural compounds. Genetic variants of the genes involved in the synthesis and regulation of folate metabolism may lead to metabolic abnormalities which have been linked in some cases with disease and birth-defect risk, particularly under conditions of sub-optimal folate status. Alcohol and specific drugs are recognized to impair folate metabolism, increasing the risk for folate deficiency. Folate intake recommendations consider differences in the bioavailability of folate which vary depending on the source (naturally occurring food folate or folic acid in fortified foods). A special folic acid intake recommendation coupled with folic acid fortification in the US (and numerous other countries globally) are specifically designed to reduce the risk of neural tube defects (NTDs). Evolving research studies have linked folate status/metabolism to key congenital and chronic diseases and have defined a challenging research agenda to address unanswered questions.

### Introduction

Folate is a generic term for this water-soluble vitamin and includes naturally occurring food folate and synthetic folic acid in supplements and fortified foods. Folate coenzymes function in the acceptance and transfer of 1-C moieties involved in the synthesis, interconversion, and modifica-

tion of nucleotides, amino acids, and other cellular components. This chapter provides a review of current knowledge related to folate mediated 1-C metabolism. Factors that may cause metabolic abnormalities in folate mediated 1-C metabolism including inadequate folate intake, incomplete bioavailability of folate, and folate-related genetic polymorphisms are discussed. The chapter

also provides an overview of current knowledge regarding the interactions between the physiological, biochemical, and genetic aspects of folate metabolism coupled with an extrapolation to human health including developmental abnormalities and chronic disease. In addition, folate–alcohol/drug interactions, dietary folate intake recommendations, folate status assessment, current estimates of intake and blood concentrations, and issues related to folic acid safety are highlighted.

## Chemistry and Sources

Common structural features of the folate family include a pteridine bicyclic ring system, *p*-aminobenzoic acid, and one or more glutamic acid residues (Figure 21.1). Naturally occurring food folates are present in the reduced, tetrahydrofolate (THF) form and typically have side chains com-

posed of five to eight glutamate residues joined in  $\gamma$ -peptide linkages. Folic acid, the fully oxidized monoglutamate synthetic form of the vitamin, is found in fortified foods and supplements but rarely occurs in nature. Reduction of the pteridine moiety to dihydrofolate (DHF) and THF, elongation of the glutamate chain, and acquisition of single carbons on the N-5, N-10, or both positions are required for folate to participate in cellular 1-C metabolism (Shane, 2009). The 1-C substituted folates exist with methyl ( $\text{CH}_3$ ), methylene ( $-\text{CH}_2-$ ), methenyl ( $-\text{CH}=\text{}$ ), formyl ( $-\text{CH}=\text{O}$ ), or formimino ( $-\text{CH}=\text{NH}$ ) groups mainly in the polyglutamyl form of the THF molecule.

Naturally occurring dietary folate is concentrated in foods such as orange juice, dark green leafy vegetables, asparagus, strawberries, peanuts, and certain legumes (e.g., black beans and kidney beans) (Kauwell, 2009). As of January 1, 1998, all US cereal grain products labeled as

**FIG. 21.1** Folic acid structures. Folic acid consists of a *p*-aminobenzoic acid molecule linked at one end to a pteridine ring and at the other end to a molecule of glutamic acid. Food folates exist in various forms, containing from two to ten additional glutamate residues joined to the first glutamate. The folate/folic acid structure can vary by reduction of the pteridine moiety to form dihydrofolic acid and tetrahydrofolic acid (THF), elongation of the glutamate chain, and substitution of 1-C units at the N5, N10, or both positions. Folate coenzymes are formed by the attachment of 1-C units including methyl ( $\text{CH}_3$ ), methylene ( $-\text{CH}_2-$ ), methenyl ( $-\text{CH}=\text{}$ ), formyl ( $-\text{CH}=\text{O}$ ), or formimino ( $-\text{CH}=\text{NH}$ ) groups to the polyglutamyl form of the THF molecule.

“enriched” (i.e., bread, pasta, flour, breakfast cereal, and rice) and mixed food items containing these grains were required by the Food and Drug Administration (FDA) to be fortified with folic acid (Department of Health and Human Services Food and Drug Administration, 1996). In addition to the US, more than 50 countries are now implementing mandatory folic acid fortification programs (Berry *et al.*, 2009).

## Physiology and Metabolism

### Absorption

Naturally occurring food folate occurs predominantly in the polyglutamate form which must be converted to the monoglutamate form prior to absorption. The hydrolysis of polyglutamyl folates occurs primarily in the proximal part of the jejunum with the involvement of the brush-border enzyme glutamate carboxypeptidase II (GCPII; EC 3.4.17.21), previously also known as folate hydrolase, foyllypolyglutamate hydrolase, pteroylpolyglutamate hydrolase or pteroylpoly- $\gamma$ -glutamate carboxypeptidase. The enzyme acts as an exopeptidase, cleaving terminal  $\gamma$ -linked glutamate residues from polyglutamyl folates (Chandler *et al.*, 1986; Gregory *et al.*, 1987). The optimal pH for GCPII is 6.5 (Chandler *et al.*, 1986) and studies have shown that the maintenance of this optimal pH is critical for the complete deconjugation of polyglutamyl folates in the jejunum (Tamura *et al.*, 1976; Chandler *et al.*, 1986).

Membrane transport of folates into intestinal cells is mediated mainly by the facilitative carrier, protein-coupled folate transporter (PCFT), as described in the next section. When pharmacological doses ( $>10\ \mu\text{M}$ ) of folate are consumed, absorption takes place by a nonsaturable diffusion-like process and most of the diffused vitamin appears unchanged in portal circulation (Shane, 2009).

In the large intestine another potential source of folate is that produced by microorganisms. Evidence for the absorption of folate across the large intestine was provided by a study in which participants were infused with a physiological dose of stable-isotopically labeled folate during colonoscopy (Aufreiter *et al.*, 2009).

### Transport

Folate transport systems are classified as either transmembrane carriers or systems mediated by folate binding proteins (i.e. folate receptors) (Shane, 2009). The reduced folate carrier (RFC) is a bi-directional transmembrane protein that is saturable and has a fairly high affinity for

reduced folates with  $K_m$  values in the low micromolar range ( $\sim 1\text{--}3\ \mu\text{M}$ ) (Zhao *et al.*, 2002; Matherly and Goldman, 2003) but a greatly reduced affinity for folic acid ( $K_m \sim 200\ \mu\text{M}$ ). PCFT is a more recently identified transmembrane unidirectional transport protein whose proton coupling allows the concentrative transport of folates at acidic pH (Qiu *et al.*, 2006; Zhao *et al.*, 2009). Unlike RFC, this carrier has similar affinity for reduced folates and folic acid ( $K_m$  values 0.5 to  $0.8\ \mu\text{M}$  at pH 5.5). PCFT appears to play a primary role in intestinal folate absorption since it is expressed in the apical brush border of the duodenum and the jejunum (as is RFC) and, in addition, has characteristics consistent with the requirements for folate transport in the small intestine (acidic pH optimum, high affinity for both folic acid and reduced folates) (Subramanian *et al.*, 2008; Zhao *et al.*, 2009). Intestinal basolateral transport occurs via the multidrug resistance-associated proteins (Mutch *et al.*, 2004).

When synthetic folic acid is consumed, it shares both a common transport mechanism and metabolic fate with most naturally occurring dietary folates since the different chemical forms are metabolized to 5-methylTHF during passage across the intestinal mucosa into portal circulation (Pietrzik *et al.*, 2010). Folic acid is first reduced to DHF and then to THF by DHF reductase in the mucosal cells with some of this metabolism occurring in the liver prior to the release of 5-methylTHF into peripheral circulation (Whitehead and Cooper, 1967; Melikian *et al.*, 1971). Unmetabolized folic acid may appear in the circulation when the metabolic capacity of DHF reductase is exceeded (Kelly *et al.*, 1997; Sweeney *et al.*, 2006).

Once folate enters portal circulation, it is transported into the liver by one of several transporters (Matherly and Goldman, 2003) where it is metabolized to the polyglutamate form which can be used intracellularly, stored, or released into blood or bile (following its conversion back to the monoglutamate form). The predominant form of folate in circulation is the monoglutamyl form of 5-methylTHF. Low- and high-affinity proteins bind folate in circulation with the largest percentage ( $\sim 50\%$ ) bound loosely to albumin (Ratnam and Freisheim, 1990).

Cellular uptake by peripheral tissues utilizes mainly RFC (Herbert and Das, 1994), although PCFT is widely expressed and prominent in kidney, liver, and brain (Yuasa *et al.*, 2009; Zhao *et al.*, 2009). Folate receptors (FR $\alpha$ ), high-affinity binding proteins, mediate folate uptake (via an endocytotic process) in the central nervous system

(Matherly and Goldman, 2003) and are also involved in folate reabsorption from the kidney proximal tubules (Matherly and Goldman, 2003; Matherly and Hou, 2008). In addition to internalization of folate, PCFT plays a role in FR $\alpha$ -mediated endocytosis by serving as a route of export of folates from acidified endosomes (Zhao *et al.*, 2009).

### Cellular Storage

Once within cells, 5-methylTHF is demethylated through the action of methionine synthase (EC 1.16.1.8) and converted to a polyglutamyl form by folylpolyglutamate synthetase (EC 6.3.2.17) (Shane, 1989). Since folate polyglutamates do not cross cell membranes due to their charge and binding to folate enzymes, polyglutamylation serves as a mechanism to help sequester folate inside the cell (Shane, 1989). Prior to release from tissues, folate polyglutamates are reconverted to the monoglutamate form by  $\gamma$ -glutamyl hydrolase (EC 3.4.19.9) (Shane, 2009). Tissues are limited in their ability to store folate beyond that required for metabolic function. The total body content of humans is estimated to be approximately 15–30 mg based on measurements of liver tissue concentration (Whitehead, 1973; Hoppner and Lampi, 1980), assumptions of liver mass (~1400 g) and relative folate content (i.e. ~50% of total body folate) (Herbert and Zalusky, 1962). Calculations based on in vivo kinetic studies yield similar estimates of body folate pools (Gregory *et al.*, 1998, 2001), but conflicting data have been reported (Lin *et al.*, 2004).

### Excretion

The fraction of plasma folate that is not associated with protein is freely filtered at the glomerulus and most folate is reabsorbed in the proximal renal tubules (Shane, 2009). Folate is effectively reabsorbed in the kidney proximal tubules and little or no folate is lost in the urine at normal folate intakes. Urinary excretion occurs mainly as the products of folate cleavage, and the urinary excretion of intact folates represents only a small percentage of dietary folate except in populations exposed to folic acid fortification and/or consuming multivitamins with folic acid (Caudill *et al.*, 1998; Shane, 2009). Biliary secretion of folate has been estimated to be as high as 100  $\mu$ g/day providing for enterohepatic circulation of folate (Shane, 2009). Fecal folate losses are difficult to assess due to the contribution of colonic microbial synthesis of folate.

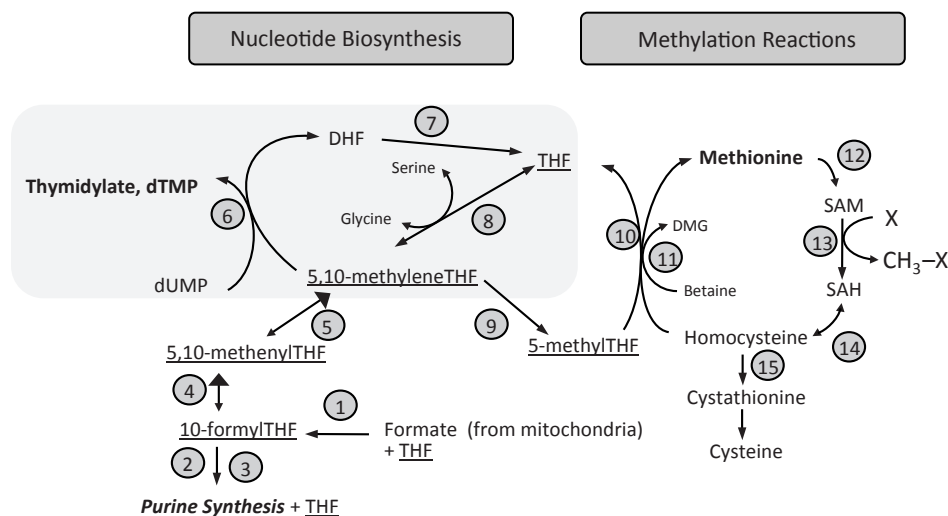

Excretion of fecal folate has been estimated to be similar to that of total urinary excretion of intact folate and cleavage products based on data from a study involving radiolabeled folate (Krumdieck *et al.*, 1978).

### In Vivo Kinetics

Knowledge of in vivo kinetics (study of rates) aids in understanding the requirements of a nutrient and provides an insight into experimental design in interventions to alter nutritional status (Gregory *et al.*, 2009). Most kinetic studies of folate metabolism in humans utilizing either stable or radiolabeled folate have shown one or more fast-turnover pools and larger slow-turnover pools (Krumdieck *et al.*, 1978; Stites *et al.*, 1997; Clifford *et al.*, 1998; Gregory *et al.*, 1998). The folate pools that exhibit fastest turnover in whole-body kinetic studies typically have half-lives of a few hours or less and appear to be comprised mostly of monoglutamyl species primarily in plasma. In contrast, the far slower-turnover folate pools often exhibit half-lives of the order of months and are comprised primarily of polyglutamyl folates in tissues (Gregory *et al.*, 2009).

### Bioavailability

The concept of folate bioavailability as reviewed refers to the overall efficiency of utilization, including the physiological and biochemical processes involved in intestinal absorption, transport, metabolism, and excretion (McNulty and Pentieva, 2009; Caudill, 2010). In contrast to supplemental folic acid, folate from naturally occurring food sources exhibits variable and often incomplete bioavailability. Many dietary variables, physiological conditions, and pharmaceuticals may affect the bioavailability of food folate. These include: (a) entrapment of naturally occurring folates in the cellular structure or insoluble matrix of certain foods; (b) instability of labile tetrahydrofolates during passage through the stomach; (c) inhibition of the intestinal deconjugation of polyglutamyl folates by food constituents; and (d) indirect impairment of folate deconjugation and absorption by alteration of jejunal pH. Because of variation among individuals in folate digestion, absorption, and metabolism, variability in the bioavailability of food folate is a common finding, and conflicts exist among published studies (Tamura and Stokstad, 1973; Babu and Srikantia, 1976; Prinz-Langenohl *et al.*, 1999). The higher bioavailability of folic acid consumed as fortified food relative to food folate provided the rationale for the derived term dietary folate equivalents (DFEs) cur-

**FIG. 21.2** Cytosolic folate-mediated biosynthetic reactions and interconversions of folates (polyglutamates) emphasizing the mostly unidirectional flow of 1-C units through reactions 4 and 5. The thymidylate cycle denoted by the gray background also occurs in the nucleus. Each reaction shows the product plus THF, which is recycled to accept another formate from the mitochondria. The enzymes and reactions are described in Table 21.1. DHF, dihydrofolate; DMG, dimethylglycine; SAM, S-adenosylmethionine; SAH, S-adenosylhomocysteine; THF, tetrahydrofolate; X, methyl group acceptor.

rently used for dietary folate intake recommendations as described in more detail later in this chapter.

## Biochemical Functions

Folate coenzymes function in the acquisition and donation of 1-C units and are localized to three cellular compartments: cytosol, nucleus, and mitochondrion. Cytosolic 1-C metabolism is involved in phases of amino acid metabolism, purine and thymidylate biosynthesis, and the formation of the primary methylating agent, S-adenosylmethionine (SAM). The pyrimidine, thymidylate, is also generated in the nucleus during DNA replication and repair. The 1-Cs used in cytosolic folate-mediated 1-C metabolism are derived primarily from the mitochondria in the form of formate through mitochondrial catabolism of serine, glycine, and choline (Stover, 2009).

### Cytosolic Folate Metabolism

Cytosolic folate-mediated 1-C metabolism includes three interconnected biosynthetic pathways that catalyze the de novo biosynthesis of purines and thymidylate, and remethylation of homocysteine to methionine (Figure 21.2 and Table 21.1). The trifunctional cytosolic enzyme C<sub>1</sub>-THF synthase, encoded by *MTHFD1*, (Figure 21.2, reactions

1, 4, and 5) (Christensen and MacKenzie, 2008), enables entry of mitochondrial 1-Cs into the cytosol with its 10-formylTHF synthetase activity (reaction 1) and facilitates the interconversions of 10-formylTHF, 5,10-methenylTHF and 5,10-methyleneTHF in reactions catalyzed by the activities of 5,10-methenylTHF cyclohydrolase (MTHFC) and 5,10-methyleneTHF dehydrogenase (MTHFD), respectively (Figure 21.2, reactions 4 and 5). Although mitochondria are a primary source of single carbons for these biosynthetic reactions, 1-Cs can be also be generated in the cytosol from serine via the action of cytosolic serine hydroxymethyltransferase (cSHMT) (Figure 21.2, reaction 8), as well as from histidine and purines, which enter the cytosolic pool as 5,10-methenylTHF (Stover, 2009).

### Purine Biosynthesis

10-FormylTHF is the required folate coenzyme for the de novo synthesis of the purines, adenine and guanine. The formyl group of 10-formylTHF is incorporated at the C-2 and C-8 positions of the purine ring during de novo purine biosynthesis by reactions catalyzed by glycinaimide ribonucleotide formyltransferase (GARFT) and aminoimidazole carboxamide ribonucleotide (AICARFT) (Figure 21.2, reactions 2 and 3). 10-Formyl is generated

**TABLE 21.1** Major cytosolic metabolic reactions for folate (as shown in Figure 21.2)

Reaction <sup>a</sup>	Enzyme (abbreviation)	EC number
1	10-FormylTHF synthetase	6.3.4.3
2	Glycinamide ribonucleotide formyltransferase (GARFT)	2.1.2.2
3	Aminoimidazole carboxamide ribonucleotide formyltransferase (AICARFT)	2.1.2.3
4	5,10-MethenylTHF cyclohydrolase (MTHFC)	3.5.4.9
5	5,10-MethyleneTHF dehydrogenase (MTHFD)	1.5.1.5
6	Thymidylate synthase (TS)	2.1.1.45
7	Dihydrofolate reductase (DHFR)	1.5.1.3
8	Serine hydroxymethyltransferase (SHMT)	2.1.2.1
9	5,10-MethyleneTHF reductase (MTHFR)	1.5.1.20
10	Methionine synthase	2.1.1.13
11	Betaine: homocysteine methyltransferase (BHMT)	2.1.1.5
12	S-Adenosylmethionine synthase	2.5.1.6
13	Cellular methyltransferases	Various
14	S-Adenosylhomocysteine hydrolase	3.3.1.1
15	Cystathionine $\beta$ -synthase (CBS)	4.2.1.22

<sup>a</sup>Enzymes 1, 4, and 5 represent the three activities associated with the trifunctional C<sub>1</sub>-THF synthase.

by the coupling of formate to THF catalyzed by the activity of 10-formylTHF synthetase of the C<sub>1</sub>-THF synthase trifunctional enzyme (Figure 21.2, reaction 1). 5,10-MethyleneTHF is not believed to be a significant contributor to 10-formylTHF production because the reductive environment in the cytosol favors the conversion of 10-formylTHF to 5,10-methyleneTHF (Christensen and MacKenzie, 2008) in reactions catalyzed by the activities of MTHFC and MTHFD of the C<sub>1</sub>-THF synthase trifunctional enzyme (Figure 21.2, reactions 4 and 5, respectively)

### Thymidylate Biosynthesis

The synthesis of the pyrimidine, thymidylate, is dependent on the availability of 5,10-methyleneTHF, a required coenzyme of thymidylate synthase (TS) which catalyzes the rate-limiting step during the cell cycle thereby enabling DNA replication to proceed. 5,10-MethyleneTHF can be generated from THF in conjunction with the conversion of serine to glycine by cSHMT (Figure 21.2, reaction 8) or from 10-formylTHF by the trifunctional C<sub>1</sub>-THF synthase (Figure 21.2, reactions 4 and 5). In the biosynthesis of thymidylate, 5,10-methyleneTHF donates the 1-C group to deoxyuridine monophosphate (dUMP), forming deoxythymidine monophosphate (dTMP) (Figure 21.2, reaction 6). This reaction is unique in folate 1-C transfers in that the THF carrier is oxidized to DHF, with the electrons being used to reduce the 1-C unit to the methyl level. THF is subsequently regenerated in a reaction cata-

lyzed by dihydrofolate reductase (DHFR) (Figure 21.2, reaction 7).

De novo thymidylate biosynthesis also occurs in the nucleus. During cell division, the cytosolic enzymes, constituting the thymidylate cycle (SHMT, TS, and DHFR), are translocated to the nucleus by small ubiquitin-like modification (Anderson *et al.*, 2007; Woeller *et al.*, 2007).

### Methylation Reactions

5,10-MethyleneTHF can also be reduced to the methyl donor, 5-methylTHF, in a unidirectional reaction catalyzed by methylenetetrahydrofolate reductase (MTHFR) (Figure 21.2, reaction 9). The production of 5-methylTHF by MTHFR is an important functional and regulatory step in the regeneration of methionine from homocysteine. The folate-dependent remethylation process is catalyzed by methionine synthase, and requires cobalamin and 5-methylTHF (Figure 21.2, reaction 10). Homocysteine remethylation is the only known reaction involving 5-methylTHF. In the methionine synthase reaction, a methyl group is sequentially transferred from 5-methylTHF to cobalamin, and then to homocysteine, thus forming methionine. The dependence of methionine synthase on both folate and cobalamin provides a biochemical explanation of why a single deficiency of either vitamin leads to the same megaloblastic changes in the bone marrow and other tissues with rapidly dividing cells. In a cobalamin deficiency, folate is “trapped” in the 5-methylTHF form and THF is not regenerated for the formation of

5,10-methyleneTHF, required for thymidylate and thus DNA synthesis.

Methionine, either from dietary protein or produced from homocysteine, can be activated to SAM, the principal methylating agent in all cells (Figure 21.2, reaction 12). SAM is the methyl donor in over 100 transmethylation reactions, including methylation of DNA, RNA, histones, neurotransmitters, and phospholipids. The main consumers of SAM include phosphatidylethanolamine *N*-methyltransferase, guanidinoacetate methyltransferase, and glycine *N*-methyltransferase (GNMT) which synthesize phosphatidylcholine, creatine, and sarcosine, respectively. Sarcosine is a source of 1-C units following its degradation in the mitochondria as discussed in subsequent text. As a result of methyl-group transfer by a variety of methyltransferases, SAM is converted to *S*-adenosylhomocysteine (SAH) (Figure 21.2, reaction 13), which is subsequently hydrolyzed to homocysteine and adenosine by SAH hydrolase (Figure 21.2, reaction 14). This reaction is reversible and, although the equilibrium favors SAH synthesis (Melnik *et al.*, 2000), utilization of adenosine and the remethylation of homocysteine provide the kinetic impetus that drives this reaction in the direction of homocysteine formation.

Homocysteine can be removed permanently from the methionine cycle via the transsulfuration pathway leading ultimately to cysteine. Cystathionine  $\beta$ -synthase (CBS) (Figure 21.2, reaction 15) catalyzes the committing step in transsulfuration in which homocysteine and serine are coupled to form cystathionine in a pyridoxal phosphate-dependent reaction that is activated by SAM. This promotes CBS activation and favors the transsulfuration pathway under conditions of ample methionine.

### **Mitochondrial Folate Metabolism**

Mitochondria generate 1-C units in the form of formate for cytosolic folate-mediated 1-C metabolism (Figure 21.3 and Table 21.2). The C3 of serine, derived from the diet, glycolytic intermediates and serine produced by cSHMT, is a primary source of 1-C units from which 5,10-methyleneTHF is formed through the action of mitochondrial SHMT (Figure 21.3, reaction 1). 5,10-MethyleneTHF is converted to 10-formylTHF by a bifunctional enzyme encoded by *MTHFD2* (embryos) or the putative *MTHFD2L* (adults) with MTHFD and MTHFC activities (Christensen and MacKenzie, 2006; Tibbetts and Appling, 2010) (Figure 21.3, reactions 2 and 3 respectively). In the final step, 10-formylTHF is hydrolyzed to formate and THF by mitochondrial 10-formylTHF

synthetase (Figure 21.3, reaction 4), a monofunctional enzyme encoded by *MTHFD1L* (Christensen *et al.*, 2005). The formate is then delivered to the cytosol where it is converted to 10-formylTHF for purine synthesis (Figure 21.2, reaction 1) or is reduced to 5,10-methyleneTHF which can be diverted to cellular methylation reactions (Figure 21.2, reaction 9) or thymidylate biosynthesis (Figure 21.2, reaction 6). Alternatively, the 1-C unit in the form of 10-formylTHF may be oxidized to CO<sub>2</sub> by the enzyme, 10-formylTHF dehydrogenase, which removes excess 1-C groups (Figure 21.3, reaction 8).

Additional sources of 1-C units in select tissues (e.g., liver) include the mitochondrial glycine cleavage system and the oxidative catabolism of choline. The glycine cleavage system is a multienzyme complex that cleaves glycine to produce CO<sub>2</sub>, ammonia and 5,10-methyleneTHF (Figure 21.3, reaction 7), the latter of which can be oxidized to 10-formylTHF to recover 1-C units. Choline catabolism involves its oxidation to betaine which, like 5-methylTHF, is used in the remethylation of homocysteine to methionine in a reaction catalyzed by cytosolic betaine-homocysteine methyltransferase (BHMT) (Figure 21.2, reaction 11) (also, see Chapter 26). The other product of this reaction, dimethylglycine, undergoes two sequential mitochondrial oxidations catalyzed by dimethylglycine dehydrogenase and sarcosine dehydrogenase to form glycine and two molecules of 5,10-methyleneTHF (Figure 21.3, reactions 5 and 6 respectively).

Only a limited exchange of free folate occurs between the cytosolic and mitochondrial compartments. However, these compartments are metabolically connected by transport of 1C donors (serine, glycine, and formate) across the mitochondrial membranes, supporting a mostly unidirectional flow from serine to formate (mitochondria) and on to methionine (cytosol) (Tibbetts and Appling, 2010).

## **Regulation of Cytosolic One-Carbon Metabolism**

### **Methylation Reactions**

SAM and SAH are major regulators of the use of methyl groups and exert control at several regulatory points.

### **SAM Regulation**

Surplus SAM binds to the regulatory domain of MTHFR and inhibits enzyme activity thereby reducing the production of 5-methylTHF which is required for the recycling of homocysteine through the methionine synthase reaction. Diminished production of 5-methylTHF by MTHFR

**FIG. 21.3** Mitochondrial folate-mediated 1-C metabolism emphasizing the generation of formate from the catabolism of serine, choline, and glycine. Serine, glycine, and dimethylglycine (from oxidative choline catabolism) can traverse the mitochondrial inner membrane enabling their entry from the cytosolic compartment and their conversion to formate. The enzymes and reactions in this diagram are described in Table 21.2.

**TABLE 21.2** Major mitochondrial enzymes and reactions (as shown in Figure 21.3)

Reaction <sup>a</sup>	Enzyme (abbreviation)	EC number
1	Serine hydroxymethyltransferase (SHMT)	2.1.2.1
2	5,10-MethyleneTHF dehydrogenase (MTHFD)	1.5.1.5
3	5,10-MethenylTHF cyclohydrolase (MTHFC)	3.5.4.9
4	10-FormylTHF synthetase	6.3.4.3
5	Dimethylglycine dehydrogenase	1.5.99.2
6	Sarcosine dehydrogenase	1.5.99.1
7	Glycine cleavage system (GCS)	2.1.2.10
8	10-FormylTHF dehydrogenase	1.5.1.6

<sup>a</sup>Enzymes 2 and 3 represent the two activities associated with the bifunctional C-1 THF synthase.

also yields an active GNMT which is normally inhibited by 5-methylTHF. GNMT catalyzes the SAM-dependent methylation of glycine to sarcosine (Ogawa *et al.*, 1998) thereby metabolizing excess SAM. Sarcosine is converted back to glycine and 5,10-methyleneTHF via sarcosine dehydrogenase following its transport into the mitochondria (Figure 21.3, reaction 6), which allows for the conservation of 1-C units. SAM also activates CBS (Figure 21.2, reaction 15), the first step in the transsulfuration pathway that initiates homocysteine catabolism and its permanent removal from the methionine cycle.

Under conditions of inadequate SAM concentration, methionine conservation is preserved by recycling homocysteine to methionine through activation of MTHFR and inhibition of CBS. Further, as a result of enhanced MTHFR activity and greater production of 5-methylTHF, GNMT is inhibited, sparing SAM for essential methylation reactions.

### SAH Regulation

SAH is a potent product inhibitor of most methyltransferases (Melnyk *et al.*, 1999, 2000). Accumulation of SAH and the associated inhibition of cellular methyltransferases will occur under metabolic conditions that interfere with product removal of homocysteine or adenosine (Melnyk *et al.*, 2000). Increased cytosolic SAH concentrations have also been reported to up-regulate CBS activity, decrease BHMT activity, and decrease MTHFR activity in certain tissues (Melnyk *et al.*, 2000).

### Purine and Thymidylate Biosynthesis

10-FormylTHF is essential for purine biosynthesis and is also the primary source of 5,10-methyleneTHF which is required for thymidylate biosynthesis. The availability of 10-formylTHF for de novo nucleotide synthesis is regulated at multiple points (Stover, 2009). *MTHFD1* encodes the trifunctional enzyme, C<sub>1</sub>-THF synthase, which harbors 10-formylTHF synthetase, MTHFD and MTHFC activities and thus influences the availability of 10-formylTHF and 5,10-methyleneTHF which exist in equilibrium (Pelletier and MacKenzie, 1995). Although the transcriptional levels of *MTHFD1* are not modified by growth factors in cultured fibroblasts, mRNA is stabilized post-transcriptionally by growth factors, which in turn decreases the loss of message due to mRNA turnover (Peri and MacKenzie, 1991). Additional enzymes with regulatory functions include: 10-formylTHF dehydrogenase, which regulates the availability of folate coenzymes

for nucleotide biosynthesis by depleting 10-formylTHF pools (Anguera *et al.*, 2006); MTHFR, which mediates the flow of 1-C units between thymidylate biosynthesis and methylation reactions; and cSHMT, which preferentially partitions cSHMT-derived 5,10-methyleneTHF towards thymidylate biosynthesis at the expense of methylation reactions (Herbig *et al.*, 2002).

### Mitochondrial 1-Carbon Metabolism

Redox and equilibrium conditions support the flow of 1-C units through the mitochondria in the oxidative direction of 5,10-methyleneTHF to 10-formylTHF to formate (Tibbetts and Appling, 2010) as shown in Figure 21.3. In adult hepatic cells, however, the mitochondria may transiently favor serine production for use in gluconeogenesis (Christensen and MacKenzie, 2008). Although *MTHFD1L*, which encodes mitochondrial 10-formyl synthetase, is up-regulated under conditions requiring increased DNA synthesis (Christensen and MacKenzie, 2006), many questions remain regarding the control of 1-C flux through the mitochondria.

### Genetic Polymorphisms

Normal folate metabolism is dependent on genes encoding the ~150 proteins directly or indirectly involved in folate metabolism and transport. Hundreds of single nucleotide polymorphisms (SNPs) have been identified in these genes. These genetic variants or polymorphisms can alter enzyme activity or regulation, or influence gene expression, resulting in changes in the concentrations of critical metabolites, or they could have no effect (Christensen and Rozen, 2009). Examples of select SNPs which do result in metabolic alterations and have been associated with increased disease or birth-defect risk are discussed below. More in-depth descriptions of these and other folate-related genetic variants and their relevance to birth defects and chronic diseases are available elsewhere (Christensen and Rozen, 2009; Molloy *et al.*, 2009; Shaw *et al.*, 2009).

The most extensively studied of the folate-related polymorphisms is a C to T substitution at base pair 677 in the gene encoding the enzyme MTHFR that catalyzes the reduction of 5,10-methyleneTHF to 5-methylTHF, the methyl donor for homocysteine remethylation to methionine (Frosst *et al.*, 1995). Individuals who are homozygous for the *MTHFR* C677T (rs1801133) variant (i.e. TT genotype) exhibit lower specific activity of

MTHFR, and reduced stability of the enzyme in vitro (Frosst *et al.*, 1995).

The prevalence of the 677TT genotype varies widely between regions and ethnic groups (Christensen and Rozen, 2009). In North American Caucasians the frequency has been reported as 8–14%. In European populations, the frequency appears to increase from north to south: 6–14% in Northern Europe and 15–24% in Southern Europe. The genotype is particularly common in Mexican and other Hispanic populations at 15–35%, whereas less than 2% of African and African-American populations are homozygous for the variant. In Asia, the reported frequencies may also be quite high, ranging from ~15% to 39% (Christensen and Rozen, 2009; Crider *et al.*, 2011).

The C677→T variant leading to reduced MTHFR activity increases homocysteine concentrations by decreasing the 5-methylTHF available for homocysteine methylation. Elevations in homocysteine in individuals with the 677TT genotype compared with 677CC individuals have been reported in numerous studies, however, the evidence indicates that homocysteine may only be elevated in individuals with the TT genotype when folate status is low (Jacques *et al.*, 1996; Hustad *et al.*, 2007).

The distribution of folate derivatives is altered when MTHFR activity is reduced, resulting in an increase in 5,10-methyleneTHF which can then be used for dTMP synthesis or converted to other folate forms, such as 10-formylTHF. As 5-methylTHF is the major transport form of folate, reduced MTHFR activity is expected to decrease the amount of circulating folate, possibly exacerbating its metabolic impact (Christensen and Rozen, 2009). Altered distribution of folate forms appears to confound the measurement of total RBC folate by certain assay methods (Molloy *et al.*, 1998b), leading to conflicting results regarding the association between *MTHFR* variants and RBC folate. However, the measurement of folate in plasma/serum is unaffected by these technical difficulties; the variant TT genotype is usually associated with a 10 to 35% reduction in circulating folate (Gueant-Rodriguez *et al.*, 2006; Yang *et al.*, 2008).

The methionine synthase reductase (*MTRR*) enzyme reactivates the cobalamin cofactor of MTR when it is oxidized to cobalt(II) (Olteanu *et al.*, 2002). The *MTRR* A66G (rs1801394) polymorphism has a relatively high frequency in Caucasians (20–38%) but a much lower frequency in other ethnic groups (Christensen and Rozen, 2009). The *MTRR* A66G (rs1801394) variant may modu-

late homocysteine concentrations when coupled with other genetic variants and/or low vitamin B<sub>12</sub> concentrations (Christensen and Rozen, 2009).

RFC has a higher affinity for circulating 5-methylTHF relative to folic acid, therefore the common gene variant *RFC* A80G (rs1051266) theoretically may disturb folate metabolism by reducing the cellular pool of 1-C donors, although there is limited evidence to support this (Christensen and Rozen, 2009). It is possible that other folate transporters may compensate for reduced RFC activity and therefore the variant may affect folate metabolism only under specific circumstances (Christensen and Rozen, 2009).

## Severe Clinical Deficiency, Pregnancy Complications, Fetal Growth

### Severe Clinical Deficiency

Chronic severe folate deficiency is associated with decreased DNA synthesis which leads to impaired maturation of erythropoietic precursors resulting in a gradual increase in red blood cell mean cell volume. The resulting megaloblastic anemia is characterized by large abnormal nucleated erythrocytes that accumulate in the bone marrow (Lindenbaum and Allen, 1995; Stabler, 2009). There are also decreased numbers of white cells and platelets, as a result of general impairment of cell division related to folate's role in nucleic acid synthesis (Lindenbaum and Allen, 1995; Stabler, 2009). Since the intestinal mucosa undergoes continuous regeneration, with replacement of epithelial cells every 3 days, its folate requirements are greater than other tissues (Lindenbaum and Allen, 1995; Stabler, 2009). Gastrointestinal symptoms frequently result from severe folate deficiency and are often associated with impaired absorption (Lindenbaum and Allen, 1995; Stabler, 2009). Overconsumption of alcohol is the most likely cause of folate deficiency anemia due to alcohol's well documented negative effects on folate metabolism that result in a depletion of folate body stores (Halsted *et al.*, 2009).

### Pregnancy Complications and Fetal Growth

Pregnant women are at increased risk of developing a folate deficiency due to the accelerated demands placed on the supply of folate for the synthesis of DNA and other 1-C transfer reactions (Tamura and Picciano, 2006). A number of pregnancy complications including placental abruption,

preeclampsia, spontaneous abortion, stillbirths, and fetal growth restriction have been inversely associated with impaired folate status and linked to hyperhomocysteinemia; however, data are inconclusive, and definitive conclusions cannot be drawn (as recently reviewed: Tamura *et al.*, 2009).

Infant birth-weight has been reported to positively respond to folic acid supplementation in some studies but not others (Tamura *et al.*, 2009). Improved birth-weight in response to folic acid supplementation is likely associated with impaired maternal folate status (Tamura *et al.*, 2009). Analysis of data from over 5 million birth records in California indicated significant reductions in rates of low- and very-low-birth-weight incidence as well as preterm delivery after initiation of the folic acid fortification program (Shaw *et al.*, 2004).

### Neural Tube Defects

Embryological malformations of the central nervous system, commonly referred to as NTDs, result from a failure of fusion of the neural folds in the developing embryo (Botto *et al.*, 1999). Folic acid taken periconceptionally significantly reduces the risk of NTDs, a conclusion based on definitive evidence from randomized controlled intervention trials (RCT) and supported by observational studies (Hobbs *et al.*, 2009). The implementation of mandatory folic acid fortification programs has resulted in convincing reductions in NTDs during the post-fortification era, providing further evidence of the efficacy of this nutrient for NTD risk reduction (Berry *et al.*, 2009).

The mechanism(s) by which folic acid facilitates the reduction in NTD risk is unknown and is the focus of on-going research endeavors by numerous research groups around the globe. It is hypothesized that folic acid intake reduces the risk of NTDs by overcoming metabolic inefficiencies linked to genetic abnormalities (Wallis *et al.*, 2009). The research evidence to date suggests that maternal/fetal folate metabolism is disordered in some cases and this metabolic error may affect uptake and/or metabolism of folate which can in turn adversely affect gene expression critical to normal embryogenesis.

The *MTHFR* 677T variant, either in the mother or in the child, has been associated with an increased risk for NTD (Botto and Yang, 2000; Amorim *et al.*, 2007; Molloy *et al.*, 2009; Shaw *et al.*, 2009). The association between the *MTHFR* C677T variant and NTDs is not always observed, possibly due to various modifiers including

vitamin use/folate status (Molloy *et al.*, 1998a, 2009; Shaw *et al.*, 1998). The impact of the *MTRR* A66G variant in the mother has been found to significantly increase NTD risk in some but not all studies (O'Leary *et al.*, 2005) with low vitamin B<sub>12</sub> and high MMA magnifying the risk significantly (Wilson *et al.*, 1999; van der Linden *et al.*, 2006).

Homozygosity for the variant RFC 80G allele has been associated with a significant increase in NTD risk by some investigators (De Marco *et al.*, 2003; Pei *et al.*, 2005) but not others (O'Leary *et al.*, 2006). The inconsistency may be due to potential interaction between maternal genotype and folate intake since it has been reported by multiple investigators that the combination of low folate intake and maternal GG genotype is associated with an increased risk for NTD (Shaw *et al.*, 2002; Pei *et al.*, 2005).

### Congenital Heart Defects

Congenital heart defects are the most common birth defect with the highest prevalence among stillbirths and miscarriages (Tennstedt *et al.*, 1999; Botto *et al.*, 2003). A considerable body of evidence does support the conclusion that maternal use of folic-acid-containing supplements in early pregnancy significantly reduces the risk for some heart defects (Botto *et al.*, 2003; Hobbs *et al.*, 2009). Finnell and coworkers (Wallis *et al.*, 2009) have provided an in-depth description of how folate may be involved in overcoming select metabolic/genetic abnormalities that may increase the risk for congenital heart defects. Of interest is the fact that the development of both the neural tube and cardiac tissue depends on neural crest cells which have a high demand for folate to support cellular differentiation, growth, and migration (Wallis *et al.*, 2009).

The risk for congenital heart defects has also been mildly associated with the *MTHFR* C677T variant (van Beynum, *et al.*, 2007; Verkleij-Hagoort *et al.*, 2007). Shaw *et al.* (2009) reported that the risk for conotruncal heart defects was not strongly associated with any of the 118 folate-related SNPs evaluated by this research group. The folate status of the mother as well as the heterogeneity of the type of defect should be considered when examining the potential impact of gene variants on risk.

### Vascular Disease

A large number of epidemiological and mechanistic studies have provided evidence for the "homocysteine hypothesis" linking elevated homocysteine to increased risk for vascular disease thus providing the impetus for folic acid

intervention strategies and controlled trials to lower homocysteine and related vascular disease risk (Hannibal *et al.*, 2009; Kalin and Rimm, 2009). Recently, results from numerous major randomized controlled trials of high-dose folic acid, vitamin B<sub>6</sub>, and vitamin B<sub>12</sub> supplementation for secondary prevention of cardiovascular disease (CVD) have been reported (Baker *et al.*, 2002; Toole *et al.*, 2004; Bonaa *et al.*, 2006; Lonn *et al.*, 2006; Jamison *et al.*, 2007; Albert *et al.*, 2008; Ebbing *et al.*, 2008). This large body of evidence from these controlled intervention trials support the conclusion that folic acid alone or in combination with other B vitamins is not efficacious in the secondary prevention of CVD.

While these secondary intervention trials have largely failed to find any benefit for folic acid supplementation, the interpretation of some of these studies has been complicated by the advent of mandatory folic acid fortification in the US and Canada in 1998. The most recent data suggest that post-fortification, average homocysteine concentrations in the US dropped by about 10% (Pfeiffer *et al.*, 2008), enough to potentially obscure any benefit of additional folic acid supplementation. In addition, since the intervention trials were secondary in nature, they may not reflect a protective effect of ensuring adequate folate status and normal homocysteine concentrations on risk reduction for vascular disease in healthy individuals.

### Cancer

Epidemiological studies have provided convincing evidence that inadequate folate status enhances the risk of colorectal cancer as reviewed (Giovannucci, 2002; Sanjoaquin *et al.*, 2005; Chen *et al.*, 2009). There is also more limited support for an inverse relationship between folate status and cancer risk at other sites including the breast (Beilby *et al.*, 2004; Ericson *et al.*, 2007), lung (Voorrips *et al.*, 2000), pancreas (Larsson *et al.*, 2006), esophagus (Larsson *et al.*, 2006), and others. In addition to this ever increasing body of evidence demonstrating that enhancing folate status reduces the risk of cancer initiation, it is also recognized that once foci of pre-cancerous cells are established, increasing folate intake may increase cancer risk (Stolzenberg-Solomon *et al.*, 2006; Cole *et al.*, 2007; Ciappio and Mason, 2009).

There are a number of proposed mechanisms by which inadequate folate status may initiate or promote carcinogenesis (Ciappio and Mason, 2009). One of the prevailing hypotheses is that, under the conditions of low folate, enhanced uracil “misincorporation” increases the risk of

mutagenic DNA strand breaks (Dianov *et al.*, 1991; Elliott and Jasin, 2002; Ciappio and Mason, 2009). A second proposed mechanism by which folate status modulates carcinogenesis relates to observed abnormalities in DNA methylation (hypo and hyper) that are common in cancer (Gronbaek *et al.*, 2007). In contrast, it is widely accepted that excess folate intake may accelerate the growth of pre-malignant cells and established cancerous cells because the rapidly proliferating cells have an elevated requirement for folate to meet the demands for increased DNA synthesis (Voeller *et al.*, 2004; Ciappio and Mason, 2009).

Evidence suggests that the risk for colorectal cancer is lower in individuals with the MTHFR 677TT genotype who have high folate status but that protection is lost, or the TT genotype may become a risk factor, if folate concentrations are low (Sharp and Little, 2004). The protective effect of this variant may be due to an increase in 5,10-methyleneTHF for conversion of dUMP to dTMP, reducing DNA damage resulting from uracil misincorporation into DNA (Chen *et al.*, 1996; Blount *et al.*, 1997).

### Cognitive Function

Morris and Jacques (2009) have thoroughly reviewed epidemiological evidence linking folate status and a wide array of neurological functions. In patients with Alzheimer's disease with associated brain infarcts, low folate status has been linked to neuropathological indicators and to cognitive impairment (Morris and Jacques, 2009). Proposed mechanisms by which folate status could be involved in the etiology of cognitive dysfunction include direct neurotoxic effects of elevated homocysteine associated with low folate status as well as homocysteine-independent mechanisms such as biogenic amine metabolism and/or folate's role in the synthesis of SAM as previously reviewed (Bottiglieri and Reynolds, 2009). There is a great deal of inconsistency in the literature related to the potential association between folate status and cognition. The heterogeneity in findings is likely due to the complexity of assessing neurological function including consideration and control for a wide array of potentially confounding factors (Morris and Jacques, 2009).

## Drug and Alcohol Impairment of Folate Metabolism

### Antifolate Drugs

The enzymes involved in folate metabolism have been therapeutic targets for the treatment of neoplastic diseases

since the 1940s. Antifolates disrupt purine and thymidylate biosynthesis, thereby resulting in impaired DNA replication and cell death (Assaraf, 2007). Methotrexate (MTX), a derivative of aminopterin, is a primary antifolate and structural analogue of folic acid differing only by an amino group replacing the 4-hydroxyl group on the pteridine ring and a methyl group at the N-10 position. These modifications give MTX more affinity for its target, DHFR, than the natural folate substrate (Priest and Bunni, 1995). MTX and/or MTX-polyglutamates bind tightly to DHFR and inhibit it, causing accumulation of DHF and a lack of substrate for TS. A newer antifolate drug, pemetrexed, targets and inhibits various enzymes of folate metabolism including TS, DHFR, C1-THF synthase, and enzymes that catalyze the final folate-dependent steps of purine biosynthesis, GARFT and AICARFT (Exinger *et al.*, 2003).

Methotrexate, at low doses, is also a standard treatment for several inflammatory disorders, particularly rheumatoid arthritis and psoriasis. Although the precise mechanism by which MTX exerts its anti-inflammatory effects is unclear, a variety of pharmacological actions are likely to contribute including inhibition of cellular proliferation of lymphocytes involved in the inflammation process, as well as the enhanced release of adenosine, an anti-inflammatory molecule, into the intracellular space (Whittle and Hughes, 2004; Wessels *et al.*, 2008).

Folate status declines in patients on high- and low-dose methotrexate (Hellman *et al.*, 1964) and folate deficiency increases the risk of MTX toxicity (Hellman *et al.*, 1964). Folinic acid, under the drug name leucovorin, is a form of folate (5-formyl-THF) that can help “rescue” or reverse the toxic effects of methotrexate. Folic acid and folinic acid are equally effective in patients with rheumatoid arthritis, and in the US folic acid is routinely prescribed along with the MTX to prevent toxicity and prolong the use of the medication (Whittle and Hughes, 2004). However, a careful balance must be maintained between drug therapy and adjunct folic acid supplementation to ensure both drug efficacy and prevention of severe folate deficiency (van Ede *et al.*, 2001).

### **Anticonvulsants**

There are numerous reports of impaired folate status associated with chronic use of the anticonvulsants, diphenylhydantoin (phenytoin, Dilantin®) and phenobarbital; however, the mechanism of the drug–nutrient interaction has not been determined.

### **Sulfonamides**

Salicylazosulfapyridine (Aztilfidine®, sulfasalazine) is an anti-inflammatory drug with antifolate properties (Selhub *et al.*, 1978) and is commonly used for the treatment of ulcerative colitis. Sulfasalazine is a potent inhibitor of PCFT (Yuasa *et al.*, 2009) and supplementation with folic acid is often advised (Jansen *et al.*, 2004).

### **Alcohol**

Alcohol consumed chronically in large amounts has been shown to contribute to folate deficiency by interfering with folate absorption, decreasing hepatic folate uptake, and increasing urinary folate excretion as reviewed by Halsted *et al.* (2009). The combination of a folate-deficient diet and chronic alcohol consumption accentuates abnormal hepatic methionine metabolism and accelerates the development of alcoholic liver injury (Halsted *et al.*, 2009).

## **Recommended and Estimated Folate/Folic Acid Intakes in the US and the Impact of Fortification**

### **Dietary Reference Intakes**

The Institute of Medicine (IOM) established the dietary reference intakes (DRIs), which include a series of reference values for folate intake including the estimated average requirement (EAR), recommended dietary allowance (RDA), adequate intake (AI), and the tolerable upper intake level (UL) (Table 21.3) (IOM, 1998). The EAR is defined as the median usual intake of folate needed to meet the requirements of 50% of the population. The RDA is estimated from the EAR by correcting for population variance and represents the average daily dietary intake level sufficient to meet the nutrient requirement of approximately 98% of the population (Table 21.3). The AI was estimated when there were insufficient data on which to derive an EAR and is defined as the quantity of folate consumed by a group with no evidence of folate inadequacy (Table 21.3). The UL pertains specifically to folic acid (rather than food folate) and is characterized as the maximum daily *usual* intake at which consumption would pose no risk of adverse health effects (IOM, 1998).

The IOM considered differences in bioavailability between synthetic folic acid in fortified foods and naturally occurring dietary folate when expressing the DRIs as DFEs (IOM, 1998). The conversion of dietary folate

**TABLE 21.3** Folate dietary reference intakes ( $\mu\text{g}$  of DFE/day)

Group	Adequate intake	Recommended dietary allowance
<i>Infants</i>		
0–6 months	65	
6–11 months	80	
<i>Children and adolescents</i>		
1–3 years		150
4–8 years		200
9–13 years		300
14–18 years		400
<i>Adults</i>		
$\geq 19$ years		400
<i>Pregnant women</i>		
All ages		600
<i>Lactating women</i>		
All ages		500

intake to DFE is a method to convert all forms of dietary folate, including folic acid in fortified food, to an amount that is equivalent to naturally occurring food folate. DFEs are defined as micrograms of naturally occurring food folate plus 1.7 times the micrograms of synthetic folate. The use of the 1.7 multiplier for converting folic acid to DFE was based on the assumption that added folic acid (consumed with a meal as a supplement or fortificant) is ~85% available (Pfeiffer *et al.*, 1997) and food folate is ~50% available (Sauberlich *et al.*, 1987); thus the ratio 85/50 yielded the multiplier of 1.7 in the DFE calculation.

A UL was estimated (IOM, 1998) for folic acid (1000  $\mu\text{g}/\text{day}$ ); however, no UL was established for naturally occurring food folate. The UL for folic acid is primarily based on case reports describing vitamin B<sub>12</sub>-deficient patients whose anemia responded to folic acid alone, which is referred to as “masking” (IOM, 1998). In addition, the IOM committee considered evidence that excessive folic acid may precipitate or exacerbate neuropathy in vitamin B<sub>12</sub>-deficient patients (IOM, 1998). Unlike the case for other nutrients for which there is a UL; there are no substantiated toxic side-effects and no dose response associated with the reported masking on which the UL is based (IOM, 1998).

### **Folic Acid Intake Recommendation for Neural Tube Defect Risk Reduction**

The IOM recommendation for NTD risk reduction is not the same as the RDA, a common misconception, since the recommendation specifies that the supplemental form of the vitamin, folic acid (400  $\mu\text{g}/\text{day}$ ), be taken (or consumed as a fortified food) in addition to folate in a varied diet (IOM, 1998). This recommendation is consistent with that of the US Public Health Service (CDC, 1992).

### **Effect of Folic Acid Fortification on Folate Intake and Status in the United States and NTDs**

In the United States, total dietary folate intake includes food folate plus folic acid from enriched cereal grain products (140  $\mu\text{g}/100$  g flour) and fortified RTE cereals, including those with up to 400  $\mu\text{g}/\text{serving}$  (FDA, 1996). Estimates of dietary folate intake ( $\mu\text{g}/\text{day}$ ) can be determined and categorized as (1) naturally occurring food folate; (2) folic acid; (3) total folate as  $\mu\text{g}/\text{day}$ ; and (4) total folate as  $\mu\text{g}/\text{day}$  DFEs using the USDA Food and Nutrient Database for Dietary Studies (USDA, 2009). Total folate intake ( $\mu\text{g}/\text{day}$  DFEs) in the US has been estimated to be 813 for men and 724 for women (Bailey *et al.*, 2010).

Yang *et al.* (2010) estimated that usual median intake of folic acid differed across folic acid consumption groups for the non-pregnant adult US population aged  $\geq 19$  years from the National Health and Nutrition Examination Surveys (NHANES) 2003–2004 and 2005–2006 using the US Department of Agriculture (USDA) Food and Nutrient Databases for Dietary Studies (USDA, 2009). The usual median intakes ( $\mu\text{g}/\text{day}$ ) of folic acid for enriched cereal grain products (ECGP) only, ECGP plus ready-to-eat cereals (RTE), ECGP plus supplements (SUPP), and ECGP + RTE + SUPP were 138, 274, 479, and 635, respectively (Yang *et al.*, 2010).

During the first post-fortification survey period (1999–2000) median serum folate concentrations for the population increased by approximately three times compared with the pre-fortification period (1988–1994) (Pfeiffer *et al.*, 2007). A comprehensive evaluation of blood folate concentrations from 1988 to 2006 demonstrates that the median serum and RBC folate concentrations of the US population 4 years of age and older have increased significantly over the time period from 1988 to 2006 (McDowell *et al.*, 2008). The large increases that occurred between 1988–1994 and 1999–2000 were followed by small fluctuations from 1999 to 2006 (McDowell *et al.*, 2008).

Mandatory fortification of flour with folic acid has proven to be one of the most successful public-health interventions in preventing morbidity and mortality from NTDs. The reduction in birth prevalence rates of NTDs has been substantial in every country that has implemented mandatory fortification, with overall declines ranging from 19% to 55% (Berry *et al.*, 2009).

## Analytical Methods

Essentially all aspects of research related to folate nutrition are predicated on reliable measurement of the vitamin in biological specimens and diet components. The major approaches to the measurement of folate in biological specimens and foods or diet samples include microbiological growth procedures, protein–ligand binding methods, and chromatographic and mass-spectrometry methods as extensively reviewed by Pfeiffer *et al.* (2009).

The selection of the best method for folate analysis is dependent on the setting in which the assay will be used and the type of data needed. When one is monitoring trends in folate concentrations in a population over time, either the microbiological assay (low-resource settings) or ID-LC-MS/MS (specialized laboratories) are suitable tools; commercial assays are less suited because they will likely change over time (Pfeiffer *et al.*, 2009). In contrast, in the clinical setting, where assay accuracy and continuity are trumped by the need for throughput and low cost, commercial assays may be the answer. Finally, in the research setting, the various types of chromatographic assays would be best suited for the analysis of specific folate species (Pfeiffer *et al.*, 2009).

## Status Assessment

Folate status assessment in the research setting and in population surveys routinely includes blood folate concentrations and some indicators of metabolic function, as previously reviewed (IOM, 1998). Since hematological findings such as macrocytic anemia occur late in the development of a folate deficiency, the emphasis in status assessment studies is on changes that precede clinical indicators (IOM, 1998).

### Static Indicators

Serum folate concentrations are generally determined when folate status is assessed; however, changes may indicate a transient reduction in folate intake and not represent

body stores (IOM, 1998). Serum folate is considered to be a sensitive indicator of recent dietary folate intake and may require repeated measurements over time in the same individual to reflect long-term status (IOM, 1998). The criterion for serum folate concentration routinely used to define inadequate folate status is  $<7$  nmol/L ( $<3$  ng/mL) (IOM, 1998).

In contrast to serum folate concentration, red blood cell (RBC) folate concentration is considered an indicator of long-term status. Since folate is not taken up by the mature erythrocytes in circulation, RBC folate concentration represents folate taken up in the developing reticulocytes early in the  $\sim 120$ -day erythrocyte lifespan. RBC folate concentration is considered representative of tissue folate stores based on associations with liver folate concentration determined by biopsy (IOM, 1998). A cut-off value of  $<305$  nmol/L ( $<140$  ng/mL) is the criterion commonly used to define inadequate folate status (IOM, 1998).

### Functional Indices

In addition to blood folate concentrations, it is also considered important to evaluate folate status indices that may indicate changes in metabolic function. One such “functional” indicator is plasma total homocysteine concentration, which increases when there is a deficiency of 5-methylTHF, the folate form necessary to convert homocysteine to methionine. The inverse association between blood folate concentrations and plasma total homocysteine concentration is well established (IOM, 1998). Although plasma homocysteine concentration is considered a sensitive functional indicator, it is not specific for folate status since it may be influenced by a number of other nutrient deficiencies, genetic abnormalities, and renal insufficiency (IOM, 1998). Various cutoff values for elevated homocysteine have been reported to define normal folate status and most frequently have ranged from  $>10$  to  $>16$   $\mu\text{mol/L}$  (IOM, 1998).

Human studies in postmenopausal women have shown that global DNA methylation decreases as a function of dietary folate depletion (Jacob *et al.*, 1998; Rampersaud *et al.*, 2000). DNA methylation is dependent on an adequate supply of 5-methylTHF for the synthesis of SAM. However, like homocysteine, global DNA methylation is not specific to folate and can be modified by other nutritional and environmental factors.

Estimation of uracil misincorporation into DNA may also serve as a functional index of folate status (Blount *et al.*, 1997; Jacob *et al.*, 1998). Folate in the form of

5,10-methyleneTHF is required for the conversion of dUMP to dTMP, by thymidylate synthase (Figure 21.2, reaction 6). When this reaction is impaired due to poor folate status, deoxyuridylate may accumulate leading to deoxynucleotide pool imbalances and an increase in the dUMP:dTTP ratio. As a result, uracil, which is normally only present in RNA, may be incorporated into DNA in place of thymine, initiating an excision–repair cycle that may cause DNA strand breaks and chromosome damage (Blount *et al.*, 1997).

## Safety of Folic Acid

Safety concerns include the detection of folic acid versus the metabolically reduced form in circulation; the reported association between high folic acid intake and impaired cognitive function; and the potential for folic acid intake to promote the growth of established tumors. Unmetabolized folic acid will be found circulating in the blood if the capacity of dihydrofolate reductase is exceeded. The amount of folic acid as a bolus dose that may result in the appearance of folic acid in circulation has been reported to be  $>200\ \mu\text{g}$  (Sweeney *et al.*, 2007). Intakes exceeding this threshold are common in the United States since the average dose of folic acid in supplements is  $400\ \mu\text{g}$  which is taken in addition to folic acid consumed in enriched grain products and fortified breakfast cereals (Rock, 2007). The presence of unmetabolized folic acid has been detected in many groups evaluated, including older adults in the US (Bailey *et al.*, 2010) and newborn infants (Obeid *et al.*, 2010). High intakes of folic acid have been hypothesized to be associated with cognitive impairment among seniors (Morris *et al.*, 2010), although the findings might have been confounded by the presence of vitamin B<sub>12</sub> deficiency pernicious anemia and related neurological decline. As reviewed by Ciappio and Mason (2009), folate deficiency has been associated with an increased risk of cancer. Of concern, however, is the potential for folic acid to promote the growth of tumors that may already exist, and this is the focus of on-going research investigations (Ciappio and Mason, 2009). The potential for supplemental folic acid to increase cancer risk was evaluated in a recent meta-analysis involving  $>37,000$  individuals who participated in vitamin D intervention trials designed to assess cardiovascular disease endpoints (Clarke *et al.*, 2010). No increase in cancer risk was associated with supplemental folic acid intake in these large-scale intervention trials.

## Future Directions

There are still fundamental gaps in our knowledge of 1-C metabolism and its regulation. Much can still be learned about the interactions among mitochondrial, cytosolic, and nuclear 1-C metabolism and their role in gene expression and genome stability. In addition, the entire metabolic pathway for the folate-dependent conversion of serine to formate and glycine has yet to be established and is the focus of on-going and future research investigations. One-carbon metabolism can be disrupted by folate-related genetic polymorphisms with outcomes modulated by nutrient (e.g. folate, choline, betaine) status. Future studies in genetically engineered mice will be required to model and elucidate the gene–nutrient interactions and associated mechanisms that can alter 1-C metabolism and increase risk for folate-related pathologies.

It is well established that NTD risk is significantly reduced in response to increased folate intake. The biological mechanism by which the vitamin is protective is not, however, fully understood. It is recognized that folate is only one component of a complex metabolic pathway consisting of multiple metabolites, enzymes, and other micronutrients, thus presenting a major challenge to research scientists. New technologies and strategies for investigating biomarkers, genetic variants, and epigenetic phenomena will be essential to further understand the complex relationship between folate and NTDs as well as other birth defects that may be folate responsive.

Reports of the presence of circulating “oxidized unreduced” folic acid will likely increase as the amount and number of sources of this synthetic form of the vitamin increase. Future research studies are warranted to investigate potential physiological consequences of “unmetabolized” folic acid.

The complexity of the relationship between folate intake, cancer, and vascular diseases presents future research challenges. Definitive data from controlled intervention trials are often difficult to interpret for healthy population groups since the studies have been conducted in patients with established histories of disease. Since primary prevention trials are unlikely to be conducted, other means to address this question would need to be considered. With the advent of network analyses from genome-wide association studies, the most important biological pathways in the etiology of cardiovascular disease and cancer can be investigated to determine whether these pathways are folate responsive.

Many additional polymorphisms in genes associated with folate metabolism are yet to be identified. Genome-wide technologies will facilitate conduction of numerous association studies to evaluate the impact of genetic variation on human health in a variety of populations across the globe.

### Suggestions for Further Reading

Folate's role in health and disease with accompanying metabolic background is the highlight of a recently published book with more than 50 experts in the folate field as contributing authors (Bailey, 2009). Present knowledge of compartmentalization of folate-mediated 1-C metabolic pathways has been detailed in a comprehensive review (Tibbetts and Appling, 2010).

The basis of our current DRIs for folate was written by scientific experts in the folate field, and their report (IOM, 1998) provides a fundamental overview of the derivation of intake recommendations including the folic acid intake recommendation for NTD risk reduction (IOM, 1998).

## VITAMIN B<sub>12</sub>

SALLY P. STABLER, MD

*University of Colorado School of Medicine, Denver, Colorado, USA*

### Summary

Vitamin B<sub>12</sub> (cobalamin) is a cobalt-containing corrin ring cofactor required for two enzymes in higher animals, methionine synthase and L-methylmalonyl-CoA mutase. It is a product of microbial synthesis, and therefore elaborate mechanisms of uptake and transport have evolved to insure availability of this rare nutrient in higher animals. Vitamin B<sub>12</sub> ingested in the diet binds to intrinsic factor and is internalized in the distal small intestine by the cubam receptor. It is delivered to all the cells in the body by transcobalamin, a binding protein. Human B<sub>12</sub> deficiency is caused by lack of animal source food, or lack of intrinsic factor due to the autoimmune disease, pernicious anemia, and other malabsorption syndromes. Human deficiency causes megaloblastic anemia and/or demyelinating neurologic syndromes. A deficiency of vitamin B<sub>12</sub> causes a build-up of methylmalonic acid and homocysteine which can be assayed for diagnostic purposes. Treatment with parenteral or high-dose oral vitamin B<sub>12</sub> is effective in malabsorption syndromes and will completely correct megaloblastic anemia. Neurologic abnormalities due to B<sub>12</sub> deficiency may only partially correct, especially in infants. The development of inexpensive B<sub>12</sub>-containing foods acceptable to populations unwilling to eat or unable to afford animal source foods would be of benefit because of the high prevalence of B<sub>12</sub> deficiency worldwide.

### Introduction

Vitamin B<sub>12</sub> (cobalamin, Cbl) holds a unique position in the science of human nutrition since there is a specific disease (pernicious anemia) which results in the isolated malabsorption of vitamin B<sub>12</sub>, and was ultimately fatal prior to the development of vitamin therapy. This unique syndrome of megaloblastic anemia and demyelinating lesions of the central nervous system was recognized and described by Thomas Addison as early as 1855 (Castle,

1975). Pernicious anemia has such specific manifestations and such a dramatic response to the replacement of vitamin B<sub>12</sub> that a patient response could actually be used as a bioassay. In 1926 Minot and Murphy showed that a diet containing large amounts of liver would stimulate red blood cell production in patients with pernicious anemia (Minot and Murphy, 1926). Their early work eventually culminated in the purification of vitamin B<sub>12</sub> from liver by Folkers at Merck, Sharp & Dohme in 1948, and Smith and Parker at Glaxo in the same year (Folkers, 1982).

During the next 50 years the structure, X-ray crystallography, synthesis of coenzyme forms, and chemistry and biochemistry of the cobamides have been elucidated (Hogenkamp, 1999). Much of what we know about the role of vitamin B<sub>12</sub> in metabolism and the pathophysiology of the deficient state has been determined by studying patients with pernicious anemia since this accident of nature results in a very selective model of a deficiency disease not complicated by protein-calorie malnutrition or multiple vitamin and mineral deficiencies.

### Structure of Vitamin B<sub>12</sub>

The structure of vitamin B<sub>12</sub> (OH-Cbl) is shown in Figure 22.1. It is a very complex molecule containing a corrin ring (which coordinates a cobalt molecule), 5,6-dimethylbenzimidazole, a sugar, and an aminopropanol group. An upper axial ligand is coordinated to the cobalt and can be hydroxy, cyano, glutathione or the coenzyme forms, methyl (CH<sub>3</sub>) and adenosyl (Banerjee and Ragsdale, 2003). The chemistry of the carbon-cobalt bond found in the coenzyme forms is unique and has been studied extensively (Ludwig and Matthews, 1997; Randaccio *et al.*, 2010). Only microorganisms retain the ability to synthesize cobalamins, and microbial synthesis

FIG. 22.1 The structure of OH-cobalamin.

pathways have been elucidated in a series of elegant studies (Martens *et al.*, 2002). Plants do not use Cbl, therefore the source of Cbl in all higher animals is the product of microbial synthesis. Analogues of Cbl with bases other than 5,6-dimethylbenzimidazole are widely found in nature including in the human intestinal tract (Allen and Stabler, 2008), but do not support coenzyme activity in higher animals, though they are utilized by various microorganisms.

### Vitamin B<sub>12</sub>-Dependent Enzyme Reactions

Microorganisms use different forms of Cbl in many reactions, including methionine synthesis, carbon skeleton mutation, elimination reactions, aminomutations, and acetate and methane synthesis (Randaccio *et al.*, 2010). Higher animals require Cbl as a cofactor for only two enzymes, L-methylmalonyl-CoA mutase and methionine synthase (Banerjee and Ragsdale, 2003). The binding of the coenzyme forms to these two enzymes has been studied by X-ray crystallography (Drennan *et al.*, 1994; Mancía *et al.*, 1996; Randaccio *et al.*, 2010). It appears that the dimethylbenzimidazole is displaced from the cobalt and a histidine residue from the enzyme coordinates at that position. Although both of these enzymes use vitamin B<sub>12</sub>, they perform very different types of chemical reaction. During methionine synthesis and other methyltransfer reactions, the methyl-cobalt bond undergoes heterolytic cleavage, whereas the mutase performs a homolytic cleavage of adenosyl-Cbl which results in the formation of a radical. Methionine synthase must be reactivated since the cobalamin cofactor is occasionally oxidized (every 2000 cycles) (Koutmos *et al.*, 2009). A recent review describes structural-functional relationships of the cobalt-carbon bonds in the coenzymes and the role that bond cleavage plays in the specific reactions (Randaccio *et al.*, 2010).

#### L-Methylmalonyl CoA Mutase

The pathway of propionyl-CoA metabolism is shown in Figure 22.2. The metabolism of various amino acids such as valine, isoleucine, and odd-chain fatty acids results in the formation of propionyl-CoA which is carboxylated to form D-methylmalonyl-CoA. A racemase interconverts the two isomers, and L-methylmalonyl-CoA is a substrate for the adenosyl-Cbl-dependent enzyme L-methylmalonyl-CoA mutase (Fenton *et al.*, 2001). D-Methylmalonyl-CoA

FIG. 22.2 The pathways of propionyl-CoA and methylmalonyl-CoA.

can be hydrolyzed to methylmalonic acid (MMA). The mutase is a mitochondrial matrix enzyme. It has been purified from humans (Kolhouse *et al.*, 1980) and other sources and the genes have been cloned and sequenced also from human (Jansen *et al.*, 1989) and bacterial sources. The enzyme is a homodimer which binds 2 mol of adenosyl-Cbl per dimer. During the last decade the reaction mechanisms have been intensively studied (Randaccio *et al.*, 2010).

The mutase is not completely saturated with adenosyl-Cbl *in vivo* (Kondo *et al.*, 1981). OH-Cbl infusions in rats over 14 days increased holo-L-methylmalonyl-CoA mutase activity and decreased the serum MMA (Stabler *et al.*, 1991c). High-dose oral vitamin B<sub>12</sub> lowered mean MMA concentrations in normal subjects who had baseline concentrations > 240 nmol/L (Rasmussen *et al.*, 1996).

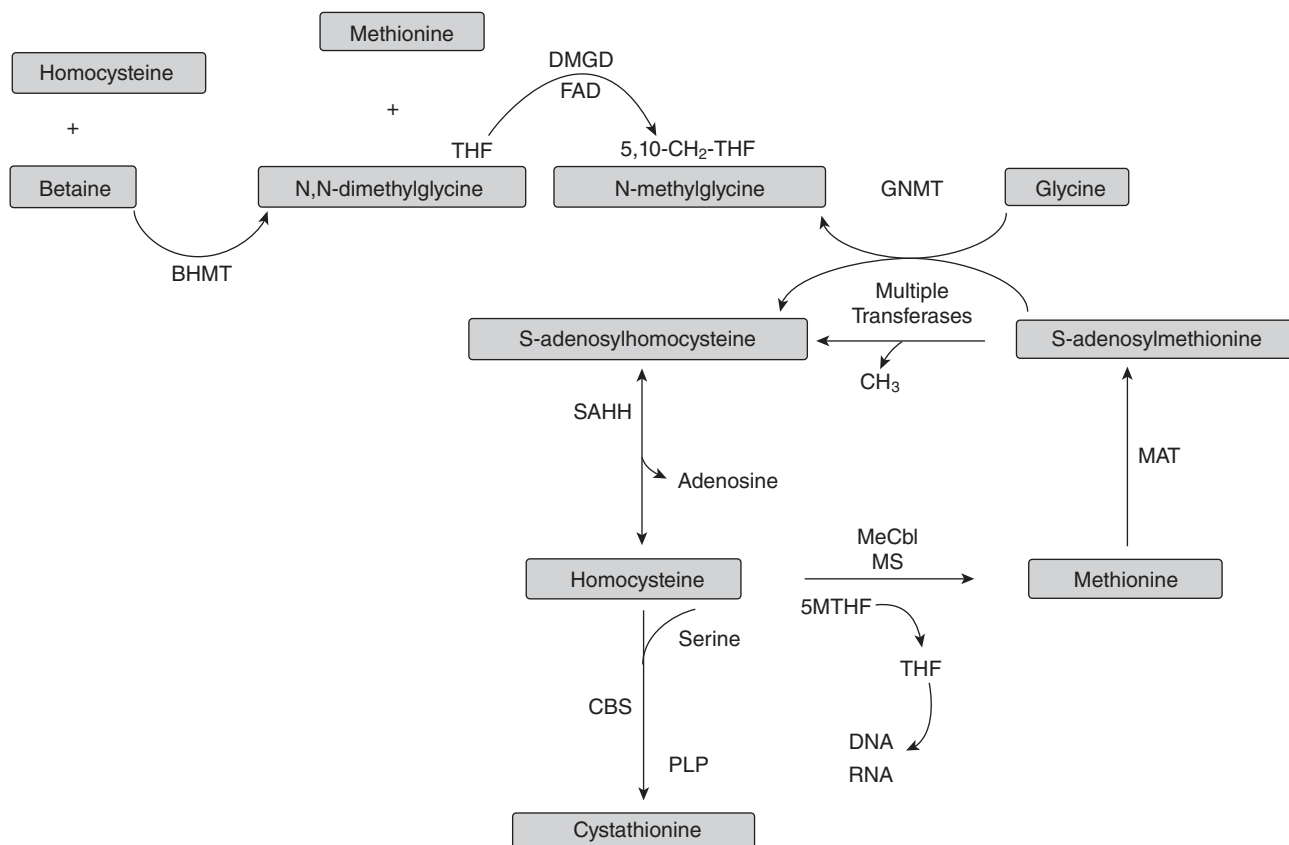

This pathway is an important source of energy in ruminants since the bacterial fermentation in the rumen produces large quantities of propionic acid. However, this pathway is also important in humans since congenital defects of the mutase or of the ability to synthesize adenosyl-Cbl result in life-threatening methylmalonicaciduria which is complicated by severe metabolic ketoacidosis (Fenton *et al.*, 2001). Serum, urine or CSF MMA concen-

trations are always increased in conditions of B<sub>12</sub> deficiency (Cox and White, 1962; Lindenbaum *et al.*, 1990; Savage *et al.*, 1994b), human or animal nitrous-oxide-induced cobalamin inactivation (Stabler *et al.*, 1991b,c), experimental animal deficiency (Stabler *et al.*, 1991c), ruminants with cobalt deficiency (Rice *et al.*, 1989), and tissue culture cells (Kolhouse *et al.*, 1993).

## Methionine Synthase

The pathway of methionine metabolism is shown in Figure 22.3 (Allen *et al.*, 1993a). Methionine is an essential amino acid which is necessary for protein synthesis but also is a crucial methyl donor after activation to S-adenosylmethionine (SAM). SAM is a source of methyl groups for the synthesis of creatine and phospholipids (quantitatively the most important together) and also for synthesis of neurotransmitters, DNA, RNA, and protein methylation (Mudd *et al.*, 2007). After donating the methyl group, S-adenosylhomocysteine (SAH) is formed which is cleaved to homocysteine and adenosine by SAH-hydrolase. The homocysteine that is generated can either be remethylated to form methionine or condensed with serine to form cystathionine by a vitamin B<sub>6</sub>-dependent

**FIG. 22.3** The pathways of methionine metabolism.

enzyme, cystathionine beta-synthase. Cystathionine is further metabolized to cysteine and alpha-ketobutyrate by another vitamin B<sub>6</sub>-dependent enzyme, gamma-cystathionase (Mudd *et al.*, 2007).

Methionine can be synthesized by two different enzymes, Cbl-dependent methionine synthase and betaine-homocysteine methyltransferase (Erickson, 1960; Matthews *et al.*, 2008). Methionine synthase transfers a methyl group from 5-methyltetrahydrofolate to homocysteine. The methyl-Cbl bound to the methionine synthase is demethylated in the reaction with the homocysteine and then remethylated by the reaction with 5-methyltetrahydrofolate. SAM is also required because occasionally the active Cbl form, cob(1)alamin is oxidized and must be reduced by obtaining a methyl group from SAM (Koutmos *et al.*, 2009). Recent investigations show that there is also a human methionine synthase reductase which is a flavoprotein (Leclerc *et al.*, 1998). Methionine synthase is a cytoplasmic enzyme. It contains 1 mol of Cbl

per mol of protein. Mechanisms of methionine synthase have been studied extensively (Matthews *et al.*, 2008).

It is readily appreciated from Figure 22.3 that the balance of methionine metabolism is dependent on three vitamins, vitamin B<sub>12</sub>, folate, and vitamin B<sub>6</sub>. Congenital defects of the methionine synthase, methionine synthase reductase or the synthesis of methyl-Cbl have been described and they cause severe hyperhomocysteinemia (Rosenblatt and Fenton, 2001). Deficiencies of either vitamin B<sub>12</sub> or folic acid also result in hyperhomocysteinemia (Stabler *et al.*, 1988; Savage *et al.*, 1994a). Elevations of serum total homocysteine (tHcy) are associated with accelerated vascular disease and thrombosis. The field of congenital and acquired defects has therefore generated much interest (Fowler, 2005).

Homocysteine is at a branch point between the remethylation to methionine or the reaction to form cystathionine which is termed transsulfuration. Transsulfuration is not reversible and eventually results in removal of the sulfhy-

dral group. Cystathionine beta-synthase is activated by SAM; thus, in conditions of high methionine intake, transsulfuration is stimulated and homocysteine is removed (Finkelstein, 1990). The concentrations of SAM are regulated by the methylation of glycine by glycine N-methyltransferase, an enzyme that is found in a high concentration in the liver (Cook and Wagner, 1984). This reaction is inhibited by 5-methyltetrahydrofolate, a form of folate which may build up in B<sub>12</sub> deficiency because methionine synthase activity is impaired.

Another area of interest is in the regulation of the concentrations of cystathionine since both vitamin B<sub>12</sub> and folate deficiency cause marked rises in serum cystathionine, despite the fact that there is experimental evidence and theoretical reasons to believe that the deficiency of SAM in these conditions should result in a decrease in transsulfuration and the formation of cystathionine (Stabler *et al.*, 1993).

## Metabolic Abnormalities in Vitamin B<sub>12</sub> Deficiency

Box 22.1 shows the metabolites, MMA, homocysteine, S-adenosylhomocysteine, cystathionine, 2-methylcitric acid, and N,N-dimethylglycine, that are found in elevated concentrations in body fluids (serum, urine, cerebrospinal fluid) and tissues in both humans with pernicious anemia and in other forms of vitamin B<sub>12</sub> deficiency as well as in experimental models of vitamin B<sub>12</sub> deficiency. Cox and White in 1962 demonstrated that 95% of symptomatic vitamin B<sub>12</sub>-deficient humans had elevated concentrations of urine MMA which responded to therapy. Their work has been repeatedly confirmed and it is now well accepted that virtually every patient who has clinical abnormalities that will respond to vitamin B<sub>12</sub> replacement has elevated MMA (Stabler *et al.*, 1986, 1990; Moelby *et al.*, 1990; Savage *et al.*, 1994a). Elevations of MMA are highly specific to Cbl metabolism with the exception of modest elevations seen in chronic renal insufficiency (Rasmussen *et al.*, 1990; Allen *et al.*, 1993b). Thus, monitoring MMA is extremely useful in diagnosis, for studying responses to treatment, and in documenting vitamin B<sub>12</sub> deficiency in animal or cellular models.

Figure 22.2 showed that propionyl-CoA can be condensed with oxaloacetic acid to form 2-methylcitric acid. Elevated concentrations of 2-methylcitric acid are found in patients with inborn errors of mutase and in severely affected vitamin B<sub>12</sub>-deficient subjects (Allen *et al.*, 1993a).

### BOX 22.1 Laboratory abnormalities in vitamin B<sub>12</sub> deficiency

#### Metabolites

- High methylmalonic acid
- High total homocysteine
- High cystathionine
- High 2-methylcitric acid
- High N,N-dimethylglycine
- High S-adenosylhomocysteine

#### Megaloblastic anemia

##### Peripheral blood

- Low red blood cell count
- Low hemoglobin and hematocrit
- Low white blood cell count
- Low platelet count
- High mean cell volume
- High red cell distribution width
- Hypersegmented granulocytes

##### Bone marrow

- Hypercellularity
- Nuclear-cytoplasmic dys-synchrony
- Open immature nuclear chromatin pattern
- Giant metamyelocytes and bands
- Intramedullary cell death

#### Blood chemistry

- Increased unconjugated bilirubin
- Increased lactate dehydrogenase
- Decreased haptoglobin

Total homocysteine is frequently elevated in the serum in humans with pernicious anemia (Stabler *et al.*, 1988; Savage, 1994a) and other forms of vitamin B<sub>12</sub> deficiency as well as animal models of vitamin B<sub>12</sub> deficiency (Stabler *et al.*, 1991a). Elevated homocysteine is not specific to vitamin B<sub>12</sub> deficiency, in contrast to MMA, but is found in folate deficiency, and in defects of cystathionine beta-synthase, methionine adenosyltransferase, 5,10-methylenetetrahydrofolate reductase, and methionine synthase, and in the methyl-Cbl reductive pathway (Fowler, 2005). Homocysteine concentration is highly correlated with the serum creatinine, at least partly because of the role of SAM in the formation of creatine, the precursor of creatinine (Soria *et al.*, 1990). The mean homocysteine value of a population is highly dependent on the dietary and supplement intake of folate and vitamin B<sub>12</sub>. These additional influences make elevated tHcy less specific as a diagnostic tool for vitamin B<sub>12</sub> deficiency. However, it has been shown

**FIG. 22.4** Serum methylmalonic acid and total homocysteine concentrations in 491 episodes of B<sub>12</sub> deficiency. Closed circles represent patients with hematocrit <38% and open circles ≥38%. Patient values are collated from the following references: Lindenbaum *et al.*, 1988, 1990, 1994; Stabler *et al.*, 1988, 1990, 1997, 1999; Pennypacker *et al.*, 1992; Savage *et al.*, 1994a,b; Kuzminski *et al.*, 1998; Sekhar and Stabler, 2007; Guerra-Shinohara *et al.*, 2007. The hatched lines represent three standard deviations above the mean for normal controls, MMA, 376 nmol/L and total homocysteine, 21.3 μmol/L.

that elevated homocysteine due to vitamin B<sub>12</sub> deficiency will not correct with folic acid treatment (Allen *et al.*, 1990).

The serum cystathionine concentration is elevated in most subjects with severe vitamin B<sub>12</sub> deficiency (Stabler *et al.*, 1993). Like the total homocysteine, it is not specific to vitamin B<sub>12</sub> deficiency since folate deficiency and especially vitamin B<sub>6</sub> deficiency also cause elevated concentrations.

Both the serum MMA and homocysteine concentrations can reach extremely high levels in symptomatic vitamin B<sub>12</sub> deficiency, as shown in Figure 22.4. Only three out of 313 episodes of well documented vitamin B<sub>12</sub>-deficient megaloblastic anemia had normal concentrations of both metabolites (Savage *et al.*, 1994a). The MMA and

homocysteine were elevated in 121 subjects who had neurologic syndromes without anemia in the same report, and, as can be seen in Figure 22.4, patients with normal hematocrit are found at all levels of metabolites.

There are alterations in the total coenzyme-A pools and in carnitine metabolism as a result of the build-up of methylmalonyl-CoA in animal models of vitamin B<sub>12</sub> deficiency (Brass *et al.*, 1990a,b). The increase in propionyl-CoA appears to lead to increased formation of branched-chain and odd-chain fatty acids in both inborn errors of the mutase and severe vitamin B<sub>12</sub> deficiency (Frenkel, 1973; Coker *et al.*, 1996).

Figure 22.3 demonstrates that there are interactions between vitamin B<sub>12</sub> and folate metabolism. The irreversible reaction forming 5-methyltetrahydrofolate results in a

metabolically inactive form of folate unless it is demethylated by methionine synthase. 5-Methyltetrahydrofolate is a poor substrate for folyl polyglutamate synthase and thus is not retained intracellularly and can be lost in the urine (Cichowicz and Shane, 1987). Thus there is “trapping” of folate as 5-methyltetrahydrofolate in severe vitamin B<sub>12</sub> deficiency and this may result in secondary folate deficiency (Savage and Lindenbaum, 1995; Smulders *et al.*, 2006). N-Methylglycine is elevated in folate-deficient but not B<sub>12</sub>-deficient patients, suggesting that “trapped” methylfolate may be bound to and inhibiting glycine N-methyltransferase (Allen *et al.*, 1993a) further sparing SAM but not SAH concentrations in B<sub>12</sub> deficiency (Guerra-Shinohara *et al.*, 2007). Since other forms of folate are necessary for thymidine and purine synthesis, there are resulting impairments in DNA synthesis likely causing megaloblastosis (see the section of megaloblastic anemia). There are also abnormalities in one-carbon metabolism in vitamin B<sub>12</sub> deficiency, probably due to the secondary folate deficiency (Deacon *et al.*, 1990).

## Clinical Manifestations

The clinical manifestations of vitamin B<sub>12</sub> deficiency have been best studied in the human with pernicious anemia. Although there are spontaneously occurring animal models of vitamin B<sub>12</sub> deficiency such as ruminants pastured on cobalt-deficient soil (Rice *et al.*, 1989) and dogs (Fyfe *et al.*, 1989) with selective malabsorption of vitamin B<sub>12</sub>, these animals do not display similar syndromes. In one investigation, Cbl analogue treatment of mini-pigs caused spinal lesions and mild anemia and leucopenia, although the rise in mean red cell volume and morphologic changes in the bone marrow were very subtle as compared with what would be expected in a human (Stabler *et al.*, 1991c). The lack of convenient animal models has certainly been a detriment to the study of the pathophysiology of vitamin B<sub>12</sub>.

### Megaloblastic Anemia

In humans, vitamin B<sub>12</sub> and folate deficiency cause identical forms of megaloblastic anemia (Koury and Ponka, 2004; Wickramasinghe, 2006). Thus, the secondary block in folate metabolism in vitamin B<sub>12</sub> deficiency must be the underlying cause. This constellation of morphologic changes and clinical and laboratory abnormalities is due to an imbalance of decreased DNA synthesis with adequate RNA synthesis. Impaired methylation due to an

increase in SAH, which inhibits methyltransferases, may also be important (Guerra-Shinohara *et al.*, 2007). The nuclei of the developing hematopoietic precursor cells in the bone marrow remain immature as compared with the cytoplasm. The morphologic result is a macrocytic red blood cell precursor (high mean cell volume), with an open chromatin pattern. The white blood cells are enlarged with hypersegmentation of granulocyte nuclei. Many cells die in the bone marrow (ineffective erythropoiesis), possibly by apoptosis which leads to the cellular release of bilirubin and lactate dehydrogenase. The megaloblastic nuclei demonstrate decreased DNA synthesis, increased precursors in S phase, misincorporation of uracil into DNA, little evidence for decreased DNA methylation, chromosomal breakage and rescue by both purines and thymidine (Koury and Ponka, 2004). The cellular bone marrow packed with very immature-appearing erythroblasts has led to the mistaken diagnosis of acute leukemia. The fragmentation of the red blood cells may also lead to erroneous diagnoses such as hemolysis, or thrombotic microangiopathies (Sekhar and Stabler, 2007). Megaloblastic anemia can be completely cured with vitamin B<sub>12</sub> treatment, and can be partially corrected with folate treatment which leads to diagnostic errors, as has been thoroughly reviewed by Savage and Lindenbaum (1995). Ultimately, many of such incorrectly treated patients succumbed to relapse of anemia and/or neurologic disease.

The megaloblastic anemia outlined above is the classic picture of severe vitamin B<sub>12</sub>-deficient anemia. More recently it has been noted that there are many patients who have only mild abnormalities of blood cells and bone marrow but who may have severe abnormalities of the nervous system (Lindenbaum *et al.*, 1988). Figure 22.4 demonstrates that many of the patients with normal or near-normal hematocrit (open circles) had profound elevation of MMA and/or homocysteine. The reason an individual is susceptible to megaloblastic anemia vs. neurologic abnormalities is unknown. The use of MMA and homocysteine as screening tests has also led to the realization that there is a significant fraction of individuals with biochemically severe vitamin B<sub>12</sub> deficiency who appear to have no signs of megaloblastic anemia, or neurologic abnormalities.

### Neurologic Abnormalities

Vitamin B<sub>12</sub> deficiency, whether naturally occurring or induced by nitrous oxide (which inactivates methionine

synthase), leads to a demyelinating disorder of the central nervous system in humans (Healton *et al.*, 1991; Stabler *et al.*, 1991a; Singer *et al.*, 2008), non-human primates (Scott *et al.*, 1981), fruit bats (Metz, 1992), and swine (Weir *et al.*, 1988; Stabler *et al.*, 1991c), but no other animal species. This lesion was described long before the underlying vitamin B<sub>12</sub> dependence was recognized. It has been termed “subacute combined degeneration” or “combined systems disease.” The pathology includes swelling of myelin sheaths and patchy vacuolation of myelin with spongy degeneration of the spinal cord, starting in the thoracic and cervical dorsal columns and progressing to the lateral columns. Lesions are also seen in the brain and optic nerves and possibly peripheral nerves (Stabler, 2006). Signs and symptoms vary considerably. The most common symptom seen in a large review of well-documented cases was painful paresthesia of the extremities (Healton *et al.*, 1991). The most common sign was loss of proprioception and vibration sense in the toes or ankles. One of the most intriguing discoveries has been the strong inverse relationship between the severity of the hematologic and neurologic abnormalities (Healton *et al.*, 1991; Savage *et al.*, 1994a). Only about one-third of patients with pernicious anemia will develop the neurologic abnormalities, and 25% of these will have almost completely normal hematologic parameters, which has caused great difficulty in diagnosis in the past (Lindenbaum *et al.*, 1988). Serum MMA and homocysteine and all of the other metabolic changes are similar in the subjects with involvement of the nervous system as compared with those with just hematologic involvement (Allen *et al.*, 1993c). Vitamin B<sub>12</sub> treatment will partially or completely correct the lesions if begun promptly (Healton *et al.*, 1991).

The underlying biochemical abnormalities leading to demyelination of the central nervous system are not understood. There is intriguing negative data from observation of individuals with methylmalonic aciduria due to mutase defects who do not develop the demyelinating disease of the spinal cord seen in vitamin B<sub>12</sub> deficiency (Fenton *et al.*, 2001). Likewise patients with severe folate deficiency and elevations of homocysteine similar to the levels seen in vitamin B<sub>12</sub> deficiency do not develop myelopathy (Savage and Lindenbaum, 1995). However, the combined defects (cbl-C, D, F) do cause central nervous system disease very similar to that seen with B<sub>12</sub> deficiency. It appears that the activity of both cobalamin-dependent enzymes need to be impaired in order to cause the demyelinating disease, although defects of methionine synthase

might be an exception (Rosenblatt and Fenton, 2001). There is also no explanation for why most animal species are resistant to the development of spinal cord defects. A gastrectomized rat model has shown abnormalities of cytokines and growth factors (Scalabrino and Peracchi, 2006), in the nervous system. Similar changes were found in humans with B<sub>12</sub> deficiency (Scalabrino *et al.*, 2004). Magnetic resonance imaging techniques of the brain and spinal column demonstrate the areas of demyelination and surprisingly often show improvement long before signs and symptoms abate (Singer *et al.*, 2008). Functional studies have shown brain choline depletion, especially in infants (Horstmann *et al.*, 2003; Dror and Allen, 2008).

### **Clinical Spectrum of Vitamin B<sub>12</sub> Deficiency**

Vitamin B<sub>12</sub> deficiency has a very wide spectrum of severity and manifestations (Stabler, 2006). In addition to anemia and/or neurologic disease, some subjects may have additional symptoms such as glossitis of the tongue, megaloblastic gut, weight loss, mental changes, and even infertility. The clinical spectrum in infants is also markedly different from that in adults (Whitehead, 2006; Dror and Allen, 2008), with failure to thrive, irritability, movement disorders, and poor brain growth leading to permanent developmental delay in some cases (Graham *et al.*, 1992).

### **Causes of Vitamin B<sub>12</sub> Deficiency**

All animals require vitamin B<sub>12</sub> and obtain it ultimately from the products of microbial synthesis. Ruminant animals actually carry bacteria that synthesize cobalamins in their rumen (Girard *et al.*, 2009). Humans obtain vitamin B<sub>12</sub> from products of animal origin including meats, fish, shellfish, dairy products, and eggs (Watanabe, 2007). Improved methods of corrinoid analysis have shown that fermented vegetable foods, some algae and other plant products may contain B<sub>12</sub> (Watanabe, 2007). Synthetic vitamin B<sub>12</sub> has been added to cereal and other supplemented foods in the western world.

### **Absorption and Intracellular Metabolism of Vitamin B<sub>12</sub>**

Vitamin B<sub>12</sub> is generally bound to one of the two enzymes or other carrier proteins in food. It must therefore be released prior to absorption. This process starts when food is chewed and mixed with saliva, which contains a Cbl binding protein, haptocorrin (R-protein). The bound Cbl is further released in the acid environment of the stomach

where peptic digestion of proteins begins. The released vitamin B<sub>12</sub> is bound to haptocorrin and carried to the duodenum. The specific Cbl binding protein intrinsic factor (IF) is released by the gastric parietal cells, but does not bind Cbl until stomach acid is neutralized in the duodenum, and digestive enzymes remove the haptocorrin from the vitamin (reviewed by Quadros, 2010). The binding of IF is very specific for Cbl and thus may prevent the binding and absorption of Cbl analogues also found in foods. The IF-Cbl is carried to the ileum where it is taken up by the cubam receptor (formed from cubulin and amnionless, a transmembrane protein [Fyfe *et al.*, 2004; Andersen *et al.*, 2010]). The IF-Cbl then goes to the lysosomes and is eventually released bound to transcobalamin. Inborn errors of IF, cubulin or amnionless cause juvenile megaloblastic anemia and Imerslund–Grasbeck syndrome (Tanner *et al.*, 2004, 2005). The Cbl F defect has now been shown to be a defective lysosomal membrane transporter (Rutsch *et al.*, 2011).

It is not known exactly how the absorbed Cbl is then processed so that a complex of transcobalamin-Cbl (TC-Cbl) is secreted into the portal blood and thus delivered to the liver and ultimately all tissues. TC is the primary serum transport protein for vitamin B<sub>12</sub>. The TC-Cbl is taken up by receptor-mediated endocytosis by the recently purified TCblR (Quadros, 2010) and fused to lysosomes in which the Cbl is released. Recent evidence suggests that Cbl export from cells may be mediated by the ATP-binding cassette drug transporter, ABCC1 (Beedholm-Ebssen *et al.*, 2010). Cobalamin in the circulation is bound to haptocorrin (R-binder, TCI and III), 70–90%, and transcobalamin, 10–30%. The function of haptocorrin is unclear but could be protective since it also binds corrinoids other than cobalamin and can deliver them to the liver (Alpers, 2005). Defects of TC cause a severe megaloblastic anemia, elevations of MMA and homocysteine, neurologic disease, and immune deficiency in the first few months of life (Whitehead, 2006). Deficient haptocorrin appears to be relatively common and a cause of the “false positive” low serum B<sub>12</sub> level.

After the Cbl is released from the lysosomes, the coenzyme forms must be synthesized. A number of defects of intracellular Cbl metabolism have been described which form eight complementation groups with three generally similar clinical syndromes (Whitehead, 2006). If there is a defect in methionine synthase or in regenerating CH<sub>3</sub>-Cbl (MS, cblE, cblG), the patients have only hyperhomocysteinemia. Other complementation groups have defects

in L-methylmalonal-CoA mutase or in the formation of adenosyl-Cbl (mut<sup>o</sup>, mut<sup>r</sup>, cblA, cblB) and these patients have only methylmalonicacidemia. However, there are also patients who have difficulty with the lysosomal release of Cbl (cblF), described above, or with a reduction step common to the synthesis of both coenzymes (cblC, cblD) who have combined hyperhomocysteinemia and methylmalonicaciduria (Lerner-Ellis *et al.*, 2009). Recently cblD has been shown to be associated also with isolated hyperhomocysteinemia or methylmalonicacidemia (Miousse *et al.*, 2009).

### Acquired Vitamin B<sub>12</sub> Deficiency

The major causes of acquired vitamin B<sub>12</sub> deficiency are shown in Box 22.2. By far the most common causes of vitamin B<sub>12</sub> deficiency relate to acquired malabsorption.

Dietary deficiency of vitamin B<sub>12</sub> develops if foods of animal origin are not consumed (Stabler and Allen, 2004;

#### BOX 22.2 Causes of vitamin B<sub>12</sub> deficiency

##### Animals

- Cobalt-deficient soil – ruminants only
- Congenital ileal malabsorption – dogs and cats

##### Human

###### Dietary

- Lack of foods of animal origin
- Vitamin B<sub>12</sub>-deficient breast milk

###### Malabsorption

- Pernicious anemia
- Protein-bound B<sub>12</sub> malabsorption
- Pancreatic insufficiency
- Jejunal bacterial overgrowth
- Fish tapeworm
- Tropical sprue
- Total or partial gastric resection or bypass
- Ileal disease or resection
- Ileal–urinary conduit

###### Drugs

- Nitrous oxide
- Metformin
- Stomach acid blockers

###### Congenital

- Intrinsic factor defect
- Transcobalamin defect
- Imerslund–Gräsbeck syndrome
- CblA–CblG defects

Gilting *et al.*, 2010). The bioavailability of vitamin B<sub>12</sub> may vary between foods. Many meat-substitute foods in the United States are supplemented with vitamin B<sub>12</sub>, thus deficiency is rare if such products are consumed. Exclusively breast-fed infants of mothers with untreated pernicious anemia or a vegetarian diet are at risk for deficiency since the breast milk may be deficient in vitamin B<sub>12</sub> at a time when a mother is asymptomatic (Dror and Allen, 2008).

The autoimmune disease pernicious anemia is the most common cause of severe malabsorption of vitamin B<sub>12</sub> (Stabler, 2006). Chronic autoimmune atrophic gastritis (Type A atrophic gastritis) develops with antibodies to gastric parietal cells and in 50% of the individuals also to IF (Toh *et al.*, 1997; Lahner and Annibale, 2009). The gastric parietal cell H<sup>+</sup>/K<sup>+</sup>-ATPase has been shown to be the antigen against which parietal-cell antibodies are directed. There is a complete loss of IF so vitamin B<sub>12</sub> malabsorption ensues. The disease is found in all races and ethnic groups throughout the world (Savage *et al.*, 1994a,b; Chui *et al.*, 2001; Stabler and Allen, 2004) and the prevalence increases with age and female sex (Stabler, 2006). Though rare, pernicious anemia occurs even in young people, and those of African origin may be at higher risk for young onset (Carmel, 1992). One study found that the prevalence in persons over age 65 years was 1.9% (Carmel, 1996). In pernicious anemia there is impaired enterohepatic circulation of Cbl since the Cbl secreted in the bile cannot be bound to IF and is lost in the stool leading to more rapid depletion of Cbl when treatment is discontinued (Lindenbaum *et al.*, 1990).

Surgical manipulations of the gastrointestinal tract including total and partial gastrectomy, gastric bypass operations, ileal resections or ileal urinary conduit constructions frequently lead to vitamin B<sub>12</sub> malabsorption (Sumner *et al.*, 1996; Lahner and Annibale, 2009). Parasitic infection with the fish tapeworm and jejunal bacterial overgrowth, chronic inflammatory diseases of the ileum such as Crohn's disease and tropical sprue or resection have been shown to cause vitamin B<sub>12</sub> deficiency. *Helicobacter pylori* may be a cause of atrophic gastritis also (Lahner and Annibale, 2009).

Up to 15% of elderly subjects are found to have mild to moderate vitamin B<sub>12</sub> deficiency documented by elevated MMA and homocysteine concentrations and decreased serum Cbl levels (Pennypacker *et al.*, 1992; Lindenbaum *et al.*, 1994; Johnson *et al.*, 2010). Only a minority of the subjects discovered in screening studies have true pernicious anemia; the others may have abnor-

malities in the release of vitamin B<sub>12</sub> from food and varying degrees of atrophic gastritis and achlorhydria (Carmel, 1997).

Recent reports suggest that, if borderline vitamin B<sub>12</sub>-deficient patients are treated with nitrous oxide anesthesia, they can develop a rapid onset of the demyelinating syndrome in the weeks to months postoperatively (Singer *et al.*, 2008). The widespread use of stomach acid blockers such as the histamine blockers or the proton pump inhibitors may lead to a syndrome similar to the malabsorption of protein-bound B<sub>12</sub>. Metformin (widely used in treatment of diabetes) may induce vitamin B<sub>12</sub> deficiency (de Jager *et al.*, 2010).

## Diagnosis

The mainstay of diagnosis of vitamin B<sub>12</sub> deficiency has been the demonstration of a low serum-Cbl level (Hvas and Nexø, 2006; Stabler, 2006), although the specificity and sensitivity vary according to the lab cut-off values. Many methods can be used to assay total Cbl in serum, including microbiologic assays with *Lactobacillus leichmannii*, intrinsic factor competitive binding assays, utilizing radioisotope, chemiluminescence or enzyme-linked detection methods and chromatographic methods (Kumar *et al.*, 2010). Standardization between assays is problematic (Carmel *et al.*, 2000; Thorpe *et al.*, 2007). The use of serum assays for diagnosis is complicated by the fact that only about 20% of total serum Cbl is carried by TC (the cellular delivery protein) and the known roles for Cbl are all intracellular so tissue levels may not necessarily reflect those found in the plasma. In general, there is a rough correlation with the serum Cbl values such that extremely low concentrations often do indicate clinical deficiency, and values above the mean for a population generally can be interpreted as adequate (Lindenbaum *et al.*, 1990, 1994). There is a theoretical advantage to measuring Cbl on TC, known as holo-TC; however, diagnostic accuracy for elevated MMA is about equal between total Cbl and holo-TC (Hvas and Nexø, 2005; Miller *et al.*, 2006).

A comparison of the serum Cbl concentration versus serum or red-cell folate concentration has been frequently used to distinguish between the megaloblastic anemia resulting from deficiencies of either Cbl or folate. This is problematic because red-cell folate can be low in both vitamin B<sub>12</sub>- and folate-deficient subjects and serum folate can occasionally be low in vitamin B<sub>12</sub> deficiency (Savage and Lindenbaum, 1995). However, since MMA concen-

trations are elevated only due to vitamin B<sub>12</sub> deficiency, it is possible to determine that a patient with megaloblastic anemia has at least vitamin B<sub>12</sub> deficiency, although in some cases there may also be coexisting folate deficiency (Savage *et al.*, 1994a). The lack of hematologic abnormalities should never prevent assessment of Cbl status in a patient with compatible neurologic disease because of the strong inverse correlation between the two.

In some cases there will be clinical utility in determining the cause of deficiency since there may be gastrointestinal pathology that needs to be treated. The presence of blocking anti-IF antibodies is diagnostic of pernicious anemia but the test is not very sensitive (Carmel, 1992; Khan *et al.*, 2009). The Schilling test determines the quantity of radioactive Cbl that is excreted in the urine after an oral dose of crystalline Cbl, with or without added IF; however, it is not routinely available (Carmel, 2007). A new absorptive test has been proposed based on the appearance of an increase in holo-TC after oral Cbl loading (Hvas *et al.*, 2007). Children who are found to have metabolic Cbl deficiency should obviously be evaluated for inborn errors of metabolism or the congenital defects of malabsorption, and such individuals will need lifelong surveillance and treatment as well as case finding among siblings.

## Treatment of Vitamin B<sub>12</sub> Deficiency

The minimum quantity of B<sub>12</sub> required to sustain life is not known, but is likely less than 0.5 µg/day, and would not maintain normal biochemical values. Although the United States has set an RDA of 2.4 µg (Institute of Medicine, 1998), MMA is higher in those with an intake less than 6 µg; dietary supplements should therefore reflect this (Bor *et al.*, 2010). Vegetarians can be treated with small doses of oral vitamin B<sub>12</sub> supplements. Parenteral vitamin B<sub>12</sub> has been primarily used in the United States for the treatment of vitamin B<sub>12</sub> deficiency due to pernicious anemia and other forms of malabsorption. A standard regimen would be to start with weekly intramuscular injections of 1000 µg of CN-Cbl for 4–8 weeks until the clinical response is clearly evident, followed by monthly injections for life. An occasional patient will have serum MMA levels above the normal range on monthly injections and will require more frequent treatment (Kuzminski *et al.*, 1998). Hydroxy-Cbl is used in Europe and is claimed to need less frequent dosing; however, that has not been proven (Hvas and Nexø, 2006). High-dose daily oral therapy may be a good alternative to intermittent parenteral

treatment. Whereas IF-mediated Cbl uptake is limited, investigations from 40 years ago showed that subjects with or without pernicious anemia will absorb about 1% of a radioactively labeled oral dose (Berlin *et al.*, 1978). It has been shown that subjects with pernicious anemia can be maintained on daily oral doses of greater than 500 µg/day (Waife *et al.*, 1963), also 2000 µg oral daily resulted in much higher serum Cbl concentrations and lower MMA concentrations than monthly injections of Cbl (Kuzminski *et al.*, 1998). Patients should be offered a choice of high oral dose vs. parenteral therapy (Andrès *et al.*, 2010). The commonly available multivitamin preparations in the United States contain much lower quantities of vitamin B<sub>12</sub>, usually 6–9 µg although some marketed to seniors contain up to 100 µg. Although serum Cbl concentrations are higher in seniors who take multivitamins, the serum MMA concentrations are not corrected in many individuals (Stabler *et al.*, 1999). Also, subjects with pernicious anemia and other malabsorption syndromes cannot be treated with standard multivitamin preparations containing low quantities of vitamin B<sub>12</sub>. In most cases, vitamin B<sub>12</sub> therapy must be continued for life, thus it is imperative to have fully documented the deficiency prior to treatment and to convince the patient that this treatment is an ongoing necessity.

## Future Directions

Folic acid has been added to fortified grain products in the United States since January 1998 (and in many other countries). Since then, low serum-folate concentrations have virtually been eliminated in the United States (Pfeiffer *et al.*, 2007), whereas Cbl status has been largely unchanged. Patients with pernicious anemia or other forms of severe Cbl deficiency may have been put at risk by masking of megaloblastic anemia. New concerns that B<sub>12</sub>-deficient seniors with cognitive disorders may have been harmed by high folate intake have surfaced, although this is controversial. Vitamin B<sub>12</sub>-deficient seniors may have impairments in cognition and abnormalities on neurophysiologic testing despite having no evidence of megaloblastic anemia (Carmel *et al.*, 1995). Because it has been difficult to prove clinical benefit with mild deficiency in seniors, there is controversy about the benefits of screening and treating (Stanger *et al.*, 2009; Werder, 2010). Another approach would be to fortify the food supply with B<sub>12</sub> as well as folic acid. Questions about adequate dose, stability of B<sub>12</sub> after cooking and storage (since B<sub>12</sub> analogs could be harmful)

and the intended target population all remain (Allen *et al.*, 2010; Carmel, 2010). The recognition that B<sub>12</sub> deficiency may be related to birth defects and poor pregnancy outcomes is part of the impetus driving these recommendations (Li *et al.*, 2009). Evaluating inexpensive microbial or fermented vegetarian food sources of B<sub>12</sub> may have a large impact for the world populations who either cannot afford or choose not to consume animal source foods (Stabler and Allen, 2004; Watanabe, 2007). Newer methods of analysis which distinguish B<sub>12</sub> analogs from true B<sub>12</sub> will be necessary for this endeavor. Finally, the actual biochemical lesion in demyelination of the vitamin B<sub>12</sub>-deficient nervous system continues to elude us. Further research should be directed to the role of vitamin B<sub>12</sub> in these processes since the basic mechanisms learned may be important in other demyelinating syndromes.

## BIOTIN

JANOS ZEMPLÉNI, PhD, SUBHASHINEE S.K. WIJERATNE, PhD  
AND TOSHINOBU KUROISHI, PhD

*University of Nebraska–Lincoln, Lincoln, Nebraska, USA*

### Summary

Biotin is a water-soluble vitamin and serves as a coenzyme for five carboxylases, which catalyze key steps in the metabolism of fatty acids, glucose, and amino acids in humans. Biotin also regulates gene expression, mediated by biotinylation of lysine residues in histones H2A, H3, and H4, and by various transcription factors. Holocarboxylase synthetase, biotinidase, sodium-dependent multivitamin transporter, and the biotin transporters SMVT and MCT1 play crucial roles in biotin homeostasis in mammals. Human biotin requirements are unknown, and recommendations for dietary intake are based on estimates of biotin intake in apparently healthy populations (“adequate intake”). Individuals carrying mutations in genes coding for holocarboxylase synthetase and biotinidase require lifelong supplementation with pharmacological doses of biotin. Reliable markers for biotin status include the activity of propionyl-CoA carboxylase in lymphocytes, and the urinary excretion of biotin and the metabolite 3-hydroxyisovaleric acid. Anticonvulsants and lipoic acid may interfere with biotin metabolism, thereby increasing biotin requirements. Severe biotin deficiency has been linked to birth defects and impaired immune function in animal studies. Whether these effects of marginal biotin deficiency occur spontaneously in humans remains unclear.

### Introduction

Humans and other metazoans cannot synthesize the water-soluble vitamin biotin and depend on dietary biotin that originated in plants and microorganisms (Zempleni *et al.*, 2009). Major advances have been made over the past 10 years, leading to a more complete understanding of the roles of biotin as a key regulator at various crossroads of intermediary metabolism and gene regulation. Biotin is now known to play key roles in the metabolism of macronutrients, in histone modification, and in various signal

transduction pathways. Importantly, clinical evidence now exists that life stages (e.g. pregnancy) and lifestyle factors (e.g. smoking) affect biotin requirements. This chapter reviews the current state of knowledge in biotin nutrition in humans and, occasionally, other organisms.

### History

Boas demonstrated a requirement for the water-soluble vitamin biotin in mammals over 80 years ago (Boas, 1927).

FIG. 23.1 Pathways of biotin catabolism (data from McCormick and Wright, 1971).

Biotin was first isolated by Kögl and Tönnis (1932) and its chemical structure was determined by du Vigneaud *et al.* (1942). Biotin was first chemically synthesized by Harris *et al.* (1943).

## Biosynthesis

Mammals and other metazoans cannot synthesize biotin and depend on dietary biotin originating in microbial and plant biosynthetic pathways. The route of biosynthesis of biotin was largely elaborated by Eisenberg *et al.* working with *Escherichia coli* (Rolfe and Eisenberg, 1968; Eisenberg *et al.*, 1975). In this pathway, dethiobiotin is formed from pimelyl-CoA (which can be synthesized from oleic acid) and carbamyl phosphate (Hatakeyama *et al.*, 1997). Sulfur is incorporated into dethiobiotin in a synthase-dependent step, generating biotin (Flint and Allen, 1997).

## Catabolism of Biotin

McCormick and co-workers identified two pathways of biotin catabolism in microorganisms and mammals (Figure

23.1). In one pathway, biotin is catabolized by  $\beta$ -oxidation of the valeric acid side chain (McCormick and Wright, 1971). The repeated cleavage of two-carbon units leads to the formation of bisnorbiotin, tetranorbiotin, and related catabolites that are known to result from  $\beta$ -oxidation of fatty acids (i.e.  $\alpha,\beta$ -dehydro-,  $\beta$ -hydroxy, and  $\beta$ -keto-intermediates).  $\beta$ -Ketobiotin and  $\beta$ -ketobisnorbiotin are unstable and may decarboxylate spontaneously to form bisnorbiotin methyl ketone and tetranorbiotin methyl ketone (McCormick and Wright, 1971). After degradation of the valeric acid side chain to one carbon (tetranorbiotin), microorganisms cleave and degrade the heterocyclic ring (McCormick and Wright, 1971); degradation of the heterocyclic ring is quantitatively minor in mammals (Lee *et al.*, 1972). In a second pathway of biotin catabolism, the sulfur in the heterocyclic ring is oxidized to produce biotin-*l*-sulfoxide, biotin-*d*-sulfoxide, and biotin sulfone (McCormick and Wright, 1971). It is likely that sulfur oxidation in the biotin molecule occurs in the smooth endoplasmic reticulum in a reaction that depends on nicotinamide adenine dinucleotide phosphate (Lee *et al.*, 1970). Finally, biotin is also catabolized by a combination

of both  $\beta$ -oxidation and sulfur oxidation, producing compounds such as bisnorbiotin sulfone.

## Biological Functions of Biotin

Biotin serves as a covalently bound coenzyme for five human carboxylases (Zempleni *et al.*, 2009). In addition, biotin also plays unique roles in gene regulation, mediated by both biotinylation of histones and “classical” pathways of cell signaling (Zempleni *et al.*, 2009).

### Biotin-Dependent Carboxylases

In mammals, biotin serves as a covalently bound coenzyme for acetyl-CoA carboxylases (ACC) 1 and 2, pyruvate carboxylase (PC), propionyl-CoA carboxylase (PCC), and 3-methylcrotonyl-CoA carboxylase (MCC) (Zempleni *et al.*, 2009). The attachment of biotin to the  $\epsilon$ -amino group of a specific lysine residue in holocarboxylases is catalyzed by holocarboxylase synthetase (HCS); biotinylation of carboxylases requires ATP and proceeds in the following two steps.

Both the N- and C-termini in HCS are important for recognition of carboxylases (Hassan *et al.*, 2009). Holocarboxylases mediate the covalent binding of bicarbonate (not carbon dioxide), using 1'-N-carboxybiotinyl as an HCS-bound carboxyl donor (Knowles, 1989).

Both the cytoplasmic ACC1 and the mitochondrial ACC2 catalyze the binding of bicarbonate to acetyl-CoA to generate malonyl-CoA, but the two isoforms play distinct roles in intermediary metabolism (Kim *et al.*, 1997). ACC1 produces malonyl-CoA for the synthesis of fatty acid synthesis in the cytoplasm; ACC2 is an important regulator of fatty acid oxidation in mitochondria. The malonyl-CoA produced by ACC2 inhibits mitochondrial uptake of fatty acids for  $\beta$ -oxidation.

PC, PCC, and MCC localize in mitochondria. PC is a key enzyme in gluconeogenesis. PCC catalyzes an essential step in the metabolism of propionyl-CoA, which is pro-

duced in the metabolism of some amino acids, the cholesterol side chain, and odd-chain fatty acids. MCC catalyzes an essential step in leucine metabolism (Figure 23.2). Both PCC and MCC are composed of non-identical subunits, i.e. biotinylated  $\alpha$  subunits and non-biotinylated  $\beta$  subunits, which are encoded by distinct genes.

Proteolytic degradation of holocarboxylases leads to the formation of biotinyl peptides and biocytin (biotin- $\epsilon$ -lysine). These compounds are further degraded by biotinidase to release biotin, which is then recycled in holocarboxylase synthesis (Wolf *et al.*, 1985).

### Biotinylation of Histones

Histones are quantitatively the most important proteins in chromatin and play essential roles in processes such as DNA packaging and repair, replication, and gene regulation (Wolffe, 1998). Mammals express five major classes of histones: linker histone H1, and core histones H2A, H2B, H3, and H4. Histones consist of a globular domain and a flexible N-terminal tail. Chromatin is made of repetitive nucleoprotein complexes, the nucleosomes. Each nucleosome (“nucleosomal core particle”) consists of 146 base pairs of DNA, wrapped around an octamer of core histones (one H3/H3/H4/H4 tetramer, two H2A/H2B dimers). The N-terminal tails of core histones protrude from the nucleosomal surface; covalent modifications of these tails affect the structure of chromatin and play critical roles in gene regulation. Some modifications also exist in the globular domain and C-terminal regions (Kouzarides and Berger, 2007; Zempleni *et al.*, 2009) (Figure 23.3).

Biotinylation of distinct lysine (K) residues is among the recognized modification marks in histones (Hymes *et al.*, 1995; Stanley *et al.*, 2001). As of today, 11–13 biotinylation sites have been identified in histones H2A, H3, and H4 (Zempleni *et al.*, 2009). Initially, it was believed that biotinylation of histones is catalyzed by biotinidase (Hymes *et al.*, 1995). However, subsequent studies revealed that HCS is much more important than biotinidase for biotinylation of histones *in vivo* (Camporeale *et al.*, 2006; Bao *et al.*, 2011), while acknowledging that biotinidase has histone biotinyl transferase activity *in vitro* (Camporeale *et al.*, 2004). HCS can be detected in both nuclear and extranuclear compartments (Narang *et al.*, 2004; Chew *et al.*, 2006); nuclear HCS is a chromatin protein (Camporeale *et al.*, 2006) and its binding to chromatin might be mediated by physical interactions with histones H3 and H4 (Bao

**FIG. 23.2** Biotin-dependent carboxylases (data from Zempleni *et al.*, 2009). ACC, acetyl-CoA carboxylase; MCC, 3-methylcrotonyl-CoA carboxylase; PC, pyruvate carboxylase; PCC, propionyl-CoA carboxylase.

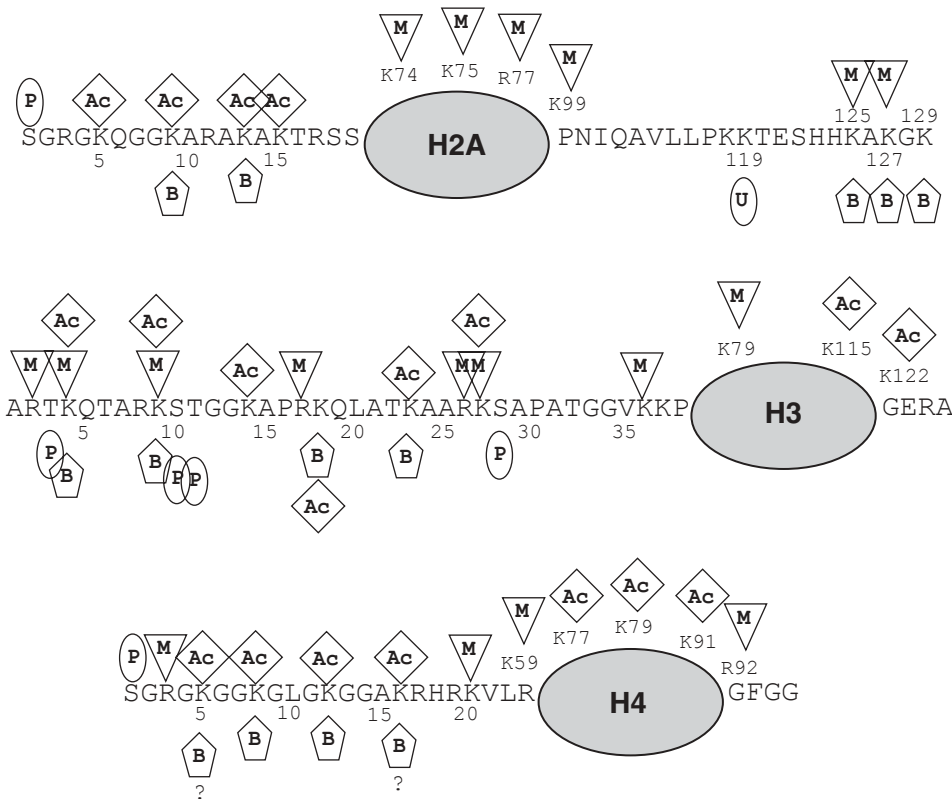

*et al.*, 2011). Phenotypes of HCS knockdown include decreased lifespan and heat survival in *Drosophila melanogaster* (Camporeale *et al.*, 2006).

Evidence is emerging for the biological functions of K12-biotinylated histone H4 (H4K12bio), while information regarding other biotinylation marks is scarce. The H4K12bio mark is enriched in heterochromatin repeats (telomeres, long-terminal repeats, and pericentromeric alpha satellite repeats) and transcriptionally repressed genes (Zempleni *et al.*, 2009). H4K12bio plays a role in the regulation of biotin transporter expression and the repression of long-terminal repeats (Chew *et al.*, 2008; Gralla *et al.*, 2008). Importantly, the abundance of histone biotinylation marks depends on biotin supply (Chew *et al.*, 2008). Low levels of histone biotinylation in biotin-deficient cells and model organisms has been linked to increased frequency of retrotransposition events, suggest-

ing a role for histone biotinylation in chromosomal stability (Chew *et al.*, 2008). Biotinylation of lysines other than K12 in histone H4 appears to have biological functions similar to that described for H4K12bio (Pestinger *et al.*, 2010).

### Gene Expression

Pioneering studies by Dakshinamurti and co-workers suggested a role for biotin in the regulation of the *glucokinase* gene (Dakshinamurti and Cheah-Tan, 1968). Subsequently, it was shown that biotin affects gene regulation by “classical” signaling pathways such as cGMP, NF- $\kappa$ B, Sp1 and Sp3, nitric oxide, and receptor tyrosine kinases, and by the intermediate biotinyl-5'-AMP (Solorzano-Vargas *et al.*, 2002; Zempleni *et al.*, 2009). Biotin also affects gene expression at the post-transcriptional level (Collins *et al.*, 1988).

**FIG. 23.3** Modification sites in histones H2A, H3, and H4 (data from Kouzarides and Berger (2007) and Zempleni *et al.* (2009). Ac, acetate; B, biotin; M, methyl; P, phosphate; U, ubiquitin.

## Methods of Biotin Analysis

### Microbial Growth Assays

Biotin auxotroph microorganisms have been used for biotin analysis, but these microbes lack chemical specificity and show variable growth responses to biotin and the various biotin precursors, catabolites, and analogs (Zempleni and Mock, 2000a). In addition, binding of biotin to proteins can be a meaningful confounder in microbial growth assays.

### (Strept)Avidin-Binding Assays

The proteins avidin and streptavidin are widely used in biotin analysis because they bind biotin with extraordinary strength and specificity; the dissociation constant of the avidin–biotin complex is  $1.3 \times 10^{-15} \text{ M}$  (Green, 1975). Avidin and streptavidin are purified from egg white and *Streptomyces* sp., respectively. Streptavidin has greater spe-

cificity for biotin compared with avidin, and is the probe of choice in avidin-binding assays. In our laboratory, we are currently relying on an assay developed by Kuroishi *et al.* (2008).

Biotin catabolites and compounds that are structurally similar to biotin also bind to avidin, causing the following potential pitfalls in biotin analysis. First, avidin binds biotin catabolites less tightly compared with biotin (Zempleni and Mock, 2000a). Hence, avidin-binding assays may underestimate the true concentration of biotin plus catabolites if calibrated by using biotin. Second, compounds other than biotin or catabolites may bind to avidin and cause artificially large readings for “apparent biotin.” Therefore, avidin-binding compounds in biological samples need to be resolved by chromatography prior to analysis of individual chromatographic fractions against authentic standards, as reviewed elsewhere (Zempleni and Mock, 2000a).

### 4'-Hydroxyazobenzene-2-Carboxylic Acid

4'-Hydroxyazobenzene-2-carboxylic acid is a robust probe to quantify chemically pure biotin at concentrations that exceed those typically found in biological samples, e.g. in pharmaceutical preparations (Zempleni and Mock, 2000a).

### Biotin Analogs

Synthetic biotin analogs (e.g. iminobiotin) and some naturally occurring biotin metabolites (e.g. biocytin) are available commercially. Likewise, a large number of reagents are available for chemical biotinylation of amines, sulfhydryl groups, carboxyl groups, nucleic acids, and others.

## Absorption, Transport Proteins, Storage, and Excretion

### Digestion

Biotin in foods is largely protein bound (Wolf *et al.*, 1985). Several gastrointestinal proteases may hydrolyze biotin-containing proteins to generate biotinyl peptides. Biotinyl peptides are further hydrolyzed by intestinal biotinidase to release biotin. Intestinal biotinidase is found in pancreatic juice, secretions of the intestinal glands, bacterial flora, and the brush-border membranes. Biotinidase activities are similar in mucosa from duodenum, jejunum, and ileum. The primary site or sites for hydrolysis of biotinyl peptides are unknown. Small quantities of biotinyl peptides may be absorbed without prior hydrolysis (Said *et al.*, 1993).

### Intestinal Transport and Bioavailability

Early investigations of biotin transport in rat jejunum suggested that intestinal biotin uptake is mediated by both saturable and non-saturable components (Bowman *et al.*, 1986). At biotin concentrations less than 5  $\mu\text{mol/L}$ , biotin absorption proceeds largely by the saturable process, whereas, at concentrations above 25  $\mu\text{mol/L}$ , non-saturable uptake predominates (Bowman *et al.*, 1986). The saturable mechanism of biotin transport is sodium dependent (Said and Redha, 1987). Transport of biotin is faster in the jejunum than in the ileum, and is minimal in the colon (85 vs. 36 vs. 2.8 pmol/g tissue wet weight/25 min, respectively); the apparent  $K_m$  (Michaelis–Menten constant) of the transporter for biotin in rat jejunum is 3.7  $\mu\text{mol/L}$ . The biotin transporter was cloned and has comparable affinities for biotin, pantothenic acid, and lipoic acid, if overexpressed in mammalian cells (Prasad *et al.*, 1998). Consequently, this transporter was named the sodium-

dependent multivitamin transporter (SMVT) (Prasad *et al.*, 1998). Four splicing variants of SMVT transcripts have been identified in rats (Said, 2004). The expression of SMVT is regulated by protein kinase C and histone biotinylation (Said, 2004; Gralla *et al.*, 2008).

The 5'-regulatory regions of *SMVT* genes in rats and humans have been cloned and characterized (Dey *et al.*, 2002). The rat and human *SMVT* genes contain three and two distinct promoters, respectively. Both promoter sequences in the human gene are TATA-less, CAAT-less, contain highly GC-rich sites, and have multiple putative regulatory *cis*-elements, e.g. AP-1, AP-2, C/EBP, SP1, NF1, and GATA (Dey *et al.*, 2002). The minimal region required for basal activity of the human SMVT promoter is encoded by a sequence between -5846 to -5313 for promoter 1 and between -4417 to -4244 for promoter 2 relative to the translation initiation codon. The three promoters in the rat *SMVT* gene contain *cis*-elements similar to the elements observed in the human promoters, but the rat 5'-regulatory region also contains two TATA-like elements (Chatterjee *et al.*, 2001).

Chemically pure biotin is about 100% bioavailable, even if the dose administered is 600 times the normal dietary intake (Zempleni and Mock, 1999a). Biotin exits enterocytes at the basolateral membrane by a carrier-mediated, sodium-independent process that does not accumulate biotin against a concentration gradient (Said *et al.*, 1988).

### Protein-Binding in Plasma

Human albumin,  $\alpha$ -globulin, and  $\beta$ -globulin bind biotin rather unspecifically (Dakshinamurti and Chauhan, 1994). Biotinidase has one high-affinity (dissociation constant  $K_d = 0.5$  nmol/L) and one low-affinity ( $K_d = 50$  nmol/L) binding site for biotin and might serve as a biotin-carrier protein in the plasma of normal adults (Chauhan and Dakshinamurti, 1988). A biotin-binding glycoprotein (mol. wt. 66 000) is present in serum of pregnant and estrogenized female rats and appears to be essential for embryonic survival (Seshagiri and Adiga, 1987). The protein binding of biotin in plasma is somewhat controversial; evidence has been provided for the importance of a low-affinity, high-capacity system such as albumin (Mock and Malik, 1992).

### Biotin Uptake into Liver and Peripheral Tissues

The SMVT is the most important transporter for mediating biotin uptake into liver and most peripheral tissues

(Said, 2004). In contrast, monocarboxylate transporter 1 contributes importantly towards biotin uptake into lymphoid cells and perhaps keratinocytes (Daberkow *et al.*, 2003).

### Cell Compartments

Biotin is distributed unequally across cellular compartments (Petrelli *et al.*, 1979). For example, the vast majority of biotin in rat liver localizes in mitochondria and cytoplasm, whereas only a small fraction localizes in microsomes. The relative enrichment of biotin in mitochondria and cytoplasm is consistent with the role of biotin as a coenzyme for carboxylases in these compartments. A quantitatively small but qualitatively important fraction of biotin localizes in the cell nucleus, i.e. about 0.7% of total biotin in human lymphoid cells can be recovered from the nuclear fraction (Stanley *et al.*, 2001). The relative abundance of nuclear biotin increases to about 1% of total biotin in response to proliferation, consistent with a possible role for biotinylated histones in cell proliferation.

### Storage

A relatively large fraction of intravenously administered biotin accumulates in rat liver, consistent with a role for this organ in biotin storage (Petrelli *et al.*, 1979). Depletion and repletion experiments of biotin-dependent carboxylases in rat liver suggest that ACC2 serves as a reservoir for biotin (Shriver *et al.*, 1993), but our own studies are not consistent with a role of any holocarboxylase as a biotin reservoir (Kaur Mall *et al.*, 2010).

### Urinary Excretion

Healthy adults excrete approximately 100 nmol/day of biotin and catabolites into urine (Zempleni *et al.*, 1997b). Biotin accounts for approximately half of the total; bisnorbiotin, biotin-*d,l*-sulfoxides, bisnorbiotin methyl ketone, biotin sulfone, and tetranorbiotin-*l*-sulfoxide account for most of the balance. If physiological or pharmacological doses of biotin are administered parenterally to humans, rats, or pigs, 43% to 75% of the dose is excreted into urine (Lee *et al.*, 1972; Zempleni and Mock, 1999a); the remainder is unaccounted for and might be due to excretion of metabolites not detectable by avidin assays; incorporation into biotin sinks such as histones or carboxylases; or excretion via non-renal routes. Renal epithelia reclaim biotin that is filtered in the glomeruli in an SMVT-mediated process (Nabokina *et al.*, 2003).

### Biliary Excretion

The biliary excretion of biotin and catabolites is quantitatively minor, i.e. <2% of an intravenous dose of [<sup>14</sup>C] biotin (Zempleni *et al.*, 1997a). The concentration ratios of biotin, bisnorbiotin, and biotin-*d,l*-sulfoxide (bile versus serum) in pigs are at least one order of magnitude smaller than the ratio measured for the cholephil compound, bilirubin.

### Pharmacokinetics

[<sup>3</sup>H]Biotin efflux from human lymphocytes is best described by using a three-compartment model; the half-lives of the three elimination phases are approximately 0.2 hours, 1.2 hours, and 22 hours (Zempleni and Mock, 1999c). Likely, the half-life of [<sup>3</sup>H]biotin during the terminal, slow phase of efflux is determined by the breakdown of biotin-dependent carboxylases to release free [<sup>3</sup>H]biotin, followed by efflux of [<sup>3</sup>H]biotin from lymphocytes. The half-life of [<sup>3</sup>H]biotin during the terminal phase of efflux (22 hours) resembles the half-lives of pyruvate carboxylase (28 hours) and acetyl-CoA carboxylase (4.6 days). Studies in pigs also generated valuable insights into biotin pharmacokinetics (Mock *et al.*, 1997c).

### Biotin Status

#### Direct Measures

The serum concentrations and the urinary excretions of biotin and catabolites are potential markers of biotin status. Biotin accounts for about half of the total of all biotinyl compounds in human urine and serum (Zempleni *et al.*, 2009) (Table 23.1). Tetranorbiotin-*l*-sulfoxide was detected in human urine but its avidin affinity is too low to allow meaningful quantitation.

The urinary excretion of biotin and biotin catabolites decreases rapidly and substantially in biotin-deficient individuals (Mock *et al.*, 1997d), suggesting that the urinary excretion is an early and sensitive indicator of biotin deficiency. In contrast, serum concentrations of biotin, bisnorbiotin, and biotin-*d,l*-sulfoxide do not decrease in biotin-depleted individuals and in patients on biotin-free total parenteral nutrition (Velazquez *et al.*, 1990) during reasonable periods of observation. Hence, serum concentrations are not good indicators of marginal biotin deficiency.

**TABLE 23.1** Serum concentrations and urinary excretions of biotin and catabolites

Compound	Serum (pmol/L)	Urine (nmol/24 hours)
Biotin	244 ± 61	35 ± 14
Bisnorbiotin	189 ± 135	68 ± 48
BSO <sup>a</sup>	15 ± 33	5 ± 6
BNBMK <sup>a</sup>	ND <sup>a</sup>	9 ± 9
Biotin sulfone	ND <sup>a</sup>	5 ± 5
Total biotin	464 ± 178 <sup>b</sup>	122 ± 66

Means ± SD are reported ( $n = 15$  for serum;  $n = 6$  for urine).

<sup>a</sup>BSO, Biotin-d,l-sulfoxides; BNBMK, bisnorbiotin methyl ketone; ND, not determined (BNBMK and biotin sulfone had not been identified at the time when this study of serum was conducted and, hence, quantification of these “unknowns” was based on using biotin as a standard).

<sup>b</sup>Including three unidentified biotin catabolites.

Data from Zempleni *et al.*, 2009.

### Indirect Measures

Lymphocyte PCC and its activation by biotin *ex vivo* are reliable markers for human biotin status (Stratton *et al.*, 2006). The carboxylase activation index equals the ratio of PCC activities in lymphocytes incubated with and without excess biotin (Velazquez *et al.*, 1990). High values for the activation index suggest that a substantial fraction of total PCC is apo-PCC, indicating biotin deficiency.

Reduced carboxylase activities in biotin deficiency cause metabolic blocks in intermediary metabolism (Figure 23.2). Reduced activity of MCC impairs leucine catabolism. As a consequence, 3-methylcrotonyl-CoA is shunted to alternative pathways, leading to an increased formation of 3-hydroxyisovaleric acid and 3-methylcrotonyl glycine. The urinary excretion of 3-hydroxyisovaleric acid is an early and sensitive indicator of biotin status (Mock *et al.*, 2002a). The derivative, carnityl-3-hydroxyisovaleric acid, also appears to be a robust indicator of biotin status (Stratton *et al.*, 2010).

Reduced activity of PCC causes a metabolic block in propionic acid metabolism. Consequently, propionic acid is shunted to alternative metabolic pathways. In these pathways, 3-hydroxypropionic acid and 2-methylcitric acid are formed. The urinary excretion of 3-hydroxypropionic acid and 2-methylcitric acid is not a good indicator of marginal biotin deficiency (Mock *et al.*, 2004). The accumulation of propionyl-CoA likely leads to occasional incorporation of a three-carbon fragment

(instead of the usual acetyl group) in fatty acid elongation and consequently to significant accumulation of odd-chain fatty acids in plasma phospholipids, plasma triglycerides and RBC membrane phospholipids (Mock *et al.*, 1988).

ACC and PC activities might also be reduced in biotin deficiency, but the responses of these pathways to biotin depletion have not yet been thoroughly investigated. Apparently, lactate levels increase in biotin-depleted *Drosophila melanogaster* compared with biotin-sufficient controls, presumably due to decreased PC activity (Smith *et al.*, 2007). This observation is consistent with the biotin responsiveness of lactate and pyruvate levels observed in an individual with inborn biotin transporter deficiency (Mardach *et al.*, 2002).

## Biotin Deficiency

### Clinical Findings of Frank Biotin Deficiency

Signs of frank biotin deficiency have been described in patients receiving parenteral nutrition without biotin supplementation (Zempleni and Mock, 1999b) and in patients with biotinidase deficiency (Wolf and Heard, 1991). Frank biotin deficiency may also be observed in individuals consuming large amounts of raw egg white, which contains non-denatured avidin. Binding of biotin to avidin in the gastrointestinal tract prevents absorption of biotin (Spencer and Brody, 1964).

Clinical findings of frank biotin deficiency include periorificial dermatitis, conjunctivitis, alopecia, ataxia, hypotonia, ketolactic acidosis/organic aciduria, seizures, skin infection, and developmental delay in infants and children (Wolf and Heard, 1991). In addition, the following symptoms were observed in adults and adolescents on egg white diet:

- thinning hair, often with loss of hair color;
- skin rash described as scaly (seborrheic) and red (eczematous); in several cases the rash was distributed around the eyes, nose, and mouth;
- depression, lethargy, hallucinations, and paresthesias of the extremities.

### Immune System

Biotin deficiency has adverse effects on cellular and humoral immune functions. For example, children with hereditary abnormalities of biotin metabolism developed candida dermatitis; these children had absent delayed-

hypersensitivity skin-test responses, IgA deficiency, and subnormal percentages of T lymphocytes in peripheral blood (Cowan *et al.*, 1979). In biotin-deficient rats, the synthesis of antibodies is reduced (Kumar and Axelrod, 1978). Biotin deficiency in mice decreases the number of spleen cells and the percentage of B lymphocytes in spleen (Báez-Saldaña *et al.*, 1998); inhibits thymocyte maturation (Báez-Saldaña and Ortega, 2004); and increases the production of pro-inflammatory cytokines (Kuroishi *et al.*, 2009).

### **Cell Proliferation**

Biotin deficiency causes decreased rates of cell proliferation and cell cycle arrest in HeLa cells and choriocarcinoma cells (Zempleni *et al.*, 2009). Human lymphoid cells respond to mitogen-induced proliferation with a 200% to 600% increase in biotin uptake compared with quiescent controls. This effect is mediated by an increased expression of biotin transporters rather than by an increased affinity of transporters for biotin (Zempleni and Mock, 1999d; Stanley *et al.*, 2002). The increased biotin uptake in proliferating cells is paralleled by increased activities of MCC (180% increase compared with quiescent controls) and PCC (50% increase), and by increased biotinylation of histones (400% increase) (Stanley *et al.*, 2001, 2002). These observations suggest that cell proliferation generates an increased demand for biotin.

### **Cell Stress and Survival**

HCS deficiency mimics biotin deficiency. HCS knock-down flies exhibited a decreased survival in response to heat stress in comparison with wild-type controls (Camporeale *et al.*, 2006). In contrast, biotin deficiency increased survival of human lymphoid cell cultures treated with cell death signals and anti-neoplastic agents, possibly due to increased nuclear translocation of the transcription factor NF- $\kappa$ B (Rodríguez-Melendez *et al.*, 2004). *Drosophila melanogaster* exhibits greater survival rates in response to stress compared with biotin-sufficient controls, if fed biotin-defined diets for 11 days (Landenberger *et al.*, 2004). The reason for the differences in HCS- and biotin-deficient organisms is unknown.

### **Lipid Metabolism**

Three biotin-dependent carboxylases are directly linked to lipid metabolism: ACC 1 and 2 (fatty acid synthesis and  $\beta$ -oxidation) and PCC (metabolism of odd-chain fatty acids). Biotin deficiency causes alterations of the fatty acid

profile in liver, skin, and serum of several animal species, which was paralleled by a >80% decrease in carboxylase activities (Zempleni and Mock, 2000b). The observed increase in the abundance of odd-chain fatty acids suggests that odd-chain fatty acid accumulation might be a marker for reduced PCC activity in biotin-deficient individuals. In patients who developed biotin deficiency during parenteral alimentation, the percentage of odd-chain fatty acids (15:0, 17:0) in serum increased for each of the four major lipid classes, i.e. cholesterol esters, phospholipids, triglycerides, and free fatty acids, but the relative changes have not always been consistent among studies (Zempleni and Mock, 2000b). Some tissues might be more susceptible than others, e.g. biotin deficiency affected the fatty acid composition in liver to a much greater extent than in brain tissue (Zempleni and Mock, 2000b).

### **Teratogenic Effects of Biotin Deficiency**

Severe biotin deficiency is teratogenic in several animal species, including cleft palate, micrognathia, and micro-melia in rats and mice (Mock, 2005). About half of the pregnant women in the US are marginally biotin deficient despite a normal dietary biotin intake (Mock *et al.*, 2002b), judged by increased urinary 3-hydroxyisovaleric acid, and decreased urinary biotin and PCC activity in lymphocytes. Marginal biotin deficiency in pregnant women might be caused by accelerated biotin catabolism and fetal accumulation of biotin (Mock and Stadler, 1997; Mock *et al.*, 1997a). The fetal-to-maternal concentration ratio of biotin plus metabolites is about 6:1, suggesting that fetal biotin accumulation might contribute to maternal biotin depletion (Mantagos *et al.*, 1998). Yet, the activity of PCC is reduced by approximately 90% in the fetus at term in response to feeding an egg-white diet that causes only a 50% reduction in maternal hepatic PCC activity in mice, suggesting that the fetus may not really be an efficient biotin parasite (Sealey *et al.*, 2005). If conclusive evidence was provided that marginal biotin deficiency causes birth defects in a quantitatively important fraction of pregnant women, this line of research would have major implications for health-care professionals and policy makers.

### **Biotin Homeostasis in the Central Nervous System (CNS)**

Disturbances in biotin homeostasis in the CNS cause encephalopathies (Ozand *et al.*, 1998). Factors leading to biotin imbalances in CNS include deficiencies of

biotinidase, HCS, and perhaps biotin transporters as described below. Afflicted patients typically respond to the administration of large doses of biotin by maintaining normal neurologic function. The reader should note that the biotin-responsive defect observed by Ozand *et al.* (1998) turned out to be a thiamin transporter defect (Subramanian *et al.*, 2006); the link between biotin and thiamin transport remains to be elucidated.

Moderate dietary biotin deficiency is typically not associated with neurologic symptoms, because the CNS maintains normal concentrations of biotin at the expense of other tissues. Evidence has been provided that biotin deficiency causes a >90% decrease in holocarboxylases in rat liver, whereas brain carboxylases remain unchanged (Pacheco-Alvarez *et al.*, 2005). Apparently, biotin deficiency decreases expression of SMVT in rat liver while maintaining normal expression of SMVT in brain.

## Disorders of Biotin Metabolism

### **Biotinidase Deficiency**

Low activities of the enzyme biotinidase cause a failure to recycle biotin from degraded carboxylases, i.e. to release biotin from biocytin (Wolf and Heard, 1991). Substantial amounts of biocytin are excreted into urine (Suormala *et al.*, 1988), eventually leading to biotin deficiency. Thus, clinical and biochemical features in children with biotinidase deficiency are similar to those described for biotin deficiency (Wolf and Heard, 1991).

Typically, symptoms of biotinidase deficiency appear at age 1 week to >1 year (Wolf and Heard, 1991). Wolf proposed to distinguish between patients with profound biotinidase deficiency (<10% of normal serum biotinidase activity), and patients with partial deficiency (10–30% of normal biotinidase activity). The estimated incidence of profound biotinidase deficiency is 1 in 112 000 and the incidence of partial biotinidase deficiency is 1 in 129 000. The combined incidence of profound and partial deficiency is 1 in 60 000 live births; an estimated 1 in 123 individuals is heterozygous for the disorder. Most of the children in whom biotinidase deficiency has been diagnosed are Caucasian. Mutations of the *biotinidase* gene have been well characterized at the molecular level (Neto *et al.*, 2004). Children with profound biotinidase deficiency are treated with 5–20 mg of biotin per day to compensate for urinary loss of biotin (Wolf and Heard, 1991). If identified early, symptomatic patients improve rapidly after lifelong biotin supplementation is initiated.

Procedures for prenatal diagnosis of biotinidase activity in cultured amniotic fluid cells and for neonatal screening using blood samples have been proposed (Wolf and Heard, 1991). Biotinidase activity is measured by quantifying the release of *p*-aminobenzoic acid from *N*-biotinyl-*p*-aminobenzoate (Wolf *et al.*, 1983). The mean ( $\pm$  SD) normal activity of biotinidase is  $5.8 \pm 0.9$  nmol *p*-aminobenzoate liberated/min/mL serum (Wolf *et al.*, 1983). Synthetic inhibitors are available for studies of biotinidase *in vitro* (Kobza *et al.*, 2008).

### **Carboxylase Deficiencies**

Afflicted individuals present with either isolated deficiencies of individual carboxylases or multiple deficiencies of multiple biotin-dependent carboxylases, i.e. multiple carboxylase deficiency (MCD) (Wolf and Feldman, 1982). MCD is caused by mutations in the *HCS* gene (reducing binding of biotin to carboxylases) or mutations in biotin transporter genes (reducing intracellular concentrations of biotin). MCD patients characteristically exhibit low activities of all five biotin-dependent carboxylases. Mutations of the *HCS* gene (Suzuki *et al.*, 1994) have been well characterized at the molecular level (Suzuki *et al.*, 2005). The incidence of HCS deficiency is less than 1 in 100 000 live births in Japan (Suzuki *et al.*, 2005). Afflicted individuals typically respond well to administration of pharmacological doses of biotin, in particular if the mutation of the gene resides in the biotin-binding region of the protein. In addition to the ~30 mutations in the human *HCS* gene that have been described, 2200 SNPs have been mapped in the *HCS* locus (National Center for Biotechnology Information, 2008) but their importance for HCS activity and human health is unknown.

Isolated PCC deficiency is a rare disorder with an estimated incidence of one in 350 000 individuals (Wolf and Feldman, 1982). Afflicted individuals become symptomatic during early infancy with vomiting, lethargy, and hypotonia (Wolf and Feldman, 1982). Treatment by administration of oral biotin may be successful. PCC deficiency can be diagnosed prenatally either by demonstrating deficient enzyme activity in cultured amniotic fluid cells or by detecting the presence of elevated concentrations of methylcitrate in amniotic fluid. Mutations of genes coding for both  $\alpha$  and  $\beta$  subunits of PCC have been identified (Perez *et al.*, 2003).

A small number of patients (21 patients as of 1982) with isolated PC deficiency have been reported (Wolf and Feldman, 1982). Symptoms appear in early infancy.

Biotin administration was not a successful treatment. PC deficiency presents either as the North American phenotype (lacticacidemia, hyperalaninemia, hyperproline-mia) or the French phenotype (elevated blood levels of ammonia, citrulline, proline, and lysine) (Robinson *et al.*, 1987). Very little information is available in regard to mutations in genes coding for MCC and ACC (Wolf and Feldman, 1982; Desviat *et al.*, 2003, Baumgartner *et al.*, 2004).

### **Biotin Transporter Deficiency**

Recently, a case of inborn biotin transporter deficiency has been identified (Mardach *et al.*, 2002). Of note, the patient with biotin transporter deficiency did not have any of the cutaneous symptoms of biotin deficiency. Rather, central nervous system signs and profound metabolic disturbances consistent with deficiencies of multiple carboxylases dominated that patient's clinical picture. All resolved with biotin supplementation. Evidence was provided that biotin transporter deficiency was not caused by abnormal SMVT, but the identity of the afflicted transporter remained unknown.

## **Biotin–Drug Interactions**

### **Anticonvulsants**

Biotin requirements may be increased during anticonvulsant therapy. The anticonvulsants primidone and carbamazepine inhibit biotin uptake into brush-border membrane vesicles from human intestine (Zempleni and Mock, 1999b). Long-term therapy with anticonvulsants increases both biotin catabolism and urinary excretion of 3-hydroxyisovaleric acid. Phenobarbital, phenytoin, and carbamazepine displace biotin from biotinidase, conceivably affecting plasma transport, renal handling, or cellular uptake of biotin. This is associated with decreased plasma concentrations of biotin.

### **Lipoic Acid (Thioctic Acid)**

Lipoic acid may be administered to treat heavy-metal intoxication, to reduce signs of diabetic neuropathy, and to enhance glucose disposal in patients with non-insulin-dependent diabetes mellitus (Zempleni *et al.*, 1997c). Lipoic acid competes with biotin for binding to SMVT (Prasad *et al.*, 1998), potentially decreasing the cellular uptake of biotin. Indeed, chronic administration of pharmacological doses of lipoic acid decreased the activities of

**TABLE 23.2** Adequate intakes of biotin

Life-stage group	Adequate intake (µg/day)

Data from Institute of Medicine, 1998.

PC and MCC in rat liver to 64–72% of controls (Zempleni *et al.*, 1997c).

## **Requirements and Recommended Intakes**

### **Adequate Intakes**

The Food and Nutrition Board of the National Research Council has released recommendations for adequate intake of biotin (Table 23.2) (Institute of Medicine, 1998). These data are based on estimated biotin intakes (not to be confused with requirements) in a group of healthy people. Adequate intakes may serve as goals for the nutrient intake of individuals. Biotin supplements may contribute substantially to biotin intake. For example, 15–20% of individuals in the United States report consuming biotin-containing dietary supplements (Institute of Medicine, 1998).

### **Life Stages and Lifestyle Factors that Affect Biotin Requirements**

Pregnancy and use of drugs may be associated with an increased requirement for biotin as described above. Smoking might further accelerate biotin catabolism in women (Sealey *et al.*, 2004) and alcohol impairs human placental biotin transport (Schenker *et al.*, 1993).

Lactation may generate an increased demand for biotin. At 8 days postpartum, biotin in human milk is approximately 8 nmol/L and accounts for 44% of biotin plus catabolites; bisnorbiotin and biotin-*d,l*-sulfoxide account

for 48% and 8%, respectively (Mock *et al.*, 1997b). By 6 weeks postpartum, the biotin concentration increases to approximately 30 nmol/L and accounts for about 70% of biotin plus catabolites; bisnorbiotin and biotin-*d,l*-sulfoxides account for about 20% and less than 10%, respectively.

## Intake and Food Sources

The majority of biotin in meats and cereals appears to be protein bound (Zempleni and Mock, 1999b). Most studies of biotin content in foods have depended on using bioassays. Despite potential analytical limitations due to interfering endogenous compounds, protein binding, and lack of chemical specificity for biotin, there is reasonably good agreement among published reports. Biotin is widely distributed in natural foodstuffs. Foods relatively rich in biotin include egg yolk, liver, and some vegetables. The dietary biotin intake in Western populations is about 35–70 µg/day (143–287 nmol/day). Infants consuming 800 mL of mature breast milk per day ingest approximately 6 µg (24 nmol) of biotin (Mock *et al.*, 1997b). It remains unclear whether biotin synthesis by gut microorganisms contributes importantly to the total biotin absorbed (Zempleni and Mock, 1999b).

## Excess and Toxicity

Empirically, ingestion of pharmacological doses of biotin has been considered safe. For example, lifelong treatment of biotinidase deficiency patients with biotin doses that exceed the normal dietary intake by 300 times does not produce frank signs of toxicity (Wolf and Heard, 1991). Likewise, no signs of biotin overdose were reported after acute oral and intravenous administration of doses that exceeded the dietary biotin intake by up to 600 times (Zempleni and Mock, 1999a). Note, however, that biotin supplementation is associated with alterations of gene expression in healthy adults and human cell culture models as described above (Rodriguez-Melendez and Zempleni, 2003). Some of these changes might have undesired effects in cell biology. For example, biotin supplementation decreases expression of the gene coding for sarco/endoplasmic reticulum ATPase 3 in human lymphoid cells; decreased expression of this calcium transporter is associated with impaired protein folding in the endoplasmic reticulum, causing cell stress (Griffin *et al.*, 2006).

## Future Directions

In the foreseeable future, biotin research likely will focus on the following priority areas:

1. Decipher the complex role of histone biotinylation in gene regulation and genome stability.
2. Use transgenic animal models to characterize the roles of HCS, biotinidase, and biotin transporters in biotin homeostasis and histone biotinylation.
3. Determine whether marginal biotin deficiency causes birth defects in humans.
4. Quantify human biotin requirements and determine the true prevalence of biotin deficiency in vulnerable subgroups of the population.
5. Determine whether polymorphisms in genes coding for HCS, biotinidase, and biotin transporters affect biotin requirements.
6. Characterize the biological effects of marginal biotin deficiency.

## Acknowledgments

A contribution of the University of Nebraska Agricultural Research Division, supported in part by funds provided through the Hatch Act. Additional support was provided by NIH grants DK063945, DK077816, DK082476, and ES015206, USDA CSREES grant 2006-35200-17138, and NSF grants MCB 0615831 and EPS 0701892.

## PANTOTHENIC ACID

JOSHUA W. MILLER<sup>1</sup>, PhD AND ROBERT B. RUCKER<sup>2</sup>, PhD

<sup>1</sup>University of California Davis Medical Center, Sacramento, California, USA

<sup>2</sup>University of California, Davis, California, USA

### Summary

Identified almost 60 years ago, pantothenic acid is an essential vitamin, which serves as the metabolic precursor for coenzyme A. In the form of coenzyme A and as a component of acyl carrier protein, pantothenic acid is a participant in a myriad of metabolic reactions involving lipids, proteins, and carbohydrates. Though essential, pantothenic acid deficiency in humans is rare owing to its ubiquitous distribution in foods of both animal and plant origin. Pantothenic acid supplementation may have some efficacy, but further investigation into various health claims is necessary before any specific recommendations can be given.

### Introduction

The discovery of pantothenic acid followed the same path that led to the discovery of other water-soluble vitamins, i.e. studies utilizing bacteria and single-cell eukaryotic organisms (e.g. yeast), animal models, and thoughtful chemical analysis. It was largely the efforts of research groups associated with R.J. Williams, C.A. Elvehjem, and T.H. Jukes that resulted in the identification of pantothenic acid as an essential dietary factor. Williams *et al.* (1933) established that pantothenic acid was required for the growth of certain bacteria and yeast. Next, Elvehjem and associates (Wooley *et al.*, 1939) and Jukes and associates (Jukes *et al.*, 1939; Spies *et al.*, 1940) demonstrated that

pantothenic acid was a growth and “anti-dermatitis” factor for chickens. Williams coined the name pantothenic acid from the Greek meaning “from everywhere” to indicate its widespread occurrence in foodstuffs (Williams *et al.*, 1933; Williams and Majors, 1940). The eventual characterization of pantothenic acid by Williams took advantage of observations that the anti-dermatitis factor present in acid extracts of various food sources, i.e. pantothenic acid, did not bind to fuller’s earth under acidic conditions. Using chromatographic and fractionation procedures that were typical of the 1930s (solvent-dependent chemical partitioning), Williams isolated several grams of pantothenic acid for structural determination from 250 kg of liver as starting material (Williams and Majors, 1940). With this

information, a number of research groups contributed to the chemical synthesis and commercial preparation of pantothenic acid.

In the 1950s, one of the functional forms of pantothenic acid, coenzyme A, was discovered as the cofactor essential for the acetylation of sulfonamides and choline (Plesofsky-Vig and Brambi, 1988). In the mid-1960s, pantothenic acid was next identified as a component of acyl carrier protein (ACP) in the fatty acid synthesis complex (Wakil, 1989). These developments, in addition to a steady series of observations throughout this period on the effects of pantothenic acid deficiency in humans and other animals, provide the foundation for our current understanding of this vitamin.

## Chemistry and Nomenclature

The chemical structure of pantothenic acid consists of pantoic acid and  $\beta$ -alanine bound in amide linkage (Figure 24.1A). Metabolic processing of pantothenic acid, described in detail below, produces the important intermediate, 4'-phosphopantetheine (Figure 24.1B), which includes  $\beta$ -mercaptoethylamine (cysteamine) bound in amide linkage to the terminal carboxyl group of the molecule. 4'-Phosphopantetheine serves as a covalently linked prosthetic group for ACP (Figure 24.1C). Further metabolic processing with the addition of adenine and ribose 3'-phosphate produces the essential cofactor, coenzyme A (CoA) (Figure 24.1D).

Pure pantothenic acid is a water-soluble, viscous, yellow oil. It is stable at neutral pH, but is readily destroyed by acid, alkali, and heat. Calcium pantothenate, a white, odorless, crystalline substance, is the form of pantothenic acid usually found in commercial vitamin supplements because it has greater stability than the pure acid (Bird and Thompson, 1967). Early literature referred to pantothenic acid as chick anti-dermatitis factor, filtrate factor, and vitamin B<sub>3</sub>. Today, it is often referred to as vitamin B<sub>5</sub>, though the origin of this designation is obscure.

## Intestinal Absorption, Cellular Uptake and Efflux, Plasma Transport, and Excretion

The vast majority of pantothenic acid in food is present as a component of CoA or 4'-phosphopantetheine. In order to be absorbed, these substances must first be hydrolyzed (Shibata *et al.*, 1983). This occurs in the intestinal

lumen by the sequential activity of two hydrolases, pyrophosphatase and phosphatase, with pantetheine as the product. Pantetheine is either absorbed as is, or further metabolized to pantothenic acid by a third intestinal hydrolase, pantetheinase. In rats, pantothenic acid absorption was initially found to occur in all sections of the small intestine by simple diffusion (Shibata *et al.*, 1983). However, subsequent work in rats and chicks indicated that at low concentrations the vitamin is absorbed by a saturable, sodium-dependent transport mechanism (Fenstermacher and Rose, 1986), sometimes referred to as the sodium-dependent multivitamin transporter (SMVT), which is shared with biotin (Said, 1999). In vitro experiments utilizing Caco-2 cell monolayers as a model of intestinal absorption established that pantothenic acid uptake is inhibited competitively by biotin, and vice versa (Said, 1999).

After absorption, pantothenic acid enters the circulation from which it is taken up by cells in a manner similar to that of intestinal absorption (Spector and Mock, 1987; Beinlich *et al.*, 1990; Grassl, 1992). The process for pantothenic acid cellular uptake appears saturable with an apparent  $K_m$  of 15–20  $\mu$ M. Transport across cell membranes occurs by carrier-mediated, sodium gradient-dependent and electroneutral mechanisms (Smith and Milner, 1985; Lopaschukf *et al.*, 1987; Beinlich *et al.*, 1989, 1990; Said *et al.*, 1998). Pantothenic acid cellular uptake has also been linked to protein kinase C (PKC) and calmodulin-dependent regulatory and signaling pathways (Lopaschukf *et al.*, 1987). The dependence on PKC is based on observations that pretreatment of cells with a PKC activator, such as phorbol 12-myristate 13-acetate (PMA) or 1,2-dioctanoyl-glycerol, significantly inhibits pantothenic acid uptake. If an inward sodium gradient is imposed, a rapid uptake of pantothenic acid is observed. Uptake of pantothenic acid is reduced when sodium is replaced by potassium or if external sodium is reduced below 40 mM. Ouabain, gramicidin D, cyanide, azide, and 2,4-dinitrophenol also act as inhibitors.

With regard to cellular efflux, unlike uptake, the export of pantothenic acid is unaffected by the addition of pantothenic acid, sodium, ouabain, gramicidin D, or 2,4-dinitrophenol to the external medium. Moreover, the metabolic state also has an impact on uptake. For example, in the perfused heart, pantothenic acid transport is significantly increased when hearts are perfused and are acting as “working” hearts because of addition of a fuel source (Lopaschukf *et al.*, 1987). That active uptake of pan-

**FIG. 24.1** Chemical structures of pantothenic acid, 4'-phosphopantetheine, acyl carrier protein, and coenzyme A.

tothenic acid is important is underscored by the differences in cellular versus plasma concentrations of free pantothenic acid. The cellular concentration of free pantothenic acid in the liver is 10–15  $\mu\text{M}$  and in the heart  $\sim 100 \mu\text{M}$  compared with 1–5  $\mu\text{M}$  observed in plasma. Similarly, the unidirectional influx of pantothenic acid across cerebral capillaries (the blood–brain barrier) occurs by a low-capacity, saturable transport system with a half-saturation concentration approximately 10 times the plasma pantothenic acid concentration (Spector, 1986, 1987). For comparison, the concentrations of CoA and ACP are 50–100  $\mu\text{M}$  and 10  $\mu\text{M}$ , respectively, in the cytosol of typical cells. In mitochondria, the CoA concentration can be as much as 10- to 20-fold higher, i.e. 70–90% of the total cellular CoA content.

The vitamin is excreted in the urine primarily as pantothenic acid. This occurs after its release from CoA by a series of hydrolysis reactions that cleave off the phosphate and  $\beta$ -mercaptoethylamine moieties.

## Cellular Regulation and Functions

### CoA and ACP Synthesis

Pantothenic acid is nutritionally essential due to the inability of animal cells to synthesize the pantoic acid moiety of the vitamin. The primary function of pantothenic acid is to serve as substrate for the synthesis of CoA and ACP (Figure 24.2). The first step is phosphorylation of pantothenic acid to 4'-phosphopantothenic acid by pantothenic acid kinase (Fisher *et al.*, 1985; Rock *et al.*, 2000). Three distinct types of pantothenic acid kinase (PanK) have been identified. PanK-I and III are found in bacteria. PanK-II is mainly found in eukaryotes and occurs in four different isoforms (PanK1, PanK2, PanK3, and PanK4) (Leonardi *et al.*, 2005). Pantothenic acid kinase possesses a broad pH optimum (between pH 6 and 9) with a  $K_m$  for pantothenic acid of  $\sim 20 \mu\text{M}$ . Mg-ATP is used as the nucleotide substrate for this phosphorylation reaction with a  $K_m$  of  $\sim 0.6 \text{ mM}$ .

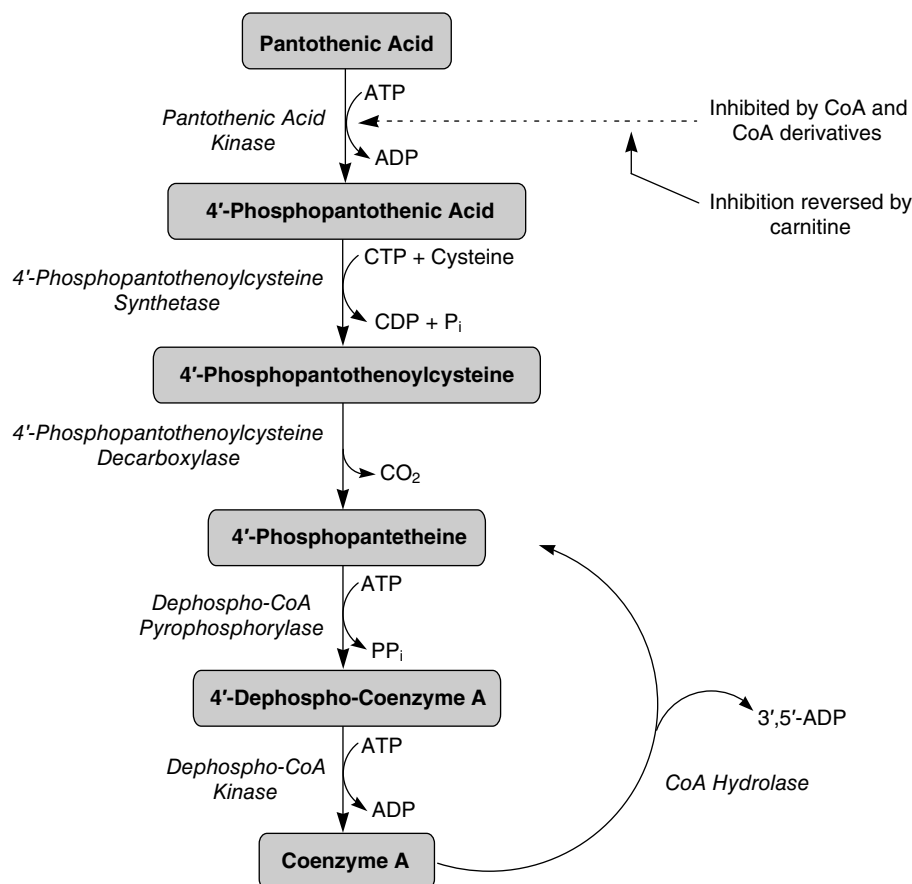

FIG. 24.2 Metabolic conversion of pantothenic acid to coenzyme A.

The pantothenic acid kinase reaction also serves as the primary control point in the synthesis of CoA and ACP. The reaction is activated and inhibited non-specifically by various anions (e.g. thiazolidinediones, sulfonyleureas, and steroids are inhibitors and fatty acyl-amides and tamoxifen are activators) (Leonardi *et al.*, 2010). In cells, feedback inhibition of the kinase by CoA or CoA derivatives governs flux through the subsequent steps in the CoA synthesis pathway and defines the upper threshold for intracellular CoA cofactor levels. Inhibition by acetyl-CoA is greater than that of free CoA. The inhibition by free CoA is uncompetitive with respect to pantothenate concentration, with a  $K_i$  for inhibition of  $0.2\ \mu\text{M}$ . Substrates are added to pantothenic acid kinase sequentially with ATP as the leading substrate. The allosteric regulatory domain responsible for acetyl-CoA inhibition also binds the substrates, pantothenate and pantetheine, and the various small molecule inhibitors and activators that can influence pantothenic acid kinase activity. Thus, descriptive features of mechanisms involving pantothenic acid kinase at the substrate level are often complex.

Of interest, L-carnitine, important for the transport of fatty acids into mitochondria, is a non-essential activator of pantothenic acid kinase. Carnitine has no effect by itself, but specifically reverses the inhibition by CoA. In heart, the free carnitine content varies directly with the phosphorylation of pantothenic acid. Thus, these properties of the kinase provide a potential mechanism for the control of CoA synthesis and regulation of cellular pantothenic acid content, i.e. feedback inhibition by CoA and its acyl esters that is reversed by changes in the concentration of free carnitine. However, it is important to underscore that the free concentration of acyl CoA in cells is low and variable because the bulk of acyl derivatives are protein bound. Moreover, similar to CoA, carnitine exists in both free and acylated forms, and reversal of kinase inhibition by CoA does not occur when carnitine is acylated (Fisher *et al.*, 1985). The ratio of free to acylated carnitine varies considerably depending on feeding and hormonal influences, with insulin particularly important. Fasting and type 1 diabetes (states of low insulin) increase pantothenic acid kinase activity and the total content of CoA (Reibel *et al.*, 1981; Robishaw *et al.*, 1982; Kirschbaum *et al.*, 1990). In addition, perfusion of heart preparations or incubation of liver cells with glucose, pyruvate or palmitate markedly inhibits pantothenic acid phosphorylation, due to reduction in free carnitine and increases in the free and acylated forms of CoA.

Following 4'-phosphopantothenic acid formation, the subsequent steps in CoA synthesis are carried out on a protein complex (~400 000 Da) with multifunctional catalytic sites. Important enzymatic features of this complex include dephospho-CoA-pyrophosphorylase activity, which catalyzes the reaction between 4'-phosphopantetheine and ATP to form 4'-dephospho-CoA; dephospho-CoA-kinase activity, which catalyzes the ATP-dependent final step in CoA synthesis; and coenzyme A hydrolase activity, which catalyzes the hydrolysis of CoA to 3',5'-ADP and 4'-phosphopantetheine. This sequence of reactions is referred to as the CoA/4'-phosphopantetheine cycle and provides a mechanism by which the 4'-phosphopantetheine can be recycled to form CoA. Each turn of the cycle utilizes two molecules of ATP and produces one molecule of ADP, one molecule of pyrophosphate, and one molecule of 3',5'-ADP (Figure 24.2) (Bucovaz *et al.*, 1998).

ACP is sometimes referred to as a "macro-cofactor," because, in bacteria, yeast and plants, it is composed of a polypeptide chain (MW ~8500–8700 Da) to which 4'-phosphopantetheine is attached. However, in higher animals, ACP is most often associated with a fatty acid synthase complex that is composed of two very large protein subunits (MW ~250 000 Da each). The carrier segment or domain of the fatty acid synthetic complex is also called acyl carrier protein, i.e. one of seven functional or catalytic domains on each of the two subunits that comprise fatty acid synthase. The inactive ACP apopolyptide (or domain) is converted to an active holoform (or domain) by the post-translational transfer of a 4'-phosphopantetheinyl moiety to the side-chain hydroxyl of a serine residue at the active center of ACP. The reaction is catalyzed by 4'-phosphopantetheinyl transferase, which uses CoA as the 4'-phosphopantetheine substrate. Although there are few data related to the regulation of holoACP peptide or domain formation, the 4'-phosphopantetheine transferase gene has been cloned from a human source (Praphanphoj *et al.*, 2001). Although data are limited on phosphopantetheine transferase and ACP regulation in animals, in plants the addition of exogenous CoA to intact chloroplasts stimulates the conversion of apoACP to holoACP. It should also be appreciated that, in addition to fatty acid synthesis, phosphopantetheine transferase catalyzes the transfer of 4'-phosphopantetheine from CoA to other proteins. For example, it has been shown that in human cell lines one of the enzymes of folate metabolism, 10-formyltetrahydrofolate dehydrogenase (FDH), requires

**TABLE 24.1** Selected functions of CoA and ACP

Function	Importance
<i>Carbohydrate-related</i>	
Citric acid cycle transfer reactions	Oxidative metabolism
Acetylation of sugars (e.g. N-acetylglucosamine)	Production of carbohydrates important to cell structure
<i>Lipid-related</i>	
Phospholipid biosynthesis	Cell membrane formation and structure
Isoprenoid biosynthesis	Cholesterol and bile salt production
Steroid biosynthesis	Steroid hormone production
Fatty acid elongation	Ability to modify cell membrane fluidity
Acyl (fatty acid) and triacyl glyceride synthesis	Energy storage
<i>Protein-related</i>	
Protein acetylation	Altered protein conformation; activation of certain hormones and enzymes, e.g. adrenocorticotropin; transcription, e.g. acetylation of histone
Protein acylation (myristic and palmitic acid additions) and prenylation	Compartmentalization and activation of hormones and transcription factors

a 4'-phosphopantetheine prosthetic group to aid the conversion of 10-formyltetrahydrofolate to tetrahydrofolate and CO<sub>2</sub> (Strickland *et al.*, 2010).

As an additional point, various agonists of fatty acid catabolism can affect CoASH-related metabolism. Peroxisome proliferator-activated receptors, such as PPAR $\alpha$ , when activated are often related to an increase in fatty acid  $\beta$ -oxidation. Targets of PPAR $\alpha$  also influence PanK and genes encoding proteins involved in the transport and synthesis of acylcarnitines. Using state-of-the-art metabolomic approaches (e.g. high-resolution NMR and mass spectrometry technology), it has been shown in humans that significant depletion of both pantothenic acid (as much as five-fold) and acetylcarnitine (as much as 20-fold) occurs in response to PPAR agonists, such as fenofibrate, based on analysis of urinary metabolites (Patterson *et al.*, 2009). As a transcriptional regulator, PPAR $\alpha$  includes pantothenate kinase and genes encoding proteins involved in the transport and synthesis of acylcarnitines.

### **Selected Functions of CoA and ACP**

Important functions of CoA and ACP are listed in Table 24.1. Principally, CoA is involved in acetyl and acyl transfer reactions and processes related to oxidative metabolism and catabolism, whereas ACP is involved primarily in synthetic reactions. The adenosyl moiety of CoA provides a site for tight binding to CoA-requiring enzymes, while

allowing the phosphopantetheine portion to serve as a flexible arm to move substrates from one catalytic center to another. Similarly, when pantothenic acid (as 4'-phosphopantetheine) in ACP is used in the transfer reactions associated with the fatty acid synthase process, 4'-phosphopantetheine also functions as a flexible arm that allows for an orderly and systematic presentation of acyl derivatives to each of the active centers of the fatty acid synthase complex. A summary of catalytic sites and their functions in the fatty acid synthase complex is presented in Table 24.2. In addition to fatty acid synthesis, hints that ACP-like factors may perform other functions in humans and animals come from observations that an oligosaccharide-linked acyl carrier protein acts as a transmethylation inhibitor in porcine liver (Seo *et al.*, 2002). ACP is also structurally homologous to acidic ribosomal structural proteins, e.g. ribosomal protein P2 (Raychaudhuri and Rajasekharan, 2003). Moreover, in bacteria and plants, ACP is important in a number of pathways, such as amino acid synthesis and formation of polyketides, a remarkably diverse group of secondary metabolites that include antibiotics, such as erythromycin, cholesterol-lowering drugs, such as lovastatin, and putative anti-aging compounds, such as resveratrol (Khosla and Tang, 2005).

It is also important to appreciate that intermediates arising from the transfer reactions catalyzed by CoA and 4'-phosphopantetheine in ACP may be viewed as "high energy" compounds. CoA or ACP reacts with acetyl or acyl

**TABLE 24.2** Catalytic sites associated with the fatty acid synthase complex

Enzyme	Catalytic function
1. Acetyl transferase	Catalyzes the transfer of an activated acetyl group on CoA to the sulfhydryl group of 4'-phosphopantetheine (ACP domain). In a subsequent step, the acetyl group is transferred to a second cysteine-derived sulfhydryl group near the active site of 3-oxoacyl synthase (see step 3) leaving the 4'-phosphopantetheine sulfhydryl group free for step 2
2. Malonyl transferase	Catalyzes the transfer of successive incoming malonyl groups to 4'-phosphopantetheine
3. 3-Oxoacyl synthetase	The first condensation reaction in the process, catalyzed by 3-oxoacyl synthase, in which attack on malonyl-ACP by the acetyl moiety (transferred in step 1) occurs with decarboxylation and condensation to yield a 3-oxobutyl (acetoacetyl) derivative. In the second through the seventh cycles, it is the newly formed acyl moieties that attack the malonyl group added at each cycle (see step 6)
4. Oxoacyl reductase	Reductions of acetoacetyl or 3-oxoacyl intermediates involve NADPH. The first cycle of this reaction generates D-hydroxybutyrate, and in subsequent cycles, hydroxy fatty acids
5. 3-Hydroxyacyl dehydratase	Catalyzes the removal of a molecule of water from the 3-hydroxyacyl derivatives produced in step 4 to form enoyl derivatives
6. Enoyl reductase	Reduction of the enoyl derivatives (step 5) by a second molecule of NADPH generates a fatty acid. This acyl group is also transferred to the sulfhydryl group adjacent to 3-oxoacyl synthase, as described in step 1, until a 16-carbon palmitoyl group is formed. This group, still attached to the 4'-phosphopantetheine arm, is the highly specific substrate for the remaining enzyme of the complex, thioester hydrolase
7. Thioester hydrolase	Liberates palmitic acid (step 6) from the 4'-phosphopantetheine arm

groups to form thioesters. Thioesters ( $-S-CO-R$ ) are thermodynamically less stable than typical esters ( $-O-CO-R$ ) or amides ( $-N-CO-R$ ). The double-bond character of the C–O bond in  $-S-CO-R$  does not extend significantly into the C–S bond. This causes thioesters to have relatively high energy potential, and for most reactions involving CoA or ACP no additional energy, e.g. from ATP hydrolysis, is required for transfer of the acetyl or acyl group. For example, consider that, at pH 7.0, the  $-\Delta G$  of hydrolysis is  $\sim 7.5$  kcal for acetyl-CoA and 10.5 kcal for acetoacetyl-CoA compared with 7–8 kcal for the hydrolysis of ATP to AMP and pyrophosphate or ADP and phosphate. The terminal thiol group of CoA and ACP is also ideally suited for nucleophilic substitution reactions involving activated carboxylic acids and  $\alpha$ - and  $\beta$ -carbonyl functions (Nicholis and Ferguson, 2002).

## Dietary Sources and Requirements

Pantothenic acid is found in a wide variety of foods of both plant and animal origin at levels in the range 20–50  $\mu\text{g/g}$ . Particularly rich sources of pantothenic acid

include chicken, beef, liver and other organ meats, whole grains, potatoes, and tomato products (Walsh *et al.*, 1981). Royal bee jelly and ovaries of tuna and cod also have high levels of the vitamin (Robinson, 1966). Because of its thermal lability and susceptibility to oxidation, significant amounts of pantothenic acid are lost from highly processed foods, including refined grains and cooked or canned meats and vegetables. Processing and refining whole grains results in a 37–47% loss of pantothenic acid, while canning of meats, fish, and dairy products leads to losses of 20–35% (Schroeder, 1971). Greater losses of the vitamin occur during canning (46–78%) and freezing (37–57%) of vegetables. Pantothenic acid is also synthesized by intestinal microorganisms (Stein and Diamond, 1989), though the amount produced and the availability of the vitamin from this source is unknown.

The primary source of pantothenic acid in food is CoA. Intestinal phosphatases and nucleosidases are capable of very efficient hydrolysis of CoA so that near quantitative release of pantothenic acid occurs as a normal part of digestion. Further, the overall  $K_m$  for pantothenic acid intestinal uptake is 10–20  $\mu\text{M}$ . At an intake of  $\sim 10$ –15 mg

**TABLE 24.3** Adequate intakes (AIs) for pantothenic acid

Age group	AI (mg/day)
<i>Infants</i>	
0–5 months	1.7
6–12 months	1.8
<i>Children</i>	
1–3 years	2.0
4–8 years	3.0
9–13 years	4.0
<i>Adolescents</i>	
14–18 years	5.0
<i>Adults</i>	
19–50 years	5.0
>50 years	5.0
Pregnancy	6.0
Lactation	7.0

Data from Institute of Medicine, 1988.

of CoA, the amount of CoA in a typical meal, the pantothenic acid concentration in luminal fluid would be ~1–2  $\mu\text{M}$ . At this concentration, pantothenic acid would not saturate the transport system, and as a consequence should be efficiently and actively absorbed (Said, 1999).

A dietary reference intake has yet to be established for pantothenic acid. Adequate intakes (AI) for men and women throughout the life-cycle have been suggested based on observed mean intakes and estimates of basal excretion in urine (Table 24.3) (Institute of Medicine, 1988). Urinary excretion of pantothenic acid only exceeds basal levels when intakes are greater than 4 mg/day in young adult males. Thus, an intake of 4 mg/day likely reflects the level at which saturation of the body pool occurs (Tarr *et al.*, 1981). Estimates of dietary intake in healthy adults have ranged from 4 to 7 mg/day (Srinivasan *et al.*, 1981; Tarr *et al.*, 1981; Bull and Buss, 1982; Kathman and Kies, 1984). There is no evidence to suggest that this range of intake is inadequate, and 5 mg/day has been set as the AI for adults. For adults older than 51 years, the AI remains the same (5 mg/day) as there is currently no basis for expecting an increased requirement in elderly individuals. During pregnancy, the AI is increased to 6 mg/day based on usual intakes of 5.3 mg/day (Song *et al.*, 1985) with rounding up. During lactation, the AI is increased further to 7 mg/day, accounting for additional secretion of the vitamin in human milk (1.7 mg/day) and the lower maternal blood concentrations reported when

intakes are about 5–6 mg/day (Deodhar and Ramakrishnan, 1961; Cohenour and Calloway, 1972; Song *et al.*, 1985). This is likely the result of efficient sequestering of the vitamin in human milk, estimated to be 0.4 mg for every 1 mg pantothenic acid consumed during active lactation (Song *et al.*, 1984).

The AI for infants reflects the mean intake of infants fed principally with human milk. Human milk contains about 5–6 mg of pantothenic acid per 1000 kcal. Values for children and adolescents have largely been extrapolated from adult values. These values are supported by studies comparing intake and urinary excretion of the vitamin in preschool children (Kerrey *et al.*, 1968). Dietary intake of pantothenic acid was 3.8 and 5 mg/day in children of high and low socioeconomic status, respectively, and urinary excretion was 3.36 and 1.74 mg/day, respectively. In a separate study, 35 healthy girls, 7–9 years of age, were fed defined diets, and urinary excretion was measured (Pace *et al.*, 1961). The average daily excretion was 1.3 mg/day when intake was 2.79 mg/day, and 2.7 mg/day when intake was 4.45 mg/day. Therefore, intakes of 2.8–4.5 mg/day exceed urinary excretion of the vitamin. In healthy adolescents (13–19 years of age), 4-day diet records indicated that the average pantothenic acid intake was 6.3 mg/day for males and 4.1 mg/day for females (Eissenstat *et al.*, 1986). Average urinary excretion in this latter study was 3.3 and 4.5 mg/day for males and females, respectively, while whole blood pantothenic acid concentrations averaged 1.86  $\mu\text{mol/L}$  and 1.57  $\mu\text{mol/L}$  respectively. Normal blood concentrations of the vitamin in healthy individuals have been reported to range from 1.6 to 2.7  $\mu\text{mol/L}$  (Wittwer *et al.*, 1989). Taken together, these data indicate that intake of 4 mg/day is sufficient to maintain normal blood concentrations in adolescents.

Using the estimate of 20–50  $\mu\text{g}$  pantothenic acid per gram typically found in edible animal and plant tissues, it is possible to meet the AI for adults with a mixed diet containing as little as 100–200 g of solid food, i.e. the equivalent of a mixed diet corresponding to 600–1200 kcal or 2.4–4.8 MJ. The typical western diet contains 6 mg or more of available pantothenic acid (Tarr *et al.*, 1981). For a more detailed review of the AI for pantothenic acid, see Institute of Medicine (1988).

## Deficiency and Toxicity

The essentiality of pantothenic acid has been documented in a wide variety of animal species. The classical signs

**TABLE 24.4** Effects of pantothenic acid deficiency in selected species

Species	Symptoms
Chicken	Dermatitis around beak, feet, and eyes; poor feathering; spinal cord myelin degeneration; involution of the thymus; fatty degeneration of the liver (Jukes, 1939; Wooley <i>et al.</i> , 1939; Spies <i>et al.</i> , 1940; Kratzer and Williams, 1948; Milligan and Briggs, 1949; Gries and Scott, 1972)
Rat	Dermatitis; loss of hair color; loss of hair around the eyes; hemorrhagic necrosis of the adrenals; duodenal ulcer; spastic gait; anemia; leukopenia; impaired antibody production; gonadal atrophy with infertility (Subba Row and Hitchings, 1939; Sullivan and Nicholls, 1942; Axelrod, 1971; Eida <i>et al.</i> , 1975; Pietrzik <i>et al.</i> , 1975)
Dog	Anorexia; diarrhea; acute encephalopathy; coma; hypoglycemia; leukocytosis; hyperammonemia; hyperlactemia; hepatic steatosis; mitochondrial enlargement (Schaefer <i>et al.</i> , 1942; Noda <i>et al.</i> , 1991)
Pig	Dermatitis; hair loss; diarrhea with impaired sodium, potassium, and glucose absorption; lachrymation; ulcerative colitis; spinal cord and peripheral nerve lesions with spastic gait (Wintrobe <i>et al.</i> , 1943; Nelson, 1968)
Human	Numbness and burning of feet and hands; headache; fatigue; insomnia; anorexia with gastric disturbances; increased sensitivity to insulin; decreased eosinopenic response to adrenocorticotrophic hormone (ACTH); impaired antibody production (Glusman, 1947; Hodges <i>et al.</i> , 1958, 1959)

of deficiency, first recognized by Elvehjem, Jukes and colleagues in chickens, include growth retardation and dermatitis (Jukes, 1939; Wooley *et al.*, 1939; Spies *et al.*, 1940). Many other physiological systems are affected by pantothenic acid deficiency, owing to the diversity of metabolic functions in which CoA and ACP participate. Neurological, immunological, hematological, reproductive, and gastrointestinal pathologies have been reported. The effects of pantothenic acid deficiency in different species are summarized in Table 24.4 (Subba Row and Hitchings, 1939; Schaefer *et al.*, 1942; Sullivan and Nicholls, 1942; Wintrobe *et al.*, 1943; Glusman, 1947; Kratzer and Williams, 1948; Milligan and Briggs, 1949; Hodges *et al.*, 1958, 1959; Nelson, 1968; Axelrod, 1971; Gries and Scott, 1972; Eida *et al.*, 1975; Pietrzik *et al.*, 1975; Noda *et al.*, 1991).

Assuming that the human adult requirement for pantothenic acid is ~5 mg/day, it may be predicted that, with a severe dietary deficiency, 5–6 weeks would be required before clear signs of deficiency are observed. This is based on the estimate that daily excretion of 5 mg represents a 1–2% loss of the total body pool of pantothenic acid. Consistent with this estimate, limited studies in humans indicate that about 6 weeks of severe depletion are required before urinary pantothenic acid decreases to a basal level of excretion (Fox and Linkswiler, 1961; Fry *et al.*, 1976; Annous and Song, 1985).

Because pantothenic acid is such a ubiquitous component of foods, both animal and vegetable, deficiency of this vitamin in humans is very rare. If present, pantothenic acid deficiency is usually associated with multiple nutrient deficiencies, thus making it difficult to discern effects specific to a lack of pantothenic acid. What is known about pantothenic acid deficiency in humans comes primarily from two sources of information. During World War II, malnourished prisoners of war in Japan, Burma, and the Philippines experienced numbness and burning sensations in their feet. While these individuals suffered multiple deficiencies, this specific syndrome was only reversed upon pantothenic acid supplementation (Glusman, 1947). Experimental pantothenic acid deficiency has also been induced in both animals and humans by administration of the pantothenic acid kinase inhibitor,  $\omega$ -methylpantothenate, in combination with a diet low in pantothenic acid (Drell and Dunn, 1951; Hodges *et al.*, 1958, 1959). Observed symptoms in humans included numbness and burning of the hands and feet similar to that experienced by the World War II prisoners of war, as well as a myriad of other symptoms listed in Table 24.4. Some of the same symptoms are produced when individuals are fed a semi-synthetic diet from which pantothenic acid has been essentially eliminated, but without addition of  $\omega$ -methylpantothenate (Fry *et al.*, 1976). Another pantothenic acid antagonist, calcium hopantenate, has been

shown to induce encephalopathy with hepatic steatosis and a Reye-like syndrome in both dogs and humans (Noda *et al.*, 1988, 1991).

Further evidence of the essentiality of pantothenic acid metabolism is revealed by an autosomal recessive disorder, initially called Hallervorden-Spatz syndrome and subsequently referred to as pantothenate kinase-associated neurodegenerative disease or neurodegeneration with brain-iron accumulation-1 (Zhou *et al.*, 2001; Hayflick *et al.*, 2003; Johnson *et al.*, 2004; Gregory *et al.*, 2009). Mutations in the gene encoding PANK2 (gene map locus: 20p13-p12.3) underlie this disorder, which is characterized by iron accumulation in the brain, progressive neurodegeneration, and early death. The pathogenesis of the disorder is believed to be related to mitochondrial CoA deficiency, inhibition of fatty acid  $\beta$ -oxidation, and oxidative stress. In addition, lack of phosphopantothenic acid synthesis may lead to accumulation of cysteine, the substrate required for step 2 of pantothenic acid metabolism, i.e. synthesis of phosphopantothenoylecysteine (Figure 24.2). It has been proposed that accumulated cysteine rapidly auto-oxidizes in the presence of free iron, leading to the generation of free radicals and additional oxidative stress (Zhou *et al.*, 2001; Johnson *et al.*, 2004).

Oral pantothenic acid, even in doses as high as 10–20 g/day, is well tolerated (Ralli and Dumm, 1953; Tahiliani and Beinlich, 1991). Occasional mild diarrhea may occur.

## Status Determination

Pantothenic acid status is reflected by both whole blood concentration and urinary excretion. As cited above, whole blood concentrations typically range from 1.6 to 2.7  $\mu\text{mol/L}$  (Wittwer *et al.*, 1989), and a value  $<1 \mu\text{mol/L}$  is considered low. Urinary excretion is considered a more reliable indicator of status because it is more closely related to dietary intake (Hodges *et al.*, 1958, 1959; Fry *et al.*, 1976; Tarr *et al.*, 1981; Eissenstat *et al.*, 1986). Excretion of  $<1 \text{ mg}$  pantothenic acid per day in urine is considered low. Plasma level of the vitamin is a poor indicator of status because it is not highly correlated with changes in intake or status (Cohenour and Calloway, 1972; Sauberlich, 1999).

Pantothenic acid concentrations in whole blood, plasma, and urine are measured by microbiological assay employing *Lactobacillus plantarum*. For whole blood, enzyme pre-treatment is required to convert CoA

to free pantothenic acid since *L. plantarum* does not respond to CoA. Other methods that have been employed to assess pantothenic acid status include radioimmunoassay, ELISA, and gas chromatography. The topic of pantothenic acid status assessment has been reviewed (Sauberlich, 1999).

## Health Claims

With the rapid development of the internet, information about nutritional supplements and their putative health benefits is disseminated to the general public with an ease and pace never before possible. However, many health claims for nutritional supplements have little or no scientific basis. Although overt deficiency of pantothenic acid is extremely rare in humans, an internet search for “pantothenic acid” reveals numerous websites providing background information, health claims, and of course an opportunity to buy the vitamin for oral consumption. Many of the claims made on these websites are completely unwarranted. For example, the use of pantothenic acid to prevent and treat graying hair was based on the observation that pantothenic acid deficiency in rodents causes their fur to turn gray (Sullivan and Nicholls, 1942). No association between graying of hair in humans and pantothenic acid status has ever been demonstrated. Moreover, although other claims for pantothenic acid have a more credible scientific basis and are summarized below, it should be noted that many such claims are based on studies that were conducted in the 1940s, 1950s, and 1960s, and still await validation.

## Cholesterol Lowering

Pantothenic acid is not particularly effective in lowering serum cholesterol levels. Rather, oral doses of its metabolite, panteine, or more specifically the dimer, panteine, induce favorable effects on serum cholesterol concentrations. Several studies indicated that panteine, in doses typically ranging from 500 to 1200 mg/day, can lower total serum cholesterol, low-density lipoprotein cholesterol, and triacylglycerols, and raise high-density lipoprotein cholesterol in individuals with dyslipidemia, hypercholesterolemia, and hyperlipoproteinemia associated with diabetes (Avogaro *et al.*, 1983; Gaddi *et al.*, 1984; Miccoli *et al.*, 1984; Arsenio *et al.*, 1986; Bertolini *et al.*, 1986; Binaghi *et al.*, 1990). The effects are favorable when compared with those of the more conventional lipid-lowering drugs, such as lovastatin, which may be

associated with side-effects and liver toxicity. There appear to be no adverse side-effects associated with high-dose pantothenic therapy. Furthermore, evidence exists that pantothenic therapy is more effective than dietary modification in reducing serum cholesterol and lipid concentrations (Avogaro *et al.*, 1983). The mechanism by which pantothenic exerts its hypolipemic effects is unclear. A hypothesized site of action is in the regulation of liver sterol biosynthesis. Because pantothenic is a coenzyme precursor, it may shunt active acetate from sterol synthesis to mitochondrial oxidative and respiratory pathways (Kameda and Abiko, 1980). Additionally, pantothenic may promote improved triacylglycerol and low-density lipoprotein cholesterol catabolism, as well as reduced cholesterol synthesis via inhibition of the enzyme hydroxymethyl glutaryl-CoA-reductase (Cighetti *et al.*, 1986, 1987, 1988).

### **Enhancement of Athletic Performance**

Scientific support for an effect of pantothenic acid supplements on athletic performance is also limited. Until recently, most of the potential benefit has been inferred from animal studies. More than 60 years ago, frog muscles soaked in pantothenic acid solution were shown to do twice as much work as control muscles before exhaustion (Shock and Sebrell, 1944), and more than 30 years ago rats supplemented with high doses of pantothenic acid were shown to withstand exposure to cold water longer than unsupplemented mice (Ralli, 1968). Moreover, rats deficient in pantothenic acid became exhausted more rapidly during exercise than did pantothenic acid replete controls (Smith *et al.*, 1987). In this latter study, deficiency was associated with lower tissue CoA concentrations and greater depletion of glycogen reserves during exercise.

Studies assessing the influence of pantothenic acid on human performance are mixed. In one study, well-trained distance runners were supplemented with 2 g/day of pantothenic acid for 2 weeks (Litoff *et al.*, 1985). These athletes outperformed other equally well-trained distance runners who received placebo. Those who received the supplements also used 8% less oxygen to perform equivalent work and had ~17% less lactic acid accumulation. However, in a separate study, no effect on performance was observed in highly conditioned distance runners after receiving 1 g/day of pantothenic acid for 2 weeks (Nice *et al.*, 1984). Additionally, no difference in performance was observed among highly trained cyclists given either a combination of thiamin (1 g) and pantothenic/pantothenic acid (1.9 g) or placebo. The supplement or placebo was given for 7 days before each exercise test. The investigators

found no effect on any physiological or performance parameters during steady-state or high-intensity exercise (Webster, 1998).

### **Rheumatoid Arthritis**

Over 50 years ago researchers noted that young rats made acutely deficient in pantothenic acid suffered defects in growth and development of bone and cartilage that were reversed by repletion of the vitamin (Nelson *et al.*, 1950). Subsequently, blood levels of pantothenic acid in humans with rheumatoid arthritis were found to be lower than in healthy controls. On the basis of this finding, a clinical trial was conducted in which 20 patients with rheumatoid arthritis were injected daily with 50 mg calcium pantothenate (Barton-Wright and Elliot, 1963). Blood levels of pantothenic acid increased to normal, and relief from rheumatoid symptoms was achieved in most cases. Symptoms recurred when supplementation was discontinued. Similar results were obtained in arthritic vegetarians (Barton-Wright and Elliot, 1963). More recently, it was found in a double-blind, placebo trial that oral doses of calcium pantothenate ( $\leq 2$  g/day) reduced the duration of morning stiffness, degree of disability, and severity of pain in patients with rheumatoid arthritis (US General Practitioner Research Group, 1980). Individuals with other forms of arthritis were not helped by the supplements, indicating that the therapeutic effect of pantothenic acid is specific for rheumatoid arthritis.

### **Wound Healing**

Oral administration of pantothenic acid and application of pantothenol ointment to the skin have been shown to accelerate the closure of skin wounds and increase the strength of scar tissue in animals. Adding calcium D-pantothenate to cultured human skin cells given an artificial wound increased the number of skin cells and the distance that they migrated across the edge of the wound (Weimann and Hermann, 1999). These effects are likely to accelerate wound healing. Little *in vivo* data, however, exist for humans to support the findings of accelerated wound healing in cell culture and animal studies. A randomized, double-blind study examining the effect of supplementing patients undergoing surgery for tattoo removal with 1000 mg of vitamin C and 200 mg of pantothenic acid did not demonstrate any significant improvement in the wound healing process in those that received the supplements (Vaxman *et al.*, 1995). Furthermore, no benefits were observed when the doses were increased to

3000 mg of ascorbic acid and 900 mg of pantothenic acid (Vaxman *et al.*, 1996). A topical form of pantothenic acid, panthenol or dexapanthenol, appears to play some role in the management of minor skin disorders. Dexpanthenol may help maintain skin hydration in cases of radiation dermatitis (Schmuth *et al.*, 2002), and may reduce skin irritation caused by experimental sodium lauryl sulfate exposure (Biro *et al.*, 2003). Dexpanthenol has also been recommended to treat cheilitis and dry nasal mucosa associated with treatment with the acne drug, isotretinoin (Romiti and Romiti, 2002).

### **Lupus Erythematosus**

It has been hypothesized that lupus erythematosus, a systemic autoimmune disorder that affects the skin, joints, and various internal organ systems, may be the result of pantothenic acid deficiency (Leung, 2004). The hypothesis is based on the supposition that pantothenic acid deficiency may be induced by three drugs – procainamide, hydralazine, and isoniazid – that are also known to cause drug-induced lupus erythematosus. These drugs are metabolized via CoA-dependent acetylation, and the increased demand for CoA may cause pantothenic acid deficiency. It must be noted, however, that no data have been generated on the effect of these drugs on cellular CoA or pantothenic acid concentrations. It is further postulated that non-drug-induced systemic lupus erythematosus may be the consequence of an increased need for pantothenic acid in susceptible individuals with genetic polymorphisms in CoA-dependent enzymes. Such polymorphisms remain to be identified. None the less, it is recommended that lupus erythematosus be treated with a combination of vitamins and minerals, including 10 g/day of pantothenic acid (Leung, 2004). Support for such pharmacological doses comes from studies carried out in the 1950s. Some symptoms of lupus erythematosus, but not all, were alleviated with high doses (8–15 g/day) of pantothenic acid derivatives (calcium pantothenate, panthenol, or sodium pantothenate) alone (Goldman, 1950) or in combination with vitamin E supplements (Welsh, 1952, 1954). No improvements in disease symptoms were observed with lower doses (400–600 mg) of calcium pantothenate (Cochrane and Leslie, 1952). With modern technology available to probe genes for polymorphic variability, supplementation trials in lupus erythematosus patients should be repeated to test the hypothesis that a genetic-based increased requirement of pantothenic acid underlies the pathogenesis of this disease.

### **Antimalarial Drugs**

More recently, *inhibitors* of the pantothenic acid pathway have been investigated for use as antimalarial drugs, most specifically related to the malaria parasite *Plasmodium falciparum*, which is the most virulent of the *Plasmodium* species in humans. *Plasmodium falciparum* requires an external supply of pantothenic acid to support its intracellular growth (Saliba *et al.*, 2005). Erythrocytes infected with *P. falciparum* rapidly take up pantothenate via the “new permeability pathways” (NPP) induced in the erythrocyte membrane by the maturing parasite (Saliba *et al.*, 1998). This increased permeability of the membrane via the NPP is not present in uninfected erythrocytes. The *P. falciparum* parasite relies on the endogenous synthesis of CoA from pantothenate and does not require exogenous CoA (Bozdech *et al.*, 2003). Thus, the CoA biosynthesis pathway has been a target for antimicrobial drug discovery. The antiparasitic activity of the many pantothenic acid analogs already available now needs to be determined for *P. falciparum* in vitro in continuous culture. The compounds that are found to be effective at inhibiting the in vitro growth of the parasite should then be tested in a mammalian model. As the spread of the resistance to antimalarial agents widens, the development of new therapies for the treatment and prevention of malaria is essential.

### **Future Directions**

Although CoA and ACP have been the focus of numerous investigations, far less attention has been paid to pantothenic acid. In part this is due to the rarity of naturally occurring pantothenic acid deficiency, and to the fact that descriptions of pantothenic acid deficiency and functions in humans have largely evolved indirectly from the administration of pantothenic acid antagonists; in particular, inhibitors of pantothenic acid kinase. Though these studies were informative, better information is needed regarding pantothenic acid requirements. The Food and Nutrition Board of the Institute of Medicine has yet to consider an RDA, because scientific evidence is currently insufficient for such estimations, although an AI has been set (Table 24.3) (Institute of Medicine, 1988). An RDA has been difficult to establish because CoA and ACP are involved in so many aspects of metabolism that biochemical markers or clinical deficiency criteria *specific* for pantothenic acid deficiency in humans have been difficult to define. In this regard, more information is needed related to the extent

to which dietary pantothenic acid supplementation can stimulate or influence CoA or ACP synthesis.

Another area for future investigation is the potential for pantothenic acid–drug interactions. This could be important given that pantothenic acid and cofactors such as biotin share common receptors (Said *et al.*, 1998). For example, oral contraceptives containing estrogen and progesterin may increase the requirement for pantothenic acid (Lewis and King, 1980). Also, though pantetheine has lipid lowering effects (Avogaro *et al.*, 1983; Gaddi *et al.*, 1984; Miccoli *et al.*, 1984; Arsenio *et al.*, 1986; Bertolini *et al.*, 1986; Binaghi *et al.*, 1990), little is known as to whether combining pantetheine with 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase inhibitors (statins) or nicotinic acid will produce additive effects on blood lipid profiles. In this regard, clinical studies are warranted, as well as basic investigations into the mechanisms of these interactions. The potential for pantothenic acid inhibitors to serve as antimalarial agents is also of great interest for future investigation.

## Acknowledgment

The authors wish to acknowledge the contribution of Lisa M. Rogers, PhD, in the preparation and writing of this chapter.

## L-CARNITINE

CHARLES J. REBOUCHE, PhD

*University of Iowa, Iowa City, Iowa, USA*

### Summary

L-Carnitine has essential roles in intermediary metabolism. For normal humans, endogenous synthesis of carnitine is adequate and therefore there is no dietary requirement. L-Carnitine has been proven to be useful in treatment in several diseases of genetic and acquired origin. For a number of other conditions L-carnitine and/or its acetyl or propionyl esters may prove useful in alleviation or moderation of symptoms. Use of L-carnitine and/or its esters may be valuable as dietary supplements to maintain or improve physical and mental function and slow decline during the aging process.

### Introduction

L-Carnitine (Figure 25.1) is a low-molecular-weight (161.5 g/mol) biologically active amino acid derived from the essential amino acids L-lysine and L-methionine. The optical isomer D-carnitine has no biological activity and is not produced in eukaryotic organisms. At physiological pH carnitine<sup>1</sup> exists as a zwitterion, containing a positively charged quaternary amine and a negatively charged carboxyl group separated by a three-carbon chain. A hydroxyl group is attached to the middle carbon. This hydroxyl group is utilized biologically to form short-, medium-, and long-chain esters of organic and fatty acids with carni-

tine (e.g. acetyl-L-carnitine, palmitoyl-L-carnitine; Figure 25.1). Transfer of activated acyl moieties between carnitine and coenzyme A, catalyzed by several chain-length-specific carnitine acyltransferases, forms the core of the biological activity of carnitine. Esterification to carnitine permits transfer of activated acyl moieties, most notably acetyl and long-chain fatty acyl units, across membranes of cellular organelles, particularly the inner membrane of mitochondria and the peroxisomal membrane.

### Carnitine in the Diet, Bioavailability, and Absorption

For human adults typical omnivorous diets provide 0.1 to 1.0 mmol of L-carnitine per day (2–12  $\mu\text{mol/kg}$  body weight/day) (Rebouche, 1992). Diets rich in animal

<sup>1</sup>The term “carnitine” in this text refers specifically to the L stereoisomer.

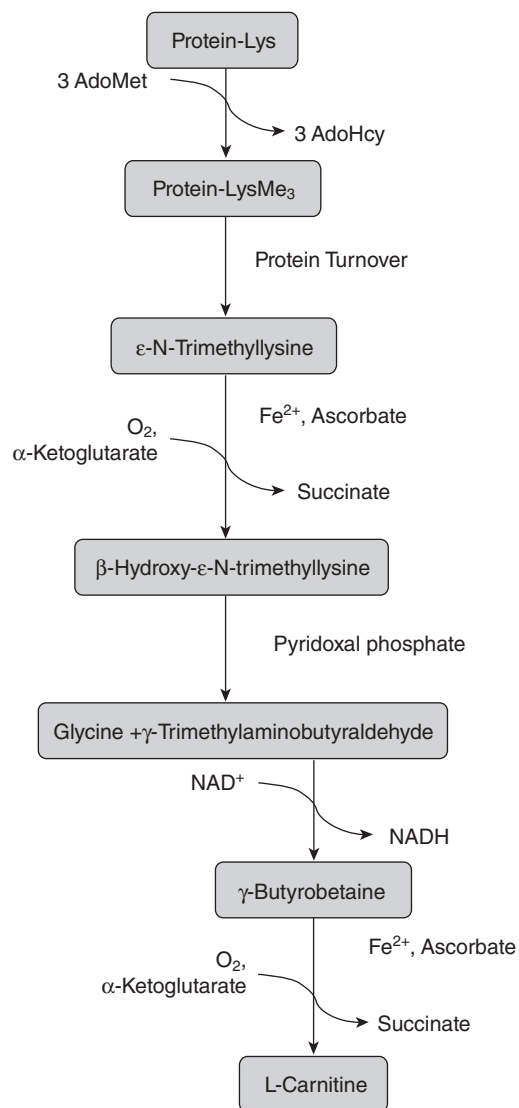

**FIG. 25.1** Structures of carnitine and representative acylcarnitine esters.

products (meat, poultry, fish, and dairy products) provide almost all of the carnitine obtained from mixed diets (Rebouche and Engel, 1984; Demarquoy *et al.*, 2004). Fruits and vegetables contain very little carnitine. Vegan diets provide less than 1  $\mu\text{mol}$  of carnitine/kg body weight/day. Fractional absorption of dietary carnitine is variable, generally in the range of 54–86% (Rebouche, 2004). Fractional absorption of dietary supplements (0.6–7 g/day) is 5–25% (Rebouche, 2004). At low carnitine intakes at least part of the absorption process may be facilitated or active. However, carnitine in the form of oral supplements is probably almost entirely absorbed by passive process(es).

## Biosynthesis and Metabolism

Carnitine is synthesized from  $\epsilon$ -*N*-trimethyllysine, an amino acid derived from post-translational modification of lysine in a variety of proteins (Figure 25.2). Probably the great majority of  $\epsilon$ -*N*-trimethyllysine arises from turnover of muscle proteins. Many proteins are known to contain one or a few methylated lysine residues, including

**FIG. 25.2** Pathway for carnitine biosynthesis in mammals.

actin, myosin, ATP synthase, histones, cytochrome *c*, and calmodulin. No single protein has been identified that contains a large number of these residues and/or that turns over rapidly such that it could provide a primary source of  $\epsilon$ -*N*-trimethyllysine for carnitine synthesis. Rather, from an evolutionary perspective, accrual of this derivative from normal protein synthesis and degradation has been adequate for mammalian requirements for carnitine. It is noted that the fungus *Neurospora crassa* is able to methylate unbound lysine (Rebouche and Broquist, 1976; Borum

and Broquist, 1977), but no other organism has been shown to possess this capability.

$\epsilon$ -*N*-Trimethyllysine is converted to carnitine via a series of four enzymatic reactions, catalyzed by two dioxygenases ( $\epsilon$ -*N*-trimethyllysine hydroxylase and  $\gamma$ -butyrobetaine hydroxylase), an aldolase (serine hydroxymethyltransferase), and a dehydrogenase (aldehyde dehydrogenase) (Vaz and Wanders, 2002). Thus the process also requires the cofactors  $\text{Fe}^{2+}$ , ascorbic acid and pyridoxal phosphate, and co-substrates  $\alpha$ -ketoglutarate,  $\text{O}_2$ , and  $\text{NAD}^+$ . Conversion of  $\epsilon$ -*N*-trimethyllysine to carnitine is not quantitative in mammals. Significant amounts of this amino acid and the penultimate precursor of carnitine,  $\gamma$ -butyrobetaine, are normally excreted in urine. The normal rate of carnitine synthesis in humans is estimated to be about  $1.2 \mu\text{mol/kg}$  body weight/day (Rebouche, 1992). This estimate was obtained indirectly from rates of carnitine excretion at steady state in the absence of significant dietary intake of carnitine. The variability among individuals or populations is not known.

Carnitine is not degraded by enzymes of animal origin. However, degradation products of carnitine have been identified in urine and feces of rats and humans. These arise from catabolism of carnitine by bacterial enzymes in the gastrointestinal tract. Enterobacteria metabolize carnitine to  $\gamma$ -butyrobetaine anaerobically via a two-step process (not a reverse of the single-step hydroxylation of  $\gamma$ -butyrobetaine in carnitine biosynthesis) (Figure 25.3). In

these organisms carnitine may serve as a growth-promoting electron acceptor in the absence of preferred substrates (Rebouche and Seim, 1998). Carnitine is degraded aerobically by some organisms, by carbon–nitrogen cleavage resulting in trimethylamine and malic semialdehyde (Figure 25.3). Trimethylamine is absorbed from the lumen of the large intestine, and is oxidized in the liver to trimethylamine oxide (Higgins *et al.*, 1972). Following oral administration of carnitine radiolabeled in the methyl groups, radiolabeled trimethylamine oxide and  $\gamma$ -butyrobetaine were the major degradation products observed in urine and feces, respectively, in both rats and humans (Rebouche *et al.*, 1984; Rebouche and Chenard, 1991).

Carnitine and its esters are distributed into three kinetically defined pools in the body (Rebouche and Engel, 1984). The largest corresponds to muscle tissues, and contains 92–97% of total body carnitine. A pool corresponding to other tissues including liver and kidneys contains 2–6% of total body carnitine. The extracellular fluid pool of carnitine accounts for the remaining 0.7–1.5%. Turnover of the muscle carnitine pool is relatively slow (191 hours), but, because of its size, the flux (movement into and out of a compartment) of carnitine is relatively rapid ( $427 \mu\text{mol/hour}$  in adult humans). Collective turnover time and flux of carnitine for other tissues are 11.6 hours and  $277 \mu\text{mol/hour}$ , respectively. Turnover time for the extracellular carnitine pool is 1.13 hours, and

FIG. 25.3 Catabolism of L-carnitine by microorganisms in the rat and human gastrointestinal tract.

whole-body turnover of carnitine is 66 days. The total carnitine pools in tissues and extracellular fluid consist of approximately 10–20% esterified carnitine and 80–90% non-esterified carnitine. The esterified carnitine fraction consists primarily of acetyl-L-carnitine, with smaller amounts of propionyl-L-carnitine and long-chain fatty acyl carnitine esters. The concentration of carnitine is generally greater in tissues than in extracellular fluid. In skeletal muscle and liver, respectively, the total carnitine concentrations are 76 and 50 times that in extracellular fluid. The highest concentrations of carnitine and acetyl-L-carnitine (1–80 mmol/L) are found in seminal plasma and within epididymal tissue and spermatozoa (Jeulin and Lewin, 1996).

Entry of carnitine and its short-chain acyl esters acetyl-L-carnitine and propionyl-L-carnitine into most tissues is facilitated by the organic cation transporter OCTN2. This protein has a high affinity for carnitine and its short-chain acyl esters ( $K_t = 3\text{--}5\ \mu\text{mol/L}$ ). Transport is dependent on an inwardly directed sodium-ion gradient, and sodium ions are co-transported with carnitine. This protein is highly expressed in kidney, skeletal muscle, heart, placenta, pancreas, testis and epididymis, and modestly expressed in liver, lung, and brain (Wu *et al.*, 1998). OCTN2 also is expressed in the colon, where it may facilitate salvage of dietary carnitine and  $\gamma$ -butyrobetaine formed from dietary carnitine by action of colonic microbes (Fujiya *et al.*, 2007; D'Argenio *et al.*, 2010). In addition, it has been implicated in transport of a bacterial quorum-sensing peptide that activates cell survival pathways in colonic epithelia (Fujiya *et al.*, 2007). Other proteins that are capable of transporting carnitine across cell membranes include the organic cation transporters OCTN1, OCTN3, Oat9S and the amino acid transporter ATB<sup>0+</sup> (Lamhonwah *et al.*, 2003; Rebouche, 2006; Tsuchida *et al.*, 2010). OCTN3 is involved in peroxisomal transport of carnitine and acylcarnitine esters (Lamhonwah *et al.*, 2005). The physiological role(s) of OCTN1, Oat9s, and ATB<sup>0+</sup> in carnitine transport and carnitine homeostasis are unknown or are poorly characterized.

A unique carnitine transporter, designated CT-2, is specifically expressed in testes (Enomoto *et al.*, 2002). The transporter is highly specific and has high affinity ( $K_t = 20\ \mu\text{mol/L}$ ) for carnitine. It is located phylogenically between the OAT and OCT/OCTN families of organic ion transporters. CT2 protein is localized to the luminal membrane of the epididymal endothelium and within Sertoli cells.

The major route for excretion of carnitine is via the kidney. Carnitine is filtered across the glomerulus. Normally 90–98% of filtered carnitine is reabsorbed by humans. OCTN2 in the renal brush-border membrane is primarily or totally responsible for reabsorption of carnitine and its short-chain acyl esters, and probably also the immediate precursor of carnitine,  $\gamma$ -butyrobetaine. Renal reabsorption of carnitine is thought to be a primary regulator of carnitine homeostasis in humans (Rebouche, 2004). Carnitine reabsorption is highly efficient when plasma carnitine concentrations are at or below about 60  $\mu\text{mol/L}$  (normal plasma total carnitine concentration is 30–65  $\mu\text{mol/L}$ ). When the plasma carnitine concentration is increased above 60  $\mu\text{mol/L}$ , by, for example, intravenous infusion of carnitine or oral consumption of a carnitine supplement, the efficiency of carnitine reabsorption rapidly decreases and a greater proportion of filtered carnitine is lost to urinary excretion.

Renal tubular cells secrete carnitine, short-chain acyl esters of carnitine, and  $\gamma$ -butyrobetaine into the tubular lumen (Rebouche and Engel, 1980; Hokland and Bremer, 1986; Mancinelli *et al.*, 1995). Some of these are reabsorbed and some are lost in the urine. Urine total carnitine typically contains a higher percentage of acylcarnitine esters than does the circulating carnitine pool (Lombard *et al.*, 1989). Under normal conditions the acylcarnitine ester fraction in urine is mostly comprised of acetyl-L-carnitine. Because the affinity of the renal brush-border membrane transporter OCTN2 for carnitine and acetyl-L-carnitine is similar, one should not be selectively reabsorbed from the glomerular filtrate over the other. Thus renal tubular cells may produce and secrete acylcarnitine esters selectively as a means to remove excess acyl burden from the body.

## Requirements and Consequences of Deficiency

Carnitine is not required by normal humans. It is often described as a conditionally essential nutrient (Borum, 1995), but this designation applies to abnormal or special circumstances such as prematurity at birth, genetic or acquired diseases, and chronic use of some drugs. Vegan adults and children, who acquire only minimal amounts of carnitine from their diets, have plasma carnitine concentrations approximately 10% and 25%, respectively, lower than their omnivorous counterparts (Lombard *et al.*, 1989). There is no dietary reference intake for L-carnitine.

Primary systemic carnitine deficiency in humans occurs as a result of defects in the gene coding for OCTN2. Clinical features include hypoketotic hypoglycemia, seizures, vomiting, lethargy progressive to coma, cardiomyopathy, and chronic muscle weakness (Nyhan and Ozand, 1998; Laforêt and Vianey-Saban, 2010). Therapeutic treatment with carnitine is highly successful. Plasma and liver carnitine concentrations are restored, attacks of hypoketotic hypoglycemia are prevented, and heart size is reduced to normal within months of treatment initiation. Skeletal muscle weakness improves, despite only slight increases in muscle carnitine concentration. A murine model (the *jvs* mouse) of spontaneous origin has been described (Hashimoto *et al.*, 1998).

Carnitine deficiency or depletion occurs secondary to many genetic inborn errors and acquired medical conditions, and with use of some medications. These have been reviewed extensively elsewhere (Pons and De Vivo, 1995). In numerous case reports of low circulating carnitine concentrations “a defect in carnitine biosynthesis” has been suggested. However, there is no documented case of car-

nitine deficiency in humans caused by absent or defective proteins associated with carnitine biosynthesis.

## Mechanisms of Action/ Biological Activity

A primary function of carnitine in cellular metabolism is to facilitate transport of activated long-chain fatty acids into mitochondria (Figure 25.4). Activated long-chain fatty acids (as coenzyme A esters) are transesterified to carnitine on the outer membrane of mitochondria. This reaction is catalyzed by carnitine palmitoyltransferase I (CPT I). Long-chain fatty acylcarnitine is transported across the mitochondrial inner membrane by carnitine-acylcarnitine translocase (CACT) (Iacobazzi *et al.*, 1998), a member of the mitochondrial metabolite carrier protein family (Palmieri *et al.*, 1995). Carnitine palmitoyltransferase II (CPT II) associated with the matrix side of the mitochondrial inner membrane then catalyzes transesterification of the activated fatty acid to intramitochondrial coenzyme A. The activated fatty

**FIG. 25.4** Facilitation of entry of long-chain fatty acids into mitochondria by carnitine. CPT I, carnitine palmitoyltransferase I; CPT II, carnitine palmitoyltransferase II; CACT, carnitine-acylcarnitine translocase; CAT, carnitine acetyltransferase; CoA, coenzyme A.

acids are oxidized through multiple cycles of the  $\beta$ -oxidation pathway.

CPT I is rate-controlling, although not necessarily rate-limiting, for  $\beta$ -oxidation of fatty acids (Eaton, 2002). CPT I is inhibited by malonyl-CoA and stimulated by AMP-activated protein kinase (Bartlett and Eaton, 2004). Two major forms of CPT I have been identified and are products of different genes (*CPT1A* and *CPT1B*) (Ramsay *et al.*, 2001). M-CPT I is found in skeletal muscle and heart, and L-CPT I is found in liver and many other non-muscle tissues. The two forms differ in their affinity for both the inhibitor, malonyl-CoA, and the substrate, carnitine. The carnitine concentration in tissues is not limiting for CPT I activity, unless it is abnormally low. Michaelis constants for carnitine binding to L-CPT I and M-CPT I are 30 and 500  $\mu\text{mol/L}$ , respectively (Ramsay *et al.*, 2001).

Carnitine participates in maintenance of intramitochondrial non-esterified coenzyme A availability. Carnitine is released in the mitochondrial matrix after import of long-chain fatty acylcarnitine and transesterification of the acyl group to coenzyme A. It can exit mitochondria via CACT, or it may be used as a reservoir for excess acetyl groups formed during  $\beta$ -oxidation and/or pyruvate oxidation. This process allows for maintenance of sufficient non-esterified coenzyme A concentration in the mitochondrial matrix to supply the  $\beta$ -oxidation cycle, pyruvate dehydrogenase, and the citric acid cycle. Transesterification of acetyl groups to carnitine from coenzyme A is catalyzed by carnitine acetyltransferase. Acetyl-L-carnitine may exit the mitochondrial matrix via CACT for use in other compartments of the cell, for use by other cells or tissues, or for excretion. The ability of carnitine to act as a reservoir for activated acyl residues is also important in abnormal cellular metabolism, particularly in genetic diseases associated with defects in organic and fatty acid metabolism (Rebouche, 2006). Experimental studies in mice, monkeys, and humans (Yamaguti *et al.*, 1996) show that, during starvation, acetyl-L-carnitine concentration in the circulation increases, perhaps due to higher rates of  $\beta$ -oxidation of fatty acids in some tissues, with consequent export of excess acetyl units. This phenomenon may also provide a means to transfer readily oxidizable carbon to tissues such as kidney and brain in times of metabolic stress. Following glucose re-feeding, the circulating acetyl-L-carnitine concentration decreases as this metabolite is transported into the liver.

Carnitine participates in shuttling of chain-shortened fatty acids from peroxisomes to mitochondria. Very-long-

chain fatty acids are partially oxidized in peroxisomes. Activated medium-chain-length organic acid products are transesterified to carnitine in peroxisomes, the acylcarnitine esters are exported from peroxisomes and the acyl moieties are subsequently oxidized in mitochondria. In peroxisomes transesterification of medium-chain acyl groups from coenzyme A to carnitine is catalyzed by carnitine octanoyltransferase (Ramsay, 1999).

In addition to the functions described above, carnitine and its esters have a number of physiological and pharmacological interactions and effects that have been demonstrated in animal, cell culture, and in vitro experimentation. These interactions and effects may be physiological in nature, but may also be magnified by pharmacological use of these compounds.

Carnitine and extra-mitochondrial carnitine palmitoyltransferase function in utilization of long-chain fatty acids for phospholipid biosynthesis and remodeling. Fatty acids bound to carnitine are incorporated into erythrocyte membrane phospholipids during repair after oxidative insult (Arduini *et al.*, 1990a), and into dipalmitoylphosphatidylcholine, a major component of surfactant, in lung alveolar cells (Arduini *et al.*, 2001). Carnitine and acetyl-L-carnitine may increase membrane stability in mature erythrocytes, presumably by a specific interaction with cytoskeletal proteins (Arduini *et al.*, 1990b).

Carnitine at millimolar concentrations reduces binding of dexamethasone to the glucocorticoid receptor  $\alpha$ , while itself triggering nuclear translocation of the receptor and stimulating transcription of glucocorticoid receptor  $\alpha$ -responsive promoters (Manoli *et al.*, 2004). L-Carnitine mimics several immunomodulatory effects of glucocorticoids, including suppressing lipopolysaccharide-induced cytokine production in rats, promoting fetal lung development in pregnant rats, and decreasing serum levels of tumor necrosis factor  $\alpha$  in surgical and HIV-infected patients (Manoli *et al.*, 2004). Carnitine may share some of the therapeutic properties of glucocorticoids, but without their deleterious side-effects.

Carnitine supplementation attenuates hyperammonemia and its toxic effects in a number of clinical and experimentally induced conditions, including primary systemic carnitine deficiency, medium-chain acyl-CoA dehydrogenase deficiency, valproic acid administration and ammonium chloride intoxication. This effect may derive from stabilization of mitochondrial function and/or by maintaining urea cycle activity. In the *jvs* mouse, a model for human primary systemic carnitine deficiency, carnitine

administration attenuated hyperammonemia and normalized hepatic expression of urea cycle enzymes suppressed by accumulation of long-chain fatty acids (Horiuchi *et al.*, 1992; Tomomura *et al.*, 1996). These effects may be mediated by the interaction of carnitine with the glucocorticoid receptor (Tomomura *et al.*, 1996; Manoli *et al.*, 2004).

Carnitine and its short-chain acyl esters may block formation or mitigate toxic effects of intracellular reactive oxygen species. Direct antioxidant effects of carnitine have been demonstrated *in vitro*. Model reactions revealed concentration-dependent reducing power (potassium ferricyanide reduction method) and hydrogen peroxide and radical scavenging (1,1-diphenyl-2-picryl-hydrazyl free radical (DPPH) assay) activities of carnitine similar in magnitude to  $\alpha$ -tocopherol (Gülçin, 2006). Ferrous iron chelating ability of carnitine was also demonstrated. Gülçin (2006) speculated that, in the reaction with DPPH, a radical centered on carbon 2 of carnitine is generated with reduction of DPPH $\cdot$  to 1,1-diphenyl-2-picryl hydrazine (DPPH). This reaction is purportedly energetically favorable:  $\Delta H$  for the reaction was calculated to be  $-181$  kcal/mol.

Carnitine may indirectly attenuate oxidative stress. It has been shown to inhibit arachidonic acid incorporation into platelet lipids, agonist-induced arachidonic acid release, and arachidonic acid-induced NADPH oxidase activation (Pignatelli *et al.*, 2003). Carnitine may also up-regulate expression of redox-sensitive transcription factors, sirtuins, and heat-shock proteins that protect against oxidative damage (Calabrese *et al.*, 2009).

### **Supplements: Infant Nutrition, Health Maintenance, Performance Enhancement, and Prevention or Retardation of Aging and Chronic Disease**

Carnitine and acetyl-L-carnitine are available commercially as diet supplements in the US. Propionyl-L-carnitine is available in Europe. Typical recommendations for use are 0.5 to 4 g/day for children and adults. Little or no toxicity is associated with consumption of these amounts of supplement. Occasional occurrences of diarrhea or body odor ("fish odor syndrome") have been reported.

Carnitine has been described as a conditionally essential nutrient for infants. An Expert Panel commissioned by the

US Food and Drug Administration's Center for Food Safety and Applied Nutrition has recommended a minimum carnitine content in infant formulas of  $7.5 \mu\text{mol}/100$  kcal, a level similar to that found in human milk, and a maximum level of  $12.4 \mu\text{mol}/100$  kcal, a value similar to the upper limit reported for human milk (Raitan *et al.*, 1998). These recommendations were made on the basis of reported biochemical differences when infants were fed carnitine-free diets compared with similar diets with carnitine, and despite the lack of evidence that carnitine is essential for the term infant.

Carnitine is not added to premature infant formulas, enteral or parenteral, at the time of manufacture, but these formulas may be supplemented with carnitine at the time of use. The rationale for supplementation is twofold: infants utilize lipids as a primary source for energy and growth after birth, requiring a high rate of mitochondrial oxidation, and the concentration of carnitine in infant circulation and tissues typically is lower without supplementation than in infants fed human milk or formulas containing carnitine. Studies in premature infants have focused on the effect of carnitine supplements on growth rate and lipid metabolism, with mixed results. In one study, no differences in 2-week weight gain over 8 weeks were observed between supplemented and non-supplemented infants (Shortland *et al.*, 1998). In another study, supplemented neonates regained their birth-weight more rapidly than placebo-group neonates, indicating that L-carnitine supplementation may promote more rapid catch-up growth (Crill *et al.*, 2006). An extensive review of these and other relevant studies has been published (Crill and Helms, 2007). For infants expected to be on parenteral nutrition for 7 days or longer, supplementation with carnitine 10–20 mg/kg body weight/day, given intravenously or orally, is recommended (Crill and Helms, 2007).

Carnitine has been investigated for its potential for performance enhancement and recovery from physical exertion. Several commercial entities market carnitine as an ergogenic aid. This strategy is based on the notion that supplemental carnitine will increase oxidative metabolism of fatty acids and perhaps spare muscle glycogen. It presumes that an increase of available carnitine will increase the flux of long-chain fatty acids into mitochondria. Clinical data suggest that muscle function is sensitive to changes in carnitine content when carnitine concentration is less than 25 to 50% of normal, but is insensitive to changes when the carnitine concentration is normal (Brass,

2004). If an increase in carnitine concentration alone is the sole factor in performance enhancement, it is unlikely that improvements would occur with carnitine supplementation, both because normal carnitine concentration is saturating for muscle CPT I kinetics, and only a very modest increase in carnitine concentration would be expected with even the most rigorous supplementation regimen. Even though carnitine supplements are not likely to substantially increase muscle carnitine concentration, they may improve the efficiency of muscle metabolism by exchange of non-esterified carnitine (provided by the supplement) into muscle for excess activated acetate (as acetyl-L-carnitine) formed from  $\beta$ -oxidation, when the citric acid cycle and/or oxidative phosphorylation pathways are operating at maximum capacity. In addition, the antioxidant and radical scavenging activity may assist in preventing damage from reactive oxygen species generated during prolonged physical exertion. Most studies of carnitine use to improve athletic performance have not shown any benefit. However, due to limitations in study design, the lack of evidence should not necessarily be taken to conclude that carnitine supplements are not beneficial (Brass, 2004). Particularly for elite athletes, very small increments in performance enhancement that are not quantifiable or statistically significant by standard experimental paradigms may have substantial impact on competitive outcome.

Propionyl-L-carnitine administered as a dietary supplement may provide some modest enhancement in physical performance. In a double-blind, placebo-controlled, crossover-design clinical trial, propionyl-L-carnitine (as glycine propionyl-L-carnitine), 4.5 g, administered orally to trained athletes significantly enhanced peak power production in resistance-trained males with significantly lower lactate accumulation (Jacobs *et al.*, 2009). The incremental differences in power production were modest and were observed only after repeated short-duration Wingate cycle sprints. Propionyl-L-carnitine may be more effective in enhancement of exercise performance than carnitine, because of its ability to increase nitric oxide production and vasodilation. Moreover, propionyl-L-carnitine may enhance citric acid cycle activity by providing propionyl units that can be converted to succinate.

Carnitine may reduce chemical damage to tissues after exercise and optimize the processes of muscle repair and remodeling (Kraemer *et al.*, 2008). In double-blind, placebo-controlled, crossover studies, 3 weeks of carnitine supplementation 2 g/day, followed by an acute resistance

exercise challenge, biochemical markers of purine metabolism, free radical formation, muscle tissue disruption, and muscle soreness were attenuated in non-trained young men (Spiering *et al.*, 2007) and middle-aged men and women (Ho *et al.*, 2010). The authors of these studies speculate that supplemental carnitine acts to protect vascular endothelial cells, improving regulation of blood flow to deliver oxygen to tissues and reducing hypoxia and oxidative stress generated by physical activity (Ho *et al.*, 2010). Whereas the results of these studies are impressive, the benefit-to-cost of this supplement regimen may only be attractive to competitive athletes and individuals pursuing very active lifestyles.

Some vendors have marketed carnitine as a dietary supplement to promote weight loss. The term “fat burner” has been used to describe carnitine. The rationale for this claim is based mostly on animal studies carried out in very highly controlled settings. In commercial animal husbandry the impetus for use of carnitine is to partition nutrients away from fat accretion and toward muscle deposition. In growing pigs fed energy-limited, fat-containing diets with or without supplemental carnitine, those receiving the supplement for 10 days had improved nitrogen retention and reduced carcass fat (Heo *et al.*, 2000), thus supporting a role for supplemental carnitine to improve body composition. Obesity affects a significant proportion of domestic pets, particularly dogs and cats. Carnitine added to a weight reduction diet for dogs resulted in a substantially greater loss of weight (7% vs. 2%) and fat mass (4% vs. 2%) in dogs receiving the supplement compared with diet alone, over a period of 7 weeks (Anonymous, 2009).

The success observed in animal studies has not been achieved in humans. For example, in a double-blind investigation to test the weight-loss efficacy of L-carnitine, 36 moderately overweight premenopausal women were pair-matched on body mass index and randomly assigned to two groups (Villani *et al.*, 2000). For 8 weeks one group ingested 2 g of carnitine twice daily, and the placebo group ingested the same amount of lactose. All subjects walked for 30 minutes (60–70% maximum heart rate) 4 days per week. No significant changes in mean total body mass, fat mass, and resting lipid utilization occurred over time. The success in animals suggests that it may be possible to achieve weight reduction and more desirable body composition with use of carnitine supplements in humans, but the regimens necessary to achieve these goals may be too rigid to be widely effective.

Carnitine and acetyl-L-carnitine have been investigated for use in maintenance of mental and physical function and reversal of decline with aging. In rats mitochondrial function declines with aging. Mitochondria of old rats have higher levels of products of oxidation of lipids, proteins and nucleic acids than do mitochondria of young rats. In old rats, cellular oxygen uptake and mitochondrial membrane potential, cardiolipin concentration, and respiratory control ratio are lower than in young rats (Ames and Liu, 2004). In heart mitochondria of old rats, DNA transcription and activity of cytochrome oxidase, adenine nucleotide translocase, and CACT are reduced compared with mitochondria of young rats (Gadeleta *et al.*, 1994; Paradies *et al.*, 1994, 1995). Administration of acetyl-L-carnitine to old rats restores cardiolipin concentration and mitochondrial function to near those in young rats (Paradies *et al.*, 1994, 1995; Ames and Liu, 2004). One mechanism proposed to explain these effects is protection afforded by acetyl-L-carnitine against oxidative decline in activity of carnitine acetyltransferase observed *in vivo* and *in vitro* (Liu *et al.*, 2002). Although this effect may contribute to overall restoration of mitochondrial function, the more general effects on membrane-associated enzyme activities and transporters probably are related to the restoration of cardiolipin concentration in the mitochondrial inner membrane.

Administration of acetyl-L-carnitine to old rats improves ambulatory activity and restores some memory loss by improving mitochondrial function and reducing accumulation of oxidation products (Liu *et al.*, 2002; Ames and Liu, 2004). Administration of carnitine to old rats restores activities of citric acid cycle and electron-transferring enzymes to near those of young rats (Kumaran *et al.*, 2005). In one study, acetyl-L-carnitine but not L-carnitine attenuated appearance of malondialdehyde, a lipid oxidation product (Liu *et al.*, 2004), but in another study carnitine supplementation increased the activities of the antioxidant enzymes superoxide dismutase and glutathione peroxidase (Juliet *et al.*, 2005).

In elderly humans, patients with depressive syndrome scored significantly lower on the Hamilton Rating Scale for Depression following supplementation with acetyl-L-carnitine (Tempesta *et al.*, 1987). Elderly subjects with mild mental impairment had better scores on cognitive performance tests following supplementation with acetyl-L-carnitine (Salvioli and Neri, 1994). A meta-analysis of the efficacy of acetyl-L-carnitine for cognitive impairment in mild Alzheimer's disease showed a significant advantage

for the supplement over placebo on both clinical scales and psychometric tests (Montgomery *et al.*, 2003). Ames (2003) has advocated a "metabolic tune-up" that includes micronutrients with acetyl-L-carnitine to maintain mitochondrial function during the life cycle and prevent age-related cognitive dysfunction and other degenerative diseases associated with aging.

## Therapeutic Use and Health Claims

L-Carnitine is approved by the US Food and Drug Administration for treatment of primary and secondary carnitine deficiency diseases (e.g. OCTN2 deficiency, glutaric aciduria type II, methylmalonic aciduria, propionic acidemia, and medium-chain acyl-CoA dehydrogenase deficiency), and in end-stage renal-disease patients undergoing hemodialysis. It has been suggested that carnitine is beneficial for relief of symptoms in a number of other diseases and medical conditions (see Table 25.1). In most cases these claims are supported by experimental and/or clinical evidence, but additional clinical trials may be required to establish efficacy.

## Future Directions

More basic studies are needed to elucidate the chemical basis for antioxidant and anti-apoptotic effects of carnitine and acetyl-L-carnitine. These should include examination of intracellular direct antioxidant effects (neutralizing reactive oxygen species), facilitation of acetylation of proteins that affords protection from oxidative damage from reactive oxygen species, improvement of mitochondrial function by facilitating a more orderly flow of substrates through the tricarboxylic cycle and electrons through the electron transport chain, or direct effects on transcription of genes whose products are important in intracellular antioxidant defense. Any or all of these effects could be operational *in vivo* either physiologically or pharmacologically. Novel experimental approaches may be necessary to sort out the relative importance of one over others. Examples of the obvious importance of the role of carnitine lie in the observations in experimental animals that carnitine supplements can attenuate the nephrotoxicity of cisplatin (Chang *et al.*, 2002) and the cardiotoxicity of doxorubicin (Alberts *et al.*, 1978), two important but perhaps under-utilized chemotherapeutic agents, due to their inherent toxicity toward normal cells.

**TABLE 25.1** Potential therapeutic uses for carnitine and/or its esters in humans

Disease or condition	Comment	References
HIV infection and antiretroviral therapy	Increase CD4 cell count, reduce lymphocyte apoptosis; improve symptoms of neuropathy; prevent cardiovascular damage; decrease serum triacylglycerols; treat antiretroviral therapy-associated lipodystrophy	Ilias <i>et al.</i> , 2004; Youle <i>et al.</i> , 2007
Cancer chemotherapy	Alleviation of chemotherapy-induced fatigue, nephrotoxicity, cardiomyopathy	Graziano <i>et al.</i> , 2002; Cruciani <i>et al.</i> , 2009
Type 2 diabetes	Improves non-oxidative glucose disposal; enhances effects of treatment with sibutramine or orlistat on lipid profile, insulin resistance parameters, glycemic control and inflammation indices	Mingrone, 2004; Arduini <i>et al.</i> , 2008; Derosa, <i>et al.</i> , 2010a,b
Chronic diabetic neuropathy	Alleviates pain, improves nerve-fiber regeneration and vibration perception	Sima <i>et al.</i> , 2005
Endothelial dysfunction associated with type 2 diabetes mellitus and/or obesity	Attenuates free-fatty-acid-induced endothelial dysfunction	Shankar <i>et al.</i> , 2004
Peripheral vascular disease	Improves initial and maximal treadmill walking distance	Hiatt, 2004; Andreozzi, 2009
Congestive heart failure	Increases exercise capacity and reduces ventricular size	Anand <i>et al.</i> , 1998
Angina pectoris	Increases exercise workload tolerated prior to onset of angina, and decreases ST segment depression (electrocardiographic evidence of ischemia) during exercise	Higdon and Drake, 2007
Long-term therapy following acute myocardial infarction	Reduction of left ventricular dilation; lowered incidence of death, congestive heart failure, and ischemic events	Iliceto <i>et al.</i> , 1995
Seizure disorders treated with valproic acid	Attenuates hyperammonemia; may be particularly effective with anticonvulsant polytherapy that includes valproic acid	Coulter, 1995; Gidal <i>et al.</i> , 1997
Treatment of conditions with pivoxil-containing prodrugs	Pivalate is transesterified to carnitine and is quantitatively excreted as pivaloyl-L-carnitine, which may lead to carnitine depletion if exogenous carnitine is not provided	Brass, 2002
Male reproductive dysfunction	Improve sperm concentration, total sperm counts and forward motility, and viability of sperm in patients with astheno- and oligoasthenozoospermia	Agarwal and Said, 2004
Hyperthyroidism	Inhibits thyroid action by inhibiting thyroid hormone entry into the nucleus	Benvenga <i>et al.</i> , 2003

Note: Some "therapeutic" uses may also be considered "dietary supplement" use. For example, L-carnitine is included in a formula marketed as a diet supplement to enhance fertility and improve reproductive health.

Controlled clinical trials should be designed and implemented to establish efficacy in the many clinical conditions in which carnitine and/or its esters are presumed to be of benefit. Some health claims for nutritional supplements have little or no scientific or medical basis. For carnitine and its esters, claims have been made based on studies in experimental animals, testimony, anecdotal evidence, and research studies in humans that do not meet accepted standards for proof of efficacy. For some claims the standard placebo-controlled, double-blind paradigm would be very difficult or impossible to implement, due to lack of accessibility of definitive, quantitative endpoint(s), and/or the requirement for large sample sizes to detect small but meaningful physiological or pathological differences in a heterogeneous population. Nevertheless, there is great promise for the use of these supplements to restore and/or maintain healthy metabolic function.

## CHOLINE

STEVEN H. ZEISEL, MD, PhD AND KAREN D. CORBIN, PhD, RD

*University of North Carolina at Chapel Hill, Kannapolis, North Carolina, USA*

### Summary

Choline is an essential nutrient for numerous biological functions. Experience derived from research on choline has pioneered a new way of thinking about nutrition requirements for optimal health. This body of knowledge has demonstrated that the dietary need for choline is highly individual, and is based on several factors including genetics and gender. In addition, measurable biological consequences related to inadequate choline intake can be improved with dietary interventions at various life stages, from the embryo to adulthood. In this chapter, we describe key aspects of choline function and metabolism in health and disease.

### Introduction

#### ***Function of Choline and Its Metabolites***

Choline is needed for the normal function of all cells since its derivatives contribute to the structural integrity and signaling functions of cell membranes. It is a major source of methyl-groups in the diet, directly affects cholinergic neurotransmission, and is required for hepatic lipid homeostasis (Zeisel, 2006a). Growing experimental evidence has identified important roles for choline in multiple metabolic processes such as gene expression (Niculescu *et al.*, 2004), carcinogenesis (Zeisel *et al.*, 1997), apoptosis (Albright *et al.*, 1996), lipid metabolism (Noga *et al.*, 2002; Watkins *et al.*, 2003), and early brain development (Albright *et al.*, 1999b, 2003; Cermak *et al.*, 1999; Craciunescu *et al.*, 2003; Meck and Williams, 2003).

Choline-containing compounds of physiologic importance include betaine, acetylcholine (ACh), phosphatidylcholine (PtdCho), platelet-activating factor, sphingomyelin (SM), lysosphingomyelin, glycerophosphocholine, and phosphocholine (some of these compounds are depicted in Figure 26.1). Choline (via its metabolite betaine), is a methyl group donor that can influence gene expression (discussed later in this chapter) (Zeisel, 2009). Also, betaine is an osmolyte used in the glomerulus of the kidney to help reabsorb water. PtdCho (lecithin) is the predominant phospholipid (>50%) in most mammalian membranes and is also important for regulating hepatic lipid packaging and export (Li and Vance, 2008). SM is another choline-containing phospholipid important for membrane and myelin formation (Diringer and Koch, 1973). Transmembrane signaling processes can involve hydrolysis of both of these choline-phospholipids, thereby generating

**FIG. 26.1** Structures of several important choline-containing molecules.

second messengers (including diacylglycerol, arachidonic acid, and ceramide) that alter cell function (Exton, 1994; Merrill *et al.*, 1995). ACh is a neurotransmitter important in brain functions such as memory and mood (Blusztajn and Wurtman, 1983).

## Choline Metabolism

### Choline Synthesis and Metabolic Fate

Aside from diet, new choline molecules can only be derived from de novo synthesis of PtdCho that is catalyzed by phosphatidylethanolamine-N-methyltransferase (PEMT) (Vance *et al.*, 1997). This pathway is primarily active in the liver. PEMT catalyzes the methylation of phosphatidylethanolamine (PtdEtn) to PtdCho. During this process, *S*-adenosylmethionine (SAM) is used as a methyl donor for the formation of a new choline moiety. Free choline can be generated by the catabolism of PtdCho (it can also be formed by the catabolism of SM and ACh). It is important to note that two pathways that use choline molecules to catalyze PtdCho biosynthesis are ubiquitously active in the body: the cytidine diphosphocholine and base-exchange pathways. Neither of these pathways leads to a net synthesis of choline moiety; rather, they allow for redistribution of existing choline molecules (Zeisel, 2006a).

Although the main metabolic fate of choline is the formulation of PtdCho, this fate is, in part, tissue specific. All tissues form PtdCho via the cytidine diphosphocholine pathway, and the first enzyme in this pathway has high

affinity for choline. Once this pathway is saturated, the available choline can be oxidized to form betaine (in selected tissues such as kidney and liver) or it can be acetylated to form ACh (in selected tissues such as placenta and neurons). These pathways are highly regulated and interrelated to maintain choline homeostasis (Li and Vance, 2008).

### Methyl Group Metabolism

The metabolism of choline, folate, vitamin B<sub>12</sub>, vitamin B<sub>6</sub>, and methionine are interrelated (Figure 26.2) and disturbances in one of these metabolic pathways are associated with compensatory changes in the others. This means the methyl groups from methyltetrahydrofolate (MTHF), methionine, and choline can be interchangeable. For example, methionine can be formed via two pathways: from homocysteine using methyl groups donated by MTHF (Finkelstein, 2000), or from methyl groups donated by betaine (derived from choline) (Park and Garrow, 1999). MTHF synthesis also has two pathways: via one-carbon units derived from serine or from the methyl groups of choline through dimethylglycine (Gregory *et al.*, 2000). Finally, choline can be formed from methyl groups derived from SAM (Vance *et al.*, 1997). When animals and humans are fed a diet deficient in choline, dietary folate requirements increase because more MTHF is used to remethylate homocysteine in the liver (Selhub *et al.*, 1991; Varela-Moreiras *et al.*, 1992). If instead they are fed a diet deficient in folate, dietary

**FIG. 26.2** Choline, folate, and homocysteine metabolism are closely interrelated. The pathways for the metabolism of these three nutrients intersect at the formation of methionine from homocysteine. BADH, betaine aldehyde dehydrogenase; BHMT, betaine homocysteine methyltransferase; ChAT, choline acetyltransferase; CHDH, choline dehydrogenase; CK, choline kinase; CPT, choline phosphotransferase; CT, CTP:phosphocholine cytidylyltransferase; MS, methionine synthase; mTHF, methyl tetrahydrofolate; PEMT, phosphatidylethanolamine-N-methyltransferase; THF, tetrahydrofolate.

choline requirements increase as choline becomes the primary methyl donor (Kim *et al.*, 1995; Jacob *et al.*, 1998, 1999). That several parallel pathways have evolved to help ensure adequate supply of methyl donors demonstrates the physiologic importance of these compounds.

### **Digestion, Absorption, and Transport**

Choline in foods is mostly in the form of phospholipids, phosphocholine, glycerophosphocholine, and choline. After ingestion and subsequent digestion by pancreatic and mucosal enzymes, the water-soluble compounds, choline, phosphocholine, and glycerophosphocholine, enter the portal circulation and are taken up by the liver. They rapidly accumulate in the liver where most are phos-

phorylated and used to make membranes and lipoproteins (Zeisel *et al.*, 1980c). Approximately half of the lipid-soluble choline compounds in foods, PtdCho and SM, persist intact after digestion. They enter via the lymphatic system in chylomicrons, miss first-pass metabolism by the liver, and can reach other organs (Garner *et al.*, 1995). Choline enters tissues by diffusion and mediated transport. Several genes have been identified in the control of choline transport across plasma and mitochondrial membranes (Brandon *et al.*, 2004; Ferguson *et al.*, 2004; Yuan *et al.*, 2004; Michel and Bakovic, 2009). In brain, a specific carrier mechanism transports free choline across the blood–brain barrier at a rate proportional to the serum choline concentration (Cornford *et al.*, 1978; Pardridge,

1986). Cholinergic neurons have a special high-affinity choline transporter that helps them accumulate choline (Vickroy *et al.*, 1984).

## Dietary Requirements for Choline

### **Choline Is an Essential Nutrient**

The human requirement for the nutrient choline was officially recognized with the establishment of adequate intake (AI) recommendations by the US Institute of Medicine in 1998 (Institute of Medicine, 1998). Previously, choline was not considered an essential nutrient for humans because there is an endogenous pathway for de novo biosynthesis of the choline moiety as part of PtdCho (Bremer and Greenberg, 1961). Despite this capacity to synthesize some choline in liver, healthy humans with normal folate and vitamin B<sub>12</sub> status that are fed a choline-deficient diet develop fatty liver, liver damage (elevated plasma alanine [or aspartate] transaminase), or muscle damage (elevated creatine phosphokinase-CPK) that resolves when choline is restored to the diet (da Costa *et al.*, 2004; Fischer *et al.*, 2007). Metabolic abnormalities (decreased clearance of homocysteine) (da Costa *et al.*, 2005), elevations in markers of DNA damage (da Costa *et al.*, 2006b) and alterations in lymphocyte gene expression (Niculescu *et al.*, 2007) are also observed in choline deficiency. In addition, humans fed intravenously with solutions low in choline develop liver dysfunction that resolves when choline is added back to their diets (Buchman *et al.*, 1995). Clearly, endogenous synthesis is not sufficient to prevent signs of choline deficiency, and thus choline is not a dispensable nutrient for some humans. The same is true for most non-ruminant species of animals (Zeisel and Blusztajn, 1994).

The Institute of Medicine suggests an AI for choline for adult men of 550 mg/day and for adult women 425 mg/day (Institute of Medicine, 1998). Pregnancy creates increased demands for dietary choline, and pregnant female rats are susceptible to choline deficiency (Zeisel *et al.*, 1995). In rats, maternal liver choline concentration over the course of pregnancy declines from 130  $\mu\text{mol/L}$  in non-pregnant adult rats to 38  $\mu\text{mol/L}$  in late pregnancy (Gwee and Sim, 1978). The AI for choline during pregnancy is 450 mg/day (Institute of Medicine, 1998). Because lactation further consumes maternal choline stores, sensitivity to choline deficiency is higher in lactating rats than non-lactating rats (Zeisel *et al.*, 1995). Thus, the AI for lactating women is estimated to be 550 mg/day of choline

(Institute of Medicine, 1998). Though no experimental data exists, AIs for infants have been extrapolated from amounts that would be consumed in breast milk, and AIs for children have been extrapolated based on adult requirements per kilogram of body mass, resulting in estimates of the AI that vary between 125 and 375 mg/day, depending on age (Institute of Medicine, 1998). Currently, studies are underway to refine these estimates of human choline requirements; some report that a subset of adult humans become depleted of choline at intakes of 750 mg/day (Fischer *et al.*, 2007), suggesting that the estimates for the AI may be too low for adults.

### **Dietary Sources of Choline**

Many foods contain significant amounts of choline or choline-containing compounds (Zeisel *et al.*, 2003a,b). Eggs, beef, chicken, fish, and milk as well as select plant foods like cruciferous vegetables and certain beans are particularly good sources of choline, providing at least 10% of the daily requirement per serving (Caudill, 2010). (See also <http://www.nal.usda.gov/fnic/foodcomp/Data/Choline/Choline.html> [last accessed July 5 2010] and Zeisel *et al.*, 2003a,b). Humans on an *ad libitum* diet ingest between 150 mg and 600 mg choline/day (as free choline and choline esters) (Shaw *et al.*, 2004; Fischer *et al.*, 2005; Cho *et al.*, 2006; Bidulescu *et al.*, 2007; Konstantinova *et al.*, 2008; Xu *et al.*, 2009). In the 2005 NHANES study, only a small portion of Americans in all age groups ate diets achieving the recommended intake for choline (Jensen *et al.*, 2007).

Foods also contain the choline metabolite betaine (Zeisel *et al.*, 2003a,b). It cannot be converted to choline, but can be used as a methyl donor, thereby sparing some choline requirements (Craig, 2004; Dilger *et al.*, 2007). Plant-derived foods can be a rich source of betaine (named after beets), with grain products being particularly good sources. Lecithin, a phosphatidylcholine-rich fraction prepared during commercial purification of phospholipids, is often added to foods as an emulsifying agent, or may be taken as a dietary supplement (Zeisel *et al.*, 2003a,b).

### **Supply of Choline to the Fetus and Infant**

In mammals, the placenta delivers choline to the fetus by pumping it against a concentration gradient (Sweiry *et al.*, 1986). The placenta may serve as a special reserve storage pool (in the form of ACh) to ensure adequate delivery of choline to the fetus. Choline concentration in amnio-

tic fluid is several-fold higher than in maternal blood (Ozarda Ilcol *et al.*, 2002). The mammary gland extracts choline from maternal blood, synthesizes important choline metabolites, and secretes all of these into milk (Zeisel *et al.*, 1986; Chao *et al.*, 1988; Yang *et al.*, 1988; Holmes-McNary *et al.*, 1996).

The total choline content of human milk is approximately 1.3–1.5 mmol/L (Holmes-McNary *et al.*, 1996) and is likely important for sustaining tissue choline in the infant. Many commercially available infant formulas were reformulated to deliver amounts of choline similar to that in mature human breast milk; before 2007 many formulas had less than is present in human breast milk (Holmes-McNary *et al.*, 1996). Choline concentrations in the plasma or serum of human infants are elevated during the perinatal period (compared with adults) and slowly decrease after birth until they reach adult levels some time after the first year of life (Zeisel *et al.*, 1980a; Zeisel and Wurtman, 1981; Ozarda Ilcol *et al.*, 2002; Ilcol *et al.*, 2005). Presumably these very high levels ensure enhanced availability of choline to the developing tissues.

### **Deficiency and Assessment of Choline Nutrition Status**

Given that many people consume less than the AI level of choline, it is plausible that some are choline deficient. Animal studies have given us important clues as to the biological consequences of choline deficiency. Choline deficiency in the rat reduces concentrations of choline and choline-containing compounds in the liver (Zeisel *et al.*, 1989). Low intake of dietary choline in rodents is associated with liver dysfunction, compromised renal function, infertility, growth impairment, and hypertension (Zeisel, 2006a). In adults, particularly those with genotypes that increase susceptibility to choline deficiency, low choline intake leads to fatty liver, elevated liver enzymes, and muscle abnormalities (Buchman *et al.*, 2001; Kohlmeier *et al.*, 2005). Low choline intake by women during pregnancy and lactation affects brain development and other important health parameters in offspring (Albright *et al.*, 2001; Zeisel, 2006a,b; Fischer *et al.*, 2007). Further discussions on the role of choline for critical biological functions and health outcomes are found later in this chapter.

Choline nutrition status can be assessed in several ways. Hepatic phosphocholine levels are highly correlated with dietary choline intake, are quite sensitive to even moderate choline deficiency, and can be measured via magnetic reso-

nance spectroscopy in humans (Pomfret *et al.*, 1990; Cohen *et al.*, 1995; da Costa *et al.*, 2005). Plasma concentrations of choline are also responsive to dietary intake; concentrations increase accordingly with intake of choline and decrease with a choline-inadequate diet (Burt *et al.*, 1980; Sheard *et al.*, 1986; Chawla *et al.*, 1989; Zeisel *et al.*, 1991; Buchman *et al.*, 1993). Studies in humans suggest plasma choline concentrations normally exhibit a two-fold variation in response to consumption of common foods (Zeisel *et al.*, 1980b). There appears to be an internal mechanism to keep choline concentrations above a certain minimal level: approximately 50–75% of normal, even after a week-long fast (Savendahl *et al.*, 1997). Plasma PtdCho concentrations also decrease with choline deficiency and have been looked at as another possible marker of choline status, however, this measure may not accurately reflect choline status if lipoprotein metabolism is perturbed. An individual with an elevation in homocysteine concentrations after a methionine load, who has adequate status for folate and vitamins B<sub>6</sub> and B<sub>12</sub>, should be suspected to be choline deficient (da Costa *et al.*, 2005).

In a recent study, metabolomic profiling of individuals was an effective measure that could predict which individuals would develop organ dysfunction when fed a choline-deficient diet. Metabolites in several pathways, including choline, lipid, carnitine, and amino acid metabolism, predicted which individuals would develop choline deficiency-related fatty liver (Sha *et al.*, 2010). Apparently, there is a complex and interrelated profile of metabolites that can define those at increased risk for the consequences of choline deficiency.

### **Individual Variation in Choline Requirements**

As discussed earlier, choline deficiency in humans leads to liver dysfunction and muscle damage. Susceptibility to organ damage due to choline deficiency is linked to genetics (da Costa *et al.*, 2006a). Dietary choline requirements are governed by an individual's ability to make choline *de novo*, and genes in choline and folate metabolism are intertwined in this process. Several very common single nucleotide polymorphisms (SNPs) in these genes have a profound impact on choline needs (Kohlmeier *et al.*, 2005; da Costa *et al.*, 2006a). For example, the PEMT rs12325817 SNP has an obvious effect in postmenopausal women where one allele is sufficient to increase the risk of developing choline deficiency-induced organ dysfunction by 25-fold (Kohlmeier *et al.*, 2005; da Costa *et al.*, 2006a; Fischer *et al.*, 2007). Another SNP in the PEMT gene

(rs7946) is present more often in people with fatty liver (Song *et al.*, 2005).

Premenopausal women who are carriers of the very common 5,10-methylenetetrahydrofolate dehydrogenase SNP (MTHFD1; rs2236225) are more than 15 times as likely as non-carriers to develop choline deficiency-induced organ dysfunction (Kohlmeier *et al.*, 2005). A choline intake exceeding current dietary recommendations also preserves markers of cellular methylation and attenuates DNA damage in a genetic subgroup of folate-compromised men with an SNP in the methylenetetrahydrofolate reductase *MTHFR* gene (Shin *et al.*, 2010). Based on these diet–gene interactions, the polymorphisms in choline-related genes seem to become important when humans eat diets low in choline content.

When deprived of dietary choline, 77% of men and 80% of postmenopausal women, develop fatty liver, liver damage or muscle damage, while only 44% of premenopausal women develop such signs of organ dysfunction (Kohlmeier *et al.*, 2005; da Costa *et al.*, 2006a; Fischer *et al.*, 2007). The promoter for the *PEMT* gene is estrogen responsive (da Costa *et al.*, 2006a; Resseguie *et al.*, 2007), and this likely explains why premenopausal women are more resistant to developing organ dysfunction when fed a choline-deficient diet (Resseguie *et al.*, 2007). Indeed, an SNP in the promoter region of *PEMT* (rs12325817) marks a haplotype with decreased estrogen-responsive induction of *PEMT* activity; likely there is a defect in the estrogen-responsive sites in the promoter of *PEMT*. These findings suggest that gender and estrogen status also influence individual requirements for choline.

We now have a much better set of parameters to define an individual's requirement for choline. These parameters include a combination of genetics, gender, and metabolomics, and there are likely additional mechanisms such as epigenetics and proteomics. Research to fine-tune our understanding of these signatures is ongoing.

## Role of Choline in Normal Cell and Organ Function

### Cell and Mitochondrial Membranes

Choline is an important component of membranes. Choline deficiency significantly decreases the PtdCho concentrations in plasma membranes (da Costa *et al.*, 1995; Yen *et al.*, 1999). Mitochondrial membranes are similarly affected, with resulting loss of mitochondrial membrane potential and leakage of reactive oxygen species (Vrablic

*et al.*, 2001; Albright *et al.*, 2003a). Several species of lipids are components of cell membranes. Docosahexaenoic acid (DHA) is an omega-3 polyunsaturated fatty acid important for cell membranes. It is an essential nutrient, and its metabolism is linked to choline metabolism. DHA and choline work together to promote healthy brain development by affecting gene expression and membrane signaling. The aberrant effects of choline deficiency on brain cell differentiation and apoptosis can be corrected by DHA supplementation via the normalization of membrane lipid composition (da Costa *et al.*, 2010).

Aside from the important role of choline in mitochondrial membrane integrity, several effects of choline on mitochondrial function are known. In choline-deficient rodents, mitochondria have abnormal morphology and bioenergetics (Teodoro *et al.*, 2008). Choline dehydrogenase (CHDH), one of the enzymes catalyzing the formation of betaine from choline, is located on the inner mitochondrial membrane. Deletion of the *Chdh* gene in mice impairs mitochondrial function, especially in sperm (Burg, 1995). These effects of choline on plasma and mitochondrial membranes are vital for normal cellular and organelle function.

### Gene Regulation

Through its function as a methyl donor, choline has important roles in regulation of gene expression via epigenetic mechanisms. Epigenetics refers to alterations in gene expression that do not involve changes to the DNA sequence. These modifications include methylation of DNA, several modifications to histones (proteins around which DNA is wrapped), imprinting, and small interfering RNA. Methylation is an important modification on proteins (histones) or DNA (typically on cytosines in regions where cytosines are followed by guanines) that regulates gene expression by altering chromatin structure or promoter activity, respectively (Dolinoy *et al.*, 2007).

Epigenetic patterns are heritable, but can change over an individual's lifetime. Since the inherited DNA code is generally not changeable, with the exception of rare mutations, epigenetics represents a mechanism by which gene expression can be altered differentially throughout one's lifetime. Epigenetics is responsive to many environmental cues including diet, exercise, smoking, and pollution, allowing for integration of environmental signals with genetics (Zeisel, 2009). Even though methylation patterns are inherited, a mother's diet during pregnancy can lead to changes that manifest in altered, permanent health out-

comes for offspring. Choline-deficiency during pregnancy induces changes in DNA methylation and gene expression in multiple tissues including brain and liver (Meck and Williams, 1999, 2003; Niculescu *et al.*, 2005; Mehedint *et al.*, 2010b). The functional consequences of choline-mediated epigenetic changes in gene expression are discussed in subsequent sections of this chapter.

### **Brain**

Perhaps the most comprehensive knowledge related to the role of choline in organ function concerns the brain. The perinatal period is a critical time for cholinergic organization of brain function (Meck *et al.*, 1988; Pyapali *et al.*, 1998; Albright *et al.*, 1999a; Jones *et al.*, 1999; Montoya *et al.*, 2000). In rats and mice, choline availability is very important for development of the hippocampus and septum (Meck *et al.*, 1988; Albright *et al.*, 1999b; Craciunescu *et al.*, 2003; Meck and Williams, 2003). In humans, hippocampal development occurs from day 56 of pregnancy through 4 years after birth (Dani *et al.*, 1997; Seress *et al.*, 2001); no experiments have yet been completed to determine if human hippocampal development can be influenced by dietary choline, though there is no reason to believe that it would not be. It should be noted that the hippocampus is one of the few areas of the brain in which nerve cells continue to multiply slowly in adults (Markakis and Gage, 1999; van Praag *et al.*, 1999).

During brain development, neural progenitor cells must proliferate, migrate, differentiate, and survive to form the structures that we recognize in adult brain. Choline regulates neural precursor cell proliferation, migration, differentiation, and apoptosis (Albright *et al.*, 1998, 1999a,b, 2001, 2003b; Craciunescu *et al.*, 2003). The development of the nervous system (neurogenesis) is coordinated with blood-vessel formation (angiogenesis) so that there is adequate delivery of nutrients and oxygen to developing neurons. In mice, choline deficiency during pregnancy prevents normal angiogenesis, and this is presumably tightly associated with the effects of choline deficiency on neurogenesis (Mehedint *et al.*, 2010a).

The effects of dietary choline during embryonic brain development are detectable later in life. Neurons of the hippocampus have larger soma and an increased number of primary and secondary basal dendritic branches in rodents exposed to extra choline during the perinatal period (Loy *et al.*, 1991; Williams *et al.*, 1998; Li *et al.*, 2004). In rodents, choline supplementation during critical periods of neonatal development can have long-term ben-

eficial effects on memory (Wong-Goodrich *et al.*, 2008). The likely mechanisms for these effects of choline involve DNA methylation, altered gene expression, and associated changes in stem-cell proliferation and differentiation (Zeisel, 2006b). In mice, choline deficiency during critical periods of brain development leads to impaired differentiation and function of brain cells due to global and gene-specific alterations in methylation (Niculescu *et al.*, 2006). These types of changes lead to irreversible changes in hippocampal function manifesting in impaired nerve cell potentiation, memory, and behavior that persist into adulthood (Meck and Williams, 1999, 2003; Niculescu *et al.*, 2005; Zeisel, 2009). Overall, substantial evidence exists to support the enduring nature of the changes in brain function induced by choline availability.

### **Liver**

Two key roles for choline in the normal function of the liver have been studied extensively. The first relates to gene expression. A diet devoid of methyl-group donors, including choline, leads to altered expression of proteins that are necessary for the DNA methylation process to function properly. These genetic alterations increase the risk of cancer and fat accumulation in the liver (Ghoshal *et al.*, 2006; Pogribny *et al.*, 2009). A second key role of choline in liver function involves lipid metabolism. The packaging and transport of lipids in the liver are dependent on the formation of very-low-density lipoprotein (VLDL). PtdCho, produced by PEMT in the liver, is indispensable for the export of triglycerides from the liver so they can be delivered to other tissues. Without this function of PEMT, due to either choline deficiency (Varela-Moreiras *et al.*, 1992; Buchman *et al.*, 2001; Kohlmeier *et al.*, 2005; da Costa *et al.*, 2006a) or gene deletion (Noga *et al.*, 2002; Zhu *et al.*, 2003), fat accumulates in the liver and this can lead to significant dysfunction. In addition to its function in the formation of PtdCho, PEMT is involved in regulating the flux of lipids between liver and plasma and the delivery of essential fatty acids (such as DHA) to tissues (Watkins *et al.*, 2003).

## **Choline in Human Health**

### **Birth Defects**

Inhibition of choline uptake and metabolism is associated with the development of NTDs in mice (Fisher *et al.*, 2001, 2002). Recent evidence suggests this may also be the case in humans: A retrospective case-control study

(400 cases and 400 controls) of periconceptional dietary intakes of choline in women in California found that women in the lowest quartile for daily dietary choline intake had four times the risk of having a baby with an NTD than did women in the highest quartile for intake (Shaw *et al.*, 2004). Elevated NTD risk was also associated with lower concentrations of serum total choline in a folate-fortified population (Shaw *et al.*, 2009). Additional birth defects have been associated with choline deficiency including cleft lip (Shaw *et al.*, 2006), hypospadias (defect in male urethra) (Carmichael *et al.*, 2009), heart defects (Chan *et al.*, 2010), and congenital diaphragmatic hernia (Yang *et al.*, 2008).

### **Cancer**

Choline is the only nutrient for which dietary deficiency causes development of hepatocarcinomas without any known carcinogen. Interestingly, choline-deficient rats not only have a higher incidence of spontaneous hepatocarcinoma, but they are markedly sensitized to the effects of administered carcinogens. Choline deficiency is therefore considered to stimulate both cancer-initiating and cancer-promoting activities (Newberne and Rogers, 1986). Breast cancer also has been associated with choline deficiency. In the first study to examine the association between choline and breast cancer, Xu *et al.* (2008) found that breast cancer risk was reduced by 24% among women with high dietary intakes of choline and was increased in women with the PEMT rs12325817 SNP (previously discussed; reduces estrogen-induced PEMT activity). Importantly, a subsequent analysis determined that breast cancer mortality was reduced by high intakes of choline and betaine and by an SNP in the betaine homocysteine methyltransferase gene (BHMT; rs3733890; catalyzes the synthesis of methionine from betaine and homocysteine) (Xu *et al.*, 2009).

### **Neurological Disorders**

In addition to the role of choline in brain development, behavior, and memory (Zeisel, 2006b), there are suggestions that choline supplementation may be a useful treatment in several neurological disorders. Choline and DHA promote neuronal membrane and synapse formation, and diminish the accumulation of amyloid plaque in brain, especially when used in combination (Kamphuis and Wurtman, 2009). These mechanisms are of particular importance in ameliorating the cognitive derangements associated with Alzheimer's disease (Kamphuis and Wurtman, 2009). In addition, Citicoline (cytidine 5'-

diphosphocholine), a choline-containing molecule, is being used to treat stroke and traumatic brain injury (Conant and Schauss, 2004). A recent study in a mouse model of Down syndrome reported improvements in cognitive function and emotion regulation in mice born to mothers supplemented with choline during the perinatal period (Moon *et al.*, 2010). Other studies in mice suggest that perinatal choline supplementation may reduce the neurological consequences of fetal alcohol syndrome (Thomas *et al.*, 2007).

### **Fatty Liver**

As discussed earlier, one important function of the liver is the maintenance of whole-body lipid homeostasis. Choline, especially via its metabolite, PtdCho, is essential for the export of lipids from the liver (Noga *et al.*, 2002; Noga and Vance, 2003). In animal models and humans, choline deficiency is associated with fat accumulation in the liver (steatosis). Such non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disorder, occurring in 30% of the general population and 65–90% of overweight or obese individuals (Ong and Younossi, 2007). Although choline deficiency in humans is associated with hepatic steatosis, not all individuals are affected equally. Thus far, genetics and gender have been implicated as factors that mediate risk (Kohlmeier *et al.*, 2005; Song *et al.*, 2005; da Costa *et al.*, 2006a; Fischer *et al.*, 2007). However, the mechanisms by which these factors lead to NAFLD, additional factors that are involved, and how these factors are associated with the progression of benign NAFLD to more severe liver disease, are still unknown. It is important to note that fatty liver is tightly associated with metabolic syndrome, obesity, insulin resistance and cardiovascular disease (Moore, 2010), providing further evidence that choline-mediated pathways could have far reaching effects on chronic disease.

### **Heart Disease**

Little is known about the health consequences of choline overnutrition, but emerging evidence suggests this is a cause of concern. Dietary intake of choline results in bacteria-mediated formation of trimethylamine (TMA) which is then absorbed and oxidized by flavin monooxygenases in the liver to form TMAO. These metabolites of choline impart a fishy body odor after very large doses of choline (grams) (Institute of Medicine and National Academy of Sciences USA, 1998; Zeisel *et al.*, 1983). Of greater concern, small molecules formed from dietary

choline are associated with increased risk for cardiovascular disease (Wang *et al.*, 2011). Three metabolites present in the blood of humans (choline, betaine and trimethylamine N-oxide (TMAO) predicted risk for atherosclerotic cardiovascular disease (CVD) in an independent large clinical cohort (Wang *et al.*, 2011). In addition, dietary supplementation of apolipoprotein E knockout mice with choline or TMAO increased the development of atherosclerotic lesions. TMAO, formed by gut bacteria from the choline metabolite trimethylamine (TMA) was the critical intermediate responsible for the atherosclerotic effects of dietary choline as the atherosclerotic effect of choline did not occur in germ-free mice or in mice where there was antibiotic-suppression of intestinal microbiome, while TMAO retained its atherogenic effect in these mice (Wang *et al.*, 2011). Additional side effects observed due to excess dietary choline include vomiting, sweating, gastrointestinal side effects, and hypotension. A tolerable upper limit of choline for adults has been set at 3.5 g/day (Institute of Medicine and National Academy of Sciences USA, 1998), but at that time, link between dietary choline and CVD was not known. It is evident that research is needed to delineate the individual upper limit for dietary choline.

## Future Directions

The decades of research invested in understanding the biological functions of choline in humans have resulted in an impressive body of knowledge about the health implications of choline insufficiency and supplementation. There are several areas of research that warrant further attention to enhance our understanding of the choline needs of individuals and the potential to use this nutrient, and its derivatives, as therapeutic agents. For example, little is known about the role of choline in inflammation, and epidemiological studies have linked low dietary choline intake to higher concentrations of proinflammatory markers (Detopoulou *et al.*, 2008; Fargnoli *et al.*, 2008). Another area where additional research is needed is assessment of the prevalence of choline variants in large populations. Thus far, most of our knowledge about choline variants, particularly as they relate to the role of choline deficiency and organ function, stems from populations in North Carolina. As we broaden our knowledge, it will be important for groups of researchers around the world to assess the impact of ethnicity and environment on the prevalence and consequences of

choline-related SNPs. This will greatly enhance our ability to evaluate the role of choline in disease. We are only beginning to understand the wide-reaching effects of choline in systems biology as a direct result of its role as a methyl donor. The implications of epigenetics in health and disease are becoming increasingly evident, and the specific mechanisms by which choline is involved remain to be elucidated. The interesting links between genetics and metabolomics in determining risk for diseases associated with choline deficiency are initial examples of the complexities of the signatures that we will need to define to distinguish those who are at risk of disease from those who are not. This is true not just for choline, but for all nutrients. Finally, the observations that dietary choline influences brain development and can perhaps moderate the severity of several neurological diseases is mostly based on data obtained in rodents. Human studies confirming these effects are needed. The future of choline and nutrition research in general is exciting and complex. The hope is to ultimately understand how all nutrients act in concert with systems biology to determine the health outcomes of individuals.

## DIETARY FLAVONOIDS

GARY WILLIAMSON, PhD

*University of Leeds, Leeds, UK*

### Summary

Flavonoids are found in a wide variety of plant-based foods and beverages. Intake varies widely between individuals but is typically several hundred milligrams per day. The pathways of absorption are quite well understood and the amount absorbed and excreted for many flavonoids has been documented. For many flavonoids, a substantial percentage of the dose is absorbed, but is also rapidly metabolized and excreted within 24 hours. Some flavonoids such as proanthocyanidins and anthocyanins are poorly absorbed intact, but their catabolites are very efficiently absorbed after microbial biotransformation. Flavonoids are chemical antioxidants, but work *in vivo* primarily by indirect antioxidant mechanisms, such as inhibition of oxidative enzymes and induction of antioxidant defenses. Certain flavonoids modulate sugar metabolism, blood pressure, LDL cholesterol, and platelet function. Together, these mechanisms reduce the risk of cardiovascular disease, and possibly type 2 diabetes and inflammatory diseases, as supported by human intervention and epidemiological studies. Future work should focus on long-term dietary dose intervention studies and also consider the introduction of some form of recommended intake values for flavonoids.

### Introduction

Flavonoids are present in all diets where plants, or foods or beverages derived from plants, are present. In plants, they protect against stress and excess ultraviolet light exposure. They also are responsible for the color of most fruits and flowers, and also contribute to the taste sensation of foods such as red wine, tea, coffee, and chocolate, as well as fruits. Flavonoids possess antioxidant activity *in vitro* and affect cellular and molecular processes to provide health benefits by reducing the risk of chronic diseases

such as cardiovascular disease. Over the last 20 years there has been an enormous and growing interest in this class of compounds which have also been referred to as polyphenols, phytonutrients, non-nutrients, protective factors, dietary bioactives, and phytochemicals. Although there are many thousands of compounds in the plant kingdom, only a handful are present in significant amounts in the diet of most humans. This review will focus only on the flavonoids that are most abundant and important in the Western diet, and not on the minor or rare compounds, or those that are present in more exotic foods.

**FIG. 27.1** Representative chemical structures and content of commonly occurring flavonoid-rich foods in mg per 100g fresh weight: flavanols ([epi]catechin, procyanidins, epigallocatechin [EGC], and epigallocatechin gallate [EGCG]); anthocyanins (cyanidin, delphinidin, malvidin, pelargonidin, and petunidin); flavonols (quercetin); and flavanones (hesperidin and naringenin). All data are from the phenol explorer database ([www.phenol-explorer.eu](http://www.phenol-explorer.eu)) and are in aglycone equivalents.

Catechins (including galloylated catechins and procyanidins), selected anthocyanins, quercetin, and citrus flavanones (hesperetin and naringenin) are covered, but not isoflavones (present only in soya), and phenolic compounds which are not flavonoids such as hydroxycinnamates (widely present in food and drinks, especially coffee, but less work has been done on these lower molecular weight compounds).

### Classification and Distribution in Foods

Figure 27.1 shows the flavonoid content of foods and some representative chemical structures of the most abundant flavonoids. They can be considered as minor constituents

as the maximum amount in foods is always less than 1%, although the biological activity can be quite high. Figure 27.1 does not include the higher molecular weight tannins, which are not well defined at a molecular level, such as the thearubigens and theaflavins in black tea (Lewis *et al.*, 1998), and the larger procyanidins, which have only been measured in a limited range of foods such as apples (Huemmer *et al.*, 2008) and cocoa (Lazarus *et al.*, 1999). The foods highest in flavonoids are cocoa, berries, apples, onions, stone fruits, tea, citrus, and grapes. The intake of flavonoids is difficult to estimate, since the average intake will be very variable within the population. Estimates range from 26 mg/day of flavonols in the Dutch diet (Hertog *et al.*, 1993) to a median intake of total flavonoids

of 239 mg/day, with a very wide range of 0.6 to 3524 mg/day among 34708 US women (Cutler *et al.*, 2008). Mean pro(antho)cyanidin intake in the US population (>2 years old) was 58 mg/day, with the main contributions coming from consumption of apples (32%), chocolate (18%), and grapes (18%). The average consumption of 2- to 5-year-olds was 68 mg/day, for men >60 years old it was 71 mg/day, for 4- to 6-month-old infants 1.3 mg/day, and for 6- to 10-month-old infants 27 mg/day (Gu *et al.*, 2004). The mean intake of anthocyanins was also estimated in the United States to be 12.5 mg/day (Wu *et al.*, 2006). This value is surprisingly low and is subject to enormous inter-individual variation, since one portion of fresh blueberries contains 300–400 mg anthocyanins per 100 g fresh weight, but the stated “average” intake is only ~1 g blueberries per day. An individual consuming 100 g blueberries in a day will therefore consume ~30 times the average US consumption of anthocyanins (Wu *et al.*, 2006).

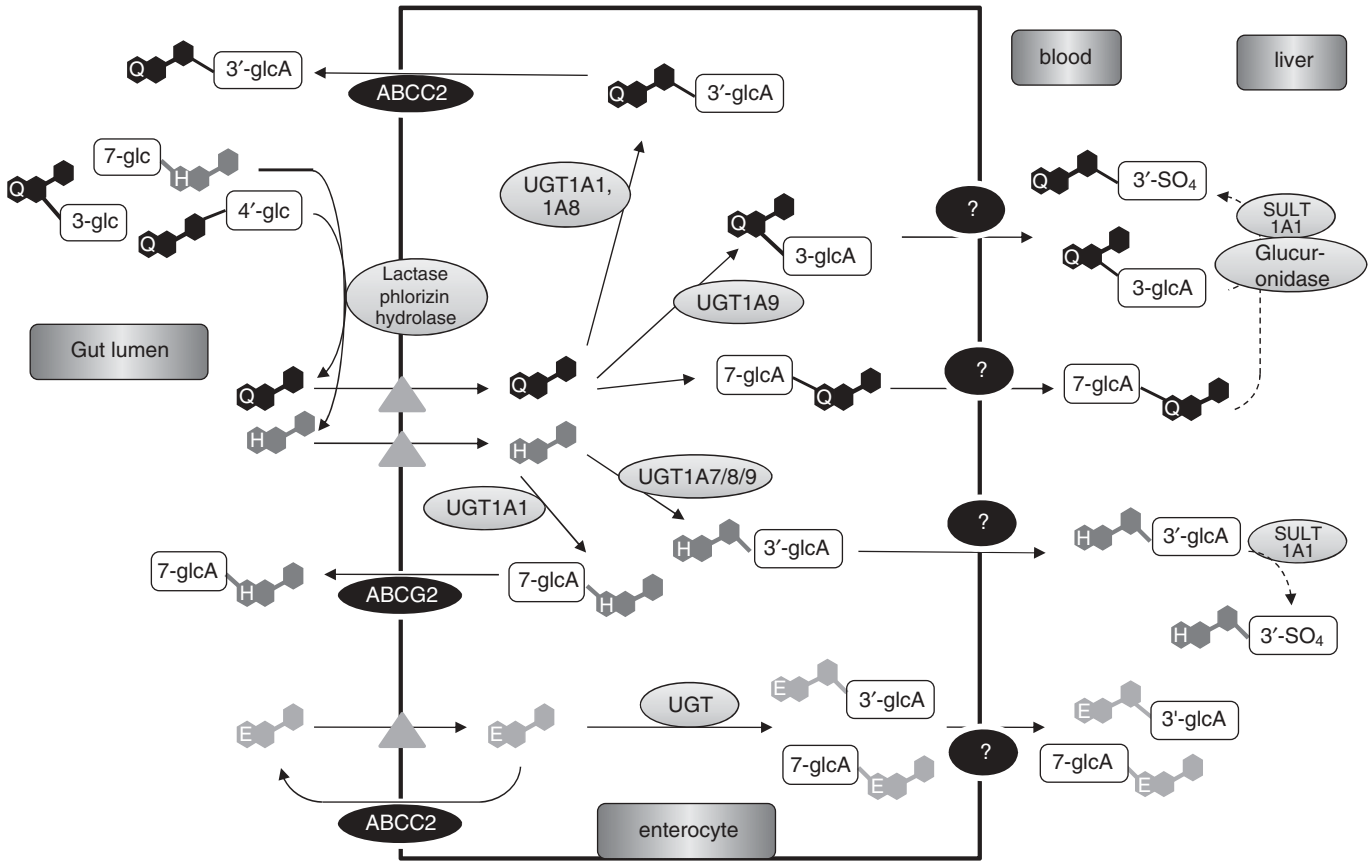

### Absorption, Metabolism, and Excretion – Quantitative and Mechanistic Aspects

The principles controlling absorption and metabolism in the small intestine are now broadly understood for common flavonoids. After consumption of food, flavonoids are generally stable in the stomach (Rios *et al.*, 2002) and reach the small intestine unchanged. Figure 27.2 shows the metabolic pathways for quercetin, epicatechin, and hesperetin in the small intestine and liver, for which the mechanisms of uptake, conjugation, and export are now fairly well established. The pathways shown in Figure 27.2 are when the flavonoid is either unconjugated in the food or is glucosylated. When other sugars are present, this can affect dramatically the site of absorption. Other flavonoids, such as anthocyanins, procyanidins, and other flavonoids with a sugar attached which is not hydrolysable by mammalian enzymes such as rhamnose, are not absorbed in the small intestine, but pass through and enter the colon where they are absorbed after microbial metabolism into lower molecular weight compounds (Williamson and Clifford, 2010). Absorption into the blood is often measured as a pharmacokinetic profile after consumption of a single “dose,” usually in the form of a flavonoid-rich food. For simplicity, this is often presented as a total of all forms (free plus unconjugated). The  $C_{\max}$  (concentration at the time point corresponding to maximum concentration of a compound at any time point in a pharmacokinetic study) for various flavonoids has been reported in many papers

(Williamson and Manach, 2005), and an updated indication for various flavonoids is shown in Figure 27.3. The values are normalized for dose assuming a linear relationship, and indicate only the concentration of the parent compound (normally after deconjugation with  $\beta$ -glucuronidase and sulfatase). Quercetin and hesperetin glucosides are the most efficiently absorbed (but after deglycosylation since they are not present in plasma as glucosides [Day and Williamson, 2001]), and epicatechin and epigallocatechin are also well absorbed. These compounds are all absorbed in the small intestine and have a relatively rapid  $T_{\max}$  (time point corresponding to maximum concentration of a compound at any time point in a pharmacokinetic study) of between 0.5 and 2 hours. Hesperidin, naringin, and rutin (hesperetin, naringenin, and quercetin, respectively, linked to glucose and rhamnose) are all absorbed less efficiently, and exhibit a higher  $T_{\max}$  of ~6 hours, indicating absorption in the colon after removal of the rhamnose by microflora. Anthocyanins are very poorly absorbed in the intact form and appear to be the only flavonoid class which are absorbed and appear in plasma as the glucosylated form but at an extremely low level (Felgines *et al.*, 2007) in addition to some glucuronide forms (Mullen *et al.*, 2008). Intact procyanidins are only just detectable in plasma after consumption of large quantities of the compound (Holt *et al.*, 2002). After absorption, the flavonoids circulate in the blood as a mixture of conjugated forms, such as glucuronides, sulfates, or methylated forms (Williamson *et al.*, 2005). The amount of unconjugated forms is generally small, with some exceptions, such as epigallocatechin gallate where ~90% of the total plasma EGCG was unconjugated after consumption of green tea (Chow *et al.*, 2003).

Flavonoids can be excreted in the urine or bile. The amount in urine can be used as a biomarker of flavonoid intake (Perez-Jimenez *et al.*, 2010). The percentage excretion in urine is an indicator of the *minimum* amount that has been absorbed. Some flavonoids such as quercetin are well absorbed but only a few percent of the dose appears in urine, since the majority is excreted via the bile or catabolized by gut microflora. The food matrix has a substantial effect on the absorption of flavonoids, where factors such as fat content affect bioavailability (Scholz and Williamson, 2007). Many flavonoids are degraded during food processing, especially processes that involve alkaline pH conditions (Gil-Izquierdo *et al.*, 2003).

The amount absorbed in the small intestine has been estimated for some flavonoids using the ileostomy model.

**FIG. 27.2** Pathways of absorption of the flavonoids, quercetin, hesperetin, and epicatechin. Quercetin (Q) is glucosylated (glc) in some foods and is deglycosylated by lactase phlorizin hydrolase (Day *et al.*, 2000c; Sesink *et al.*, 2003). The resulting quercetin aglycone passively diffuses across the apical membrane of enterocytes. Hesperetin-7-O-glucoside also follows the same pathway (hesperetin aglycone is shown by the letter H). Once inside the cell, quercetin and hesperetin can be conjugated with glucuronic acid by the action of defined isoforms of UDP-glucuronosyl transferases (UGT): for hesperetin, 1A1 preferentially glucuronidates position 7, whereas isoforms 1A7, 1A8, and 1A9 favor position 3'; for quercetin, 1A9 is more active at the 3 and 7 positions (Chen *et al.*, 2005; Brand *et al.*, 2010). The resulting conjugates can be absorbed by as yet unknown transporters on the basolateral membrane, or effluxed back into the intestinal lumen via ABC transporters (Brand *et al.*, 2007, 2008). Epicatechin is not glycosylated and enters the cell by passive diffusion, whereupon it can be rapidly effluxed by ABC2 transporter (Zhang *et al.*, 2004). Alternatively it can be glucuronidated and transported into the blood. It is likely that some sulfation and methylation also take place in the enterocytes. The absorbed compounds can be further processed in the liver to produce further conjugates (O'Leary *et al.*, 2003).

These are patients who have had their colon removed owing to a disease, and the contents of the small intestine are ejected into a pouch. The contents of this can be collected and analysed, and the amount compared with the original dose. For quercetin glucosides in onions, the amount absorbed was estimated to be 52%, but rutin absorption (for reasons stated above) was much lower

(Hollman *et al.*, 1995). For flavonols administered in green tea, the amount absorbed in the small intestine was ~30% (Stalmach *et al.*, 2010). However, identification of metabolites shows that an additional ~37% of the dose was absorbed into the enterocyte and effluxed back into the gut lumen as conjugates. Less than 10% of procyanidins were apparently absorbed in the ileostomy model

**FIG. 27.3** Plasma levels of flavonoids. The values are presented as  $C_{max}$  values ( $\mu\text{M}$ ) normalized to a 50 mg dose of aglycone (data from [Manach *et al.*, 2005]; except for hesperetin-7-*O*-glucoside [Nielsen *et al.*, 2005] and for EGCG/EGC [calculated as weighted averages from Henning *et al.* [2004], Stalmach *et al.* [2009], and Yang *et al.* [1998]]. Form of flavonoids present in plasma: A, unknown free and conjugated procyanidin dimers (Holt *et al.*, 2002); B, anthocyanin glycosides, free and conjugated with glucuronic acid (Felgines *et al.*, 2003); C, EGCG, mainly unconjugated; D, quercetin-3-*O*-glucuronide, quercetin-3'-*O*-sulfate and some methylated derivatives (Day *et al.*, 2001; Mullen *et al.*, 2004); E, EGC conjugates, especially methylated EGC derivatives (Lee *et al.*, 2002; Stalmach *et al.*, 2009); F, epicatechin conjugates such as epicatechin-3'-*O*-glucuronide (Natsume *et al.*, 2003); G, hesperetin-3'-*O*-glucuronide and hesperetin-3'-*O*-sulfate, with some hesperetin-7-*O*-glucuronide (Brett *et al.*, 2008; Bredsdorff *et al.*, 2010a); H, naringenin-4'-*O*-glucuronide and naringenin-7-*O*-glucuronide (Brett *et al.*, 2008; Bredsdorff *et al.*, 2010b).

(Kahle *et al.*, 2007), and less than 15% for anthocyanins (Kahle *et al.*, 2006). However, some of the data indicated a higher level of absorption (Kahle *et al.*, 2006), but for anthocyanins such as cyanidin-3-*O*-glucoside this could be due to inherent instability of the compound at physiological pH (Kay *et al.*, 2009).

It is now considered that the microbial metabolites contribute to the biological effects of dietary flavonoids (Williamson and Clifford, 2010). Flavonoids which are not absorbed in the small intestine reach the colon and are subject to extensive catabolism. Reactions that occur are dehydroxylation, reduction, ring cleavage, and hydroly-

ysis of esters and sugars. Although intact procyanidins are hardly absorbed, radiolabel studies in rodents have shown that ~80% of the microbial metabolites are absorbed and appear in the urine (Stoupi *et al.*, 2010). Equol is a microbial metabolite of the isoflavone, daidzein, and has increased biological activity compared with the parent compound (Setchell *et al.*, 2002). The main products in the colon from flavonoid catabolism are benzoic acids including protocatechuic acid, phenylacetic acids, and phenylpropionic acids, where the latter are mainly in the dihydro form, especially dihydrocaffeic acid, dihydroferulic acid, phenylpropionic acid, and hydroxyphenylpropionic acid. Some of these compounds can each reach millimolar concentrations in fecal water (Jenner *et al.*, 2005). Although some biological activities of these breakdown products are known (Williamson and Clifford, 2010), the activity of these lower molecular weight phenolics deserves further research in the future.

## Biological Effects of Flavonoids

There have now been several hundred human intervention studies on flavonoids and flavonoid-rich foods, and these have been the subject of several reviews (Manach *et al.*, 2005; Erdman *et al.*, 2007; Cooper *et al.*, 2008; Thieckle and Boschmann, 2009). The role of flavonoid-rich foods in health has also been supported by many epidemiological studies including meta-analyses comprising large total numbers of volunteers (Arab *et al.*, 2009). These studies support a general and consistent protection against heart disease and biomarkers of cardiovascular risk, although the evidence for protection against cancer is weaker. Intervention studies have generally been short term, high dose. However, health benefits of polyphenols in real life are likely due to long-term chronic exposure to relatively low doses, but these types of intervention studies are difficult to do. A 10% change in a biomarker for a year may be highly significant biologically, but a 10% measurement error is difficult to achieve for biomarker measurements. Therefore higher doses are used acutely and the data extrapolated to the longer term (Sies, 2010). In addition, inter-individual variation also contributes substantially to biomarker variability. For a flavonoid to exert a biological effect, it is necessary for the compound to reach the target site or to exert a secondary effect which in turn affects the target site. From bioavailability studies it is probable that flavonoids are not stored in the body. Studies on rodents have shown, for example, that radiolabeled quercetin is

extensively metabolized (Graf *et al.*, 2005) and that 80% of metabolites of procyanidins are excreted in the urine (Stoupi *et al.*, 2010). Effects of polyphenols are more conceptually comparable to those of drugs, where an effect is produced and then the compound is excreted, rather than to those of vitamins or minerals, which are stored and can therefore be defined by a status measurement. Thus any effects measured *in vitro* only show a potential mechanism which must then be demonstrated *in vivo*. There are many thousands of studies on the action of flavonoids *in vitro*, utilizing a wide range of concentrations. Since flavonoids are at low micromolar concentrations *in vivo*, it is usually considered that an effect should be seen *in vitro* at  $<10\mu\text{M}$  in order for it to have potential dietary relevance (Kroon *et al.*, 2004).

### Direct Antioxidant Effects

Many biological activities of flavonoids have been reported *in vitro*. The most commonly reported in the last 20 years has been antioxidant activity, and there have been many papers describing this activity, including structure–function relationships (Rice-Evans *et al.*, 1995). Flavonoids can act as antioxidants by chelating iron, scavenging free radical species, donating an electron to an oxidant, scavenging peroxy radicals, and inhibiting lipid peroxidation. These chemical characteristics led to the development of antioxidant assays to measure activity *in vitro*, such as TEAC (Trolox equivalent antioxidant capacity), TRAP (total reactive antioxidant potential), and ORAC (oxygen radical absorbance capacity). These assays measure a chemical aspect of the test compound (Huang *et al.*, 2005) such as the ORAC assay, which is based on a hydrogen atom transfer reaction mechanism. Many foods have been characterized by these methods (Wu *et al.*, 2004) and they are reasonably good indicators of total phenolic content. In addition, some of these methods, especially FRAP (ferric reducing ability of plasma), have also been used to measure the antioxidant activity of plasma (Romay *et al.*, 1996; Prior, 2004), and many studies have reported the effect of flavonoid consumption on plasma antioxidant activity (Cao *et al.*, 1998). However, endogenous antioxidants such as albumin, uric acid, and vitamin C, present at high concentrations, dominate the antioxidant activity of blood. Since the bioavailability of flavonoids is known, and concentrations are in the low micromolar range, these concentrations will not have a direct effect on the plasma

antioxidant activity, and the concept of using these assays *in vivo* has received major criticism (Sies, 2007). It is now considered that more specific biochemical measurements are useful in determining the effect of flavonoids *in vivo* rather than a global antioxidant estimation. The antioxidant assays are still useful for measuring total redox active compounds (dominated by flavonoids, phenolic acids, (ellagi)tannins, and comparable compounds) in foods (Wu *et al.*, 2004). The advantage of the global antioxidant effect is that the concept is simple. In fact the action of flavonoids is more complex than this, and it is unlikely that direct antioxidant effects are relevant *in vivo*. However, flavonoids *in vivo* can affect oxidative status, antioxidant enzymes, and oxidative processes, and so act as potent indirect antioxidants by influencing cell function. The overall effect of flavonoids *in vivo* can still be an antioxidant one, but by specific mechanisms rather than a generalized, global effect. Some of these more specific effects are discussed below. However, there is not enough space to discuss all effects, and so only certain well studied effects are considered that are most likely to be physiological.

### Effects in the Gut Lumen

There is a high concentration of flavonoids in the lumen of the gastrointestinal tract after consumption of flavonoid-rich foods, and a high concentration of lower molecular weight phenolics, derived at least partly from flavonoid catabolism, in the colon (Jenner *et al.*, 2005). A portion (100 g) of blackberries might contain 120 mg of flavonoids (Figure 27.3). If consumed with a small drink of  $\sim 200\text{ ml}$ , then this equates to very approximately  $\sim 1\text{ mM}$  concentration of total flavonoids. This is of course diluted by digestive fluids but the exposure of the gut tissues can therefore be several hundred micromolar. This concentration would elicit responses in the various cells of the small intestine (Erlejan *et al.*, 2008; Romier-Crouzet *et al.*, 2009), and may also affect the action of digestive enzymes.

### Effects in the Gut Lumen Related to Diabetes

The postprandial glucose spike, particularly influenced by the transporter GLUT2, can affect endothelial function (Ceriello *et al.*, 2008; Kellett *et al.*, 2008) and oxidative stress (Sies *et al.*, 2005), and is considered undesirable

for diabetics and those with metabolic syndrome. Sugar absorption, also important for regulating many other physiological functions, is influenced by flavonoids, with effects on the glycemic index and blood glucose levels. In vitro studies have shown that certain flavonoids inhibit  $\alpha$ -amylase (Lo *et al.*, 2008), interact with the sugar transporters SGLT1 (Gee *et al.*, 1998) and GLUT2 (Song *et al.*, 2002), and inhibit sucrose-isomaltase (Ramachandra *et al.*, 2005). This is supported by studies in vitro on volunteers, where effects on insulin are also seen, involving various flavonoid-rich foods such as cranberry (Wilson *et al.*, 2008), black tea (Bryans *et al.*, 2007), and dark chocolate (Grassi *et al.*, 2008). These effects have been reviewed (Cazarolli *et al.*, 2008) and may play an important role in the metabolic syndrome and type 2 diabetes. Flavonoids may also reduce reactive oxygen species in the gut (Halliwell, 2007), thereby protecting gut cells against oxidative damage (Erlejman *et al.*, 2006), and also affect barrier function through modification of tight junctions (Suzuki and Hara, 2009).

There is also evidence from intervention studies that certain flavonoids, such as grape seed extract, can affect markers of diabetes risk in type 2 diabetic patients (Kar *et al.*, 2009), and pycnogenol (a flavonoid-rich pine bark extract) can improve metabolic markers in diabetic patients (Zibadi *et al.*, 2008). Kuna Indians with very high flavonol intake have lower rates of diabetes and heart disease (Bayard *et al.*, 2007), although not all epidemiological studies show an effect of flavonoids at reducing diabetes risk (Song *et al.*, 2005).

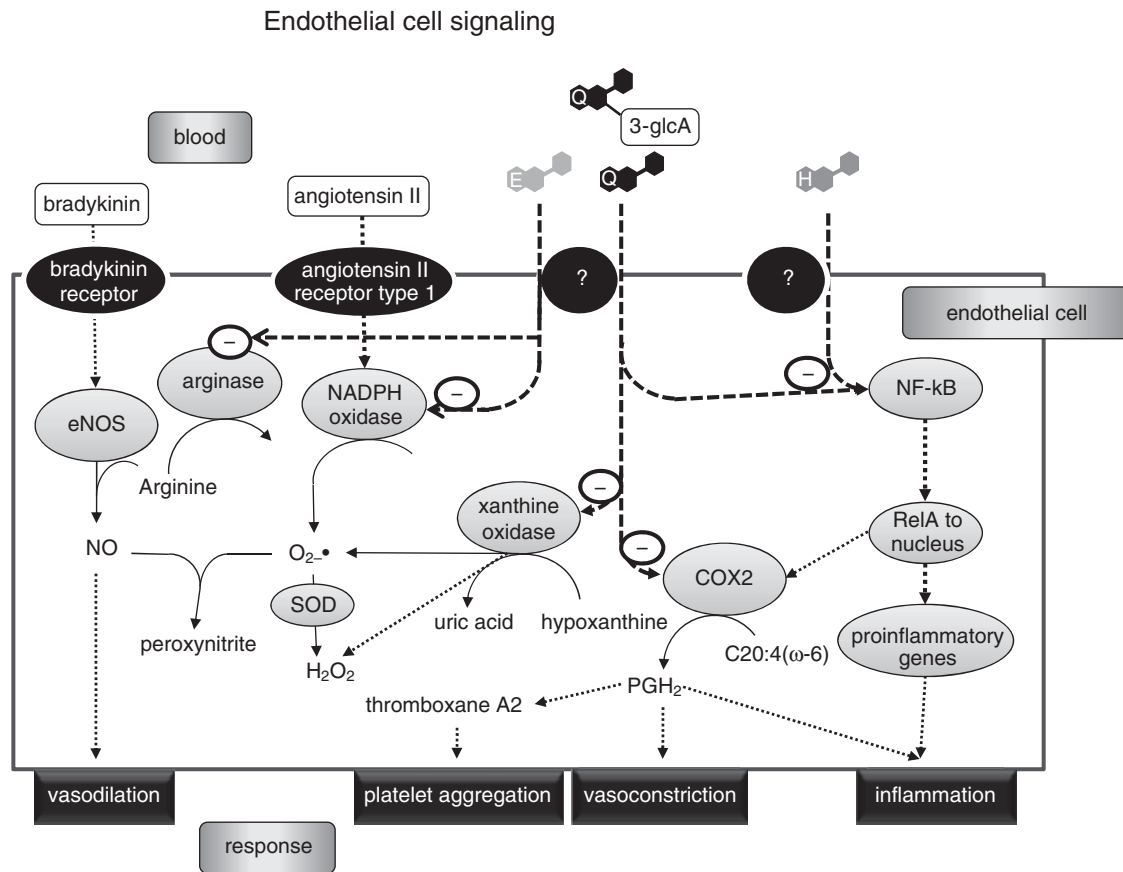

## Systemic Effects Related to Cardiovascular Disease

There is now a substantial body of evidence, both in vivo and mechanistic in vitro, to show that flavonoids affect risk factors for cardiovascular disease. Several mechanisms of action have been elucidated to explain the effects, with support from human intervention studies and epidemiology. One of the important indicators of cardiovascular risk is endothelial function (Widlansky *et al.*, 2003a) and this biomarker is disrupted by factors such as a high-fat diet (Vogel *et al.*, 1997). Protective effects on endothelial function by flavonoids have been widely reported, especially for the flavanol, epicatechin. Improvement of endothelial function is seen in vivo in volunteers from red wine (Cuevas *et al.*, 2000), tea (Vita, 2003), and cocoa (Heiss

*et al.*, 2003), and by pure epicatechin (Schroeter *et al.*, 2006). The mechanism of modulation of endothelial function is summarized in Figure 27.4. Epicatechin, and especially its metabolite, methylepicatechin, inhibit NADPH oxidase (Steffen *et al.*, 2007), inhibit arginase (Schnorr *et al.*, 2008), and modulate nitric oxide concentration in endothelial cells. This affects cellular pathways resulting in vasodilatation and improvement of endothelial function. Other complementary mechanisms also operate within the cell. Xanthine oxidase produces superoxide and this enzyme is inhibited by quercetin metabolites found in vivo (Day *et al.*, 2000b). It has been shown that cyclooxygenase-2 (COX-2) inhibition improves endothelial function (Widlansky *et al.*, 2003b), and some flavonoids are potent COX-2 inhibitors at levels of both enzyme activity and transcription (Michihiro *et al.*, 2000; O'Leary *et al.*, 2004). Inhibition of COX-2 and NF- $\kappa$ B leads to reduced inflammation, improved platelet activity, and less vasoconstriction, thus leading to improved endothelial function. Flavanones, flavonols, and flavanols suppress NF- $\kappa$ B activity (Frei and Higdon, 2003; Kim *et al.*, 2006; Min *et al.*, 2007). Endothelial function has been shown to be improved by dark chocolate in many intervention studies including those on hypertensive patients (Grassi *et al.*, 2008), young soccer players (Fraga *et al.*, 2005), and smokers (Heiss *et al.*, 2005), and by green tea flavanols in healthy women (Lorenz *et al.*, 2007). A meta-analysis of 133 intervention studies (Hooper *et al.*, 2008) has supported these effects. It is concluded that many flavonoid-rich foods can improve endothelial function via subtle effects on several cellular targets.

Another parameter of cardiovascular disease risk, blood pressure (Bogers *et al.*, 2007), is decreased by flavonoids and flavonoid-rich foods in various subjects including glucose-intolerant, hypertensive patients (Hooper *et al.*, 2008; Grassi *et al.*, 2010). Part of this activity may be via inhibition of angiotensin converting enzyme (Actis-Goretta *et al.*, 2003). Platelet function is another risk factor and is affected by flavonoids (Vita, 2005), and there was a suppressive effect of cocoa flavanols on platelet reactivity in human subjects (Keevil *et al.*, 2000). Red grape juice has more effect than citrus juices on platelets in volunteers, suggesting that flavanols are more effective than flavanones (Rein *et al.*, 2000); flavonols (quercetin) are also active on platelets after oral consumption in vivo (Hubbard *et al.*, 2004). Cardiovascular disease is also influenced by lipid metabolism, and LDL oxidation and

**FIG. 27.4** Effect of flavonoids on endothelial cell signaling. Several compounds in blood can affect endothelial cell function. Flavonoids and their conjugates/metabolites can inhibit intracellular oxidative enzymes such as xanthine oxidase (Day *et al.*, 2000a), NADPH oxidase (Steffen *et al.*, 2007), NF-κB (Kim *et al.*, 2006), and cyclooxygenase 2 (COX2) (O’Leary *et al.*, 2004). Modification of these targets affects processes related to cardiovascular disease risk, such as vasodilation and endothelial function.

cholesterol levels are markers of risk (Verhoye and Langlois, 2009). Effects on lipid metabolism have been reported *in vivo* in rodents (Odbayar *et al.*, 2006), including beneficial effects on cholesterol and LDL oxidation in humans summarized in Williamson and Manach (2005). There is an improvement of lipid profile in hyperlipidemic patients (Esmailzadeh *et al.*, 2004), and hesperidin reduces cholesterol levels in mice (Jeong *et al.*, 2003).

The protective effect of flavonoids is supported by epidemiological studies. For example, tea flavonoids protect against stroke in epidemiological meta-analyses (Arab *et al.*, 2009), and various flavonoids protected against risk of cardiovascular disease-induced death in 34 400 postmenopausal women (Mink *et al.*, 2007).

## Systemic Effects Related to Inflammation

Chronic inflammation is associated with obesity, arthritis, Crohn’s disease, and ulcerative colitis, and may be influenced by diet, including flavonoids with anti-inflammatory effects (Pan *et al.*, 2010). Although many animal studies report an effect of flavonoids on acute inflammation, it is unlikely that acute inflammation would be affected by normal dietary levels in humans. However, some epidemiological studies support an effect against chronic inflammation, and there is an inverse association of flavonoid intake with C-reactive protein (a marker of inflammation) in a US population (Chun *et al.*, 2008). In animal

models, microbial catabolites of flavanones are anti-inflammatory (Larrosa *et al.*, 2009), and grape-seed pro-cyanidins modify cytokine expression in rats fed a high-fat diet (Terra *et al.*, 2009). Effect of flavonoids on inflammation in humans has been reviewed (Rahman *et al.*, 2006; Biesalski, 2007).

## Detoxification and Carcinogenesis

Cells *in vivo* are continuously subject to stresses from endogenous metabolism as well as exogenous compounds, and many defense mechanisms are in place to protect the cell. Detoxification reactions are important defenses in this respect. Phase 2 enzymes catalyze the conjugation of xenobiotics (Prester and Talalay, 1995) and hence improve their solubility and excretion. Phase 2 enzymes are also important as defense against carcinogens, and induction of these enzymes has been proposed to reduce the risk of carcinogenesis (Prester *et al.*, 1993; Cornblatt *et al.*, 2007). Flavonoids, especially quercetin, affect detoxification mechanisms and modulate the effect of toxic insults (Uda *et al.*, 1997). *In vitro*, flavonols, especially quercetin, induce cellular antioxidant defenses via nrf2 and the ARE (Tanigawa *et al.*, 2007; Arredondo *et al.*, 2010). Other detoxification reactions have been observed including effects of some metabolites. For example, quercetin and quercetin 3'-sulfate opposed glyceryl trinitrate-induced tolerance *in vitro*, and quercetin selectively enhanced cyclic-GMP-dependent relaxation (Suri *et al.*, 2010). However, these effects have been demonstrated in rodents and cells, where protective effects against toxic insults are often observed (Anjaneyulu and Chopra, 2003; Dihal *et al.*, 2006), but very few human studies have been performed in this area. The consequence *in vitro* is lowered damage to DNA. This protection is observed by, for example, apple extracts (Bellion *et al.*, 2010). Other mechanisms have also been proposed, such as (-)-epigallocatechin-3-gallate inhibition of membrane receptor (Met) signaling, proliferation, and invasiveness in human colon cancer cells (Larsen and Dashwood, 2010), and protection by hesperetin against aberrant crypts in dimethylhydrazine-induced colon carcinogenesis in rats (Aranganathan *et al.*, 2008).

There are very few reported studies on flavonoids and carcinogenesis in human intervention studies, and these studies are often confounded by inter-individual variation (Wilms *et al.*, 2007). There are some epidemiological studies but the evidence for reduction in the risk of cancer

is ambiguous (Neuhouser, 2004; Fink *et al.*, 2007; Arts, 2008; Wang and Stoner, 2008) or shows no effect (Wang *et al.*, 2009).

## Effect of Flavonoids on Neurodegenerative Diseases

This is an area of much interest, but there is only limited data at the current time. Most research has been done on anthocyanin-rich foods such as berries (Joseph *et al.*, 2009; Spencer, 2009). Several mechanisms have been suggested, and it has been shown that quercetin and some metabolites affect cell signaling in neurons (Spencer *et al.*, 2003).

## Future Directions

There is still a need for more human intervention studies, especially using equivalent experimental foods containing a high content and with an absence of flavonoids, and for human intervention studies using intermediate biomarkers of chronic exposure and effects. The field would be advanced by standardization of analytical methods for flavonoids in food and in biological samples, and by better designed *in vitro* experiments, especially using combinations that could occur and be found *in vivo*. An obvious gap in bioavailability is the possible role of active transporters in tissue uptake. The focus should be to better understand and develop the effects of flavonoids on the main targets of action. Finally, communication of nutritional issues to the public could be improved by the development of recommended intake values for flavonoids, perhaps based around the 5-a-day recommendation.

## CALCIUM

CONNIE M. WEAVER, PhD

*Purdue University, West Lafayette, Indiana, USA*

### Summary

Calcium is the most abundant mineral in the body, existing primarily in the skeleton where it serves a structure–function role but also serves as a reserve when dietary calcium is inadequate. All homeostatic mechanisms are evolved to maintain constant serum calcium levels to ensure cell signal transmission. Dietary calcium intakes around the world are below recommended intakes. Concern over risk of osteoporosis has public health messages and clinical guidelines calling for use of calcium supplements. Consequently, calcium intakes are increasing, but heavy supplement use is raising concerns for increased risk of adverse events. Yet, the incidence of osteoporosis continues to climb, with suboptimal development of peak bone mass during growth and loss of bone later in life, periods when diet and physical activity play important roles.

### Introduction

Calcium is the most abundant mineral in the body, with >99% in the skeleton. The skeleton is a functional reserve that supports our mobility and can be drawn upon during periods of dietary inadequacy of calcium. Because essentially all body processes require calcium, finely tuned homeostatic control mechanisms to maintain constant blood levels of calcium have evolved, as have complex cellular mechanisms to control movement of intracellular calcium. Inadequate dietary calcium is associated with increased risk of a number of diseases.

### Distribution

The whole body calcium of an adult female is 23–25 M (920–1000 g) and for adult males is 30 M (1200 g). Calcium occurs mainly in the skeleton as hydroxyapatite,  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ . The remaining calcium in the body is in soft tissue, primarily in extracellular fluids and in subcellular stores. Fluxes in intracellular calcium concentration are key signaling events. About half of the calcium in plasma exists in free ionized form and is functionally available. Most of the rest is bound to albumin; some to globulin; and <10% is complexed to phosphate, citrate, and other anions.

## Chemistry and Function

Calcium is a divalent cation. It is the most abundant element in the body. Because calcium is of intermediate solubility, it exists in both solid form (bones) and in solution (plasma). Calcium binds to proteins through the oxygen atoms of glutamic and aspartic acid residues which fix the tertiary structures of proteins, thereby governing their activity and stability. In this capacity, calcium serves as the most common signal transmitter in cell biology. Calcium has only one oxidation state so it is not prone to be toxic at high concentrations.

Calcium is unusual in that the storage form is also functional. As part of hydroxyapatite, it forms a material strong enough to support our bodies for many decades but light enough to allow mobility. Lifelong cumulative calcium status can be assessed by measuring bone mineral content by bone densitometry because >99% of the body's calcium is in the skeleton and it is present in a constant ratio (36% of total body bone mineral content).

Bone remodeling occurs throughout life except in teeth. Bone resorption initiated by osteoclasts (bone-resorbing cells) results in microscopic pits on bone surfaces. This is necessary for modeling changes in bone size during growth, microarchitectural damage, and maintaining serum calcium levels as well as serving as a source of other minerals. Bone formation under the control of osteoblasts fills in the pits. It exceeds resorption during growth and often lags behind resorption later in life, resulting in age-related bone loss.

### *Extracellular Fluid Calcium*

Calcium concentrations in blood and extracellular fluids are maintained under tight regulation at ~2.5 mM. Extracellular calcium levels can be perceived by a surface  $\text{Ca}^{2+}$  sensing receptor (CaR), a member of the superfamily of G-protein-coupled receptors in parathyroid, kidney, intestine, lung, brain, skin, bone marrow, osteoblasts, breast, and other cells (Brown, 1999). The CaR permits  $\text{Ca}^{2+}$  to act as an extracellular first messenger in the manner of a calciotropic hormone. For example, parathyroid glands detect small changes in extracellular concentrations of  $\text{Ca}^{2+}$ , which regulate the release of parathyroid hormone (PTH) into the circulation. Similarly, CaR allows minute-to-minute regulation of renal tubular calcium reabsorption. The role of these actions in calcium homeostasis is described below.

Extracellular calcium serves mainly as a source of  $\text{Ca}^{2+}$  to the skeleton and cells but fulfills essential functions in its own right including participating in blood clotting and intercellular adhesion.

### *Intracellular Calcium*

Intracellular calcium concentrations, at 100 nmol/M, are >10 000-fold less than extracellular calcium concentrations. In response to a chemical, electrical, or physical stimulus interaction with a cell surface receptor, intracellular calcium concentrations rise from an influx of extracellular calcium or from intracellular calcium stores such as the endoplasmic or sarcoplasmic reticulum. The rise in intracellular calcium triggers a specific cellular response, usually through activating one or more kinases to phosphorylate one or more proteins. Thus, calcium acts as a second messenger to activate a wide range of physiological responses including muscle contractions, hormone release, neurotransmitter release, vision, glycogen metabolism, cellular differentiation, proliferation, and motility.

A number of enzymes are activated or stabilized by  $\text{Ca}^{2+}$ , a function unrelated to changes in intracellular calcium concentration. These include several proteases and dehydrogenases.

### *Calcium Absorption and Homeostasis*

Blood calcium levels are almost invariant. Thus, serum calcium concentrations do not reflect nutritional status. The homeostatic regulation of serum calcium to ensure a constant supply to tissues is complex and incompletely understood. When calcium levels fall even slightly, levels are returned to normal by a PTH–vitamin D–controlled increase in calcium absorption, increase in renal tubular reabsorption, and bone resorption (Figure 28.1). Elevated levels of extracellular  $\text{Ca}^{2+}$  inhibit secretion of PTH and production of calcitriol (1,25-dihydroxy vitamin D) as well as stimulating secretion of calcitonin, a peptide hormone produced in the thyroid gland. This results in decreased calcium absorption, increased urinary calcium excretion, and decreased bone resorption. Extracellular  $\text{Ca}^{2+}$  binds to CaR on the surface of parathyroid cells, which stimulates a conformational change in the receptor leading to an inhibition of PTH secretion from the parathyroid (Pearce, 1999). CaR has also been located on the calcitonin-secreting c-cells of the thyroid gland, in the calcitriol-producing cells of the renal proximal tubule and the intestine, and in osteoblast cell lines (Brown, 1999) suggesting CaR plays a similar role in monitoring  $\text{Ca}^{2+}$

levels at these sites in order to normalize serum calcium levels.

Calcium is not efficiently absorbed or retained in the body. The intestine is the dominant site of adaptation to dietary calcium deficiency. Calcium absorption efficiency (fractional absorption) is influenced by calcium status and physiological state (higher in adolescence, pregnancy, and lactation, and lower in aging). However, prolonged calcium deficiency is not completely corrected by an increase in absorption efficiency, so bone loss ensues to maintain serum calcium concentration. Calcium absorption occurs by two routes. The vitamin D–PTH-dependent transcellular route is saturable and subject to homeostatic regulation. Calcium absorption by this route is up-regulated with increased calcitriol due to reduced levels of serum calcium, as shown in Figure 28.1, which interacts with the vitamin D receptor in the enterocyte and stimulates the synthesis of calcium-binding proteins. Epithelial calcium channels, i.e. TRPV<sub>6</sub>, mediate calcium entry into the cell, and calcium transporters, i.e. calbindin 9K, shuttle Ca<sup>2+</sup> across the intestinal epithelial cell (Song *et al.*, 2003). Calcium absorption by the paracellular route (passive diffusion which occurs between cells) is largely dependent upon intestinal luminal calcium concentration.

For calcium intakes approaching 800 to 1000 mg/day, the saturable component of calcium absorption may account for half of total calcium absorption (Fleet and Schoch, 2010). Calcium absorption is also influenced by the calcium content of the meal. As the calcium load increases, absorption efficiency from the saturable pathway decreases (Heaney *et al.*, 1990) although net calcium absorbed increases as the non-saturable component becomes increasingly dominant (Figure 28.2). Practically, calcium absorption is more efficient if consumed in divided doses throughout the day.

Some dietary constituents have an important role in calcium retention. Urinary calcium excretion accounts for ~50% of the variability in calcium retention. Dietary sodium is the key dietary factor which influences urinary calcium loss. Every additional 43 mmol (1g) sodium results in an additional loss of ~0.66 mmol (26.3 mg) calcium in adults (Weaver *et al.*, 1999). The effect of sodium on urinary calcium loss and net calcium retention is greater in white than black children (Wigertz *et al.*, 2005). A longitudinal study in postmenopausal women illustrated the negative consequences of high salt intakes on bone density (Devine *et al.*, 1995). No bone loss

**FIG. 28.1** Homeostatic regulation of calcium. The + and – signs indicate the stimulatory and inhibitory responses to a fall in serum or extracellular fluid (ECF) Ca<sup>2+</sup> below 2.5 mM. The Ca<sup>2+</sup>-sensing receptor, CaR, has been localized in each of the cells depicted, but its direct role in calcium homeostasis in the intestine has not been demonstrated.

occurred on calcium intakes as high as 44.2 mmol/day (1768 mg/day) or on urinary sodium excretion (reflecting dietary intakes) as low as 92 mmol/day (2115 mg/day). Dietary protein also increases urinary calcium loss, but does not decrease net calcium retention because of offsetting changes in endogenous secretion or calcium absorption (Kerstetter *et al.*, 2005). In fact, bone loss and fractures in the elderly are reduced by higher protein intakes (Dawson-Hughes, 2003). Calcium intake explains only 1 to 6% of the variation in urinary calcium (Jackman *et al.*, 1997).

## Calcium Requirements

The 2010 DRIs for calcium relied on bone health as the indicator in setting calcium recommendations, as with previous recommendations (Institute of Medicine, 2011). Newer balance studies (Braun *et al.*, 2006, 2007; Hunt

**FIG. 28.2** Theoretical relationship between calcium intake and net calcium absorbed (solid line) and absorption efficiency (dashed line). To convert grams to moles, multiply by 0.023.

and Johnson, 2007; Lu *et al.*, 2010), meta-analyses of large-scale randomized trials (Tang *et al.*, 2007; Avenell *et al.*, 2009), and longitudinal calcium accretion reports (Vatanparast *et al.*, 2010) have been published giving sufficient confidence to set RDAs rather than AIs for all life stages except infants (Table 28.1). The only absolute values that changed for this transition from the 1997 DRIs was for young children. The 2010 RDAs for children aged 1–3 years increased from an AI of 500 mg/day to an RDA of 700 mg/day and for children aged 4–8 years the RDA increased from an AI of 800 mg/day to 1000 mg/day. The 2010 IOM DRI committee considered the interdependence of calcium and vitamin D and concluded that “calcium appears to be the more critical nutrient in the case of bone health” and “calcium, or lack thereof, ‘drives’ the need for vitamin D”. In Western populations, vitamin D status appears to be sufficiently high so that supplementation has little benefit for calcium absorption.

The range in calcium recommendations around the world is large; for example, recommended calcium intakes for adolescents range between 500 and 1300 mg/day. In addition to assumed differences in peoples, differences in calcium requirements occur through aiming for the prevention of deficiencies vs. optimal health and preventing chronic disease, with different endpoints from maximal

**TABLE 28.1** Dietary reference intakes for calcium by life-stage group for the United States and Canada

Life-stage group	AI (mg)	EAR (mg)	RDA (mg)	UL (mg)
0–6 months	200	–	–	1000
7–12 months	260	–	–	1500
1–3 years	–	500	700	2500
4–8 years	–	800	1000	2500
9–13 years	–	1100	1300	3000
14–18 years	–	1100	1300	3000
19–30 years	–	800	1000	2500
31–50 years	–	800	1000	2500
51–70 years, male	–	800	1000	2000
51–70 years, female	–	1000	1200	2000
71+ years	–	1000	1200	2000
14–18 years pregnant	–	1100	1300	3000
19–30 years pregnant	–	800	1000	2500
31–50 years pregnant	–	800	1000	2500
14–18 years lactating	–	1100	1300	3000
19–30 years lactating	–	800	1000	2500
31–50 years lactating	–	800	1000	2500

retention to replacing losses, and using different assumptions for absorption efficiency, losses, and safety margins. Many countries simply adopt the requirements determined by North America, the United Kingdom, or authoritative bodies such as the FAO or WHO.

Recommended calcium intakes for women in North America are not higher for pregnancy and lactation, in contrast to the increased requirement during lactation established by the United Kingdom (Department of Health, 1998). Calcium supplementation does not prevent lactation-induced bone loss, but the bone calcium is regained upon weaning (Kalkwarf *et al.*, 1997). Calcium absorption efficiency is enhanced by the second trimester of pregnancy and greatest during the third trimester, when fetal demand for calcium is greatest (Ritchie *et al.*, 1998). Generally, fetal skeletons are protected at all but exceptionally low calcium intakes of mothers and there is no association between pregnancy, lactation, and risk of fracture (Kalkwarf and Specker, 2002). A longitudinal study showed some compromise of pelvic and spine bone mineral density despite an increase in arm and leg bone mineral density during pregnancy (Naylor *et al.*, 2000). Low dairy intake was associated with decreased fetal femur length in pregnant African-American adolescents (Chang *et al.*, 2003). The need for calcium in breast milk to support

neonatal development is met by maternal adaptation of increased bone resorption (Prentice *et al.*, 1995). The additional allowance for lactation (17.5 mmol for non-lactating women vs. 30 mmol for lactating women) by the United Kingdom brings their requirements closer to and even higher than the recommendation for adult women in North America.

## Dietary Sources of Calcium

Calcium intakes declined when cultivated cereal grains became the staple plants in the diet of most of the world, as the calcium content of grains and fruits are typically quite low. Consequently, the major source of concentrated calcium from foods in most parts of the world is dairy products. A recent estimate in the United States is that 64% of food calcium comes from dairy products and mixed foods containing dairy ingredients (Institute of Medicine, 2011).

Sources of calcium should be evaluated for their calcium bioavailability as well as content. A summary of calcium bioavailability from a variety of foods and a comparison of the number of servings necessary to provide an amount of absorbable calcium equivalent to that from a glass of milk is given in Table 28.2.

**TABLE 28.2** Comparing food sources for absorbable calcium

Food	Serving size (g)	Calcium content (mg)	Fractional absorption (%)	Estimated absorbable Ca/serving (mg)	Servings needed to = 1 cup milk
Milk	240	300	32.1	96.3	1.0
Beans, pinto	86	44.7	26.7	11.9	8.1
Beans, red	172	40.5	24.4	9.9	9.7
Beans, white	110	113	21.8	24.7	3.9
Bok choy	85	79	53.8	42.5	2.3
Broccoli	71	35	61.3	21.5	4.5
Cheddar cheese	42	303	32.1	97.2	1.0
Chinese mustard green	85	212	40.2	85.3	1.1
Juices fortified with most calcium salts	240	300	32.1	96.3	1.0
calcium citrate malate	240	300	52.0	15.6	0.62
Kale	85	61	49.3	30.1	3.2
Soy milk fortified with calcium carbonate	240	387	31.2	121	0.80

Sweet potatoes	164	44	22.2	9.8	9.8
Rhubarb	120	174	8.54	10.1	9.5
Yogurt	240	300	32.1	96.3	1.0

Adapted from Weaver *et al.* (1999).

Typically, bioavailability of calcium is dictated by the ability of the cation to become free of its ligands or dissociated from the salt and then to remain soluble. However, calcium does not have to be dissociated from low-molecular-weight salts such as calcium carbonate or calcium oxalate to be absorbed, presumably by the paracellular route or by pinocytosis (Hanes *et al.*, 1999). That low-molecular-weight calcium salts can be absorbed without the aid of a vitamin D-inducible calcium transporter, as is required in active calcium absorption, suggests possible treatments for individuals with impaired kidney function who cannot synthesize calcitriol. Solubility of calcium salts in water over the wide range of 0.1–10.0 mmol/L did not influence calcium absorption (Heaney *et al.*, 1990). The condition of achlorhydria also does not reduce calcium absorption as long as the salt is consumed with food (Recker, 1985). Not considered by Recker (1985) is the possibility that appreciable quantities of calcium carbonate were absorbed intact in patients with achlorhydria. Thus, either the pH of the intestinal milieu is an important factor in calcium bioavailability or we need to revise our understanding of calcium absorption, because it appears that solubility of a calcium source may be less important than we have traditionally thought.

Calcium absorption can be inhibited by some ligands and enhanced by others. The strongest known inhibitor of calcium absorption, oxalate, forms a salt with calcium that has a solubility (0.04 mmol/L) considerably below the solubility range discussed above (Heaney *et al.*, 1990). Other modest inhibitors to calcium absorption form salts that cannot be completely dissociated in the gut and are too large to be absorbed intact by the paracellular route. Phytic acid is such an inhibitor. A threefold difference in phytic acid content in soybeans reduced calcium absorption by 25% (Heaney *et al.*, 1991). Although phytate is a more modest inhibitor of calcium absorption than oxalate, it is consumed in higher amounts. However, in developed countries, phytate consumption is less detrimental where bread is leavened and phytate complexes are hydrolyzed by enzymes in yeast during fermentation. Fiber was once thought to inhibit calcium absorption, but it is now considered to be more likely that the phytate associated with fibers in seeds is the inhibitor. Purified fibers have little effect on 5-hour calcium absorption (Heaney and Weaver, 1995). Enhanced calcium absorption can result from extremely soluble salts. Enhancers may work by preventing precipitation of calcium by phosphates in the gut or they

alter the calcium absorption capacity of the intestinal epithelium.

Calcium citrate malate, with a solubility of 80 mmol/L, is the best-studied example of a salt with superior calcium absorption (Heaney *et al.*, 1990). Some casein and whey peptides prevent precipitation of calcium by phosphates (Mykkanen and Wasserman, 1980). Inulin and fructooligosaccharides have been shown to increase calcium absorption, suppress bone resorption, and improve accretion during growth and inhibit bone resorption later in life (Zafar *et al.*, 2004; Abrams *et al.*, 2005). As a rule, calcium absorption determined on the same calcium intake or load is similar for most dairy foods, salts used to fortify foods, and supplements which provide the major contributors of calcium to the diet. Consequently, when assessing dietary calcium, it is appropriate to ensure adequate total intake without undue focus on bioavailability. However, if alternatives to dairy products are selected as the primary source of calcium, it is important to ensure that nutrients other than calcium provided by dairy products – including magnesium, vitamin D (fluid milk), riboflavin, and vitamin B<sub>12</sub> – are also adequate.

## Calcium Deficiency

Calcium intakes of most populations, especially adolescent females, are below the calcium requirements of their country (Figure 28.3). Generally, calcium intakes are

**FIG. 28.3** Percent of adolescents and adults in 20 countries meeting country-specific calcium recommendations. Data from Looker (2006).

**FIG. 28.4** RDAs for calcium with age (line) compared with mean intakes of calcium for men and women in the US (bars). Mean intakes for calcium are from the NHANES 2003–2006 data (Bailey *et al.*, 2010).

highest in Scandinavian countries and lowest in Asian countries. The current marketing trend of so many additional calcium-fortified foods and supplements has shifted total calcium intakes in the United States upward according to a recent analysis of NHANES 2003–2006 data (Figure 28.4). Most Americans older than 9 years of age still are not reaching the recommended calcium intakes, but the gap has decreased substantially since 1997 when the last DRIs were set and compared with intake data using CFS II food intake data (Institute of Medicine, 1997), although all sources of calcium were not included at that time. Adolescent and elderly males and most females over age 9 years are the age groups of most concern for inadequacy. Only 15% of females aged 9–13 years and 13% of females aged 14–18 years met the recommended intake for calcium (Bailey *et al.*, 2010).

### Effects of Calcium Deficiency

Low calcium intake has been associated with a multitude of disorders. When the functional reserve (skeleton) is depleted chronically to maintain normal serum calcium levels, low bone mass ensues and can lead to osteoporosis. Low amounts of calcium reaching the lower bowel (unabsorbed calcium) can increase vulnerability to colon cancer and kidney stones. Failure to maintain extracellular calcium concentrations may increase risk of hypertension, pre-eclampsia, premenstrual syndrome, obesity, polycystic ovary syndrome, and hyperparathyroidism.

### Osteoporosis

Of the relationships between dietary calcium and disease prevention, osteoporosis is the most studied (see Chapter 50). Connecting calcium intake to skeletal health is obvious given that 99% of the body's calcium resides in the skeleton. Osteoporosis is characterized by reduced bone mass resulting in increased skeletal fragility and susceptibility to fractures.

The benefit of calcium for skeletal health has been reviewed (Heaney, 2000; Cranney *et al.*, 2002; Chung *et al.*, 2009). Most guidelines recommend adequate calcium intake as an integral part of the prevention or treatment of osteoporosis (US DHHS, 2004; NOF, 2008). Calcium enhances skeletal strength, both as the principal constituent of mineralization and by lowering bone turnover rate through reduction of serum PTH (Heaney and Weaver, 2005). Calcium is not the only nutrient important to bone health, but it is the one most likely to be deficient. Good nutrition is not the only requisite for good bone health; also important are physical activity, especially weight-bearing exercise and not smoking. Hormonal sufficiency promotes bone maintenance, but estrogen therapy after menopause has also been associated with increased risk of breast cancer and stroke (Rossouw *et al.*, 2002). Adequate calcium intake can potentiate the advantage to bone of physical activity in growth (Iuliano-Burns *et al.*, 2003) and adulthood (Specker, 1996) and estrogen in postmenopausal women (Nieves *et al.*, 1998). The primary

strategies for reducing the risk of osteoporosis are to maximize development of peak bone mass during growth and to reduce bone loss later in life. Adequate calcium intakes are important for both of these aims. Maximizing peak bone density protects against fracture at any age. Children who avoid milk had a fracture rate 1.75 times higher than expected from their birth cohort (Goulding *et al.*, 2004). Milk may have skeletal benefits beyond adequate calcium. Rats provided calcium from non-fat dry milk solids during growth grew stronger bones than rats fed calcium from calcium carbonate, and the advantages were largely retained after switching to a low-calcium diet where all calcium came from calcium carbonate during maturity (Weaver *et al.*, 2009). Whether the advantage of milk is due to bioactive constituents or simply to providing one or more nutrients such as phosphorus at higher levels requires further investigation.

In adults, systematic reviews have shown the strongest evidence for bone outcomes from trials of combined calcium and vitamin D (Craney *et al.*, 2002; Tang *et al.*, 2007; Chung *et al.*, 2009). Response to supplementation depends in part on the nutrient status at the start of the intervention and the magnitude of change with the intervention. As with children, within populations, milk avoiders have a higher risk of fractures than milk consumers (Honkanen *et al.*, 1997).

On cessation of calcium supplementation, the skeletal advantage gained during treatment in randomized, controlled trials disappears with follow-up in most trials (Dawson-Hughes *et al.*, 2000) unless on low habitual calcium intakes when the trial began (Dodink-Gad *et al.*, 2005). In children habitually consuming approximately 850 mg/day, skeletal advantages in the radius and total body BMD with calcium supplementation compared with the placebo group gained during puberty disappeared on average in spite of continued supplementation during postpuberty (Matkovic *et al.*, 2005). However, the ability for girls to exhibit “catch up” skeletal growth was size dependent as those who were taller at peak bone mass had reduced bone accretion at the forearm if on placebo compared with calcium treatment from age 10 to 18. Furthermore, other skeletal sites such as the hip failed to exhibit complete catch-up growth (Matkovic *et al.*, 2004). At this time, the best recommendation is to maintain adequate calcium intakes throughout life to optimize development of peak bone mass during growth and to minimize bone loss later in life.

### Hypertension and Cardiovascular Disease

The ability of calcium supplementation to control hypertension has been controversial. High dietary calcium intake may reduce cardiovascular risk through decreasing blood lipid and cholesterol levels (Pereira *et al.*, 2002; Reid *et al.*, 2002). Lipids are less well absorbed and are therefore excreted in the stools when calcium binds fatty acids and forms insoluble soaps. Ensuring adequate calcium intake, particularly through dairy products, is a primary non-pharmacologic strategy for reduction of high blood pressure recommended by the Joint Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (Chobanian *et al.*, 2003). In 85 764 women participating in the Nurses' Health Study, those who had calcium intakes in the lowest quintile of calcium intake had a significantly greater incidence of ischemic stroke than those in the highest quintile of calcium intake (Iso *et al.*, 1999). Meta-analyses of randomized-controlled calcium supplement trials show that blood pressure reduction is greater in persons with low habitual calcium intakes (Bucher *et al.*, 1996a) and during pregnancy (Bucher *et al.*, 1996b). However, a recent meta-analysis of RCTs of calcium supplementation with or without vitamin D found no relation to CVD (Wang *et al.*, 2010).

The influence of dietary patterns rather than individual nutrients is more closely linked to disease prevention. The Dietary Approaches to Stop Hypertension (DASH) study showed an impressive and quick response of lowered blood pressure to a diet rich in fruits and vegetables and an even greater reduction if three servings of low-fat dairy foods were consumed daily (Appel *et al.*, 1997). Approximately 70% of subjects who would have required antihypertension drug therapy experienced normalization of blood pressure on the DASH diet. Calcium may influence blood pressure by reducing sympathetic nervous system activity or through its role in intracellular signaling.

### Cancer

Increasing calcium and dairy food intakes appears to reduce the risk of colon cancer, particularly of the distal colon (Wu *et al.*, 2002; Chia and Newcomb, 2004). Calcium may lower fecal free bile acid and free fatty acid concentrations, thereby lowering cytotoxicity and/or it may have direct effects on the colorectum epithelium (Chia and Newcomb, 2004). Recurrent colorectal adenomas were decreased ~20% with calcium supplementation (Shaikat *et al.*, 2005).

A systematic review (Chung *et al.*, 2009) found no association between calcium intake and risk for breast cancer. Nor was there an effect of calcium supplementation at 1000 mg/day on breast-cancer incidence or risk in the Woman's Health Initiative trial (Chelbowski *et al.*, 2008). A secondary analysis of calcium at 1400 mg/day plus vitamin D at 1000 IU/day in postmenopausal women showed a significant ( $p < 0.03$ ) reduction in total cancer (Lappe *et al.*, 2007).

### Kidney Stones

Observational studies suggest that adequate dietary calcium decreases incidence of kidney stones (Curhan *et al.*, 1993). A controlled trial demonstrated that increased calcium intake reduced kidney-stone incidence by half and was associated with a decreased urinary oxalate excretion (Borghi *et al.*, 2002). In the gut, calcium combines with oxalate from dietary sources. The rather insoluble calcium oxalate salt is poorly absorbed (Hanes *et al.*, 1999) and oxalic acid is less available for stone formation. However, when calcium supplements are not consumed with meals, they have no opportunity to bind with dietary oxalate and may increase urinary calcium levels which are often already high in people who form stones, further aggravating stone formation (Curhan *et al.*, 1997). People who form kidney stones are often characterized by a renal leak of calcium that reduces skeletal mass (Heller, 1999). Lowering calcium intake in such individuals would not likely correct their kidney-stone problem but would undoubtedly further compromise their skeletal health.

### Other Disorders

Adequate calcium intake may be associated with protection against several other disorders. One multicenter trial showed that calcium supplementation at 30 mmol/day (1200 mg/day) of calcium for 3 months significantly reduced symptoms of premenstrual syndrome by 48% compared with 30% in the placebo group (Thys-Jacobs *et al.*, 1998). An observational study showed a protective effect of calcium and vitamin D against polycystic ovarian syndrome, a common cause of menstrual dysfunction and infertility (Thys-Jacobs *et al.*, 1999). All of these relationships may work through regulation of parathyroid hormone levels by dietary calcium.

## Calcium Supplementation

Dietary supplements are popular in some populations. From an analysis of NHANES 2003–2006 data, 43% of

Americans over age 1 and almost 70% of older women were found to use calcium supplements (Bailey *et al.*, 2010). Among users, 17% of women over age 70 years met the RDA for calcium simply through the use of dietary supplements.

Calcium absorption from calcium salts used in supplements is often comparable to that from milk, but adjuvants used in pharmaceutical preparations may reduce bioavailability of calcium (Weaver *et al.*, 1999). Choice of calcium supplement is dependent on cost and preference. Calcium citrate is recommended for some patients. Divided doses with meals can improve absorption and decrease risk of kidney stones.

### Potential Problems of Excessive Calcium Intake

Tolerable upper intake levels (ULs) for calcium were established by the Food and Nutrition Board for North America for the first time in 1997 at 2500 mg/day. They were revised in 2010 (Table 28.1) to adjust for increased requirements for adequacy at various lifestages. An upper limit of 2500 mg/day for calcium has also been adopted by the European Community, Japan, the Nordic countries, and Taiwan. The prevalence of intake above UL is small on average (<2% exceeding 2500 mg/day except for 4% for adolescent males and females over age 50 years) (Bailey *et al.*, 2010).

The hallmark concern of excessive calcium intake is hypercalcemia where serum calcium levels exceed 10.5 mg/dL or 2.63 mmol/L, and hypercalciuria where urinary calcium exceeds 250 mg/day in women or 275–300 mg/day in men. This is rare in healthy people and is usually caused by conditions such as malignancy or urinary hyperparathyroidism but has been increasing, especially in postmenopausal and pregnant women with ingestion of large quantities of supplements (>3 g/day) together with alkali (Patel and Golfarb, 2010). This calcium alkali syndrome may be accompanied by renal insufficiency and is associated with hypophosphatemia (Patel and Golfarb, 2010). Symptoms of hypercalcemia include lax muscle tone, constipation, large urine volumes, anorexia, and, ultimately, confusion, coma, and death.

Concerns over prolonged calcium supplementation have been raised for risk of kidney stones, prostate cancer, myocardial infarction, and vascular calcification. There was a 17% increase in incidence of kidney stones in the Women's Health Initiative trial (Jackson *et al.*, 2006). However, as discussed earlier, obtaining calcium from food or by taking supplements with food to bind any oxalates minimizes risk of stones. Of recent concern is the

observation that calcium supplements (without co-ingested vitamin D) increased myocardial infarction, stroke, and mortality (Bolland *et al.*, 2010) and vascular calcification (Daly and Ebeling, 2010). These observations are inconsistent with the reported benefits to cardiovascular health of high calcium intakes. The studies to date are secondary analyses and tend to be small with few events.

Risk of prostate cancer has been associated with calcium intake in observational studies. A twofold increased intake in prostate cancer was reported for milk consumption but not for other dairy products or dietary calcium (Raimonde *et al.*, 2010). Generally, risk for prostate cancer has been observed at calcium intakes associated with supplement use, i.e. >2000 mg/day, and the association lacks strong biological plausibility. Some concern about calcium supplementation and reduced absorption of trace elements has been raised, especially regarding iron. However, Minihane and Fairweather-Tate (1998) showed that although calcium at 10 mmol (400 mg) can significantly reduce iron absorption in a single meal, chronic calcium supplementation at 30 mmol/day (1200 mg/day) does not decrease iron status. Presumably, iron absorption is up-regulated as stores decrease. Neither iron status nor zinc metabolism or retention was affected by 1 g calcium supplementation in girls (McKenna *et al.*, 1997; Ilich-Ernst *et al.*, 1998).

Individuals should avoid exceeding the ULs. However, at present, inadequate calcium intake is still the primary concern for optimizing calcium nutrition for most individuals.

## Future Directions

More is known about the relationship between calcium and bone health than for any other disorder, yet several questions remain. The US Surgeon General's Report on Bone Health and Osteoporosis (US DHHS, 2004) emphasized the role of good nutrition, and calcium and vitamin D in particular, for normal bone growth and osteoporosis prevention and treatment. Important areas for future research include strategies to maximize peak bone mass in boys and girls in ethnically diverse populations. The prevention and reversibility of calcium and vitamin D deficiency and disease states need to be better understood. Can calcium protect the skeleton against low vitamin D status except for very low levels, i.e. <10 nmol/L? Future research should focus on more complex interactions that consider not only calcium and vitamin D, but also phosphorus.

For each of the other calcium nutrition-related disorders outlined above, additional research will clarify benefits of adequate calcium and risks of excess. We need to better understand the importance of calcium intake in late-stage cancers. A new area of active research stemming from increased incidence of obesity is the consequence of bone loss accompanying weight loss. The Surgeon General's report identified finding mechanisms and interventions to preserve bone during weight loss as an important area for future research. Adequate dietary calcium has been shown to be a useful countermeasure (Shapses *et al.*, 2004). Epidemiological studies would become more useful in identifying the relationship of calcium intake and disease once more accurate means for assessing calcium intake are developed. For each calcium-related disease and metabolic parameter, the interaction between diet and genetics will be a dominant area of investigation in the coming decades. Vitamin D polymorphisms have been associated with fractional calcium absorption (Ames *et al.*, 1999). Further insights into genetics and nutrition are likely to help explain racial and sex differences in calcium absorption as well as identify individuals who can benefit by rigorous interventions. Concern over excesses is a modern phenomenon as more people turn to supplements to meet their calcium needs. Still, we should understand the risks of this popular alternative to meeting calcium recommendations through food.

## PHOSPHORUS

ROBERT P. HEANEY, MD

*Creighton University Medical Center, Omaha, Nebraska, USA*

### Summary

Phosphorus, as phosphate, is essential for all life and is widely distributed in both plant and animal foods. A diet adequate in other nutrients, particularly calcium and protein, will automatically be adequate in phosphorus. ECF  $[P_i]$ , which varies little with dietary phosphorus intake, is itself vital for normal physiological function in all the higher vertebrates, and the principal abnormalities of phosphate metabolism involve either excessively low or excessively high concentrations of this critical anion. ECF  $[P_i]$  is regulated by a feedback control loop in which fibroblast growth factor-23 (FGF-23) is the effector hormone. Low serum phosphorus is most commonly due to increased renal phosphorus clearance produced by high levels of parathyroid hormone or FGF-23. The result is rickets or osteomalacia as well as muscle weakness and general metabolic dysfunction of all body tissues and organs. High serum phosphorus is most commonly due to decreased renal clearance as a result of kidney failure. The results include extra-osseous calcification, especially of critical arterial systems.

### Introduction

Phosphorus in the biosphere most commonly occurs in its pentavalent form, as phosphate ( $PO_4^{3-}$ ), and it is in this form that it is found in living organisms. Phosphorus is a limiting nutrient in the sense that the mass of the biota in any given environment is determined strictly by phosphorus availability in that environment. As a reflection of that dependence, and with the exception of guano deposits, virtually all of the phosphorus in an environment will be tied up in its biota.

Phosphorus is an essential constituent of the fabric of all life. In addition to its role in the mineral component of the endoskeleton of vertebrates, phosphorus is involved,

for example, in cell membrane structure as phospholipids, in information coding as DNA and RNA, in energy metabolism as ATP and GTP, and in enzymatic activation, by phosphorylation of catalytic proteins. Additionally, inorganic phosphate ( $P_i$ ) concentration in the extracellular fluid (ECF) of higher vertebrates plays a vital role in supporting both mineralization of bone and the intermediary metabolism of all body tissues.

### Phosphorus in the Human Body

Phosphorus is the sixth most abundant element in the human body, comprising in adults about 1.0–1.4% of

fat-free mass or ~12 g (0.4 mol) per kilogram. Of this total 85% is in the mineral of bones and teeth, with 15% distributed through the blood and soft tissues (especially myelin). Thus a 70-kg adult with 25% fat mass would have a total body phosphorus of ~630 g (~21 mol). ECF  $P_i$  makes up <0.1% of total body phosphorus, but it is into this virtual compartment that phosphorus is transferred from digestion of food in the gut and resorption of mineral from bone; and it is out of the phosphorus of this compartment that bone mineral is formed and urine phosphorus is derived. At physiological pH (7.4), ECF inorganic phosphorus exists as a mixture of  $H_2PO_4^-$  and  $HPO_4^{2-}$ , with an effective valence of -1.8. While serum  $[P_i]$  is not always a faithful reflection of tissue phosphate levels, it is nevertheless the case that most situations of phosphate deficiency or excess express themselves and are mediated through excessively low or high values of serum  $[P_i]$ .

## Phosphorus in Foods

Phosphorus is found widely distributed in various foods, with a strong relation to protein content. This is simply a reflection of the fact that protein and phosphorus are each the stuff of which protoplasm is made, and most foods, plant or animal, come ultimately from living organisms. Although the phosphorus density of foods varies widely, depending mainly upon fat and carbohydrate content, the phosphorus to protein ratio is quite narrow (ranging typically from 0.25 to 0.65 mmol P per gram of protein in, for example, muscle meats).

### Bioavailability

With the exception of seed foods and unleavened breads, most food phosphorus is in the form of readily hydrolyzable organic phosphate esters. Seed foods contain, in addition to such digestible, protoplasmic phosphorus, a storage form of phosphorus, phytic acid (hexainositol phosphate), needed to make up for the lack of phosphorus in most soils, and absolutely required in order for the plant embryos to increase their protoplasmic mass. The principal significance of phytic acid for human nutrition is that the human intestine lacks phytase and is hence unable to utilize most of the phytate phosphorus in any given diet. Colonic bacteria, which do possess phytase, are able to release some of that phosphorus for absorption. Additionally, yeasts can hydrolyze phytic acid, and hence leavened cereal-grain foods (e.g. many breads) exhibit good phosphorus availa-

**TABLE 29.1** Usual phosphorus intakes (mg/day) for females (NHANES 2005–2006)<sup>a</sup>

Age	Percentiles						
	5	10	25	50	75	90	95
19–30	585 <sup>b</sup>	681	864	1090	1344	1596	1753
31–50	623 <sup>b</sup>	729	924	1166	1438	1704	1876
51–70	679 <sup>b</sup>	758	899	1079	1279	1480	1605
71+	576 <sup>b</sup>	648 <sup>b</sup>	785	956	1163	1372	1502

<sup>a</sup>Moshfegh *et al.* (2009).

<sup>b</sup>Below the adult RDA (700 mg/day).

bility whereas unleavened products do not. Finally, diets high in phytate-containing foods can lead to iron, zinc, and calcium malabsorption, and hence to deficiencies of these minerals, because ingested phytate complexes with them and blocks their absorption. Aside from phytate, the principal factor influencing phosphorus bioavailability is not the food itself, but co-ingested calcium (see below, Phosphorus Absorption), which binds phosphorus in the digestate and prevents its absorption.

### Human Diet Phosphorus

Table 29.1 sets forth the diet phosphorus distribution for adult women from NHANES 2005–2006 by age (Moshfegh *et al.*, 2009). As can be seen, median diet phosphorus ranges from 1090 mg/day (35 mmol) for individuals in the age range 19–30, to 956 mg/day (31 mmol) for individuals 71 years and older. At any given age (e.g. 51–70), phosphorus intake ranges from 679 mg/day (22 mmol) at the 5th percentile to 1605 mg (52 mmol) at the 95th. The RDA for phosphorus (Institute of Medicine, 1997) in adult women (see below), is 700 mg/day (22.6 mmol), and, as Table 29.1 shows, by age 71 more than 10% of women have intakes below the RDA.

By contrast, various animal chows have relatively higher phosphorus densities. Table 29.2 sets forth the phosphorus nutrient densities of various standard lab chows based on their labeled nutrient contents. As can be seen, these diets, even those of the non-human primates, have substantially higher phosphorus densities (by factors of two to four times) than do even the most extreme of human diets. This is an important consideration in evaluating studies of the effect of raising phosphorus intakes in animals and then extrapolating the results thereof to humans.

For further information on the foregoing topics see the review by Nordin (1988), the introductory material in

**TABLE 29.2** Diet phosphorus densities for various animals<sup>a</sup>

Animal	Phosphorus density (mmol P/100 kcal)
Human	2.0
Chimpanzees	4.6–5.4
Swine	6.0–6.5
Dogs	8.7
Cats	6.5
Rats and mice	4.2–6.6
Guinea pigs	5.6

<sup>a</sup>Calculated from labeled content values of standard laboratory chows.

Institute of Medicine (1997), and *Documenta Geigy* (any of several editions).

## Phosphorus Metabolism

Because phosphorus, in contrast to calcium, is a trace element in the biosphere, the principal components of phosphorus homeostasis differ substantially from those regulating calcium homeostasis. For phosphorus, the regulatory apparatus is optimized to deal with environmental scarcity whereas for calcium the organism must deal with environmental surfeit. Increase in protoplasmic mass, as in generation and growth of new organisms or tissues, creates an obligatory requirement for phosphorus. In addition to the structural role of phosphorus in protoplasm, as inorganic phosphate, it buffers pH changes in the extracellular fluid, and is involved in the storage of intracellular energy (e.g. glycogen synthesis).

### Extracellular Fluid Phosphorus

In complex vertebrate organisms, phosphorus availability is critically expressed in the concentration of inorganic phosphate ( $P_i$ ) in the extracellular fluid (ECF) bathing all of the tissues and organs. Table 29.3 sets forth mean ( $\pm$  standard deviation [SD]) values for serum  $[P_i]$  in healthy humans (Institute of Medicine, 1997). Note the higher values during growth. Maintenance of an adequate concentration of phosphate ( $[P_i]$ ) in the ECF is a critical concern of the organism, and will be described in detail in what follows.

At physiological pH and  $pCO_2$ , the calcium phosphate salt that would likely precipitate from the ECF is  $CaHPO_4$  (Nordin, 1988). Normally ECF is only about half saturated with respect to this product. However, ECF calcium and phosphorus concentrations are supersaturated with

**TABLE 29.3** Prevalent serum phosphorus concentrations in healthy individuals, by age<sup>a</sup>

Age	Mean	SD
2	1.81 (5.61)	0.19 (0.59)
6	1.72 (5.33)	0.19 (0.59)
10	1.63 (5.05)	0.19 (0.59)
14	1.53 (4.74)	0.24 (0.74)
18	1.44 (4.46)	0.19 (0.59)
Adult	1.15 (3.59)	0.13 (0.40)

<sup>a</sup>Units are mmol/L (mg/dL).

Data from Institute of Medicine (1997).

respect to another crystal form, hydroxyapatite, and readily precipitate as such in the presence of a suitable crystal nucleus. Hence the ECF supports mineralization when and where the body creates a suitable crystal nucleus, but is indefinitely stable as it circulates and bathes the other tissues.

The concentrations of ionized calcium and phosphorus in serum (and ECF) of adults are typically 1.1–1.3 mmol/L for calcium and 0.9–1.4 mmol/L for phosphorus. These values produce a  $Ca \times P$  ion product  $\cong 1.3 \text{ mmol}^2/\text{L}^2$ . Since serum calcium is typically held much more constant than is serum phosphorus, most of the clinically encountered variation in the  $Ca \times P$  product is produced by variations in serum  $[P_i]$ .

There is a common misconception that ECF concentrations of calcium and phosphorus are reciprocally related by solubility product considerations. In other words, when one goes up, the other must go down. That would be true only if the ECF were saturated with respect to  $CaHPO_4$ , but, as just noted, it is not. For example, serum  $[P_i]$  actually rises in response to an intravenous calcium infusion, and both concentrations fall in nutritional vitamin D deficiency. (The mechanisms underlying these changes will be described in what follows.) While sometimes the concentrations of these two ions do seem to vary inversely, that is through physiological regulation of their respective levels, not because of a physical chemical equilibrium.

When ECF  $Ca \times P$  rises by a factor of about 2 $\times$ , the solubility constant for  $CaHPO_4$  is exceeded and spontaneous calcification of non-osseous tissues tends to develop. And when the ion product falls by a factor of about 0.5 $\times$ , bone mineralization effectively stops. Thus metastatic calcification occurs when  $[P_i]$  rises above 2.4–2.5 mmol/L, and rickets or osteomalacia occurs when serum  $[P_i]$  falls

below 0.5–0.6 mmol/L. However, even within the nominal normal range, the rate of bone mineralization is to some extent dependent upon the serum  $\text{Ca} \times \text{P}$  product. It is not that a higher  $\text{Ca} \times \text{P}$  product is inherently more mineralizing, but rather that, since blood flow past a mineralizing site is pulsatile, the blood in each pulse is more quickly depleted of its minerals at lower  $\text{Ca} \times \text{P}$  values, and mineralization slows or stops until another pulse of blood comes by. During infancy, rapid skeletal growth requires a high ECF  $\text{Ca} \times \text{P}$ , with serum  $[\text{P}_i]$  reaching as high as 2.0–2.4 mmol/L. At such  $\text{Ca} \times \text{P}$  values, there is simply more mineral in a pulse, facilitating greater transfer from blood to bone per unit time.

### Regulation of ECF $[\text{P}_i]$ Concentration

The relatively small mass of phosphate in the ECF turns over many times each day. Phosphate traffic in and out of the ECF consists mainly, on the input side, of intestinal absorption of ingested phosphorus and release of bone mineral phosphorus in the resorptive phase of bone remodeling. On the output side, phosphate leaves the ECF mainly in the urine, in gastrointestinal secretions, and in the mineralization of newly forming bone (in the reconstruction phase of bone growth and remodeling).

While ECF  $[\text{P}_i]$  is inevitably affected by this ion traffic, the actual *regulation* of this critical concentration, as is true also for calcium, is mainly through adjusting the kidney threshold for excretion. Approximately 200 mmol of phosphorus is filtered each day at the kidney, the vast majority of which is reabsorbed from the glomerular filtrate in the proximal tubule. This tubular reabsorption is mediated by sodium-dependent phosphate co-transporters in the brush border of the proximal tubular epithelium. This reabsorption has a limited capacity (termed the “tubular maximum” for phosphate [ $\text{TmP}$ ]), which in turn is regulated up or down so as to adjust serum  $[\text{P}_i]$  concentration. The two factors most involved in this regulation are parathyroid hormone (PTH) and several agents known collectively as phosphatonins, principally fibroblast growth factor-23 (FGF-23). Both FGF-23 and PTH lower the  $\text{TmP}$  and hence increase renal phosphorus clearance, i.e. the virtual volume of serum effectively cleared of its  $\text{P}_i$  per unit time. When the  $\text{TmP}$  decreases (i.e. serum phosphorus clearance rises), serum  $[\text{P}_i]$  falls, and vice versa.

Long an enigma, the details of the regulation of ECF  $[\text{P}_i]$  are just now becoming clearer (Ferrari *et al.*, 2005; White and Econs, 2008; Jüppner *et al.*, 2010). Following the general scheme of a classical negative feedback control

loop, the principal regulator is FGF-23, produced in bone by cells of the osteoblast lineage. The principal stimulus to FGF-23 production is a rise in ECF  $[\text{P}_i]$ , whether due to normal dietary absorption, or, with inability of the kidneys to clear absorbed phosphorus, to renal failure. By lowering the  $\text{TmP}$ , FGF-23 increases phosphorus clearance, leading to a fall in ECF  $[\text{P}_i]$  and reducing the secretion of FGF-23. PTH, as noted, also lowers the  $\text{TmP}$  and reduces serum  $[\text{P}_i]$ , but this effect is not a direct part of the  $[\text{P}_i]$  feedback control loop.

Not surprisingly, FGF-23 serum concentration is typically quite high in patients with end-stage renal disease (ESRD); whether sustained high levels of FGF-23 are themselves responsible, through “off-loop” effects, for some of the morbidity of this condition is uncertain (Jüppner *et al.*, 2010).

FGF-23 also directly regulates renal synthesis of 1,25(OH)<sub>2</sub>D (calcitriol), but in a direction opposite to the effect of PTH. FGF-23 down-regulates and PTH up-regulates the expression of the renal 1- $\alpha$ -hydroxylase. This discordance is a direct reflection of the differing control systems for which these hormones are the effector molecules. PTH is responsive to ECF  $[\text{Ca}^{2+}]$ , and its up-regulation of calcitriol synthesis leads to increased calcium entry from the gut and decreased renal calcium clearance, thus raising ECF  $[\text{Ca}^{2+}]$ . FGF-23, for its part, is responsive to ECF  $[\text{P}_i]$  and adjusts renal phosphorus clearance to keep  $[\text{P}_i]$  from rising unduly (Ferrari *et al.*, 2005). PTH on the other hand, by lowering  $[\text{P}_i]$ , enhances osteoclastic release of bone mineral at pre-existing resorption loci (Raisz and Niemann, 1969), thereby raising ECF  $[\text{Ca}^{2+}]$ . Where the two control systems intersect is in their similar effect on the  $\text{TmP}$  and, accordingly,  $[\text{P}_i]$ .

Serum  $[\text{P}_i]$  is itself active in this regulation, with low  $[\text{P}_i]$  leading to independent up-regulation of renal calcitriol synthesis. By contrast, FGF-23, although it lowers serum  $[\text{P}_i]$  as a consequence of increasing renal phosphorus clearance, does not lead to the expected increase in 1- $\alpha$ -hydroxylation of 25(OH)D. This is because, as just noted, FGF-23 itself down-regulates the 1- $\alpha$ -hydroxylase, thus preventing the increase in calcitriol synthesis that would otherwise have accompanied the drop in serum  $[\text{P}_i]$ .

The general relationship between absorbed phosphorus intake and plasma  $\text{P}_i$  in adults is set forth in Figure 29.1, derived by Nordin (1988) from the infusion studies of Bijovet (1969). (In Bijovet’s studies, a neutral phosphate solution was infused intravenously at a steadily increasing rate, producing a controlled hyperphosphatemia.) The

**FIG. 29.1** Relation of serum  $[P_i]$  to absorbed intake in adults with normal renal function. (See Nordin [1988] for further details.) The lower row of values on the horizontal axis is for ingested intake, and the upper row for absorbed intake (estimated at 62.5% of ingested). The solid curve can be empirically approximated by the following equation:

$$P_i = 0.00765 \times \text{AbsP} + 0.8194 \times (1 - e^{(0.2635 \times \text{AbsP})}).$$

in which  $P_i$  = serum  $P_i$  (in mmol/liter), and AbsP = absorbed phosphorus intake (also in mmol). The dashed horizontal lines represent approximate upper and lower limits of the normal range, while the dashed curves reflect the relationship between serum  $P_i$  and ingested intake for absorption efficiencies about 15% higher and lower than average. Copyright Robert P. Heaney, 1996. Reproduced with permission.

achieved plasma  $P_i$  could thus be directly related to actual intakes. When intake is low, the filtered load will be below the  $T_mP$ , and little of the infused/absorbed phosphorus will be lost in the urine. The steep, ascending portion of the curve in Figure 29.1 thus represents a filling up of the ECF with absorbed phosphate. At higher intakes, the  $T_mP$  is exceeded and urinary excretion rises to match absorbed input and plasma levels change much more slowly.

The relationship shown in Figure 29.1 holds only in adult individuals with adequate renal function; that is, the slow rise of plasma  $[P_i]$  with rising phosphorus intake over most of the intake range applies only so long as excess absorbed phosphate can be spilled into the urine. As renal function is reduced, phosphorus clearance remains

essentially normal so long as GFR is at least 20% of mean adult normal values. Below that level, excretion of absorbed phosphate requires higher and higher levels of plasma  $P_i$  to maintain a filtered load at least equal to the absorbed load. This is the reason for the hyperphosphatemia typically found in patients with ESRD.

### Bone Mineralization

There are three main features of the relation of phosphorus to bone: (1) bone mineral is not just calcium but specifically a complex calcium phosphate salt (hydroxyapatite) comprising 85% of total body phosphorus; (2) adequate quantities of ingested phosphorus, expressed physiologically as a serum phosphate concentration of 1.5–2.0 mmol/L, are essential for bone building during growth; and (3) hypophosphatemia from whatever cause limits mineralization at new bone-forming sites at all ages, impairs osteoblast function, and enhances osteoclastic bone resorption. The amorphous calcium phosphate formed in the first stages of mineralization exhibits a Ca:P molar ratio of about 1.33:1, or very close to the molar ratio of Ca:P in adult ECF. At active bone-forming sites, ECF is depleted of both its calcium and its phosphate. Osteoblast function seems not to be appreciably affected by ECF  $[Ca^{2+}]$ , but, like other tissues, the osteoblast needs a critical level of  $[P_i]$  in its bathing fluid for fully normal cellular functioning. Local  $P_i$  depletion both impairs osteoblast function and limits mineral deposition in previously deposited matrix.

### Bone Resorption

$[P_i]$  also affects the responsiveness of the osteoclast to PTH: for any given PTH level, resorption is higher when  $[P_i]$  is low (Raisz and Niemann, 1969), while high  $[P_i]$  values reduce bony responsiveness to PTH, leading to increased PTH secretion in order to maintain calcium homeostasis, and thereby to a lowering of ECF  $[P_i]$ . Similarly, high plasma  $[P_i]$  suppresses renal synthesis of  $1,25(OH)_2D$  (Portale *et al.*, 1989), thereby slightly reducing net phosphorus absorption from the diet. Both mechanisms reduce phosphorus input into the ECF when  $[P_i]$  is high and augment it when  $[P_i]$  is low. However, in neither circumstance is the effect on plasma  $[P_i]$  more than modest. (See below for other special circumstances.)

### Intestinal Absorption of Phosphorus

Most organisms get the phosphorus they need by consuming the tissues of other organisms (plant and animal), and they absorb that ingested phosphorus with high efficiency.

In adult humans, for example, net phosphorus absorption typically ranges from 55% to 80% of ingested intake, and in infants from 65% to 90%. The most active intestinal absorptive site is the jejunum.

Most protoplasmic phosphorus in ingested foods is quickly hydrolyzed by intestinal phosphatases, and hence most absorbed phosphorus is in the form of inorganic phosphate. The principal exception is the phosphorus in phytic acid (see above under “Bioavailability”). Otherwise intrinsic bioavailability of most food phosphorus sources is high.

Because phosphorus is intimately involved in virtually all of the functions and structures of living organisms, phosphorus content of most animal tissues varies little, ranging, as noted earlier, from 0.25 to 0.65 mmol per gram of protein. The resulting ubiquitous distribution of phosphorus in all natural foods makes it all but impossible to construct, for patients on renal dialysis, a diet that is low in phosphorus and at the same time nutritionally adequate.

Absorption of phosphorus, as for calcium, is considered to be by a combination of active transport and passive diffusion, with the former being the regulated component. It is widely held that active phosphorus absorption is influenced by vitamin D status. It is also true that the molecular apparatus for vitamin D-stimulated active absorption of phosphorus exists in the intestine (Fleet, 2011). Indeed, it is almost an article of faith that the canonical function of vitamin D is to promote absorption of calcium *and phosphorus*. In support of this effect, Ferrari *et al.* (2005) showed in 29 normal humans that large increases in phosphorus intake induced a decrease in serum 1,25(OH)<sub>2</sub>D level, a change which, if associated with a reduction in phosphorus absorption, would suggest endocrine feedback regulation of phosphorus absorption (see also below). Ramirez *et al.* (1986), using an intestinal wash-out method, showed an appreciable effect of large daily doses of calcitriol on meal phosphorus absorption in five patients on chronic hemodialysis, producing essentially normal phosphorus absorption efficiency, and suggesting that the loss of renal synthesis of calcitriol reduced phosphorus absorption in patients with end-stage renal disease. Nevertheless, despite low calcitriol production, dietary phosphorus absorption in ESRD patients is higher than the body can handle – which is the rationale for use of intestinal phosphate binders.

Despite the foregoing evidence of a vitamin D effect, the net result is probably small. It is instructive to note that net phosphorus absorption in adults is approximately 65%, leaving relatively little room for vitamin D-mediated

absorption to increase. (By contrast, net absorption of calcium is approximately 10%, leaving much room for further increases due to vitamin D.) Such vitamin D effects on phosphorus absorption as can be found in intact humans may be more indirect than direct, as the following data suggest.

Heaney and Nordin, pooling two large datasets of human metabolic balance studies (Heaney and Nordin, 2002), showed that, over a wide range of ingested calcium:phosphorus ratios, the principal determinant of fecal phosphorus (and therefore inversely of *absorbed* phosphorus) was fecal calcium, with phosphorus intake itself exerting a significant but weaker effect. Figure 29.2 is a plot of 470 measurements of net phosphorus absorption in adult women. Together, and altogether apart from vitamin D status, fecal calcium and diet phosphorus explained about 80% of the observed variance of phosphorus absorption. Each 10 mmol of ingested calcium, by complexing phosphate in the intestinal lumen, blocked the absorption of ~4 mmol of diet phosphorus. (As noted earlier, this phenomenon is the basis for the use of calcium salts as phosphate binders in patients with ESRD.) This very high correlation leaves little room for an effect of vitamin D status. However, as calcium absorption rises in response to vitamin D, less calcium is left behind in the intestinal lumen to bind still unabsorbed phosphorus, and hence phosphorus absorption would predictably rise under conditions of high vitamin D status. But that would not necessarily mean that vitamin D directly stimulated phosphorus absorption. Thus experiments such as those of Brown *et al.* (2002), in which calcitriol increased absorption of both calcium and phosphorus in rats, cannot be interpreted unambiguously. In brief, the actual effect of vitamin D on adult phosphorus absorption under usual conditions and in health remains unclear.

### **Endogenous Fecal Phosphorus**

The emphasis in the foregoing section is on transfer of phosphorus from the gut lumen into the blood. But it should be noted that there is a substantial transfer in the opposite direction, i.e. from the mucosa into the chyme. The magnitude of this outward-directed flux has been estimated from studies involving systemic administration of a phosphorus isotope, with measurement of its appearance in the feces (Kierulf-Jensen, 1941; Nordin, 1988). Best current estimates for the magnitude of this flux lie in the range of 8–10 mmol/day (250–300 mg/day). Probably much of that total is in the form of sloughed-off gastroin-

**FIG. 29.2** Plot of net phosphorus absorption expressed as a function of diet phosphorus and fecal calcium. (Units on all three axes are grams.) See text for details. Copyright Robert P. Heaney, 2002. Reproduced with permission.

testinal mucosal cells (which typically turn over approximately every 5 days). This phosphorus source is digested just as is food phosphorus, and thereby becomes available for reabsorption. Using 8.8 mmol/day (275 mg/day) for intestinally secreted phosphorus, and 65% for net phosphorus absorption, and taking the median phosphorus intake for women aged 50–70 from NHANES, i.e. 34.8 mmol/day (1079 mg/day), one can easily compute that the total phosphorus load presented to the absorptive sites amounts to 43.6 mmol/day (1354 mg/day), with fecal phosphorus amounting to 12.2 mmol/day (378 mg/day). That means that gross absorption was 72%. This is but one indication of the avidity of the organism for ingested phosphorus.

### Urinary Phosphorus Excretion

Normally, most phosphorus loss from the body is through the kidneys. Under steady-state conditions (neither building nor reducing tissue mass), 24-hour urine phosphorus excretion is equal to net intestinal absorption of phosphorus. The kidney capacity for excretion of phosphorus is

very great, as can be seen from Figure 29.1. Across a doubling of phosphorus intake, ECF  $[P_i]$  rises very little, with essentially all the absorbed phosphorus being excreted. Very little elevation of the filtered load (as reflected in the serum  $[P_i]$ ) is needed to clear the body of unneeded phosphorus.

### Recommended Dietary Intake of Phosphorus

An adequate intake for any nutrient is one such that additional inputs of the same nutrient confer no further benefit. This concept is expressed in Figure 29.3A, which is a schematic plot of effect (or benefit) against intake. Intakes above the beginning of the plateau region are judged “adequate,” in the sense that no further benefit accrues to further intake. Not everyone reaches the plateau at the same intake, and Figure 29.3B shows schematically a family of intake–effect curves for different individuals. The intake at the average of these inflection points is what is meant by the estimated average requirement (EAR); the

**FIG. 29.3** Schematic intake–effect diagrams for a typical nutrient. (A) The basic plateau (or threshold) relationship for a typical nutrient, showing individual variation in approach to a plateau. **TABLE 29.4** Dietary reference intakes for phosphorus<sup>a</sup>

Ages	EAR <sup>b</sup>	RDA <sup>b</sup>	UL <sup>b</sup>
1–3	380 (12.3)	460 (14.8)	3000 (96.8)
4–8	405 (13.1)	500 (16.1)	3000 (96.8)
9–18	1055 (34)	1250 (40.3)	4000 (130)
19–50	580 (18.7)	700 (22.6)	4000 (130)
51–70	580 (18.7)	700 (22.6)	4000 (130)

<sup>a</sup>Values given as mg/day (mmol/day).

<sup>b</sup>EAR, estimated average requirement; RDA, recommended dietary allowance; UL, tolerable upper intake level.

Data from Institute of Medicine (1997).

recommended dietary allowance (RDA) is the intake at which 97.5% of a population would have achieved their individual plateaus.

Table 29.4 sets forth the 1997 Institute of Medicine (IOM) dietary reference intakes (DRIs) for phosphorus by age (Institute of Medicine, 1997). (The DRIs for pregnancy and lactation are the same as for women of the same age.) The adult value for the EAR in Table 29.4 is based on the intake required to sustain ECF  $[P_i]$  at or above the lower limit of normal (see Figure 29.1). Interestingly, the 1997 DRIs were the first to use a functional indicator (i.e.

ECF  $[P_i]$ ) as a basis for determining the phosphorus intake requirement.

The DRIs in Table 29.4 reflect the obvious need for higher intakes as body size is increasing, and particularly for periods of the greatest tissue accumulation (e.g. adolescence). However, the recommendations for children and adolescents, while reasonable, are not so firmly based as for the adult. The sole reflection of the diet which the tissues “see” is the serum  $[P_i]$ , and, as Figure 29.1 shows, mean serum  $[P_i]$  rises by less than 0.2 mmol/L as intake increases from 20 to 40 mmol/day (620–1240 mg/day). Serum  $[P_i]$  in this range is generally considered “normal,” and whether the higher end of that range would be more or less beneficial than the lower end is simply unknown.

There is a sense in which the phosphorus requirement is moot. The occurrence of an isolated dietary phosphorus deficiency is highly unlikely (except in low-birth-weight newborn infants). Individuals meeting even the modest published requirements for calcium and protein will automatically meet the phosphorus requirement. As a reflection of this tie between total nutrition and phosphorus status, the first seven editions of the US RDAs did not so much as list phosphorus, and, as recently as 20 years ago, most nations had not established an RDA for phosphorus.

## Phosphorus-Related Human Disease

### Deficiency

Phosphorus deficiency is expressed as hypophosphatemia. This only rarely occurs because of inadequate dietary phosphorus intake, and is almost always due to non-dietary metabolic disorders.
