# CONTENTS

Contributors .....	xxi
Foreword .....	xxix
Preface to the Second Edition .....	xxxix
Preface to the First Edition .....	xxxiii
Tissue Engineering in Perspective .....	xxxv
<i>Eugene Bell</i>	
Origins of Tissue Engineering .....	xxxv
The Tissue Engineering Triad.....	xxxv
What Parts of the Body Can Tissue Engineering Replace? .....	xxxvi
Acellular Prosthesis .....	xxxvii
The Relevance of Developmental Biology .....	xxxvii
Can Nature Be Imitated? .....	xxxviii
The Need for Vascularization <i>in Vitro</i> and <i>in Vivo</i> .....	xxxix
Stem Cells.....	xxxix
Cell Signaling.....	xxxix
Looking Forward.....	xl
References .....	xl
Introduction to Tissue Engineering .....	1
1. The History and Scope of Tissue Engineering .....	3
<i>Joseph P. Vacanti and Charles A. Vacanti</i>	
Introduction .....	3
Scientific Challenges .....	4
General Scientific Issues .....	6
Social Challenges .....	6
References .....	7
2. The Challenge of Imitating Nature .....	9
<i>Robert M. Nerem</i>	
Introduction .....	9
Cell Technology .....	10
Construct Technology .....	12
Integration into the Living System .....	13
Concluding Discussion .....	14
References .....	15
Part I. The Basis of Growth and Differentiation .....	17
3. Organization of Cells into Higher Ordered Structures .....	19
<i>Carol A. Erickson</i>	
Introduction .....	19
Cellular Changes Involved in the EMT .....	20
Stimuli of the Transformation .....	24
Conclusion .....	26
References .....	27
4. Dynamics of Cell–ECM Interactions .....	33
<i>Manuela Martins-Green</i>	
Introduction .....	33
Composition and Diversity of the ECM .....	34
Receptors for Extracellular Matrix Molecules .....	34

Cell–ECM Interactions.....	36
Signal Transduction Events during Cell–ECM Interactions.....	42
Relevance for Tissue Engineering .....	46
References.....	48
<b>5. Matrix Molecules and Their Ligands .....</b>	<b>57</b>
<i>Björn Reino Olsen</i>	
Introduction .....	57
Fibrillar Collagens: Major Scaffold Proteins in the ECM.....	58
Elastic Fibers and Microfibrils.....	63
Fibronectin: A Multidomain, Multifunctional Adhesive ECM Glycoprotein .....	63
Laminins: Large, Adhesive Basement Membrane Molecules.....	64
Modulators of Cell–Matrix Interactions.....	66
Proteoglycans: Multifunctional ECM and Cell Surface Molecules..	67
Summary .....	68
References.....	68
<b>6. Inductive Phenomena .....</b>	<b>73</b>
<i>Matthias Hebrok and Douglas A. Melton</i>	
Introduction .....	73
Epithelial to Mesenchymal Signaling in Endoderm Development ..	73
Lung Development and Instructive Signaling.....	73
Permissive Signaling during Pancreas Development .....	75
References.....	78
<b>7. Morphogenesis and Tissue Engineering.....</b>	<b>81</b>
<i>A. H. Reddi</i>	
Introduction .....	81
Bone Morphogenetic Proteins.....	82
Cartilage-Derived Morphogenetic Proteins .....	84
Pleitropy and Thresholds .....	85
BMPs Bind to Extracellular Matrix .....	85
BMPs: Actions Beyond Bone .....	85
BMP Receptors.....	85
Responding Stem Cells .....	86
Morphogens and Gene Therapy.....	87
Biomimetic Biomaterials.....	87
Tissue Engineering of Bones and Joints.....	88
Future Challenges .....	88
References.....	89
<b>8. Cell Determination and Differentiation.....</b>	<b>93</b>
<i>Leon W. Browder</i>	
Introduction .....	93
Roles of MRFs during Embryogenesis.....	94
Initiation of Skeletal Muscle Development.....	95
References.....	96
<b>Part II: <i>In Vitro</i> Control of Tissue Development .....</b>	<b>99</b>
<b>9. Mechanical and Chemical Determinants of Tissue Development .....</b>	<b>101</b>
<i>Donald E. Ingber</i>	
Introduction .....	101

Extracellular Matrix Structure and Function .....	101
Pattern Formation through ECM Remodeling.....	104
Mechanochemical Switching between Growth and Differentiation .....	105
Summary .....	107
References.....	108
<b>10. Animal Cell Culture.....</b>	<b>111</b>
<i>Gordon H. Sato and David W. Barnes</i>	
References.....	116
<b>11. Regulation of Cell Behavior by Matricellular Proteins .....</b>	<b>119</b>
<i>Amy D. Bradshaw and E. Helene Sage</i>	
Introduction .....	119
Matricellular Proteins.....	119
Conclusions .....	124
References.....	125
<b>12. Growth Factors .....</b>	<b>129</b>
<i>Thomas F. Deuel and Nan Zhang</i>	
Introduction .....	129
Wound Healing .....	130
Role of Basic Fibroblast Growth Factor and Angiogenesis .....	136
Other Roles of Growth Factors and Cytokines .....	137
Conclusions .....	137
References.....	137
<b>13. Tissue Engineering Bioreactors .....</b>	<b>143</b>
<i>Lisa E. Freed and Gordana Vunjak-Novakovic</i>	
Introduction .....	143
Cell–Polymer Constructs .....	143
Bioreactor Technologies .....	144
Bioreactor Modulation of Tissue Formation.....	147
Bioreactor Cultivation of Functional Tissues.....	151
Tissue Engineering Bioreactors: State of the Art.....	152
Summary and Research Needs .....	154
References.....	154
<b>14. Tissue Assembly in Microgravity.....</b>	<b>157</b>
<i>Brian R. Unsworth and Peter I. Lelkes</i>	
Introduction .....	157
Microgravity as a Novel Tissue Culture Venue.....	158
Vascularization: Overcoming Size Limitations of Tissue Assemblies.....	159
From Single Cells to Tissues in Space.....	159
<i>In Vitro</i> Embryology .....	160
Gravitational Sensing .....	161
Caveats .....	161
Conclusions .....	162
References.....	162

<b>Part III: <i>In Vivo</i> Synthesis of Tissues and Organs .....</b>	<b>165</b>
<b>15. <i>In Vivo</i> Synthesis of Tissues and Organs .....</b>	<b>167</b>
<i>Ioannis V. Yannas</i>	
Scale of Functional Deficit: Macromolecule versus Organ.....	167
Basic Parameters of the Living Environment during <i>in Vivo</i>	
Organ Synthesis .....	168
Fundamental Design Principles for Tissue and Organ	
Regeneration Templates .....	170
Examples of <i>in Vivo</i> Organ Synthesis .....	174
Summary .....	177
References.....	177
<b>Part IV. Models for Tissue Engineering.....</b>	<b>179</b>
<b>16. Organotypic and Histiotypic Models of Engineered Tissues .....</b>	<b>181</b>
<i>Eugene Bell</i>	
Introduction .....	181
The Collagen Gel Model .....	181
Models of Cell Interactions in Collagen Lattices .....	182
Other Types of Epithelial–Mesenchymal Models.....	184
Vascular Models.....	186
Selection of Scaffolds Other Than Gels for Model Systems .....	188
Cell Signaling and the Enrichment of Scaffolds.....	189
Goals and Uses of Model Tissue and Organ Building.....	190
References.....	191
<b>17. Quantitative Aspects of Tissue Engineering: Basic Issues</b>	
<b>    in Kinetics, Transport, and Mechanics .....</b>	<b>195</b>
<i>Alan J. Grodzinsky, Roger D. Kamm,</i>	
<i>and Douglas A. Lauffenburger</i>	
Introduction .....	195
Molecular Interactions with Cells.....	196
Molecular and Cell Transport through Tissue.....	198
Cell and Tissue Mechanics .....	201
References.....	205
<b>Part V. Biomaterials in Tissue Engineering .....</b>	<b>207</b>
<b>18. Patterning of Cells and Their Environment .....</b>	<b>209</b>
<i>Shuichi Takayama, Robert G. Chapman, Ravi S. Kane,</i>	
<i>and George M. Whitesides</i>	
Introduction .....	209
Soft Lithography.....	209
Self-Assembled Monolayers.....	210
Microcontact Printing.....	212
Microfluidic Patterning.....	214
Laminar Flow Patterning.....	216
Conclusion and Future Prospects .....	217
References.....	218
<b>19. Cell Interactions with Polymers .....</b>	<b>221</b>
<i>W. Mark Saltzman</i>	
Introduction .....	221
Methods for Characterizing Cell Interactions with Polymers.....	221

Cell Interaction with Polymer Surfaces.....	224
Cell Interactions with Polymers in Suspension .....	229
Cell Interactions with Three-Dimensional Polymer Scaffolds and Gels.....	230
References.....	231
<b>20. Matrix Effects .....</b>	<b>237</b>
<i>Jeffrey A. Hubbell</i>	
Introduction .....	237
Extracellular Matrix Proteins and Their Receptors .....	237
Model Systems for Study of Matrix Interactions.....	242
Cell Pattern Formation by Substrate Patterning .....	244
Signal Transduction and Functional Regulation via the Extracellular Matrix .....	244
Translation to Working Biomaterial Systems .....	246
References.....	246
<b>21. Polymer Scaffold Processing.....</b>	<b>251</b>
<i>Robert C. Thomson, Albert K. Shung, Michael J. Yaszemski, and Antonios G. Mikos</i>	
Introduction .....	251
Fiber Bonding.....	252
Solvent Casting and Particulate Leaching.....	253
Membrane Lamination .....	255
Melt Molding .....	256
Extrusion .....	256
Three-Dimensional Printing.....	257
Gas Foaming.....	257
Freeze Drying .....	258
Phase Separation .....	258
Polymer/Ceramic Composite Foams .....	259
<i>In Situ</i> Polymerization.....	260
Conclusions .....	261
References.....	261
<b>22. Biodegradable Polymers.....</b>	<b>263</b>
<i>James M. Pachence and Joachim Kohn</i>	
Introduction .....	263
Biodegradable Polymer Selection Criteria.....	263
Biologically Derived Bioresorbables.....	264
Experimental Biologically Derived Bioresorbables.....	266
Creating Materials for Tissue-Engineered Products .....	273
Conclusion .....	274
References.....	274
<b>Part VI. Transplantation of Engineered Cells and Tissues.....</b>	<b>279</b>
<b>23. Approaches to Transplanting Engineered Cells and Tissues .....</b>	<b>281</b>
<i>Janet Hardin-Young, Jeffrey Teumer, Robert N. Ross, and Nancy L. Parenteau</i>	
Introduction .....	281
Developing Workable Strategies.....	281
Mode of Action—An Important Design Consideration .....	283
Role of the Host.....	284

Source of Cells .....	285
The Immunology of Nonautologous Cells .....	287
Safety Considerations.....	288
Conclusion .....	288
References.....	289
<b>24. Cryopreservation.....</b>	<b>293</b>
<i>Jens Ö. M. Karlsson and Mehmet Toner</i>	
Introduction .....	293
Applications of Cryopreservation Technology in Tissue Engineering.....	293
Challenges in Cryopreservation Protocol Development.....	294
Cryobiology of Cells .....	295
Cryobiology of Tissue .....	302
Summary and Future Directions .....	304
References.....	305
<b>25. Immunomodulation.....</b>	<b>309</b>
<i>Denise Faustman</i>	
Introduction .....	309
Origin of the Designer Tissue Concept .....	310
Expansion of Research on Designer Tissues.....	311
Mechanisms of Graft Survival after Class I Donor Ablation or Antibody Masking.....	314
The Launching of Xenogeneic Human Clinical Trials in the United States Using Immunomodulation.....	316
Gene Addition .....	317
RNA Ablation.....	317
Comment .....	318
References.....	318
<b>26. Immunoisolation .....</b>	<b>321</b>
<i>Beth A. Zielinski and Michael J. Lysaght</i>	
Introduction .....	321
Technology .....	321
Clinical.....	323
Future Directions.....	326
References.....	328
<b>27. Engineering Challenges in Immunoisolation</b>	
<b>Device Development.....</b>	<b>331</b>
<i>Efstathios S. Avgoustiniatos, Haiyan Wu, and Clark K. Colton</i>	
Introduction .....	331
Engineering Challenges.....	331
Oxygen-Supply Limitations .....	336
Theoretical Analysis of <i>in Situ</i> Oxygen Generation .....	339
Calculations .....	345
Concluding Remarks .....	348
References.....	348
<b>Part VII. Fetal Tissue Engineering .....</b>	<b>351</b>
<b>28. Fetal Tissue Engineering.....</b>	<b>353</b>
<i>Dario O. Fauza</i>	
Introduction .....	353

General Characteristics of Fetal Cells .....	354
The Fetus as a Transplantation Host .....	355
Fetal Tissue Engineering .....	357
Ethical Considerations .....	360
Future Perspectives.....	363
References.....	364
<b>29. Pluripotent Stem Cells.....</b>	<b>369</b>
<i>Michael J. Shablott, Brian E. Edwards, and John D. Gearhart</i>	
Introduction .....	369
Differentiation <i>in Vitro</i> .....	371
Examples of <i>in Vitro</i> Differentiation and Markers .....	374
<i>In Vivo</i> Applications.....	376
Summary and Future Prospects.....	378
References.....	378
<b>Part VIII. Gene Therapy.....</b>	<b>383</b>
<b>30. Gene-Based Therapeutics .....</b>	<b>385</b>
<i>Lee G. Fradkin, J. Dezz Ropp, and John F. Warner</i>	
Introduction .....	385
Gene Delivery.....	386
Persistent Gene Expression.....	390
Safety Considerations for Gene-Based Therapeutics.....	394
Large-Scale Production Issues.....	396
Conclusion .....	397
References.....	397
<b>Part IX. Breast .....</b>	<b>407</b>
<b>31. Breast Reconstruction .....</b>	<b>409</b>
<i>Kuen Yong Lee, Craig R. Halberstadt, Walter D. Holder,</i> <i>and David J. Mooney</i>	
Introduction .....	409
Cell Types for Soft Tissue Engineering .....	410
Materials.....	412
Animal Models .....	417
Strategies to Enhance the Vascularization of Engineered Tissue....	419
Concluding Remarks .....	420
References.....	420
<b>Part X. Cardiovascular System .....</b>	<b>425</b>
<b>32. Blood Vessels.....</b>	<b>427</b>
<i>Lian Xue and Howard P. Greisler</i>	
Introduction .....	427
Graft Healing.....	428
Strategies for the Development of Vascular Grafts.....	432
References.....	441
<b>33. Small-Diameter Vascular Grafts .....</b>	<b>447</b>
<i>Susan J. Sullivan and Kelvin G. M. Brockbank</i>	
Introduction .....	447
Synthetic Grafts .....	448
<i>In Vitro</i> Blood Vessel Tissue Engineering.....	448

<i>In Vivo</i> Tissue Engineering of Blood Vessels .....	449
Summary .....	453
References .....	453
<b>34. Cardiac Prostheses .....</b>	<b>455</b>
<i>Jack W. Love</i>	
Introduction .....	455
A Short History of Tissue Heart Valves .....	456
The Status of Tissue Valves in 1999 .....	459
The Issue of Whether to Use a Stent .....	461
The Issue of Repair versus Replacement .....	463
Speculation about the Future .....	463
Recent Developments .....	464
The Ideal Valve Repair or Replacement .....	465
References .....	466
<b>Part XI. Cornea.....</b>	<b>469</b>
<b>35. Cornea .....</b>	<b>471</b>
<i>Vickery Trinkaus-Randall</i>	
Introduction .....	471
Biology of the Cornea .....	473
Criteria for Keratoprotheses .....	477
Development of the Keratoprosthesis.....	478
Evaluation of Intact Devices.....	484
Other Devices Used to Change the Curvature of the Cornea .....	489
References .....	489
<b>Part XII. Endocrinology and Metabolism .....</b>	<b>493</b>
<b>36. Bioartificial Pancreas.....</b>	<b>495</b>
<i>Taylor G. Wang and Robert P. Lanza</i>	
Introduction .....	495
Theoretical Background.....	497
Experiment .....	500
Capsule Development .....	501
Discussion .....	504
References .....	505

Cell Preparation.....	553
Clinical Study.....	554
Conclusion .....	557
References.....	557
<b>41. Lineage Biology and Liver.....</b>	<b>559</b>
<i>Arron S. L. Xu, Thomas L. Luntz, Jeffrey M. Macdonald,</i>	
<i>Hiroshi Kubota, Edward Hsu, Robert E. London,</i>	
<i>and Lola M. Reid</i>	
Introduction .....	559
Liver Organization and Development .....	560
Identification, Isolation, and Sourcing of Cells	
for Tissue Engineering .....	562
Sourcing of Human Cells for Tissue Engineering.....	569
Microenvironment.....	570
Biodegradable Polymers .....	576
Designing Bioreactors for Tissue Engineering .....	583
Technical Aspects of Tissue Engineering.....	585
Future Considerations.....	587
Summary .....	588
References.....	589
<b>Part XIV. Hematopoietic System.....</b>	<b>599</b>
<b>42. Red Blood Cell Substitutes .....</b>	<b>601</b>
<i>Thomas Ming Swi Chang</i>	
Introduction .....	601
Why Do We Have to Modify Hemoglobin?.....	601
Sources of Hemoglobin.....	605
Circulating Time of Modified Hemoglobin .....	606
Safety of Modified Hemoglobin Blood Substitute .....	606
Efficacy of Modified Hemoglobin Blood Substitute .....	607
Present Status and Future Research and Development .....	607
References.....	608

<b>43. Lymphoid Cells.....</b>	<b>611</b>
<i>Una Chen</i>	
Introduction .....	611
Lymphocyte Engineering: Reality and Potential .....	612
Concluding Remarks and Prospects for Lymphocyte Engineering.....	625
References.....	626
<b>44. Hematopoietic Stem Cells.....</b>	<b>631</b>
<i>Anne Kessinger and Graham Sharp</i>	
Introduction .....	631
Overview of Hematopoiesis: Properties and Regulation of Hematopoietic Stem Cells Relevant to Tissue Engineering.....	632
Organization of the Stem Cell Compartment .....	633
Stromal Microenvironments .....	633
References.....	638
<b>Part XV. Kidney and Genitourinary System .....</b>	<b>643</b>
<b>45. Renal Replacement Devices .....</b>	<b>645</b>
<i>H. David Humes</i>	
Introduction .....	645
Basics of Kidney Function.....	645
Tissue Engineering Approach to Renal Function Replacement.....	646
Summary .....	652
References.....	652
<b>46. Genitourinary System .....</b>	<b>655</b>
<i>Byung-Soo Kim, David J. Mooney, and Anthony Atala</i>	
Introduction .....	655
Tissue Engineering Strategies in the Genitourinary System .....	655
Engineering Genitourinary Tissues .....	656
Future Directions.....	664
References.....	664
<b>Part XVI. Musculoskeletal System.....</b>	<b>669</b>
<b>47. Structural Tissue Engineering.....</b>	<b>671</b>
<i>Charles A. Vacanti, Lawrence J. Bonassar, and Joseph P. Vacanti</i>	
Introduction .....	671
Materials Development .....	672
Structural Tissues .....	674
Biomechanics.....	679
Conclusion .....	680
References.....	680
<b>48. Bone Regeneration through Cellular Engineering.....</b>	<b>683</b>
<i>Scott P. Bruder and Arnold I. Caplan</i>	
Introduction .....	683
Marrow: The Source of Mesenchymal Progenitor Cells.....	683
Delivery of Osteoprogenitor Cells.....	687
Bone Regeneration by MSCs .....	689
MSCs and Gene Therapy.....	692
Prevention of Age-Related Bone Loss.....	693

Conclusion .....	694
References.....	694
<b>49. Articular Cartilage Injury.....</b>	<b>697</b>
<i>John M. McPherson and Ross Tubo</i>	
Introduction .....	697
Autologous Chondrocyte Transplantation .....	699
Commercialization of Autologous Chondrocyte Implantation .....	701
Alternative Strategies for the Delivery of Cell-Based Therapies for Cartilage Repair.....	706
Conclusions .....	707
References.....	708
<b>50. Tendons and Ligaments .....</b>	<b>711</b>
<i>Francine Goulet, Denis Rancourt, Réjean Cloutier, Lucie Germain,     A. Robin Poole, and François A. Auger</i>	
Introduction .....	711
The Need for Bioengineered Tendon and Ligament Substitutes ....	711
Histologic Description of Tendons and Ligaments .....	712
Production of Bioengineered Tendons and Ligaments .....	713
A New Living Bioengineered Ligament Model.....	713
Technical Steps to Produce and Analyze Our bACL .....	715
Conclusions.....	718
Perspectives in Tendon and Ligament Bioengineering .....	719

## FOREWORD

---

---

Charles A. Vacanti

As we enter the new millennium, it is important to look back and see where we have been. Only with this perspective is it realistic to look toward the future and imagine what is possible.

Tissue engineering will ultimately have a more profound impact than we can now appreciate. It not only will modify the practice of medicine and help elucidate mechanisms of developmental biology, but also has the potential to influence economic development in the industry of biotechnology more than any single advance in science or medicine during the last several decades.

Although we can point to various milestones in history and refer to certain achievements as “tissue engineering,” focused efforts to regenerate lost tissue function were made possible only after advances in associated fields of cell biology and material sciences. Consequently, modern tissue engineering was not possible, or even feasible, until advances in cell biology enabled the large-scale production of commercially available enzymes and nutrients to isolate a large number of cells and nourish them in an incubator. It now seems clear that the use of living cells will result in a higher degree of tissue function than the use of chemotactic agents, growth factors, or hormones to stimulate development. Indeed, the ability to isolate cells from many different specialized tissues has existed for only a few decades. Even today, *in vitro* multiplication of certain cell types has been achieved with only limited success.

Early approaches to reintroducing cells into a recipient were quite simplistic and usually unsuccessful. Cells were initially injected as free suspensions in the hope that they would randomly engraft.

A further challenge to the large-scale development and application of tissue engineering is the immunologic barrier. Improvements in the understanding of immunology and the ability to trick the host into thinking foreign cells are “self” may ultimately allow for implantation of allograft or even xenograft cells to generate functional tissue. Unfortunately, at this time in history, the development of a universal donor cell type that can be used to construct the framework of a commercially available cell/polymer construct that will meet the needs of any recipient is still a dream.

After almost 20 years of serious efforts to generate new functional tissue from living cells, we have learned several basic concepts. Most important, “it is not nice to fool Mother Nature.” In this respect, many efforts have given the highest degree of success when they have mimicked nature. What we know scientifically is only a minuscule amount of all the processes related to the organization, development, and function of living systems. Although numerous theories have been proposed, explored, and replaced by more modern hypotheses, most of the biologic processes remain a “black box.”

At times, tissue engineering as a science and as a medical discipline has been called “unnatural.” When one actually considers what physicians have done for centuries, this couldn’t be

farther from the truth. The basic premise of health care is that the body heals itself. Physicians do nothing more than support a patient's vital functions by optimizing the environment most conducive to healing. Basically, physicians attempt to neutralize hostile factors at the same time that they enhance the supply of oxygen and nutrients that the body needs to heal itself. A basic principle of surgery is to debride the dead tissue that is the source of unfavorable chemical agents and to approximate tissue to protect the tissue from the hostile environment and improve the vascular supply to the injured site. In tissue engineering, we strive to achieve exactly the same goal. Necrotic and scar tissue are first excised. Rather than the remaining tissue being approximated to eliminate the dead space, living cells that belong in the injured area are configured to prevent their dissipation, like a scaffolding that dictates shape and function of the desired tissue by providing structural cues. The scientist then manipulates the environment in precisely the same manner as the physician, that is, by optimizing the delivery of oxygen to the site and the elimination of waste products. Under ideal conditions, this will then enable the body to heal itself. Tissue engineering efforts are focused on the microenvironment as opposed to the macroenvironment being manipulated in traditional health care.

A more recent critical factor in tissue engineering that is only now being more fully explored is the source of the cells to be utilized. Several studies have suggested that more immature cells are able to multiply to a higher degree *in vitro* than fully differentiated cells of specialized tissues. In contrast to the *in vitro* multiplication of fully differentiated cells, these immature or progenitor cells can be induced to differentiate and function after several generations *in vitro*. They also appear to have the ability to differentiate into many of the specialized cells found within specific tissues as a function of the environment in which they are placed.

Finally I believe that it is important to understand the current limitations of the field and the developments in associated fields on which tissue engineering is predicated. Our expectations must be aligned with our abilities as the field emerges. In that capacity, the first human applications may indeed reflect the application of the principles of tissue engineering as a component therapy to replace lost function(s) of specific organs or tissue, rather than replacement of the entire organ. In the instance of liver or pancreas engineering, for example, the patient may be experiencing only a specific enzymatic defect or may lack the ability to manufacture a vital hormone or growth factor. Perhaps only a critical mass of functional tissue need be generated, rather than the entire organ. In this fashion, advances in human application can parallel advances in the science of the field rather than generate unrealistic hopes prematurely.

Although it is believed that developments in this field will result in a tremendous advance in the treatment of many disease processes, the power of tissue engineering as a model for exploring changes associated with developmental biology may equal its special applications to human health care.

In conclusion, a well-thought-out and organized development of the science and application of the field of tissue engineering could generate benefits for humankind far into the new millennium.

## PREFACE TO THE SECOND EDITION

---

---

The first edition of this textbook, published in 1997, was rapidly recognized as the comprehensive textbook of tissue engineering. This edition is intended to serve as a comprehensive text for the student at the graduate level or the research scientist/physician with a special interest in tissue engineering. It should also function as a reference text for researchers in many disciplines. It is intended to cover the history of tissue engineering and the basic principles involved, as well as to provide a comprehensive summary of the advances in tissue engineering in recent years and the state of the art as it exists today.

Although many reviews had been written on the subject and a few textbooks had been published, none had been as comprehensive in its defining of the field, description of the scientific principles and interrelated disciplines involved, and discussion of its applications and potential influence on industry and the field of medicine in the future as the first edition.

When one learns that a more recent edition of a textbook has been published, one has to wonder if the base of knowledge in that particular discipline has grown sufficiently to justify writing a revised textbook. In the case of tissue engineering, it is particularly conspicuous that developments in the field since the printing of the first edition have been tremendous. Even experts in the field would not have been able to predict the explosion in knowledge associated with this development. The variety of new polymers and materials now employed in the generation of engineered tissue has grown exponentially, as evidenced by data associated with specialized applications. More is learned about cell/biomaterials interactions on an almost daily basis. Since the printing of the last edition, recent work has demonstrated a tremendous potential for the use of stem cells in tissue engineering. While some groups are working with fetal stem cells, others believe that each specialized tissue contains progenitor cells or stem cells that are already somewhat committed to develop into various specialized cells of fully differentiated tissue.

Parallel to these developments, there has been a tremendous “buy in” concerning the concepts of tissue engineering not only by private industry but also by practicing physicians in many disciplines. This growing interest has resulted in expansion of the scope of tissue engineering well beyond what could have been predicted five years ago and has helped specific applications in tissue engineering to advance to human trials.

The chapters presented in this text represent the results of the coordinated research efforts of several hundred scientific investigators internationally. The development of this text in a sense parallels the development of the field as whole and is a true reflection of the scientific cooperation expressed as this field evolves.

## PREFACE TO THE FIRST EDITION

---

---

Although individual papers on various aspects of tissue engineering abound, no previous work has satisfactorily integrated this new interdisciplinary subject area. *Principles of Tissue Engineering* combines in one volume the prerequisites for a general understanding of tissue growth and development, the tools and theoretical information needed to design tissues and organs, as well as a presentation of applications of tissue engineering to diseases affecting specific organ system. We have striven to create a comprehensive book that, on the one hand, strikes a balance among the diversity of subjects that are related to tissue engineering, including biology, chemistry, materials science, engineering, immunology, and transplantation among others, while, on the other hand, emphasizing those research areas that are likely to be of most value to medicine in the future.

The depth and breadth of opportunity that tissue engineering provides for medicine is extraordinary. In the United States alone, it has been estimated that nearly half-a-trillion dollars are spent each year to care for patients who suffer either tissue loss or end-stage organ failure. Over four million patients suffer from burns, pressure sores, and skin ulcers, over twelve million patients suffer from diabetes, and over two million patients suffer from defective or missing supportive structures such as long bones, cartilage, connective tissue, and intervertebral discs. Other potential applications of tissue engineering include the replacement of worn and poorly functioning tissues as exemplified by aged muscle or cornea; replacement of small caliber arteries, veins, coronary, and peripheral stents; replacement of the bladder, ureter, and fallopian tube; and restoration of cells to produce necessary enzymes, hormones, and other bioactive secretory products.

*Principles of Tissue Engineering* is intended not only as a text for biomedical engineering students and students in cell biology, biotechnology, and medical courses at advanced undergraduate and graduate levels, but also as a reference tool for research and clinical laboratories. The expertise required to generate this text far exceeded that of its editors. It represents the combined intellect of more than eighty scholars and clinicians whose pioneering work has been instrumental to ushering in this fascinating and important field. We believe that their knowledge and experience have added indispensable depth and authority to the material presented in this book and that in the presentation, they have succeeded in defining and capturing the sense of excitement, understanding, and anticipation that has followed from the emergence of this new field, tissue engineering.

# TISSUE ENGINEERING IN PERSPECTIVE

Eugene Bell

## ORIGINS OF TISSUE ENGINEERING

To write a perspective burdens the writer with the task of relating the many aspects of a subject not only to each other, but also to the subject as a whole. As we begin tracking the origins of tissue engineering, what stands out from the past, and remains with us in the present, is the role played by surgeons in creating one body part for another to meet the needs of individual patients. Improvising anatomic repair using an individual's own organ or tissue is still a technique often used by the reconstructive surgeon. For example, consider the use of a segment of ileum to create an ectopic replacement urinary bladder, to which the ureters are sewn at one end, with the other end everted. The everted end with its exposed mucosa, serving as a stoma, is installed transdermally in the abdominal area, providing an organ through which urine can flow into a sac attached to the surrounding skin. The procedure has been remarkably successful, but in the new age of tissue engineering, our thinking is directed to the fabrication of a substitute bladder that the surgeon can take off the shelf.

It was in the tradition of innovative surgical borrowing to rebuild a body part that new materials were sought to substitute for what the patient's own tissues might provide. The idea of improving on nature by using man-made materials was nurtured by the discovery and availability of the new synthetics during World War II. Since that time of technological expansion, the quest for substitutes for autologous tissues has been a roller-coaster ride. Thermoplastic synthetic polymers such as nylon, Dacron, polyurethane, polypropylene, and many others, not designed for use in the human body as tissue replacement, were introduced by suppliers of surgical paraphernalia and were used by practitioners of the art of surgery, for rebuilding damaged, diseased, aged, or genetically deficient body parts. The synthetic materials were introduced into the human body as components of fabricated replacement parts at a time when the possibility of reconstituting biologic substitutes was still unexplored. Many of the postwar synthetics are still in use today, with major questions regarding their efficacy hanging over us.

What was previously called reconstructive surgery came to be called tissue engineering when the focus of attention became the fabrication of living replacement parts for the body in the laboratory. The technology represented a dramatic shift to the use of the biologic components of actual tissues for reconstructing replacements. Tissue building as it occurs in organisms during development, and for some body parts throughout life, was being imitated. The new approach, coming at a time when biotechnology was achieving widespread acceptance, quickly gained the interest of the financial market and the pharmaceutical companies because of its commercial potential.

## THE TISSUE ENGINEERING TRIAD

As we know, biologic tissues consist of the cells, the extracellular matrix (made up of a complex of cell secretions immobilized in spaces continuous with cells), and the signaling systems, which are brought into play through differential activation of genes or cascades of genes whose secreted or transcriptional products are responsible for cueing tissue building and differentiation.

Figure 1 illustrates the triad of tissue engineering, which is based on the three basic components of biologic tissues. The principal components of scaffolds (into which the extracellular matrix is organized in actual tissues)

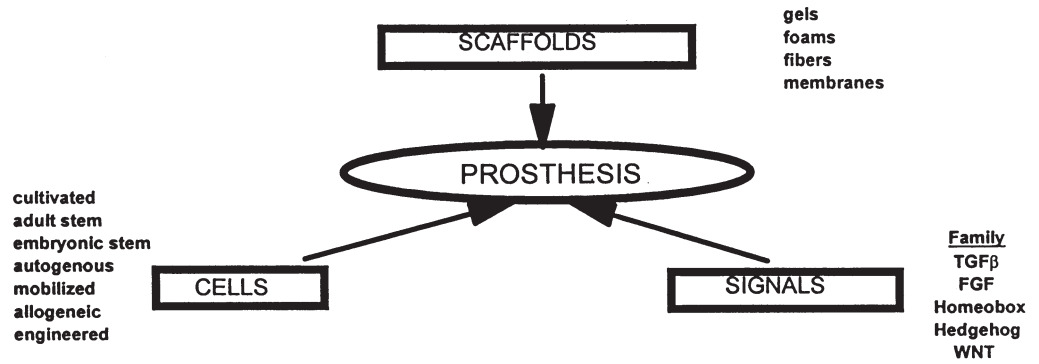

Fig. 1. The tissue engineering triad. See text for discussion.

are collagen biopolymers, mainly in the form of fibers and fibrils. Other forms of polymer organization have also been used (gels, foams, and membranes) for engineering tissue substitutes. The various forms can be combined in the laboratory to create imitations of biopolymer organization in specific tissues. Scaffolds can be enriched with signaling molecules, which may be bound to them or infused into them. Figure 1 shows some of the commonly occurring families of genes whose products play a major role in morphogenesis, pattern formation, and cell differentiation, processes that underlie histogenesis and organogenesis. The focus of the triad is the prosthesis.

The incorporation of cells in reconstituted prosthetic tissue devices often can provide the signals needed for tissue building, but the repertoire of feats of differentiation may be limited (see section on stem cells below). For example, although cultivated allogeneic keratinocytes and dermal fibroblasts, plus a collagen scaffold, can be assembled into a graftable organ that differentiates a fully formed epidermis, having a stratum corneum with barrier properties and a basal lamina, the secondary derivatives such as hair follicles and sebaceous and sweat glands do not develop. Improving the quality and functionality of tissue-engineered skin will mean the introduction of new versions of skin that address the clinical needs in a way better than their precursors have addressed them.

Another deficiency of engineered skin, for a number of significant applications, is its susceptibility to decomposition by metalloproteinases before it can be remodeled into a resistant replacement. Scaffolds of sturdier composition that will slow down enzyme action but still yield to effective rates of remodeling need to be developed. The impetus to improve engineered products will naturally be guided by the ideal, represented by evolution's achievement, the structure and function of the actual body part. It is to be expected that the competitive urges in a growing industry will be an important force in the race to imitate nature faithfully. Surely, the missions of basic scientists will also exert their effect.

Oversimplified materials used for the scaffolding component (the extracellular matrix of the tissue being engineered) may be limiting. If the scaffold cannot provide the developmental signals for tissue building needed by the cells that are seeded into it *in vitro*, or mobilized by it *in vivo*, tissue building might fail, as it does when a Dacron sleeve is used *in vivo* to replace a segment of artery. Man-made biopolymers such as poly(L-lactic acid), poly(glycolic acid), polyglycolide, and poly(L-lactide) have built-in ranges of degradation times that may not be in tune with the required rate of remodeling characteristic of regeneration, because the polymers are not susceptible to breakdown by metalloproteinases and tryptic enzymes, which function normally in the remodeling of collagen-based scaffolds. If they are out of tune with the remodeling activities of cells that occupy the transient scaffolds, including matrix biosynthesis, the process of matrix renewal may be compromised. A potentially valuable attribute of acellular materials installed *in vivo* as precursors of tissue replacements is their ability to mobilize appropriate cells from contiguous tissues, circulating body fluids, or stem cell sources, making it unnecessary to populate the prosthesis with cells before implantation. Because acellular implants of man-made biopolymers are information poor, cell mobilization and vascularization may fail, and so may the organization of the mobilized cells and their secretory output, needed to regenerate a replacement matrix and a functional tissue.

## WHAT PARTS OF THE BODY CAN TISSUE ENGINEERING REPLACE?

The breadth of possibilities for creating replacement parts was explored very early in the growth of tissue engineering as a discipline. The reconstitution of living tissues—including skin, arteries consisting of three different cell types, thyroid gland, and adipose and other tissues—was reported between 1979 and 1986 by E. Bell and colleagues. Before that period, tissues for transplantation were available from tissue banks, with allogeneic living

tissues coming into use after the discoveries of the immunosuppressants and the significance of matching tissue antigenic composition. The requirement of immunosuppressants in the transfer of allogeneic tissues has turned out not to be absolute. Being able to reconstitute tissues and organs by isolating and serially cultivating the parenchymal cells of which they consist makes it possible to select out cells of the immune system responsible for host initiation of graft rejection. The discovery by Sher *et al.* in 1983 showed that allogeneic skin parenchymal cells, separated from subsets of immune cells that normally populate the respective tissues of the skin, can be allografted without rejection in the absence of immunosuppressants. The work was the principal basis for the success of a non-custom-tailored commercial skin at Organogenesis Inc., a company founded by Bell. Some fresh tissues, such as cartilage (which is not engineered but is considered to be immunologically privileged because it has no blood circulation, and hence no subsets of cells of the immune system found in most tissues), have been grafted successfully across major histocompatibility barriers in work pioneered by A. E. Gross in Toronto and by others. The use of many other cell types for allogeneic grafting needs to be tested, to determine how universal grafting of non-self cell populations, free of immune cells, can become. Since the early work in the 1980s, Bell and colleagues and others have created prototypes of many additional tissues, including cartilage, ligament, bladder, periodontal prostheses, periosteal membrane among the soft tissues, and bone precursor cements for hard tissue replacement. We note that the late Bill Chick was a pioneer in the development of an endocrine pancreas equivalent.

It is not outlandish to consider that one day, replacement parts that are now inanimate devices may be reconstituted as biologic replicas. Some of the tissues needed for making a biologic limb or a part of one already have been fabricated. Others, such as cartilage, tendon, ligament, muscle, and bones, are works in progress. The task ahead is putting some of them together *in vitro* so that the composite becomes integrated for transplantation *in vivo*, in particular, vascularized, and made to function coordinately with the rest of the body, with the help of an artificial neural network.

## ACELLULAR PROSTHESES

The use in animal models and in humans of complex allogeneic and xenogeneic tissues, depleted of their living cells by freezing or other methods, has been shown to be immunologically acceptable without the use of immunosuppressants. It is known from studies in experimental animals and humans that acellular allogeneic and xenogeneic implants have been accepted by their hosts. The work of D. W. Metzger with the small intestinal submucosa developed for many applications by S. W. Badylak has shown that immune responses to xenogeneic acellular tissues are of the Th2 class, not involving fixation of complement or graft rejection, but rather inducing tolerance. There has been failure following repeated challenges of grafts by subsequent implants of the antigenic materials, in attempts to drive the immune reaction into a Th1, cell-mediated rejection response. Because of the evolutionary conservation of their structural and compositional likeness to the part being replaced, and the degree to which xenogeneic materials lend themselves to remodeling by host cells, the value of various foreign acellular tissues, many available through tissue banks, is becoming well established. Further, the growing economic success of a number of companies devoted to the use of materials derived from tissue banks is strong testimony to the foregoing. Processing strategies, including control of pathogenic viruses, developed by some of these companies have contributed in a major way to the usefulness of the products derived from allogeneic human tissues.

Acellular collagen matrices, in the form of foams with and without bone precursor minerals, have been used as vehicles for delivering a variety of bone morphogenetic proteins.

## THE RELEVANCE OF DEVELOPMENTAL BIOLOGY

The emergence of tissue engineering as a discipline has been stimulated by the necessary reexamination of the origin of tissues in the organism. (The discussions below of stem cells and signaling molecules, which play a role in tissue and organ ontogeny, acknowledge the debt to developmental biology studies.) Analyzing the development of a tissue reveals the significance of the extracellular matrix as a principal source of information for what cells do. In the beginning of embryonic development there are, essentially, just cells, expanding their own numbers in a rapid sequence of cleavages of the fertilized egg. By the blastula stage, or even the earlier morula stage, with as few as 128 cells present, secretion of components of the extracellular matrix has already begun. An early secretory product is collagen. Wessel and McClay (1987) have demonstrated that if collagen biosynthesis is blocked in the morula stage of sea urchin development—or, more pertinent still, if collagen cross-linking, an extracellular function performed by the enzyme lysyl oxidase, is prevented by  $\beta$ -aminopropionitrile—development is brought to a halt. Because development resumes when the blocker is removed, the point is made that the extracellular matrix is a crucial determinant required by cells cooperating in a multicellular complex to carry out their programs for cell division and morphogenesis. As development progresses, biosynthesis and secretion of structur-

al and instructive extracellular matrix molecules continue in parallel. Gradually the extracellular matrix becomes tailored, regionally, to specific tissues and organs as the cells that make them up differentiate, expressing tissue-specific repertoires of matrix secretions. The early output of collagens in embryogenesis is especially significant, because in addition to recognizing integrin receptors and through cell-binding ligands, the collagens bind a large number of different secreted matrix molecules and perform the task of immobilizing many cell-secreted products. If these products were not immobilized, they would escape and fail to contribute to the molecular diversity of the extracellular matrix tapestry. The development of the complex extracellular matrix grows as the molecules that bind to collagen bind other subsets of molecules.

I have dwelt on the origins of the extracellular matrix to bring into focus the design of tissues that are communities of cells in which individual cells, or small groups of cells, as well as large cell masses, are surrounded by networks of collagen fibrils and fibers. Sheets of cells, including epithelial, mesothelial, and endothelial cells, are underlaid by a matrix whose principal component is also fibrillar collagen. In either design the extracellular matrix is the product of the cells that live in it, or on it; it is further enriched by paracrine and endocrine secretions and by products of the wandering cells, such as macrophages, lymphocytes, neutrophils, and mast cells, that move in and out of it. The extracellular matrix is an extremely complex material of high molecular diversity and microarchitectural specificity. It is in developing and regenerating systems that the sequence of genes activated to create the definitive extracellular matrix can be detailed.

### CAN NATURE BE IMITATED?

Meeting the challenge of reconstituting tissues is in a way dependent on how the philosophic question “can nature be imitated?” is answered. To begin with, what do we mean by “imitated”? There are three senses that can be discussed: (1) It can mean making an exact or closely approximate biologic replica that exhibits at least some of the basic properties of the original tissue at the time it is implanted. (2) It can mean providing a much less well-developed precursor of a biologic substitute, with the expectation that it will be built into a faithful replica. (3) It can mean using a nonbiologic replacement. Either of the first two approaches might remedy a deficit and restore functionality in the form of a living tissue or organ. Successful examples of nonbiologic replacement parts are artificial limbs, dentures, and hearing aids, which are attached to the body but not grafted to it. Another class of nonbiologic aids includes pacemakers and elements of the skeletal system, including joints with plastic and metallic components, all of which are grafted, but not biologically integrated, remaining inanimate devices. Probably the most risky adventure in engineering an inanimate replacement part was the attempt to construct a total artificial heart (TAH) having connections to the major arterial and venous vessels of the host. Apart from the unwieldy size of the TAH, the incredible difficulty of compliance matching of the artificial to the native arterial vessels may have been given too little attention early on. Mismatches result in great turbulence of flow, as does flow through mechanical chambers of improper design, resulting in blood clot formation. With a heightened awareness of past problems there is a new optimism abroad. New research and development on the TAH is being supported at the Texas Medical Center’s Texas Heart Institute, which provides a history of their Mechanical Circulatory Support program at their internet site (<http://www.tmc.edu/thi/mcshist.html>). In current development are ventricular assist devices designed to give weak hearts the boost they need to function more adequately and to serve as interim helpers for those awaiting a heart transplant.

We may believe that nature can be imitated biologically, but it is difficult to conceive, however imperfect nature is, that it can be improved. The sense in which this is meant is that it will be difficult if not impossible to improve the genetically and developmentally *normal* endowments that define the character of tissues, such as the tissue scaffolds (the extracellular matrix of tissues) and the signaling systems needed for tissue development. We are reluctant to say absolutely that synthetic materials that precisely imitate body parts will not succeed, but given the number of genes involved in the signaling systems and the tissue scaffold systems, asking for an improvement in the roles of these complex components in the course of tissue development is like asking for a chance to evolve again. What is germane for tissue engineering is the task of improving the lives of individuals undermined by genetic and developmental aberrations, which are often expressed early, and by the degenerative diseases of aging, such as atherosclerosis, kidney failure, osteoporosis, arthritis, and skeletal wear and tear. In these individuals, degenerative states and the imperfect endowments of nature surely can be improved. Implanting an arterial substitute that resists intimal or medial hyperplasia in an individual with a propensity for atherosclerosis would provide a greatly improved vessel compared to the naturally endowed but disease-ridden vessel for which it is a substitute.

The probability seems low that nonbiologic synthetic materials that precisely imitate body parts and retain their properties without degenerating will be discovered and used successfully as prostheses; it is more likely that alternative strategies are closer at hand. Awakening the capacity of the body to regenerate by giving it assistance in the form of bioabsorbable remodelable scaffolds, instructive molecules, and cells, if they are not available to be mobilized, is the essence of current trends.

## THE NEED FOR VASCULARIZATION *IN VITRO* AND *IN VIVO*

It is no small task to design living prosthetic devices so that the cells seeded into them can survive until the implant acquires a circulation. It can be expected that there will be a risk of nonsurvival for cells deep in the prosthesis. Reducing the risk will depend on the use of angiogenic cytokines and tricks of tissue design that can provide access of a medium *in vitro* and can promote development of an adequate circulation sufficiently rapidly *in vivo*. We look forward to the possibility that small arteries and veins can be built into the prosthesis to make contact with a capillary bed *in vitro* under the influence of angiogenic factors. The small arteries and veins would eventually be anastomosed to those of the host. Much experimental work is needed to achieve the foregoing. Obviously the rate of diffusibility of tissue fluids and large molecules allowed by a prosthesis will be one of its important properties.

Although vascular prostheses may be needed to serve other engineered tissues of substance *in vitro* and afterward *in vivo*, a great need for them exists as stand-alone devices for replacing both peripheral and coronary sites affected by arterial disease. There has been a considerable history of preclinical and clinical trials both of natural vessels, mainly veins, and of nonbiologic synthetic prostheses. Those made with nonbiologic synthetic polymers have had limited replacement value and basically have not yet proved themselves. Although the materials were not strongly immunogenic, some elicited persistent inflammatory reactions and others were erodable; none was adequately compliant or able to integrate with host tissues. Remembering that these new polymers have never before been encountered by cells in the course of evolution, it is remarkable that, as foreign bodies, they have been tolerated as well as they have. It is thought by some that self-degrading man-made biopolymers have a future in tissue engineering, even though they are unfamiliar to cells and suffer the shortcomings discussed above. One promising possibility is that they may be replaced *in vivo* in a timely fashion by native scaffolds built by the cells seeded into them. But reconstituting arterial vessels entirely with biologic components—that is, with cells and naturally occurring extracellular matrix polymers such as collagen, which are also bioabsorbable and remodelable—has been in progress for some years, with significant advances being made over the earlier efforts. It has been suggested that genetically engineered smooth muscle cells can be made refractory to mitogenic stimuli that induce medial and intimal hyperplasia. The use of this and other genetic strategies may not be far off.

## STEM CELLS

Scaffolds can be populated with adult-derived cells that are capable of undergoing subsequent differentiation after being cultivated *in vitro*. In this category are cells of the skin, cartilage, muscle, tendon, ligament, bone, adipose tissue, endothelium, and many others. Aside from skin, the foregoing cell types are harbored as stem cell populations in the marrow, in addition to those of the hematopoietic and immune systems, but the diversity of mesenchymal and possibly other cell types in the marrow still needs to be probed. Stimulating factors, the cytokines, which move some of the cells into the circulation, will be important for engineering acellular scaffolds. Other stem cells are available to tissue engineering, such as the satellite cells found in striated muscle and to some degree keratinocytes of the skin. Where host cells are available, an acellular scaffold, particularly one enhanced with signals and possessing the binding sites needed for cell attachment, can mobilize host cells that will populate the prosthesis. Already, new sources of stem cells, particularly neuronal stem cells, have been discovered in the adult brain and are opening the door to the reconstitution of nerve tissue for tissue engineering. In addition to the striatum, which harbors extracellular growth factor-responsive stem cells, other central nervous system sources of stem cells in adult vertebrates include the hippocampus and the periventricular subependymal zone. Stem cells giving rise to neuronal and glial phenotypes, from the adult rat hippocampus, are isolated with the help of fibroblast growth factor 2 and are stimulated to differentiate with the help of retinoic acid. Stem cells from these sources are also present in the adult human brain.

The discovery that embryonic stem cells can be recovered from human fetal tissue and propagated for long periods without losing their toti- or pluripotency is of huge importance for tissue engineering. How to direct their differentiation is a subject of high current interest.

Engineered cells, endowed with regulators of cell division, or in which expression of specific gene products may be promoted or on which immunologic neutrality may be conferred, will no doubt become common in the future.

## CELL SIGNALING

We currently are witnessing an explosion of information relating to cell signaling, implicated in a broad range of developmental activities, including the establishment of the embryonic axis, the formation and differentiation of somites, the establishment of the central and peripheral nervous systems, and many other histio- and organogenic activities. The National Institute of Health Science Cell Signaling Networks Database (CSNDB) on the internet (<http://geo.nih.go.jp/csndb>) lists signaling molecules, their pathways, and original articles. The size of the database conveys the breadth of work in progress in the field.

Responsible for establishing the overall pattern of the body and involved in differentiation of the nervous system and limb development is the homeobox gene family. Its products are transcription factors, which are not secreted but work intracellularly. Mammals, mice, and humans, for example, have four clusters of homeobox genes, each on a different chromosome. The order of gene activation progresses from 3' to 5' through the gene sequence, with the expression of each successive gene in the complex being colinear with the anterior–posterior axis of the body plan and the specific organ system undergoing development. What happens to a cell depends on where it is. It is thought that a gradient of secreted Sonic hedgehog (Shh) protein may be responsible for the regionally differential activation of particular genes in the homeobox complex.

Although it appears that cascades of gene activation are implicated in the building of many tissues and organs, there cannot be an infinite regression of gene activation by products of genes that must in turn be expressed. At various points in the causal chain of epigenesis, physical factors and nongenetic chemical factors, distributed asymmetrically in the fertilized egg and partitioned during cleavage, may be the early initiators of gene function. Later in development as well, many events of differentiation may be initiated by nongenetic signals. One principle of signaling has become clear: multiple signals appear to be required for tissue building. For example, at least five signaling molecules appear to direct the events associated with the differentiation of the dorsal compartment of the somite into epaxial muscle, dermis, and hypaxial muscle. Many other multiple signaling pathways also have been identified. For tissue engineering a holistic approach to signaling based on the use of multiple signals identified in developmental studies may yield results superior to those achieved with single growth factors, as exemplified in orthopedic applications. Bell (United States Patent numbers 5,800,537 and 5,893,888) and co-workers have been isolating and testing complexes of tissue-specific signals [animal-derived extracellular matrix (ADMAT)] processed from developing tissues. A dental ADMAT combined with an injectible bone precursor cement has been used successfully to promote bone development around titanium implants in dogs. Along with their co-workers, T. M. Sioussat (of Tissue Engineering Inc.) and D. W. Meraw (of the Mayo Clinic) led development of the company's bone precursor cement and the dental ADMAT in which there were multiple growth factors in picogram quantities, distinguished from individual cytokine products used in microgram quantities, to stimulate new bone formation.

## LOOKING FORWARD

The excitement of tissue engineering, conveyed in the chapters of this volume, lies in the challenge of imitating nature, and in the opportunity to witness the outcomes of a discovery or invention, because the interval between conception and clinical realization of a new device or treatment is, in our time, telescoped. The value, too, of viewing cells as they are organized *in vivo*, by developing *in vitro* model tissue and organ systems for studying normal and disease states of cell replication, morphogenesis, and differentiation, represents a new opportunity. To meet the task of reconstituting tissues *in vitro*, understanding how tissues are built *in vivo* is the overwhelming challenge. The general question for those in tissue engineering asks what instructions cells need for organizing into tissues. More specifically, which cells are capable of responding to instructions in the form of signals? If they are hidden stem cells, how can they be harvested? How are responsive cells induced to increase their numbers? And how are these cells primed to engage in the synthesis of tissue-specific products? Which signals are needed to trigger the causal chain of tissue development? Is it indeed an isolated cascade or are tissue interactions required for release of signals? Moving on, what materials are synthesized for extracellular transport as a result of signals received? How are the secreted materials assembled into structures such as collagen fibrils and fibers that persist and serve as the tissue's scaffold, around which the remainder of the extracellular matrix is built? What do the anatomic and chemical fine structures of the extracellular matrix look like? Finally, how do the reconstituted tissues fare in the hosts in which they are implanted? The questions asked are relevant for the task.

The study of these questions is subsumed not by a single discipline, but by many, including microanatomy; cell, molecular, and developmental biology; immunology; materials science; and branches of engineering able to inquire into the modes of action of the physical forces on which many developmental phenomena depend. The present volume is authored by practitioners of a number of the above-mentioned disciplines as well as by others relevant for tissue engineering, reflecting the multidisciplinary character of the new field, which is truly beginning to define itself.

# THE HISTORY AND SCOPE OF TISSUE ENGINEERING

Joseph P. Vacanti and Charles A. Vacanti

## INTRODUCTION

During the past decade—in fact, since the publication of the first edition of this book in 1997—the field of tissue engineering has grown at a seemingly logarithmic rate. The expansion has not only been in interest but also in new knowledge. Major efforts in the field are now underway in most of the developed countries of the world. During the past 5 years studies of many scientific investigators have been coordinated in a collaborative effort seldom seen. Research facilities are exchanging both data and scientists to codevelop ideas and projects targeted for human studies. Regulatory agencies are working closely with academic institutions and private industry voluntarily to develop guidelines prospectively in preparation for human applications.

The hope that the concepts and techniques of tissue engineering can be applied to human disease is rapidly becoming reality, driven by the profound need for and realistic potential of this new discipline. To understand the factors that have enabled the emergence and rapid growth of this field, it is perhaps helpful to examine its roots in the context of historical developments. Although the practice of medicine is as old as humankind, its scientific roots have emerged from the development of the scientific method in the Western tradition. When tissues and organs are damaged by infection, disease, or injury, the first priority has always been the development of methods to salvage life. Infection could be controlled by drainage of pus and little else until the revolution of antibiotic therapy. With the nineteenth-century scientific understanding of the germ theory of disease and the introduction of sterile technique, modern surgery had its emergence. The advent of anesthesia by the midnineteenth century enabled the rapid evolution of many surgical techniques. With patients anesthetized, innovative and courageous surgeons could save lives by examining and treating internal areas of the body: the thorax, the abdomen, the brain, and the heart. Initially the surgical techniques were primarily extirpative—for example, removal of tumors, bypass of the bowel in the case of intestinal obstruction, and repair of life-threatening injuries. Maintenance of life without regard to the crippling effects of tissue loss or the psychosocial impact of disfigurement, however was not an acceptable end goal. Techniques that resulted in the restoration of function through structural replacement became integral to the advancement of human therapy.

Artificial or prosthetic materials for replacing limbs, teeth, and other tissues resulted in the partial restoration of lost function. Also, the concept of using one tissue as a replacement for another was developed. In the sixteenth century, Tagliacozzi of Bologna, Italy, reported in his work, “*De Custorum Chirurgia per Insitionem*,” a description of a nose replacement that he constructed from a forearm flap. With the advent of modern concepts of sterility and anesthesia, whole fields of reconstructive surgery have emerged to improve the quality of life by replacing missing function through rebuilding body structures. In our current era, modern techniques of transplanting tissue from one individual into another have been revolutionary and lifesaving.

The molecular and cellular events of the immune response have been elucidated sufficiently to suppress the response in the clinical setting of transplantation and to produce prolonged graft survival and function in patients. In a sense, transplantation can be viewed as the most extreme form of reconstructive surgery, transferring tissue from one individual into another. As with any successful undertaking, new problems have emerged. Techniques using implantable foreign body materials have produced dislodgment, infection at the foreign body/tissue interface, fracture, and migration over time. Techniques moving tissue from one position to another position have produced biologic changes because of the abnormal interaction of the tissue at its new location. For example, diverting urine into the colon can produce fatal colon cancers 20–30 years later. Making esophageal tubes from the skin can result in skin tumors 30 years later. Using intestine for urinary tract replacement can result in severe scarring and obstruction over time.

Transplantation from one individual into another, although very successful, has severe constraints. The major problem is accessing enough tissue and organs for all of the patients who need them. Currently, 65,000 people are on transplant waiting lists in the United States, and many will die waiting for available organs. Also, problems with the immune system produce chronic rejection and destruction over time. Creating an imbalance of immune surveillance from immunosuppression can cause new tumor formation. These constraints have produced a need for new solutions to provide needed tissue.

It is within this context that the field of tissue engineering has emerged. In essence, new and functional living tissue is fabricated using living cells, which are usually associated in one way or another with a matrix or scaffolding to guide tissue development. Such scaffolds can be natural, man-made, or a composite of both. Living cells can migrate into the implant after implantation or can be associated with the matrix in cell culture before implantation. Such cells can be isolated as fully differentiated cells of the tissue they are hoped to recreate, or they can be manipulated to produce the desired function when isolated from other tissues or stem cell sources. Conceptually, the application of this new discipline to human health care can be thought of as a refinement of previously defined principles of medicine. The physician has historically treated certain disease processes by supporting nutrition, minimizing hostile factors, and optimizing the environment so that the body can heal itself. In the field of tissue engineering, the same thing is accomplished on a cellular level. The harmful tissue is eliminated, and cells necessary for repair are then introduced in a configuration optimizing survival of the cells in an environment that will then permit the body to heal itself. Tissue engineering offers an advantage over cell transplantation alone in that organized three-dimensional functional tissue is designed and developed. This chapter summarizes some of the challenges that must be resolved before tissue engineering can become part of the therapeutic armamentarium of physicians and surgeons. Broadly speaking, the challenges are scientific and social.

## SCIENTIFIC CHALLENGES

As a field, tissue engineering has been defined for little more than a decade. Much still needs to be learned and developed to provide a firm scientific basis for therapeutic application. To date, much of the progress in this field has been related to the development of model systems, which have suggested a variety of approaches. Also, certain principles of cell biology and tissue development have been delineated. The field can draw heavily on the explosion of new knowledge from several interrelated well-established disciplines, and, in turn, may promote the coalescence of relatively new, related fields to achieve their potential. The rate of new understanding of complex living systems has been explosive in the past three decades. Tissue engineering can draw on the knowledge gained in the fields of cell biology, biochemistry, and molecular biology and apply it to the engineering of new tissues. Likewise, advances in materials science, chemical engineering, and bioengineering allow the rational application of engineering principles to living systems. Yet another branch of related knowledge is the area of human therapy as applied by surgeons and physicians. In addition, the fields of genetic engineering, cloning, and stem cell biology may ultimately develop hand in hand with the field of tissue engineering in the treatment of human disease, each discipline depending on developments in the others.

We are in the midst of a biologic renaissance. Interactions of the various scientific disciplines can elucidate not only the potential directions of each field of study, but also the right questions

to address. The scientific challenge in tissue engineering lies both in understanding cells and their mass transfer requirements, and the fabrication of materials to provide scaffolding and templates.

## CELLS

If we postulate that living cells are required to fabricate new tissue substitutes, much needs to be learned in regard to their behavior in two normal circumstances—namely, normal development in morphogenesis and normal wound healing. In both of these circumstances, cells create or recreate functional structures using pre-programmed information and signaling. Some approaches to tissue engineering rely on guided regeneration of tissue using materials that serve as templates for ingrowth of host cells and tissue. Other approaches rely on cells that have been implanted as part of an engineered device. As we understand normal developmental and wound healing gene programs and cell behavior, we can use them to our advantage in the rational design of living tissues.

Acquiring cells for creation of body structures is a major challenge, the solution of which continues to evolve. The ultimate goal in this regard—the large-scale fabrication of structures—may be to create large cell banks composed of universal cells that would be immunologically transparent to any individual. These universal cells could be differentiated cell types that could be accepted by any individual or could be stem cell reservoirs, which could respond to signals to differentiate into differing lineages for specific structural applications. Much is already known about stem cells and cell lineages in the bone marrow and blood. Studies suggest that progenitor cells for many differentiated tissues exist within the marrow and blood, and may very well be ubiquitous. Our knowledge of the existence and behavior of such cells in various mesenchymal tissues (muscle, bone, and cartilage), endodermally derived tissues (intestine and liver), or ectodermally derived tissues (nerves, pancreas, and skin) expands on a daily basis. A new area of stem cell biology involving embryonic stem cells holds promise for tissue engineering. The challenge to the scientific community is to understand the principles of stem and progenitor cell biology and then apply it to tissue engineering. The challenge to the scientific community is to understand the principles of stem and progenitor cell biology and then apply it to tissue engineering. The development of immunologically inert universal cells may come from advances in genetic manipulation.

As intermediate steps, tissue can be harvested as allograft, autograft, or xenograft. The tissues can then be dissociated and placed into cell culture, where proliferation of the cells can be initiated. After expansion to the appropriate cell number, the cells can then be transferred to templates, where further remodeling can occur. Which of these strategies are practical and possibly applicable in humans remains to be explored.

Large masses of cells for tissue engineering need to be kept alive, not only *in vitro* but also *in vivo*. The design of systems to accomplish this, including *in vitro* flow bioreactors and *in vivo* strategies for maintenance of cell mass, presents an enormous challenge in which significant advances have been made. The fundamental biophysical constraint of mass transfer of living tissue needs to be understood and dealt with on an individual basis as we move toward human application.

## MATERIALS

There are so many potential applications to tissue engineering that the overall scale of the undertaking is enormous. The field is ripe for expansion, and requires training of a generation of materials scientists and chemical engineers.

The optimal chemical and physical configurations of new biomaterials as they interact with living cells to produce tissue-engineered constructs are under study by many research groups. These biomaterials can be permanent or biodegradable. They can be naturally occurring materials, synthetic materials, or hybrid materials. They need to be developed to be compatible with living systems or with living cells *in vitro* and *in vivo*. Their interface with the cells and the implant site must be clearly understood so that the interface can be optimized. Their design characteristics are major challenges for the field, and should be considered at a molecular chemical level. Systems can be closed, semipermeable, or open. Each design should factor in the specific replacement therapy considered. Design of biomaterials can also incorporate the biologic signaling that the materials may offer. Examples include release of growth and differentiation factors, design of specific receptors and anchorage sites, and three-dimensional site specificity using computer-assisted design and manufacture techniques.

## GENERAL SCIENTIFIC ISSUES

As new scientific knowledge is gained, many conceptual issues need to be addressed. Related to mass transfer is the fundamental problem associated with nourishing tissue of large mass as opposed to tissue with a relatively high ratio of surface area to mass. Also, functional tissue equivalents necessitate the creation of composites containing different cell types. For example, all tubes in the body are laminated tubes composed of a vascularized mesodermal element such as smooth muscle, cartilage, or fibrous tissue. The inner lining of the tube, however, is specific to the organ system. Urinary tubes have a stratified transitional epithelium. The trachea has a pseudostratified columnar epithelium. The esophagus has an epithelium that changes along a gradient from mouth to stomach. The intestine has an enormous, convoluted surface area of columnar epithelial cells that migrate from a crypt to the tip of the villus. The colonic epithelium is, again, different for the purposes of water absorption and storage.

Even the well-developed manufacture of tissue-engineered skin used only the cellular elements of the dermis for a long period of time. Attention is now focusing on creating new skin consisting of both the dermis and its associated fibroblasts, as well as an epithelial layer consisting of keratinocytes. Obviously, this is a significant advance, but for truly “normal” skin to be engineered, all of the cellular elements should be contained, so that the specialized appendages can be generated as well. These “simple” composites will indeed prove to be quite complex and require intricate designs. Thicker structures with relatively high ratios of surface area to mass, such as liver, kidney, heart, breast, or central nervous system, will offer other engineering challenges.

Currently, studies for developing and designing materials in three-dimensional space are being developed utilizing both naturally occurring and synthetic molecules. The applications of computer-assisted design and manufacture techniques to the design of these matrices are critically important. Transformation of digital information obtained from magnetic resonance scanning or computerized tomography scanning can then be developed to provide appropriate templates. Some tissues can be designed as universal tissues that will be suitable for any individual, or may be custom-designed tissues specific to one patient. An important area for future study is the entire field of neural regeneration, neural ingrowth, and neural function toward end organ tissues such as skeletal or smooth muscle. Putting aside the complex architectural structure of these tissues, the cells contained in them have a very high metabolic requirement. As such, it is exceedingly difficult to isolate a large number of viable cells. An alternate approach may be the use of less mature progenitor cells, or stem cells, which not only would have a higher rate of survival as a result of their lower metabolic demand, but also would be more able to survive the insult and hypoxic environment of transplantation. As stem cells develop and require more oxygen, their differentiation may stimulate the development of a vascular complex to nourish them. The understanding of and solutions to these problems are fundamentally important to the success of any replacement tissue that needs ongoing neural interaction for maintenance and function.

It has been shown that some tissues can be driven to completion *in vitro* in bioreactors. However, the optimal incubation times will vary from tissue to tissue. Even so, the new tissue will require an intact blood supply at the time of implantation for successful engraftment and function.

Finally, all of these characteristics need to be understood in the fourth dimension of time. If tissues are implanted in a growing individual, will the tissues grow at the same rate? Will cells taken from an older individual perform as young cells in their new “optimal” environment? How will the biochemical characteristics change over time after implantation? Can the strength of structural support tissues such as bone, cartilage, and ligaments be improved in a bioreactor in which force vectors can be applied? When is the optimal timing of this transformation? When does tissue strength take over the biomechanical characteristics as the material degrades?

## SOCIAL CHALLENGES

If tissue engineering is to play an important role in human therapy, in addition to scientific issues, fundamental issues that are economic, social, and ethical in nature will arise. Something as simple as a new vocabulary will need to be developed and uniformly applied. A universal problem is funding. Can philanthropic dollars be accessed for the purposes of potential new human therapies? Will industry recognize the potential for commercialization and invest heavily? If this occurs, will the focus be changed from that of a purely academic endeavor? What role will governmental agencies play as the field develops? How will the field be regulated to ensure its safety and effica-

cy prior to human application? Is the new tissue to be considered transplanted tissue and, therefore, not subject to regulation, or is it a pharmaceutical that must be subjected to the closest scrutiny by regulatory agencies? If lifesaving, should the track be accelerated toward human trials?

There are legal ramifications of this emerging technology as new knowledge is gained. What becomes proprietary through patents? Who owns the cells that will be sourced to provide the living part of tissue fabrication?

In summary, one can see from this brief overview that the challenges in the field of tissue engineering remain significant. All can be encouraged by the progress that has been made in the past few years, but much discovery lies ahead. Ultimate success will rely on the dedication, creativity, and enthusiasm of those who have chosen to work in this exciting but still unproved field.

# THE CHALLENGE OF IMITATING NATURE

Robert M. Nerem

## INTRODUCTION

Tissue engineering has the potential to address the transplantation crisis caused by the shortage of donor tissues and organs. It is through the imitation of nature that tissue engineering will be able to address this patient need; however, a number of challenges need to be faced. In the area of cell technology, these include cell sourcing, the manipulation of cell function, and the future, effective use of stem cell technology. Next are those issues that are part of construct technology, and these include the design and engineering of tissue like constructs and the manufacturing technology required to provide off-the-shelf availability to the clinician. Finally, there are those issues associated with the integration of a construct into the living system, with the most critical issue being the engineering of immune acceptance. Only if we can meet the challenges posed by these issues and only if we can ultimately address the tissue engineering of the most vital of organs, will we be successful in confronting the crisis in transplantation.

An underlying supposition of tissue engineering is that the employment of the natural biology of the system will allow for greater success in developing therapeutic strategies aimed at the replacement, repair, maintenance, and/or enhancement of tissue function. Another way of saying this is that just maybe the great creator, in whatever form one believes he or she exists, knows something that we mere mortals do not, and if we can only “tap” into a small part of this knowledge base, if we can only imitate nature in some small way, then we will be able to achieve greater success in our efforts to address patient needs in this area.

It is this challenge of imitating nature that has been accepted by those who are providing leadership to this new area of technology called tissue engineering (Langer and Vacanti, 1993; Nerem and Sambanis, 1995). To imitate nature requires that we first understand the basic biology of the tissues of interest; with this we then can develop methods for the control of these biologic processes, and based on the ability to control we finally can develop strategies either for the engineering of living tissue substitutes or for the fostering of tissue repair or remodeling.

It is not only tissues that are of interest, but in many cases entire organs. In fact, even though the initial successes have been substitutes for skin, a relatively simple tissue, in the long term tissue engineering has the potential for creating vital organs such as the kidney, the liver, and the pancreas. Some even believe it will be possible to tissue engineer an entire heart. In addressing the repair and/or replacement of such vital organs, tissue engineering has the potential literally to confront the transplantation crisis, i.e., the shortage in donor tissues and organs available for transplantation.

Although research in what we now call tissue engineering started a quarter of a century ago, the term tissue engineering was not “coined” until 1987 when Professor Y. C. Fung, from the University of California, San Diego, suggested this name at a National Science Foundation meeting.

Since then there has been a large expansion in research efforts in this field, and as the technology has become further developed, an industry has begun to emerge. This industry is still very much a fledgling one, with only a few companies possessing product income streams. A study based on 1997 data documents a total of 35 companies active in the field, with \$430 million annually in industrial research and development taking place, and an annual growth rate of 20% (Lysaght *et al.*, 1998). Tissue engineering is literally at the interface of the traditional medical implant industry and the biological revolution (Galletti *et al.*, 1995). By harnessing the products of this revolution and the continuing advances in molecular and cell biology, there will be an entirely new generation of tissue and organ implants. With this there is the potential for a multibillion dollar tissue engineering industry, one that is estimated to be in excess of \$20 billion by the year 2020.

Such a revolution in the medical implant industry will only occur, however, if we successfully meet the challenge of imitating nature. Thus, in the remainder of this chapter the critical issues involved in this will be addressed. This is done by first discussing those issues associated with cell technology, i.e., issues important in cell sourcing and in the achievement of the functional characteristics required of the cells to be employed. Next to be discussed are those issues associated with construct technology. These span from the organization of cells into a three-dimensional architecture that functionally mimics tissue to the technologies required to manufacture such products and provide tissue substitutes off the shelf to the clinician. Finally, issues involved in the integration of a living cell construct into, or the fostering of remodeling within, the living system will be discussed. These range from the use of appropriate animal studies to the issues of biocompatibility and immune acceptance. Success in tissue engineering will only be achieved if issues at these three different levels, i.e., cell technology, construct technology, and the technology for integration into the living system, can be addressed.

## CELL TECHNOLOGY

### CELL SOURCING

The starting point for any attempt to engineer a tissue or organ substitute is a consideration of the cells to be employed. Not only will one need to have a supply of sufficient quantity and one that can be ensured to be free of pathogens and contamination of any type whatsoever, but one will need to decide whether the source to be employed is to provide autologous, allogeneic, or xenogeneic cells. As indicated in Table 2.1, there are both advantages and disadvantages to each of these.

The skin substitutes developed by Organogenesis (Canton, MA) and Advanced Tissue Sciences (La Jolla, CA) represent the first tissue-engineered products, and these in fact use allogeneic cells. The Organogenesis product, Apligraf, is a bilayer model of skin involving fibroblasts and keratinocytes that are obtained from donated human foreskin (Parenteau, 1999). Apligraf already is approved by the Food and Drug Administration (FDA). The first tissue-engineered product approved by the FDA was the Advanced Tissue Sciences product, TransCyte. Approved initially for third-degree burns, TransCyte is made by seeding dermal fibroblasts in a polymeric scaffold; however, once cryopreserved it becomes a nonliving wound covering. The living product of Advanced Tissue Sciences is still undergoing clinical trials, but is a dermis model, also with dermal fibroblasts obtained from donated human foreskin (Naughton, 1999). Even though the cells employed by

**Table 2.1. Cell source**

Type	Comments
Autologous	Patient's own cells; immune acceptable, does not lend itself to off-the-shelf availability
Allogeneic	Cells from other human sources; lends itself to off-the-shelf availability, but may require engineering immune acceptance
Xenogeneic	From different species; not only requires engineering immune acceptance, but must be concerned with animal virus transmission

both Organogenesis and Advanced Tissue Sciences are allogeneic, immune acceptance did not have to be engineered because both the fibroblast and the keratinocyte do not constitutively express major histocompatibility complex (MHC) II antigens.

For the next generation of tissue-engineered products, which will involve other cell types, however, the immune acceptance of allogeneic cells will be a critical issue in many cases. As an example, consider a blood vessel substitute that employs both endothelial cells and smooth muscle cells. Although allogeneic smooth muscle cells may be immune acceptable, allogeneic endothelial cells certainly would not be. Thus, for the latter, one either uses autologous cells or else engineers the immune acceptance of allogeneic cells, as will be discussed in a later section. Undoubtedly the first human trials will be done using autologous endothelial cells; however, it would appear that the use of such cells would severely limit the availability of a blood vessel substitute. Only by moving away from the use of autologous cells does the opportunity for off-the-shelf availability to the clinician and thus routine use become possible.

### CELL FUNCTION AND GENETIC ENGINEERING

Once one has selected the cell type(s) to be employed, then the next issue relates to the manipulation of the functional characteristics of a cell so as to achieve the behavior desired. This can be done either by (1) manipulating a cell's extracellular environment, e.g., its matrix, the mechanical stresses to which it is exposed, or its biochemical environment, or by (2) manipulating a cell's genetic program. In regard to the latter, the manipulation of a cell's genetic program could be used as an ally to tissue engineering in a variety of ways. A partial list of possibilities includes the alteration of matrix synthesis; inhibition of the immune response; enhancement of non-thrombogenicity, e.g., through increased synthesis of antithrombotic agents; engineering the secretion of specific biologically active molecules, e.g., a specific insulin secretion rate in response to a specific glucose concentration; or the alteration of cell proliferation.

Much of the above is in the context of creating a cell-seeded construct that can be implanted as a tissue or organ substitute; however, the fostering of the repair or remodeling of tissue also represents tissue engineering. Here the use of genetic engineering might take a form that is more what we would call gene therapy. An example of this would be the introduction of growth factors to foster the repair of bone defects. In using a gene therapy approach to tissue engineering it should be recognized that in many cases only a transient expression will be required. Because of this, the use of gene therapy as a strategy in tissue engineering may become viable prior to its employment in treating genetically related diseases.

### STEM CELL TECHNOLOGY

Returning to the issue of cell selection, there is considerable interest in the use of stem cells, the "mother" cells within the body, as a primary source for therapies based on cell and tissue replacement (Solter and Gearhart, 1999). The excitement about stem cells reached a new height with two articles in the November 6, 1998, issue of *Science*. These reported the isolation of the first lines of human embryonic stem cells.

There are in fact a variety of different stem cells, and Table 2.2 summarizes the types of human stem cells that have been isolated. The data are from the brief review of Vogel (1999) and the question marks in Table 2.2 simply indicate where there is still some uncertainty. Of most interest are the embryonic stem cells. These embryonic stem cells are pluripotent, i.e., capable of differentiating into many cell types, and perhaps are even totipotent, i.e., capable of developing into all cell types.

Although we are quite a long way from being able to use embryonic stem cells, there already is at least one company, Osiris Therapeutics (Baltimore, MD), working with stem cells in the context of tissue engineering. In this case they are using mesenchymal stem cells and the applications on which they are focusing are primarily in the orthopedic area.

To take full advantage of stem cell technology, however, it will be necessary to understand how a stem cell differentiates into a tissue-specific cell. This requires knowledge not just about the molecular pathways of differentiation, but even more importantly the identification of the combination of signals leading to a stem cell becoming a specific type of differentiated tissue cell. Only with this will it be possible to channel a stem cell, as an example, into an endothelial cell for use in a blood vessel substitute as compared to a hepatocyte for a tissue-engineered liver.

**Table 2.2. Human stem cells that have been isolated<sup>a</sup>**

Type	Source/daughter tissue
Embryonic	Embryo or fetal tissue/all types
Hematopoietic	Adult bone marrow/blood cells, brain (?)
Neuronal	Fetal brain/neurons, glia, blood (?)
Mesenchymal	Adult bone marrow/muscle, bone, cartilage, tendon

## CONSTRUCT TECHNOLOGY

### CONSTRUCT DESIGN AND ENGINEERING

With the selection of a source of cells, the next challenge in imitating nature is to develop a model in which these cells are organized in a three-dimensional architecture and with functional characteristics such that a specific tissue is mimicked. This design and engineering of a tissue like substitute is a challenge in its own right.

There are many possible approaches, and these are summarized in Table 2.3. One of these, of course, is a cell-seeded polymeric scaffold, an approach pioneered by Langer and his collaborators (Langer and Vacanti, 1993; Cima *et al.*, 1991). This technology is being used by Advanced Tissue Sciences, and many consider this the classic tissue engineering approach. There are others, however, with one of these being a cell-seeded collagen gel. This approach was pioneered by Bell in the late 1970s and early 1980s (Bell *et al.*, 1979; Weinberg and Bell, 1986), and is being used by Organogenesis in their skin substitute, Apligraf.

A rather intriguing approach is that of Auger and his group in Quebec, Canada (Auger *et al.*, 1995; Heureux *et al.*, 1998). Auger refers to this as cell self-assembly, and it involves a layer of cells secreting their own matrix, which over a period of time becomes a sheet. Originally developed as part of the research on skin substitutes by Auger's group, it has been extended to other applications. For example, the blood vessel substitute developed in Quebec involves rolling up one of these cell self-assembled sheets into a tube. One can in fact make tubes of multiple layers so as to mimic the architecture of a normal blood vessel.

Finally, any discussion of different approaches to the creation of a three-dimensional, functional tissue equivalent would be remiss if acellular approaches were not included. Although in tissue engineering the end result should include functional cells, there are those who are employing a strategy whereby the implant is without cells, i.e., acellular, and the cells are then recruited from the recipient or host. A number of laboratories and companies are developing this approach. One result of this approach is to, in effect, bypass the cell sourcing issue, and replace this with the issue of cell recruitment, i.e., the recruiting of cells from the host in order to populate the construct. Because these are the patient's own cells, there is no need for any engineering of immune acceptance.

**Table 2.3. Possible approaches to the engineering of constructs that mimic tissue**

Approach	Comments
Acellular matrix	Requires the recruitment of host cells
Cell-seeded collagen gels	Currently used in a skin substitute; has other potential applications
Cell-seeded polymeric scaffolds	Currently used in skin substitutes; has other potential applications
Cell self-assembly	Based on the cells synthesizing their own matrix

Whatever the approach, the engineering of an architecture and of functional characteristics that allow one to mimic a specific tissue is critical to achieving any success and to meeting the challenge of imitating nature. In fact, because of the interrelationship of structure and function in cells and tissues, it would be unlikely to have the appropriate functional characteristics without the appropriate three-dimensional architecture. Thus, many of the chapters in this book will describe in some detail the approach being taken in the design and engineering of constructs for specific tissues and organs, and any further discussion of this will be left to those chapters.

## MANUFACTURING TECHNOLOGY

The challenge of imitating nature does not stop with the design and engineering of a specific tissuelike construct or substitute. This is because the patient need that exists cannot be met by making one construct at a time on a bench top in some research laboratory. Accepting the challenge of imitating nature must include the development of cost-effective manufacturing processes. These must allow for a scale-up from making one at a time to a production quantity of 100 or 1000 constructs per week. Anything significantly less would not be cost-effective, and if a product cannot be manufactured in large quantities and cost-effectively, then it will not be widely available for routine use.

Much of the work on manufacturing technology has focused on bioreactor technology. A bioreactor simply represents a controlled environment—both chemically and mechanically—in which a tissuelike construct can be grown. The Massachusetts Institute of Technology MIT and Georgia Tech have large research efforts focused on bioreactor technology (Freed *et al.*, 1993; Neitzel *et al.*, 1998). Although it is generally recognized that a construct, once implanted in the living system, will undergo remodeling, it is equally true that the environment of a bioreactor can be tailored to induce the *in vitro* remodeling of a construct so as to enhance characteristics critical to the success achieved following implantation (Seliktar *et al.*, 1998). Thus, the manufacturing process can be used to influence directly the final product and is part of the overall process leading to the imitation of nature.

Once manufactured, a critical issue will be how the product is delivered and made available to the clinician. The first product of Organogenesis, Apligraf, is delivered fresh and has a 5-day shelf life at room temperature (Parenteau, 1999). On the other hand, Dermagraft, the skin substitute developed by Advanced Tissue Sciences and now in clinical trials, is cryopreserved and shipped and stored at  $-70^{\circ}\text{C}$  (Naughton, 1999). This provides for a much more extended shelf life, but introduces other issues that one must address. Ultimately, the clinician will want off-the-shelf availability, and one way or another this will need to be provided if a tissue-engineered product is to have wide use. Although cryobiology is a relatively old field and most cell types can be cryopreserved, there is much that still needs to be learned if we are successfully to cryopreserve three-dimensional tissue-engineered products.

## INTEGRATION INTO THE LIVING SYSTEM

### THE LIVING SYSTEM

The final challenge is presented by moving a tissue engineering product concept into the living system. Here one starts with animal experiments, and there is a lack of good animal models for use in the evaluation of a tissue-engineered implant. This is despite the fact that a variety of animal models have been developed for the study of different diseases. Unfortunately, these models are still somewhat unproved, at least in many cases, when it comes to their use in evaluating the success of a tissue-engineered implant.

In addition, there is a significant need for the development of methods to evaluate quantitatively the performance of an implant. This is not only the case for animal studies, but is equally true for human clinical trials. In regard to the latter, it may not be enough to show efficacy and long term patency, it may also be necessary to demonstrate the mechanism(s) that lead to the implanted tissue substitute's success. Furthermore, it is not just in clinical trials that there is a need for more quantitative tools for assessment: it also would be desirable to have available technologies to assess periodically the continued viability and functionality of a tissue substitute after implantation.

### ENGINEERING IMMUNE ACCEPTANCE

Important to the success of any tissue engineering approach is that it be immune acceptable. This comes naturally with the use of autologous cells; however, if one moves to nonautologous cell systems (as this author believes we must if we are to make the products of tissue engineering widely available for routine use), then the challenge of engineering immune acceptance is critical to our achieving success in the imitation of nature.

It should be recognized that the issues surrounding the immune acceptance of an allogeneic cell-seeded implant are no different than those associated with a transplanted human tissue or organ. Both represent allogeneic cell transplantation, and this means that much of what has been learned in the field of transplant immunology can help us understand implant immunology and the engineering of immune acceptance for tissue-engineered substitutes. For example, it is now known that to have immune rejection there must not only be a recognition by the host of a foreign body, there also must be present what is called the costimulatory signal, or sometimes simply signal 2. It has been demonstrated that, with a donated allogeneic tissue, if one can block the costimulatory signal, one can extend survival of the transplant considerably (Larsen *et al.*, 1996). Thus strategies are under development and may provide greater opportunities in the future for the use of allogeneic cells.

### BIOCOMPATIBILITY

Finally, one cannot state that one has successfully met the challenge of imitating nature unless the implanted construct is biocompatible. Even if the implant is immune acceptable, there can still be an inflammatory response. This response can be considered separate from the immune response, although obviously there can be interactions between these two. In addition to any inflammatory response, for some types of tissue-engineered substitutes thrombosis will be an issue. This is certainly an important part of the biocompatibility of a blood vessel substitute.

### CONCLUDING DISCUSSION

If we are to meet the challenge of imitating nature, there are a variety of issues. These have been divided here into three different categories. The issue of cell technology includes cell sourcing, the manipulation of cell function, and the future use of stem cell technology. Construct technology includes the engineering of a tissuelike construct and the manufacturing technology required to provide the product and ensure its off-the-shelf availability. Finally, there is the issue of integration into living systems. This has several important facets, with the most critical one being the engineering of immune acceptance.

Much of the discussion here has focused on the challenge of engineering tissuelike constructs for implantation. As noted earlier, however, equally important to tissue engineering are strategies for the fostering of remodeling and ultimately the repair and enhancement of function. As one example, consider a damaged, failing heart. Should the approach be to tissue engineer an entire heart, or should the strategy be to foster the repair of the myocardium? In this latter case, it may be possible to return the heart to relatively normal function through the implantation of a myocardial patch or even through the introduction of growth factors, angiogenic factors, or other biologically active molecules. Which strategy has the highest potential for success? Which approach will have the greatest public acceptance?

The primary issues described here (cell technology, construct technology, and integration into the living system) form the basis of the strategy being implemented in Atlanta, Georgia (Nerem *et al.*, 1998) by the Georgia Tech/Emory Center for the Engineering of Living Tissues, an Engineering Research Center newly funded by the National Science Foundation. These issues are paramount to tissue engineering meeting the challenge of imitating nature. Only if we meet this challenge can the existing patient need be addressed, and will we as a community be able to confront the transplantation crisis.

### ACKNOWLEDGMENT

The author acknowledges with thanks the support by the National Science Foundation of the Georgia Tech/Emory Center for the Engineering of Living Tissues.

# ORGANIZATION OF CELLS INTO HIGHER ORDERED STRUCTURES

Carol A. Erickson

## INTRODUCTION

Embryonic tissues are composed of cells that are organized into either epithelia or mesenchyme. Cells in epithelia are held together tenaciously by a series of lateral junctions, they display an apical–basal polarity, and their basal surface adheres to an organized extracellular matrix (ECM), the basal lamina. In contrast, mesenchymal cells are individual cells that do not adhere by way of differentiated junctions, they display a fusiform shape typical of migratory cells, and they are generally enmeshed in a loose ECM. This tissue organization is maintained by cell–cell and cell–matrix adhesive interactions, as well as the ECM in which the cells are embedded (for review, see Armstrong, 1989). The assembly and integrity of tissues thus depend on the timely regulation of the molecular interactions that stabilize the epithelial or mesenchymal phenotype (for review, see Rodriguez-Boulan and Nelson, 1989; Birchmeier and Birchmeier, 1994; Hay and Zuk, 1995; Eaton and Simons, 1995).

In the early embryo, cells are arranged primarily in epithelial sheets. From these sheets, mesenchymal cells are derived by a process known as the epithelial–mesenchymal transformation (EMT), in which individual epithelial cells detach from the epithelium and migrate away. This transformation gives rise to populations such as the cells of the neural crest, cardiac cushion cells, the midline cells of the palate (Fitchett and Hay, 1989), the dermis of the skin, the limb musculature, and the sclerotome. The reverse process, transformation from mesenchyme to epithelium (MET), also occurs in developing organs—for example, in the formation of the kidney tubules from the nephrogenic blastema (Ekblom, 1989), the generation of the endocardium of the heart from cardiac mesenchyme (Eisenberg and Markwald, 1995), or the organization of the somites from the segmental plate. Thus the assembly and composition of tissues that are generated during embryogenesis depend on the regulation of the EMTs. Similarly in the adult, tissue structure is altered by the EMTs that accompany pathological events such as tissue regeneration and repair after wounding, and the invasion and metastasis of cancer cells (Birchmeier *et al.*, 1993; Reichmann, 1994).

In this chapter the focus is on the organization of cells into higher ordered structures, particularly on the regulation of EMTs and METs as fundamental processes that establish tissue architecture. First described are the cellular changes that accompany these transformations in normal development and in tumor cell invasion. These changes include the alteration of cell–cell adhesions, the modulation of the specificity of cell–matrix adhesions, the reorganization of the cytoskeleton, and the expression of proteases. Considered next are the mechanisms that coordinate these cellular changes, thereby triggering transformation. Both growth factors and the ECM have been shown to play regulatory roles in a variety of EMTs and METs, although the signal transduction pathways that mediate responses to growth factors and ECM are still largely unknown.

## CELLULAR CHANGES INVOLVED IN THE EMT

### ADHESIVE CHANGES

In those EMTs where cellular interactions have been examined in detail, several adhesive changes have been documented to accompany the detachment of single cells from an epithelial sheet. For example, when primary mesenchyme cells detach from the vegetal plate of the sea urchin gastrula, direct measurements indicate that these cells lose adhesion to the vegetal plate epithelium and to the extracellular hyalin layer, and increase adhesion to the ECM of the basal lamina through and on which they migrate (Fink and McClay, 1985). Less direct evidence suggests that multiple adhesive changes accompany the detachment of neural crest cells from the neural epithelium (Newgreen and Gooday, 1985; Delannet and Duband, 1992), ingression of mesoderm through the primitive streak (Burdsal *et al.*, 1993), and invasion of epithelium-derived tumor cells. Considered here is the molecular basis for these adhesive changes.

### Modulation of cadherin function

Epithelial cells are held together by a series of differentiated junctions concentrated near their apical surface, as well as other cellular appositions between lateral surfaces. These adhesions are primarily mediated by homophilic interactions between cell adhesion molecules of the cadherin superfamily (Takeichi, 1991, 1995; Kemler, 1992). The most prominent epithelial cadherin is E-cadherin, although N-cadherin is localized in the adherens junctions and in apposing plasma membranes of some embryonic epithelia, such as the neural tube and somite (e.g., Duband *et al.*, 1988; Bronner-Fraser *et al.*, 1992). Numerous experimental studies have demonstrated the importance of cadherins in maintaining the epithelial phenotype. For example, if Madin–Darby canine kidney (MDCK) cells (an epithelial cell line) are treated with antifunctional antibodies against E-cadherin, the cells of the epithelium dissociate into individual mesenchymal cells (Behrens *et al.*, 1985). Similarly, embryonic epithelial structures such as somites (Duband *et al.*, 1987) or epidermis (Levine *et al.*, 1994) come apart when cadherin function is inhibited. Conversely, when some mesenchymal cells are transfected with E-cadherin expression vectors, they assemble into epithelial sheets (Nagafuchi *et al.*, 1987; Ringwald *et al.*, 1987; McNeill *et al.*, 1990). Thus, cadherins stabilize epithelial organization.

Is there evidence that modulation of cadherin function regulates EMTs in the embryo or in pathological conditions? Immunocytochemistry reveals that cadherins are lost or their levels greatly reduced during many developmental EMTs. For example, premigratory neural crest cells express N-cadherin and cad-6, but newly segregated and migrating neural crest cells express very little (Duband *et al.*, 1988; Bronner-Fraser *et al.*, 1992; Akitaya and Bronner-Fraser, 1992; Nakagawa and Takeichi, 1995, 1998). Similarly, cadherins are lost as cells ingress through the primitive streak (Damjanov *et al.*, 1986; Burdsal *et al.*, 1993), as the ventromedial wall of the somite disperses to form mesenchymal sclerotome (Duband *et al.*, 1988), as the midline seam of the palate disperses (Sun *et al.*, 1998), or as the endocardial cushion cells detach from the endocardium (Markwald *et al.*, 1996). Because of low spatial resolution and/or lack of markers for distinguishing the premigratory populations of cells from the rest of the epithelium from which they arise, these studies were unable to determine if cadherins are lost prior to cell detachment, or if the cadherins are down-regulated as a result of the cells becoming mesenchymal. These problems are circumvented in the sea urchin embryo, in which primary mesenchyme cells can be identified prior to ingression using antibody markers and in which the cells are so large that the process can be imaged with excellent clarity using confocal microscopy. In this instance a unique sea urchin cadherin is removed from the surface of the primary mesenchyme cells by endocytosis just prior to ingression (Miller and McClay, 1997b). This is the only instance of which this author is aware that cadherins have been proved to be removed from the surface of the cells that can be identified as those that will undergo the EMT.

In addition to immunocytochemical evidence, experimental studies have further supported a role for loss of cadherins in generating the EMT. Antibodies that interfere with cadherin function have been used to treat murine epiblast, which results in premature primitive streak formation (Burdsal *et al.*, 1993) or somites to generate sclerotome (Duband *et al.*, 1987; Linask *et al.*, 1998). However, such studies do not prove that normally the loss of these cadherins is required for the EMT, nor is it certain that the cellular response is identical to the EMT. In other studies, when

the N-cadherin gene was knocked-out, ill-formed somites, abnormal neural tubes, and loosely organized myocardium were observed, but no precocious EMTs were noted (Radice *et al.*, 1997). Interpretation of this mutant phenotype is complicated by the fact that other cadherins are expressed by these tissues and may compensate for the loss of N-cadherin. Conversely, cadherins have also been overexpressed in cells that normally undergo the EMT, resulting in the inhibition of migration. For example, cad-6 has been virally expressed in the dorsal neural epithelium and under these circumstances neural crest cells do not migrate (Nakagawa and Takeichi, 1998). This study shows, at a minimum, that cadherins can stabilize the epithelial phenotype and that their adhesive interactions must be reduced in order for the EMT to proceed, but leaves open the possibility that other cellular changes are required to result in the EMT.

In addition to these normal developmental events, down-regulation of E-cadherin is also observed in pathological circumstances. In many cell lines derived from carcinomas (tumors derived from epithelia), invasion and metastasis are correlated with the loss of E-cadherin (e.g., Frixen *et al.*, 1991; Navarro *et al.*, 1991). Moreover, these invasive carcinoma cell lines lose their ability to invade collagen gels and revert to an epithelial phenotype if they are transfected with E-cadherin (Frixen *et al.*, 1991; Vleminckx *et al.*, 1991).

Cadherins apparently also have an instrumental role in the reverse process of mesenchyme-to-epithelium transition. For example, as kidney mesenchyme coalesces to generate kidney tubules, E-cadherin is reexpressed and probably stabilizes the nephron epithelium (Vestweber *et al.*, 1985; Ekblom, 1989). Similarly, E-cadherin is expressed as mammalian blastomeres undergo compaction, and in null mutations for E-cadherin the trophoblast fails to form (Larue *et al.*, 1994).

Although the EMT and MET are correlated with cadherin expression in the above instances, cadherin function can also be regulated independently of transcription and translation. For example, the amount of cadherin protein is unchanged during the convergent extension movements of *Xenopus* gastrulation, even though C-cadherin-mediated adhesion is greatly reduced (Briher and Gumbiner, 1994). Intracellularly, cadherins are bound to a complex of catenins including  $\alpha$ -catenin,  $\beta$ -catenin/plakoglobin, and p120<sup>cas</sup>, which mediate attachment of cadherins to the cytoskeleton and regulate the adhesive function of cadherin (reviewed by Kemler, 1993; Gumbiner and McCrea, 1993; Ranscht, 1994; Barth *et al.*, 1997; Ben-Ze'ev and Geiger, 1998). Different combinations of the catenins bound to cadherins can effect a change in cadherin function (Bernfield *et al.*, 1992; Nathke *et al.*, 1994), or possibly result in the loss of cadherins from the surface if the catenins dissociate from the complex (Miller and McClay, 1997a). Catenin association with the cadherins, or catenin function, may be regulated, at least in part, by the level of catenin phosphorylation (Volberg *et al.*, 1991; Peifer *et al.*, 1994; Daniel and Reynolds, 1997). For example, when some epithelial cell lines are transfected with a temperature-sensitive *src* gene, which results in a mesenchymal transformation, levels of cadherin expression remain unchanged but  $\beta$ -catenin is phosphorylated (Warren and Nelson, 1987; Matsuyoshi *et al.*, 1992; Behrens *et al.*, 1993; Hamaguchi *et al.*, 1993). It is not known how the state of phosphorylation of the junctional proteins might regulate cadherin function (Daniel and Reynolds, 1997). Indeed, it has not been demonstrated directly that phosphorylation is the essential regulatory event. Nevertheless, we need to keep in mind that cell–cell adhesion can be perturbed without loss of adhesion molecules from the cell surface.

In addition to loss of function of “traditional” cadherins during the EMT, it is now apparent that “mesenchymal” cadherins (or type III cadherins) (Suzuki *et al.*, 1991) are up-regulated simultaneously. For example, cad-7 (Nakagawa and Takeichi, 1995, 1998) and cad-11 (Simonneau *et al.*, 1995) are expressed on neural crest cells as they detach from the neural epithelium. The function of these cadherins is unknown, but their timely expression suggests that they may be essential in stimulating mesenchyme migration.

### Change in cell–matrix adhesion

Loss of cadherin function may be essential for producing the EMT, but it is not the only molecular change required—a number of experimental studies show that the EMT will still not occur even after cadherin function has been perturbed (e.g., Nakajima *et al.*, 1998), and the absence of cadherins in knockout mice is not always sufficient to cause the EMT (Radice *et al.*, 1997). As mentioned previously, during ingression of primary mesenchyme cells in the sea urchin embryo, loss of cell–cell adhesion is accompanied by a simultaneous gain in cell–matrix adhesion. Similarly, when premigratory neural crest cells are released precociously from the neural epithelium af-

ter cadherin function is disrupted experimentally, they still fail to migrate for at least 18 hr, suggesting that there must be a concomitant change in their adhesion to the ECM or in their motile capability (J.-L. Duband, personal communication; C. A. Erickson, unpublished data). These cell–matrix adhesions are likely to be mediated by the integrin superfamily of adhesion molecules (Hynes, 1992).

Changes in specific integrins have been observed in certain cell types undergoing the EMT. For example, the  $\beta 1$  integrin necessary for attachment of the neural crest cells to fibronectin becomes functional just a few hours before the cells undergo the EMT (Delannet and Duband, 1992). Similarly, mouse primitive streak cells adhere with increased affinity to a variety of ECM molecules as they become mesenchymal, and this adhesion depends on the expression of  $\beta 1$  and  $\beta 3$  integrins (Burdal *et al.*, 1993). In both of these instances, perturbation of integrin function with antifunctional antibodies inhibits mesenchyme dispersion. The role that the integrins play in the EMT is not clear. They may simply mediate cell motility. Alternatively, they may have a more complex signaling role that controls downstream transcriptional events.

Changes in other cell–matrix adhesion molecules, besides the integrins, also may be important in EMTs. Syndecans are transmembrane heparan sulfate proteoglycans that have a variety of functions, including binding of growth factors, mediating attachment to ECM molecules, and organizing the cytoskeleton (Bernfield *et al.*, 1992). The distribution of the various syndecans suggests that they play a role in maintaining epithelial morphology and perhaps controlling EMTs as well. For example, syndecan-1 is expressed in epithelial sheets in the young mouse embryo but is lost during several EMTs, such as the dispersion of the sclerotome (Sutherland *et al.*, 1991). Similarly, as the palate fuses and the epithelium at the midline undergoes an EMT (Fitchett and Hay, 1989; Griffith and Hay, 1992), the levels of both syndecan-1 and E-cadherin are reduced markedly in the epithelium (McAlmon, 1992). Changes in syndecan expression are also correlated with pathological conditions. For example, at the edge of skin wounds, keratinocytes lose syndecan-1 as they detach from the epithelium and become mesenchymal (Elenius *et al.*, 1991). Experimentally eliminating syndecan-1 expression in NmuMG cells (a normal murine mammary epithelial cell line) with antisense oligonucleotides transforms many clones into mesenchymal cells (Kato *et al.*, 1995). In these same mesenchymal cell lines, cadherins are no longer expressed, the  $\beta 1$  integrins are no longer localized at sites of cell–cell contact, and the actin microfilaments become disorganized. Curiously, mesenchymal cells transfected with syndecan-1 do not assume an epithelial morphology, as might have been predicted if syndecan-1 plays a crucial regulatory role in epithelial stability. Thus the role of syndecan in regulating the epithelial phenotype, as well as the intracellular signals triggered by it, are currently unknown.

### PROTEASE EXPRESSION

As cells detach from the epithelium and extend lamellipodia from their basal surface, they must, of necessity, pass through the basal lamina at their basal surface. Similarly, epithelial tumor cells must breach a basal lamina barrier as they invade and metastasize. One way that cells can cross this normally impenetrable barrier (Erickson, 1987) is by secreting matrix-degrading enzymes. There is a rich literature that documents the importance of proteases simulating tumor invasiveness (Werb, 1989, 1997; Alexander and Werb, 1991). Thus it is not surprising that protease production has been observed to accompany some EMTs.

Plasminogen activator, a neutral serine protease, is expressed by neural crest cells after they detach from the neural tube and migrate *in vivo* and in culture (Valinsky and Le Douarin, 1985; Erickson and Isseroff, 1989; Agrawal and Brauer, 1996), by sclerotome cells that form from the ventromedial wall of the somite (McGuire and Alexander, 1992), and by cardiac cushion cells as they detach from the endocardium (McGuire and Orkin, 1992). Metalloproteases are also produced by cells that have undergone an EMT, including the neural crest cells, the dermis, the sclerotome (unpublished studies from our lab), and possibly the mesodermal cells on ingression through the primitive streak (Sanders and Prasad, 1989). Although protease activity is correlated with the EMT, there is only minimal experimental evidence that implicates proteases in the process. Inhibition of urokinase-type plasminogen activator (uPA) activity reduces the number of neural crest cells that migrate from the neural tube, although this response could be due to a toxic effect of the drugs used (Erickson and Isseroff, 1989). Additionally when antisense oligonucleotides are used to inhibit uPA production in endocardial explants, there is a reduction in the number of cushion cells that emigrate (McGuire and Alexander, 1993).

Although proteases are believed to stimulate the EMT by allowing cells to migrate through the basal lamina, some recent studies also show that metalloproteases can cause the shedding of cadherins from the cell surface, thereby reducing cadherin-mediated cell adhesion (Herren *et al.*, 1998). To date, no EMTs that occur during development have been linked with this shedding activity, but it remains an attractive mechanism.

### ALTERNATIVE MODELS OF THE EMT

The cellular changes discussed above are those that are commonly associated with the EMT. Nevertheless, there are several other models, as yet unexplored, that could account for this remarkable process (Fig. 3.1).

One alternative model is that cells detach from the epithelium by generating sufficient tractional force to rupture the junctional complexes that keep them adherent to their neighbors, just as fibroblasts rupture their trailing ends and leave bits of themselves as tracks across the substratum as they locomote (Fig. 3.1, model 2). Several reports suggest that as neural crest cells or placode-derived neurons detach from an epithelium, their adherens junctions slide through the lipid bilayer as though they are being pulled along as the cells generate tractional force (Nichols, 1986a,b, 1987). In at least one study (Bilozur and Hay, 1989), transmission electron micrographs reveal vesicles containing microfilaments and adherens junctions near the lumen of the neural tube; these may be remnants of neural crest cells that have detached. Such a model predicts that a simple change in the distribution of integrins, or a reorganization of the cytoskeleton, such as gener-

Fig. 3.1. Schematic drawings depicting three models for the EMT that produces neural crest cells. In model 1, an asymmetric mitosis results in an apical cell that remains attached to the lumen of the neural tube by adherens junctions, and a basal daughter that becomes separated from the junctions. Because the dorsal neural tube is not enveloped by a basal lamina, the basal daughter is free to emigrate away. In model 2, the premigratory neural crest cell is able to generate a strong tractional force on the surrounding substratum. As it moves out of the neural tube, it pulls its adherens junctions with it until the junctions reach the basal surface of the epithelium, where the neural crest cell pulls away and severs its connection with the junctions. In model 3, the cadherins maintaining the adherens junction are either down-regulated or endocytosed from the surface, or their function is attenuated, allowing the cell to detach from the epithelium. From Erickson and Reedy (1998), with permission.

ating stress bundles, could activate the motile machinery and would be sufficient to overcome the adhesive interactions in the epithelium. Liu and Jessell (1998) showed that RhoB is expressed in premigratory neural crest cells, and inhibition of RhoB prevents the EMT. Because Rho regulates the assembly and organization of actin filaments (Hall, 1998; Imamura *et al.*, 1998) and induces contractility in fibroblasts (Zhang *et al.*, 1998), these findings suggest that cytoskeleton mobilization is critical in the EMT. [In another model system, the MDCK epithelial cell line, injection of activated Rho inhibits the EMT stimulated by scatter factor (Ridley *et al.*, 1995) and RhoA inactivation is required for cell scattering activity (Imamura *et al.*, 1998), so that the evidence for Rho activity in the EMT is conflicting.] Curiously, Rac and Rho activity is also required for E-cadherin function (Braga *et al.*, 1997, 1999; Zhong *et al.*, 1997) thus stabilizing the epithelial organization, so at present the role of these small GTPases in the EMT is unclear.

A second alternative model for controlling the EMT proposes that asymmetric cell divisions could separate basal daughter cells from apical junctions (Erickson and Reedy, 1998). Specifically, if the mitotic spindle were oriented perpendicular to the surface of an epithelium, resulting in a horizontal cleavage furrow, one of the daughter cells would still be tethered to the apical surface via adherens junctions, whereas the basal daughter cell would be free to migrate away (Fig. 3.1, model 1). This mechanism does not require any change in the apical junction-associated cadherin function. Such an orientation of the mitotic spindle is correlated with the generation of neurons from an epithelium in *Drosophila* (Foe, 1989), and has been proposed to produce the mesenchymal cells that arise from the otic anlage to form the acoustic-vestibular ganglion (Alvarez *et al.*, 1989). Finally, direct time-lapse images of neurons labeled with 3,3'-diiodoacetylcarboxyanine perchlorate (DiO) in the cerebral cortex of the ferret brain convincingly show that the neurons detach from the apical surface of the ventricular zone only following a horizontal mitosis (Chenn and McConnell, 1995).

## STIMULI OF THE TRANSFORMATION

Our current notion of the EMT, as discussed above, is that a variety of cellular changes occur simultaneously. This implies that some regulatory process coordinates these changes (see Hay, 1990, 1991). Growth factors and the ECM have both been proposed to trigger the EMT.

### GROWTH FACTORS

Numerous *in vitro* studies have demonstrated that growth factors can activate proteinase cascades, alter cell-cell and cell-substratum adhesiveness, and modulate ECM production. Thus, they are good candidates for coordinating these same events during the EMT. And, in fact, members of the transforming growth factor  $\beta$  (TGF- $\beta$ ) family of growth factors have been shown conclusively to play a role in the detachment of cardiac cushion cells from the endothelium (Potts and Runyan, 1989; Potts *et al.*, 1991; Brown *et al.*, 1999; Boyer *et al.*, 1999), the dispersion of the palate midline seam (Brunet *et al.*, 1993; Brown *et al.*, 1999), the dissociation of the Müllerian duct to form mesenchyme (Trelstad *et al.*, 1982), and the induction and maintenance of carcinoma cell invasiveness and metastasis (Oft *et al.*, 1998). Moreover, Delannet and Duband (1992) have shown that treatment of isolated quail neural tubes with TGF- $\beta$  accelerates the timing of detachment of neural crest cells from the neural epithelium and may do so by up-regulating integrins. Interestingly, a TGF- $\beta$  family member, dorsalin-1, is produced by the dorsal neural tube and promotes the appearance of neural crestlike cells from the ventral neural plate (Basler *et al.*, 1993). Bone morphogenetic proteins (BMP4 and BMP7), also members of the TGF- $\beta$  superfamily, are expressed by the ectoderm contiguous with the neural plate and have been experimentally demonstrated to control neural crest differentiation (Liem *et al.*, 1995). Whether these growth factors directly regulate the EMT or have a more general role in the specification of the neural crest lineage (see Erickson and Reedy, 1998) remains to be determined.

Other families of growth factors have been implicated in the EMT. Neurotrophin-3, a member of the neurotrophin family of growth factors, has been shown to regulate dispersion of the epithelial dermatome to form dermis (Brill *et al.*, 1995).

The "motility-stimulating factors" belong to another class of growth factors that may play a role in regulating the EMT. These can be produced by fibroblasts and act in an autocrine fashion [e.g., migration stimulation factor (Grey *et al.*, 1989); autocrine stimulating factor (Liotta *et al.*, 1986)]. Alternatively, some motility factors have been isolated from fibroblast-conditioned medi-

um and can induce epithelial sheets to disperse and are therefore paracrine in function [scatter factor/hepatocyte growth factor (Stoker *et al.*, 1987; Weidner *et al.*, 1991)].

Scatter factor has received a great deal of attention for its potential role in the regulation of the EMT. The first evidence to suggest that it plays a critical role in some EMTs during embryogenesis was the observation that when a source of scatter factor is implanted into chick embryos, ectopic primitive streaks are produced (Stern *et al.*, 1990). Hensen's node has been identified as the probable source of scatter factor in the chick embryo (Streit *et al.*, 1995). When mice are generated that contain a null mutation for *c-met*, the receptor for scatter factor, the lateral edges of the dermamyotomes from which limb myoblasts emigrate fail to undergo the EMT and therefore myoblasts do not migrate to the limb (Bladt *et al.*, 1995). Interestingly, the limb bud is a source of scatter factor that may induce the EMT in the dermamyotomes located immediately adjacent to it. In some circumstances, scatter factor instead induces the reverse process, the MET. When fibroblasts are transfected with both *c-met* and scatter factor, the cells assemble into epithelial sheets that form a lumen (Tsarfaty *et al.*, 1994). Moreover, antibodies that inhibit the function of scatter factor also prevent the assembly of kidney mesenchyme into epithelial nephrons (Woolf *et al.*, 1995). These opposing functions of scatter factor are currently confounding. One possibility is that scatter factor works in a paracrine fashion to induce the EMT, but in an autocrine fashion in the METs. Despite the confusion about the function of scatter factor in these processes, its involvement seems certain.

Secreted factors other than scatter factor regulate other METs. Members of the Wnt family of secreted glycoproteins play many roles in specifying pattern and cell fate during embryogenesis. One of these, Wnt-4 is expressed in the mouse kidney mesenchyme that subsequently aggregates and assembles to form nephrogenic tubules (Davies, 1996). Mice lacking Wnt-4 activity fail to form pretubular cell aggregates, suggesting that Wnt-4 is an autoinducer of the MET (Stark *et al.*, 1994). Because Wnt signaling increases cadherin-mediated adhesion in established cell lines (Bradley *et al.*, 1993; Hinck *et al.*, 1994), it is reasonable to speculate that Wnt-4 may regulate E-cadherin function in the development of the kidney as well.

### EXTRACELLULAR MATRIX

In some circumstances the timely appearance of particular ECM components stimulates the EMT. Cardiac cushion cell migration is the principal example of a matrix-stimulated EMT (Mjaatvedt *et al.*, 1987, 1991). Complexes of ECM produced by the myocardium and known as "adherons" trigger cushion cell detachment from the endocardium (Eisenberg and Markwald, 1995). These matrix complexes may function by up-regulating the production of TGF- $\beta$ 1 in the premigratory cushion cells (Nakajima *et al.*, 1994). There are no data that establish that the ECM is involved in any other developmental EMTs, however. Löfberg and colleagues (1985) implanted filters containing ECM above the dorsal neural tube in axolotl embryos and simulated premature migration of the neural crest. In this situation, however, the neural crest cells have already detached from the neuroepithelium, and the ECM is probably only acting to simulate motility. Stimulation of neural crest detachment by the ECM apparently does not occur in other species, because precocious migration has never been induced with a wide variety of ECM components (e.g., Delannet and Duband, 1992).

Although there are only a few known examples of EMTs regulated by the ECM, the importance of cell-matrix adhesion in this process is suggested by the observation that authentic epithelia that normally never undergo an EMT during embryogenesis will do so if confronted by novel ECM in culture. For example, when lens or thyroid epithelium is embedded in a three-dimensional collagen gel, cellular processes extend from the apical surface and the cells disperse to form mesenchyme (Greenburg and Hay, 1982, 1986, 1988). This dispersion is accompanied by a loss of cadherins, detachment from the basal lamina, a redistribution of integrins from the basal to the apical surface (Zuk and Hay, 1994), as well as a change in integrin subunit expression (loss of  $\alpha$ 6 and expression of  $\alpha$ 5 integrin subunits). Importantly, such EMTs are inhibited if antifunctional antibodies to integrins are incorporated into the gel. How the ECM might regulate a host of cellular changes to produce this event is not understood, but this model system may afford us the opportunity to assess the regulatory processes that control the EMT.

The regulated expression of particular ECM components is instrumental in at least one instance of MET as well. When the kidney mesenchyme coalesces to form epithelial nephrons, the

condensation is apparently regulated by the expression of E-cadherin, as discussed previously, which establishes the basolateral domain of the epithelium (see Eaton and Simons, 1995). The subsequent apical-basal polarization of that tissue is correlated with the production of laminin A chain, which accumulates around the compacted cells. If adhesion to laminin is inhibited using antifunctional antibodies to either the laminin A E8 domain or to the  $\alpha 6$  subunit of integrin, this polarization fails to occur, although the cadherin-mediated condensations of the mesenchyme proceeds normally (Klein *et al.*, 1988; Sorokin *et al.*, 1990). Thus, in this instance, an ECM component has a crucial role in the establishment of epithelial polarization.

### INTRACELLULAR SIGNALING MECHANISMS

Although some progress has been made in elucidating what growth factors and ECM molecules are involved in regulating EMTs, the downstream signaling events are not yet known. Because most growth factor receptors are kinases, it seems likely that some EMTs are mediated through the Ras/Raf signaling pathway. Indeed, transfections of MDCK epithelial cell lines with v-Ha-*ras* or v-ki-*ras* result in the dispersion of the cells into mesenchyme. This morphological change is accompanied by the simultaneous loss of E-cadherin, changes in integrin distribution, and increased production of proteases (Behrens *et al.*, 1992, 1993). Conversely, interfering with the TGF- $\beta$  receptor type III (Brown *et al.*, 1999) or with the downstream signaling of Ras (Lakkis and Epstein, 1998) blocks formation of the cardiac cushions (Epstein *et al.*, 1994). Similarly, inhibition of endogenous Ras proteins prevents the scatter factor-induced EMT in MDCK cells (Ridley *et al.*, 1995).

Transcription factors that are activated by the Ras/Raf pathway include fos/jun (AP-1), and these are likely involved in coordinating the many cellular changes that accompany the EMT. For example, expression of *c-fos* precedes the EMT in the palate (Smeyne *et al.*, 1993). Induction of *c-fos* in mammary epithelial cells results in loss of epithelial polarity, loss of cadherins, and increases in the activity of proteases, including stromelysin, collagenase, uPA, and tissue plasminogen activator (tPA) (Reichmann *et al.*, 1992). Interestingly, neural crest cells express high levels of AP-1 as they detach from the neural epithelium (Mitchell *et al.*, 1991). The transcription factor NF-ATc is also regulated by Ras and has been experimentally demonstrated to control cushion cell transformation (Lakkis and Epstein, 1998). Finally, the ETS1 transcription factor is expressed in cells undergoing the EMT, such as the sclerotome and the neural crest; its expression is stimulated by scatter factor, and ETS1 activity is also activated by the Ras signaling cascade (Fafeur *et al.*, 1997).

Members of the Snail family of zinc finger transcription factors are important regulators of the EMT (Leptin and Grunewald, 1990; Kosman *et al.*, 1991; Nieto *et al.*, 1992). *Slug* is expressed in neural crest and primitive streak cells of the chicken embryo just prior to their detachment from the epithelium, and antisense oligo-treated embryos fail to undergo the EMTs (Nieto *et al.*, 1994). This observation provides us with an exciting new handle on how coordinated changes in cells undergoing the EMT are regulated, and may allow us to determine what constellations of genes are the downstream targets of this transcription factor. To date, the only known direct effect of *Slug* is the loss of desmoplakin and desmoglein (Savagner *et al.*, 1997).

Inhibitors of protein kinase C have been reported to stimulate the precocious detachment of neural crest cells from the neural epithelium (Newgreen and Minichiello, 1995). Because this stimulation occurred in the presence of inhibitors of transcription, it suggests that changes in protein phosphorylation can trigger the EMT independent of changes in protein expression.

### CONCLUSION

Considerable progress has been made in elucidating the cellular changes that accompany the EMT by combining approaches used to study pathological events, in particular the invasiveness of carcinomas, with those of normal developmental processes. Nevertheless, these data are largely correlative and it is far from clear which of the many cellular changes that are coincident with the EMT are critical. To address these issues, direct observation and perturbation of the events in the intact organism will be essential, because some aspects of tissue culture studies may be irregular owing to culture-induced artifacts or peculiarities of the established cell lines that have been studied.

Several developmental model systems seem especially amenable to experimentation. Invertebrate embryos, such as those of sea urchins, are clear and have large blastomeres, allowing direct

observation of the molecular changes as they occur during the EMT. Moreover, the precise cells that will undergo EMTs can be identified prior to onset of the process, thus allowing analysis of the earliest molecular changes in these cells. Perturbation of cadherin and integrin function during the EMT is also crucial. *Xenopus* embryos will prove especially useful in this regard, because injections of RNAs that result in the overexpression of cadherins or in the expression of dominant-negative mutations in cadherin function already have provided insight into the role of these molecules in mediating adhesion (Kintner, 1988; Briher and Gumbiner, 1994; Levine *et al.*, 1994). The role of phosphorylation of cadherin or the catenins in regulating adhesion is an obvious problem to explore using the *Xenopus* embryo.

The trigger(s) for the EMT remain a mystery, although growth factors will probably figure prominently in regulating the process. One approach to addressing this issue may come from the observation that selected subpopulations of cells are capable of undergoing the EMT. For example, only the dorsal neural tube gives rise to the neural crest, and only the endocardium from the atrioventricular (AV) region is capable of generating cushion mesenchyme (Runyan and Markwald, 1983; Mjaatvedt and Markwald, 1989). It has been established that the TGF- $\beta$  type III receptor is only found in the AV endothelium and that expression of this receptor in the nontransforming ventricular endocardium allows the cells to undergo the EMT in response to TGF- $\beta$ 2 (Brown *et al.*, 1999). A careful comparison of the signaling molecules in embryonic cells that do and do not undergo the EMT may yield important insights into the control of this process. Moreover, it is becoming apparent that different regulatory pathways may control different aspects of the EMT. For example, loss of cadherin function may be controlled independently of stimulation of motility (Levine *et al.*, 1994; Radice *et al.*, 1997; Zhong *et al.*, 1997; Savagner *et al.*, 1997; Nakajima *et al.*, 1998; Boyer *et al.*, 1999). Only by experimentally dissecting and studying each of the steps in the EMT will the regulation of the whole process be understood.

# DYNAMICS OF CELL–ECM INTERACTIONS

Manuela Martins-Green

## INTRODUCTION

In recent years the ability to perform tissue and organ replacement has led to an improvement of quality of life and health care. Most of this success can be attributed to the interdisciplinary approaches to tissue engineering. Indeed, today scientists with very diverse backgrounds, including molecular, cellular, and developmental biology, collaborate with biomechanical engineers to develop tissue analogs that allow physicians to improve, maintain, and restore tissue function. Several approaches have been taken toward this goal. One such undertaking involves the use of matrices containing specific cells and growth factors as tissue replacements. Most of the knowledge that has allowed the advancements in preparation of tissue substitutes has come from studies performed during biologic development and development-like processes, such as wound healing, on the basic mechanisms of interaction between cells and the extracellular matrix (ECM). Discussed in this chapter are some of the key findings that led to the understanding of how the dynamics of cell–ECM interactions contribute to cell migration, proliferation, differentiation, and programmed death, all of which are important parameters to consider when preparing and using tissue analogs.

For many years the ECM was thought to serve only as a structural support for tissues. However, as early as 1966, Hauschka and Konigsberg showed that interstitial collagen promoted the conversion of myoblasts to myotubes, and shortly thereafter it was shown that both collagen (Wessells and Cohen, 1968) and glycosaminoglycans (Bernfield *et al.*, 1973) play a crucial role in salivary gland morphogenesis. Based on these and other pieces of indirect evidence, Hay (1977) put forth the idea that the ECM is an important component in embryonic inductions, a concept that implicated the presence of binding sites (receptors) for specific matrix molecules on the surface of cells. By this time, the stage was set to begin to investigate in detail the mechanisms by which extracellular matrix molecules influence cell behavior. Bissell *et al.* (1982) proposed the model of “dynamic reciprocity” between the ECM on the one hand and the cytoskeleton and nuclear matrix on the other. In this model, ECM molecules interact with cell surface receptors, which then transmit signals across the cell membrane to molecules in the cytoplasm; these signals initiate a cascade of events through the cytoskeleton into the nucleus, resulting in the expression of specific genes, whose products, in turn, affect the ECM in various ways. It now has become clear that this concept is essentially correct (Ingber, 1991; Boudreau *et al.*, 1995); cell–ECM interactions participate directly in promoting cell adhesion, migration, growth, differentiation, and programmed cell death (also called apoptosis), as well as in modulation of the activities of cytokines and growth factors, and in directly activating intracellular signaling.

Most of what we know about the molecular basis of cell–ECM interactions in these events comes from studies that have used induced mutations, experimental perturbations *in vivo*, and

cell/organ cultures. In this chapter, the composition and diversity of the ECM and its receptors are briefly discussed, then selected examples illustrate the dynamics of cell–ECM interactions during development and wound healing and the potential mechanisms involved in the signal transduction pathways initiated by these interactions. Finally, the implications for tissue engineering are discussed.

## COMPOSITION AND DIVERSITY OF THE ECM

The ECM is a molecular complex that has as basic components collagens and other glycoproteins, hyaluronic acid, proteoglycans, glycosaminoglycans, and elastins; the ECM also harbors molecules such as growth factors, cytokines, matrix-degrading enzymes, and their inhibitors. The distribution of these molecules is not static, but rather varies from tissue to tissue and during development from stage to stage (Laurie *et al.*, 1989; Ffrench-Constant and Hynes, 1989; Sanes *et al.*, 1990; Martins-Green and Bissell, 1995; Werb and Chin, 1998). Furthermore, their organization varies with tissue type and has profound implications for the function of the tissues (Scheler *et al.*, 1998). Mesenchymal cells are immersed in an interstitial matrix that confers specific biomechanical and functional properties to connective tissue (Culav *et al.*, 1999). Epithelial and endothelial cells, on the other hand, contact a basement membrane only through their basal surfaces, which confers mechanical strength and specific physiological properties to the epithelia (Fuchs *et al.*, 1997; Dockery *et al.*, 1998).

This diversity of composition, organization, and distribution of the ECM results not only from differential gene expression for the various molecules in specific tissues, but also from the existence of differential splicing and posttranslational modifications of those molecules. For example, differential splicing may change the binding potential of proteins to each other (Ffrench-Constant and Hynes, 1989; Chiquet-Ehrismann *et al.*, 1991; Wallner *et al.*, 1998) or to their receptors (Aota *et al.*, 1994; Akiyama *et al.*, 1995; Cox and Huttenlocher, 1998) and variations in glycosylation can lead to changes in cell adhesion (Dean *et al.*, 1990; Vlodavsky *et al.*, 1996; Schamhart and Kurth, 1997; Cotman *et al.*, 1999). In addition, the presence of divalent cations such as  $\text{Ca}^{2+}$  (Paulsson, 1988; Ekblom *et al.*, 1994) can affect matrix organization and influence molecular interactions that are important with respect to the way ECM molecules interact with cells (Sjaastad and Nelson, 1997).

Growth factors and cytokines interact with the ECM in a variety of ways, which allows them mutually to affect each other (Nathan and Sporn, 1991; Adams and Watt, 1993). The ECM can serve as a reservoir by binding growth factors and cytokines and protecting them from being degraded, by presenting them more efficiently to their receptors, or by affecting their synthesis (Roberts *et al.*, 1988; Chiquet-Ehrismann, 1991; Flaumenhaft and Rifkin, 1992; Lamszus *et al.*, 1996; Kagami *et al.*, 1998). In this way the ECM can affect the local concentration and biological activity of these factors. For example, when neutrophils adhere to fibronectin they produce higher levels of tumor necrosis factor (Nathan and Sporn, 1991). Conversely, growth factors and cytokines can stimulate cells to alter the production of ECM molecules, their inhibitors, and/or their receptors (Streuli *et al.*, 1993; Schuppan *et al.*, 1998). Transforming growth factor  $\beta$  (TGF- $\beta$ ), for example, up-regulates the expression of matrix molecules and of inhibitors of enzymes that degrade ECM molecules (Bonewald, 1999). In a number of cases, only specific forms of these growth factors and cytokines bind to specific ECM molecules, e.g., platelet-derived growth factor (PDGF) (La Rochelle *et al.*, 1991) and the chicken chemotactic and angiogenic factor (cCAF). The latter protein, chemokine, that is overexpressed during wound repair and in the stroma of tumors (Martins-Green and Bissell, 1990; Martins-Green *et al.*, 1992), is secreted as a 9-kDa protein but can be processed to 7 kDa by plasmin. Both the 9- and 7-kDa forms of the protein are found in association with interstitial collagen, but only the smaller form binds to laminin or tenascin and neither form binds to fibronectin, collagen IV, or heparin (Martins-Green and Bissell, 1995; Martins-Green *et al.*, 1996). Importantly, binding of specific forms of these factors to specific ECM molecules can lead to their localization to particular areas of tissues and can affect their biological activities.

## RECEPTORS FOR EXTRACELLULAR MATRIX MOLECULES

In order to establish that ECM molecules directly affect cellular behavior, it was important to identify transmembrane receptors for the specific sequences present on these molecules. As early

Fig. 4.1. Integrin family of receptors and their extracellular ligands. These heterodimeric receptors are each composed of one  $\alpha$  and one  $\beta$  subunit. Extracellular ligands have now been identified for many of the integrin receptors. The  $\beta_1$  and  $\beta_3$  classes mostly mediate cell-matrix adhesion, whereas the  $\beta_2$  class mediates cell-cell adhesions. Moreover, the  $\beta_1$  class is, in general, involved in adhesion to connective tissue macromolecules such as fibronectin, laminin, and collagen, whereas  $\beta_3$  binds vascular ligands such as fibrinogen, von Willebrand factor, thrombospondin and vitronectin. CO, Collagens; C3bi, complement component; FG, fibrinogen; FN, fibronectin; ICAM-1, intercellular adhesion molecule 1; LN, laminin; TSP, thrombospondin; VCAM-1, vascular cell adhesive molecule 1; VN, vitronectin; vWF, von Willebrand factor; OSP, osteopontin; \*, RGD-mediated binding.

as 1973, it was observed that during salivary gland morphogenesis near the sites of glycosaminoglycan deposition, the intracellular microfilaments contracted (Bernfield *et al.*, 1973). These investigators proposed that the ECM could “be involved in regulating microfilament function,” suggesting that these molecules can specifically interact with cell surface receptors. Using biochemical and molecular biological approaches, it was subsequently shown that various ECM molecules contain specific amino acid motifs that allow them to bind directly to cell surface receptors (Humphries *et al.*, 1991; Hynes, 1992; Gullberg and Ekblom, 1995). The best characterized motif is the tripeptide RGD, first found in fibronectin (Pierschbacher and Ruoslahti, 1984; Yamada and Kennedy, 1984). Peptides containing this amino acid sequence promote adhesion of cells and inhibit the adhesive properties of fibronectin. This and other amino acid adhesive motifs have been found in laminin, entactin, thrombin, tenascin, fibrinogen, vitronectin, type I and VI collagens, bone sialoprotein, and osteopontin (Humphries *et al.*, 1991).

Integrins were the first ECM receptors to be identified (Hynes, 1987). These receptors make up a family of heterodimeric transmembrane proteins composed of  $\alpha$  and  $\beta$  subunits. At least 15  $\alpha$  and 8  $\beta$  subunits have been identified so far; they pair with each other in a variety of combinations, giving rise to a large family that recognizes specific sequences on the ECM molecules (Fig. 4.1). Some integrin receptors are very specific whereas others bind several different epitopes, which may be on the same or different ECM molecules (Fig. 4.1). In this way plasticity and redundan-

cy can be built into specific systems (e.g., Hynes, 1992, 1999; Faull and Ginsberg, 1996; Cotman *et al.*, 1998).

Although the  $\alpha$  and  $\beta$  subunits of integrins are unrelated, there is 40–50% homology within each subunit, with the highest divergence in the intracellular domain of the  $\alpha$  subunit. All but one of these subunits ( $\beta 4$ ) have large extracellular domains and very small intracellular domains (Briesewitz *et al.*, 1995; Fornaro and Languino, 1997). The extracellular domain of the  $\alpha$  subunits contains four binding sites for divalent cations. These binding sites are homologous to the EF-band of calmodulin and appear to be responsible for the dependence of integrin–ligand binding on the presence of these ions (Gailit and Ruoslahti, 1988). It is now well established that, on ligand binding, integrins can directly induce biochemical signals inside cells (Giancotti, 1997; Kumar, 1998). The cytoplasmic domain of integrins interacts with the cytoskeleton, suggesting that ECM signalling through integrins is transduced via the cytoskeletal elements and can induce cell shape changes, which, in turn, may lead to growth and/or differentiation (Ruoslahti and Yamaguchi, 1992; Hemler, 1998).

Although not as extensively studied as the integrins, it has been found that transmembrane proteoglycans also can be receptors for ECM molecules (Rapraeger *et al.*, 1987; Jalkehen *et al.*, 1991; McFall and Rapraeger, 1998). At least four types of proteoglycan receptors that bind to ECM molecules have been isolated and characterized: syndecan, CD44, RHAMM (receptor for hyaluronate-mediated motility), and thrombomodulin (Rapraeger *et al.*, 1987; Bernfield *et al.*, 1992; Turley, 1992; Spring *et al.*, 1994; Carey, 1997; Naot *et al.*, 1997; McFall and Rapraeger, 1998). Syndecan binds cells to the matrix via chondroitin sulfate and heparan sulfate glycosaminoglycans, sugars that vary depending on the type of tissue in which syndecan is expressed, and which modulate the capability of a particular ligand to interact with it (Kim *et al.*, 1994; Salmivirta and Jalkanen, 1995). In contrast to the binding of matrix to integrins, this binding is independent of divalent cations. Syndecan also associates with the cytoskeleton, showing that these interactions via the cytoskeleton are important in signal transduction through this cell surface receptor (Carey *et al.*, 1996; Couchman *et al.*, 1996). The CD44 receptor also carries chondroitin sulfate and heparan sulfate chains on its extracellular domain. Variation in the glycosaminoglycan composition is tissue specific and may play a role in cell adhesion similar to that shown for syndecan (Brown *et al.*, 1991). The most distant extracellular domain of CD44 contains six cysteine residues that form three disulfide bonds, creating three loops that are structurally similar to the hyaluronan-binding domain of the cartilage link protein and aggrecan. Using a lymphoid cell line and an antibody to CD44 it has been shown that this domain of CD44 can interact directly with hyaluronan (Miyake *et al.*, 1990).

RHAMM has been identified as the major receptor for hyaluronic acid, and in hematopoietic progenitor cells these interactions play an important role in their trafficking (Pilarski *et al.*, 1999). Thrombomodulin is a transmembrane receptor with an extracellular portion containing an N-terminal hydrophobic domain followed by six extracellular growth factor (EGF)-like repeats and a Ser/Thr domain with a glycosaminoglycan attachment site. This protein is expressed in endothelial cells, has anticoagulant properties, and can be found in a proteoglycan or nonproteoglycan form. Its biological activity can be regulated either by its protein or glycosaminoglycan components (Hardingham and Fosang, 1992; Blann and Seigneur, 1997).

Cell surface receptors other than integrins or proteoglycans have also been identified for ECM molecules. A laminin-binding protein of 69 kDa recognizes the YIGSR sequence of laminin that is not recognized by integrins (Mecham, 1991). A second receptor, CD36, binds collagen, thrombospondin, and malaria-infected erythrocytes to endothelial cells and to some types of epithelial cells (Greenwalt *et al.*, 1992). Each of these has a separate binding site, but all are located in the same external loop of CD36 (Asah *et al.*, 1993) and the intracellular signals occurring after ligand binding lead to activation of a variety of signal transduction molecules (Huang *et al.*, 1991; Lipsky *et al.*, 1997).

## CELL–ECM INTERACTIONS

Interactions of cells with extracellular matrix molecules play a crucial role during development and wound healing. It is the continuous cross-talk between cells and the surrounding matrix environment that leads to the formation of patterns, the development of form (morphogenesis), and the acquisition and maintenance of differentiated phenotypes during embryogenesis.

Similarly, during wound healing these interactions contribute to the processes of clot formation, inflammation, granulation tissue development, and remodeling. As we will see, many different lines of experimental evidence have shown that the basic cellular mechanisms that result in these events involve cell adhesion/deadhesion, migration, proliferation, differentiation, and programmed cell death.

## DEVELOPMENT

### Adhesion and migration

Some of the most compelling experiments that demonstrated the direct participation of the ECM in cell adhesion and migration came from studies in gastrulation, migration of neural crest cells (NCCs), angiogenesis, and epithelial organ formation. Cell interactions with fibronectin are important during gastrulation. Microinjection of antibodies to fibronectin into the blastocoel cavity of *Xenopus* embryos causes disruption of normal cell movements and leads to abnormal development (Boucaut *et al.*, 1984a). Furthermore, if RGD-containing peptides are injected during the same stage of development, they cause randomization of the bilateral asymmetry of the heart and gut (Yost, 1992). Similarly, microinjection of RGD-containing peptides and/or antibodies to the  $\beta 1$  subunit of the integrin receptor for fibronectin perturbs gastrulation in embryos of *Pleurodeles* (salamander) (Yost, 1992; Boucaut *et al.*, 1984b; Darriberre *et al.*, 1988). These effects are not unique to fibronectin. They can also be introduced by manipulation of other molecules, such as heparan sulfate proteoglycan, which can be competed out by heparin for its target-binding molecule(s) and cause perturbations in gastrulation and neurulation (Erickson and Perris, 1993; Erickson and Reedy, 1998).

The NCCs originate in the dorsal portion of the neural tube just after closure of the tube, migrate extensively throughout the embryo in ECM-filled spaces, and give rise to a variety of phenotypes. The pathways of migration of the NCCs contain collagens, proteoglycans, glycosaminoglycans, and glycoproteins (Erickson and Perris, 1993; Erickson and Reedy, 1998). Microinjection of antibodies to fibronectin (Poole and Thiery, 1986) or to the  $\beta 1$  subunit of the integrin receptor (Bronner-Fraser, 1985, 1986) into the crest pathways in chick embryos reduces the number of NCCs that leave the tube and causes abnormal neural tube development. Other ECM molecules, such as laminin, also affect NCC migration: for example, the YIGSR synthetic peptide, known to inhibit laminin binding to cells, also inhibits NCC migration (Runyan *et al.*, 1986). The importance of cell–ECM interactions in NCC migration is also supported by studies performed in the white mutant of Mexican axolotl embryos. The NCCs that give rise to pigment cells fail to emigrate from the neural tube in these embryos, but when microcarriers containing subepidermal ECM from normal embryos are implanted into the appropriate area in these mutants, the NCC precursors to pigment cells emigrate normally (Perris *et al.*, 1988; Lofberg *et al.*, 1989; Epperlein and Lofberg, 1996). Potentially relevant to these findings is the observation that fibronectin appears between chick NCCs just prior to their emigration from the neural tube (Martins-Green, 1987, 1990; Martins-Green and Bissell, 1995). Perhaps this fibronectin consists predominantly or exclusively of the RGD domain-carrying segment that, when bound to its integrin receptor, promotes secretion of adhesion-degrading enzymes, thereby facilitating emigration (Damsky and Werb, 1992; Grant *et al.*, 1998).

During angiogenesis (the development of blood vessels from preexisting vessels), endothelial cell interactions with ECM molecules and the type and conformation of the matrix play a crucial role in cell migration and the development of blood vessels (Cockerill *et al.*, 1995; Baldwin, 1996; Hanahan, 1997; Kumar *et al.*, 1998). Human umbilical vein endothelial cells migrate and arrange themselves in tubular structures when cultured for 12 hr on a matrix isolated from Engelbreth–Holm–Swarm (EHS) tumors (a basement membranelike matrix that contains mainly laminin but also has collagen type IV, proteoglycans, and entactin/nidogen) (Kleinman *et al.*, 1982). When these cells are cultured on collagen type I, however, tubular structures do not form in this period of time, but if they are grown for a week inside collagen gels, giving the endothelial cells time to deposit their own basement membrane, tubes do develop (Montesano *et al.*, 1983; Madri *et al.*, 1988). The much more rapid tubulogenesis on EHS versus inside collagen I suggests that one or more components of the basement membrane plays an important role in the development of the capillary-like structures, a speculation that has been confirmed both in culture and *in vivo*

(Sakamoto *et al.*, 1991; Grant *et al.*, 1992). Indeed, preincubation of these endothelial cells with antibodies to laminin, the major component of basement membrane, prevents the formation of tubules *in vitro*. Furthermore, synthetic peptides containing the sequence SIKVAV, present in the A chain of laminin, induce endothelial cell adhesion and elongation and promote angiogenesis (Grant *et al.*, 1992). Interestingly, however, the sequence CDPGYIGSR-NH<sub>2</sub>, a domain present in the laminin B chain, blocks angiogenesis *in vivo* (Sakamoto *et al.*, 1991; Grant *et al.*, 1992) as well as migration of endothelial cells induced by tumor-conditioned medium Sakamoto *et al.*, 1991). The mechanism of action of these sequences is unknown, but it is potentially instructive that sequences in the same molecule have opposite effects. Because endothelial cells have to migrate and penetrate adjacent tissues and matrix during angiogenesis, matrix-degrading enzymes are active, raising the possibility that angiogenic factors are provided by release from the matrix or by appropriate cleavage of ECM molecules such as laminin (Werb *et al.*, 1999). *In vivo*, angiogenic sequences or factors could be provided locally, and when they have served their purpose, inhibition of further action could similarly be initiated by suitable cleavage of CDPGYIGSR-NH<sub>2</sub> or some other comparable factor present in the ECM (Sakamoto *et al.*, 1991). Therefore, the way matrix molecules are locally cleaved and/or factors are locally released could have important consequences for the homeostasis of tissues.

### Proliferation

Interactions of ECM molecules with cells can also modulate cell proliferation. Some of these effects are well illustrated by laminin. A domain in the A chain of laminin that is rich in EGF-like repeats stimulates proliferation of a variety of different cell lines (Panayotou *et al.*, 1989), and the entire molecule appears to promote proliferation of bone marrow-derived macrophages (Ohki and Kohashi, 1994). Also, thrombospondin exerts its mitogenic activities via its amino-terminal heparin-binding domain (Majack *et al.*, 1986). Contrarily, there also are matrix molecules that are inhibitory of cell proliferation. Heparin and heparin-like molecules, for example, are inhibitors of vascular smooth muscle (VSM) cell proliferation. The conditioned medium of endothelial cells cultured from bovine aortas inhibits the proliferation of VSM cells (Castellot *et al.*, 1987), and this inhibition is obliterated by treatment of the medium with heparinase but not with chondroitinases or proteases. This suggests that heparan-type molecules have a direct antiproliferative effect on aortic VSM cells. It has also been proposed (McCaffrey *et al.*, 1989) that this effect is indirect—heparinase treatment could release associated TGF- $\beta$ , which has been shown to inhibit the proliferation of nonconfluent cultures of VSM cells. However, if the latter were the case, one would expect that treatment of the endothelial cell conditioned medium with proteases should also eliminate the antiproliferative effect. Studies in culture have lent support to this inhibitory effect of the ECM on cell proliferation. For example, normal human breast cells do not growth-arrest when cultured on plastic, but do so if grown in a basement membrane matrix (Petersen *et al.*, 1993; Weaver *et al.*, 1997). Furthermore, growth of a mammary epithelial cell line is stimulated by overexpression of Id-1, a protein that binds to and inhibits the function of basic helix-loop-helix (HLH) transcription factors that are important in cell differentiation. When these overexpressing cells are cultured on EHS they arrest growth and form three-dimensional structures (Desprez *et al.*, 1993). Similarly, in hepatocytes it has been shown that ECM suppresses the expression of immediate-early growth response genes and induces C/EBP $\alpha$ , which is necessary for expression of hepatocyte-specific genes (Rana *et al.*, 1994).

Some of the ECM effects on cell proliferation involve cooperation with growth factors. For example, basic fibroblast growth factor (bFGF), interleukins (IL-1, IL-2, IL-6), hepatocyte growth factor, PDGF-AA, and TGF- $\beta$  are found in association with the ECM at high concentrations and are released at specific times for interaction with their receptors (Schuppan *et al.*, 1994). An illustrative example of cell-ECM-TGF- $\beta$  cooperation occurs during the early developmental stages of the mammary gland (Silberstein *et al.*, 1992; Howlett and Bissell, 1993). The development of this gland occurs in two steps: during puberty, the small number of ducts present at birth undergo extensive proliferation and branching, and terminal and lateral buds develop (virgin gland); during pregnancy, further local proliferation of ductal and bud epithelial cells occurs, giving rise to numerous alveoli (pregnant gland). During virgin gland morphogenesis, inductive events taking place between the epithelium and the surrounding mesenchyme are mediated by the basement

membrane (basal lamina plus closely associated ECM molecules) and play an important role in epithelial proliferation during branching of the gland. Endogenous TGF- $\beta$  produced by the ductal epithelium and surrounding mesenchyme forms complexes with mature periductal ECM, stabilizing the epithelium by inhibiting cell proliferation and matrix-degrading enzymes (Silberstein *et al.*, 1990, 1992; Robinson *et al.*, 1991). However, TGF- $\beta$  is absent from newly synthesized ECM deposited in the branching areas (Silberstein *et al.*, 1992), hence its inhibitory effects on epithelial cell proliferation and on production of matrix-degrading enzymes do not occur, allowing the basement membrane to undergo remodeling. In these regions, proteases that are released locally partially degrade the matrix, thereby promoting cell proliferation and branching morphogenesis. In mice transgenic for the autoactivated isoform of the matrix metalloproteinase stromelysin-1, which is important in basement membrane degradation and tissue remodeling, the virgin glands are morphologically similar to the pregnant glands of normal mice (Sympson *et al.*, 1994, 1995). These results indicate that stromelysin-1 causes matrix degradation leading to the release of factors that stimulate precocious proliferation of the epithelium and development of the alveoli.

### Differentiation

Some clear-cut examples of how the ECM can affect cell behavior come from studies of the influences of the ECM on cellular differentiation and maintenance of tissue-specific gene expression. Many of these studies have been performed during keratinocyte, hepatocyte, and mammary gland epithelial differentiation. Keratinocytes form the stratified epidermal layers of the skin. The basal layer is highly proliferative, does not express the markers for terminal differentiation, and is the only cell layer in contact with the basement membrane. As these cells divide, the daughter cells lose contact with the basement membrane, move up to the suprabasal layers, and begin to express differentiation markers such as involucrin. This suggests that close interaction with the basement membrane is responsible for the lack of differentiation of the basal keratinocytes. Indeed, when keratinocytes are grown in suspension, they undergo premature terminal differentiation (Nicholson and Watt, 1991). It has also been shown that human and mouse keratinocytes adhere to fibronectin via its  $\alpha_5\beta_1$ -integrin receptor and that the expression of both integrin subunits is inversely proportional to the expression of involucrin, a differentiation factor for these cells (Nicholson and Watt, 1991). A major advance in trying to understand the biology of skin development has been the ability to culture keratinocytes on feeder layers of 3T3 cells and form stratified sheets of cells that behave very much like epidermis does *in vivo* (DeVries *et al.*, 1994; Yoshizato and Yoshikawa, 1994; Gross, 1996; Stocum, 1998). This latter development has had profound application in treating patients that have suffered extensive burns.

In culture, expression of hepatocyte-specific genes is observed only when hepatocytes are grown on an EHS matrix (Ben-Ze'ev *et al.*, 1988) or when this matrix or diluted laminin is dripped over the cells (Caron, 1990). The specific cell-ECM interactions have not yet been worked out, but three liver-specific transcription factors eE-TF, e-G-TF/HNF-3, and eH-TF, are activated when cells are cultured on or with matrix molecules, conditions that favor hepatocyte differentiation. In particular, the transcription factor eG-TF/HNF-3 appears to be regulated by the ECM (Liu *et al.*, 1991). In mouse mammary gland, basement membrane and its individual components in conjunction with lactogenic hormones are responsible for the induction of the differentiated phenotype of the epithelial cells (Lin and Bissell, 1993; Blaschke *et al.*, 1994; Werb *et al.*, 1996; M. J. Bissell, 1998). In this system, when midpregnant mammary epithelial cells are cultured on plastic they do not express any of the mammary-specific genes. However, when the same cells are plated and maintained on EHS they form alveolar-like structures and exhibit the fully differentiated phenotype, with expression of the genes for milk proteins (e.g., the expression of  $\beta$ -casein) (Barcellos-Hoff *et al.*, 1989). In the case of  $\beta$ -casein, it has been shown that there are two components to its induction by the ECM: one involves cell rounding (and therefore a change in the cytoskeleton) and the other, a tyrosine kinase signal transduction pathway through the  $\beta_1$  integrin receptor, leading to the activation of elements in the promoter region of the  $\beta$ -casein gene (Roskelly *et al.*, 1994). Using a mammary gland cell line and progressive deletions of the bovine  $\beta$ -casein promoter attached to choline acetyltransferase (CAT), it was found that this promoter contains a 160-bp enhancer for  $\beta$ -casein about 1600 bp upstream from the start site (Schmidhauser *et al.*, 1991; Boudreau *et al.*, 1995; Myers *et al.*, 1998). These ECM-response elements are

also present in other tissues. As shown above, they exist in the albumin gene in hepatocytes and they have also been found in lower vertebrates in the LpS1 genes, which are activated in aboral ectoderm cells during early development of the sea urchin *Lytechinus pictus* (Xiang *et al.*, 1991).

Another example that illustrates well how the ECM influences the expression of milk protein genes comes from work performed on the expression of whey acidic protein (WAP) in mouse mammary gland epithelial cells. WAP expression is inhibited when cells are cultured on plastic, but if they are grown on an ECM, expression is up-regulated (Cheng and Bissell, 1989; Lin and Bissell, 1993). It has been found that cells cultured on plastic produce TGF- $\alpha$ , which inhibits the expression of WAP, whereas on EHS the matrix inhibits the production of TGF- $\alpha$  and this leads to up-regulation of the milk protein (Lin *et al.*, 1995).

### Programmed cell death (apoptosis)

In the embryogenesis of higher vertebrates, cell death occurs during remodeling, such as during blastocyst formation, during development of the digits, palate, and nervous system, during positive selection of thymocytes in the thymus, during mammary gland involution, and during angiogenesis. In early mouse development a cavity surrounded by a single layer of columnar epithelium forms within the morula. This process is the result of the interplay between two types of signal: one that stimulates cell death of the inner morula cells and the other, mediated by the basal lamina, that is crucial for the survival of the ectodermal cells that line the cavity (Coucovanis and Martin, 1995).

It has been found that during development of the mammary gland, basement membrane molecules suppress apoptosis of the epithelial cells (Strange *et al.*, 1992; Boudreau *et al.*, 1996; Alexander *et al.*, 1996). Following lactation, however, the numerous alveoli that produce milk regress and are resorbed during involution as a consequence of enzymatic degradation of the alveolar basement membrane and programmed cell death (Talhouk *et al.*, 1992; Strange *et al.*, 1992; Lund *et al.*, 1996; M. J. Bissell, 1998). In this system, the loss of cell-ECM interactions resulting from matrix degradation correlates with an increase in caspase-1 (previously known as interleukin-1 $\beta$  converting enzyme), which promotes apoptosis; inhibitors of this enzyme inhibit cell death (Boudreau *et al.*, 1995). Similarly, an antibody that disrupts the interaction of the  $\beta$ 1 integrin with its ECM ligands leads to apoptosis of mammary epithelial cells.

During late developmental stages, development of the circulatory system occurs via angiogenesis. It has been found that  $\alpha$ v $\beta$ 3 integrin interactions with the ECM play a crucial role in angiogenesis during embryogenesis (Brooks *et al.*, 1994; Varner *et al.*, 1995). Disruption of these interactions with an antibody to  $\alpha$ v $\beta$ 3 inhibits the development of new blood vessels in the chorioallantoic membrane (CAM) by causing the endothelial cells to undergo apoptosis (Brooks *et al.*, 1994; Varner *et al.*, 1995).

## WOUND HEALING

### Adhesion and migration

Shortly after tissue damage and during the early stages of wound healing, there is a release of blood contents and tissue factors into the area of the wound, leading to platelet activation and adhesion, and the formation of a vascular plug containing mostly platelets, plasma fibronectin, and fibrin (cross-linked by factor XIII), but also including small amounts of tenascin, thrombospondin, and SPARC [secreted protein, acidic and rich in cysteine]. During this process, activated mast cells degranulate, releasing vasodilating and chemotactic factors that will bring to the wound site polymorphonucleocytes. These events constitute the early stages of the inflammatory response. The fibrin-fibronectin meshwork provides a provisional matrix that serves as substrate for the subsequent migration of leukocytes and keratinocytes during the very early stages of healing when inflammation and wound closure are occurring. Leukocyte interactions with ECM molecules via integrin receptors affect many of the functions of these cells, in particular those that lead to cell adhesion and migration or to production of inflammatory mediators (Rosales and Juliano, 1995; Wei *et al.*, 1997). Some of these latter molecules can be damaging to tissues when produced in excess, therefore the course of inflammation can be affected significantly by the types of ECM molecules encountered by these leukocytes (Pakianathan, 1995; Wei *et al.*, 1997).

During closure of cutaneous wounds, keratinocytes migrate over the provisional matrix pri-

marily composed of fibronectin, vitronectin, tenascin, and collagen type III. These cells express  $\alpha 2\beta 1$ ,  $\alpha 3\beta 1$ ,  $\alpha 5\beta 1$ ,  $\alpha 6\beta 1$ , and  $\alpha v$  integrins, which interact with these ECM molecules and in conjunction with matrix metalloproteinases facilitate their migration to close the wound (Juhsz *et al.*, 1993; Gailit *et al.*, 1994). Cell–ECM interactions are equally important in closure of other epithelial wounds. Studies examining the sequential deposition of ECM molecules after wounding of retinal pigment epithelial cells showed that “*de novo*” deposition of fibronectin occurs 24 hr after wounding and is followed by deposition of collagen type IV and laminin. This sequence of matrix deposition is tightly linked to adhesion and migration of cells to close the wound (Kamei *et al.*, 1998). This has also been found to occur during the repair of airway epithelial cells after mechanical injury (White *et al.*, 1999).

As healing progresses, embryonic-type cellular fibronectin produced by macrophages and fibroblasts in the wound bed contributes to formation of the granulation tissue. This matrix molecule serves as substrate for the migration of endothelial cells (which form the vasculature of the wound bed), myofibroblasts, and lymphocytes that are chemoattracted to the wound site by a variety of small cytokines (chemokines), which are secreted by both macrophages and fibroblasts. Several members of the chemokine superfamily have been found in humans, in other mammals, and in avians (Balkwill, 1998; Locati and Murphy, 1999). Chemoattraction by chemokines of cells involved in granulation tissue formation, in conjunction with the interaction of these cells with the ECM via cell surface receptors, results in processes that lead to cell adhesion and migration into the area of the wound to form the granulation tissue (Lukacs and Kunkel, 1998).

One of the most extensively studied chemokines with functions important in wound healing is cCAF (Martins-Green and Bissell, 1990; Martins-Green *et al.*, 1992; Martins-Green, 1999). This chemokine is stimulated to high levels shortly after wounding in the fibroblasts of the wounded tissue (Martins-Green and Bissell, 1990; Martins-Green *et al.*, 1992), and thrombin, an enzyme released on wounding, stimulates these cells to overexpress cCAF (Vaingankar and Martins-Green, 1998; Li *et al.*, 2000). This chemokine, in turn, chemoattracts monocyte/macrophages and lymphocytes (Martins-Green and Feugate, 1998). Expression of cCAF stays elevated during granulation tissue formation, in particular in fibroblasts and endothelial cells of the microvasculature of the wound, and the protein binds to the interstitial collagens, tenascin, and laminin, present in the granulation tissue (Martins-Green and Bissell, 1990; Martins-Green *et al.*, 1992, 1996). Furthermore, cCAF is angiogenic *in vivo* and the angiogenic portion of the molecule is localized in the C terminus of the molecule (Martins-Green and Feugate, 1998; Martins-Green and Kelly, 1998). Based on the pattern of expression and functions of cCAF, it has been proposed that this chemokine participates both in inflammation (via chemotaxis for specific leukocytes) and in formation of the granulation tissue (via stimulation of angiogenesis) (Martins-Green and Hanafusa, 1997; Martins-Green, 1999).

## Proliferation

Immediately after wounding, the epithelium undergoes changes that lead to wound closure. During this reepithelialization period, the keratinocytes trailing behind those at the front edge of migration replicate to provide a source of cells to cover the wound. Basement membrane-type ECM, still present in the basal surface of these keratinocytes, may be important in maintaining this proliferative state. In support of this possibility is the finding that during normal skin remodeling, fibronectin associated with the basal lamina of epithelia is crucial for maintaining the basal keratinocyte layer in a proliferative state for constant replenishment of the suprabasal layers (Nicholson and Watt, 1991). It has also been shown, using a dermal wound model, that basement membrane matrices are able to sustain the proliferation of keratinocytes for several days (Dawson *et al.*, 1996).

As reepithelialization is occurring, the granulation tissue begins to form. This latter tissue is composed of fibroblasts, myofibroblasts, monocytes/macrophages, lymphocytes, endothelial cells of the microvasculature, and ECM molecules (embryonic fibronectin, hyaluronic acid, type III collagen, and small amounts of type I collagen) (Clark, 1996). These ECM molecules, in conjunction with growth factors released by the platelets and secreted by the cells present in the granulation tissue, provide signals to the cells, leading to their proliferation (Tuan *et al.*, 1996; D. M. Bissell, 1998). However, the ECM molecules, e.g., fibronectin, specific fragments of laminin and collagen VI, have been shown to stimulate fibroblast and endothelial cell proliferation (Bitterman

*et al.*, 1983; Panayotou *et al.*, 1989; Kapila *et al.*, 1998). The cooperation between ECM molecules and growth factors is well illustrated in the proliferation of fibroblasts and the development of new blood vessels (angiogenesis) of the granulation tissue. In the latter case, growth factors such as vascular endothelial growth factors (VEGFs) and FGFs associate with ECM molecules and stimulate proliferation of endothelial cells which then migrate to form the new microvessels (Norrby, 1997).

### Differentiation

As healing progresses during the formation of granulation tissue, some of the fibroblasts differentiate into myofibroblasts; they acquire the morphological and biochemical characteristics of smooth muscle cells by expressing smooth muscle  $\alpha$ -actin (Desmouliere and Gabbiani, 1994; Grinell, 1994). Matrix molecules are important in this differentiation process. For example, heparin decreases the proliferation of fibroblasts in culture and induces the expression of smooth muscle  $\alpha$ -actin in these cells. *In vivo*, the local application of tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) leads to the development of granulation tissue, but the presence of cells expressing smooth muscle  $\alpha$ -actin was observed only when heparin was also applied (Desmouliere *et al.*, 1992). These results suggest that some of the properties of heparin not related to its anticoagulant effects are important in the induction of smooth muscle  $\alpha$ -actin. This function may be related to the ability of heparin to bind cytokines and/or growth factors (such as TNF- $\alpha$  and TGF- $\beta$ ) that regulate cell differentiation (Kirkland *et al.*, 1998; Kim and Mooney, 1998).

Interstitial collagens have also been shown to play a role in the acquisition of the myofibroblastic phenotype. When fibroblasts are cultured on relaxed collagen gels they remain as fibroblasts (Tomasek *et al.*, 1992), but if they are grown on anchored collagen matrices in which the collagen fibers are aligned (much like in the granulation tissue), they show myofibroblast characteristics (Bell *et al.*, 1979; Arora *et al.*, 1999). These and other observations have led to the suggestion that floating collagen matrices mimic dermis whereas anchored collagen matrices mimic granulation tissue (Grinell, 1994; Arora *et al.*, 1999).

### Programmed cell death

Apoptosis also plays a role during normal wound healing as the granulation tissue evolves into scar tissue. As the wound heals, the number of fibroblasts, myofibroblasts, endothelial cells, and pericytes decreases dramatically, matrix molecules, especially interstitial collagen, accumulate, and a scar forms (Clark, 1996). In this remodeling phase of healing, cell death by apoptosis leads to elimination of many cells of various types at once without causing tissue damage (Greenhalgh, 1998). For example, studies using transmission electron microscopy and *in situ* end-labeling of DNA fragments have shown that many myofibroblasts and endothelial cells undergo apoptosis during the remodeling process. Morphometric analysis of the granulation tissue shows that the number of cells undergoing apoptosis increases around days 20–25 after injury, resulting in a dramatic reduction in cellularity after day 25 (Desmouliere *et al.*, 1995). Moreover, using model systems that mimic regression of granulation tissue, it has been shown that release of mechanical tension triggers apoptosis of human fibroblasts. Apoptotic cell death was regulated by interstitial-type collagens in combination with growth factors and mechanical tension and did not require differentiation of the fibroblasts into myofibroblasts, strongly suggesting that contractile collagens determine the susceptibility of fibroblasts of the wound tissue to undergo apoptotic cell death (Fluck *et al.*, 1998; Grinell *et al.*, 1999).

In addition to cell death by apoptosis, it has also been shown that during lung remodeling after injury, fibroblasts present in the bronchoalveolar lavage fluid undergo cell death by a process that is distinct from that of necrosis or apoptosis (Polunovsky *et al.*, 1993). Although this process of cell death has not been extensively studied it suggests that there are other processes of programmed cell death that are distinct from apoptosis and occur preferentially in association with wound repair.

## SIGNAL TRANSDUCTION EVENTS DURING CELL–ECM INTERACTIONS

From the foregoing examples, it is clear that ECM molecules interact with their receptors and transmit signals directly or indirectly to second messengers that, in turn, unravel a cascade of

events, leading to the coordinated expression of a variety of genes involved in cell adhesion, migration, proliferation, differentiation, and death. There is increasing evidence that cell-ECM interactions, especially through integrins, activate a variety of signaling pathways that can be linked to those specific functions. Three potential categories of cell-ECM interactions can lead to these cellular events:

1. Type I interactions involve primarily integrins and proteoglycan receptors, and they are involved in cell adhesion/deadhesion processes during migration (Fig. 4.2A). For example, cell migration is promoted when fibronectin binds simultaneously to integrins through its cell-binding domain and to proteoglycan receptors through its heparin-binding domain (Hynes, 1992; Bernfield *et al.*, 1992; Hardingham and Fosang, 1992; Giancotti, 1997; Schlaepfer and Hunter, 1998; Dedhar, 1999). The proteoglycan receptors interact and colocalize in areas of adhesion, where microfilaments associate with the  $\beta 1$  subunit of the integrin receptor via structural proteins such as talin and  $\alpha$ -actinin, present in the actin cytoskeleton of the focal adhesions. The cytoplasmic domain of the  $\beta 1$  subunit also interacts directly with the focal adhesion tyrosine kinase pp125<sup>FAK</sup>, which, when activated, undergoes autophosphorylation on tyrosine 397 (Hildebrand *et al.*, 1995); Tyr-397 subsequently serves as the binding site for the SH2 domain of the nonreceptor tyrosine kinase c-Src. In turn, c-Src phosphorylates paxillin, tensin, vinculin, and the protein p130<sup>cas</sup>, all of which are present in focal adhesion plaques. The specific roles of paxillin and tensin in the process of adhesion/deadhesion during migration are not known but, once phosphorylated, they could mediate signals between the plasma membrane and the cytoskeleton. p130<sup>cas</sup> is a docking protein that, on activation, binds to the adaptor molecules Crk and Nck, which appear to be involved in migration via the Ras and MAP/JNK kinase pathways. In addition, it has also been shown that c-Src phosphorylates FAK on tyrosine 925, which serves as a site for binding of the Grb2/Sos complex, with subsequent activation of Ras and the MAP kinase cascade (Schlaepfer and Hunter, 1996, 1997; Schlaepfer *et al.*, 1997, 1998). Both pathways are potentially involved in adhesion/deadhesion and migration (Giancotti, 1997; Schlaepfer and Hunter, 1998; Dedhar, 1999).

It is also known that binding of the ECM to integrins can be enhanced by specific cytoplasmic molecules such as the cell adhesion regulator (CAR), a myristoylated protein that can potentially connect the plasma membrane to the cytoskeleton, is activated by phosphorylation, and increases the affinity of  $\alpha 2\beta 1$  to collagen type I (Pullman and Bodmer, 1992). These observations, taken together with the fact that integrins and proteoglycan receptors have no kinase or phosphatase activity in their cytoplasmic domains, suggest that the signals from these receptors leading to adhesion/deadhesion and migration are transduced via regulatory proteins that are part of the actin cytoskeleton (Giancotti, 1997; Schlaepfer and Hunter, 1998; Dedhar, 1999).

2. Type II cell-ECM interactions involve processes that affect proliferation and survival, as well as differentiation and maintenance of the differentiated phenotype (Fig. 4.2B). In these processes, the extracellular matrix interacts with its receptors and cooperates with growth factors or cytokine receptors. These cooperative effects take place, for example, during anchorage dependence of cell growth. Anchorage is required for cells to enter S phase; even in the presence of growth factors, cells will not enter the DNA synthesis phase without being anchored to a substrate (Zhu and Assoian, 1995). Adhesion of cells to ECM molecules plays a very important role in regulating cell survival and proliferation (Mainiero *et al.*, 1997; Giancotti, 1997; Murgia *et al.*, 1998). For example, studies of knockout mice for the  $\alpha 1\beta 1$  integrin, which is the sole receptor for collagen, showed that the fibroblasts of these mice have reduced proliferation even though they attach normally (Pozzi *et al.*, 1998). Collagen binding to  $\alpha 1\beta 1$  in these fibroblasts does not activate the Shc adaptor protein, which in turn is not able to recruit Grb2 and activate the Ras/ERK cascade that leads to the expression of early response genes involved in cell cycle progression (Wary *et al.*, 1998). It has also been shown that cooperation between integrins and growth factors involves the activation of phosphatidylinositol phosphate kinases, which increases the levels of phosphatidylinositol bisphosphate (PIP<sub>2</sub>). In turn, PIP<sub>2</sub> serves as substrate for phospholipase C <sub>$\gamma$</sub>  (PLC <sub>$\gamma$</sub> ), which is activated on growth factor binding to specific receptors on the surface of the cells (Schwartz, 1992). Furthermore, phosphoinositide 3-OH (PI-3) kinase has been shown to rescue cells in suspension from undergoing apoptosis. It appears that in this case PI-3 kinase is activated by Ras, leading to activation of the Akt serine/threonine kinase (Khwaja *et al.*, 1997).

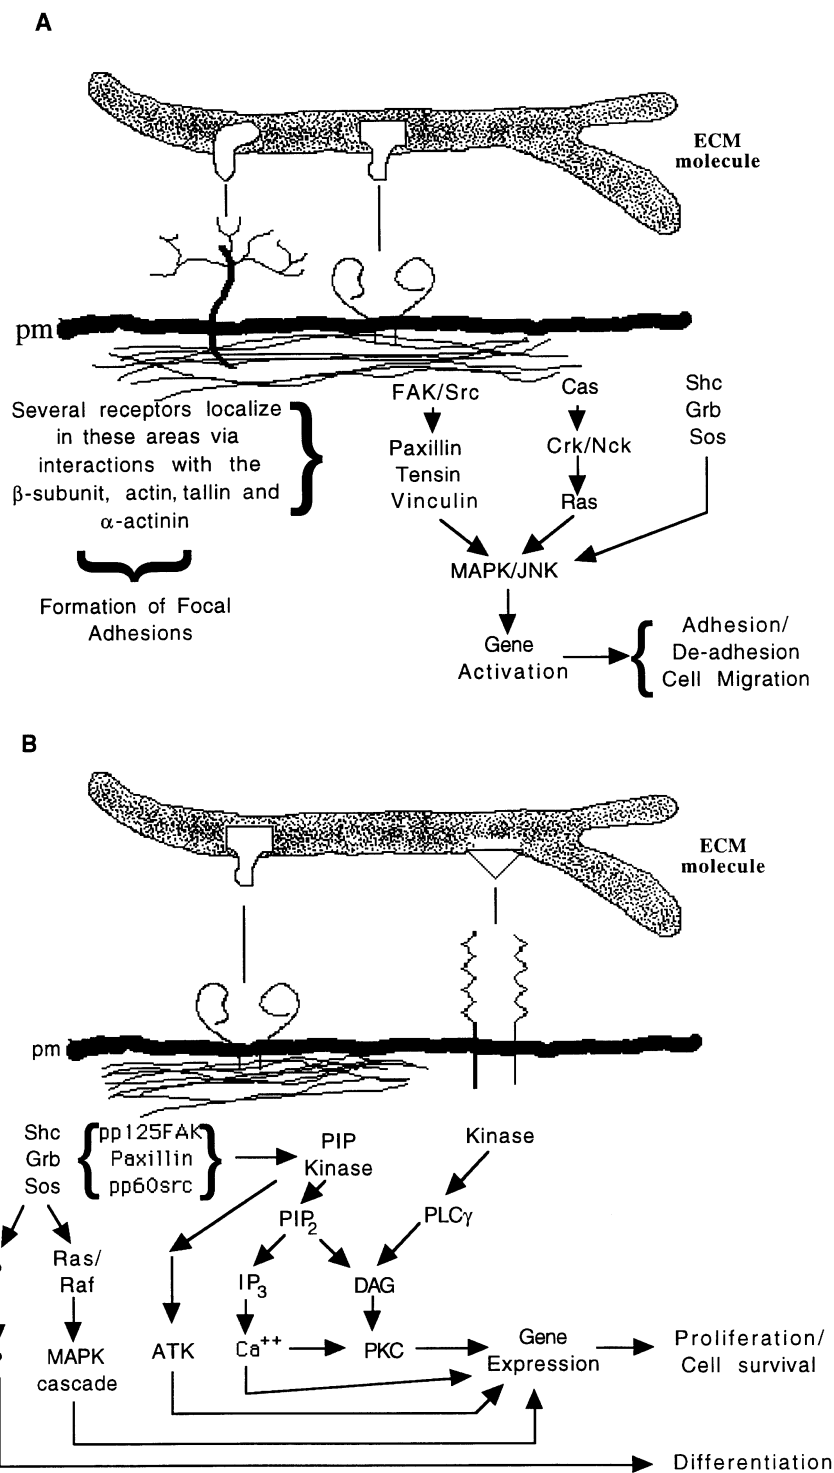

Fig. 4.2. Schematic diagrams (A–C) illustrating the three proposed categories of cell–ECM interactions. (A) At focal adhesions, proteoglycan (tree-like) and integrin (heterodimer) receptors on the plasma membrane (pm) bind to different epitopes on the same ECM molecule, leading to cytoskeletal reorganization. A variety of proteins become phosphorylated (e.g., pp125<sup>FAK</sup>, Src, PKC), leading through poorly understood pathways to activation of genes important for cell adhesion/deadhesion and for migration. (B) Integrin receptors bind to their ligands, leading to activation of cytoskeletal elements as in A, but growth factors bound to matrix molecules (triangle) also bind to their receptors, which have kinase activity. This kinase activates phospholipase C $\gamma$  (PLC $\gamma$ ), which, in turn, cleaves phosphatidylinositol bisphosphate (PIP $_2$ ), leading to inositol trisphosphate (IP $_3$ ) and diacylglycerol (DAG); IP $_3$  binds to its receptor on the smooth endoplasmic reticulum, inducing the release of Ca $^{2+}$ , which can lead directly to activation of gene expression or indirectly by co-

Fig. 4.2. Continued

operation with DAG through protein kinase C (PKC). In this case, the genes activated are important in cell proliferation, differentiation, and maintenance of the differentiated phenotype. (C) Integrin receptors bind to fragments of ECM molecules containing specific domains. This leads to activation of matrix protease genes whose products (represented by black ellipses) degrade the matrix and release peptides (squiggles) that can further interact with cell surface receptors and/or release growth factors (triangles and diamonds), which, in turn, bind to their own receptors, activating G proteins and kinases, leading to expression of genes important in morphogenesis and cell death.

Similarly, interaction of the cells with ECM molecules, hormones, and growth factors is required to activate genes that are specific for differentiation. Interestingly, in the case of stimulation of cell differentiation, studies have shown that the cell-ECM interactions that result in the differentiated phenotype are those that fail to activate Shc and the MAP kinase cascade. This has been shown for endothelial cells in which the interaction of  $\alpha 2\beta 1$  with laminin, which does not activate the Shc pathway, leads to formation of capillary-type structures (Kubota *et al.*, 1988), whereas the interaction of  $\alpha 5\beta 1$  in the same cells with fibronectin results in proliferation (Wary *et al.*, 1998). Similar observations have been made with primary bronchial epithelial cells when they are cultured on collagen matrices (Moghal and Neel, 1998).

3. Cell-ECM interactions of Type III involve mostly processes leading to cell death and to epithelial-to-mesenchymal transitions (Fig. 4.2C). Signal transduction pathways that lead to apoptosis have been delineated for endothelial cells and leukocytes and appear to involve primarily tyrosine kinase activity (Ilan *et al.*, 1998; Fukai *et al.*, 1998; Kettritz *et al.*, 1999). In the case of epithelial-to-mesenchymal transition, remodeling of the matrix is an important component of the interactions: Enzymatic degradation of the ECM contributes to release of soluble factors and fragments of ECM that contain specific sequences that affect cell behavior. For example, when fibronectin binds only through its cell-binding domain, the cells are stimulated to produce ECM-remodeling enzymes (Lukashev and Werb, 1998). There are at least three possible ways in which such a process could be initiated: (1) Changes in expression of fibronectin (FN) receptors would allow cells to bind fibronectin predominantly through its cell-binding domain and activate  $\alpha 5\beta 1$  interactions with the actin cytoskeleton, with subsequent transduction of signals that lead to up-regulation of ECM-degrading enzymes. The secretion of these enzymes would start a positive feedback loop by degrading additional fibronectin to produce cell-binding fragments, which would bind to  $\alpha 5\beta 1$ , activate it, and in this way keep the specific event going. (2) Very localized release of ECM-degrading enzymes could degrade FN into fragments containing only the cell-binding

domain, which would bind to  $\alpha 5\beta 1$  and initiate the positive feedback loop. (3) At a particular time during development, specific cells would produce spliced forms of FN that are capable of interacting only via their cell-binding domain. Binding of these fragments to  $\alpha 5\beta 1$  would trigger the feedback loop. This positive feedback loop and consequent runaway process of ECM degradation is advantageous locally during epithelial-to-mesenchymal transitions. However, during other developmental processes and during wound healing, there must be a signal that can break this circle and thereby bring it under control at the appropriate time and place. Without application of such a brake, these processes can lead to abnormal development, to wounds that do not heal, or to pathological situations such as tumor growth and invasion.

Although these three categories may not be exhaustive of the general types of cell–ECM interactions that occur during development and wound healing, they encapsulate the major interactions documented to date. Each category has its place in many developmental and repair events and they may operate in sequence. A compelling example of the latter is the epithelial-to-mesenchymal transition and morphogenesis of the neural crest cell system. These cells originate in the neural epithelium that occupies the crest of the neural folds. After the delamination event that separates the neural epithelium from the epidermal ectoderm, the folds fuse to form the tube (Martins-Green, 1988). At this time the NCCs occupy the dorsalmost portion of the tube, they are not covered by basal lamina, and the subepidermal space above them contains large amounts of fibronectin (Martins-Green and Erickson, 1987). Just before the NCCs emigrate from the neural tube, fibronectin appears between them, they separate from each other, and they migrate away, carrying fibronectin on their surfaces (Martins-Green, 1987, 1990). During the period of emigration at any particular level of the neural tube, the basal lamina is deposited progressively toward the crest from the sides of the tube (Martins-Green and Erickson 1986, 1987). NCC emigration terminates as deposition reaches the crest of the tube. The NCCs then migrate throughout the embryo following specific ECM-paved pathways, arriving at a wide variety of locations where they differentiate into many different phenotypes in response to external cues (Le Douarin, 1982; Erickson and Perris, 1993).

The appearance of fibronectin between the NCCs just before emigration must be the result of secretion by the adjacent cells or introduction from above after loss of cell–cell adhesions. In keeping with the cell–ECM interaction mechanism of Type III, either alternative could initiate a positive feedback loop and release the NCCs, leading to emigration. Enzymatic degradation of the stabilizing domain of fibronectin above the tube could cause enhanced secretion of specific enzymes by the NCCs in response to the effect of the cell-binding domain acting alone, leading to severing of adhesions between cells, and intrusion of fibronectin fragments containing the cell-binding domain. These fragments, in turn, would bind to adjacent cells and stimulate further enzymatic secretion that would be self-perpetuating. NCC emigration occurs in an anterior-to-posterior wave, hence once enzymatic activity was initiated in the head of the embryo, it could propagate posteriorly, triggering NCC emigration in a wave from head to tail.

Clearly some controlling event(s), must terminate NCC emigration at each location along the neural tube, or this scenario could empty the neural tube. Such an event has already been identified. At the time of NCC emigration, the ventral and lateral surfaces of the neural tube are covered by an intact basal lamina, which stabilizes the epithelium and separates it from the fibronectin layer around the tube (Martins-Green and Erickson, 1986). Following the delamination event at any one site (Martins-Green, 1988), the local dorsal portion of the neural tube is temporarily naked of basal lamina. During the few hours of NCC emigration at that site, basal lamina deposition progresses quickly up the side of the tube and terminates local emigration when it becomes complete over the crest of the tube (Martins-Green and Erickson, 1986, 1987). After they have emigrated from the neural tube, the NCCs are in an extracellular space filled with intact fibronectin and other ECM molecules that stimulate the focal adhesions of cell–ECM interactions of Type I, thereby providing the substrate for migration. On arrival at their final destination, further interactions of Type II stimulate differentiation into a wide range of phenotypes (Le Douarin, 1982; Erickson and Perris, 1993; Erickson and Reedy, 1998).

## RELEVANCE FOR TISSUE ENGINEERING

The major task when designing tissue and organ replacements is to simulate nature closely. One of the best approaches toward this goal is to study how tissues and organs arise during em-

bryogenesis and during normal processes of repair, and how those functions are maintained. When developing tissue replacements, one must consider several factors (Fig. 4.3):

1. *The need to avoid an immune response that can cause inflammation and/or rejection.* Ideally, one would like to identify and isolate stem cells capable of regenerating each one of the organs and tissues in the body. Selective stimulation and expansion of this cell population would allow regeneration *in vivo* without having to overcome an immune response. Alternatively, one would like to manipulate cells *in vitro* to make them more “universal” and thereby decrease the immune response. These latter cells would then differentiate in the presence of an environment conducive to expression of the appropriate phenotype.

2. *The need to create the proper substrate for cell survival and differentiation.* One of the strategies to fulfill this goal is the use of biocompatible implants composed of extracellular matrix molecules, or the appropriate biodegradable matrix, seeded with autologous cells, “universal” cells, or heterologous cells in conjunction with immunosuppressing drugs. Addition of growth and differentiation factors to these cell-containing matrices as well as agonists or antagonists that favor cell–ECM interactions can potentially increase the rate of successful tissue replacement. One example in which the knowledge obtained in studies of cell–ECM interactions has proved to be useful in tissue engineering was the discovery that most integrins bind to their ECM ligands via the tripeptide RGD. This small sequence of amino acids has been used as an agonist to make synthetic implants more biocompatible and to allow the development of tissue structure, or as an antagonist to prevent or moderate unwanted cell–ECM interactions (Tschopp *et al.*, 1994a; Cheng *et al.*, 1994; Glass *et al.*, 1994). An example of the latter is the use of these peptides to modulate platelet aggregation and formation of thrombi during reconstructive surgery (Tschopp *et al.*, 1993, 1994b; Cheng *et al.*, 1994; Glass *et al.*, 1994).

ECM-derived matrices also have been used for artificial corneas, for skin, for cartilage and bone replacement, and to enhance nerve regeneration (Bellamkonda *et al.*, 1995; Bouhadir and Mooney, 1998; Kim and Mooney, 1998). In the case of skin, patients with extensive burns have been treated with matrices of chondroitin sulfate and collagen (which support the formation of connective tissue and blood vessels) that are covered with an artificial material that prevents dehydration. Three weeks after this transplant, when the connective tissue is well established and vascularized, the superficial layer is removed and replaced with a thin layer of epithelium, which now rests on a substrate that supports the ultimate differentiation of the epidermal phenotype (Langer and Vacanti, 1993). Alternatively, the matrix is seeded with epidermal cells expanded in culture from very small skin grafts taken from the patient.

3. *The need to provide the appropriate environmental conditions for tissue maintenance.* At this stage it is crucial to maintain a balanced environment with the appropriate cues for maintenance of specific cell function(s). Unfortunately, little is known about the cross-talk between cells and

Fig. 4.3. Conceptualization of the interactions of an idealized “universal” cell and environments in which it is conditioned to a particular function (developmental environment) and maintained in that function (stabilizing environment).

ECM under such “normal” conditions. It is important to realize that such stasis on the level of a tissue is achieved via tissue remodeling—the dynamic equilibrium between cells and their environment.

Because organ transplantation is one of the least cost-effective therapies and is not always available, tissue engineering offers hope for more consistent and rapid treatment of those in need of replacement of body parts, and therefore it has the potential of improving the quality of life at a more affordable price. The selected examples presented above illustrate that to achieve this goal there is a need for continuous study of cells and how they interact with their environment. The present challenge is to make the leap in technology that will allow us to sort out complex biological phenomena and to perform simulations of specific biological processes that will guide us in planning subsequent experimental protocols. With the advent of bioinformatics it might be possible for biologists to integrate the vast body of information obtained so far and to make predictions for the future. In this context, a team at the University of Connecticut is developing a promising program called “The Virtual Cell” for modeling cellular processes (Schaff and Loew, 1999).

In summary, the intense research of the past decade on the ECM molecules and on their interactions with cell surface receptors has led to realization that these interactions are many and complex, provide for modulation of fundamental events during development and wound repair, and are crucial for the maintenance of the differentiated phenotype and tissue homeostasis.

# MATRIX MOLECULES AND THEIR LIGANDS

Björn Reino Olsen

## INTRODUCTION

Cellular growth and differentiation, in two-dimensional cell culture as well as in the three-dimensional space of the developing organism, require the presence of a structured environment with which the cells can interact. This extracellular matrix (ECM) is composed of polymeric networks of several types of macromolecules in which smaller molecules, ions, and water are bound. The major types of macromolecules are the fibrous proteins, such as collagens, elastin, fibrillins, fibronectin, and laminins, and the hydrophilic heteropolysaccharides, such as glycosaminoglycan chains in hyaluronan and proteoglycans. It is the combination of fibrous protein polymers and hydrated proteoglycans that gives extracellular matrices their resistance to tensile and compressive mechanical forces.

The macromolecular components of the polymeric assemblies of the ECM are in many cases secreted by cells as precursor molecules that are significantly modified (proteolytically processed, sulfated, oxidized, and cross-linked) before they assemble with other components into functional polymers (Fig. 5.1). The formation of matrix assemblies *in vivo* is therefore in most instances a unidirectional, irreversible process and the disassembly of the matrix is not a simple reversal of assembly, but involves multiple, highly regulated processes. One consequence of this is that polymers reconstituted in the laboratory with components extracted from extracellular matrices do not have all the properties they have when assembled by cells *in vivo*. The ECM *in vivo* is also modified by cells as they proliferate, differentiate, and migrate, and cells in turn continuously interact with the matrix and communicate with each other through it (Hay, 1991).

The ECM is therefore not an inert product of secretory activities, but influences cellular shape, fate, and metabolism in ways that are as important to tissue and organ structure and function as the effects of many cytoplasmic processes. This realization has led to a reassessment of the need for a detailed molecular understanding of the ECM. In the past the ECM was primarily appreciated for its challenge to biochemists interested in protein and complex carbohydrate structure; a detailed characterization of ECM constituents is now considered essential for understanding cell behavior in the context of tissue and organ development and function. Some of these constituents are obviously most important for their structural properties (collagens, elastin, and fibrillin), whereas others (matrix-bound fibroblast growth factors, transforming growth factor  $\beta$ , bone morphogenetic proteins) are signaling molecules. In a third category are multidomain molecules (fibronectin, laminin, thrombospondin, tenascin, syndecans, and other proteoglycans) that are both structural constituents and regulators of cell behavior (Fig. 5.1).

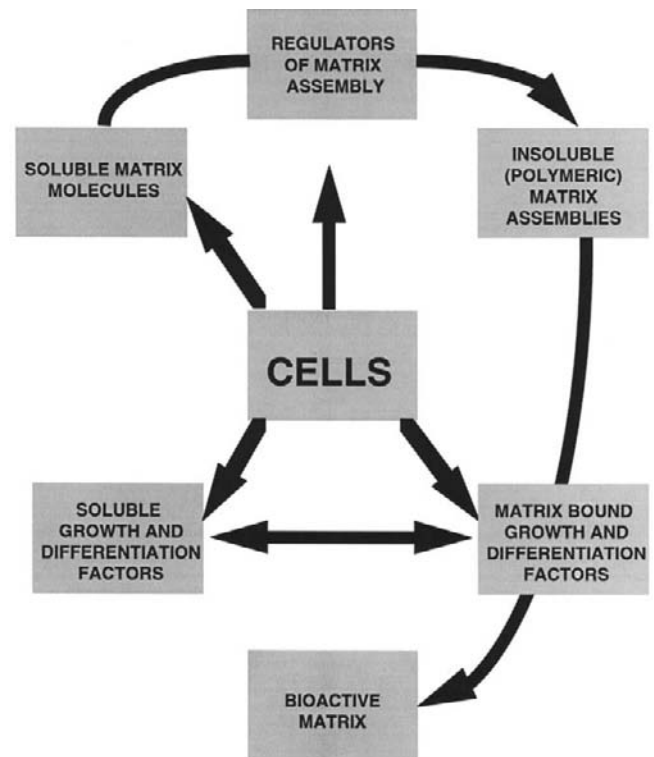

Fig. 5.1. Extracellular matrices are synthesized and assembled through many steps. Soluble matrix molecules are secreted by cells, modified, and assembled into polymeric complexes. These complexes serve as a scaffold for cells and as a reservoir for small molecules such as growth and differentiation factors.

### FIBRILLAR COLLAGENS: MAJOR SCAFFOLD PROTEINS IN THE ECM

Collagens constitute a large family of proteins that represent the major proteins (about 25%) in mammalian tissues. A subfamily of these proteins, the fibrillar collagens, contains rigid, rodlike molecules with three subunits,  $\alpha$  chains, folded into a right-handed collagen triple helix (Linsenmayer, 1991). Within a fibrillar collagen triple-helical domain, each  $\alpha$  chain consists of about 1000 amino acid residues and is coiled into an extended, left-handed polyproline II helix; three  $\alpha$  chains are in turn twisted into a right-handed superhelix (Fig. 5.2). The extended conformation of each  $\alpha$  chain does not allow the formation of intrachain hydrogen bonds, and the stability of the triple helix is instead due to interchain hydrogen bonds. Such interchain bonds can form only if every third residue of each  $\alpha$  chain does not have a side chain and is packed close to the triple-helical axis. Only glycine residues can therefore be accommodated in this position. This explains why the amino acid sequence of each  $\alpha$  chain in fibrillar collagens consists of about 300 Gly-X-Y tripeptide repeats, where X and Y can be any residue, but Y is frequently proline or hydroxyproline. It also provides an explanation for why mutations in collagens that lead to a replacement of triple-helical glycine residues with more bulky residues can cause severe abnormalities (Olsen, 1995).

Fibrillar collagen molecules are the major components of collagen fibrils. Their  $\alpha$  chains are synthesized as precursors, pro $\alpha$  chains, with large propeptide regions flanking the central triple-helical domain. The carboxyl propeptide (C-propeptide) is important for the assembly of trimeric molecules in the rough endoplasmic reticulum. Formation of C-propeptide trimers, stabilized by intra- and interchain disulfide bonds, is the first step in the intracellular assembly and folding of trimeric procollagen molecules (Olsen, 1991). The folding of the triple-helical domain proceeds in a zipperlike fashion from the carboxyl toward the amino end of procollagen molecules, with a rate that is limited by cis-trans isomerization of prolyl peptide bonds. Mutations in fibrillar procollagens that affect the structure and folding of the C-propeptide domain are therefore likely to affect the participation of the mutated chains in triple-helical assemblies. In contrast, mutations upstream of the C-propeptide, such as in-frame deletions or glycine substitutions in the triple-helical domains, exert a dominant negative effect, in that the mutated chains will participate in trimer assembly, but will interfere with subsequent folding of the triple-helical domain.

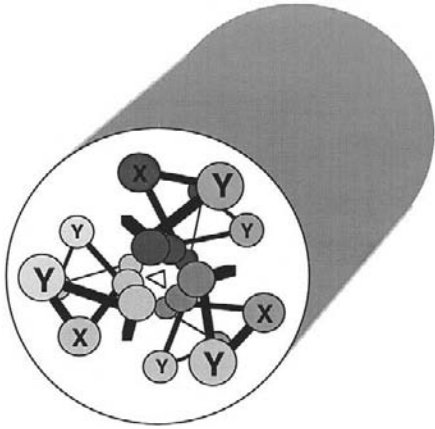

Fig. 5.2. Diagram showing a segment of a triple-helical collagen molecule. The triple helix is composed of three left-handed helices ( $\alpha$  chains) that are twisted into a right-handed superhelix. The sequence of each  $\alpha$  chain is a repeat of the tripeptide Gly-X-Y. The Gly residues are packed close to the triple-helical axis (indicated by a triangle). Only glycine (without a side chain) can be accommodated in this position. Although any residue can fit into the X and Y positions, Pro is frequently found in the Y position.

Fibrillar procollagen chains are the products of nine genes (Vuorio and de Crombrughe, 1990). The similarities of these genes suggest that they arose by multiple duplications from a single ancestral gene. Despite their similarities and the high degree of sequence identity of their protein products, they exhibit specificity in the interactions of their C-propeptides during trimeric assemblies. Thus within triple-helical procollagens a relatively small number of chain combinations is found; these combinations represent fibrillar collagen types (Jacenko *et al.*, 1991).

#### COLLAGENS V/XI—REGULATORS OF FIBRIL ASSEMBLY, SPATIAL ORGANIZATION, AND CELL DIFFERENTIATION

Some collagen types are heterotrimers (types I, V, and XI), whereas others are homotrimers (types II and III). Some chains participate in more than one type: for example, the  $\alpha 1(\text{II})$  chain forms the homotrimeric collagen II, but is also one of three different chains in collagen XI molecules. Between collagens V and XI there is extensive sharing of polypeptide subunits, and fibrillar collagen molecules previously described as belonging to either collagen V or XI are now referred to as belonging to the V/XI type. Thus, fibrillar procollagen molecules secreted by cells are members of a large group of homologous proteins. They all contain a C-propeptide that is completely removed by an endoproteinase after secretion, and their triple-helical rodlike domains polymerize in a staggered fashion into fibrillar arrays (Fig. 5.3). They differ, however, in the structure of their amino propeptide (N-propeptide) domains and in the extent to which this domain is proteolytically removed. For some collagen types, such as collagen I and II, the N-propeptide processing is complete in molecules within mature fibrils. For other types, such as collagens V/XI, this is not the case, in that a large portion of the N-propeptides in these molecules remains attached to the triple-helical domain (Fig. 5.3). It is believed that the incomplete processing of type V/XI molecules allows them to serve as regulators of fibril assembly (Linsenmayer *et al.*, 1993). Collagen fibrils are heterotypic, i.e., contain more than one collagen type, such that collagen I fibrils contain 5–10% collagen V and collagen II fibrils contain 5–10% collagen XI. The presence of N-propeptide domains on V/XI molecules represents a steric hindrance to addition of molecules at fibril surfaces. This heterotypic/steric hindrance model predicts that collagen fibril diameters in a tissue are determined by the ratio of the “minor” component (V/XI) to the “major” component (I or II). A high ratio results in thin fibrils; a low ratio results in thick fibrils. Direct support for this comes from studies of mutant and transgenic mice. For example, mice that are homozygous for a functional null mutation in  $\alpha 1(\text{XI})$  collagen and transgenic mice overexpressing collagen II have cartilage collagen fibrils that are abnormally thick (Garofalo *et al.*, 1993; Li *et al.*, 1995).

A characteristic feature of collagen fibrillar scaffolds is their precise three-dimensional patterns. These patterns follow mechanical stress lines and ensure a maximum of tensile strength with a minimum of material. Examples are the criss-crossing lamellae of collagen fibers in lamellar bone or in cornea, the arcades of collagen fibrils under the surface of articular cartilage, and the parallel fiber bundles in tendons and ligaments. Ultimately, cells are responsible for establishing these patterns, but the mechanisms they use probably involve specific molecules and interactions. The

Fig. 5.3. Diagram of a cartilage collagen fibril. Collagen II molecules are the major components. Molecules of collagen XI and IX are located on the surface. Collagen XI molecules, heterotrimers of three different  $\alpha$  chains, have amino-terminal domains that are thought to block sterically the addition of collagen II molecules at the fibril surface.

critical pattern-forming interactions are not known; however, the information for spatial organization is not contained within the different fibrillar collagen types, because the same kind of heterotypic fibril can be part of scaffolds with very different spatial organization. Transgenic mice with an alteration in the N-propeptide region of collagen V molecules show a disruption of the lamellar arrangement of fibrils in the cornea, suggesting a role for fibril surface domains in generating the spatial pattern (Andrikopoulos *et al.*, 1995). Finally, members of a unique subfamily of fibril-associated collagens with interrupted triple helices (FACIT) (Olsen *et al.*, 1995) are good candidates for molecules that allow tissue-specific fibril patterns to be generated by modulating the surface properties of fibrils.

The phenotypic consequences of mutations in fibrillar collagen genes indicate that the major function of these proteins is to provide elements of high tensile strength at the tissue level. Mutations in collagen V/XI genes also suggest that fibrillar collagen scaffolds are essential for normal cellular growth and differentiation. For example, a functional null mutation in  $\alpha 1(XI)$  collagen in cartilage causes a severe disproportionate dwarfism in mice and perinatal death of homozygotes (Li *et al.*, 1995). Histology of the mutant growth plates reveals a disorganized spatial distribution of cells and a defect in chondrocyte differentiation to hypertrophy. The explanation for this is likely to be related to the fact that in growth plates the proliferation and differentiation of chondrocytes is regulated by locally produced growth factors and cytokines. Cells that produce these factors must therefore be localized close to cells that express the appropriate receptors. The  $\alpha 1(XI)$  mutation may disrupt this relationship, because it results in a dramatic decrease in cohesive properties of the matrix and a loss of cellular organization. Transgenic mice with a mutation in  $\alpha 2(V)$  collagen have a large number of hair follicles of unusual localization in the hypodermis; this may also be related to a defect in the mechanical properties of the fibrillar collagen scaffold (Andrikopoulos *et al.*, 1995).

#### FACIT COLLAGENS—MODULATORS OF COLLAGEN FIBRIL SURFACE PROPERTIES

Molecules that are associated with collagen fibrils, contain two or more triple-helical domains, and share characteristic protein domains (modules) are classified as FACIT collagens (Olsen *et al.*, 1995; Shaw and Olsen, 1991). Of the five currently known members in the group (collagens IX, XII, XIV, XVI, and XIX) collagen IX is the best characterized both structurally and functionally. Collagen IX molecules are heterotrimers of three different gene products (van der Rest *et al.*, 1985). Each of the three  $\alpha$  chains contains three triple-helical domains separated and flanked by non-triple-helical sequence regions (Fig. 5.4). Between the amino-terminal and central triple-helical domains a flexible hinge gives the molecule a kinked structure with two arms. Type IX molecules are located on the surface of type II/XI-containing fibrils with the long arm parallel to the fibril surface and the short arm projecting into the perifibrillar space (Vaughan *et al.*, 1988) (Fig. 5.3).

Fig. 5.4. Diagrams of collagen IX and XII (long form) molecules. Collagen IX molecules contain the three chains  $\alpha 1(\text{IX})$ ,  $\alpha 2(\text{IX})$ , and  $\alpha 3(\text{IX})$ . Each chain contains three triple-helical domains (COL1, COL2, COL3), interrupted and flanked by non-triple-helical sequences. In cartilage, the  $\alpha 1(\text{IX})$  chain contains a large globular amino-terminal domain. The  $\alpha 2(\text{IX})$  chain serves as a proteoglycan core protein in that it contains a chondroitin sulfate (CS) side chain attached to the non-triple-helical region between the COL2 and COL3 domains. Collagen XII molecules are homotrimers of  $\alpha 1(\text{XII})$  chains. The three chains form two short triple-helical domains separated by a flexible hinge region. A central globule is composed of three globular domains that are homologous to the amino-terminal globular domain of  $\alpha 1(\text{IX})$  collagen chains. The amino-terminal regions of the three  $\alpha 1(\text{XII})$  chains contain multiple fibronectin type III repeats and von Willebrand factor A-like domains. These regions form three "fingers" that extend from the central globule. Through alternative splicing a portion of the fingers (white region in diagram) is spliced out in the short form of collagen XII. Hybrid molecules with both long and short fingers can be extracted from tissues.

It is believed that collagen IX may function as a bridging molecule between fibrils or between fibrils and other matrix constituents. Support from this comes from studies of transgenic mice and mutations in humans. Transgenic mice with a dominant negative mutation in the  $\alpha 1(\text{IX})$  chain (Nakata *et al.*, 1993), as well as mice that are homozygous for  $\alpha 1(\text{IX})$  null alleles (Faessler *et al.*, 1994), exhibit osteoarthritis in knee joints and mild chondrodysplasia. In humans, a splice site mutation leading to exon skipping and an in-frame deletion in the  $\alpha 2(\text{IX})$  collagen chain has been shown to cause a form of multiple epiphyseal dysplasia, an autosomal dominant disorder characterized by early-onset osteoarthritis in large joints associated with short stature and stubby fingers (Muragaki *et al.*, 1996).

Molecules of collagens XII and XIV are homotrimers of chains that are made up of several kinds of modules. Some modules are homologous to modules found in collagen IX, whereas others show homology to von Willebrand factor A domains and fibronectin type III repeats. Both types of molecules contain a central globule with three fingerlike extensions and a thin triple-helical tail attached (Fig. 5.4). For collagen XII, two forms that differ greatly in the lengths of the fingerlike extensions are generated by alternative splicing of RNA transcripts. Variations in the carboxyl regions also occur (Olsen *et al.*, 1995). Both collagens are found in connective tissues containing type I collagen fibrils, except mineralized bone matrix, and immunolabeling studies show a fibril-associated distribution. Type XIV collagen has been reported to bind to heparin sulfate and the small fibril-associated proteoglycan decorin (Brown *et al.*, 1993; Font *et al.*, 1993). This would suggest an indirect fibril association. A direct association cannot be ruled out, however, because collagen XII molecules form copolymers with collagen I even in the absence of proteoglycans. A functional interaction between fibrils and collagens XII and XIV is implied by studies showing that addition of the two collagens to type I collagen gels promote gel contraction mediated by fibroblasts (Nishiyama *et al.*, 1994). The effect is dose dependent and can be prevented by denaturation or addition of specific antisera. The association with fibrils of collagens XII and XIV may therefore modulate the frictional properties of fibril surfaces. The synthesis of different isoforms could be important in this context, because they could bind to fibrils with different affinities. Also, because the long form of collagen XII is a proteoglycan, whereas the short form is not, variations in the relative proportion of the two splice variants may serve to modulate the hydrophilic properties of interfibrillar matrix compartments. Finally, the discovery that the collagen I N-propeptide processing enzyme binds to collagen XIV and can be purified as part of a complex with antibodies against collagen XIV raises the possibility that the FACIT collagens provide binding sites for fibril-modifying extracellular matrix enzymes (Colige *et al.*, 1995).

## BASEMENT MEMBRANE COLLAGENS AND ASSOCIATED COLLAGEN MOLECULES

At epithelial (and endothelial)–stromal boundaries, basement membranes serve as specialized areas of ECM for cell attachment. By end-to-end and lateral interactions collagen IV molecules form a networklike scaffold for basement membranes (Yurchenco and O’Rear, 1994). Six different collagen IV genes exist in mammals, and their products interact to form at least three different types of heterotrimeric collagen IV molecules. These different isoforms show characteristic tissue specific expression patterns.

Within basement membranes the collagen IV networks are associated with a large number of noncollagenous molecules, such as various isoforms of laminin, nidogen, and the heparin sulfate proteoglycan perlecan. Additional collagens are also associated with basement membranes. These include the transmembrane collagen XVII in hemidesmosomes and collagen VII in anchoring fibrils. Collagens XVII and VII are important in regions of significant mechanical stress, such as skin, in that they anchor epithelial cells to the basement membrane (collagen XVII) and strap the basement membrane to the underlying stroma (collagen VII). In bullous pemphigoid, autoantibodies against collagen VII cause blisters that separate epidermis from the basement membrane (Liu *et al.*, 1994); dominant and recessive forms of epidermolysis bullosa can be caused by mutations in collagens VII and XVII (McGrath *et al.*, 1995; Uitto *et al.*, 1994). The physiological importance of collagen IV isoforms is highlighted by Alport syndrome (Tryggvason *et al.*, 1993). This disease, characterized by progressive hereditary nephritis associated with sensorineural hearing loss and ocular lesions, can be caused by mutations within  $\alpha 3(\text{IV})$  and  $\alpha 4(\text{IV})$  collagen genes (autosomal Alport syndrome) (Mochizuki *et al.*, 1994) or mutations in  $\alpha 5(\text{IV})$  collagen (X-linked Alport syndrome) (Barker *et al.*, 1990). In cases of large deletions, including both the  $\alpha 5(\text{IV})$  and the neighboring  $\alpha 6(\text{IV})$  collagen gene, renal disease is associated with inherited smooth muscle tumors (Zhou *et al.*, 1993).

Two additional basement membrane-associated collagens, collagen VIII and collagen XVIII, are of interest because of their function in vascular physiology and pathology. Collagen VIII is a short-chain, nonfibrillar collagen with significant homology to collagen X, a product of hypertrophic chondrocytes (Muragaki *et al.*, 1991; Yamaguchi *et al.*, 1989, 1991). Its expression appears to be up-regulated during cardiac morphogenesis (Iruela-Arispe and Sage, 1991), in human atherosclerotic lesions (MacBeath *et al.*, 1996), and following experimental lesions to the endothelium in large arteries (Bendeck *et al.*, 1996; Sibinga *et al.*, 1997). It has been suggested that collagen VIII may be important in mediating the migration of smooth muscle cells from the medial layer into the intima during neointimal thickening following endothelial cell injury.

Collagen XVIII, together with collagen XV, belongs to a distinct subfamily of collagens called multiplexins (so named because of their multiple triple-helix domains and interruptions) (Oh *et al.*, 1994; Rehn and Pihlajaniemi, 1994). Because of the alternative utilization of two promoters and alternative splicing, the *COL18A1* gene gives rise to three different transcripts that are translated into three protein variants. These are localized in various basement membranes, including those that separate vascular endothelial cells from the underlying intima in blood vessels (Halfter *et al.*, 1998; Muragaki *et al.*, 1995; Rehn and Pihlajaniemi, 1995; Saarela *et al.*, 1998). When collagen XVIII was initially cloned and sequenced it was noted that the sequence contained multiple consensus sequences for attachment of heparan sulfate side chains (Oh *et al.*, 1994). Subsequent studies have, in fact, confirmed that collagen XVIII forms the core protein of a basement membrane proteoglycan (Halfter *et al.*, 1998). Proteolytic processing of the carboxyl non-triple-helical domain of collagen XVIII in tissues leads to the release of heparin-binding molecules with anti-angiogenic activity (Sasaki *et al.*, 1998).

One of these fragments, named endostatin, represents the carboxyl-terminal 20-kDa portion of collagen XVIII chains (O’Reilly *et al.*, 1997). Recombinant preparations of endostatin have been shown to inhibit the proliferation and migration of vascular endothelial cells, inhibit the growth of tumors in mice and rats, and cause regression of tumors in mice (Boehm *et al.*, 1997; Dhana-bal *et al.*, 1999; O’Reilly *et al.*, 1997; Yamaguchi *et al.*, 1999). The limited data available suggest that these effects are mediated by inhibition of tumor-induced angiogenesis. The X-ray crystallographic structure of endostatin has been determined for both the mouse and human proteins (Ding *et al.*, 1998; Hohenester *et al.*, 1998). The compact structure consists of two  $\alpha$  helices and a large number of  $\beta$  strands, stabilized by two intramolecular disulfide bonds. A coordinated zinc atom

is part of the structure (Ding *et al.*, 1998) and on the surface a patch of arginyl residues forms a potential binding site for heparin (Hohenester *et al.*, 1998). Studies of mutant endostatins have shown that arginines within this patch are required for heparin binding (Yamaguchi *et al.*, 1999). Interestingly, heparin or zinc binding is not required for biological activity (Yamaguchi *et al.*, 1999).

## ELASTIC FIBERS AND MICROFIBRILS

Collagen molecules and their fibers evolved as structures of high tensile strength, equivalent to that of steel when compared on the basis of the same cross-sectional area, but three times better on a per unit weight basis. In contrast, elastic fibers, composed of molecules of elastin, provide tissues with elasticity so that they can recoil after transient stretch (Rosenbloom *et al.*, 1993). In organs such as the large arteries, skin, and lungs, elasticity is obviously crucial for normal functioning. Elastin fibers derive their impressive elastic properties, an extensibility that is about five times that of a rubber band with the same cross-sectional area, from the structure of elastin molecules. Each molecule is composed of alternating segments of hydrophobic and  $\alpha$ -helical Ala- and Lys-rich sequences. Oxidation of the lysine side chains by the enzyme lysyl oxidase leads to formation of reactive aldehydes and extensive covalent cross-links between neighboring molecules in the fiber. It is thought that the elasticity of the fiber is due to the tendency of the hydrophobic segments to adopt a random-coil configuration following stretch.

On the surface of elastic fibers one finds a cover of microfibrils, beaded filaments with molecules of fibrillin as their major components (Sakai and Keene, 1994). The fibrillins, products of genes on chromosomes 5 (Fib5) and 15 (Fib15) in humans, also form microfibrils that are found in almost all extracellular matrices in the absence of elastin. Fibrillin molecules are composed of multiple repeat domains, the most prominent being calcium-binding extracellular growth factor (EGF)-like repeats; similar repeats in latent transforming growth factor  $\beta$  (TGF- $\beta$ )-binding proteins suggest that the fibrillins belong to a superfamily of proteins (Kanzaki *et al.*, 1990). The physiological importance of fibrillin is highlighted by mutations causing the Marfan syndrome and congenital contractural arachnodactyly. The Marfan syndrome is caused by mutations in Fib15 and is characterized by dislocation of the eye lens due to weakening of the suspensory ligaments of the zonule, congestive heart failure, aortic aneurysms, and skeletal growth abnormalities resulting in a tall frame, scoliosis, chest deformities, arachnodactyly, and hypermobile joints (Ramirez *et al.*, 1993). In patients with congenital contractural arachnodactyly, mutations in Fib5 lead to similar skeletal abnormalities and severe flexion contractures, but no ophthalmic and cardiovascular manifestations (Viljoen, 1994). The tall stature and arachnodactyly seen in patients with the Marfan syndrome suggest that Fib15 is a negative regulator of longitudinal bone growth. Because fibrillin microfibrils are found in growth plate cartilage it is conceivable that they affect chondrocyte proliferation and/or maturation; the mechanisms, however, are unknown.

## FIBRONECTIN: A MULTIDOMAIN, MULTIFUNCTIONAL ADHESIVE ECM GLYCOPROTEIN

Several proteins in the extracellular matrix contain binding sites for structural macromolecules and for cells, thus contributing both to the structural organization of the ECM and its interaction with cells. The prototype of these adhesive glycoproteins is fibronectin, a disulfide-bonded dimer of 220- to 250-kDa subunits (Hynes, 1990). Each subunit is folded into five or six rodlike domains separated by flexible "joints." The domains are composed of three types of multiple repeats or modules, Fn1, Fn2, and Fn3. Fn1 modules are found in the fibrin-binding amino- and carboxyl-terminal regions of fibronectin and in the collagen (gelatin)-binding region (Fig. 5.5). Single copies of Fn1 modules are also found in tissue-type plasminogen activator (t-PA) and coagulation factor XII (Potts and Campbell, 1994).

Nuclear magnetic resonance studies of Fn1 modules demonstrate the presence of two layers of antiparallel  $\beta$  sheets (two strands in one layer and three strands in the other) held together by hydrophobic interactions. The structure is further stabilized by disulfide and salt bridges. Fn2 modules are found together with Fn1 modules in the collagen-binding region of fibronectin and in many other proteins. Their structure, two double-stranded antiparallel  $\beta$  sheets connected by loops, suggests that a ligand such as collagen may bind to this module through interactions of hydrophobic amino acid side chains with its hydrophobic surface. Fn3 modules are the major struc-

Fig. 5.5. Diagram of a fibronectin polypeptide chain. The polypeptide chain is composed of several repeats (Fn1, Fn2, and Fn3) and contains binding sites for several matrix molecules and cells. Two regions can bind heparin and fibrin and two regions are involved in cell binding as well. By alternative splicing, isoforms are generated that may or may not contain certain Fn3 domains (labeled ED-A and ED-B in the diagram). Additional splice variations in the second cell-binding domain (Cell II) generate other isoforms.

tural units in fibronectin and are found in a large number of other proteins as well. Some of these proteins (for example, the long splice variant of collagen XII) contain more Fn3 modules than does fibronectin. The structure of Fn3 is that of a sandwich of antiparallel  $\beta$  sheets (three strands in one layer and four strands in the other) with a hydrophobic core. The binding of fibronectin to some integrins involves the tripeptide sequence Arg-Gly-Asp in the tenth Fn3 module; these residues lie in an exposed loop between two of the strands in one of the  $\beta$  sheets (Potts and Campbell, 1994).

Fibronectin can assemble into a fibrous network in the ECM through interactions involving cell surface receptors and the amino-terminal region of fibronectin (Mosher *et al.*, 1991). A fibrin binding site is also contained in this region; a second site is in the carboxyl domain. The ability to bind to collagen ensures association between the fibronectin network and the scaffold of collagen fibrils. The collagen-binding domain of fibronectin can be isolated as a discrete proteolytic fragment, consisting of four Fn1 and two Fn2 modules. Binding sites for heparin and chondroitin sulfate further make fibronectin an important bridging molecule between collagens and other matrix molecules (Fig. 5.5).

Transcripts of the fibronectin gene are alternatively spliced in three regions in a cell- and developmental stage-dependent manner. As a result there are many different isoforms of fibronectin (Schwarzbauer, 1990). The main form produced by the liver and circulating in plasma lacks two of the Fn3 repeats found in cell- and matrix-associated fibronectin. One alternatively spliced domain is adjacent to the heparin-binding site, and this region binds to integrins  $\alpha 4\beta 1$  and  $\alpha 4\beta 7$  (Humphries, 1993). Thus, there is a mechanism for fine tuning of fibronectin structure and interaction properties. Not surprisingly, mice that are homozygous for fibronectin null alleles die early in embryogenesis with multiple defects (George *et al.*, 1993).

The biologically most important activity of fibronectin is its interaction with cells. The ability of fibronectin to serve as a substrate for cell adhesion, spreading, and migration is based on the activities of several modules. The Arg-Gly-Asp sequence in the tenth Fn3 module plays a key role in the interaction with the integrin receptor  $\alpha 5\beta 1$ , but synergistic interactions with other Fn3 modules are essential for high-affinity binding of cells to fibronectin (Aota *et al.*, 1991). Interactions with integrins containing the  $\beta 3$  subunit, such as  $\alpha IIb\beta 3$  on platelets, involve a peptide sequence within the ninth Fn3 (Bowditch *et al.*, 1994).

## LAMININS: LARGE, ADHESIVE BASEMENT MEMBRANE MOLECULES

Laminins are trimeric molecules of  $\alpha$ ,  $\beta$ , and  $\gamma$  chains with molecular masses of 140–400 kDa. With a large number of genetically distinct chains ( $\alpha 1$ ,  $\alpha 2$ ,  $\alpha 3$ ,  $\alpha 4$ ,  $\alpha 5$ ,  $\beta 1$ ,  $\beta 2$ ,  $\beta 3$ ,  $\gamma 1$ ,  $\gamma 2$ ), several laminin isoforms are now known (Fig. 5.6). Several forms have a cross-shaped structure as visualized by rotary shadowing electron microscopy; some forms contain Y-shaped molecules. The laminins are important components of basement membranes, where they provide interaction sites

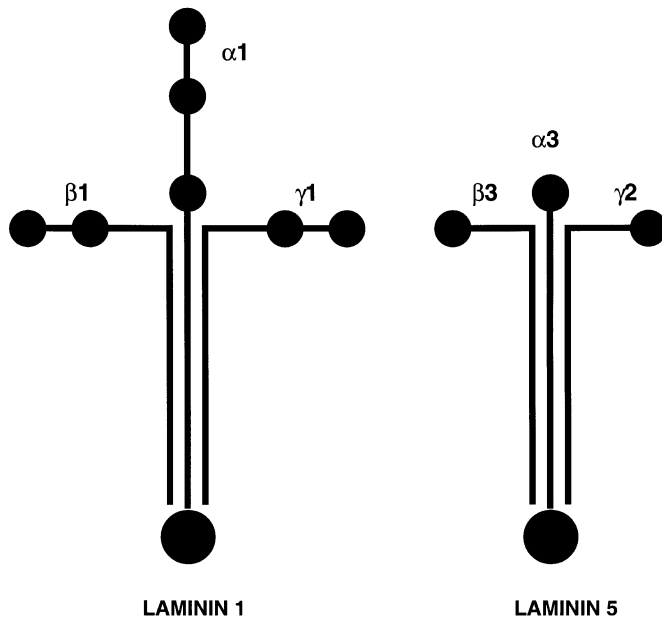

Fig. 5.6. Diagrams of two types of laminins. Laminin 1 has a cross-shaped structure, whereas laminin 5 is Y-shaped, due to a shorter  $\alpha$  chain.

for many other constituents, including cell surface receptors (Timpl, 1996; Timpl and Brown, 1994). The functional and structural mapping of these sites and the complete sequencing of many laminin chains have provided detailed insights into the organization of laminin molecules. Within the cross-shaped laminin 1 molecule, three similar short arms are formed by the N-terminal regions of the  $\alpha 1$ ,  $\beta 1$ , and  $\gamma 1$  chains, whereas a long arm is composed of the carboxyl regions of all three chains, folded into a coiled-coil structure. The three chains are connected at the center of the cross by three interchain disulfide bridges. The short arms contain multiple EGF-like repeats of about 60 amino acid residues, terminated and interrupted by globular domains. The long arm consists of heptad repeats covering about 600 residues in all three chains. The  $\alpha 1$  chain is about 1000 amino acid residues longer than the  $\beta 1$  and  $\gamma 1$  chains and forms five homologous globular repeats at the “base” of the cross; these globular repeats are similar to repeats found in the proteoglycan molecule perlecan (Iozzo, 1994). Calcium-dependent polymerization of laminin is based on interactions between the globular domains at the N termini and is thought to be important for the assembly and organization of basement membranes. Also of significance for the assembly of basement membranes is the high-affinity interaction with nidogen (Timpl and Brown, 1994). The binding site in laminin for nidogen is on the  $\gamma 1$  chain, close to the center of the cross. On nidogen, a rodlike molecule with three globular domains, the binding site for laminin is in the carboxyl globular domains; another globular domain binds to collagen IV. Thus, nidogen is a bridging molecule that connects the laminin and collagen IV networks, and is probably crucial for the assembly of normal basement membranes.

Laminin does not bind directly to collagen IV, but has binding sites for several other molecules besides nidogen. These are heparin, perlecan, and fibulin-1, which bind to the end of the long arm of the laminin cross. The biologically most significant interactions of laminin, however, involve a variety of cell surface receptors, both integrins and nonintegrin receptors. Several integrins are laminin receptors (Kramer 1994). They show distinct preferences for different laminins, and recognize binding sites on either the short or long arms of laminin molecules. In striated muscle cells laminin binds to the dystroglycan–dystrophin complex (Matsumura and Campbell, 1994). A disulfide-linked complex of laminins 5 and 6 is crucial for the firm attachment of keratinocytes to the basement membrane in skin by its interaction with  $\alpha 6\beta 4$  integrins in hemidesmosomes (Niessen *et al.*, 1994; Pulkkinen *et al.*, 1994; Sonnenberg *et al.*, 1991). Laminins with  $\beta 2$  chains appear to be important for guiding axons to neuromuscular junctions (Noakes *et al.*, 1995). Through interactions with the integrin  $\alpha v\beta 3$ , laminin is important for angiogenesis (Brooks *et al.*, 1994). Finally, laminin has important roles in induction and maintenance of differentiated cellular phenotypes and in control of cell proliferation (Grant *et al.*, 1989).

Fig. 5.7. Diagram of thrombospondin-1, showing the multidomain structure and the position of two cysteines that are involved in interchain disulfide (S—S) bonds within the trimeric molecules.

## MODULATORS OF CELL–MATRIX INTERACTIONS

Whereas proteins such as fibronectin and laminin are important for adhesion of cells to extracellular matrices, other ECM molecules appear to function as both positive and negative modulators of such adhesive interactions. Examples of such modulators are thrombospondin (Bornstein and Sage, 1994) and tenascin (Erickson, 1993).

Thrombospondins are a group of four homologous trimeric matrix proteins composed of several Ca<sup>2+</sup>-binding domains, EGF-like repeats, as well as other modules (Bornstein, 1992) (Fig. 5.7). Different members of the group show differences in cellular expression and functional properties. Thrombospondin-1, a component of  $\alpha$  granules in platelets, is released when platelets are activated and forms multimers that bind fibrin and fibrinogen in the hemostatic plug. The protein is also produced by many other cell types (fibroblasts, endothelial cells, and smooth muscle cells) and binds to a variety of matrix molecules, including fibrillar collagen, fibronectin, laminin, and heparan sulfate proteoglycan. It has a growth-promoting effect on fibroblasts and may destabilize cell–matrix interactions during wound healing and angiogenesis (Chiquet-Ehrismann, 1995). It therefore promotes cell proliferation and angiogenesis. The cellular receptor for thrombospondin appears to be a chondroitin sulfate proteoglycan; cellular contact sites with thrombospondin have a cytoskeletal organization that is different than the integrin-mediated focal adhesions seen with molecules such as fibronectin (Adams, 1995).

Cartilage oligomeric matrix protein (COMP) is a pentameric protein that is structurally related to thrombospondin and is thought to have evolved from the thrombospondin-3 and -4 branch of the family (Newton, 1994). COMP is a secretory product of chondrocytes and is localized in their territorial matrix in cartilage. Mutations in COMP have been shown to be the cause of pseudoachondroplasia and a form of multiple epiphyseal dysplasia (Briggs *et al.*, 1995).

The three members of the tenascin family (C, R, and X) are large hexameric (tenascin-C and -R) or trimeric (tenascin-X) proteins with subunits composed of multiple protein modules (Erickson, 1993). The modules include fibronectin type III repeats, EGF-like domains, and a carboxyl domain with homology to the carboxyl-terminal domains of  $\beta$ - and  $\gamma$ -fibrinogen chains. These modules form rodlike structures that interact with their amino-terminal domains within the oligomers. Although mice that are homozygous for tenascin-C null alleles have no obvious phenotype (Saga *et al.*, 1992), the multiple interactions and tissue expression patterns defined for tenascins strongly suggest that they have important functions. Tenascin-R is expressed in the central nervous system during development, tenascin-X is expressed particularly in muscle (smooth muscle as well as cardiac and skeletal), and tenascin-C is found in healing wounds, in a wide variety of tumors, and in the brain. In certain experimental conditions tenascin-C can be an adhesive molecule for cells; it can also, however, have antiadhesive effects (Chiquet-Ehrismann, 1995). The adhesive activity can be mediated by either cell surface proteoglycan or integrins, depending on cell type. Tenascin-C can bind heparin and this may be responsible for interactions with cell surface proteoglycans such as glypican (Erickson, 1993; Vaughan *et al.*, 1994). Tenascin-C can also block adhesion by covering up adhesive sites in other matrix molecules, such as fibronectin, sterically blocking their interactions with cells. Interactions with specific “antiadhesive” cell surface receptors are also conceivable. A cell surface molecule on neurons, contactin, binds to both tenascin-C and -R and may mediate their effects on neurons; tenascin can both stimulate and inhibit neurite outgrowth (Vaughan *et al.*, 1994).

## PROTEOGLYCAN: MULTIFUNCTIONAL ECM AND CELL SURFACE MOLECULES

A variety of proteoglycans play important roles in cellular growth and differentiation and in matrix structure. They range from the large hydrophilic space-filling complexes of aggrecan and versican with hyaluronan, to the cell surface syndecan receptors. In basement membranes the major heparan sulfate proteoglycan is perlecan (Iozzo, 1994; Timpl, 1994). With three heparan sulfate side chains attached to the amino-terminal region, its core protein is multimodular in structure, having borrowed structural motifs from a variety of other genes. These include a low-density lipoprotein (LDL) receptor-like module, regions with extensive homology to laminin chains, a long stretch of N-CAM-like IgG repeats, and a carboxyl-terminal region with three globular and four EGF-like repeats similar to a region of laminin. Alternative splicing can generate molecules of different lengths. Perlecan is present in a number of basement membranes, but is also found in the pericellular matrix of fibroblasts. In fact, fibroblasts, rather than epithelial cells, appear to be major producers of perlecan (for example, in skin). In liver, perlecan is expressed by sinusoidal endothelial cells and is localized in the perisinusoidal space. The precise functions of perlecan have not been defined, but mutations in the *unc-52* gene in *Caenorhabditis elegans*, encoding a short version of perlecan, cause disruptions of skeletal muscle (Rogalski *et al.*, 1993). This suggests that the molecule, as a component of skeletal muscle basement membranes, is important for assembly of myofilaments and their attachment to cell membranes. Binding of growth factors and cytokines to the heparan sulfate side chains also enables perlecan to serve as a storage vehicle for biologically active molecules such as basic fibroblast growth factor (bFGF).

Several small proteoglycans with homologous core proteins are found in a variety of tissues, where they interact with other matrix macromolecules and regulate their functions. They include decorin, biglycan, lumican, and fibromodulin (Hedbom and Heinegard, 1993; Hildebrand *et al.*, 1994; Kresse *et al.*, 1994). Decorin binds along collagen fibrils and may play a role in fibril assembly. It also has an effect on cell morphology, at least in culture, and may therefore modulate the binding of cells to matrix constituents such as collagen and fibronectin. Through binding of transforming growth factor  $\beta$  (TGF- $\beta$ ) isoforms, the small proteoglycans may help sequester growth factors within the ECM and thus regulate their activities (Hildebrand *et al.*, 1994).

A variety of proteoglycans also have important functions at cell surfaces. These include four members of the syndecan family, transmembrane molecules with highly conserved cytoplasmic domains, and glypican-related molecules that are linked to the cell surface via glycosyl phosphatidylinositol (David, 1993). Through their heparan sulfate side chains these molecules can bind growth factors, protease inhibitors, enzymes, and matrix macromolecules (Kim *et al.*, 1994). They are therefore thought to be important modulators of cell signalling pathways and cell-matrix contacts. Variations in their expression during embryogenesis support this idea (Bernfield *et al.*, 1993;

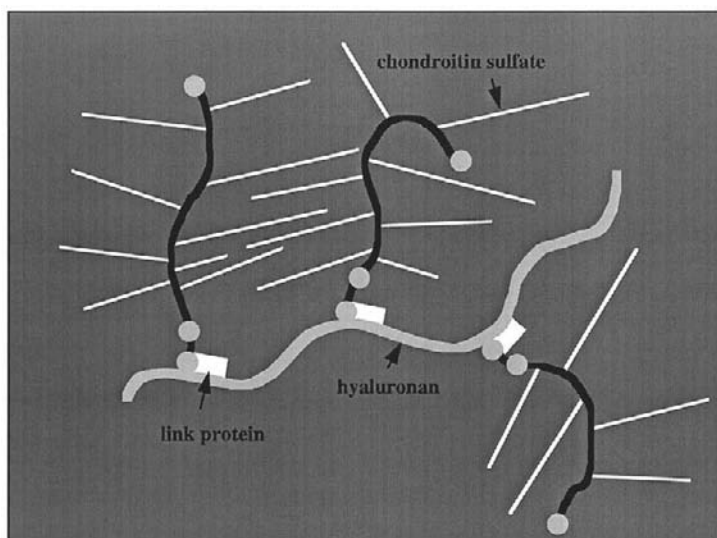

Fig. 5.8. Diagram of a portion of a large proteoglycan complex from cartilage. Monomers of aggrecan, composed of core proteins with glycosaminoglycan side chains (mostly chondroitin sulfate), are bound to hyaluronan. The binding is stabilized by link proteins. For clarity, only some of the glycosaminoglycan side chains are shown in the monomers.

Mali *et al.*, 1994). Syndecan, for example, is transiently lost from many epithelial cells during developmental shape changes, and is expressed in areas of mesenchymal condensations, in support of its function as a bridge between cells and the ECM.

Hyaluronan is an important component of most extracellular matrices (Laurent and Fraser, 1992). It serves as ligand for several proteins, including cartilage link protein and aggrecan and versican core proteins. In cartilage, based on such interactions, it is the backbone for the large proteoglycan complexes responsible for the compressive properties of cartilage (Morgelin *et al.*, 1994) (Fig. 5.8). It also is a ligand for cell surface receptors and regulates cell proliferation and migration (Sherman *et al.*, 1994). One receptor for hyaluronate is the transmembrane molecule CD44. By alternative splicing and variations in posttranslational modifications a family of CD44 proteins is generated (Lesley *et al.*, 1993). These show cell- and tissue-specific expression patterns and are thought to have distinct functional roles. The most widely expressed isoform is important for lymphocyte homing to various destinations. In lymphocyte homing, however, the ligand is not hyaluronate but other matrix molecules. In fact, CD44 is known to bind several molecules, including collagen, fibronectin, and mucosal addressin (Sherman *et al.*, 1994). Hyaluronate-mediated cell motility is based on the interaction of hyaluronan with a cell surface-associated protein called RHAMM (receptor for hyaluronate-mediated motility) (Turley, 1992). As a space-filling molecule and through its interaction with cell surface receptors, hyaluronan is important for several morphogenetic processes during development. It creates cell-free spaces through which cells (for example, neural crest cells) can migrate, and its degradation by hyaluronidase is probably important for processes of cellular condensation.

## SUMMARY

Components of the extracellular matrix affect cellular growth and differentiation in a variety of ways (Mooney *et al.*, 1992). The collagen scaffold allows cells to be organized in space and thus provides the basis for spatially defined, short-range interactions between cells. Adhesive glycoproteins bind to cell surface integrins and other receptors regulating cell attachment, cell shape, proliferation, and differentiation (Roskelley *et al.*, 1995).

Large proteoglycans can both create hydrophilic spaces for cellular migration and block cell movements. Cell surface-associated proteoglycans bind growth factors and serve as coreceptors for growth factor–receptor interactions (Mason, 1994).

# INDUCTIVE PHENOMENA

Matthias Hebrok and Douglas A. Melton

## INTRODUCTION

Vertebrate organogenesis is a multistep process involving regulated cell–cell interactions between mesenchymal and epithelial tissues. These interactions, or inductive phenomena, are orchestrated by signaling molecules that govern proliferation, migration, and morphogenesis. In general, two types of inductive phenomena have been distinguished: instructive induction and permissive induction (Slack, 1983). Instructive interactions are defined as those cases in which the responding tissue is naive and its path of differentiation depends on the signal(s) it receives. A permissive interaction takes place when the receiving tissue is already committed to one particular differentiation pathway but requires an additional signal to initiate the process. In this chapter both types of inductive phenomena are described, focusing on tissues and signaling pathways involved during formation of gut-derived organs, including lung and pancreas.

## EPITHELIAL TO MESENCHYMAL SIGNALING IN ENDODERM DEVELOPMENT

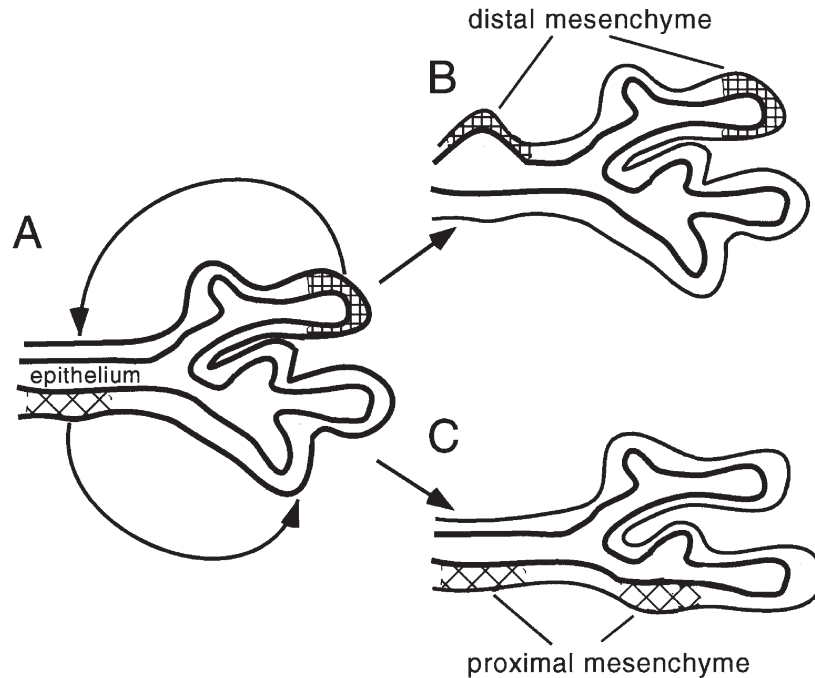

Organogenesis is initiated after gastrulation when the three germ layers, ectoderm, mesoderm, and endoderm, are formed and the basic body plan is established. During gastrulation endodermal and mesodermal precursors are separated from each other. The endodermal cells form an epithelial sheet that extends along the anteroposterior (AP) axis of the developing embryo, subsequently generating the embryonic gut. The first morphogenetic sign of gut tube formation is the folding of the anterior intestinal portal (AIP) at the rostral end, close to the forming head ectoderm. Soon after, the caudal intestinal portal (CIP) is generated at the posterior end of the embryo. Both structures grow and extend toward each other, eventually meeting and fusing in the middle, where they form the yolk stalk. Initially, the primitive gut is subdivided into fore-, mid-, and hindgut along the AP axis and from each of these regions specific organs will be generated during subsequent development, including thyroid, lungs, stomach, pancreas, liver, and small and large intestine (Gilbert, 1994; Roberts *et al.*, 1998).

Inductive interactions play an important role during morphogenesis and are involved in the formation of visceral organs of the gut. Several studies have described the cross-talk between the mesodermal and endodermal part of visceral organs (Golosow and Grobstein, 1962; Roberts *et al.*, 1998; Shannon, 1994; Shannon *et al.*, 1998; Wessells and Cohen, 1967). Here, the focus is on examples of epithelial–mesenchymal interactions leading to formation of mature organs along the AP axis of the gut. Inductive events during lung development are described and the role of signaling molecules involved in this process is discussed. Furthermore, we suggest that similar inductive mechanisms, mediated by the same signaling pathways, play important roles during several stages of pancreas development.

## LUNG DEVELOPMENT AND INSTRUCTIVE SIGNALING

The mammalian respiratory system consists of two separate structures, the trachea and the lung (Hogan and Yingling, 1998; Ten Have-Opbroek, 1981; Wessells, 1970). Both parts are de-

Fig. 6.1. Instructive signaling during lung development. (A) Proximal and distal lung mesenchymes possess different capacities to induce region-specific morphogenesis. Proximal mesenchyme governs tracheal development characterized by growth of a straight tube, whereas distal mesenchyme instructs endodermal budding to assure proper formation of lung morphology. (B) When transplanted to the proximal part of the trachea, distal mesenchyme induces budding in otherwise straight tracheal epithelium, whereas (C) proximal mesenchyme will inhibit bud formation in lung endoderm.

rived from ventral, anterior endoderm and need instructive signals from overlying mesenchyme for proper development (Hogan, 1999). Transplantation of bronchial mesenchyme to tracheal endoderm induces ectopic branching and expression of genes specific of bronchial endoderm, whereas tracheal mesenchyme suppresses epithelial budding when transplanted to distal lung epithelium (Alescio and Cassini, 1962; Shannon, 1994; Shannon *et al.*, 1998; Wessells, 1970) (Fig. 6.1). Specific genes and pathways have been identified that are involved in these processes (Bellusci *et al.*, 1997a,b). Fibroblast growth factors (FGFs) govern cell differentiation and regulation of organ formation (Martin, 1998); inhibition of FGF-signaling, through ectopic expression of a dominant negative FGF receptor, interferes with formation of secondary bronchi and terminal lung buds (Peters *et al.*, 1994). FGF-10, one of the ligands expressed in distal mesenchyme, has emerged as a factor involved in lung budding. In coculture experiments distal epithelium grows toward an FGF-10-soaked bead, reminiscent of the normal budding observed in developing/growing embryos (Bellusci *et al.*, 1997b; Park *et al.*, 1998). Furthermore, reports have described that FGF-10 also induces budding in tracheal endoderm stripped of mesenchyme, suggesting that FGF-10 might mimic the instructive effect of distal mesenchyme when grafted around tracheal endoderm (Hogan and Yingling, 1998; Park *et al.*, 1998). The importance of FGF signaling has been further confirmed in FGF-10 mutant mice, which are deficient in lung bud formation (Min *et al.*, 1998; Sekine *et al.*, 1999).

Another gene involved in lung development encodes Sonic hedgehog (Shh), a secreted glycoprotein and member of the hedgehog family of signaling molecules. Shh is expressed in foregut endoderm and is up-regulated in distal lung epithelium where branching occurs (Bellusci *et al.*, 1997a). Overexpression studies revealed that Shh acts as an endodermal signal that induces cell proliferation in lung mesenchyme (Bellusci *et al.*, 1997a). Loss-of-function experiments have shown that lung development is disturbed in Shh mutant embryos and in mice bearing mutations in downstream targets of hedgehog signaling, including zinc finger transcription factors Gli2 and Gli3 (Litingtung *et al.*, 1998; Motoyama *et al.*, 1998; Pepicelli *et al.*, 1998). Furthermore, Pepicelli *et al.* provided evidence that in lungs of Shh<sup>-/-</sup> mice, FGF-10 expression is up-regulated, suggesting that high levels of Shh in wild-type embryos might interfere with FGF-10 expression in adjacent mesenchyme. Additional evidence of FGF signaling in respiratory organs comes from studies on tracheal development in *Drosophila*, in which several genes, including FGF (branchless), FGF receptor (breathless), and an inhibitor of FGF signaling (sprouty), have been implicated in this process (reviewed in Hogan and Yingling, 1998).

These studies demonstrate that mesenchymal–epithelial interactions are required for lung development. They indicate that epithelial factors and mesenchymal genes influence cell proliferation and morphogenetic budding, and future work will further clarify how signaling pathways interact to instruct endodermal differentiation in respiratory organs.

## PERMISSIVE SIGNALING DURING PANCREAS DEVELOPMENT

For many decades pancreas development has been a preferred object to study general patterns of organ formation. During embryogenesis a dorsal evagination of the duodenum caudal to the stomach is the first morphological sign of pancreas formation. Shortly afterward ventral pancreas buds form adjacent to the liver diverticulum, and subsequently, when the stomach and duodenum move during gut rotation, the ventral bud comes into close contact with the dorsal lobe to fuse and form the mature pancreas (Fig. 6.2) (Slack, 1995).

Before molecular data were available researchers used the pancreas to investigate principles of epithelial–mesenchymal interactions. These experiments showed that mesenchyme is necessary to allow proper formation of mature exocrine structures (Golosow and Grobstein, 1962; Wessells and Cohen, 1967). More recently, numerous transcription factors have been implicated in different aspects of pancreas development (reviewed in Edlund, 1998). At least two of these, Pdx-1 and Isl-1 are involved in epithelial–mesenchymal signaling, and mutations in the genes for these factors interfere with morphogenesis and differentiation of both exocrine and endocrine lineages (Ahlgren *et al.*, 1996, 1997; Jonsson *et al.*, 1994; Offield *et al.*, 1996). Furthermore, mutations in some transcription factors, including Pdx-1, HNF-1 $\beta$ , HNF-1 $\alpha$ , and HNF-4 $\alpha$ , are linked to formation of maturity-onset diabetes (MODY) (Ahlgren *et al.*, 1998; Horikawa *et al.*, 1997; Stoffers *et al.*, 1997; Yamagata *et al.*, 1996a,b).

Classic experiments suggested that mesenchyme is required for outgrowth and differentiation of pancreas epithelium. At early developmental stages pancreas-specific mesenchyme is required to promote epithelial differentiation. Subsequently, however, heterologous mesenchyme (derived from salivary gland) or embryo extracts are sufficient for epithelial differentiation (Golosow and Grobstein, 1962; Rutter *et al.*, 1964; Wessells and Cohen, 1967), indicating that mesenchyme provides permissive signal(s) that promote induction of pancreas formation. Ronzio and Rutter (1973) did succeed in partially purifying a mesenchyme-specific factor with pancreas-inducing properties, although the identity of this signal(s) is, despite extensive efforts, still unknown. Homologous recombination studies in mice have revealed the influence of specific gene products on mesenchyme-to-epithelial signaling. Isl-1, a homeobox-containing transcription factor expressed in dorsal pancreas mesenchyme and all developing endocrine cells, is involved in two different aspects of pancreas formation. Inactivation studies have shown that Isl-1 promotes endoderm differentiation in a cell-autonomous fashion. Another function requires mesenchymal expression and is crucial for development of dorsal pancreas structures, but is not essential for formation of ventral pancreas tissue (Ahlgren *et al.*, 1997). In addition, a novel gene expressed in ventral but not dorsal pancreas mesenchyme has been identified, although the function of this gene is currently unknown (Hebrok *et al.*, 1999). These studies point to mesenchyme as an important tissue involved in pancreas organogenesis and growing evidence supports the hypothesis that morphogenesis is, at least in part, regulated by separate dorsal–ventral mechanisms.

Fig. 6.2. Stages of pancreas development. (A) During early stages of pancreas organogenesis notochord is in immediate contact with dorsal medial endoderm and signals the epithelium to initiate pancreas formation. (B) The first sign of pancreas morphogenesis is an epithelial thickening of the dorsal endoderm caudal to the stomach anlage. Ventral pancreas buds form shortly afterward, close to the liver diverticulum. (C) During the process of gut rotation the ventral lobe turns dorsally and comes into close contact with the dorsal lobe, eventually forming the mature pancreas.

Fig. 6.3. Initiation of pancreas marker genes in isolated endoderm by notochord and notochord factors. Isolated chick endoderm can be induced to express pancreas marker genes, including those for Pdx-1 and insulin, when cocultured either with notochord or with notochord factors such as activin  $\beta$ B and FGF-2 (A, C). Isolated endoderm cultured without any additional factors does not express pancreas markers.  $\beta$ -Tubulin is the positive control for polymerase chain reactions (PCR).

Although mesenchyme–epithelial interactions are indispensable at later stages of development, they cannot be responsible for initial organ induction. At the time when pancreas formation is first induced, prepancreatic dorsal epithelium is not surrounded by mesenchyme but instead contacts the notochord (Kim *et al.*, 1997; Pictet *et al.*, 1972; Wessells and Cohen, 1967), a mesodermally derived structure known to influence patterning of several tissues, including ventral floor plate and somites (Ebensperger *et al.*, 1995; Pourquie *et al.*, 1993). During subsequent development, notochord and endoderm are separated by the dorsal aorta, thereby limiting the time when endoderm can receive notochord signals. To understand if notochord directly influences expression of pancreas-specific genes, an *in vitro* system was exploited, wherein isolated endoderm is cultured alone or in combination with notochord. Results from these studies revealed that expression of pancreas marker genes, including those for insulin or Pdx-1, is initiated in endoderm–notochord cocultures. In contrast, in samples in which endoderm is cultured alone, these markers are not expressed (Hebrok *et al.*, 1998; Kim *et al.*, 1997) (Fig. 6.3). In addition, notochord fails to induce expression of pancreas markers when cultured with posterior endoderm outside the pancreas anlage. This suggests that endoderm is prepatterned at this early stage of development and that the notochord sends permissive rather than instructive signal(s) (Kim *et al.*, 1997).

The notochord is a source of several inducing molecules, including members of the transforming growth factor  $\beta$  (TGF- $\beta$ ) and fibroblast growth factor family. Using the established *in vitro* culture system it was possible to identify specific factors that mimic the notochord's effect on isolated endoderm, namely, inducing expression of insulin and Pdx-1. Two factors, activin  $\beta$ B (a TGF- $\beta$  molecule) and FGF-2, but not FGF-1 or FGF-7, can induce expression of pancreas marker genes in isolated endoderm (Fig. 6.3). Interestingly, activin increases expression of both markers in a direct concentration-dependent manner, whereas FGF-2 acts positively only at low concentrations, and higher concentrations of FGF-2 even interfere with activin-induced induction (Hebrok *et al.*, 1998). Therefore, at least two separate signaling pathways could be involved during early stages of pancreas development.

In addition to understanding which signals can induce pancreas development in prepatterned endoderm it is also crucial to determine which epithelial genes respond to these cues. Previous work had established that activin inhibits Shh expression in the node region of early chick embryos, thereby initiating asymmetric gene expression involved in left–right asymmetry (Levin *et al.*, 1997). Although Shh is expressed throughout gut epithelium along the AP axis, it is not detected in the pancreas anlage (Ahlgren *et al.*, 1997; Bitgood and McMahon, 1995; Hebrok *et al.*, 1998). During early stages Shh is found in ventral gut epithelium but is excluded from dorsal regions where endoderm contacts notochord, suggesting that notochord signals negatively regulate endodermal Shh expression. Subsequent experiments revealed that ectopic notochord interferes with Shh expression in gut epithelium and that activin  $\beta$ B can substitute for notochord. Furthermore, it was shown that Shh interferes with induction of pancreas markers, arguing that hedge-

Fig. 6.4. Molecular pathways regulating initiation of pancreas development. Notochord-derived factors, including activin and FGF, presumably act through their respective receptors to inhibit Shh expression in pancreas epithelium. This inhibition allows expression of transcription factors required for activation of endocrine hormones and exocrine enzymes.

hogs have to be excluded from pancreas epithelium to allow proper pancreas differentiation (Hebrok *et al.*, 1998) (Fig. 6.4). This hypothesis is promoted by the fact that ectopic expression of Shh later in development, under the control of the Pdx-1 promoter, leads to aberrant development of adjacent mesenchyme, adopting an intestine-like morphology (Apelqvist *et al.*, 1997).

Another function of firmly controlled hedgehog expression in stomach and duodenum might be to restrict the area of pancreas anlage and thereby regulate organ size. Evidence for this mechanism comes from experiments in which isolated chick stomach rudiments were cultured with cyclopamine, an inhibitor of hedgehog signaling (Cooper *et al.*, 1998). Examination of these rudiments revealed epithelial budding reminiscent of early pancreas buds as well as localized clusters of insulin- and glucagon-positive cells. Cyclopamine treatment of whole embryos results in formation of ectopic pancreas buds in regions expressing pancreatic transcription factor Pdx-1, concordant with the idea that pancreas formation requires epithelial expression of Pdx-1 (Kim and Melton, 1998). Cyclopamine, a steroid alkaloid teratogen similar to cholesterol, interferes with hedgehog signaling, presumably by interacting with its receptor ptc, and Shh mutant mice as well as cyclopamine-treated embryos develop holoprosencephaly (HPE) (Cooper *et al.*, 1998; Marigo *et al.*, 1996). Milder forms of HPE are observed in some patients suffering from Smith–Lemli–Opitz syndrome, a disorder that is linked to a defect in cholesterol synthesis. Interestingly, Smith–Lemli–Opitz syndrome is also characterized by appearance of nesidioblastosis and hypoglycemia (Lachman *et al.*, 1991; McKeever and Young, 1990), further suggesting that blocking of hedgehog signaling positively influences pancreas development and function.

#### SIGNALING DURING LATE STAGES OF PANCREAS DEVELOPMENT

A variety of factors, including TGF- $\beta$ , FGF, and hedgehog, are involved during induction and early stages of organogenesis. Experiments from several groups have shown that these pathways also accompany formation of more specialized organ structures. Inactivation studies of FGF ligands proved their involvement in differentiation of several organs, including development of ear, tail, lung, and adult muscle generation (Floss *et al.*, 1997; Mansour *et al.*, 1993; Min *et al.*, 1998; Sekine *et al.*, 1999). FGF ligands act through their receptors, a family of four different transmembrane molecules with cytoplasmic tyrosine kinase activity (FGFR1–4). These receptors are expressed in tissue-specific patterns and inactivation studies using a soluble dominant negative form (dnFGFR) provided evidence that FGF signaling is involved in a variety of multiorgan induction and patterning events. Overexpression of dnFGFR induces an embryonic lethal phenotype and disrupts formation of specific organs, including failure to develop kidneys and proper respiratory system as well as other malformations. In the gastrointestinal region stomach, liver, and pancreas are affected, the latter consisting of a decrease in exocrine acinar cells and an apparent lack of islets of Langerhans (Celli *et al.*, 1998). Furthermore, two of the FGF receptors, FGFR1 and FGFR4, are expressed in pancreas anlage during development, and FGF-2 stimulates proliferation of pancreatic epithelial cells (Le Bras *et al.*, 1998). However, mice bearing mutations in the FGF-2 gene are viable and phenotypically almost indistinguishable from wild-type littermates (Dono *et al.*, 1998; Ortega *et al.*, 1998; Zhou *et al.*, 1998), suggesting that pancreas formation and

function are not severely affected in these mutants. Alternatively, it is possible that the remaining members of the FGF family can substitute for FGF-2 function and that pancreas formation is regulated by the combination of these factors.

In addition to FGF signaling, TGF- $\beta$  molecules have been reported to affect pancreas function. Activin A is expressed during pancreas development (Furukawa *et al.*, 1995a) and is also detected in the mature organ in discrete islet cells including,  $\alpha$  and  $\delta$  cells (Ogawa *et al.*, 1993; Yasuda *et al.*, 1993). Insulin secretion can be stimulated by activin even in the absence of glucose (Furukawa *et al.*, 1995b), and branching morphogenesis of cultured pancreas rudiments is altered after activin treatment (Ritvos *et al.*, 1995). Accumulating evidence points to TGF- $\beta$  signaling being specifically involved in differentiation of endocrine versus exocrine cells. Follistatin, an inhibitor of TGF- $\beta$  signaling, is expressed in pancreatic mesenchyme. It has been shown to induce exocrine development and represses endocrine development in isolated pancreas rudiments (Miralles *et al.*, 1998). Furthermore, overexpression of a dominant negative activin receptor under the control of the insulin promoter in transgenic mice leads to smaller islet areas and reduced insulin content when compared to wild-type littermates. Insulin response in glucose-challenged animals is severely affected, suggesting that the remaining  $\beta$  cells are dysfunctional and do not respond properly (Yamaoka *et al.*, 1998). Interestingly, transgenic mice bearing a constitutively active activin receptor also have a reduced number of islets, indicating that the level of activin signaling may require tight regulation for proper pancreas function (Yamaoka *et al.*, 1998). In addition, formation of pancreas structures also depends on related TGF- $\beta$  factors. Ectopic expression of a dominant negative TGF- $\beta$  receptor results in increased proliferation of exocrine cells and severely perturbed acinar differentiation, indicating that TGF- $\beta$  negatively regulates exocrine development and is required for maintenance of the differentiated acinar phenotype (Böttinger *et al.*, 1997).

The identification of distinct signaling pathways has broadened our understanding of general principles of organogenesis. An exciting aspect of developmental biology will be to better understand the puzzle how the same small number of signaling pathways specifies formation of numerous distinct organs. In the case of FGF signaling, we know of at least 17 FGF ligands and four FGF receptors (Martin, 1998), suggesting that generation of individual organs requires signaling from specific combinations of ligands and receptors as well as interactions between different signaling pathways. A future aspect of research will be to investigate how gene products from different pathways, e.g., TGF- $\beta$ , FGF, and hedgehog molecules, interact during embryonic development and if combination of these factors can govern cell differentiation *in vitro*. These experiments will be useful to explore further the potential of signaling molecules in directing differentiation of undetermined cells, e.g., murine or human stem cells, toward highly specialized tissues and perhaps organs. Studies aimed to investigate the function of FGF, TGF- $\beta$ , and hedgehog pathways will not only help to understand how organs form during embryogenesis, but also provide knowledge about maintenance of mature organ function. Insights from these experiments might be used to restore functional properties in individuals suffering from diseases, for whom the capacity to perform specific tasks has been lost. In terms of pancreas research a long-term goal will be to help patients suffering from diabetes mellitus and pancreatic cancer.

# MORPHOGENESIS AND TISSUE ENGINEERING

A. H. Reddi

## INTRODUCTION

Morphogenesis is the developmental cascade of pattern formation, the establishment of body plan, and the architecture of mirror-image bilateral symmetry of musculoskeletal structures, culminating in the adult form. Tissue engineering is the emerging discipline of fabrication of spare parts for the human body, including the skeleton, to restore function of lost parts due to disease, cancer, and trauma. It is based on rational principles of molecular developmental biology and morphogenesis and is further governed by bioengineering. The three key ingredients for both morphogenesis and tissue engineering are inductive morphogenetic signals, responding stem cells, and the extracellular matrix scaffolding (Reddi, 1998). Advances in the molecular cell biology of morphogenesis will aid in the design principles and architecture for tissue engineering and regeneration.

Regeneration recapitulates embryonic development and morphogenesis. Among the many tissues in the human body, bone has considerable powers for regeneration, and is therefore a prototype model for tissue engineering. Implantation of demineralized bone matrix into subcutaneous sites results in local bone induction. The sequential cascade of bone morphogenesis mimics sequential skeletal morphogenesis in limbs, permitting the isolation of bone morphogens. Although it is traditional to study morphogenetic signals in embryos, bone morphogenetic proteins (BMPs), the primordial inductive signals for bone, can be isolated from demineralized bone matrix from adults. BMPs initiate, promote, and maintain chondrogenesis and osteogenesis and have actions beyond bone. The recently identified cartilage-derived morphogenetic proteins are critical for cartilage and joint morphogenesis. The symbiosis of bone inductive and conductive strategies is critical for tissue engineering, and is in turn governed by the context and biomechanics. The context is the microenvironment, consisting of extracellular matrix scaffolding, and can be duplicated by biomimetic biomaterials such as collagens, hydroxyapatite, proteoglycans, and cell adhesion proteins, including fibronectins and laminins. The rule of architecture for tissue engineering is an imitation and adoption of the laws of developmental biology and morphogenesis, and thus may be universal for all tissues, including bones and joints and associated musculoskeletal tissues.

The traditional approach for identification and isolation of morphogens is to first identify genes in fly and frog embryos by genetic approaches, differential displays, subtractive hybridization, and expression cloning. This information is subsequently extended to mice and humans. An alternative approach is to isolate morphogens from bone with known regenerative potential, and this is described in this chapter. The expanding knowledge of bone and cartilage morphogenesis affords a prototype paradigm for all of tissue engineering. The principles gleaned from bone morphogenesis and BMPs can be extended to tissue engineering of a variety of other tissues.

## BONE MORPHOGENETIC PROTEINS

Bone grafts have been used by orthopedic surgeons for nearly a century to aid in recalcitrant bone repair. Decalcified bone implants have been used to treat patients with osteomyelitis (Senn, 1889). It was hypothesized that bone might contain a substance (osteogenin) that initiates bone growth (Lacroix, 1945). Urist made the key discovery that demineralized, lyophilized segments of rabbit bone, when implanted intramuscularly, induced new bone formation (Urist, 1965). Bone induction is a sequential multistep cascade (Reddi and Huggins, 1972; Reddi and Anderson, 1976; Reddi, 1981). The key steps in this cascade are chemotaxis, mitosis, and differentiation. Chemotaxis is the directed migration of cells in response to a chemical gradient of signals released from the insoluble demineralized bone matrix. The demineralized bone matrix is predominantly composed of type I insoluble collagen, which binds plasma fibronectin (Weiss and Reddi, 1980). Fibronectin has domains for binding to collagen, fibrin, and heparin. The responding mesenchymal cells attach to the collagenous matrix and proliferate, as indicated by [ $^3\text{H}$ ]thymidine autoradiography and incorporation into acid-precipitable DNA on day 3 (Rath and Reddi, 1979). Chondroblast differentiation is evident on day 5; chondrocytes are evident on days 7–8 and cartilage hypertrophy, on day 9 (Fig. 7.1). There is concomitant vascular invasion on day 9, with osteoblast differentiation. On days 10–12 alkaline phosphatase is maximal. Hematopoietic marrow differentiates in the ossicle and is maximal by day 21. This entire sequential bone development cascade is reminiscent of bone and cartilage morphogenesis in the limb bud (Reddi, 1981, 1984). Hence, it has immense implications for isolation of inductive signals initiating cartilage and bone morphogenesis, and a systematic investigation of the chemical components responsible for bone induction has been undertaken.

The foregoing account of the demineralized bone matrix-induced bone morphogenesis in extraskeletal sites demonstrates the potential role of morphogens in the extracellular matrix. Therefore we have embarked on a systematic study of the isolation of putative morphogenetic proteins. A prerequisite for any quest for novel morphogens is the establishment of a battery of bioassays for new bone formation. A panel of *in vitro* assays was established for chemotaxis, mitogenesis, and chondrogenesis, and an *in vivo* bioassay, for bone formation. Although the *in vitro* assays are ex-

Fig. 7.1. Developmental sequence of the extracellular matrix-induced cartilage, bone, and marrow formation. Changes in  $^{35}\text{SO}_4$  incorporation into proteoglycans and  $^{45}\text{Ca}$  incorporation into mineral phase indicate peaks of cartilage and bone formation, respectively. The  $^{59}\text{Fe}$  incorporation into heme is an index of erythropoiesis, as plotted from the data of Reddi and Anderson (1976). The values for alkaline phosphatase indicate early stages of bone formation (Reddi and Huggins, 1972). The transitions in collagen types I–IV (summarized at the top of the figure) are based on immunofluorescent localization. From Reddi (1981), with permission.

Fig. 7.2. Dissociative extraction by chaotropic reagents such as 4 M guanidine and reconstitution of osteoinductive activity with insoluble collagenous matrix. The results demonstrate a collaboration between a soluble signal and insoluble extracellular matrix. DBM, Demineralized bone matrix.

pedient, we monitored routinely a labor-intensive *in vivo* bioassay, because it was the only bona fide bone induction assay.

A major stumbling block in the approach was that the demineralized bone matrix is insoluble and in the solid state. In view of this, dissociative extractants such as 4 M guanidine HCl or 8 M urea or 1% sodium dodecyl sulfate (SDS) at pH 7.4 were used (Sampath and Reddi, 1981) to solubilize proteins. Approximately 3% of the proteins were solubilized from demineralized bone matrix, and the remaining residue was mainly insoluble type I bone collagen. The extract alone or the residue alone was incapable of new bone induction. However, addition of the extract to the residue (insoluble collagen) and then implantation in a subcutaneous site resulted in bone induction (Fig. 7.2). Thus, it would appear that for optimal osteogenic activity there was a collaboration between soluble signal in the extract and insoluble substratum (Sampath and Reddi, 1981). This bioassay was a useful advance in the final purification of bone morphogenetic proteins and led to determination of limited tryptic peptide sequences, leading to the eventual cloning of BMPs (Wozney *et al.*, 1988; Luyten *et al.*, 1989; Ozkaynak *et al.*, 1990).

In order to scale up the procedure up, a switch was made to bovine bone. Demineralized bovine bone was not osteoinductive in rats and the results were variable. However, when the guanidine extracts of demineralized bovine bone were fractionated on an S-200 molecular sieve column, fractions less than 50 kDa were consistently osteogenic when bioassayed after reconstitution with allogeneic insoluble collagen (Sampath and Reddi, 1983; Reddi, 1994). Thus, protein fractions inducing bone were not species specific and appear to be homologous in several mammals. It is likely that larger molecular mass fractions and/or the insoluble xenogeneic (bovine and human) collagens were inhibitory or immunogenic. Initial estimates revealed 1  $\mu$ g of active osteogenic fraction in 1 kg of bone. Hence, over 1 ton of bovine bone was processed to yield optimal amounts for amino acid sequence determination. The amino acid sequences revealed homology to transforming growth factor  $\beta_1$  (TGF- $\beta_1$ ) (Reddi, 1994). The important work of Wozney and colleagues (1988) resulted in cloned BMP2, BMP2B (now called BMP4), and BMP3 (also called osteogenin). Osteogenic protein-1 and -2 (OP-1 and OP-2) were cloned by Ozkaynak and colleagues (1990). There are nearly 10 members of the BMP family (Table 7.1). The other members of the extended TGF- $\beta$ /BMP superfamily include inhibins and activins (implicated in follicle-stimulating hormone release from the pituitary), Müllerian duct inhibitory substance (MIS), growth/differentiation factors (GDFs), nodal, and the product of *lefty*, a gene implicated in establishing right/left asymmetry (Reddi, 1997; Cunningham *et al.*, 1995). BMPs are also involved in embryonic induction (Lemaire and Gurdon, 1994; Melton, 1991; Lyons *et al.*, 1995; Reddi, 1997).

BMPs are dimeric molecules and their conformation is critical for biological actions. Reduc-

BMP11	GDF-11	?

tion of the single interchain disulfide bond results in the loss of biological activity. The mature monomer molecule consists of about 120 amino acids, with seven canonical cysteine residues. There are three intrachain disulfides per monomer and one interchain disulfide bond in the dimer. In the critical core of the BMP monomer is the cysteine knot. The crystal structure of BMP7 has been determined (Griffith *et al.*, 1996). It is a good possibility in the near future that the crystal structure of the BMP–receptor complex and receptor contact domains will be determined.

### CARTILAGE-DERIVED MORPHOGENETIC PROTEINS

Morphogenesis of the cartilage is the key rate-limiting step in the dynamics of bone development. Cartilage is the initial model for the architecture of bones. Bone can form either directly from mesenchyme, as in intramembranous bone formation, or with an intervening cartilage stage, as in endochondral bone development (Reddi, 1981). All BMPs induce, first, the cascade of chondrogenesis, and therefore in this sense are cartilage morphogenetic proteins. The hypertrophic chondrocytes in the epiphyseal growth plate mineralize and serve as a template for appositional bone morphogenesis. Cartilage morphogenesis is critical for both bone and joint morphogenesis. The two lineages of cartilage are clear-cut. The first, at the ends of bones, forms articulating articular cartilage. The second, the growth plate chondrocytes, hypertrophy and synthesize cartilage matrix destined to calcify prior to replacement by bone; these are the “organizer” centers of longitudinal and circumferential growth of cartilage, setting into motion the orderly program of endochondral bone formation. The phenotypic stability of the articular (permanent) cartilage is at the crux of the osteoarthritis problem. The “maintenance” factors for articular chondrocytes include TGF- $\beta$  isoforms and the BMP isoforms (Luyten *et al.*, 1992).

An *in vivo* chondrogenic bioassay with soluble purified proteins and insoluble collagen scored for chondrogenesis. A concurrent reverse transcription–polymerase chain reaction (RT–PCR) approach was taken with degenerate oligonucleotide primers. Two novel genes for cartilage-derived morphogenetic proteins (CDMPs) 1 and 2 were identified and cloned (Chang *et al.*, 1994). CDMPs 1 and 2 are also called GDF-5 and GDF-6 (Storm *et al.*, 1994). CDMPs are related to

**Table 7.2. Cartilage-derived morphogenetic proteins**

<b>CDMP</b>	<b>Other names</b>	<b>Function</b>
CDMP 1	GDF-5	Cartilage condensation
CDMP 2	GDF-6	Cartilage formation, hypertrophy
CDMP 3	GDF-7	Tendon/ligament morphogenesis

bone morphogenetic proteins (Table 7.2). CDMPs are critical for cartilage and joint morphogenesis (Tsumaki *et al.*, 1999), and stimulate proteoglycan synthesis in cartilage. CDMP 3 (also known as GDF-7) initiates tendon and ligament morphogenesis.

## PLEIOTROPY AND THRESHOLDS

Morphogenesis is a sequential multistep cascade. BMPs regulate each of the key steps: chemotaxis, mitosis, and differentiation of cartilage and bone, and initiate chondrogenesis in the limb (Chen *et al.*, 1991; Duboule, 1994). The apical ectodermal ridge is the source of BMPs in the developing limb bud. The intricate dynamic, reciprocal interactions between the ectodermally derived epithelium and mesoderm-derived mesenchyme set into motion the train of events culminating in the pattern of phalanges, radius, ulna, and humerus.

The chemotaxis of human monocytes is optimal at femtomolar concentration (Cunningham *et al.*, 1992). The apparent affinity was 100–200 pM. The mitogenic response was optimal at the 100-pM range. The initiation of differentiation was in the nanomolar range in solution. However, caution should be exercised, because BMPs may be sequestered by extracellular matrix components and the local concentration may be higher when BMPs are bound on the extracellular matrix. Thus BMPs are pleiotropic regulators that act in concentration-dependent thresholds.

## BMPs BIND TO EXTRACELLULAR MATRIX

It is well known that extracellular matrix components play a critical role in morphogenesis. The structural macromolecules and their supramolecular assembly in the matrix do not explain their role in epithelial–mesenchymal interaction and morphogenesis. This riddle can now be explained by the binding of bone morphogenetic proteins to heparan sulfate, heparin, and type IV collagen (Paralkar *et al.*, 1990, 1991, 1992) of the basement membranes. In fact, this might explain in part the necessity for angiogenesis prior to osteogenesis during development. In addition, the actions of activin in the development of the frog, in terms of dorsal mesoderm induction, are modified to neutralization by follistatin (Hemmati-Brivanlou *et al.*, 1994). Similarly, proteins Chordin and Noggin from the Spemann organizer induce neutralization by binding and inactivation of BMP4 (Fig. 7.2). Thus neural induction is likely to be a default pathway when BMP4 is nonfunctional (Piccolo *et al.*, 1996; Zimmerman *et al.*, 1996). An emerging principle in development and morphogenesis is that binding proteins can terminate a dominant morphogen's action and initiate a default pathway. Finally, the binding of a soluble morphogen to the extracellular matrix (ECM) converts it into an insoluble matrix-bound morphogen that acts locally in the solid state (Paralkar *et al.*, 1990).

## BMPs: ACTIONS BEYOND BONE

Although BMPs were first isolated and cloned from bone, subsequent work with gene knockouts has revealed a plethora of actions beyond bone. Targeted disruption of BMP2 in mice caused embryonic lethality. Heart development was abnormal, indicating a need for BMP2 (Zhang and Bradley, 1996). BMP4 knockouts exhibit no mesoderm induction, and gastrulation is impaired (Winnier *et al.*, 1996). Transgenic overexpression of BMPs under the control of keratin 10 promoter leads to psoriasis, and targeted deletion of BMP7 revealed the critical role of this molecule in kidney and eye development (Luo *et al.*, 1995; Dudley *et al.*, 1995; Vukicevic *et al.*, 1996). Thus the BMPs are really true morphogens for tissues as disparate as skin, heart, kidney, and eye. In view of this, perhaps they may also be thought of as body morphogenetic proteins.

## BMP RECEPTORS

Recombinant human BMP4 and BMP7 bind to BMP receptor IA (BMPR-IA) and BMP receptor IB (BMPR-IB) (ten Dijke *et al.*, 1994). CDMP 1 also binds to both of the type I BMP receptors. There is a collaboration between type I and type II BMP receptors (Nishitoh *et al.*, 1996). The type I receptor serine/threonine kinase phosphorylates a signal-transducing protein substrate called Smad 1 or 5 (Chen *et al.*, 1996). Smad is a term derived from fusion of the *Drosophila* Mad gene and the *Caenorhabditis elegans* (nematode) Sma gene. Smads 1 and 5 signal in partnership with a common co-Smad, Smad 4 (Fig. 7.3). The transcription of BMP-response genes are initiated by Smad 1/Smad 4 heterodimers. Smads are trimeric molecules as determined by X-ray crystallography. The phosphorylation of Smads 1 and 5 by type I BMP receptor kinase is inhibited by

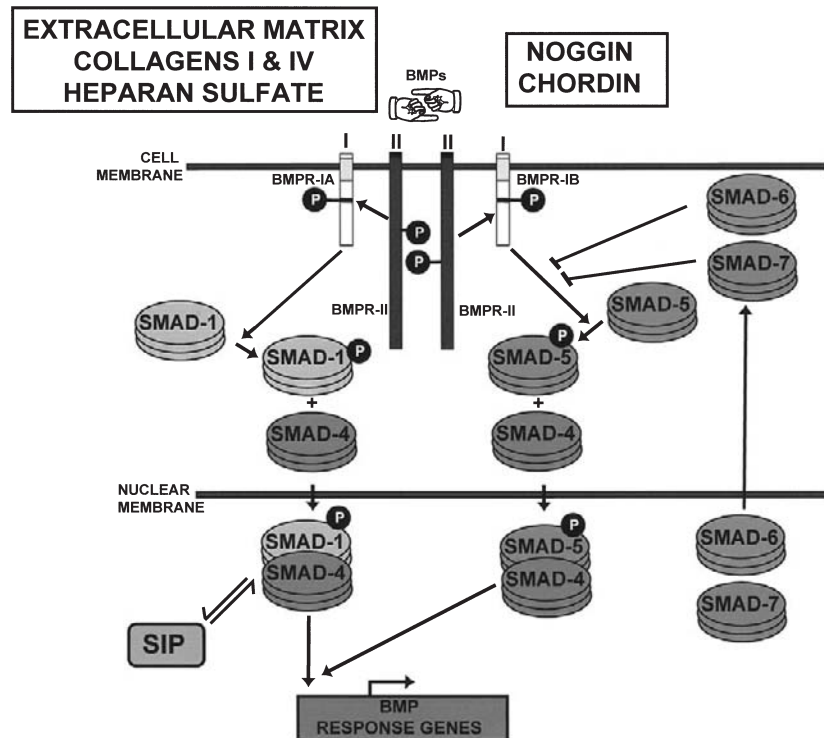

Fig. 7.3. BMP receptors and signaling cascades. BMPs are dimeric ligands with a cysteine knot in each monomer fold. Each monomer has two  $\beta$  sheets (represented as two pointing fingers). In the functional dimer the fingers are oriented in opposite directions. BMPs interact with both type I and type II BMP receptors. The exact stoichiometry of the receptor complex is currently being elucidated. BMPR-II phosphorylates the GS domain of BMPR-I. The collaboration between type I and type II receptors forms the signal-transducing complex. BMP type I receptor kinase complex phosphorylates the trimeric signaling substrate Smad 1 or 5. This phosphorylation is inhibited and modulated by inhibitory Smads 6 and 7. Phosphorylated Smad 1 or 5 interacts with Smad 4 (functional partner) and enters the nucleus to activate the transcriptional machinery for early BMP-response genes. A novel Smad-interacting protein (SIP) may interact and modulate the binding of heteromeric Smad 1/Smad 4 complexes to the DNA.

inhibitory Smads 6 and 7 (Hayashi *et al.*, 1997). Smad-interacting protein (SIP) may interact with Smad 1 and modulate BMP-response gene expression (Heldin *et al.*, 1997; Reddi, 1997). The downstream targets of BMP signaling are likely to be homeobox genes, the cardinal genes for morphogenesis and transcription. BMPs in turn may be regulated by members of the hedgehog family of genes such as Sonic and Indian hedgehog (Johnson and Tabin, 1997), their cognate receptors patched and smoothed, and downstream transcription factors such as Gli1, Gli2, and Gli3. The actions of BMPs can be terminated by specific BMP-binding proteins such as noggin (Zimmerman *et al.*, 1996). Recall that BMPs also bind to extracellular matrix components.

## RESPONDING STEM CELLS

It is well known that the embryonic mesoderm-derived mesenchymal cells are progenitors for bone, cartilage, tendons, ligaments, and muscle. However, certain stem cells in adult bone marrow, muscle, and fascia can form bone and cartilage. The identification of stem cells readily sourced from bone marrow may lead to banks of stem cells for cell therapy, and perhaps to gene therapy with appropriate "homing" characteristics to bone marrow and hence to the skeleton. The pioneering work of Friedenstein *et al.* (1968) and Owen and Friedenstein (1988) identified bone marrow stromal stem cells. These stromal cells are distinct from the hematopoietic stem cell lineage. The bone marrow stromal stem cells consist of inducible and determined osteoprogenitors committed to osteogenesis. Determined osteogenic precursor cells have the propensity to form bone calls without any external cues or signals. On the other hand, inducible osteogenic precursors re-

quire an inductive signal such as BMP or demineralized bone matrix. It is noteworthy that operational distinctions between stromal stem cells and hematopoietic stem cells are getting increasingly blurry! The stromal stem cells of Friedenstein and Owen are also called mesenchymal stem cells (Caplan, 1991), with potential to form bone, cartilage, adipocytes, and myoblasts in response to cues from environmental and/or intrinsic factors. There is considerable hope and anticipation that these bone marrow stromal cells may be excellent vehicles for cell and gene therapy (Prockop, 1997).

From a practical standpoint, these stromal stem cells can be obtained by bone marrow biopsies and expanded rapidly for use in cell therapy after pretreatment with bone morphogenetic proteins. The potential uses for both cell and gene therapy are very promising. There are continuous improvements in the viral vectors and the efficiency of gene therapy (Bank, 1996; Mulligan, 1993). For example it is possible to use BMP genes transfected in stromal stem cells to target to the bone marrow.

## MORPHOGENS AND GENE THERAPY

Advances in the understanding of morphogens are ripe for application to techniques of regional gene therapy for orthopedic tissue engineering. The availability of cloned genes for BMPs and CDMs and the requisite platform technology of gene therapy may have immediate applications. Whereas protein therapy provides an immediate bolus of morphogen, gene therapy achieves a sustained, prolonged secretion of gene products. Furthermore, improvements in regulated gene expression allow the turning on and off of gene expression. The progress in vectors for delivering genes also bodes well. The use of adenoviruses, adeno-associated viruses, and retroviruses is poised for applications in bone and joint repair (Bank, 1996; Kozarsky and Wilson, 1993; Morsy *et al.*, 1993; Mulligan, 1993). Although gene therapy has some advantages for orthopedic tissue engineering, an optimal delivery system for protein and gene therapy is needed, especially in replacement of large segmented defects and in fibrous nonunions and malunions.

## BIOMIMETIC BIOMATERIALS

In addition to inductive signals (BMPs) and responding stem cells (stromal cells), scaffolding (the microenvironment/extracellular matrix) is necessary for optimal tissue engineering. The natural scaffolding biomaterials in the composite tissue of bones and joints are collagens, proteoglycans, cell adhesion glycoproteins such as fibronectin, and the mineral phase. The mineral phase in bone is predominantly hydroxyapatite. In its native state, the associated citrate, fluoride, carbonate, and trace elements constitute the physiological hydroxyapatite. The high capacity to bind protein makes hydroxyapatite a natural delivery system. Comparison of insoluble collagen, hydroxyapatite, tricalcium phosphate, glass beads, and poly(methyl methacrylate) as carriers reveal collagen also to be an optimal delivery system for BMPs (Ma *et al.*, 1990). It is well known that collagen is an ideal delivery system for growth factors in soft and hard tissue wound repair (McPherson, 1992).

During the course of systematic work on hydroxyapatite of two pore sizes (200 or 500  $\mu\text{m}$ ) in two geometric forms (beads or disks), an unexpected observation was made: the geometry of the delivery system is critical for optimal bone induction. The disks were consistently osteoinductive with BMPs in rats, but the beads were inactive (Ripamonti *et al.*, 1992). The chemical composition of the two hydroxyapatite configurations was identical. In certain species the hydroxyapatite alone appears to be osteoinductive (Ripamonti, 1996); in subhuman primates hydroxyapatite alone induces bone, albeit at a much slower rate than with BMPs. One interpretation is that osteoinductive endogenous BMPs in circulation progressively bind to implanted disks of hydroxyapatite. When an optimal threshold concentration of native BMPs is achieved, the hydroxyapatite becomes osteoinductive. Strictly speaking, most hydroxyapatite substrata are ideal osteoconductive materials. This example in certain species also serves to illustrate how an osteoconductive biomimetic biomaterial may progressively function as an osteoinductive substance by binding to endogenous BMPs. Thus, there is a physiological–physicochemical continuum between the hydroxyapatite alone and the progressive composite with endogenous BMPs. Recognition of this experimental nuance will save unnecessary arguments among biomaterials scientists about the osteoinductive action of a conductive substratum such as hydroxyapatite.

Complete regeneration of baboon craniotomy defect was accomplished by recombinant human osteogenic protein (rhOP-1; human BMP7) (Ripamonti *et al.*, 1996). Recombinant BMP2

was delivered by poly( $\alpha$ -hydroxy acid) carrier for calvarial regeneration (Hollinger *et al.*, 1996). A copolymer of poly(lactic acid) and poly(glycolic acid) in a nonunion model in rabbit ulna yielded impressive results (Bostrom *et al.*, 1996).

Sterilization is an important problem in the clinical application of biomimetic biomaterials with BMPs and/or other morphogens. Although gas (ethylene oxide) is used, one always should be concerned about reactive free radicals. Using allogeneic demineralized bone matrix with endogenous native BMPs, as long as low temperature (4°C or less) is maintained, the samples tolerate up to 5–7 MRads of irradiation (Weintraub and Reddi, 1988; Weintraub *et al.*, 1990). The standard dose acceptable to the Food and Drug Administration is 2.5 MRads. This information is important to the biotechnology companies preparing to market recombinant BMP-based osteogenic devices, and perhaps also to the tissue bank industry with an interest in bone grafts (Damien and Parson, 1991). Various forms of freeze-dried and demineralized allogeneic bone may be used in the interim as satisfactory carriers for BMPs. The moral of this experiment is, it is not the irradiation dose but the ambient sample temperature during irradiation that is absolutely critical.

## TISSUE ENGINEERING OF BONES AND JOINTS

Unlike bone, with its considerable prowess for repair and even regeneration, cartilage is recalcitrant. But why? In part it may be due to the relative avascularity of hyaline cartilage to the high concentration of protease inhibitors, and perhaps even to growth inhibitors. The wound debridement phase is not optimal to prepare the cartilage wound bed for the optimal *milieu interieur* for repair. Although cartilage has been successfully engineered to predetermined shapes (Kim *et al.*, 1994), true repair of the tissue continues to be a real challenge in part due to hierarchical organization and geometry (Mow *et al.*, 1992). However, considerable excitement in the field has been generated by a group of Swedish workers in Göteborg, using autologous culture-expanded human chondrocytes (Brittberg *et al.*, 1994). A continuous challenge in chondrocyte cell therapy is progressive dedifferentiation and loss of characteristic cartilage phenotype. The redifferentiation and maintenance of the chondrocytes for cell therapy can be aided by BMPs, CDMPs, TGF- $\beta$  isoforms, and insulin-like growth factors (IGFs). It is also possible to repair cartilage using muscle-derived mesenchymal stem cells (Grande *et al.*, 1995). The problems posed by cartilage proteoglycans in preventing cell immigration for repair were investigated by chondroitinase ABC and trypsin pretreatment in partial-thickness defects (Hunziker and Rosenberg, 1996), with and without TGF- $\beta$ . Pretreatment with chondroitinase ABC followed by TGF- $\beta$  revealed a contiguous layer of cells from the synovial membrane, hinting at the potential source of “repair” cells from synovium. Multiple avenues exploring cartilage morphogens, cell therapy with chondrocytes, stem cells from marrow and muscle, and a biomaterial scaffolding may lead to an optimal tissue-engineered articular cartilage.

## FUTURE CHALLENGES

It is inevitable that, during aging, humans will confront impaired locomotion due to wear and tear in bones and joints. The need to repair and possibly completely regenerate the musculoskeletal system and other vital organs thus arises. Can we create spare parts for the human body? There is much reason for optimism that tissue engineering can help prolong physical comfort and function. We are living in an extraordinary time in the development of biology, medicine, surgery, and computational and related technology. The confluence of advances in molecular developmental biology and attendant advances in understanding the biology of inductive signals for morphogenesis, stem cells, biomimetic biomaterials, and the extracellular matrix promise future breakthroughs.

The symbiosis of biotechnology and biomaterials has set the stage for systematic advances in tissue engineering (Reddi, 1994; Langer and Vacanti, 1993; Hubbell, 1995). Advances in enabling platform technology include molecular imprinting (Mosbach and Ramstrom, 1996); in principle, specific recognition and catalytic sites are imprinted using templates. The applications include biosensors, catalytic applications to antibodies, and receptor recognition sites. For example, the cell-binding RGD site in fibronectin (Ruoslahti and Pierschbacher, 1987) or the YIGSR domain in laminin can be imprinted in complementary sites (Vukicevic *et al.*, 1990).

The rapidly advancing frontiers in morphogenesis with BMPs, hedgehogs, homeobox genes,

and a veritable cornucopia of general and specific transcription factors, coactivators, and repressors will lead to cocrystallization of ligand–receptor complexes, to protein–DNA complexes, and to other macromolecular interactions. This will in turn lead to peptidomimetic agonists for large proteins, as exemplified by erythropoietin (Livnah *et al.*, 1996). To such advances one can add new developments in self-assembly of millimeter-scale structures floating at the interface of perfluorodecalin and water and interacting by capillary forces controlled by the pattern of wettability (Bowden *et al.*, 1997). The final self-assembly is due to minimization of free energy in the interface. These truly incredible advances will lead to man-made materials that mimic the extracellular matrix in tissues. Superimpose on such chemical progress a biological platform in a bone and joint mold. Let us imagine the head of the femur and a mold that is fabricated with computer-assisted design and manufacture. The mold faithfully reproduces the structural features and may be imprinted with morphogens, inductive signals, and cell adhesion sites. This assembly can be loaded with stem cells and BMPs and other inductive signals, with a nutrient medium optimized for the optimal number of cell cycles, and a predictable exit into differentiation phase, reproducing a totally new bone femoral head. In fact, such a biological approach with vascularized muscle flap and BMPs has yielded new bone with a defined shape and has demonstrated the proof of the principle for further development and validation (Khouri *et al.*, 1991). We indeed are entering a brave new world of prefabricated biological spare parts for the human body based on sound architectural rules of inductive signals for morphogenesis, responding stem cells with lineage control, and growth factors immobilized on a template of biomimetic biomaterial based on the extracellular matrix. Like life, such technologies evolve with continuous refinements to benefit mankind by reducing the agony of human pain and suffering.

# CELL DETERMINATION AND DIFFERENTIATION

Leon W. Browder

## INTRODUCTION

Much of the current research in developmental biology is focused on identifying the genes that are involved in determinative events in development and unraveling the roles of the proteins they encode. Our understanding of the molecular events leading to functional cells and tissues remains quite sketchy. A major advance that has facilitated progress in understanding cell determination and cell differentiation came with the discovery of a family of myogenic regulatory factors (MRFs), which are a group of transcription factors involved in switching on the muscle cell lineage during development. This mechanism serves as a model for the gene control of cell determination and differentiation.

The initial member of the MRF family to be discovered was MyoD, which was identified by its ability to convert cultured fibroblasts into skeletal myoblasts (Davis *et al.*, 1987). The other members of this family in vertebrates are Myf-5, myogenin, and MRF4. Each of these factors has the potential to turn tissue culture cells into myoblasts, which can—in turn—fuse with one another and differentiate into muscle. Myoblast fusion occurs when growth factors become limiting and the myoblasts cease dividing (Olson, 1992).

The genes encoding the MRFs are thought to be master regulatory genes, whose expression initiates a cascade of events that lead to muscle cell differentiation. They are expressed in a hierarchical fashion during myogenesis. Myf-5 and MyoD are expressed in cultured myoblasts (and continue to be expressed after muscle differentiation), whereas myogenin is expressed after myoblast fusion (Braun *et al.*, 1989; Wright *et al.*, 1989; Edmondson and Olson, 1989). Myogenin is an essential intermediate, as shown by the prevention of myoblast differentiation by inhibition of myogenin expression with antisense oligonucleotides (Florini and Ewton, 1990). Myogenin functions as a transcriptional switch to activate all of the genes that are necessary for muscle differentiation. The fourth factor, MRF4, is expressed only after muscle differentiation.

The MRFs share a region of homology with two functionally significant domains: the helix–loop–helix (HLH) domain, which facilitates dimerization, and the basic region, which contains positively charged amino acids that mediate binding to DNA. These characteristics define a large family of proteins that function primarily as transcriptional activators. These are the basic helix–loop–helix (bHLH) proteins.

MRF proteins bind to a sequence in the promoter of target genes called the E box. E boxes contain the sequence CANNTG (where N is any nucleotide). The genes encoding the MRFs contain an E box, which suggests that these proteins may regulate their own and one another's transcription. Each MRF presumably owes its functional distinctiveness to unique sequences outside the bHLH domain. MRFs form functional entities that bind to DNA by dimerizing with a member of the ubiquitously expressed E protein family. This family includes E12, E47, ITF1, and ITF2 (Murre *et al.*, 1989; Davis *et al.*, 1990; Henthorn *et al.*, 1990; Lassar *et al.*, 1991). The most preva-

lent heterodimers in myotube extracts contain E12, but any of the E proteins can pair with the MRFs to form a functional heterodimer.

Dimerization is essential for bHLH protein function, but their specificity of binding to DNA is due to the basic region. Modifications to this region can either abolish the DNA-binding capability of MyoD or eliminate its ability to activate transcription of muscle-specific genes (Davis *et al.*, 1990). Thus, these mutants act like dominant negative inhibitors of wild-type MyoD by competing with it for binding to its partners and inhibiting its activity.

Nature has produced its own dominant negative inhibitor of the MRFs. The interactions of MRFs with DNA can be prevented by members of a family of HLH factors called "Id," which stands for "inhibitor of DNA binding." Id proteins lack a basic region. When they bind to MRF proteins, they impede their ability to bind to DNA and activate transcription of target genes (Benezra *et al.*, 1990). Likewise, their ability to bind E proteins sequesters these proteins and makes them unavailable for forming functional heterodimers with the MRF factors (Langlands *et al.*, 1997). The inhibitory role of Id proteins is supported by the following observations:

1. Id proteins are expressed in proliferating myoblasts in culture, but disappear when the myoblasts differentiate to form myotubes.
2. Overexpression of Id protein in cultured myoblasts prevents their differentiation into myotubes (Jen *et al.*, 1992).
3. Id transcripts are detected during the gastrula stage of mouse development before MRF transcripts first appear and are down-regulated before MRFs are expressed (Wang *et al.*, 1992).

Although the roles of Id in embryonic development are uncertain, the evidence suggests that Id is initially an inhibitor of myogenesis and its down-regulation then permits myogenesis to proceed by allowing MRFs to bind DNA of target genes.

Another negative regulator of MRF activity is Mist1, which is a novel bHLH protein that accumulates in myogenic precursors and decreases as myoblasts differentiate to form myotubes. Mist1 lacks a transcription activation domain and instead has a repressor region that inhibits transcription. Like Id, Mist1 can act as a dominant negative inhibitor of myogenesis by forming inactive heterodimers with MyoD and E proteins. It can also form homodimers that bind to MRF-specific target sites in DNA (Lemerrier *et al.*, 1998).

Lu *et al.* (1999) have identified yet another dominant negative inhibitor of myogenesis. This protein (MyoR, for myogenic repressor) is expressed in undifferentiated myoblasts in the skeletal muscle lineage. MyoR forms heterodimers with E proteins. The MyoR/E protein heterodimers bind MRF-specific target sites in DNA and block transcription of skeletal muscle-specific genes. Myogenesis can proceed only when these proteins are depleted and replaced with MRFs, which bind to E proteins and activate skeletal muscle-specific gene transcription (Lu *et al.*, 1999). This observation begs the question: How is MyoR regulated?

## ROLES OF MRFs DURING EMBRYOGENESIS

### WHAT DO THE MRFs DO IN THE EMBRYO?

The roles of MRFs in promoting myogenesis in cultured cells suggest that they may also play a role in muscle development during embryogenesis. Most of the skeletal muscle in vertebrates originates from progenitor cells in the somites. The somites are transient metameric condensations of paraxial mesoderm that later become compartmentalized into the dermamyotome dorsally and the sclerotome ventrally. The dermamyotome subdivides into the dermatome and the myotome. The medial myotomal cells form the axial musculature, and the lateral cells migrate to the limbs to form limb muscle.

A role for MRFs in promoting muscle development during embryonic development is suggested by the location and timing of their expression during development. The MRFs are expressed sequentially in the somites, although details vary somewhat between species. In mice, the first MRF protein detected in trunk somites is Myf-5, which is first seen in medial somite cells (Smith *et al.*, 1994). Myogenin expression follows shortly after the initial detection of Myf-5, and MRF4 is expressed next. MyoD appearance is delayed and is first localized to the lateral portion of the somites.

Initially, Myf-5 and MyoD expression is mutually exclusive and later overlaps (Smith *et al.*, 1994). Myf-5 and MyoD may be involved in establishing the two distinct subdomains of muscle: back musculature and limb musculature (Ordahl and Le Douarin, 1992).

### MRF KNOCKOUTS

Data from knockout mice have helped to clarify the roles of the MRF genes in murine development. The initial null mouse experiments produced quite unexpected results. Mice that were null for either *Myf-5* or *MyoD* genes developed normal amounts of skeletal muscle (Rudnicki *et al.*, 1992; Braun *et al.*, 1992). In homozygous *MyoD* null newborn mice, there was a three- to four-fold increase in *Myf-5* expression. This gene is normally down-regulated after day 14 of development. The prolongation and enhancement of *Myf-5* expression suggests that *Myf-5* compensates for the lack of *MyoD*. In the *Myf-5* knockouts, muscle development was delayed until *MyoD* was expressed, and then it proceeded (Braun *et al.*, 1994). These observations suggest that *MyoD* and *Myf-5* may be redundant. If so, does elimination of expression of both genes eliminate muscle development? The *Myf-5* and *MyoD* mutant mice were interbred; the progeny that lacked both of these early-acting MRF genes were unable to initiate myogenesis, produced no myogenin, and were devoid of skeletal muscle (Rudnicki *et al.*, 1993).

If myogenin is an essential intermediate in myogenesis, one would predict that myoblasts would form in myogenin knockout mice, but that skeletal muscle formation would be impaired. This is what has been observed (Hasty *et al.*, 1993; Nabeshima *et al.*, 1993). The myogenin knockout mice had deficient accumulation of transcripts for a number of muscle-specific proteins, including muscle creatine kinase, myosin heavy chain, the  $\alpha$  and  $\gamma$  subunits of the acetylcholine receptor, and MRF4. However, normal amounts of *MyoD* transcripts were present, consistent with the hypothesis that *MyoD* acts upstream of myogenin (Hasty *et al.*, 1993). During development of myogenin knockouts, somites developed normally and compartmentalized into myotome, dermatome, and sclerotome (Venuti *et al.*, 1995). They even initiated muscle mass differentiation, but myosin heavy chain protein expression was attenuated, and myofibers were diffuse. The disparity between mutant and wild-type embryos widened as development continued (Venuti *et al.*, 1995). Large numbers of myoblasts that failed to differentiate appeared to be present in the mutant muscle masses.

The picture of myogenesis that is emerging is that *MyoD* and *Myf-5* are partially redundant and initiate myogenesis in the myoblasts. They control expression of myogenin, which—in turn—controls muscle cell differentiation via activation of muscle-specific genes and may control expression of MRF4. MRF4 may be responsible for events in fully differentiated myofibers, possibly by maintaining the differentiated state (Rudnicki *et al.*, 1993). According to this scheme, transcription of distinct sets of genes at each stage is regulated by MRFs, which also control the expression of the MRF that initiates the next stage of differentiation (Venuti *et al.*, 1995).

## INITIATION OF SKELETAL MUSCLE DEVELOPMENT

### WHAT REGULATES THE MRF GENES?

Transplantation experiments with chick embryos have shown that the somites are induced by the neural tube/notochord complex to form muscle (Rong *et al.*, 1992; Buffinger and Stockdale, 1994). Additional evidence has indicated that dermomyotome-specific gene expression is induced by the protein Wnts, produced by the dorsal neural tube, and signals (possibly Wnts) from the surface ectoderm, whereas the protein Sonic hedgehog (Shh) from the notochord and ventral floorplate of the neural tube induces sclerotome-specific gene expression (Yun and Wold, 1966; Ikeya and Takada, 1998). The activation of the myogenic pathway in the myotome is a consequence of combinatorial effects of the Wnts and Shh. Yet another signal from the lateral mesoderm (possibly bone morphogenetic protein; BMP) inhibits myogenesis (Porqu   *et al.*, 1996). The function of BMP is, in turn, antagonized by Noggin, which is expressed within the dorsomedial lip of the dermomyotome (Reshef *et al.*, 1998). These various signals diffuse from their respective origins. The overlapping signals produce discrete concentrations and activities of the secreted factors in the somite and specify cellular identities in the different somite domains (Rawls and Olson, 1997).

How do these signals cause the expression of the MRF genes, which promote myogenesis? The paired-type homeobox gene *Pax-3* has now been shown to be a key trigger of the myogenic

program by virtue of its activation of *MyoD* expression (Rawls and Olson, 1997). Pax-3 is expressed in the paraxial mesoderm before the somites form. When the somites become epithelial, Pax-3 is expressed in the dorsal halves of the somites. Later, it becomes restricted to the ventrolateral domain and in the myogenic precursors that migrate from the dermomyotome into the limb buds (Goulding *et al.*, 1991; Jostes *et al.*, 1991).

The *plotch* mutant in the mouse lacks a functional *Pax-3* gene. Consequently, this mutant provides a means to establish whether there is any functional relationship between Pax-3 and myogenesis (Bober *et al.*, 1994; Tremblay *et al.*, 1998). The lack of limb muscles in these mice indicates that Pax-3 expression is necessary to initiate the formation of the migratory limb myogenic precursors that are derived from the ventrolateral edge of the dermomyotome. However, most of the muscles of the back and body wall are unaffected. Thus, this lineage is not dependent on Pax-3.

Evidence on the role of Pax-3 in trunk myogenesis has come from examinations of mice that were deficient for both *Pax-3* and *Myf-5* (Tajbakhsh *et al.*, 1997). These mice developed virtually no muscle and did not express MyoD in the trunk region. It has previously been shown that *Myf-5* mutant mice will express MyoD and form muscle in the trunk. Therefore, this result suggests that there are two pathways for formation of muscle in the trunk: a pathway in which Pax-3 regulates expression of MyoD and a Pax-3-independent pathway in which MyoD is regulated by Myf-5. So, is Pax-3 sufficient to initiate the myogenic program? Maroto *et al.* (1997) have shown that viral-mediated ectopic expression of *Pax-3* in chick embryonic tissue activated *MyoD* expression and myogenesis.

The experiments of Tajbakhsh *et al.* (1997) and Maroto *et al.* (1997) have shown that the “master regulator” MyoD is a component of a continuum of regulatory events. The ultimate aim of contemporary developmental biology is to describe all of the components of that continuum and understand how a fertilized egg can produce muscle (and all other differentiated cell types) in the right place and at the right time.

Myogenic determination and differentiation occur through a complex cascade of events involving a network of factors whose interaction ensures that muscle forms in the right places and at the right times to facilitate orderly embryonic development. Muscle development serves as a valuable paradigm for the understanding of determination and differentiation of other tissue types, whose development likely involves networks of factors similar to those described here.

# MECHANICAL AND CHEMICAL DETERMINANTS OF TISSUE DEVELOPMENT

Donald E. Ingber

## INTRODUCTION

Tissue engineering has as its main goal the fabrication of artificial tissues for use as replacements for damaged body structures. Great advances have been made in terms of the developing prosthetic devices that can repair structural defects (e.g., vascular grafts) and even replace complex mechanical behaviors (e.g., artificial joints). However, the challenge for the future is to develop tissue substitutes that restore the normal biochemical functions of living tissues, in addition to their structural features. To accomplish this feat, we must first establish precise design criteria for tissue fabrication. These design features should be based on a thorough understanding of the molecular and cellular basis of tissue regulation. They also must take into account the important role that insoluble extracellular matrix (ECM) scaffolds and mechanical stresses play in tissue formation and repair. This latter point is critical because the spatial organization of cells and the mechanical constraints imposed on them as they grow appear actively to regulate tissue development (Ingber, 1991; 1997).

The goal of this brief chapter is not to provide an extensive review of literature in the field of ECM biology or tissue development. Rather, the intent is to summarize the known functions of the ECM and describe some recent insights relating to how ECM regulates cell growth and function as well as tissue morphogenesis. The analysis of this regulatory mechanism should be of particular interest to the tissue engineer, because it has led to the identification of critical chemical and mechanical features of the ECM that are responsible for control of the growth and differentiation of many cell types. In addition, the reader will be introduced to some unanswered puzzles in developmental biology, which, if deciphered, could provide powerful new approaches to tissue regeneration and repair.

## EXTRACELLULAR MATRIX STRUCTURE AND FUNCTION

### COMPOSITION AND ORGANIZATION

One of the most critical elements of tissue engineering is the ability to mimic the ECM scaffolds that normally serve to organize cells into tissues. ECMs are composed of different collagen types, large glycoproteins (e.g., fibronectin, laminin, entactin, osteopontin), and proteoglycans that contain large glycosaminoglycan side chains (e.g., heparan sulfate, chondroitin sulfate, dermatan sulfate, keratan sulfate, hyaluronic acid). Although all ECMs share these components, the organization, form, and mechanical properties of ECMs can vary widely in different tissues depending on the chemical composition and three-dimensional organization of the specific ECM

components that are present. For example, interstitial collagens (e.g., types I and III) self-assemble into a three-dimensional lattice, which, in turn, binds fibronectin and proteoglycans. This type of native ECM hydrogel forms the backbone of loose connective tissues, such as dermis. In contrast, basement membrane collagens (types IV and V) assemble into planar arrays; when these collagenous sheets interact with fibronectin, laminin, and heparan sulfate proteoglycan, a planar ECM results (i.e., the “basement membrane”). The ability of tendons to resist tension and of cartilage and bone to resist compression similarly result from local differences in the organization and composition of the ECM.

### ***In Vivo* FOUNDATION FOR CELL ANCHORAGE**

The first and foremost function of the ECM in tissue development is its role as a physiological substratum for cell attachment. This feature is easily visualized by treating whole tissues with ECM-degrading enzymes (collagenase, proteases); cell detachment and loss of cell and tissue morphology rapidly result. Cells that are dissociated in this manner can reattach to an artificial culture substrate (e.g., plastic, glass). However, adhesion is again mediated by cell binding to ECM components that are either experimentally immobilized on the culture surface, deposited *de novo* by the adhering cells, or spontaneously adsorbed from serum (e.g., fibronectin, vitronectin) (Kleinman *et al.*, 1981; Madri and Stenn, 1982; Stenn *et al.*, 1979; Wicha *et al.*, 1979; Salomon *et al.*, 1981; Bissell *et al.*, 1986; Ingber *et al.*, 1987). In fact, standard tissue culture plates are actually bacteriological (nonadhesive) plastic dishes that have been chemically treated using proprietary methods to enhance adsorption of serum- and cell-derived ECM proteins. To summarize, cells do not attach directly to the culture substrate (i.e., plastic or glass), rather they bind to intervening ECM components that are adsorbed (or derivatized) to these substrates. For this reason, cell adhesion can be prevented by coating normally adhesive culture surfaces with polymers that prevent protein adsorption, such as poly(hydroxyethyl methacrylate) (Folkman and Moscona, 1978).

### **SPATIAL ORGANIZER OF POLARIZED EPITHELIUM**

Living cells exhibit polarized form as well as function (e.g., basal nuclei, supranuclear Golgi complex, apical secretory granules in secretory epithelia). Dissociated cells lose this normal orientation when cultured on standard tissue culture substrata or on interstitial connective tissue. In the case of epithelial cells, normal polarized form is often restored if the cells synthesize and accumulate their own ECM or if they are cultured on exogenous basement membrane (i.e., the specialized epithelial ECM) (Emerman and Pitelka, 1977; Chambard *et al.*, 1981; Ingber *et al.*, 1986b). These types of studies suggest that basement membrane normally serves to integrate and maintain individual cells within a polarized epithelium. Clearly, there are many intracellular and intercellular determinants of polarized cell form and function (e.g., cytoskeletal organization, organelle movement, junctional complex formation). However, anchorage to the ECM appears to provide an initial point of orientation and stability on which additional steps in the epithelial organization cascade can be built. The ECM may regulate the orientation of other cell types (e.g., chondrocytes, osteoclasts) as well.

### **SCAFFOLDING FOR ORDERLY TISSUE RENEWAL**

All tissues are dynamic structures that exhibit continual turnover of all molecular and cellular components. Thus, it is the maintenance of tissue pattern integrity that is most critical to the survival of the organism. Maintenance of specialized tissue form requires that cells that are lost due to injury or aging must be replaced in an organized fashion. Importantly, orderly tissue renewal has been shown to depend on the continued presence of insoluble ECM scaffoldings, which act as templates that maintain the original architectural form and ensure accurate regeneration of pre-existing structures (Vracko, 1974). For example, when cells within a tissue are killed by freezing or treatment with toxic chemicals, all of the cellular components die and are removed; however, the basement membranes often remain intact. These residual ECM scaffoldings ensure correct repositioning of cells (e.g., cell polarity) and restore different cell types to their correct locations (e.g., muscle cells within muscle basement membrane, nerve cells in nerve sheaths, endothelium within vessels), in addition to promoting the cell migration and growth that are required for repair of all the component tissues (see below). Conversely, loss of ECM integrity during wound healing results in disorganization of tissue pattern and, thus, scar formation. Uncoupling between

basement membrane extension and cell doubling also leads to disorganization of tissue morphology during neoplastic transformation (Ingber *et al.*, 1981).

### ESTABLISHMENT OF TISSUE MICROENVIRONMENTS

Specialized ECMs often establish a physical boundary between neighboring tissues. For example, the basement membrane normally restricts mixing between the epithelium and the underlying connective tissue, and compromise of basement membrane integrity is indicative of the onset of malignant invasion when seen in the context of tumor formation (Ingber *et al.*, 1981). The ECM boundary also may regulate macromolecular transport between adjacent tissues given that the basement membrane provides the semipermeable filtration barrier in the kidney glomerulus (Farquhar, 1978). However, little is known about this potential function of the ECM in the local tissue microenvironment.

### SEQUESTRATION, STORAGE, AND PRESENTATION OF SOLUBLE REGULATORY MOLECULES

ECMs also may modulate tissue growth and morphogenesis through their ability to bind, store, and eventually release soluble regulators of morphogenesis. For example, basic fibroblast growth factor (bFGF), a mitogen for fibroblasts, smooth muscle cells, and endothelial cells, has been identified within ECMs deposited by cells cultured *in vitro* (Vlodavsky *et al.*, 1987) and within basement membranes in certain normal tissues (e.g., cornea) *in vivo* (Folkman *et al.*, 1988). The low growth rate observed in most normal tissues may result from sequestration of mitogens whereas release of these stored factors ("stormones"), due to injury or hormonally induced changes in ECM turnover, may help to switch growth on locally. Binding of other types of regulatory molecules to the endothelial basement membrane (e.g., plasminogen activator inhibitor) (Pollanen *et al.*, 1987) also may play a role in tissue physiology (e.g., blood coagulation, cell migration).

### REGULATOR OF CELL GROWTH, DIFFERENTIATION, AND APOPTOSIS

Most normal (nontransformed) cells grow only when attached and spread on a solid substrate (Folkman and Moscona, 1978). Cells attach and spread *in vitro* either by depositing new ECM components or by binding to exogenous ECM (Kleinman *et al.*, 1981; Madri and Stenn, 1982; Stenn *et al.*, 1979; Wicha *et al.*, 1979; Salomon *et al.*, 1981; Bissell *et al.*, 1986; Ingber *et al.*, 1987). In fact, cell spreading and growth can be suppressed by inhibiting ECM deposition *in vitro* using drugs (Madri and Stenn, 1982; Stenn *et al.*, 1979; Wicha *et al.*, 1979). Cell growth stimulated by soluble mitogens also has been shown to vary depending on the type of ECM component used for cell attachment (e.g., collagen versus fibronectin) (Kleinman *et al.*, 1981; Bissell *et al.*, 1986; Ingber *et al.*, 1987) as well as on the mechanical properties of the ECM (e.g., malleable gel versus rigid ECM-coated dish) (Li *et al.*, 1987; Kubota *et al.*, 1987; Ben Ze'ev *et al.*, 1988; Opas, 1989; Vernon *et al.*, 1992). Furthermore, the substrates that promote growth tend to suppress differentiation and vice versa. For examples, many cells proliferate and lose differentiated features when cultured on attached type I collagen gels that can resist cell tension and promote cell spreading. In contrast, the same cells cease growing and increase expression of tissue-specific functions (e.g., albumin secretion in hepatocytes, milk secretion and acinus formation by mammary cells, capillary tube formation by endothelial cells) if cultured on the same gels that are made flexible by floating them free in medium or on attached ECM gels that exhibit high malleability (e.g., basement membrane gels, such as Matrigel). Under these conditions, the cells exert tension across their adhesions, resulting in contraction of the ECM gel and cell rounding, which, in turn, shut off growth and turn on differentiation-specific gene functions. The differentiation-inducing effects of these malleable ECM substrates also can be suppressed by making the gels rigid through chemical fixation (Li *et al.*, 1987; Opas, 1989), thus confirming the critical role of cell-generated mechanical forces in this response.

Although local changes in ECM turnover may promote tissue remodeling, large-scale breakdown of the ECM may force the same growing tissues to undergo involution. Many cultured cells rapidly lose viability and undergo programmed cell death (i.e., apoptosis) when they are detached from the ECM and maintained in a round form in suspension (Meredith *et al.*, 1993). Loss of basement membrane integrity is also observed in regions of tissues that are actively regressing (Trelstad *et al.*, 1982; Ingber *et al.*, 1986a), and growing tissues (e.g., capillaries, mammary gland) can

be induced to involute using pharmacological agents (e.g., proline analogs) that inhibit ECM deposition and lead to basement membrane dissolution *in vivo* (Ingber *et al.*, 1986a; Wicha *et al.*, 1980; Ingber and Folkman, 1988). Transgenic mice studies confirm that growing tissues can be made to involute by shifting the endogenous proteolytic balance such that total ECM breakdown results (Talhok *et al.*, 1992). These findings suggest that local changes in ECM composition and flexibility may regulate cell sensitivity to soluble mitogens and, thereby, control cell growth, viability, and function in the local tissue microenvironment.

## PATTERN FORMATION THROUGH ECM REMODELING

### MESENCHYMAL CONTROL OF EPITHELIAL PATTERN

Probably the greatest insight into the role of the ECM in tissue development comes from analysis of embryogenesis. In the embryo, genesis of a tissue's characteristic form (e.g., tubular versus acinar) and deposition of ECM are both controlled by complex interactions between adjacent epithelial and mesenchymal cell societies. The epithelial cell is genetically programmed to express tissue-specific (differentiated) functions and to deposit the insoluble basement membrane, which functions as a common attachment foundation that both separates adjacent tissues and stabilizes tissue form (Banerjee *et al.*, 1977; Dodson and Hay, 1971). However, although production of tissue-specific cell products (cytodifferentiation) is determined by the epithelium, tissue pattern (histodifferentiation) is usually directed by the surrounding mesenchyme. For example, when embryonic mammary epithelium is isolated and combined with salivary mesenchyme, the mammary epithelial cells take on the form of the salivary gland, although they still produce milk proteins (Sakakura *et al.*, 1976). However, the specificity of these epithelial–mesenchymal interactions can vary widely from organ to organ. For instance, embryonic salivary epithelia specifically require salivary mesenchyme for successful development, whereas pancreatic epithelia will undergo normal cytodifferentiation and histodifferentiation in response to mesenchyme isolated from a variety of embryonic tissues (Golosow and Grobstein, 1962).

### TISSUE PATTERNING THROUGH LOCALIZED ECM REMODELING

The complex tissue patterns that are generated through epithelial–mesenchymal interactions result from the establishment of local differentials in tissue growth and expansion in a microenvironment that is likely saturated with soluble mitogens. The classic work on salivary gland development by Bernfield and co-workers revealed that the epithelium imposes morphological stability through production of its basement membrane whereas the mesenchyme produces local changes in tissue form, specifically by degrading basement membrane at selective sites (Banerjee *et al.*, 1977; Bernfield and Banerjee, 1978; Smith and Bernfield, 1982; Bernfield *et al.*, 1972; David and Bernfield, 1979). An increased rate of cell division is observed in the tips of growing lobules that also exhibit the highest rate of ECM breakdown and resynthesis (i.e., highest turnover rate). At the same time, the mesenchyme slows basement membrane turnover and suppresses epithelial cell growth in the clefts of the glands. This is accomplished by secretion of fibrillar collagens that slow ECM degradation locally, thereby promoting basement membrane accumulation in these regions. Similar local coupling between ECM turnover, cell growth rates, and tissue expansion is observed in many other developing tissues, including growing capillary blood vessels (Folkman, 1982).

It is important to note that increased ECM turnover involves enhanced rates of matrix synthesis as well as degradation. In fact, net basement membrane accumulation (i.e., increased area available for cell attachment) must result for epithelial tissues to grow and expand laterally, and thus the local rate of ECM synthesis must be greater than that of degradation in these high-turnover regions. If the rate of ECM degradation is significantly greater than synthesis, then net basement membrane dissolution results. As described above, this would lead to cell death and tissue regression rather than expansion.

### ROLE OF MECHANICAL STRESSES

Before ending the discussion of the role of ECM in pattern formation, it is critical to emphasize that although chemical regulators mediate tissue morphogenesis, the signals that are actually responsible for dictating tissue pattern are often mechanical in nature. The pattern-generating effects of compression on bone, shear on blood vessels, and tension on muscle are just a few ex-

amples. Mechanical stresses are also important for embryological development; however, internal cell-generated forces appear to play a more critical role. For example, mechanical tension that is generated via actomyosin filament sliding within the cytoskeleton of the cells that compose the embryo plays a key role during gastrulation (Beloussov *et al.*, 1975) as well as during tissue morphogenesis (Ash *et al.*, 1973). In fact, the pattern of development can be experimentally altered by applying external stresses to the embryo using micropipettes (Beloussov *et al.*, 1988). Tensile forces that are generated internally within mesenchyme and transmitted across the ECM are also likely required for the “condensation” of mesenchyme that commonly precedes formation of new organ rudiments. In this context, it is interesting to note that the pattern-generating capabilities of mesenchyme isolated from different developing tissues have been shown to correlate with differences in their ability to exert mechanical tension on external substrates (e.g., microbeads) (Nogawa and Nakanishi, 1987). Local changes in ECM turnover may drive morphogenetic patterning of tissues, in part, by altering the mechanical compliance of the ECM and thereby changing cell shape or cytoskeletal tension (Ingber and Jamieson, 1985; Huang and Ingber, 1999). More in-depth discussion of the role of cell-generated mechanical stresses in embryogenesis and wound healing can be found elsewhere (Ingber, 1991; Ingber *et al.*, 1994).

## MECHANOCHEMICAL SWITCHING BETWEEN GROWTH AND DIFFERENTIATION

Given the pivotal role that the ECM plays in tissue development, many studies have been carried out to analyze how changes in cell–ECM interactions might act locally to regulate cell sensitivity to soluble mitogens and thereby establish the growth differentials that are required for tissue morphogenesis. To accomplish this, simplified *in vitro* model systems have been developed to retain the minimal determinants necessary for maintenance of the physiological functions of interest (i.e., cell growth and differentiation) (Ingber, 1990; Ingber and Folkman, 1989; Mooney *et al.*, 1992b). For example, to determine the effects of varying cell–ECM contacts directly, bacteriological petri dishes that were otherwise nonadhesive were precoated with different densities of purified ECM molecules, such as fibronectin, laminin, or different collagen types. Quiescent, serum-deprived cells were plated on these dishes in a chemically defined medium that contained a constant and saturating amount of soluble growth factor.

When capillary endothelial cells were studied, DNA synthesis and cell doubling rates were found to increase in an exponential fashion as the density of immobilized ECM ligand was raised and cell spreading was promoted (Ingber and Folkman, 1989; Ingber, 1990). When higher cell plating numbers were used to promote cell–cell interactions as well as cell–ECM contact formation, the capillary cells could be switched between growth and differentiation (capillary tube formation) in the presence of saturating amounts of soluble mitogen (FGF) simply by varying the ECM coating density (Ingber and Folkman, 1989). Specifically, when plated on a high ECM density (e.g.,  $>500$  ng/cm<sup>2</sup> fibronectin), the cells attached, spread extensively, formed many cell–cell contacts, and organized into a planar cell monolayer. When the same cells were plated on a low ECM density ( $<100$  ng/cm<sup>2</sup>), the cells attached but they could not spread, and thus only cell clumps or aggregates were observed. When the same capillary cells were plated on a moderate density, cells attached, spread, and formed cell–cell contacts as they did on the higher ECM densities. However, the tensile forces generated by the cells appeared to overcome the resistance provided by their relatively weak ECM adhesions and thus the cell aggregates began to retract over a period of hours until a mechanical equilibrium was attained. Under these conditions, formation of an extensive network composed of interconnected capillary tubes resulted. Many of these capillary tubes became elevated above the culture surface, although the network remained adherent to the culture dish at discrete points through interconnected multicellular aggregates. The importance of mechanical forces for this switching between growth and differentiation was confirmed by demonstrating that similar capillary tube formation could be induced on the high ECM density, which normally promoted spreading and growth, simply by increasing the cell plating numbers and thereby amplifying the level of cell tension.

The same system was used to demonstrate similar shape (stretch)-dependent switching between growth and differentiation in other cell types. For example, the growth and differentiation of primary rat hepatocytes could be controlled independently of cell–cell contact formation by varying cell–ECM contacts and cell spreading using the method described above (Mooney *et al.*,

1992a). Additional studies confirmed that ECM exerts its regulatory effects at the level of gene expression (Mooney *et al.*, 1992a; Hansen *et al.*, 1994) and that these effects are mediated at least in part through modulation of the cytoskeleton (Mooney *et al.*, 1995). These results are consistent with those from other laboratories demonstrating that malleable ECM gels (e.g., Matrigel, native collagen gels) that promote cell rounding also induce differentiation and suppress growth, whereas the opposite effects are produced when these gels are fixed and made rigid (Li *et al.*, 1987; Kubota *et al.*, 1987; Ben Ze'ev *et al.*, 1988; Opas, 1989).

Altering cell–ECM contacts by varying ECM coating densities appears to influence cell function via two distinct but integrated mechanisms. First, increasing the local density of immobilized ECM ligand promotes clustering of integrins, which are transmembrane ECM receptors on the cell surface (Hynes, 1987). Integrin clustering, in turn, activates a number of different chemical signaling pathways (e.g., tyrosine phosphorylation, inositol lipid turnover,  $\text{Na}^+/\text{H}^+$  exchange, MAP kinase) that are also utilized by growth factor receptors to alter cellular biochemistry and gene expression (Ingber *et al.*, 1990; Schwartz *et al.*, 1991; McNamee *et al.*, 1993; Plopper *et al.*, 1995). Activation of these signaling pathways likely plays an important role in control of cell differentiation and survival; however, integrin-dependent chemical signaling alone is not sufficient to explain how cells are induced to enter S phase and proliferate (Ingber, 1990; Hansen *et al.*, 1994). A second mechanism that involves tension-dependent changes in cell shape and cytoskeletal organization also comes into play.

The importance of cell tension was demonstrated directly by developing a model system in which cell shape or distortion was varied independently of the local density of immobilized matrix molecule. This was made possible by adapting a technique for forming spontaneously assembled monolayers (SAMs) of alkanethiols (Prime and Whitesides, 1991) to create micropatterned surfaces containing adhesive islands with defined surface chemistry, shape, and position on the cell (micrometer) scale (Singhvi *et al.*, 1994; Chen *et al.*, 1997). The method involves fabrication of a flexible elastomeric stamp that exhibits the particular surface features of interest using photolithographic techniques. The topographic high points on the stamp (e.g.,  $40 \times 40 \mu\text{m}$  square plateaus raised above recessed intervening regions) are coated with an alkanethiol ink and the stamp is then apposed to a gold-coated surface. The alkanethiol forms SAMs covering only the regions where the stamp contacts the surface (i.e.,  $40 \times 40 \mu\text{m}$  squares). Then the surrounding uncoated regions are filled with a SAM composed of similar alkanethiols that are conjugated to poly(ethylene glycol) (PEG), which prevents protein adsorption. The result is a chemically defined culture surface that is completely covered with a continuous SAM of alkanethiols; however, the local adhesive islands of defined geometry support protein adsorption whereas the surrounding boundary regions coated with PEG do not. Thus, when these substrates are coated with a high density of purified ECM protein, such as laminin or fibronectin, the result is adhesive islands of defined shape and position, coated with a saturating density of matrix molecule. Using this technique, cell position and shape could be precisely controlled because the cells attach only to the ECM-coated adhesive islands. In fact, even square and rectangular cells exhibiting  $90^\circ$  corners could be engineered using this approach (Singhvi *et al.*, 1994).

This micropatterning method was first used to probe the question of cell function: if cells are restricted to a small size, similar to that produced on a low-concentration ECM coating, but the local density of immobilized integrin ligand is increased 1000-fold, which is the critical determinant of cell function, the ECM density or cell shape? The answer was that it was cell shape. Primary hepatocytes remained quiescent on small adhesive islands coated with a high ECM density, even though the cells were stimulated with high concentrations of soluble growth factors (Singhvi *et al.*, 1994). Furthermore, cell growth (DNA synthesis) increased in parallel as the size of the adhesive island was increased, and similar results were obtained with capillary endothelial cells (Chen *et al.*, 1997), thus confirming that cell shape was the critical governor of this response. Inhibition of hepatocyte growth on the small islands also was accompanied by a concomitant increase in albumin secretion. In the case of endothelial cells, the cells were similarly induced to differentiate into capillary tubes when cultured on linear patterns that supported cell–cell contact as well as a moderate degree of cell distension, whereas the cells were induced to undergo apoptosis (cellular suicide) when cultured on the smallest islands that fully prevented cell extension (Chen *et al.*, 1997; Dike *et al.*, 1999). Thus, cell shape and function could be engineered simply by altering the geometry of the adhesive substrate.

Integrin signaling elicited in response to ECM binding has been shown to be critical for control of cell growth and function (Hynes, 1987; Ingber *et al.*, 1990; Schwartz *et al.*, 1991; McNamee *et al.*, 1993; Plopper *et al.*, 1995). Thus, one could argue that cell shape and mechanical distortion of the cytoskeleton are not important. Instead, it might be the increase in total area of cell–ECM contacts and associated integrin binding that dictate whether cells will grow, differentiate, or die on large versus small adhesive islands. To explore this further, substrates were designed in which a single small adhesive island (which would not support spreading or growth) was effectively broken up into many smaller islands (3–5  $\mu\text{m}$  in diameter) that were spread out and separated by nonadhesive barrier regions (Chen *et al.*, 1997). When capillary cells were plated on these substrates, their processes stretched from island to island and the cells exhibited an overall extended form similar to cells on large islands. However, the total area of cell–ECM contact was almost identical to that exhibited by nongrowing cells on the smaller islands. These studies revealed that in the presence of optimal growth factors and high ECM binding, DNA synthesis was high in the cells that spread over multiple small islands whereas apoptosis was completely shut off (Chen *et al.*, 1997). Additional studies have revealed that shape exerts this control over growth by harnessing the cell's molecular machinery (cyclins and cdk inhibitors) that normally controls cell cycle progression late in  $G_1$  phase, and that similar control can be exerted by altering the level of isometric tension within the cytoskeleton, independently of any cell shape change (Huang *et al.*, 1998). Thus, local changes in cell shape and cytoskeletal tension appear to govern how individual cells will respond to chemical signals (soluble mitogens and insoluble ECM molecules) in their microenvironment. This mechanism for establishing local growth differentials may play a critical role in morphogenesis in all developing systems (Ingber and Jamieson, 1985; Huang and Ingber, 1999).

## SUMMARY

In summary, our work has shown that the development of functional tissues, such as branching capillary networks, requires both soluble growth factors and insoluble ECM molecules. The ECM appears to be the dominant regulator, however, because it dictates whether individual cells will either proliferate, differentiate, or die locally in response to soluble stimuli. This local control mechanism is likely critical for the establishment of local cell growth differentials that mediate pattern formation in all developing tissues.

Analysis of the molecular basis of these effects revealed that ECM molecules alter cell growth via both biochemical and biomechanical signaling mechanisms. ECM molecules cluster specific integrin receptors on the cell surface and thereby activate intracellular chemical signaling pathways (Ingber *et al.*, 1990; Schwartz *et al.*, 1991; McNamee *et al.*, 1993; Plopper *et al.*, 1995), stimulate expression of early growth response genes (e.g. *c-fos*, *jun-B*) (Hansen *et al.*, 1994), and induce quiescent cells to pass through the  $G_0/G_1$  transition. However, in addition, the immobilized ECM components must physically resist cell tension and promote changes of cell shape (Ingber, 1990; Ingber and Folkman, 1989; Mooney *et al.*, 1992a,b; Singhvi *et al.*, 1994; Chen *et al.*, 1997) and cytoskeletal tension (Mooney *et al.*, 1995; Huang *et al.*, 1998; Ingber *et al.*, 1995) in order to promote full progression through  $G_1$  and entry into S phase. Studies with living and membrane-permeabilized cells confirm that changes in cell shape result from the action of mechanical tension that is generated within microfilaments and balanced by resistance sites within the underlying ECM (Ingber, 1991; Sims *et al.*, 1992; Ingber *et al.*, 1994). Taken together, this work suggests that the pattern-regulating information the ECM conveys to cells is both chemical and mechanical in nature. Thus, design of future artificial ECMs for tissue engineering applications must take into account both of these features.

## THE FUTURE

Early tissue engineering efforts by reconstructive surgeons and materials scientists started with a knowledge of the clinical need for and the mechanical behavior of connective tissues on the macroscopic scale, and worked backward. The long-term goal for the field is to design and fabricate tissue substitutes starting from first principles. This includes mechanical and architectural principles as well as an in-depth understanding of the molecular and biophysical bases of tissue regulation. Clearly, given the potent and varied functions of the ECM, fabrication of artificial ECMs will play a central role in all of these future efforts. We and others have already begun to

explore the utility of synthetic bioerodible polymers as cell attachment substrates (Cima *et al.*, 1991; Mikos *et al.*, 1993) and the potential usefulness of immobilized synthetic ECM peptides for controlling cell growth and function (Hansen *et al.*, 1994; Mooney *et al.*, 1992a,b; Roberts *et al.*, 1998). These materials offer a major advantage in terms of biocompatibility because the artificial substrates completely disappear over time, and thus the implanted donor cells become fully incorporated into the host. They also provide great chemical versatility as well as the potential for large-scale production at relatively low cost. In addition, use of synthetic chemistry reduces the likelihood of batch-to-batch variation during large-scale production, a problem that can potentially complicate use of purified ECM components. For these reasons, polymer chemistry and novel fabrication techniques will likely lead to development of more effective tissue substitutes.

However, if we understood the fundamental principles that guide ECM remodeling and pattern formation in tissues, perhaps tissue engineering might take a different approach in the future. For example, one could envision entirely new methods of clinical intervention if we understood how tissue-specific mesenchyme generates tissue pattern, how ECM turnover is controlled locally, or how compressing or pulling tissues alters their growth and form. Such knowledge could lead to methods for identifying and isolating relevant “pattern-generating” cells; for developing pharmacological modifiers of ECM remodeling that may be incorporated in local regions of implants to promote or suppress tissue expansion locally; and for fabricating biomimetic scaffolds that mimic the mechanical and architectural features of natural ECMs necessary to switch on or off the function of interest (e.g., growth vs. differentiation or apoptosis) at a particular time or place (Oslakovic *et al.*, 1998). These are just a few of the challenges for the future.

#### ACKNOWLEDGMENTS

The success of many of the studies summarized would not have been possible without the assistance of my major collaborators, including Judah Folkman, Robert Langer, Jay Vacanti, Martin Schwartz, and George Whitesides, and the multiple students and postdoctoral fellows who executed these experiments in our laboratories. This work was supported by grants from NIH, NASA, and NSF.

# ANIMAL CELL CULTURE

Gordon H. Sato and David W. Barnes

From the enunciation of the cell theory by Schleiden and Schwann emerged the grand concept that understanding living organisms could come from understanding the fundamental unit—the cell. The concept that organisms are composed of smaller units (“cellulae”) derived from the description in 1665 by Robert Hooke of cells in a multicellular organism (Hooke, 1665). What Hooke actually saw was the holes in cork where cells had been, and the relationship of these structures to the “animalcules” observed by van Leeuwenhoek in 1674 using a simple microscope was not immediately clear. More advanced propositions awaited the development of the more sophisticated compound microscope. In 1838, Matthias Schleiden, working with plants, and a year later Theodor Schwann, working with animal cells, concluded that cells were the basic units of life and that complex organisms were composed of “aggregates” of these units (Howland, 1973). For some time this concept competed with Haeckel’s idea formulated in 1868 that life consisted of protein aggregates (“monera”) that were formed directly from inorganics, a notion that can be traced to Aristotle (Howland, 1973).

The concept that cells contain material vital for life (“protoplasm”) was advanced during this era by Purkinje (1825), and the concept that cells were derived from other cells came from Virchow in 1858. Interestingly, both Schleiden and Schwann supported a competing idea to Virchow’s, that cellular structure derived directly from the nucleus and the nucleus derived from the nucleolus (Howland, 1973). Virchow also applied his observations to medical theory of the time, giving rise to modern pathology (Florey, 1959).

The cell theory is to biology what the atomic theory is to chemistry or elementary particles are to physics. Our preoccupation has been with the question of how studies of animal cells in culture could lead to an understanding of the whole organism or integrated physiology. Since the first experiments in tissue culture by Ross Harrison (1907), the possibility was raised that knowledge could be gained about these fundamental units in an environment that could be manipulated and controlled. Observations of Harrison concerning the appearance of cellular-processes in the cultures helped settle a debate between pioneer cytologist Camillo Golgi and neuroanatomist Ramón y Cajál regarding the genesis of the processes. One proposal was that processes developed independently, then fused with the cells, while the idea supported by Harrison’s data called for the cells themselves to produce the processes. Almost immediately outcries were raised about the artificiality of the situation and the artifactual nature of cellular behavior. These objections are still being raised and the purpose of this chapter is to address these questions. Our approach will be general but not comprehensive, as this would be beyond our present ability and inclination (Sato *et al.*, 1960).

The single most important objection to the suitability of studying cells in culture was that for over 50 years after the experiments of Harrison there did not exist cultures that exhibited the specialized properties of the tissue of origin. Cultures from muscle did not contract, from glandular tissue did not secrete hormones, from liver did not secrete bile, etc. How, then, could culture studies contribute to the understanding of integrated physiology? Everything in culture looked like fi-

broblasts. The predominant view for decades was that the artificial conditions of culture caused cells to “differentiate” into some tissue culture-type cell. This was shown to be due to the selective overgrowth of fibroblasts, which had a selective advantage in the serum-based media available at the time. With the discovery of platelet-derived growth factor (Balk *et al.*, 1973; Ross *et al.*, 1974; Antoniades and Scher, 1977) and hormonally defined media (Sato *et al.*, 1982; Hayashi and Sato, 1976; Barnes and Sato, 1980), the selective advantage of fibroblasts becomes perfectly understandable.

With knowledge of the selective advantage of fibroblasts, methods analogous to the enrichment culture methods of microbiology were devised to culture specialized cells with physiological properties of the tissue of origin (Sato *et al.*, 1970; Sato, 1981). A number of specialized cell lines were developed in this way, mostly from differentiated tumors developed by Jacob Furth (1955). These include adrenal cortical cells that respond to adrenocorticotrophic hormone (ACTH) to produce steroids (Y1), pituitary cells that secrete ACTH (ATT20), pituitary cells that secrete growth hormone and prolactin (GH series), neuroblastoma cells that secrete transmitters, teratocarcinoma cells that undergo differentiation in culture, glioma cells with properties of astrocytes (C6), Leydig cells that produce steroids, and pigmented melanoma cells (Sato *et al.*, 1970, 1982; Sato and Ross, 1979). Other labs around this time were establishing gamma globulin-secreting B cell myelomas, muscle cells, mast cells, etc. (Sato, 1981).

Some comments would be appropriate at this time. Certainly cells in culture must exhibit differentiated function if culture studies would be of value in understanding integrated physiology. The establishment of the above-mentioned cell lines is a beginning. The Y1 cells deserve special mention. These adrenal cortical cells secrete steroids in response to ACTH. This means that the cultured cells display at least a part of the repertoire of physiologic responses found in the animal. Since its establishment many physiologic responses have been found in cultured cells. Perhaps someday all the effector substances and responses found in physiology will be displayed and studied in culture. It has been estimated that there are 400 different kinds of cells in the animal body. This estimate is mostly based on histology and surely is an underestimate because of the limits of the methodology. We have a fair way to go before each and every cell type is established in culture and available for study.

In the face of skepticism concerning the relevance of studying cells in culture, it would be useful to draw some generalizations on this matter. The first generalization that might be useful is that the more basic the question the more likely the answer will be relevant for whole animal physiology. Some examples are given. In the 1950s and 1960s Harry Eagle (1955) and associates studied the nutritional requirements of cells in culture and found they required more amino acids and less vitamins than were required by the whole animal. This is because some amino acids, such as arginine, are produced in specialized tissues, such as the liver, and some of the vitamins, such as vitamin E, are required by specialized tissues. The cultured cells gave an accurate picture of the situation in the animal, where there is a division of labor between the tissues. Cultured cells did not, as a result of culturing, assume new biosynthetic properties or suddenly require vitamins useful for specialized function. Vitamins that are involved in coenzymes in basic metabolic pathways are required by all cultured cells. The results of Eagle's experiments are that they point out the stability of differentiated properties throughout experimental manipulation.

In the 1960s, Perry, Penman, and Darnell showed that ribosomal RNA molecules in cultured cells are first formed as large precursors, which are cleaved to the final subunit size. Such a basic process could not be different in cultured cells and cells in the body, and this has proved to be the case. Steiner (1977), using cultured insulinomas, showed that the double-chained insulin molecule was formed as a single chain with a connecting peptide. The connecting peptide is cleaved out and the two chains are joined by disulfide bonds. Such a basic process could not be different in culture and the whole animal and such has been found to be true. The concept of messenger RNA was challenged by Henry Harris when he found that most of the RNA synthesized in cultured cells did not exit the nucleus. This was later shown to be due to the fact that mRNAs are synthesized as large precursors, of which only a portion emerges from the nucleus to direct protein synthesis. Such a phenomenon contributed to the discovery of introns and RNA splicing. The organization of genes into introns and exons and the synthesis of messenger RNA as first a large precursor are too basic to be reinvented by cells when they are put into culture.

In some cases the ease of manipulation of cells in culture makes it possible to obtain infor-

mation that would be extremely difficult to get from whole animal experiments. Two examples come readily to mind. In the period of intense nuclear bomb testing a controversy raged over the sensitivity of human cells to ionizing irradiation. This was settled by the Puck group using single-cell plating tissue culture methods (Puck and Marcus, 1955). Their results showed that human cells were much more sensitive to irradiation than previously thought. Prior to 1957, the diploid number of human chromosomes was thought to be 48. J. H. Tjio, using cultured cells and the hypotonic method of T. C. Hsu, found the correct number to be 46 (Tjio and Levan, 1956). This led to the Denver classification of chromosomes, the association of chromosomal anomalies with disease, and the detailed characterization of human chromosomes. These tissue culture experiments have had a large impact on medical practice—especially genetic counseling.

In some cases, culture techniques have made possible the discovery of substances that could not be made in whole animal experiments. If a young animal is hypophysectomized it ceases growth and radioactive sulfur is not incorporated into the cartilage of the epiphysis of the long bones. If the animal is injected with growth hormone these processes are restored. If the bones are incubated *in vitro* with hypophysectomized serum,  $^{35}\text{S}$  is not incorporated into cartilage. If growth hormone is added, sulfation still does not occur but the serum of hypophysectomized animals injected with growth hormone supports sulfation. This led to the discovery of the insulin-like growth factors that are made in the liver in response to growth hormone (Salmon and Daughaday, 1957). The classic approach of ablating the liver of hypophysectomized animals injected with growth hormone is not feasible.

If an animal is ovariectomized and fragments of its ovary are implanted in its spleen, the implant grows as a large tumorous mass (Biskind and Biskind, 1944). The explanation offered at the time was that ovarian steroids were not produced and delivered to inhibit gonadotropin secretion, because the ovarian tissue in the spleen would deliver its steroids through the hepatic portal system to the liver, where they would be inactivated before reaching the general circulation. As a result the pituitary would oversecrete gonadotrophin, causing the implant to grow. When the implanted ovaries were grown in culture and cloned, the cloned cells would grow in the spleens of animals only if they were ovariectomized. The cells did not exhibit a dependence on gonadotrophin in culture but to a contaminant in preparations of luteinizing hormone. This led to the conclusions that serum was masking hormonal dependencies and that the function of serum in cell culture media might be to provide complexes of hormones and that some of these hormones might be novel. The novel factor was called ovarian growth factor (OGF) and its name was later changed to fibroblast growth factor (FGF) (Clark *et al.*, 1972). Two possible avenues of these studies that were not followed up on were that OGF (FGF) might be a gonadotrophin or a mediator of gonadotrophin. In several instances results from culture were so at odds with conventional wisdom that they were discounted as cell culture artifacts.

In several instances, Levi-Montalcini discovered that animals bearing a certain tumor had enlarged sympathetic ganglia (Levi-Montalcini and Hamburger, 1953). In a culture assay, extracts of the tumor, snake venom, and salivary gland extracts greatly stimulated explanted ganglia. That such an odd assortment and sources of activity in a dubious assay system should evoke suspicion of its relevance to physiology was understandable. The active principle turned out to be nerve growth factor (NGF), and later Levi-Montalcini showed that antibodies to NGF injected into fetal animals prevented the normal development of the sympathetic ganglia. Today there is little doubt that NGF plays a central role in the development and regulation of the sympathetic nervous system. Thyrotropin releasing hormone (TRH) was discovered and isolated by measuring thyrotropin-stimulating hormone (TSH) release from explanted pituitaries. TRH was shown to release prolactin from cultured growth hormone (GH) cells (Tashjian *et al.*, 1968). This was naturally viewed as an artifact of pituitary tumor cultures until it was shown that injection of TRH into animals also released prolactin.

Perhaps the most extreme example of cell culture as the essential means to discovery and characterization of physiological regulators has been the characterization of the heparin-binding fibroblast growth factor family and the transforming growth factor  $\beta$  superfamily. Although members of the two families can be delivered to tissues by blood cells (platelets, leukocytes, etc.) in rare situations, members of the family largely serve as intrinsic mediators of external signals to tissues and cell-to-cell communication within tissues. Both were discovered and characterized by cell culture methods, and to date there have been no tissues in which one or more members of these two

families are not present. The FGF family now consists of 9 genetically distinct ligands and upward of 100 receptor variants that arise by combinatorial alternate splicing in four genes (Jaye *et al.*, 1992).

Largely, analyses from cells in culture have revealed that different FGF ligands and splice variants of the receptor are expressed in different cell types within the same tissue at different times and in different combinations. In addition to this diversity, monomeric products of the FGF receptor genes oligomerize to result in the active signal transduction complex. To have impact on this, different monomers must be expressed in the same cell at the same time. On top of all this, results show that the FGF receptor complex is probably a ternary one of FGF ligand, ectodomain of monomeric variants described above, and a heparan sulfate chain that is heterogeneous with respect to length, monosaccharide composition, and sulfation, but may be a third source of diversity in biological function of the FGF family (Kan *et al.*, 1993). Cultured cells in the absence of the confounding complexity of the tissue matrix with respect to carbohydrates are the means to dissect out the latter contribution.

Can the use of culture techniques raise the level of conceptualization of integrated physiology to new heights? Two lines of argument suggest that such is the case. First of all, the classic methods of discovering hormones—glandular ablation and injection of extracts—has probably run its course. This method will not serve for paracrine and autocrine factors, which are becoming recognized as real and important factors both for the regulation of normal cells and for the development of cancer. This point is aptly illustrated by the experiments of Salmon and Daughaday (1957) in the discovery of insulin-like growth factors and the experiment of De Larco, which first discovered the transforming growth factors (De Larco and Todaro, 1976). The second argument comes from the fact that when the serum of a medium is replaced with hormones, it is a complex mixture. Classic experiments tended to reveal a single hormone for a target tissue. What is the significance of this finding? Probably that  $10^{13}$  cells cannot coexist in a coordinated fashion in an organism without the finest subtlety in the regulation of its basic units. The simplicity we seek for intellectual satisfaction is likely to elude us. Probably simple unit processes are assembled in such great combinatorial complexity as to boggle the mind. The complexity of hormone mixtures required by cell cultures is only the tip of a large iceberg. These are the regulatory factors we can find by present methods. As new methods appear, the situation will become more complex.

Complexity and interactions in extracellular influences on cellular functions is not limited to hormones and growth factors, but includes nutrients and vitamins also, as shown by Ham and colleagues (see Bettger and Ham, 1982). These cellular responses and processes are as basic as those by which cells replicate and transcribe nucleic acid or translate proteins, and culture studies have been useful in devising therapeutic approaches to cancer. The human myelogenous leukemia cell line HL60 has played a pivotal role for studying differentiation of human leukemia cells. In particular, differentiation induced by all-*trans* retinoic acid (RA) led directly to the finding that cells from patients with acute promyelocytic leukemia [APL; French–American–British (FAB) classification M3] terminally differentiate in response to RA both *in vitro* and *in vivo* (Breitman *et al.*, 1980). Cytodifferentiation therapy of APL by RA is now an established alternate treatment for this disease. This therapy offers many benefits, including the decreased need for intensive hospital care. Kaoru Miyazaki showed similar effects on lung tumor cells in culture (Barnes *et al.*, 1981).

Takahashi and Breitman discovered retinoylation (retinoic acid acylation) a covalent modification of proteins occurring in a variety of eukaryotic cell lines (Breitman *et al.*, 1980). They also found that proteins in HL60 cells were labeled by  $17\beta$ -estradiol, progesterone,  $1,25-(OH)_2$  vitamin D, triiodothyronine, thyroxine, and prostaglandin  $E_2$  ( $PGE_2$ ). All of these hormones, except  $PGE_2$ , may be nongenomic and mediated by covalently modifying proteins. Are these reactions found in culture experiments operative in the animal, and what is their physiological significance? How dangerous is it to extrapolate cell culture results to the situation *in vivo*?

We have sought examples of culture experiments that have given erroneous results. Although these are not abundant, some possibilities can be cited. For instance, it is well recognized that cells often become chromosomally unstable and karyotypically abnormal as culture progresses (Todero and Green, 1963). A prediction of the diploid mouse chromosome number based on a 3T3 cell line karyotype, for example, would be grossly inaccurate. As another example, it is often observed that on continual passage in culture, cells are selected that are capable of producing autocrine growth factors. These may confer a selective advantage on the cell in culture and probably result

from aberrant expression of genes normally repressed in the cell type from which the cultures are derived. A direct application of observations using such cells to the normal endocrine physiology of the organism thus would be misleading.

It has been suggested that senescence *in vitro*, one of the accepted characteristics of normal cell cultures, may actually be an artifact, resulting from abnormal oxidative damage under routine culture conditions for other nonphysiological stresses, such as exposure to nonphysiological serum components (Ames *et al.*, 1993). Some cell types can be grown without senescence if the endocrine stimulation is appropriate (e.g., thyroid epithelial cells in the presence of thyroid-stimulating hormone *in vitro*), and these serum-free cells are inhibited by serum in the culture medium (Ambesi-Impiombato *et al.*, 1980; Loo *et al.*, 1987). In fact, serum is toxic at 100% for all cells in culture except for vascular endothelial cells. Certainly serum differs from interstitial fluid. What is toxic in serum? Is the factor(s) important in physiology? It is unlikely that we can recreate the *in vivo* environment of a cell sufficiently well as not to produce occasional artifacts. If an ovarian cell is implanted under the kidney capsule, a teratoma results. Surely we are at times placing cells in an unsuitable situation in culture as to evoke unnatural responses such as teratoma formation.

What problems seem important at the moment, related to the question of culture and *in vivo* relevance? We come back to the situation in which, when the serum in the medium of various cell types is replaced by hormones (factors), the cells require a complex mixture. Do these operate *in vivo* and how will we be able to tell? Part of the complexity is likely the result of redundancy of function among extracellular messengers, protecting the organism from catastrophic failure should interference occur with a single physiological signaling pathway. An understanding of the physiological significance of these more complex and interrelated interactions will probably require the most recent and sophisticated techniques: transgenic and gene knockout animals, highly specific synthetic hormone antagonists based on detailed knowledge of ligand–receptor interactions, and dominant negative receptor constructions based on a similarly detailed understanding of receptor interactions and signaling mechanisms. At the present time two very active fields of research using cell culture are the mechanism of hormone action and the nature of cancer. Cancer biology and hormone mechanism studies converge at several points at surface protein tyrosine kinases, at transcriptional control, and the hormonal stimulation of the transcription of protooncogenes. Hormone mechanism studies and cancer biology studies are most conveniently carried out in culture. The phenomena discovered in culture are so basic as surely to apply to the situation *in vivo*. In the case of cancer the oncogenes discovered *in vitro* are found in the animal and a therapeutic approach suggested by culture experiments is efficacious in humans.

Cohen found that epidermal growth factor (EGF) activates a tyrosine kinase that begins a complex cascade (Ushiro and Cohen, 1980). Hunter and Sefton (1980) found that the *src* oncogene is a tyrosine kinase that begins a cascade that results in overriding growth control. Nishizuka and Berridge have in culture studies elucidated the diacyl glycerol formation by phospholipase, the diacyl glycerol activation of protein kinases, and the mobilization of calcium by the phosphatidyl inositols (Nishizuka, 1986). Rodbell discovered G proteins, etc. Much of the present knowledge in these areas derived from work in animal virology and tumor virus biology, areas that are dependent on cell culture approaches in most respects.

Several neural progenitor cells have been identified first in cultures. Raff *et al.* (1983) showed that proliferating O-2A stem cells were able to differentiate into oligodendrocytes and type 2 astrocytes *in vitro*. Groves *et al.* (1993) demonstrated that week-old cultured O-2A progenitor cells could be successfully transplanted into demyelinated lesions in adult spinal cords and produce extensive remyelination. These data suggest the possibility of expanding O-2A progenitors in culture for transplants to humans afflicted with demyelinating disorders, e.g., multiple sclerosis. In addition, several groups are studying the effects of growth factors of O-2A progenitors, suggesting that endogenous regulation of adult O-2A progenitor proliferation may provide another therapeutic strategy to enhance remyelination.

Neural stem cells with the potential to give rise to differentiated subtypes of central nervous system neurons are of particular importance in future advances in tissue transplantation and engineering. These cultures cannot be established by routine means developed for rodent or human fibroblasts in serum-containing medium. For instance, one such line derived from mouse embryonic brains is dependent on epidermal growth factor for survival, and is growth inhibited by serum (Loo *et al.*, 1987). Cultured under serum-free conditions, these cells maintain a normal karyotype

despite extended passage in culture. These cells express astrocyte markers in the presence of transforming growth factor  $\beta$  (Sakai *et al.*, 1990), and express nestin, a marker of neural stem cells, in the neural precursor state in the absence of transforming growth factor  $\beta$  (Loo *et al.*, 1994). A variety of systems of this type exist, each requiring specialized cell culture techniques (see Chapter 58).

Cancer biology studies in culture are instructive to contemplate in regard to the relationship between *in vivo* and *in vitro* behavior. The Rous sarcoma virus assay was based on the formation of foci *in vitro*, which was based on the ability to overcome contact inhibition and grow in soft agar. These properties correlate well with tumorigenicity in the animal (Freedman and Shin, 1974). These aspects of cell culture behavior have been used to identify and isolate oncogenes. Cell culture experiments identifying oncogenes such as *ras* strengthen the argument that basic processes can be identified with assurance in cell culture, because these genes have subsequently been implicated in a variety of human tumors *in vivo* (Shi and Weinberg, 1982). Studies of transforming growth factors were an offshoot of tumor virology studies that depended on cell culture methodology almost entirely from conception to proof (De Larco and Todaro, 1976). Now it is clear that these molecules have important functions in basic processes such as embryonic development. That these molecules had not been discovered in the previous 50 years by scientists using the classic approaches of developmental biology points out the power of the cell culture approach to identify extracellular endocrine-like messengers.

In a related approach, human papilloma virus (HP16) genes E6 and E7 have been used to immortalize cells from fetal cartilage, lung epithelium, skin (keratinocyte), tracheal epithelium, pancreas, kidney, and liver (Thompson *et al.*, 1997; Zabrenetzky *et al.*, 1997). The viral genes are introduced via retrovirus vectors produced with a packaging cell line. Interestingly, human leukocyte antigen (HLA) Class I and Class II molecules are not expressed in these cells, suggesting potential for wide application to transplantation and tissue engineering if the neoplastic potential of the cells can be resolved favorably.

Cell culture approaches have contributed to major modern advances in the development and use of embryonal and lineage-specific stem cells. These provide essential models in studies of normal and abnormal biological processes, as well as potentially unlimited sources of differentiation-competent cells for tissue engineering. Differentiation toward multiple lineages can be induced in culture by treatment with retinoic acid, substratum manipulation, growth factor addition or withdrawal, and other approaches. Stem cell lines now include embryonal stem cells from rhesus monkeys, common marmosets, and humans (Thomson *et al.*, 1995, 1996, 1998; Thomson and Marshall, 1998), as well as human primordial germ cells developed by Gerhardt *et al.* (see Chapter 58). Tissue-specific stem cell precursor culture systems (both tissue and embryonal stem cell derived) exist for a variety of tissues, including cardiomyocyte, endothelial, neural, hematopoietic, liver, pancreas, and other endoderm-derived endocrine cell types.

We are passing from a period when the *in vivo* relevance of culture studies was rejected out of hand to a period of uncritical acceptance. We are counseling critical acceptance. In physics we are told we are nearing the end of knowing all we can about the material universe by knowing all the fundamental particles and their interactions. One day we will approach this situation in biology, when we know all the cells and their interactions. As we progress, we will transition from marveling at the enormity of what we do not know to marveling at the complexity, subtlety, and coordination of what we learn about the biochemistry of life.

#### ACKNOWLEDGMENT

We are grateful to Emily Amonett for stylistic and scholarly contributions to this chapter and for steadfast friendship over the years.

# REGULATION OF CELL BEHAVIOR BY MATRICELLULAR PROTEINS

Amy D. Bradshaw and E. Helene Sage

## INTRODUCTION

The extracellular milieu is critical for the control of the behavior of every cell in all tissues. Many factors can contribute to the environment of a cell—for example, cell–cell contact, growth factors, extracellular matrix proteins, and matricellular proteins. All of these components act together to regulate cell surface protein activity, intracellular signal transduction, and subsequent gene expression, which lead to proliferation, migration, differentiation, and ultimately the formation of complex tissues. This chapter focuses on matricellular proteins as modulators of extracellular signals. The matricellular proteins are characterized as secreted, modular proteins that are associated with the extracellular matrix but do not act as structural constituents (Bornstein, 1995). Presumably, the function of matricellular proteins is to provide a link between the extracellular matrix and the cell surface receptors, or the cytokines and proteases localized in the extracellular environment, the activity of which might be affected by this interaction. Thrombospondin-1 and thrombospondin-2, tenascin-C, osteopontin, and SPARC (an acronym for “secreted protein, acidic and rich in cysteine”) are representatives of this class of proteins. A growing body of evidence points to these proteins as important mediators of growth factor, extracellular matrix, and cell signaling pathways (Table 11.1). Consequently, *in vitro* systems designed to mimic tissue conditions should consider the influence of matricellular proteins.

## MATRICELLULAR PROTEINS

### THROMBOSPONDIN-1 AND THROMBOSPONDIN-2

Thrombospondin-1 is a 450,000-Da glycoprotein with seven modular domains (Bornstein and Sage, 1994). To date, five different paralogs of thrombospondin have been identified, thrombospondins-1–5. This chapter reviews the two most characterized forms, thrombospondin-1 and thrombospondin-2. At least five different extracellular matrix-associated proteins are able to bind to thrombospondin-1: collagens I and V, fibronectin, laminin, fibrinogen, and SPARC (Bornstein, 1995; Clezardin *et al.*, 1988). Likewise, cell surface receptors for thrombospondin are multiple and include the integrin family of extracellular matrix receptors (Bornstein, 1995; Hynes, 1992). Given the significant number and variety of thrombospondin-1-binding proteins, it is of little surprise that a wide variety of functions have been attributed to this protein, some of which appear to be contradictory. Many of these disparities may, however, actually reflect the dynamic interaction of thrombospondin-1 with other extracellular factors, which can influence cells in different ways to give rise to distinct cellular outcomes.

Several published studies describe the antiangiogenic properties of thrombospondin-1, whereas other investigators have reported an apparent stimulation of new blood vessel formation by thrombospondin-1. A potential source of variability is the assay used to perform the experiments.

**Table 11.1. Matricellular proteins<sup>a</sup>**

Protein	Extracellular matrix interaction	Receptor	Adhesive (+) vs. counteradhesive (-)	Growth factor modulation	Extracellular matrix formation
Thrombospondin-1	Col I and V, Fn, Ln, Fg	Integrin, CD-36	-	HGF (-), TGF- $\beta$ (+)	?
Thrombospondin-2	?	?	-	?	+
Tenascin-C	Fn	Integrin, annexin II	- +	EGF (+), bFGF (+), PDGF (+)	?
Osteopontin	Fn; Col I, II, III, IV, and V	Integrin, CD-44	+	?	+
SPARC	Col I, III, IV, and V	?	-	bFGF (-), VEGF (-), PDGF (-), TGF- $\beta$ (+)	+

<sup>a</sup>This is not a complete list of all activities and receptors for these proteins. For references, refer to the text. Abbreviations: Col, collagen; Fn, fibronectin; Ln, laminin; Fg, fibrinogen; HGF, hepatocyte growth factor; TGF- $\beta$ , transforming growth factor  $\beta$ ; EGF, epidermal growth factor; PDGF, platelet-derived growth factor; bFGF, basic fibroblast growth factor; VEGF, vascular endothelial growth factor.

A number of the studies that support an antiangiogenic function for thrombospondin-1 were carried out *in vitro* in a defined environment. For example, incubation of both aortic and microvascular endothelial cells with antithrombospondin antibodies significantly inhibited cord formation, a model of angiogenesis *in vitro* (Iruela-Arispe *et al.*, 1991). Likewise, aortic endothelial cells transfected with antisense thrombospondin-1 cDNA generated twice as many capillary-like structures on a gelled basement membrane in comparison to control cells that produce higher levels of thrombospondin-1 (DiPietro *et al.*, 1994). In contrast, the rat aortic explant model, in which thrombospondin-1 has been found to stimulate angiogenesis, is more complex, with many cell types that affect the outcome (Nicosia and Tuszynski, 1994). Rings of rat aorta grown in collagen or fibrin matrices supplemented with increasing amounts of thrombospondin-1 showed a concentration-dependent increase in the number of microvessels. Thrombospondin-1 did not appear to act directly on the endothelial cells in this assay, but rather affected the myofibroblasts present in the aortic rings by stimulation of their proliferation as well as their secretion of a heparin-binding protein(s). The authors speculated that perhaps the secreted protein could orient thrombospondin-1 in the matrix in such a way as to promote microvessel formation. The effect of thrombospondin-1 in angiogenic assays illustrates the versatility of function of this matricellular protein in distinct microenvironments. In all likelihood, the activity of thrombospondin-1 in these experiments reflects the interaction of the matricellular protein with specific cell surface receptors and other extracellular cytokines to elicit defined cellular responses.

One cytokine known to interact with thrombospondin-1 is scatter factor/hepatocyte growth factor (HGF), a known angiogenesis-promoting factor (Lamszuz *et al.*, 1996). Apparently, thrombospondin-1 is able to sequester HGF in the matrix through its association with other matrix molecules and prevent interaction of the cytokine with its cellular receptor. Thus in the rat corneal model of angiogenesis, thrombospondin-1 will inhibit HGF-induced neovascularization in a concentration-dependent manner (Lamszuz *et al.*, 1996).

Thrombospondin-1 has also been shown to interact specifically with another cytokine, transforming growth factor  $\beta$  (TGF- $\beta$ ) (Schultz-Cherry and Murphy-Ullrich, 1993). This interaction leads to activation of the latent form of TGF- $\beta$ , presumably through a conformational change in the cytokine that allows interaction with cell surface receptors (Schultz-Cherry *et al.*, 1994). Consequently, the presence of thrombospondin-1 in the extracellular milieu can affect the activity of this potent, multifunctional cytokine. In fact, generation of a thrombospondin-1 null mouse has confirmed the importance of thrombospondin-1-mediated activation of TGF- $\beta$  *in vivo*. The phe-

notype manifested in the absence of thrombospondin-1 expression mimics to some degree the phenotype of the TGF- $\beta$  null mouse (Crawford *et al.*, 1998). Specifically, similar pathologies of the lung and pancreas were observed in both mice; importantly, thrombospondin-1 null mice treated with thrombospondin-1 peptides showed a partial restoration of active TGF- $\beta$  levels and a reversal of the lung and pancreatic abnormalities toward tissues of wild-type mice.

Thrombospondin-1 is also able to influence cell adhesion and cell shape. For example, it will diminish the number of focal adhesions of bovine aortic endothelial cells and thus will promote a migratory phenotype (Murphy-Ullrich and Höök, 1989). Thrombospondin-1, therefore, has been proposed to modulate cell–matrix interaction to allow for cell migration when necessary. Accordingly, thrombospondin-1 expression is observed during events such as dermal wound repair, when cell movement is required (DiPietro *et al.*, 1996). Thrombospondin-1 is also expressed by many tumor cells and might also facilitate metastatic migration (Tuszynski and Nicosia, 1996; Weinstat-Saslow *et al.*, 1994). In fact, metastatic human carcinoma cells, transfected with antisense thrombospondin-1 cDNA to reduce thrombospondin-1 protein expression, lost their capacity to proliferate and metastasize in athymic mice (Castle *et al.*, 1991).

Fewer functional studies have been performed with thrombospondin-2, although a thrombospondin-2 null mouse has been generated that has revealed some interesting insight into this protein. Thrombospondin-2 has been shown to inhibit angiogenesis *in vivo*. Pellets containing recombinant thrombospondin-2 were implanted in the rat cornea to test whether neovascularization was enhanced. Thrombospondin-2 was able to inhibit basic fibroblast growth factor (bFGF)-induced vessel invasion to nearly the same degree as thrombospondin-1 (Volpert *et al.*, 1995). Thus, the observation that the thrombospondin-2 null mouse appears to have a greater degree of vascularization in the skin was in accordance with the hypothesis that thrombospondin-2 could serve as an endogenous regulator of angiogenesis in mice (Kyriakides *et al.*, 1998). In fact, the expression pattern of thrombospondin-2 is more consistent with the importance of this protein in vascular formation, because the mRNA for thrombospondin-2 is more closely associated with the vasculature in developing tissues in comparison to that of thrombospondin-1 (Iruela-Arsipe *et al.*, 1993). However, the mechanism by which thrombospondin-2 affects the degree of vascularization is unknown. Interestingly, another observation from the thrombospondin-2 null mouse was that of altered collagen fibrillogenesis in the skin, relative to that seen in wild-type mice. The collagen fibrils in the null mice were larger in diameter, had aberrant contours, and were disordered. Presumably this effect on collagen fibril formation resulted in less tensile strength of the skin in thrombospondin-2-null mice versus their wild-type counterparts (Kyriakides *et al.*, 1998).

Thrombospondin-1 and -2 can act as negative regulators of cell growth. In particular, endothelial cells are susceptible to an inhibition of proliferation by both proteins and, as such, have been classified as inhibitors of angiogenesis. However, the variety of cell surface receptors for thrombospondin allows for diverse signaling events in different cell types; consequently, there might be situations when thrombospondin appears to support angiogenesis as well. Thrombospondin-1 has been shown to modulate the activity of at least two cytokines, TGF- $\beta$  and HGF, and thus, either diminish activity, in the case of HGF, or enhance activity, as seen for TGF- $\beta$ . Finally, thrombospondin-1 can alter cell shape to promote a migratory phenotype. Further characterization of the thrombospondins, including closer examination of the remaining family members (thrombospondins 3–5), will no doubt yield fascinating insight into this multifunctional gene family.

## TENASCIN-C

Tenascin-C is a matricellular protein with a widespread pattern of developmental expression in comparison to a restricted pattern of expression in adult tissues (Koukoulis *et al.*, 1991). In addition to tenascin-C, two other less characterized forms of tenascin have been identified: tenascin-R and tenascin-X (Erickson, 1993; Jones and Copertino, 1996). This review focuses on tenascin-C, because it is the best characterized of the three known tenascins. Tenascin-C consists of six subunits (or arms) linked by disulfide bonds into a 2000-kDa molecule that can associate with fibronectin in the extracellular matrix (Erickson, 1993). Like thrombospondin-1, a number of different functions have been attributed to tenascin-C and, accordingly, a number of cell surface receptors appear to mediate distinct properties of this matricellular protein. At least five different integrins are known receptors for tenascin-C, as well as annexin II (Yokosaki *et al.*, 1996; Srira-

marao *et al.*, 1993; Chung *et al.*, 1996). Although the integrins appear to support cell adhesion to tenascin-C, annexin II is thought to mediate the counteradhesive function attributed to this protein. Hence, tenascin-C can act as either an adhesive or as a counteradhesive substrate for different cell types, dependent on the profile of receptors expressed on the cell surface (Crossin, 1996).

Tenascin-C has also been shown to modulate the activity of growth factors: specifically, it promotes epidermal growth factor (EGF)-dependent and bFGF-dependent cell growth (End *et al.*, 1992; Jones and Rabinovitch, 1996). In fact, Jones *et al.* (1997) have shown that smooth muscle cells plated in a collagen gel secrete matrix metalloproteinases (MMPs) that degrade the collagen to expose integrin receptor binding sites. Engagement of these receptors induces tenascin-C expression; tenascin-C is subsequently deposited into the extracellular matrix and can itself serve as an integrin ligand. The deposition of tenascin-C leads to cell shape changes initiated by a redistribution of focal adhesion complexes concomitant with a clustering of EGF receptors on the cell surface. Presumably, clustering of the EGF receptors facilitates EGF signaling and thereby enhances the mitogenic effect of EGF. Conversely, when MMP activity is inhibited, tenascin-C expression is decreased and the cells become apoptotic (Jones *et al.*, 1997). Thus, tenascin-C is able to modulate EGF activity such that the presence of this matricellular protein supports cell growth and its absence induces programmed cell death.

Given the widespread expression of tenascin-C in the developing embryo, the lack of an overt phenotype in the tenascin-C null mouse was surprising (Saga *et al.*, 1992). In particular, the high level of tenascin-C expression in the central and peripheral nervous systems had indicated that the absence of this protein might lead to neuronal abnormalities. Although no histologic differences could be detected in the brains of tenascin-C null mice, they do appear to have some behavioral aberrations (Steindler *et al.*, 1995; Fukamauchi *et al.*, 1996). Interestingly, the genetic background of the tenascin-C null mouse is likely to be a major factor in the identification of tissues in which tenascin-C might be functionally important. For example, Nakao *et al.* (1998) used three different congenic mouse lines to study the effect of Habu-snake venom-induced glomerulonephritis in a tenascin-C null background. Although the disease was worse in all tenascin-C null mice in comparison to wild-type controls, each line exhibited a different level of severity. Induction of the disease in one strain, GRS/A, resulted in death from irreversible renal failure. Moreover, mesangial cells cultured from tenascin-C null animals did not respond to cytokines such as platelet-derived growth factor (PDGF) unless exogenous tenascin-C was included in the culture medium (Nakao *et al.*, 1998). Hence, tenascin-C is also able to modulate the activity of this growth factor as observed previously for EGF. Tenascin-C provides another example of a matricellular protein able to affect growth factor efficacy.

Although tenascin-C shows a limited pattern of expression in the adult, an induction of tenascin-C is seen in many tissues undergoing wound repair or neoplasia (Mackie *et al.*, 1988; Higuchi *et al.*, 1993; Giachelli *et al.*, 1998). Thus tenascin-C, like the other matricellular proteins, is ideally suited to act as a modulator of cell shape, migration, and growth. That no developmental abnormalities are manifested in the tenascin-C null mouse points to the greater importance of tenascin-C in remodeling events that take place in response to injury or transformation.

## OSTEOPONTIN

As the name implies, osteopontin was originally classified as a bone protein. A more thorough examination, however, reveals a widespread expression pattern for this protein with multiple potential functions (Denhardt and Guo, 1993). Osteopontin associates with the extracellular matrix, in that it binds to fibronectin and to collagens I, II, III, IV, and V (Mukherjee *et al.*, 1995; Chen *et al.*, 1992; Butler, 1995). Osteopontin also affects cellular signaling pathways by virtue of its capacity to act as a ligand for multiple integrin receptors as well as CD44 (Denhardt and Noda, 1998; Weber *et al.*, 1996). Thus osteopontin, like most of the matricellular proteins, is able to act as a bridge between the extracellular matrix and the cell surface. Because matricellular proteins might be synthesized, secreted, and incorporated into the extracellular matrix with greater ease than more complex secreted proteins, which must be incorporated into fibrils and assembled into a network, a bridging function might be useful during remodeling events in the organism when rapid conversion of the cellular substrata is required for cell movement.

In support of this concept, Weintraub *et al.* (1996) showed that transfection of vascular smooth muscle cells with antiosteopontin cDNA reduced adhesion, spreading, and invasion of

three-dimensional collagen matrices. Addition of osteopontin to the collagen gel restored the ability of these cells to invade the gel. Interestingly, osteopontin also appears to be susceptible to modification by extracellular proteases, which have revealed cryptic integrin binding sites within the sequence. The protease thrombin cleaves osteopontin at the N-terminal domain and exposes an integrin  $\alpha 9 \beta 1$  binding site (Smith *et al.*, 1996; Smith and Giachelli, 1998). In addition, Senger *et al.* (1996) reported that endothelial cells treated with vascular endothelial growth factor (VEGF) increased their expression of the integrin  $\alpha v \beta 3$ , another osteopontin cell surface receptor, concomitantly with an increase in osteopontin. These investigators also showed an increase in the amount of thrombin-processed osteopontin in tissues injected with VEGF and radiolabeled osteopontin. The significance of this result lies in the enhanced support of endothelial cell migration *in vitro* by thrombin-cleaved versus full-length protein. Because the migratory activity of the endothelial cells was blocked partially by an anti- $\alpha v \beta 3$  antibody, the remainder of the activity was attributed to  $\alpha 9 \beta 1$  or to another cell surface receptor (Senger *et al.*, 1996).

The promotion of cell survival is another property ascribed to osteopontin. Denhardt and Noda (1998) have reported that human umbilical vein endothelial cells plated in the absence of growth factors will undergo apoptosis. If these cells are plated on an osteopontin substrate, however, apoptosis is inhibited. Furthermore, rat aortic endothelial cells subjected to serum withdrawal undergo programmed cell death, a response inhibited by an osteopontin substratum. In fact, it is the ligation of integrin  $\alpha v \beta 3$  by osteopontin at the cell surface that induces NF- $\kappa$ B, a transcription factor that controls a variety of genes through direct binding to their promoter regions. Thus osteopontin and other  $\alpha v \beta 3$  ligands can protect cells from apoptosis (Scatena *et al.*, 1998).

Finally, osteopontin appears to be involved in inflammatory responses. Expression of osteopontin was found to increase during intradermal macrophage infiltration, and purified osteopontin injected into the rat dermis led to an increase in the number of macrophages at the site of administration. Importantly, antiosteopontin antibodies inhibited macrophage accumulation in a rat intradermal model after a potent macrophage chemotactic peptide was used to induce an inflammatory response (Giachelli *et al.*, 1998).

The phenotype of the osteopontin null mouse supports the hypothesis that osteopontin can affect macrophage activity. Although the number of macrophages did not appear to differ significantly in incisional wounds of wild-type and osteopontin null mice, the amount of cell debris was higher in wounds of the latter animals. Because macrophages are thought to be primary mediators of wound debridement, osteopontin could be important in the regulation of macrophage function (Liaw *et al.*, 1998). Collagen fibril formation in the deeper dermal layers of the wounded osteopontin null mice also appeared to be affected. Osteopontin null mice have smaller collagen fibrils compared to wild-type controls. Similar to thrombospondin-2, osteopontin might affect collagen fibrillogenesis especially at wound sites, because no differences were seen in the size of collagen fibrils in unwounded skin (Liaw *et al.*, 1998).

Osteopontin and its repertoire of cell surface receptors represent components of a pathway used by cells in need of rapid movement or migration. In addition, the ligation of osteopontin by certain cell surface receptors supports cell survival and thus provides a mechanism for a given tissue to protect a subset of cells, expressing the appropriate receptor, from apoptosis. Hence, osteopontin is a useful protein in events that require cell movement and discriminate cell survival, such as wound healing and angiogenesis.

## SPARC

SPARC (also known as BM-40 and osteonectin) was first identified as a primary component of bone but has since been known to have a wider distribution (Lane and Sage, 1994). Increased expression of SPARC is observed in many tissues undergoing diverse remodeling events. For example, SPARC is found in the gut epithelium, which normally exhibits rapid turnover, and in healing wounds. An increase in SPARC is observed during glomerulonephritis, liver fibrosis, and in association with many different tumors. Like the other matricellular proteins, SPARC interacts with the extracellular matrix by binding to collagens I, III, IV, and V (Lane and Sage, 1994). SPARC has also been shown to bind to thrombospondin-1 and to a variety of growth factors present in the extracellular space. For example, SPARC binds to PDGF AB and BB and prevents their interaction with PDGF cell surface receptors. PDGF-stimulated mitogenesis is inhibited by the addition of SPARC (Raines *et al.*, 1992). SPARC can also prevent VEGF-induced endothelial cell

growth, in that it binds directly to the growth factor and thereby prevents VEGF receptor stimulation of the mitogen-activated protein kinases, Erk-1 and Erk-2 (Kupprion *et al.*, 1998). Interestingly, a variety of mitogenic stimulators are inhibited by SPARC in culture, some of which do not necessarily associate physically with this protein. For example, SPARC is thought not to bind to bFGF, but SPARC inhibits bFGF-stimulated endothelial cell cycle progression (Hasselaar and Sage, 1992). Apparently, the effect of SPARC on cell proliferation is complex and could occur through (1) a direct prevention of receptor activation and/or (2) a pathway mediated by a cell surface receptor recognizing SPARC. Unlike the other matricellular proteins described here, a receptor(s) for SPARC is currently unidentified.

Another significant effect of SPARC on cells in culture is its capacity to elicit changes in cell shape. Many cell types plated on various substrata retract their filopodia and lamellopodia and assume a rounded phenotype after exposure to SPARC. Bovine aortic endothelial cells, for example, are prevented from spreading in the presence of SPARC (Sage *et al.*, 1989). Clearly cell rounding could contribute to the inhibition of cell cycle, mentioned previously; however, these two effects of SPARC appear to be independent. Motamed and Sage (1998) have shown that inhibition of tyrosine kinases reverses the counteradhesive function of SPARC but has no effect on cell cycle inhibition. Thus, at least in endothelial cells, SPARC appears to mediate two aspects of cell behavior through different mechanisms.

The targeted inactivation of the SPARC gene in mice has allowed a more thorough examination of SPARC activity. In support of SPARC as a regulator of cell proliferation, primary mesenchymal cells isolated from SPARC null mice proliferated faster than did their wild-type counterparts. In addition, kidney mesangial cells exhibited a more spread morphology and a higher proportion of intact transcytoplasmic actin cables *in vitro* (Bradshaw *et al.*, 1999). These results indicate that the absence of endogenous SPARC affects the intracellular architecture that gives this cell type its characteristic shape. The identification of a SPARC receptor(s) will elucidate the distinct properties of SPARC in different cell types.

In addition to its effect on cell cycle, evidence shows that SPARC mediates extracellular matrix accumulation through a TGF- $\beta$ -dependent pathway. Mesangial cells isolated from SPARC null mice showed a decreased collagen I expression accompanied by a decrease in the levels of the cytokine TGF- $\beta$ 1 in comparison to wild-type cells. TGF- $\beta$  is a known positive regulator of extracellular matrix synthesis in the kidney (MacKay *et al.*, 1989). Addition of recombinant SPARC to SPARC null mesangial cultures restored the levels of collagen I and TGF- $\beta$  nearly to those of wild-type cells (Francki *et al.*, 1999). Thus it appears that SPARC can act as a regulator of TGF- $\beta$  and, by extension, collagen I in mesangial cells.

Once again, we see SPARC as an example of a multifunctional protein able to regulate cell shape and modulate growth factor activity. In addition, SPARC appears to govern cell cycle traverse, perhaps in some cases independently of direct growth factor interaction (Funk and Sage, 1991). Surprisingly, a cell surface receptor for SPARC has proved elusive, given that most other matricellular proteins appear to be ligands for a variety of receptors. Characterization of the SPARC receptor(s) will provide valuable information for understanding SPARC activity as well as the action of matricellular proteins in general.

## CONCLUSIONS

In addition to the proteins described here, others are also potential candidates for inclusion in the family of matricellular proteins. These include small proteoglycans such as the matrix-associated protein, decorin, which has been shown to be an endogenous regulator of TGF- $\beta$  activity (Border *et al.*, 1992), as well as the connective tissue growth factor, Cyr 61/Def10, and neuroblastoma overexpressed gene (CCN) gene family (Bork, 1993). The CCN family of proteins are secreted, modular, and show adhesive activity for various cell types. Cyr 61 enhances bFGF-induced mitogenesis in fibroblasts (Kireeva *et al.*, 1996). Furthermore, Cyr 61 protein associates with both the extracellular matrix and cell surfaces (Yang and Lau, 1991). Further analysis of these proteins and their actions will expand our comprehension of matricellular proteins and the functions they serve in regulating cell interaction with components of their immediate environment.

In any cellular environment, numerous extracellular signals are in place to control cell behavior. In adult tissues, injury and disease both lead to a wide-scale release of multiple factors, either secreted from cells or sequestered in the extracellular matrix, all of which are capable of elic-

iting potent cellular responses. Appropriately, an increase in the expression of many matricellular proteins is associated with pathologic events. Hence, the matricellular proteins appear to be ideally suited to act as modulators of these extracellular signals. They are able to serve as bridges between the extracellular matrix and cell surface receptors, such that cell shape changes or cell movements can be initiated prior to matrix breakdown or synthesis. At least three matricellular proteins, thrombospondin-2, osteopontin, and SPARC, appear to participate in matrix synthesis, either through the promotion of collagen fibrillogenesis or the enhancement of collagen production. Matricellular proteins can either inhibit or potentiate specific growth factor signal transduction pathways. Thus, different growth factor effects may be amplified or subdued by the presence or absence of these proteins. The fact that multiple receptors exist for most of the matricellular proteins allows for diverse functional consequences for different cell types in a complex tissue in response to a matricellular ligand. A given repertoire of cell surface receptors can stimulate (or inhibit) a particular pathway in a cell-type-dependent manner. Apparently, evolution has fine-tuned these proteins to serve as specialized mediators of extracellular signals that provide a coordinated, efficient resolution of tissue injury.

# GROWTH FACTORS

Thomas F. Deuel and Nan Zhang

## INTRODUCTION

Tissue remodeling is an essential component in the process of wound healing and thus in the normal maintenance and survival of all organisms. Tissue remodeling occurs throughout the entire temporal span of injury and repair. However, although abundant evidence using histologic methods has accumulated to detail the sequence of appearance of cell types that characterize wound healing, the mechanisms that initiate and sustain the process remain to be established (Ross, 1968; Deuel *et al.*, 1991; Pierce and Mustoe, 1995). What has become increasingly clear from analysis of properties of growth factors and other cytokines is their importance in the initiation and propagation of the processes that begin with injury and end with a healed wound. These factors and their receptors dictate cell type and tissue specificity of response, and the regulation of their genes at the level of transcription has established the time course of their expression. Their properties are those needed in the wound healing process.

Because growth factors applied directly to wounds accelerate the normal process of wound healing *in vivo*, it seems likely that the properties described for the growth factors *in vitro* are recapitulated *in vivo* (Grotendorst *et al.*, 1985; Paulsson *et al.*, 1987; Sprugel *et al.*, 1987; Pierce *et al.*, 1988, 1989a, 1991, 1992; Terracio *et al.*, 1988; Greenhalgh *et al.*, 1990; Hart *et al.*, 1990; Quaglino *et al.*, 1990; Shaw *et al.*, 1990; Antoniades *et al.*, 1991; Deuel *et al.*, 1991; Mustoe *et al.*, 1991; Nagaoka *et al.*, 1991; Soma *et al.*, 1992; Reuterdaahl *et al.*, 1993; Sundberg *et al.*, 1993; Pierce and Mustoe, 1995). It is also important to recognize that properties of growth factors may be important in the development of abnormalities in the vascular wall, such as atherosclerosis and in tumor growth, suggesting that deregulation of growth factors and other cytokines may have serious consequences for the host and that tight regulation of their activities is needed for normal function (Broadley *et al.*, 1989; Golden *et al.*, 1991; D'Amore and Smith, 1993; Forsberg *et al.*, 1993). Compelling evidence is therefore available to indicate the importance of growth factors and other cytokines in the wound healing process. However, the specific roles of these endogenous factors remain to be established in normal wound healing, and the signals that regulate the sites and time of their expression are little understood.

This chapter provides an overview of roles of the platelet-derived growth factor (PDGF) and other cytokines as models of factors that initiate and propagate a number of the normal processes required for the orderly progression of inflammation, tissue remodeling, and repair.

PDGF was initially described as a potent mitogen. However, PDGF directs cell migration, activates diverse cell types, and up-regulates expression of genes that otherwise are quiescent and not expressed at significant levels. This latter property of PDGF appears to establish gene activation pathways that are unique to different cell types. It provides a temporal sequence of expression of different pathways that may be of central importance in tissue remodeling and repair, a property required of a signaling molecule in the wound healing process. Experiments in which PDGF has been directly applied to wounds have shown that PDGF accelerates the normal healing process; it does not distort it, indicating that PDGF can up-regulate genes needed for wound healing in a

precise order. However, there is little if any information to establish the relative contributions of PDGF and different growth factors to the healing of normal wounds, and thus experimental strategies continue to focus on *in vitro* properties of growth factors. Additional models and reagents are needed to directly test these results *in vivo*.

## WOUND HEALING

Normal wound healing may be separated operationally into different stages that overlap and proceed in a clear sequence to a healed wound. Initially, platelets release granule products, and products of the coagulation process are deposited locally. The sequential migration of neutrophils, monocytes, and fibroblasts into wounds begins immediately and continues over the first several days. Wound macrophages (derived from circulating monocytes) and fibroblasts become activated, to initiate a cascade of new gene expression that results in *de novo* synthesis of growth factors and other cytokines, synthesis of extracellular matrix proteins (including collagen), and proliferation of fibroblasts. Later, tissue remodeling results in active collagen turnover and cross-linking that lasts from 2 weeks to 1 year postwounding.

Factors that arise locally account for the cell migration and activation of fibroblasts in wounds (Arey, 1936; Dunphy, 1963; Liebovich, 1975). However, circulating platelets are invariably associated with wounds and are now known to release factors originally stored within intracellular compartments, such as the platelet granules, into wounds. These factors attract neutrophils, monocytes, fibroblasts, and other (tissue-specific) cells, such as the smooth muscle cell. Platelets are now considered to be important mediators in the initiation of inflammation and subsequent tissue remodeling and repair. Platelet release is initiated by products of coagulation, such as thrombin, and by platelet exposure to foreign surfaces, such as collagen. Platelet release occurs within seconds of platelet activation. Synthesis of other potent molecules, such as the prostaglandins and leukotrienes, also influences intracellular responses and extracellular activities that contribute significantly to early events within wounds. These factors also initiate the transcriptional activation of genes that encode proteins with other signaling roles, serving to attract inflammatory cells locally. Because inflammatory cells are in close proximity to platelets in a number of models of inflammation (immune complex disease and atherosclerosis), it is likely that platelets are important in the earliest stages of different inflammatory states. Platelets and inflammatory cells appear to “talk” to each other in essential ways, through release of cytokines and growth factors to attract additional inflammatory cells and to activate transcription of factors that regulate or encode additional mediators of inflammation and wound repair. Studies with PDGF in the *in vivo* context support these functional roles for platelet secretory proteins.

PDGF was originally identified as a potent mitogen in serum for mesenchymally derived cells. Purified human PDGF is predominantly a heterodimeric molecule consisting of two separate but highly related polypeptide chains (A and B chains) (Hart *et al.*, 1990). The B chain of PDGF is ~92% identical with the protein product of the *v-sis* gene, the oncogene of simian sarcoma virus, an acute transforming retrovirus, and thus is a protooncogene. Both BB and AA homodimers of PDGF also have been isolated from natural sources and have been shown to be expressed in many cell types of diverse origins, including macrophages, endothelial cells, smooth and skeletal muscle cells, fibroblasts, glial cells, and neurons. These cells secrete molecules with PDGF-like activity. The detection of these molecules has been associated with the expression of the mRNAs for A and B chains that can be specifically associated with chain isoforms of PDGF. However, identification of the specific isoform(s) at the level of the protein has been difficult because reagents to detect each isoform specifically are not readily available. Multiple PDGF-AA transcripts have been detected in cells that appear to be alternative splice variants of a single seven-exon gene (Collins *et al.*, 1987; Tong *et al.*, 1987). Three splice variants result in short and long processed proteins, 110 and 125 amino acids (Collins *et al.*, 1987; Tong *et al.*, 1987; Matoskova *et al.*, 1989) in length, and may be important because of differential regulation of the transcripts and because they appear to bind with different affinities to the extracellular matrix (Ostman *et al.*, 1989; Nagaoka *et al.*, 1991). The transcripts for both proteins are widely expressed in multiple cell types.

Each of the three isoforms (BB, AB, and AA) binds to the PDGF- $\alpha$  receptor, whereas only the BB isoform binds with significant affinity to the type of PDGF receptor- $\beta$  (Hart *et al.*, 1988; Heldin *et al.*, 1988; Matsui *et al.*, 1989). Both receptor types are highly homologous transmembrane tyrosine kinases and are expressed in a cell type-specific manner, not only governing cell tar-

get specificity of the PDGF response (Eriksson *et al.*, 1992), but also adding both complexity and thus diversity to the potential roles of PDGF in inflammation and wound healing. The functions of PDGF *in vivo* thus are regulated by the need for specific ligand–receptor interactions to transduce the signals required for various functions of PDGF and the up-regulation of other genes that propagate the cascade of events initiated by PDGF.

### GROWTH FACTORS AND CYTOKINES ACTIVE AS EARLY MEDIATORS OF THE INFLAMMATORY PROCESS

In order to investigate and thus to understand the roles of growth factors and other cytokine mediators of inflammation, tissue remodeling, and wound healing, experimental strategies were designed to first isolate and characterize these factors, to analyze their properties *in vitro*, to determine the sites and levels of expression achievable *in vivo*, and to develop reagents and experimental models to analyze normal functions of growth factors and other cytokines in the intact animal. Early work focused on the roles of PDGF as a mitogen largely because it was the first mitogen to be purified. However, in addition to the striking potency of PDGF as a mitogen, PDGF also is strongly chemotactic for human monocytes and neutrophils, a property of PDGF that may be more important in early phases of inflammation. Optimal concentrations of PDGF that are required for maximum chemotactic and mitogenic activity are 20 and 1 ng/ml, respectively (Deuel *et al.*, 1982), concentrations of PDGF that are well below those measured in human serum (~50 ng/ml) (Deuel *et al.*, 1982). Because platelets aggregate and release at wound sites, the concentrations of PDGF at these sites may be substantially higher than those in serum. Furthermore, PDGF is a chemoattractant for fibroblasts and smooth muscle cells but requires a somewhat higher concentration (Seppa *et al.*, 1981; Senior *et al.*, 1983), suggesting that PDGF may also be involved later in wound healing through its influence on fibroblast and smooth muscle cell movement (Senior *et al.*, 1983).

In contrast to the PDGF AB isoform, the chemotactic potential of PDGF AA has been controversial. This controversy was important to resolve because the A chain homodimers of PDGF (PDGF AA) are widely expressed in normal and transformed cells. However, PDGF AA has been independently established as a strong chemoattractant for human monocytes, granulocytes, and fetal bovine ligament fibroblasts. Relevant to the roles of monocytes/tissue macrophages in the wound healing process, it was shown that highly purified (>98%) monocytes require the addition of lymphocytes or interleukin 1 (IL-1) for chemotactic responsiveness to PDGF AA but not for the chemotactic activity of formyl-methionyl-leucyl-phenylalanine (fMLP) or C5a. Monocytes therefore require activation before becoming responsive to PDGF as a chemoattractant. Activation of lymphocytes or exogenous cytokines is required for monocytes to respond chemotactically to PDGF AA but not to fMLP or C5a, suggesting that regulation of the chemotactic response of the monocyte to PDGF AA by the lymphocyte or cytokines may be another regulatory level of importance in the ultimate pathway to tissue remodeling and wound healing *in vivo* (Shure *et al.*, 1992).

The effect of PDGF on cell migration was extended to other platelet granule proteins when it was shown that  $\beta$ -thromboglobulin (TG- $\beta$ ) is a highly active chemotactic factor for fibroblasts (Senior *et al.*, 1983). Platelet factor 4 also is a potent chemoattractant. Lymphokines, a peptide derived from the fifth component of complement, collagen-derived peptides, fibronectin, tropoelastin, and elastin-derived peptides are wound-associated factors that also are potent chemoattractants with differing cell type specificity (Postlethwaite *et al.*, 1976, 1978, 1979; Senior *et al.*, 1982).

In addition to its roles in cell migration, PDGF also activates the polymorphonuclear leukocyte (Tzeng *et al.*, 1984) and is capable of inducing monocyte activation responses, as evaluated by generation of superoxide anion ( $O_2^-$ ) from the membrane-associated oxidase system, release of granule enzymes, and enhanced cell adherence and cell aggregation. Superoxide anion release in monocytes is observed at 10 ng/ml and the levels of PDGF-dependent release are comparable to release induced by  $10^{-7}$  ml/liter fMLP. The potency of PDGF to induce this response in monocytes is of the same magnitude as that observed in polymorphonuclear leukocytes (PMNs). Similarly, lysozyme release and monocyte adherence are increased in a dose-dependent manner in response to PDGF and achieve maximal responses at 40 ng/ml PDGF. The PDGF concentration required to achieve maximal monocyte aggregation was twofold (60 ng/ml) that found for PMNs and, at this concentration of PDGF, it is likely to occur only in the immediate vicin-

ity of platelet aggregates. PDGF thus induces the full sequence of cell activation events in human monocytes, similar to human PMNs, and this property may well be of major significance in the release of enzymes and other factors required to begin the process of tissue breakdown required for remodeling.

Other early cellular effects important to inflammation and repair also may be initiated by the release of PDGF from platelets and cells within the wound. For example, collagenase expression was studied in normal human skin fibroblasts that were cultured for 24 hr in the presence of PDGF. Collagenase release is required for the breakdown of collagen necessary for the later remodeling of collagen and for tissue repair (Gross, 1976; Bauer *et al.*, 1985; Pierce *et al.*, 1989b). A dose-dependent, saturable increase in collagenase activity in culture media was observed with paralleled increases in immunoreactive collagenase protein, suggesting the enhanced synthesis of an immunologically unaltered enzyme. The specificity of this effect was demonstrated by comparing the collagenase stimulatory effect with that on total protein synthesis and DNA synthesis. Under *in vitro* conditions that produced a 2.5-fold increase in collagenase synthesis, there was an ~20% increase in total protein synthesis and no detectable change in DNA synthesis. In addition, as a second control, platelet factor 4, another platelet-derived protein, caused a <20% increase in collagenase expression. In time-course studies, stimulation of collagenase synthesis was first observed 8–10 hr after exposure to the growth factor. Furthermore, when cells were exposed to PDGF for ~24 hr, an increase in the rate of collagenase synthesis was seen for ~6 hr after PDGF was removed, after which the rate reverted to control levels. Growth factor-regulated expression of collagenase may be of unique importance to tissue remodeling, because it occurs somewhat later than the most immediate responses to PDGF at the time collagen degradation may be essential for progression of remodeling and tissue repair (Bauer *et al.*, 1985).

Patients with Werner's syndrome, an autosomal recessive disorder, undergo an accelerated aging process and premature death. Fibroblasts from such patients typically grow poorly in culture but have a markedly attenuated mitogenic response to platelet-derived growth factor and fibroblast growth factor (FGF). In contrast, these cells have a full mitogenic response to fetal bovine serum. The Werner's syndrome cells express high constitutive levels of collagenase *in vitro*. However, no induction of collagenase occurs in the Werner's syndrome fibroblasts in response to PDGF. The coupling of the failure of one or more PDGF-mediated pathways in Werner's syndrome cells with the phenotype of this disorder is perhaps important support for roles of PDGF and other cytokines in tissue remodeling (Bauer *et al.*, 1986).

#### INFLAMMATORY RESPONSE MEDIATORS ACTIVATE TRANSCRIPTION OF QUIESCENT GENES

Another potentially highly important role of PDGF and other growth factors and cytokines in wound healing is the up-regulation of early-intermediate response genes in cells activated by PDGF. In response to PDGF and other cytokines, fibroblasts and other cells initiate transcription and expression of genes that are dormant in the absence of stimulation. The products of some of these genes are important in the intracellular propagation of the mitogenic signal but others are important for intercellular communication, directed cell migration, and activation of cells of different types. The products of these genes (Cochran *et al.*, 1983; Kohase *et al.*, 1987; Rollins *et al.*, 1988; Pierce *et al.*, 1989a,b) may serve to coordinate a second wave of diverse responses designated to combat wound infection and to initiate and propagate the healing process.

The PDGF early/early-intermediate response genes *JE* and *KC* were first isolated by differential colony hybridization (Cochran *et al.*, 1983) and only later were identified as cytokines belonging to a newly described superfamily of small inducible genes (SIGs) (Kawahara and Deuel, 1989) (now known as the chemokine family). This family surprisingly includes platelet granule proteins, such as the platelet basic protein and platelet factor 4. These PDGF-induced cytokines suggest pathways of gene activation that may account in part for cell type specificity and the normal temporal responses of wound healing. The *JE* gene encodes a basic ( $pI = 10.4$ ) 148-amino acid polypeptide (Rollins *et al.*, 1988; Kawahara and Deuel, 1989) that shows 82% amino acid identity with the murine *JE* gene (Timmers *et al.*, 1990). Both rat and murine *JE* gene products contain N-terminal hydrophobic leader sequences, virtually identical alternating hydrophobic and hydrophilic domains, a single N-linked glycosylation site at position 126 that is conserved in both the murine and rat *JE* genes, and identical intron–exon splice junctions.

The importance of the *JE* gene product was suggested when the human homolog of the rodent *JE* gene was identified as monocyte chemotactic protein-1 (MCP-1) (Yoshimura *et al.*, 1989b). MCP-1 is identical with monocyte chemotactic and activating factor (MCAF) (Furutani *et al.*, 1989), MCP (Decock *et al.*, 1990), HC11 (Chang *et al.*, 1989), and with the smooth muscle cell chemotactic factor (SMC-CF) (Graves *et al.*, 1989). Both the MCP-1 and rodent *JE* genes are induced in fibroblasts by PDGF [also serum, phorbol myristate acetate (PMA), double-stranded RNA, and interleukin-1] and each cross-hybridizes to the same bands on Southern blots (Rollins *et al.*, 1989). Antibodies raised to the murine *JE* cross-react with MCP-1. MCP-1 is a potent factor chemotactic for monocytes but not for neutrophils (Yoshimura *et al.*, 1989a), a specificity of cell type recognition that is not seen with many of the other chemotactic factors that have been characterized (Senior *et al.*, 1989), suggesting a unique role in the inflammatory process. Other cytokines with sharply defined functional activity also have been identified in the chemokine family. MCP-1/SMC-CF or related molecules appear to be the major chemotactic factor(s) released by a number of tumor cell lines as well (Graves *et al.*, 1989). This relationship calls to attention the surprising parallels that have been found between tumor cells and activated cells such as the fibroblast.

The genes of this family are normally not expressed at detectable levels but can be induced in the presence of the appropriate stimuli. Remarkably, each of the inducers has an important role in cell growth, inflammation, or immune responses. Increasing knowledge of this family of genes and their products has suggested an enlarging role for PDGF and other cytokines in the sequential and cell type-specific development of inflammation and the evolution of the wound healing process (Kawahara *et al.*, 1991).

#### BIOLOGIC PROPERTIES OF SIG (CHEMOKINE) FAMILY MEMBERS

Neutrophil activation protein/IL-8 (NAP-1/IL-8) is a highly cell type-specific activator and chemotactic factor for neutrophils but not monocytes (Yoshimura *et al.*, 1987). NAP-1/IL-8 was identified in conditioned medium of lipopolysaccharide-stimulated monocytes (Walz *et al.*, 1987; Yoshimura *et al.*, 1987) and its gene (*3-10C*) was cloned independently as a staphylococcal enterotoxin A-induced gene from peripheral blood leukocytes (Schmid and Weissmann, 1987). NAP-1 is also chemotactic for T lymphocytes and basophils (Larsen *et al.*, 1989; Leonard *et al.*, 1990) and is the N-terminal processed form of endothelial-derived leukocyte adhesion inhibitor (LAI), an inhibitor of neutrophil adhesion that protects endothelial cells from neutrophil-mediated damage (Gimbrone *et al.*, 1989; Kawahara *et al.*, 1991).

MCP-1 is chemotactic for monocytes. It was purified from the culture media of human glioma cell line U-105MG (Yoshimura *et al.*, 1989a), THP-1 cells (Matsushima *et al.*, 1989), phytohemagglutinin-stimulated mononuclear cells (Robinson *et al.*, 1989), and double-stranded RNA [poly(rI)·poly(rC)]-stimulated fibroblasts (Van Damme *et al.*, 1989; Kawahara *et al.*, 1991).

Macrophage inflammatory protein-1 (MIP-1) was purified in two forms (MIP-1, MIP-2) from lipopolysaccharide-stimulated RAW264.7 cells and is chemotactic for polymorphonuclear cells (Wolpe *et al.*, 1988). MIP-1 induces oxidative burst and degranulation in neutrophils and promotes inflammatory reactions. MIP-1 is also a prostaglandin-independent pyrogen (Davatellis *et al.*, 1989). MIP-2 is a potent chemotactic factor for neutrophils and causes neutrophil degranulation, but does not induce an oxidative burst (Kawahara *et al.*, 1991).

Platelet factor 4 (PF4) is a platelet granule protein that is chemotactic for both neutrophils and monocytes (Deuel *et al.*, 1981). It has immunoregulatory activity (Katz *et al.*, 1986) and can inhibit angiogenesis (Maione *et al.*, 1990). Platelet basic protein, connective tissue-activating peptide III (CTAP-III),  $\beta$ -thromboglobulin, and neutrophil-activating peptide-2 (NAP-2) are N-terminal proteolytic processed forms of a single gene product, CTAP-III is mitogenic for human dermal fibroblasts (Castor *et al.*, 1983), and NAP-2 is induced in monocytes when they are exposed to lipopolysaccharide and can stimulate the release of elastase from human neutrophils (Walz and Baggiolini, 1986; Kawahara *et al.*, 1991).

Melanoma growth stimulatory activity (MGSA) is a mitogen for cultured melanoma and pigmented (nevus) cells (Richmond *et al.*, 1988). Primary melanoma cells secrete MGSA and for this reason it has been suggested to be an autocrine regulator of growth. The protein product of MGSA is identical to the *gro- $\alpha$*  gene isolated by subtractive hybridization of mRNA from transformed hamster CHEF/16 cells. The rat analog, cytokine-induced neutrophil chemoattractant (CINC),

is chemotactic for neutrophils (Watanabe *et al.*, 1989). The murine analog (KC) is a PDGF inducible gene (Cochran *et al.*, 1983; Kawahara *et al.*, 1991).

### REGULATION OF *JE* GENE EXPRESSION BY GLUCOCORTICOIDS

The role of PDGF and other cytokines in the induction of otherwise unexpressed genes has resulted in additional insights into the wound healing process. The addition of dexamethasone and other steroid drugs to PDGF- and serum-stimulated BALB/c 3T3 fibroblasts prevents the PDGF- and serum-dependent induction of the *JE* gene in a dose-dependent manner. Furthermore, induction follows the rank order of potency expected for glucocorticoid receptor-mediated antiinflammatory activity. The inhibition appears to be highly specific for inflammatory mediators, suggesting that the role of PDGF in the induction of selective SIG family members may be a highly important step at which glucocorticoids negatively influence both inflammation and repair (Kawahara *et al.*, 1991).

### GROWTH FACTORS AND ACCELERATED HEALING

Much new information vis-à-vis the roles of growth factors and other cytokines has resulted from the direct application of PDGF to experimental wounds in animals. Morphometric methods and histologic techniques have been used to compare wounds treated with supraphysiological concentrations of growth factors to untreated wounds. This approach, coupled with the *in vitro* approaches cited above, has greatly clarified roles of PDGF-enhanced tissue repair and remodeling and has stimulated similar experiments with other cytokines as well.

In one set of experiments, exogenous PDGF was applied locally, and once only, to incisional wounds in rats and rabbits. PDGF accelerated tissue repair in a dose-dependent manner (Pierce *et al.*, 1988; Mustoe *et al.*, 1991). The single application of PDGF to rat incisions enhanced by 150 to 170% over a 3-week time course the strength required to “break” the healing wound (Pierce *et al.*, 1988). PDGF accelerated healing by 4–6 days over the first 2 weeks and by 5–10 days between 2 and 7 weeks postwounding (Pierce *et al.*, 1989a). At 89 days postwounding, both PDGF-treated and control wounds had achieved similar wound strength (~90% of unwounded dermis), and doses therefore induced a long-lasting enhancement rate of healing, supporting the view that PDGF and other growth factors initiate events required for normal healing of wounds and enhance the normal rate of wound healing and tissue remodeling.

In these wounds, PDGF significantly increased the rate of increase of cellularity and granulation tissue formation. The early appearance of wounds treated with PDGF is that of a highly exaggerated inflammatory response. An increased neutrophil influx was seen at 12 hr. A marked increase in influx of macrophages and, later, fibroblasts was found from day 2, persisting through 21 days postwounding (Pierce *et al.*, 1988). Furthermore enhanced cellular function of fibroblasts could be established in treated wounds. Increased numbers of procollagen-containing fibroblasts were strikingly apparent as early as 2 days postwounding. At 28 days, it was not possible to distinguish activated from nonactivated fibroblasts in treated and untreated wounds. These results indicate that PDGF accelerates the healing response.

Furthermore, within limits of detection, PDGF also results in a healed wound that cannot be distinguished from its untreated counterpart (Pierce *et al.*, 1989a). PDGF also appears to be multifunctional in diverse ways, perhaps through the recruitment and activation of macrophages and fibroblasts and through up-regulation of expression at different cytokine genes whose functions and cell type specificity provide additional diversity to the normal healing process.

Another polypeptide growth factor that is stored in the granules of platelets, transforming growth factor  $\beta$  (TGF- $\beta$ ), may also be very important in tissue repair (Sporn *et al.*, 1986). Both PDGF and TGF- $\beta$  increase collagen formation, DNA content, and protein levels in wound chambers implanted in rats (Sporn *et al.*, 1983; Grotendorst *et al.*, 1985). TGF- $\beta$  enhances the reversible formation of granulation tissue when injected subcutaneously into newborn mice (Roberts *et al.*, 1986). A single application of human TGF- $\beta$  at the time of wounding advanced by 2–3 days the breaking strength required to rupture the incision margins after when assayed at 1 week. The marked augmentation of wound healing using both human PDGF (hPDGF) and recombinant *cis*-homodimers (rPDGF-B) revealed a unique pattern of response when compared with the results obtained with TGF- $\beta$  (Mustoe *et al.*, 1987; Pierce *et al.*, 1988).

Circular excisional wounds also were placed through the dermis of the rabbit ear to the level

of underlying cartilage, a model that does not allow contraction from the wound margins (Mustoe *et al.*, 1991). Ingrowth of extracellular matrix and granulation tissue was measured by histomorphometric techniques (Mustoe *et al.*, 1991). A single application of PDGF increased granulation tissue ~200% at 7 days in association with a predominance of fibroblasts and collagen-containing extracellular matrix (Mustoe *et al.*, 1991). The healed wound again was indistinguishable from the control, non-PDGF-treated healed wound. Interestingly, PDGF also nearly doubled the rate at which reepithelialization occurred and neovascularization was prominent in granulation tissue. These unexpected findings in view of the known cell type specificity of PDGF suggested up-regulation either of PDGF receptors or of other cytokine genes with resultant cell type-specific epithelial and/or endothelial cell functions. Whereas again the mechanisms of the PDGF effect are not established, the influence of a single application of a growth factor remarkably accelerated the inflammatory response and the subsequent tissue remodeling to result in a healed wound of normal appearance.

In this model, PDGF accelerated deposition of matrix largely composed of glycosaminoglycans and later of collagen (Pierce *et al.*, 1991). The normal sequence in repair and the acceleration of wound healing, to all appearances, are identical to those in an untreated wound, supporting the view that the role of PDGF is to accelerate normal wound healing in human wounds. It has been demonstrated in human wounds that PDGF AA expression is increased within healing pressure ulcers. The accumulation of PDGF AA is accompanied by activated fibroblasts, extracellular matrix deposition, and active neovessel formation. However, far less PDGF AA is present in chronic nonhealing wounds. Thus, up-regulation of PDGF AA may be important in the normal repair process as well (Robson *et al.*, 1992; Mustoe *et al.*, 1994; Pierce *et al.*, 1994).

PDGF BB, bFGF, and epidermal growth factor (EGF), applied locally at the time of wounding, cause a twofold increase in complete reepithelialization of treated wounds, whereas TGF- $\beta$  significantly inhibits reepithelialization. Both PDGF BB and TGF- $\beta$  increased the depth and area of new granulation tissue, the influx of fibroblasts, and the deposition of new matrix into wounds. Explants from treated wounds remained metabolically more active than controls, incorporating 473% more [ $^3$ H]thymidine into DNA and significantly more [ $^3$ H]leucine and [ $^3$ H]proline into collagenase-sensitive protein (Mustoe *et al.*, 1991). The different response to growth factors underscores the importance of tissue and cell type specificity of the growth factors to tissue repair and perhaps also the need for exquisite timing of induction of different factors in the orderly progression of the healing process.

The use of these wound healing models provided the basis to suggest at least one mechanism whereby PDGF may function *in vivo* (Mustoe *et al.*, 1989; Pierce *et al.*, 1989a). Animals that were pretreated with glucocorticoids or total body irradiation to reduce circulating monocytes to non-detectable levels had a sharply reduced influx of wound macrophages. PDGF was tested in these animals. It was shown that the PDGF-induced acceleration of incisional repair was abrogated in glucocorticoid-treated animals (Pierce *et al.*, 1989a). However, PDGF attracted a significant influx of fibroblasts into the compromised wounds of animals. The fibroblasts lacked procollagen type I, suggesting the requirement of the wound macrophage to support stimulation of fibroblast procollagen type I synthesis. PDGF alone does not stimulate procollagen type I synthesis when added directly to fibroblasts *in vitro* (Blatti *et al.*, 1988; Rossi *et al.*, 1988). However, PDGF-activated macrophages synthesize TGF- $\beta$  (Pierce *et al.*, 1989a), a potent activator of the fibroblast procollagen type I gene (Ignatz and Massague, 1986; Rossi *et al.*, 1988). It is suggested that TGF- $\beta$  may be a second signal messenger to induce collagen formation in PDGF-treated wounds. This suggestion is supported directly in experiments in which macrophages and fibroblasts in PDGF-treated incisional wounds were shown to contain increased levels of intracellular TGF- $\beta$  (Pierce *et al.*, 1989a).

The results with wound healing models and PDGF have illustrated much about inflammation, tissue remodeling, and the process of wound healing. Other *in vivo* models of PDGF-treated wounds also indicate that PDGF stimulates normal and reverses deficient dermal repair (Grotendorst *et al.*, 1985; Lynch *et al.*, 1987; Sprugel *et al.*, 1987; Greenhalgh *et al.*, 1990), and have suggested roles for this growth factor in inflammation (Circolo *et al.*, 1990), uterine smooth muscle hypertrophy (Mendoza *et al.*, 1990), lens growth and transparency (Brewitt and Clark, 1988), and central nervous system gliogenesis (Richardson *et al.*, 1988). What may be the most important conclusions are that PDGF has the potential to initiate and accelerate the process and to sus-

tain the process to an end point that is effectively identical to untreated wounds. The most important mechanisms of its activity may be the consequences of its potent chemotactic activity and its ability to induce multiple autocrine loops that lead to an endogenous cascade of new gene activation and cell-specific cytokine synthesis within the healing wound. Clinical trials have now established the efficacy of PDGF in advancing the healing of diabetic ulcers. PDGF is now "in the clinic."

### ROLE OF BASIC FIBROBLAST GROWTH FACTOR AND ANGIOGENESIS

Normal wound healing can be divided into three phases: inflammation, fibroplasia, and maturation provoked by liberated angiogenic factors. Vessel-dense granulation tissue is central to the process of tissue repair. The formation of new blood vessels provides a route for oxygen and nutrient delivery, as well as a conduit for components of the inflammatory response. Endogenous bFGF, like PDGF, is also found in the wound site and is presumed to be a necessary part of natural wound healing. Mechanically damaged endothelial cells and burned wound tissue release significant amounts of bFGF into the wound area, suggesting that damaged endothelial cells at the cut edges of blood vessels, as well as other damaged cells at the site of a wound, may provide an early source of bFGF (McNeil *et al.*, 1989; Muthukrishnan *et al.*, 1991; Gibran *et al.*, 1994). A slightly later and more sustained supply of bFGF at the wound site is delivered by the invading activated macrophages (Baird *et al.*, 1985; Rappolee *et al.*, 1988; Fiddes *et al.*, 1991). Moreover, recombinant bFGF has been shown to enhance healing, if added exogenously to a wound site (Brew *et al.*, 1995). It is now clear that bFGF can act as an angiogenic factor *in vitro* (Montesano *et al.*, 1986) and *in vivo* (Folkman and Klagsbrun, 1987), directing endothelial cell migration and proliferation, and that bFGF is a mitogen to endothelial cells. It also up-regulates expression of plasminogen activator and the  $\alpha v \beta 3$  integrin that promotes both migration of endothelial cells and luminal formation (Pepper *et al.*, 1991; Friedlander *et al.*, 1995). The effects of stimulating endothelial cell growth, capillary differentiation, and connective tissue cell growth by bFGF contribute to wound healing and tissue regeneration (Gibran *et al.*, 1994; Steenfos, 1994).

Wound healing involves the interactions of many cell types, and is controlled in part by growth factors. Intercellular communication mediated by gap junctions is considered to play an important role in the coordination of cellular metabolism during the growth and development of tissues and organs. Basic fibroblast growth factor, known to be important in wound healing, has been found to increase gap junctional protein annexin 43 expression and intercellular communication in endothelial cells and cardiac fibroblasts (Abdullah *et al.*, 1999). It has been proposed that an increased coupling is necessary for the coordination of these cells in wound healing and angiogenesis, and that one of the actions of bFGF is to modulate intercellular communication. In a variety of animal models, exogenous bFGF has been shown to accelerate wound healing by speeding granulation tissue formation and increasing fibroblast proliferation and collagen accumulation at the site of a subcutaneously implanted sponge in rats (Davidson *et al.*, 1985; Buckley-Sturrock *et al.*, 1989). Fresh wound tensile strength has also been increased (McGee *et al.*, 1988). However, the greatest benefit from the application of exogenous bFGF can probably be obtained in cases in which wound healing is impaired. Research on skin flaps indicates that bFGF has the potential to increase viability by accelerating flap revascularization when administered in a sustained release manner (Hom and Winters, 1998). This may have applications to open or nonunion fractures with impaired wound healing. Despite encouraging experimental results to date coming from studies showing that treatment of genetically diabetic mice with recombinant bFGF not only increased fibroblast and capillary density in the wound, but also accelerated wound closure, clinical application of recombinant human bFGF has fallen short of expectations. In a randomized double-blind placebo-controlled study, direct application of bFGF to nonhealing ulcers of diabetic patients did not accelerate wound healing (Richard *et al.*, 1995). In a subsequent randomized placebo-controlled trial to study the effect of recombinant bovine bFGF on burn healing, all patients treated with bFGF had faster granulation tissue formation and epidermal regeneration, compared with those in the placebo group. Superficial and deep second-degree burns treated with bFGF healed in a mean of 9.9 days (SD 2.5) and 17.0 days (SD 4.6), respectively, compared with 12.4 (2.7) and 21.2 (4.9) days. No adverse effects were seen locally or systematically with bFGF.

It is indicated that bFGF effectively decreased healing time and improved healing quality. Clinical benefits for use of bFGF in burn wounds would be shorter hospital stays and the patients' skin quickly becoming available for harvesting and grafting (Fu *et al.*, 1998).

## OTHER ROLES OF GROWTH FACTORS AND CYTOKINES

A growing appreciation for roles of growth factors in many normal and abnormal processes is emerging from numerous other investigations of a diverse nature. For example, TGF- $\alpha$  and TGF- $\beta$  are expressed with high specificity in developing mouse embryo (Twardzik, 1985; Heine *et al.*, 1987), PDGF may mediate normal gliogenesis (Richardson *et al.*, 1988); maternally encoded FGF, TGF- $\beta$ , and PDGF have been implicated as important in the developing *Xenopus* embryo (Kimelman and Kirschner, 1987; Weeks and Melton, 1987; Mercola *et al.*, 1988); and bFGF is a potential neurotrophin during development (Anderson *et al.*, 1988). PDGF also has been identified within plaques and is a potent vasoconstrictor and thus has been implicated in the genesis of atherosclerosis (Berk *et al.*, 1986; Libby *et al.*, 1988). Furthermore, it is secreted from endothelial cells and arterial smooth muscle cells (Jaye *et al.*, 1985; Sejersen *et al.*, 1986; Martinet *et al.*, 1987; Tong *et al.*, 1987; Barrett and Benditt, 1988; Majesky *et al.*, 1988; Rubin *et al.*, 1988) and activated monocytes/macrophages (Martinet *et al.*, 1987). Elevated levels of PDGF receptors are found on synovial cells in patients with rheumatoid arthritis (Rubin *et al.*, 1988). In each instance, however, when the *in vitro* studies are considered in the context of roles of the growth factors in inflammation and tissue repair, it seems likely that common roles of growth factors are associated with normal development and the abnormal remodeling is associated with disease states, indicating the importance of attention to mechanisms that regulate cell type and temporal levels of expression of the growth factors and their cognate receptors.

## CONCLUSIONS

Much needs to be learned concerning the roles of growth factors and cytokines if we are to establish fully how they function in both normal and dysregulated tissue remodeling. Remarkable progress over the past several years has resulted from the identification, isolation, cloning, and characterization of the properties of these molecules and their use in wound healing models. The most important lesson learned from their use appears to be that the growth factors and cytokines are important to initiate and accelerate the normal processes involved in going from injury to repair. Questions for future avenues of investigation should address mechanisms by which these factors initiate and propagate the processes and the regulatory signals that govern cell type specificity, differentiation responses in cells migrating into and dividing within wounds, and the temporal sequences needed for orderly progression to a healed and ultimately functional tissue.

# TISSUE ENGINEERING BIOREACTORS

Lisa E. Freed and Gordana Vunjak-Novakovic

## INTRODUCTION

One approach to tissue engineering is to create an *in vitro* environment that embodies the biochemical and mechanical signals that regulate tissue development and maintenance *in vivo*. Figure 13.1 shows our *in vitro* tissue engineering system, which has three major components (Freed and Vunjak-Novakovic, 1998): (1) metabolically active cells able to express their differentiated phenotype, (2) polymeric scaffolds that provide a three-dimensional (3D) structure for cell attachment and tissue growth, and (3) bioreactor culture vessels that provide an *in vitro* environment in which cell–polymer constructs can develop into functional tissues. These constructs can potentially be used *in vitro*, for controlled studies of tissue growth and function, or *in vivo*, for tissue repair. As compared to *in vivo* implantation of dissociated cells and/or biodegradable materials alone, the implantation of a functional engineered tissue can improve the localization of cell delivery and promote graft fixation and survival. In addition, *in vitro* bioreactor studies can be designed to distinguish the effects of specific biochemical and physical signals from the complex *in vivo* milieu (e.g., host endocrinologic and immunologic responses), thus providing useful, complementary information regarding the process of the formation of 3D tissues starting from isolated cells.

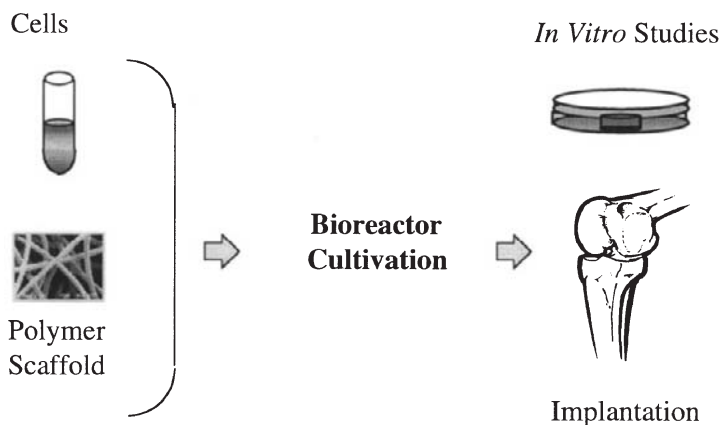

In this chapter, we focus on tissue engineering bioreactors, which will be defined as *in vitro* culture systems designed to perform at least one of the following four functions: (1) establish spatially uniform cell distributions on 3D scaffolds, (2) maintain desired concentrations of gases and nutrients in the culture medium, (3) provide efficient mass transfer to the growing tissue, and (4) expose developing tissues to physical stimuli. We further focus this chapter on engineered tissues based on biodegradable cell culture templates, although bioreactors are also being utilized in conjunction with nondegradable cell culture substrates (e.g., microcarriers, hollow fibers, membranes) to study the assembly of cells into 3D structures (e.g., Jessup *et al.*, 1993; Unsworth and Lelkes, 1998; Qiu *et al.*, 1999) and to develop hybrid bioartificial organs (e.g., Jauregui *et al.*, 1997; Lanza and Chick, 1997; Bader *et al.*, 1995).

The dimensional and functional requirements of the tissue to be engineered determine the specific design requirements for the cell–polymer–bioreactor system. In this chapter, we will use two examples of engineered tissues, cartilage and cardiac muscle, to illustrate general and tissue-specific principles of bioreactor design and operation.

## CELL–POLYMER CONSTRUCTS

Cell types studied using our model system (Fig. 13.1) were obtained from cartilage, bone marrow, or cardiac muscle of developmentally immature animals. In particular, we have studied articular chondrocytes from 2- to 4-week-old bovine calves (Freed *et al.*, 1994b) and 2- to 8-month-old rabbits (Freed *et al.*, 1994a), bone marrow stromal cells from 16-day-old embryonic chicks (Martin *et al.*, 1998) and 2- to 4-week-old bovine calves (Martin *et al.*, 1999a), and cardiac cells from 14-day-old embryonic chicks and 1- to 2-day-old neonatal rats (Carrier *et al.*, 1999). Cells

Fig. 13.1. Tissue engineering system. Cells (e.g., isolated from cartilage or cardiac tissue) are seeded onto three-dimensional polymer scaffolds (e.g., fibrous meshes) using bioreactors (e.g., spinner flasks, rotating vessels, or perfused cartridges). The resulting engineered tissue constructs can be used either for *in vitro* research or *in vivo* implantation (Freed and Vunjak-Novakovic, 1998).

were isolated by enzymatic digestion, in some cases serially expanded in monolayers, and inoculated into bioreactors containing 3D polymer scaffolds.

The polymer scaffold we have best characterized and most used to date is made of polyglycolic acid (PGA), processed into a 97% porous, nonwoven mesh of fibers 13  $\mu\text{m}$  in diameter (Freed *et al.*, 1994c). The average distance between the fibers was calculated to be 62  $\mu\text{m}$  (Vunjak-Novakovic *et al.*, 1998). This scaffold decreases its mass by 50 or 70% after 4 or 8 weeks of cultivation, respectively (Freed *et al.*, 1994c). In this chapter, we consider our “scaffold” to be a fibrous PGA disk with a diameter of 5 mm and a thickness of 2 mm.

Structural assessments of engineered tissues include (1) presence and spatial arrangement of cells and extracellular matrix (ECM), determined histologically, immunohistochemically, and by electron microscopy (e.g., Riesle *et al.*, 1998; Carrier *et al.*, 1999), (2) quantitative distributions of specific components, determined by computer-based image analysis of histological sections (Martin *et al.*, 1999b; Vunjak-Novakovic *et al.*, 1998), (3) cell number, determined from the amount of DNA (Kim *et al.*, 1988), (4) sulfated glycosaminoglycan (GAG) content, determined by dimethylmethylene blue dye binding (Farndale *et al.*, 1986), (5) total protein content, determined by a Biorad protein assay kit (Carrier *et al.*, 1999), (6) total collagen content, determined from hydroxyproline (Woessner, 1961), (7) type II collagen content, determined by inhibition enzyme-linked immunosorbent assay (ELISA) (Freed *et al.*, 1998), and (8) amounts of type IX collagen, creatine kinase, and sarcomeric myosin, determined by densitometric analysis of Western blots (Riesle *et al.*, 1998; Papadaki *et al.*, 1999).

Functional assessments of engineered tissues include (1) cell metabolism, assessed from glucose consumption and lactate production (Obradovic *et al.*, 1999) and from enzymatic conversion of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) (Carrier *et al.*, 1999), (2) cell damage, assessed from medium concentrations of lactate dehydrogenase (LDH) (Carrier *et al.*, 1999), (3) ECM synthesis rates, determined by macromolecular incorporation of radiolabeled tracers (Freed *et al.*, 1998), (4) cartilage mechanical properties (equilibrium modulus, dynamic stiffness, hydraulic permeability, streaming potential), determined in static and dynamic radially confined compression (Vunjak-Novakovic *et al.*, 1999a), and (5) cardiac tissue electrophysiological properties (conduction velocity, signal amplitude, excitation threshold, maximum capture rate), assessed from macroscopic impulse propagation studies using an array of extracellular electrodes (Bursac *et al.*, 1999).

## BIOREACTOR TECHNOLOGIES

### CELL SEEDING

Cell seeding of 3D scaffolds is the first step of bioreactor cultivation of engineered tissues. Seeding requirements include (1) high yield, to maximize cell utilization, (2) high kinetic rate, to minimize the time in suspension for anchorage-dependent and shear-sensitive cells, and (3) high and spatially uniform distribution of attached cells, for rapid and uniform tissue growth.

In the case of engineered cartilage, these requirements are best met using mixed flasks (Fig.

Fig. 13.2. Dynamic cell seeding. Schematic: mixed flask system used to seed cells onto 3D polymer scaffolds. Graph: normalized concentration of cells remaining in the culture medium as a function of time following flask inoculation (Reprinted with permission from Vunjak-Novakovic *et al.*, 1998. Copyright 1998 American Chemical Society).

13.2) containing scaffolds threaded onto needles embedded in the flask stopper (up to 12 scaffolds on four needles per flask). Isolated cells and culture medium are added (120 ml medium,  $5 \times 10^6$  cells per scaffold) and the flask is magnetically stirred at 50–80 rpm. Under these conditions, essentially all cells attach throughout the scaffold volume in less than 24 hr (Fig. 13.2) and maintain their spherical shape (Vunjak-Novakovic *et al.*, 1998). In this system, magnetic stirring maintains a uniform cell suspension and provides relative velocity between the cells and the scaffolds at an average intensity of turbulence below that causing cell damage or detachment (Cherry and Papatoukakis, 1988). The kinetics and possible mechanisms of cell seeding were related to the formation of cell aggregates using a simple mathematical model, which can be used to optimize seeding conditions for specific scaffold sizes and cell seeding densities (Vunjak-Novakovic *et al.*, 1998).

The above cell seeding requirements can also be met using rotating vessels. These bioreactors are filled with culture medium, to which prewetted scaffolds and cells are added, and the vessel is rotated as a solid body in a horizontal plane at 12–15 rpm (Freed and Vunjak-Novakovic, 1995, 1997a). Cardiac constructs seeded in rotating vessels had higher metabolic activity indexes than those seeded in spinner flasks, implying that optimal hydrodynamic conditions for cell seeding depend on cell type (Carrier *et al.*, 1999).

## TISSUE CULTIVATION

Approximately 1–3 days after seeding, cell–polymer constructs are transferred into a variety of cultivation vessels, including static and mixed flasks, and rotating and perfused vessels, as depicted in Fig. 13.3. The flask system contains 120 ml of culture medium and up to 12 tissue constructs that are fixed in place (Fig. 13.3a). Flasks either are operated statically or are mixed at 50–80 rpm using a 4-cm-long magnetic stir bar. Medium is exchanged batchwise (at a rate of 50% every 2–3 days or 3 ml per construct per day), whereas gas exchange is provided by surface aeration of culture medium via loosened side arm caps.

Rotating bioreactors with two different geometries, the slow-turning lateral vessel (STLV) (Fig. 13.3b) (Schwarz *et al.*, 1992) and the high-aspect-ratio vessel (HARV) (Fig. 13.3c) (Prewett *et al.*, 1993), have been used to engineer cartilage and cardiac tissues in ground-based studies (e.g., Freed and Vunjak-Novakovic, 1995, 1997a). The STLV is configured as the annular space between two concentric cylinders, the inner of which is a silicone gas exchange membrane, whereas the HARV is a cylindrical vessel with a gas exchange membrane at its base. These vessels contain 100–110 ml of culture medium and up to 12 tissue constructs, and are operated by solid-body rotation in a horizontal plane at rates of 15–40 rpm. Viscous coupling induces a rotational flow field that can suspend tissue constructs without external fixation (Freed and Vunjak-Novakovic, 1995). Vessel rotational speed is adjusted such that constructs remain suspended close to a stationary point within the vessel, relative to an observer on the ground, due to a dynamic equilibrium between the acting gravitational, centrifugal, and drag forces. Medium is exchanged batchwise (at a rate of 50% every 2–3 days or 3 ml per construct per day), and is equilibrated with gas continuously.

A rotating-wall perfused vessel (RWPV) (Fig. 13.3d) developed at the National Aeronautics and Space Administration (NASA) (Jessup *et al.*, 1996) was used to engineer cartilage in the microgravity environment of space and in a control study on Earth (Freed *et al.*, 1997). The RWPV is configured as an annular space between two concentric cylinders, with the medium inlet at one

end and the medium outlet via a filter on the central cylinder. A flat disk at one end of the central cylinder serves as a viscous pump. The RWPV contains 125 ml of culture medium and holds up to 10 tissue constructs. In microgravity, the inner and outer cylinders were differentially rotated at rates of 10 and 1 rpm, respectively; on Earth, the vessel was rotated as a solid body at 28 rpm. Medium was periodically recirculated between the culture vessel and an external membrane gas exchanger at a rate of 4 ml/min for 20 min four times per day, and was exchanged at a rate of 5–10 ml per construct per day.

Perfused columns were designed to allow nondestructive assessment of tissue development over the course of cultivation using magnetic resonance imaging (Fig. 13.3e) (Obradovic *et al.*, 1997; Williams *et al.*, 1998). The columns have an inlet at the base, an outlet at the top, and contain 15 ml of culture medium and up to four constructs that are fixed to a centrally positioned needle. Medium is continuously recirculated between the column and an external membrane gas exchanger at a rate of 2–3 ml/hr, and is exchanged at rates of 2–15 ml per construct per day.

Perfused chambers (Fig. 13.3f) were designed to allow tissue culture in the microgravity environment of space, and for control studies under conditions of unit gravity on Earth or artificial gravity in space (Vunjak-Novakovic *et al.*, 1999b). The chamber is configured as a central compartment bounded by a porous membrane and an annular space. The medium inlet is in the central tissue culture space and the medium outlet is in the peripheral cell-free space. Chambers contain 3, 10, or 30 ml of medium and up to five tissue constructs. Medium is continuously recirculated between the chamber and an external membrane gas exchanger at rates of 1–30 ml/min, and is exchanged at rates of 1–30 ml per construct per day. Chambers are mounted on a circular tray that allows automated sampling and on-line microscopy.

## HYDRODYNAMIC CONDITIONS IN BIOREACTORS

In static flasks, mass transfer in the bulk medium occurs by molecular diffusion, and there is no fluid flow at the surfaces of the tissue constructs. In mixed flasks, mass transfer is by convection, and fluid flow at the surfaces of the tissue constructs is turbulent, such that the smallest turbulent eddies have sizes of 250  $\mu\text{m}$  and velocities of 0.4 cm/sec (Vunjak-Novakovic *et al.*, 1996).

In rotating vessels, laminar flow at the construct surfaces was demonstrated by flow visualization conducted using tracer particles illuminated by a sheet of laser light (Neitzel *et al.*, 1998) (Fig. 13.4a). Particle image velocimetry (PIV) studies, done by either cross-correlation of particle images in window of the flow field or by individual particle tracking, allowed quantitation of the velocity vector at every location in the plane of the light sheet (Fig. 13.4b) (Neitzel *et al.*, 1998). These data were used to calculate maximal shear stresses at the construct surface, which were on the order of 0.8 dyn/cm<sup>2</sup> for a 120-ml rotating vessel containing one model construct and operated such that the inner and outer cylinders were rotated at 13 and 37 rpm, respectively. The observed velocity fields were predicted numerically (Fig. 13.4c) and were used to calculate the rates of mass transport of chemical species through the medium to the construct. Residence time distribution studies demonstrated efficient convective mixing due to gravitational construct settling in rotating vessels (Freed and Vunjak-Novakovic, 1997b). In particular, mixing efficiencies were comparable for an STLV containing 12 model constructs and rotated at 15–28 rpm and a spinner flask containing 12 constructs and stirred at 50–80 rpm.

In perfused columns and chambers, fluid flow is laminar and mass transfer is by convection due to recirculation.

## BIOREACTOR MODULATION OF TISSUE FORMATION

In this section, we describe several studies that demonstrate how bioreactors can modulate 3D tissue formation *in vitro*. General design principles for tissue engineering bioreactors include maintaining desired levels of chemical species in the bulk medium, providing efficient mass transfer from the medium to the tissue surfaces, and exposing developing tissues to physical stimuli. These bioreactor functions can result in increased size and improved structure and function of engineered tissues, as follows. The effects of biochemical, hydrodynamic, and mechanical factors were studied for engineered cartilage cultured in rotating bioreactors (Fig. 13.5). In one case, medium oxygen tension,  $p\text{O}_2$ , and pH were varied using STLVs operated under the same hydrodynamic conditions (Fig. 13.5a); in another case, hydrodynamic and mechanical factors were varied using RWPVs operated with comparable medium compositions (Fig. 13.5b). The specific effects of hy-

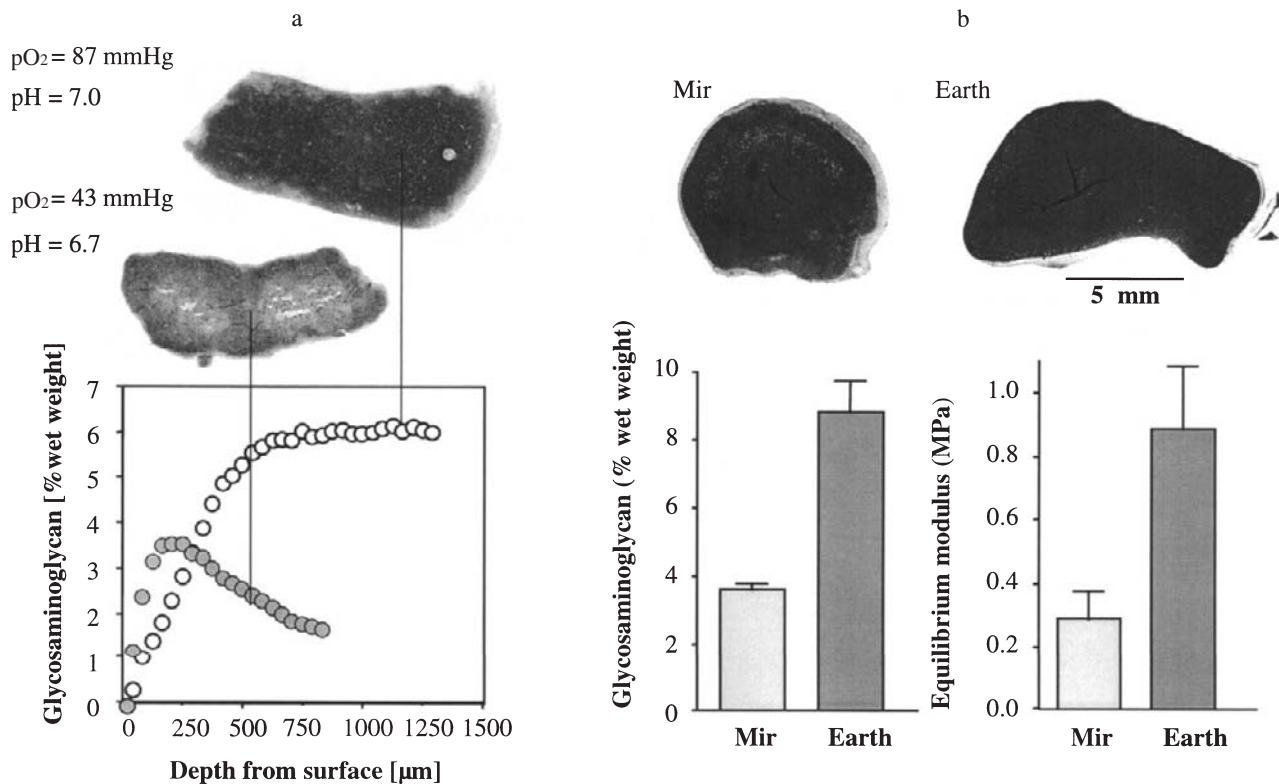

Fig. 13.5. (a) Effects of biochemical factors on engineered cartilage. Comparison of constructs cultivated in medium with relatively high  $p\text{O}_2$  and pH, or with lower  $p\text{O}_2$  and pH (due to higher or lower rates of bioreactor gas exchange). Histology: safranin-O staining for glycosaminoglycan. Graph: glycosaminoglycan fraction as a function of depth from the construct surface (From Obradovic *et al.*, 1999, *Oxygen is essential for bioreactor cultivation of tissue engineered cartilage*. *Biotechnol. Bioeng.* **63**, 197–205. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.). (b) Effects of hydrodynamic and mechanical factors on engineered cartilage. Comparison of constructs cultivated in the presence of higher levels of hydrodynamic and mechanical stimuli (due to gravitational settling on Earth) or relatively quiescently (aboard the Mir Space Station). Histology: safranin-O staining for glycosaminoglycan. Graphs: glycosaminoglycan fraction and equilibrium modulus (Freed *et al.*, 1997). Data are the average  $\pm$ SD of three to four independent measurements.

drodynamic factors and the accompanying changes in mass transfer were further studied by systematically comparing engineered cartilage and cardiac muscle cultured in different bioreactors (Fig. 13.6).

Biochemical factors were varied by establishing two groups: (1)  $p\text{O}_2 = 87$  mm Hg, pH = 7.0 and (2)  $p\text{O}_2 = 43$  mm Hg, pH = 6.7 in STLVs operated with or without an internal gas exchange membrane (Obradovic *et al.*, 1999). Cartilaginous constructs were compared with respect to several parameters, including yield of lactate to glucose ( $Y_{L/G}$ ), construct thickness, and the amounts and distributions of glycosaminoglycan. In group 2, low  $p\text{O}_2$  and pH were associated with anaerobic cell metabolism ( $Y_{L/G}$  of 2.2 mol/mol) as compared to group 1, in which higher values of  $p\text{O}_2$  and pH were associated with more aerobic cell metabolism ( $Y_{L/G}$  of 1.7–1.8 mol/mol). Constructs grown aerobically for 5 weeks were approximately 2.5 mm thick and had a high fraction [ $\sim$ 6% of wet weight (ww)] of uniformly distributed GAG, except for a 460- $\mu\text{m}$ -thick outer capsule (Fig. 13.5a). In contrast, constructs grown anaerobically were only about 1.6 mm thick and had markedly lower GAG fractions (1.5–3.5% ww) that decreased with increasing depth. One key bioreactor function is thus to provide efficient gas exchange for control of medium  $p\text{O}_2$  and pH.

Hydrodynamic conditions and mechanical factors were varied by utilizing rotating bioreactor vessels on Earth and in the microgravity environment of space, aboard the Mir Space Station (Freed *et al.*, 1997). In particular, cartilaginous constructs were first cultured in STLVs for 3

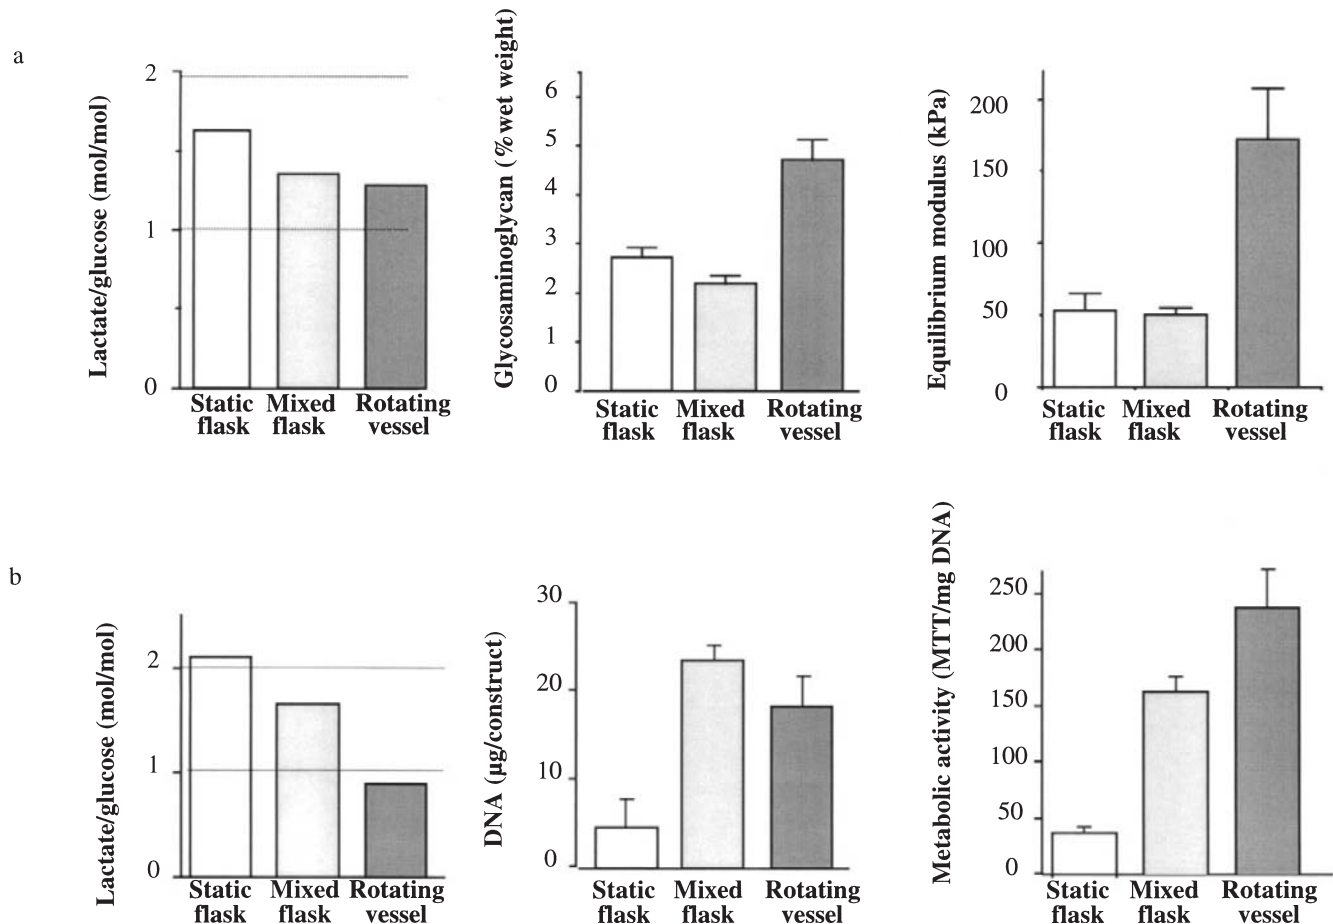

Fig. 13.6. Effects of hydrodynamic factors. (a) Effects on engineered cartilage. Molar ratio of lactate production and glucose utilization (lactate/glucose), glycosaminoglycan fraction, and equilibrium modulus in constructs cultured in static or mixed flasks, or in rotating vessels (STLVs) (Obradovic et al., 1997; Vunjak-Novakovic et al., 1999a). (b) Effects on engineered cardiac tissue. Glucose/lactate ratio, DNA content, and metabolic activity index (MTT/DNA) of constructs cultured in static or mixed flasks, or in rotating vessels (HARVs) (From Carrier et al., 1999, *Cardiac tissue engineering: Cell seeding, cultivation parameters and tissue construct characterization. Biotechnol. Bioeng.* **64**, 580–589. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.). (a,b) Horizontal lines represent lactate/glucose ratios of 2 and 1, which correspond to theoretical values for anaerobic and aerobic metabolism, respectively. Data are the average  $\pm$  SD of three to four independent measurements.

months on Earth and then in RWPVs for an additional 4 months either on Earth or aboard Mir. During cultivation on Earth, constructs were exposed to relatively higher levels of hydrodynamic shear (due to gravitational settling) and mechanical stimuli (due to construct collisions with the rotating vessel walls) as compared to on Mir, where constructs floated freely in the culture medium. Medium values of pH and  $p\text{O}_2$  were comparable in the two groups. Cartilaginous constructs were compared with respect to several parameters, including dimensions, wet weight fractions of GAG, and equilibrium moduli in radially confined compression. Constructs grown for 7 months on Earth retained their initial discoid shape, were large (429 mg ww), and had high GAG fractions (8.8% ww) and equilibrium moduli (0.93 MPa) (Fig. 13.5b). In contrast, constructs grown for 3 months on Earth and then 4 months on Mir tended to become more spherical, were smaller (330 mg ww), and had lower GAG fractions (3.6% ww) and equilibrium moduli (0.31 MPa). Other important functions of tissue engineering bioreactors are thus to provide appropriate levels of hydrodynamic and mechanical stimuli.

Cartilaginous constructs seeded in mixed flasks (Fig. 13.2) and then cultured for 6 weeks in static or mixed flasks (Fig. 13.3a) or in rotating vessels (STLVs) (Fig. 13.3b) were compared with respect to several parameters, including  $Y_{L/G}$ , wet weight fractions of GAG, and equilibrium mod-

ulus in radially confined compression (Obradovic *et al.*, 1997; Vunjak-Novakovic *et al.*, 1999a). Values of  $Y_{L/G}$  for constructs cultured statically, in mixed flasks, and in rotating vessels were, respectively, 1.7, 1.3, and 1.3 mol/mol, implying that cell metabolism was more aerobic under mixed than static culture conditions (Fig. 13.6a) (Obradovic *et al.*, 1997). GAG fractions and equilibrium moduli were significantly higher for constructs grown in rotating vessels as compared to either static or mixed flasks (Fig. 13.6a) (Vunjak-Novakovic *et al.*, 1999a). In static flasks, diffusional constraints of mass transport resulted in thin, fragile constructs in which GAG accumulated mainly in a 1-mm-thick outer region. In mixed flasks, turbulent conditions apparently induced the formation of capsules at the construct surfaces that were up to 400  $\mu\text{m}$  thick and consisted of multiple layers of elongated cells and little GAG. In rotating vessels, dynamic laminar flow patterns permitted the growth of constructs with high, spatially uniform GAG fractions. These studies demonstrate that hydrodynamic factors, such as mixing pattern and flow regime, play a key role in determining the structure and function of engineered cartilage.

Cardiac-like constructs seeded in mixed flasks (Fig. 13.2) and then cultured for 2 weeks in static or mixed flasks (Fig. 13.3a) or in rotating vessels (HARVs) (Fig. 13.3c) were compared with respect to several parameters, including  $Y_{L/G}$ , cellularity (DNA per construct), and metabolic activity index (MTT units/mg DNA) (Carrier *et al.*, 1999). Values of  $Y_{L/G}$  for constructs cultured statically, in mixed flasks, and in rotating vessels were, respectively, 2.0, 1.6, and 1.0 mol/mol, implying anaerobic, partially aerobic, and aerobic cell metabolism (Fig. 13.6b). Cellularities and metabolic activity indexes of constructs cultured statically were markedly lower than those of constructs cultured in either mixed flasks or rotating vessels (Fig. 13.6b) (Carrier *et al.*, 1999). These studies demonstrate that hydrodynamic factors affect the structure and function of engineered cardiac tissue in a manner consistent with that observed for engineered cartilage (Fig. 13.6a).

## BIOREACTOR CULTIVATION OF FUNCTIONAL TISSUES

### CARTILAGE

Cartilaginous constructs cultured for 6 weeks in rotating bioreactors (STLVs) were continuously cartilaginous over their entire cross-sectional areas (6.7 mm in diameter  $\times$  5mm thick) (Freed *et al.*, 1998) and contained an interconnected network of collagen fibers that resembled that of articular collagen with respect to overall organization, fiber diameter (Fig. 13.7a) (Riesle *et al.*, 1998), and molecular structure (type II represented more than 90% of the total collagen) (Freed *et al.*, 1998). As compared to native bovine calf articular cartilage, 6-week constructs had comparable cellularities, 68% as much GAG, and 33% as much collagen type II per unit wet weight (Freed *et al.*, 1998). Extracellular matrix synthesis rates decreased to approximately 60% of initial over 6 weeks, and the fraction of newly synthesized macromolecules released into the culture medium decreased from about 25% of total at 4 days to less than 4% at 6 weeks. Over 7 months of *in vitro* cultivation, the GAG fraction and equilibrium modulus reached or exceeded values measured for native cartilage (Fig. 13.7a). However, other properties of 7-month constructs remained subnormal (e.g., collagen fraction, the concentration of pyridinium cross-links, and dynamic stiffness were, respectively, 34, 30, and 46% as high as in native cartilage) (Freed *et al.*, 1997; Riesle *et al.*, 1998). Construct mechanical properties (i.e., equilibrium modulus, hydraulic permeability, dynamic stiffness, and streaming potential) correlated with the wet weight fractions of GAG, collagen, and water (Vunjak-Novakovic *et al.*, 1999a).

### CARDIAC TISSUE

Cardiac-like tissues cultivated for 1 week in mixed flasks were 5 mm in diameter and 1.3 mm thick and had a 50- to 70- $\mu\text{m}$ -thick tissuelike region at the construct periphery in which cells expressed the muscle-specific protein sarcomeric tropomyosin and exhibited cardiac-specific ultrastructural features, including intercalated disks and sarcomeres (Bursac *et al.*, 1999) (Fig. 13.7b). As compared to native neonatal rat ventricles, 1-week constructs had 16% as much DNA per unit wet weight (Fig. 13.7b), and similar indexes of cell size (protein/DNA) and metabolic activity (MTT/DNA). The peripheral region of constructs was electrically excitable and could be captured over a wide range of pacing frequencies (80–270 beats/min) (Fig. 13.7b) (Bursac *et al.*, 1999). Impulses propagated at conduction velocities that were half of those in native neonatal rat ventricles (Bursac *et al.*, 1999) (Fig. 13.7b). Contractile cardiac-like tissues were also grown in rotating

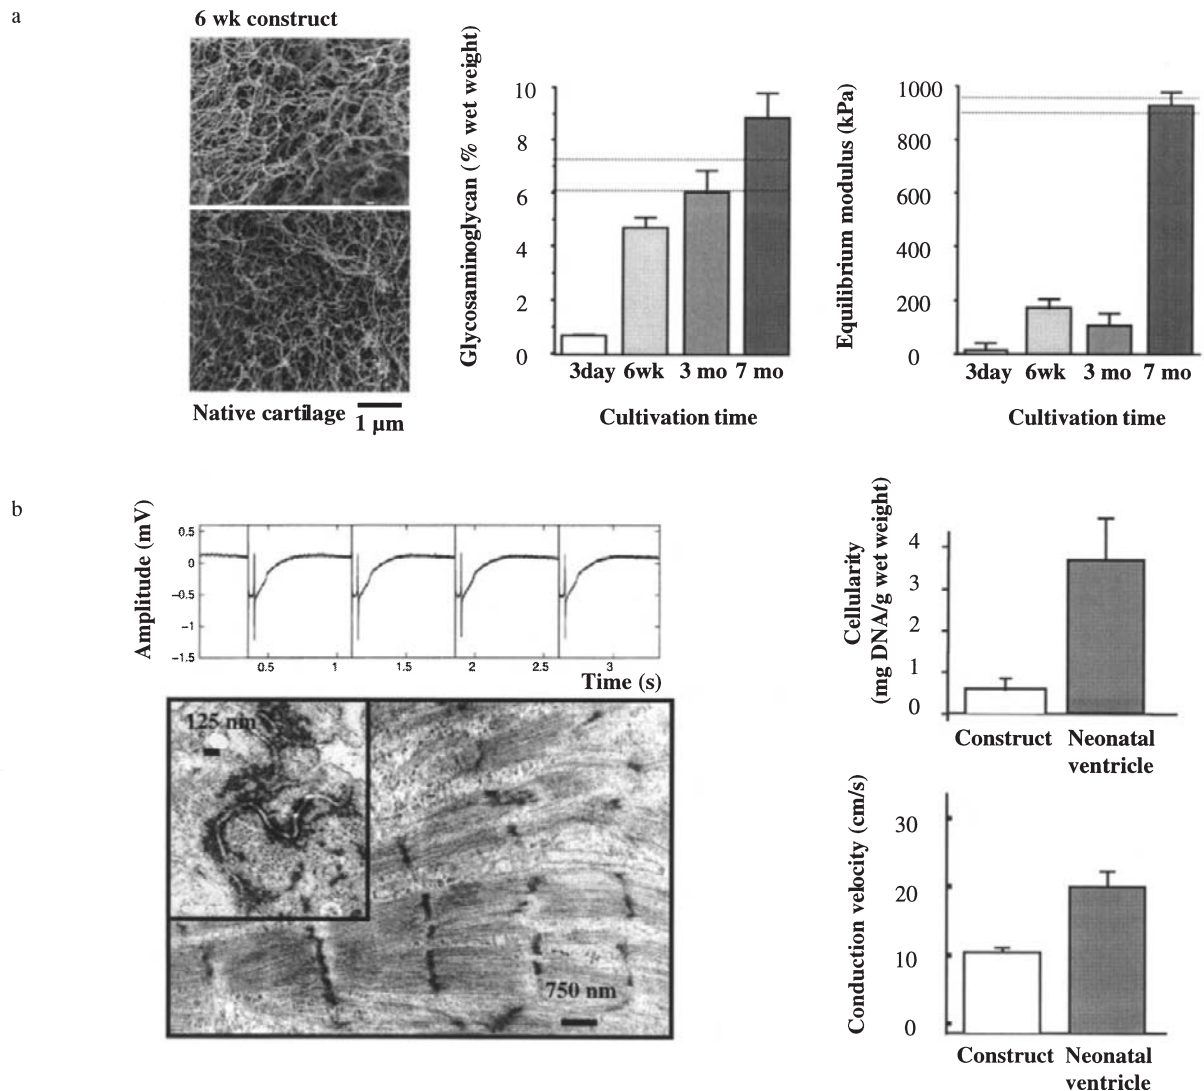

Fig. 13.7. Bioreactor cultivation of functional tissues. (a) Cartilage. Micrographs show the ultrastructural appearance of collagen networks in a 6-week construct and in native calf articular cartilage (Riesle *et al.*, 1998, *Collagen in tissue engineered cartilage: Types, structure and cross-links. J. Cell. Biochem.* **71**, 313–327. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.). Graphs: glycosaminoglycan fraction and equilibrium modulus of constructs cultivated in rotating vessels (STLVs) for 3 days, 6 weeks, and 3 or 7 months (Freed *et al.*, 1997; Vunjak-Novakovic *et al.*, 1999a). Dotted lines represent ranges of parameters measured for native cartilage. (b) Cardiac muscle. Recording: electrophysiological response of construct to electrical stimulation at a rate of 80 bpm. Micrographs: ultrastructural demonstration of sarcomeres (outer photo) and an intercalated disk (inset). Graphs: DNA content and conduction velocity of 1-week constructs and native neonatal rat ventricles (Bursac *et al.*, 1999). Data are the average  $\pm$ SD of three to six independent measurements.

vessels (HARVs), and were shown to contain the gap-junctional protein connexin-43, creatine kinase isoform MM, sarcomeric myosin heavy-chain protein (Papadaki *et al.*, 1999), muscle desmin, cardiac troponin T, and sarcomeric tropomyosin (Carrier *et al.*, 1999).

## TISSUE ENGINEERING BIOREACTORS: STATE OF THE ART

In contrast to a large number of tissue engineering studies focusing on scaffold design and *in vivo* tissue repair using cells and/or biomaterials, there has been relatively little work in the area of bioreactors. As described in this chapter, specific bioreactor design features can be exploited to improve the structure and function of engineered tissues, including in particular (1) flow and mixing patterns that can result in efficient and spatially uniform seeding of polymer scaffolds, (2) en-

hanced mass transport of chemical species through the medium and to the tissue surfaces, and (3) physical stimulation of the tissue during its development.

Our early studies demonstrated increased thickness and improved structure of engineered cartilage when scaffolds were seeded in orbitally mixed petri dishes as compared to static dishes (Freed *et al.*, 1994b). The concept of maintaining a uniform suspension of isolated cells and providing relative velocity between cells and the scaffold during seeding was improved by using mixed flasks and rotating vessels (Freed and Vunjak-Novakovic, 1995, 1997a; Vunjak-Novakovic *et al.*, 1996, 1999a). The kinetics and mechanisms of seeding in mixed flasks, which are at this time the preferred system for cell seeding of 3D scaffolds, were characterized in detail (Vunjak-Novakovic *et al.*, 1998).

Engineered cartilage cultured in mixed flasks was structurally superior to that grown in orbitally mixed dishes, which was in turn superior to that grown statically (Vunjak-Novakovic *et al.*, 1996). Efficient convective mixing demonstrated for mixed flasks and rotating vessels (Freed and Vunjak-Novakovic, 1997b) implies that both bioreactors can maintain constant concentrations of chemical species in the bulk medium. The hydrodynamic environment present in rotating vessels (Fig. 13.4) stimulated the development of engineered cartilage that was metabolically and mechanically functional (Fig. 13.5). Engineered tissues (cartilage, cardiac) grown in rotating vessels were structurally and functionally superior to constructs grown in either static or mixed flasks (Fig. 13.6). Although the mechanisms underlying these effects are yet to be determined, others have hypothesized that hydrodynamic forces affect cultured cells via pressure fluctuations, stretching the cell membrane, and/or shear stress (Berthiaume and Frangos, 1993; Smith *et al.*, 1995).

The bioreactor systems we have used to date (Fig. 13.3) promote mass transfer to the construct surface, but do not enhance the relatively slow diffusion of chemical species to the construct interior. This has not been an overwhelming problem in the engineering of cartilage, an avascular tissue with low cellularity (only about 4–5% of the wet weight), which can be cultivated in bioreactors to a thickness exceeding that of native articular cartilage (i.e., 5 mm) (Freed *et al.*, 1998). However, diffusional limitations of mass transport have severely curtailed efforts to engineer tissues that normally have high vascularity and/or cellularity. In particular, only very low thicknesses were reported to date for engineered bone (250–500  $\mu\text{m}$ ) (Ishaug *et al.*, 1997; Martin *et al.*, 1998) and cardiac tissue (50–180  $\mu\text{m}$ ) (Eschenhagen *et al.*, 1997; Bursac *et al.*, 1999; Carrier *et al.*, 1999).

Other groups have demonstrated advantages of using culture systems that provide continuous perfusion and mechanical stimulation during cultivation. In one system, growing constructs were directly perfused with culture medium within 1.2 ml cartridges (Dunkelman *et al.*, 1995). Engineered cartilage cultivated in these bioreactors for 2–4 weeks repaired osteochondral defects and integrated with underlying bone in a 2-year rabbit study (Schreiber *et al.*, 1999). In other systems, cartilage (Grande *et al.*, 1997) and skeletal muscle (Chromiak *et al.*, 1998) constructs were surrounded by culture medium that was continuously recirculated through a closed loop. In all the above cases, perfusion of medium reportedly improved tissue growth and metabolism by enhancing mass transfer and reducing the variations in medium concentrations of gases, nutrients, metabolites, and regulatory factors that occur in periodically refed cultures. In addition, closed-loop perfused bioreactors reduce the risk of contamination during long-term cell cultivation.

The fact that physical stimuli modulate tissue development has motivated the design of several bioreactor systems in which growing tissues are exposed to mechanical forces. A system that exposed cartilaginous constructs to dynamic compression at physiological frequencies enhanced ECM synthesis rates as compared to statically loaded controls (Buschmann *et al.*, 1995). Likewise, a system that exposed cartilaginous constructs to physiological levels of intermittent hydrostatic pressure enhanced GAG deposition as compared to nonpressurized controls (Carver and Heath, 1999). A system that exposed skeletal muscle constructs to static and dynamic tension was associated with increased size and improved function (Vandenburgh *et al.*, 1991). The concept of tensile loading was extended by exploiting the native contractile properties of collagenous cell culture substrates. Examples include engineered tissue containing genetically modified cells that secreted human growth hormone for up to 3 months in mice (Vandenburgh *et al.*, 1996), engineered cardiac muscle that contracted and in some cases secreted recombinant  $\beta$ -galactosidase for up to 10 days *in vitro* (Eschenhagen *et al.*, 1997), and engineered tendon that repaired gap defects over 3 months in rabbits (Young *et al.*, 1998). In all of the above studies, the presence of mechanical forces

(externally applied or internally generated) during cultivation stimulated the development of engineered tissues, presumably by providing physical stimuli normally present *in vivo*.

A novel bioreactor system for vascular tissue engineering elegantly demonstrates the combined benefits of continuous perfusion and mechanical stimulation (Niklason *et al.*, 1999). Tubular polymer scaffolds seeded with smooth muscle cells were placed in a stirred vessel and cultivated in the presence of pulsatile radial stress, applied via highly distensible silicone tubing in the construct lumen. Under these conditions, small-caliber (<6 mm in diameter) arteries with high rupture strengths and high suture retention strengths could be cultivated over 2 months *in vitro*; these remained patent for up to 24 days following *in vivo* implantation in swine.

## SUMMARY AND RESEARCH NEEDS

In this chapter, we have discussed the design and operating principles of tissue engineering bioreactors developed for the cultivation of engineered tissues starting from isolated cells and 3D biodegradable scaffolds. Bioreactor technologies can be utilized to grow functional tissues for *in vivo* implantation, and for controlled *in vitro* studies of how biochemical and physical factors regulate tissue development. In general, the functions of the bioreactor are to seed cells onto 3D scaffolds and to provide appropriate stimuli during *in vitro* tissue development. Specific design requirements depend on the dimensions, complexity, and application of the tissue to be engineered. Further advances in bioreactor technologies that are likely to have a major impact on the field of tissue engineering include (1) improved control over culture medium composition, (2) new methods to provide physiological levels of mechanical stimuli to engineered tissues *in vitro*, (3) new techniques to induce and/or mimic vascularization of engineered tissues *in vitro*, (4) determination of appropriate conditions and duration of *in vitro* culture prior to implantation, and (5) extension from animal model systems to human cell sources and scales.

## ACKNOWLEDGMENTS

This work was supported by the National Aeronautics and Space Administration (Grants NAG9-836 and NCC8-174). The authors thank G. P. Neitzel, J. B. Brown, and M. Smith for the bioreactor fluid dynamics data shown in Fig. 13.4, and R. Langer for helpful advice.

# TISSUE ASSEMBLY IN MICROGRAVITY

Brian R. Unsworth and Peter I. Lelkes

## INTRODUCTION

The increasing disparity between demand and availability of human donor organs for the replacement of dysfunctional organs in patients has raised serious ethical and legal issues and prompted an intensive search for alternatives to human allotransplants or xenotransplantation. Generation of tissue-engineered replacement organs, e.g., by means of three-dimensional (3D) *in vitro* cell culture, may present a suitable substitute for donor organ transplantation. Multicellular spheroids can be generated from one cell type only (homotypic), or comprise different cell types from the same tissue (heterotypic). Such spheroids have provided new insights into the biological responses of *in vivo*-like multicellular assemblies, e.g., on radiation injury (Schwachöfer, 1990), in developing drug resistance (Kerbel *et al.*, 1994), and in understanding phenotypic changes associated with tumor invasiveness (Schuster *et al.*, 1994). Although such multicellular spheroids are a first step toward assembling complex 3D tissue equivalents, there are several inherent limitations, such as their size and the restricted diffusion of nutrients and oxygen; additionally, spheroids >1 mm in diameter generally contain a hypoxic, necrotic center surrounded by a rim of viable cells (Sutherland *et al.*, 1986).

In progressing beyond spheroids, creation of properly assembled and differentiated tissues from single cells in suspension has attracted an interdisciplinary approach, collectively known as tissue engineering. One major aim of this potentially multibillion dollar venture is to generate viable/functional tissue-equivalents that can serve as replacement tissues, in lieu of allotransplantation (Langer and Vacanti, 1993). Resorbable polymeric scaffolds, made, for example, of fibrous polyglycolic acid, serve as provisional, biodegradable matrices for cell seeding (Cima *et al.*, 1991). As detailed elsewhere in this volume, such scaffolds can be molded into complex geometric shapes. Importantly, these scaffolds, in particular when treated with growth factors or adhesive proteins, promote cellular proliferation and 3D assembly (Kim and Mooney, 1998). After the controlled biodegradation of the scaffolds, the 3D cellular constructs form neotissues and neoorgans, such as skin, cartilage, blood vessels, bladders, and heart valves (Langer and Vacanti, 1995; Shinoka *et al.*, 1997, 1998; Atala, 1998; Niklason and Langer, 1997; Mayer *et al.*, 1997). Similarly, RGD peptides conjugated to poly(ethylene glycol) promote aggregation and differentiation of neural cells in suspension, thus eliminating the need for microcarriers and facilitating the use of these aggregates as replacement tissues (Dai *et al.*, 1994). Some of these bioengineered replacement tissues are currently being tested in animals (Krewson and Saltzman, 1996; Atala, 1998; Shinoka *et al.*, 1998; Fauza *et al.*, 1998) and await human trials.

A major focus of tissue engineering is how to best generate functional 3D constructs, large enough to serve as replacement organs or suitable for scientific studies of *in vitro* drug effects/toxicity, oxygen diffusion in tissues, etc. The high shear forces of conventional stirred fermentors/rollers are a disadvantage because they damage the cells and hinder proper tissue-specific differentiation. Decreasing the stir rate while increasing the medium viscosity might partially reduce the hydrodynamic damage (Moreira *et al.*, 1995); however, aggregates formed under these conditions

still exhibit necrotic centers. As detailed in Chapter 13, tissue constructs on biodegradable scaffolds have been successfully cultured in stirred bioreactors (Freed and Vunjak-Novakovic, 1997).

### MICROGRAVITY AS A NOVEL TISSUE CULTURE VENUE

Efforts at tissue assembly would benefit from a venue that promotes cell–cell association, while avoiding the detrimental effects of high shear stress. Such a venue might be provided by microgravity (Dintenfass, 1986). In an effort to embellish the potential beneficial effects of microgravity and low fluid shear for cell culture here on Earth, scientists at the National Aeronautics and Space Association (NASA) introduced rotating-wall vessel (RWV) cell culture biotechnology. The principles of this system, which combines low fluid shear stress and randomization of the gravitational vectors, are described in detail in Chapter 13.

The use of the different incarnations of the RWV bioreactors is largely dictated by oxygen requirements of the cultured cells. Due to its geometry and the use of a large-surface-area, flat-membrane oxygenator at the rear of the chamber, the oxygenation capacity of the high-aspect-ratio vessel (HARV) is higher than that of the slow-turning lateral vessel (STLV). STLV-type bioreactors, consisting of a cylindrical growth chamber that contains an inner corotating cylinder with a gas-exchange membrane, are suited for cells with low oxygen requirements. HARVs, on the other hand, are mostly used for cell types that require more oxygen per unit volume of culture medium.

In the past, conventional stirred fermentors were used as “controls” for assessing the contributions of impeller-induced shear forces on tissue assembly (Lelkes *et al.*, 1998). Alternatively, Fang *et al.* suggested use of vertically positioned RWVs as dynamic controls, with the axis of the vessels being parallel to gravity. Due to the centrifugal forces of the rotating motion, the vertical position provides a near-normal gravity environment, as opposed to the simulated microgravity in the horizontal position (Fang *et al.*, 1997).

A more sophisticated version of the STLV-type RWV bioreactor, called the rotating-wall perfused vessel, allows the investigator to study the individual contributions of fluid shear stress and (simulated) microgravity. In these vessels, controlled shear stress can be induced by independently rotating the inner and the outer walls. An addition to the family of RWVs, specifically developed by NASA for use in space, is the hydrodynamic focusing bioreactor, which provides new capabilities for long-duration operation in orbit as well as on the ground. Of additional advantage, both of these systems can be fully automated for changing, sampling, and/or modifying the culture medium without stopping the vessel rotation. This capability is very important, in view of our finding that even short cessation of microgravity, or its initiation, can activate cellular signaling pathways (Lelkes and Unsworth, 1998).

The differentiation of cell aggregates grown in the simulated microgravity environment of RWV bioreactors is based on the interplay between two beneficial factors: (1) low shear stress, which promotes close apposition (spatial colocation) of the cells, and (2) randomized gravitational vectors, which either directly affect gene expression or indirectly facilitate paracrine/autocrine intercellular signaling, e.g., through restricted diffusion of differentiative humoral factors (Jessup *et al.*, 1993; Schwarz *et al.*, 1992). To date, numerous groups have been utilizing RWV bioreactor biotechnology to facilitate the assembly of macroscopic, differentiated, tissue-like 3D constructs (also called proto-tissues, tissue equivalents, or organoids) from a variety of normal and transformed cell types. RWV bioreactors provide a suitable *in vitro* venue for culturing otherwise recalcitrant cells, such as viruses (Long *et al.*, 1998) and human tumor cells (Becker *et al.*, 1997; Ingram *et al.*, 1997). The resulting differentiated 3D tissue constructs secrete valuable bioproducts, such as antibodies and antigens (Jessup *et al.*, 1997), and ultimately may serve as possible replacement organs.

RWV bioreactors are also used to further differentiate *in vitro* preassembled bioengineered tissue equivalents, such as skin (D. Dimitrijevic, personal communication) and cartilage (Freed and Vunjak-Novakovic, 1997), as well as to culture intact tissues, such as fragments of liver (Khaoustov *et al.*, 1995), tonsils (Margolis *et al.*, 1997) or kidney (A. Nor and P. I. Lelkes, unpublished). RWV biotechnology in conjunction with an appropriate scaffold/matrix might also provide a suitable venue for generating 3D constructs of neuronal cells, capable of “thinking,” i.e., establishing functional neuronal connections (P. I. Lelkes *et al.*, unpublished). For a summary of the diverse cell types (to date more than three dozen) cultured in RWV bioreactors, see Unsworth and Lelkes (1998a). This a very dynamic, rapidly evolving field of research, and a very up-to-date list of

publications and other information may be found on the NASA web site at [http://idi.usra.edu/peer\\_review/taskbook/taskbook.html](http://idi.usra.edu/peer_review/taskbook/taskbook.html).

In the RWV culture environment, homotypic organoids express tissue-specific differentiation markers beyond the levels seen in conventional tissue culture (Jessup *et al.*, 1997; Unsworth and Lelkes, 1998b). RWV culture also induces significant changes in the repertoire of expressed genes (Hammond *et al.*, 1999). Nonetheless, these prototissues fail to recapitulate faithfully the phenotypic diversity of the parental tissues. Important components, notably mesenchymal/interstitial cells, as well as tissue-specific extracellular matrices, are absent, as is the microvasculature.

Organotypic differentiation of the 3D constructs, both normal and neoplastic, is enhanced in heterotypic cocultures comprising phenotypically diverse cells (Galvan *et al.*, 1995; Goodwin *et al.*, 1997; Zhau *et al.*, 1997). Specifically, coculture of tumor cells and normal stromal cells in RWV bioreactors leads to the formation of “differentiated” tumor masses, which may become valuable tools in cancer research (Zhau *et al.*, 1997). Such 3D tumor cell constructs could also serve as *in vitro* models for studying inter- and intracellular signaling involved in clonal expansion, for studying phenotypic instability, and for testing drug/radiation resistance. On the other hand, differentiated 3D constructs from normal tissue, besides their potential usefulness as replacement organs, could also serve as tissue equivalents for more realistic toxicity studies and thus provide yet another novel alternative to animal testing.

## VASCULARIZATION: OVERCOMING SIZE LIMITATIONS OF TISSUE ASSEMBLIES

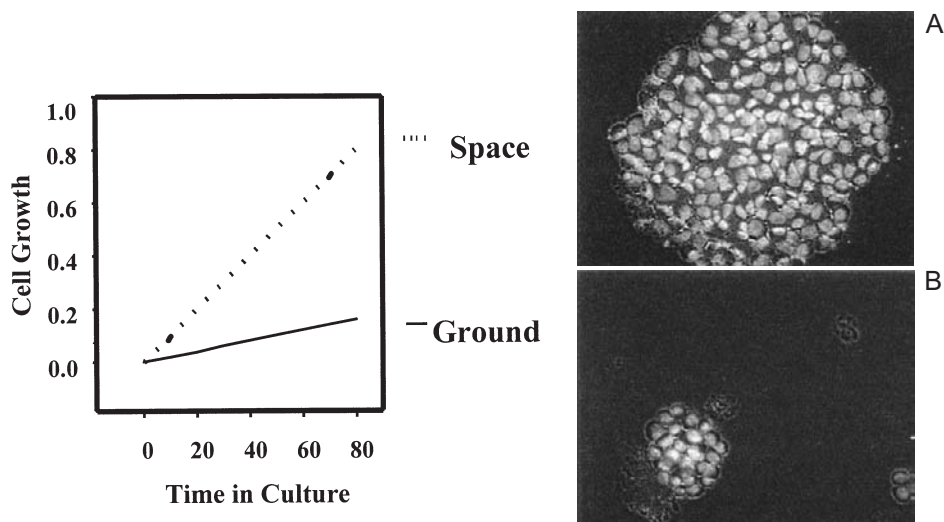

In conventional fermentors, macroscopic assemblies of cell aggregates that exceed about 1 mm in size invariably develop necrotic cores. In the unique culture conditions in RWV bioreactors, dissociated cells can assemble into macroscopic tissue aggregates up to 1 cm in size, and these are largely devoid of such necrotic cores. Clearly, all *denovo* tissue-engineered constructs will eventually require internal, blood vessel-like conduits for the delivery of oxygen and nutrients as well as for the removal of waste products. In spite of sporadic claims to the contrary, inclusion of endothelial cells in the mixture of cells cultured in the RWV bioreactors, with the stated purpose of generating vessel-like conduits (Goodwin *et al.*, 1993), has, to the best of our knowledge, so far failed to yield spontaneous *in situ* “vasculogenesis” (Chopra *et al.*, 1998). In these simplistic cocultures, endothelial cells remain viable and organize largely into homotypic clusters without forming tubular structures. In contrast, the expansion of tissue fragments, such as of liver (Khaoustov *et al.*, 1995) and kidney (A. Nor and P. I. Lelkes, unpublished studies), in the RWV environment is accompanied by a commensurate increase in the density of microvessels. This process, suggestive of angiogenesis, indicates that it may be possible to grow blood vessels in RWV bioreactors, provided the cells are seeded onto/into an appropriate permissive environment, such as a branching scaffold or an extracellular matrix construct containing angiogenic growth factors (Eiselt *et al.*, 1998; Griffith *et al.*, 1997). Clearly, organoid vascularization is one of the foremost, yet so far elusive, goals that may determine the medical/clinical usefulness of *in vitro*-generated tissue equivalents.

## FROM SINGLE CELLS TO TISSUES IN SPACE

It has been known for more than 20 years that single cells respond to microgravity in space by alterations in cellular morphology and function (Montgomery *et al.*, 1978; Claassen and Spooner, 1994). According to Cogoli and Cogoli-Greuter (1998), more than 25 different cell types have been flown in space. Earlier studies reported that during space flight, cell suspensions preferentially aggregate and yield higher cell densities than they do on Earth (Lorenzi *et al.*, 1995). One reason for enhanced cell–cell interactions may be that microgravity induces a tissue-specific up-regulation of cell adhesion molecules, extracellular matrix proteins, and their respective receptors. In line with this notion, studies on board Spacelab indicated a significant increase in collagen synthesis in human dermal fibroblasts in microgravity (Seitzer *et al.*, 1995). However, in whole animals the response might be different and might be determined by hormonal and other physiological factors (Backup *et al.*, 1994; Lelkes *et al.*, 1994; Davidson *et al.*, 1999).

For some cultured cells, for which the expression of certain “glue proteins” such as collagen is up-regulated in simulated microgravity in the RWV environment (Lelkes *et al.*, 1998), one might predict that an excursion into space may be beneficial. Indeed, when PC12 pheochromocytoma

Fig. 14.1. PC12 cell culture maintained for a prolonged period of time (up to 80 days) in space. The left panel shows enhanced "cell growth" in space vs. ground-based controls. Cell growth was inferred from the rate of glucose consumption. The micrographs depict the relative sizes of DNA-stained cell aggregates in space (A) and on Earth (B). Original magnification:  $\times 50$ .

cells were grown in space and serially passaged over approximately a 10-week period, the degree of aggregation and the rate of proliferation of the samples in space was significantly accelerated in comparison to ground controls (Unsworth and Lelkes, 1998a). The rate of glucose consumption, a measure of cellular metabolic activity and of proliferation, was approximately five times higher in space than on the ground (Fig. 14.1). Similarly, large cellular aggregates were observed in space, but not under static conditions on Earth (Unsworth and Lelkes, 1998a). These results, although preliminary, suggest that the space environment might be advantageous for generating neuronal/neuroendocrine tissue equivalents using PC12 cells. For these cells, the ensuing cultures yielded larger and/or more differentiated organoids, compared with parallel cultures maintained at 1 g on Earth.

For other cells, however, which are adversely affected by microgravity, such as bone, cartilage, or muscle, a "space-walk" might yield inferior results. This hypothesis was tested, in part, on Shuttle/Mir missions: in one of these outings, cartilaginous constructs that were flown for 4 months in space proved to be mechanically inferior to the ground controls (Freed *et al.*, 1997). This finding might reflect a direct adverse effect of microgravity on cellular processes involved in the synthesis, secretion, and assembly of glycosaminoglycans and other extracellular matrix proteins, in keeping with the well-known adverse effects of space flight on bone and cartilage (Bonting, 1992). On the other hand, the superiority of cartilaginous constructs on Earth might reflect the effects of mechanical loading on the differentiation of the bioengineered constructs (Freed *et al.*, 1997).

Thus, mass culture in space may not be advantageous for each and every cell type in terms of generating functional replacement tissues. In contrast to the cartilage experiment, other investigators in the cadre of the Office of Life and Microgravity Sciences Applications/Microgravity Research Division (OLMSA/MRD) Cell Culture Biotechnology Group, who have flown cells in the RWV aboard diverse Shuttle missions, reported enhanced cellular responses (e.g., aggregation and secretion of bioactive products) as compared to control cells cultured in RWVs on Earth (Jessup *et al.*, 1996). Taken together, these data suggest a rather cautionary approach toward the potential use of "space factories" for producing medically/scientifically useful tissue equivalents. The outcome might be highly cell type specific.

### IN VITRO EMBRYOLOGY

In addition to their potential usefulness as a cell culture venue for mass producing replacement prototissues, simulated microgravity in the RWV bioreactors also offers an innovative, *in vitro* tool for studying instructional cues and mechanisms involved in organogenesis. Importantly, the RWV environment supports both cellular differentiation and tissue expansion. This mimics developmental organogenesis *in vivo*, and is in stark contrast to conventional tissue culture, where cells either differentiate or proliferate (see also Chapter 9).

We are using RWV bioreactors for *in vitro* embryology, in order to understand mechanisms controlling neuroendocrine differentiation of bipotential, sympathoadrenal cells of the adrenal gland (Lelkes *et al.*, 1998). The culture environment of the RWV specifically induces the formation of macroscopic, 3D organoids and causes differentiation of PC12 cells, an adrenal medullary tumor cell line, along the neuroendocrine pathway. This differentiation is associated with rapid activation of intracellular signaling pathways involved in the control of organ-specific differentiation (Lelkes and Unsworth, 1998). The tissue-specific differentiation in the RWV bioreactors seems to mimic closely events occurring during *in vivo* organogenesis. Thus the system offers a promising approach to investigating molecular mechanisms operating during embryogenesis. The repertoire of genes expressed in microgravity-reared 3D tissue constructs, both in RWV cultures on Earth and in space, is significantly altered from that observed in cells cultured at unit gravity and might resemble more closely the panel of genes expressed *in situ* (Kaysen *et al.*, 1999).

## GRAVITATIONAL SENSING

The gravity responsiveness of single cells has raised speculations about the existence of gravity-sensing mechanisms and of specialized gravity receptors (Montgomery *et al.*, 1978). A prime candidate for gravitational sensing is the cytoskeleton (Ingber, 1997; Hughes-Fulford and Lewis, 1996). At the single-cell level, alterations in the cytoskeletal architecture might explain changes in the vectorial cascade of intracellular phosphorylation cascades (Schmitt *et al.*, 1996). The functional impairment of space-flown lymphocytes, such as altered capping/patching and locomotion (Cogoli-Greuter *et al.*, 1996; Pellis *et al.*, 1997), which has been attributed to alterations in protein kinase C (PKC)-dependent signaling, may also result from cytoskeletal rearrangement in microgravity. In this context, studies by us and others suggest that the simulated microgravity conditions in RWV bioreactors may mimic some of the alterations in cellular signaling observed in space (Cooper and Pellis, 1998; Lelkes and Unsworth, 1998). For example, when PC12 cells were briefly (15 min to 24 hr) cultured in RWV bioreactors, neurotrophin signaling was impaired at the levels of receptor autophosphorylation and postreceptor signaling, resulting in impaired MAP kinase activation, altered integrin signaling, and changes in the nuclear translocation of transcription factors (Lelkes and Unsworth, 1998).

The question remains: What is fundamentally different between simulated microgravity in RWV bioreactors and the real thing in space? Are the differences due to distinct  $g$  levels ( $10^{-2} g$  in RWV vs.  $10^{-4}$ – $10^{-6} g$  in space), or due to residual physical forces (sedimentation; low but finite shear stress) on Earth? A definite answer will have to wait until the experiments can be performed on board the International Space Station—in microgravity in the absence of shear stress—as well as under conditions in which gravitational forces can be artificially restored by using an on-board, low-speed centrifuge.

## CAVEATS

Microgravity, either simulated or in space, has the potential to become a useful venue for the mass production of replacement tissues, which could help to overcome the shortage of donor organs. For the time being the usefulness of this approach is just a promise, yet to be realized. Similarly, the advantages of RWV-generated 3D tumor cell organoids have to be substantiated scientifically and clinically. And yet, although this field is just barely beyond its infancy, microgravity-based organoid formation should and will find its niche in the wider area of tissue engineering.

It has yet to be proved whether tissue-engineered 3D constructs “from space,” once removed from suspension cultures, will remain intact and functional long enough to become fully vascularized by anastomosing with the host tissue. To further enhance their postmicrogravity coherence, the prototissues can be encapsulated into semipermeable poly(lysine)/alginate microcapsules. This encapsulation may also facilitate xenotransplantation by providing an immunoprotective barrier (Sagen *et al.*, 1993).

The anticipated differentiation of certain cell types, such as endothelial cells or neuronal cells, might be thwarted in microgravity by blunted cellular responses to a variety of growth factors, such as basic fibroblast, platelet-derived, or neuronal growth factors (Davidson *et al.*, 1999; Lelkes and Unsworth, 1998). Therefore, the concept of directly applying these growth factors, as intriguing as it sounds, may not work in microgravity. Alternative signaling pathways leading to cellular differentiation may have to be targeted (Cooper and Pellis, 1998).

Using the space environment, rather than the simulated microgravity facilities here on Earth, requires a round-trip ticket. The beginning and the end of this voyage are particularly stressful, both for astronauts and at the level of single cells, for which simulated launch conditions were found to cause alterations in gene expression (Fitzgerald and Hughes-Fulford, 1996; Tjandrawinata *et al.*, 1997). Therefore, when conducting cellular experiments in space, it is mandatory to include both an additional set of ground controls that simulate the conditions of a shuttle launch, and an onboard 1-g centrifuge to control for these potentially deleterious forces. At present it is not clear how cellular responses induced by launch conditions will impact subsequent experiments carried out in space.

Another problem may be posed by DNA damage owing to elevated levels of radiation in space. Enhanced DNA damage could translate into cytogenetic alterations of the tissues formed in space (Horneck *et al.*, 1996, 1997).

## CONCLUSIONS

Microgravity, either simulated on Earth or experienced in space, provides a venue for the formation of tissue-engineered, highly differentiated 3D constructs. In this venue, recalcitrant cells thrive, even if they otherwise would not grow outside the body. Prototissues generated in this environment will be of importance clinically as potential replacement tissues, thus alleviating the current shortage of donor organs. Moreover, these constructs will serve as differentiated macroscopic tissue equivalents in diverse areas of *in vitro* biomedical research, such as toxicology and tumor biology, thus providing a possible alternative to animal testing. The possibility for recapitulating, *in vitro*, the complex cellular events occurring during organogenesis, for example, opens the door for a comprehensive analysis of the molecular control of developmental processes that depend on cell-cell and cell-extracellular matrix interactions. The advent of the International Space Station early in the next millennium will provide laboratory facilities in which we may be able to expand our current studies from simulated microgravity on the ground to real microgravity in space.

## ACKNOWLEDGMENTS

This chapter is dedicated to the memory of Gabor J. Lelkes. We would like to thank numerous colleagues who have freely shared unpublished results and/or preprints of their work. On the other hand, we wish to apologize to those colleagues whose work, for space limitations, we were unable to cite. Our own studies cited herein were supported in part by grants from the National Aeronautics and Space Administration (NAG 9-651 and NCC8-173).

PART III: *In Vivo* SYNTHESIS  
OF TISSUES AND ORGANS

This Page Intentionally Left Blank

# *In Vivo* SYNTHESIS OF TISSUES AND ORGANS

Ioannis V. Yannas

## SCALE OF FUNCTIONAL DEFICIT: MACROMOLECULE VERSUS ORGAN

Medical treatment in antiquity emphasized the use of herbs, potions, and, eventually, the semi-purified chemical substances that were extracted from them. In the twentieth century, advances in the chemistry of natural substances led to the discovery, and later synthesis, of vitamins, hormones, and antibiotics. Inevitably, the ancient predisposition to believe in the healing power of drugs spawned the gigantic pharmaceuticals industry. The successes of chemical therapeutics have been based on the fact that a large number of medical problems are caused by some kind of defect at the macromolecular level—usually an excess or a deficiency of a protein (e.g., insulin), sometimes resulting from an error in a gene—that can be chemically treated.

Failure of an entire organ is a very different medical problem. Rather than originating in a defect at the nanoscale, loss of organ function occurs at the scale of the centimeter. Such failure can occur as a result of a large variety of causes, such as heart failure due to oxygen deficiency of heart muscle (itself resulting frequently from circulatory failure), kidney failure due to cancer, and failure of the central nervous system due to spinal cord injury. Drug treatment is not effective in organ failure because the cause of the problem is loss of an entire mass of functioning tissue, representing loss of a large number of cells, soluble proteins, and insoluble extracellular matrix, rather than being a singular defect in molecules.

Five approaches have been successfully used to treat loss of organ function: transplantation, autografting, implantation of passive prosthesis, *in vitro* synthesis, and *in vivo* synthesis (regeneration). Transplantation from a donor to another person (host) has led to certain spectacular but short-lived successes (Medawar, 1944), unless the host and donor were identical twins, because the host typically rejects the transplanted organ after a period of weeks to a few years. Studies have emphasized development of techniques for increasing host tolerance (Cooper *et al.*, 1997). Autografting circumvents this problem by ensuring that donor and host are the same person, as in patients with serious burns (Burke *et al.*, 1974) or with seriously injured nerves (Millesi, 1967). This procedure has suffered from the trauma that is inflicted on the patient during harvesting of the autograft; also, the procedure falls short when the loss of organ mass exceeds typically 50% of the total. Implantation of passive prostheses provides temporary function, extending to 15 years in some cases; in the long run, the biologic environment destroys, and is itself damaged by, the man-made materials used in these prostheses. Examples are the total hip prosthesis (Kohn and Ducheyne, 1992) and the cardiac pacemaker (Neuman, 1998). *In vitro* synthesis of tissues and organs has been attempted over the past 15 years and the progress that has been made is reviewed in detail in several chapters in this volume. *In vivo* synthesis leads to organ regeneration and is the focus of this chapter. This process was originally developed in the context of treatment of massive

skin wounds in animals and humans; however, over the past 15 years it has led to synthesis not only of skin but also of peripheral nerves and the knee meniscus.

The description of *in vivo* organ synthesis will start with an examination of the basic parameters of the living environment (wound bed, animal) in which the desired synthesis takes place. Because it is subject to homeostatic control, the living environment offers unexpectedly controlled conditions for the synthesis.

### BASIC PARAMETERS OF THE LIVING ENVIRONMENT DURING *IN VIVO* ORGAN SYNTHESIS

The most successful procedure used to achieve *in vivo* synthesis requires use of an analog of the extracellular matrix (ECM). Examples are grafting of the analog onto a freshly excised skin wound bed or bridging the gap between the tubulated stumps of a freshly transected peripheral nerve with an ECM analog. In each of these two cases the wound bed is typically supplied with a constant flow of exudate that contains cells and cytokines or growth factors. Following a process of induced regeneration, the exudate is converted into physiologic tissue by the process of regeneration; if such conversion does not occur in adult mammals, the exudate will be spontaneously converted into nonphysiologic scar or fibrotic tissue by the process of repair. Unlike in the fetus, the vast majority of tissues and organs in adults are not spontaneously regenerated following removal, e.g., by surgical excision. If the ECM analog has been appropriately selected, i.e., if it is a regeneration template, normal repair processes are blocked and a regenerate (newly synthesized physiologic organ) is synthesized in the wound bed within weeks. The ECM analog may not, by itself, suffice to induce regeneration of physiologic tissue: cells of a given type may have to be seeded into it before grafting. Rigid rules are used to study the structure and function of the new organ and the term “regenerate” is usually reserved for an almost completely faithful replica of the physiologic organ.

The process of *in vivo* synthesis is modeled as if it were taking place inside a bioreactor (wound bed) surrounded by a reservoir (animal) (Fig. 15.1). Conditions inside the animal are subject to homeostatic control; this environment offers approximate constancy in many characteristics of the exudate that flows into the wound bed. Although the flow rate of exudate as well as its composition vary somewhat from day to day during the wound healing process, the temperature and the pH are maintained constant. The exudate and the template (possibly seeded with cells in advance) are the two critically necessary components in the synthetic reaction. The stability of the living environment that supplies this basic reaction component effectively cancels the conventional need of the experimenter to isolate the bioreactor from the reservoir.

The bioreactor feed consists of two components. The flow of exudate from surrounding tissues into the wound bed starts seconds after formation of the wound bed by excision and constitutes the endogenous feed. The ECM analog, occasionally seeded with cells, is supplied immediately after excision as well and constitutes the exogenous feed. The reservoir maintains the bioreactor contents at constant temperature and pH and, in addition, supplies it with a continu-

Fig. 15.1. *In vivo* synthesis of tissues and organs is modeled as if it were taking place inside a bioreactor (wound bed) that is surrounded by a reservoir (animal). Exudate flows continuously from the reservoir to the bioreactor. The exudate contains cells, cytokines, and several other soluble substances, but not insoluble matrix components. Conditions inside the animal are subject to relatively strict homeostatic control. (Courtesy of M.I.T.)

ous flow of exudate consisting of cells, cytokines, and other diffusible components. Exudate typically does not contain ECM components; matrix components that are required for the synthesis are supplied exogenously in the form of an ECM analog. The selection of structural features of the ECM analog supplied to the wound bed is critical and is discussed in the next section. If the appropriate ECM analog (template) is omitted entirely, or if the selection of analog and cell content is inappropriate, the reaction sequence inside the wound bed eventually yields repaired, not regenerated, tissue. The template is therefore required to block the normal repair process in the wound bed. Repaired tissue typically consists of epithelialized, undifferentiated connective tissue, often referred to as scar or fibrotic tissue. An organ consisting mostly of repaired tissue does not function physiologically. The process of *in vivo* synthesis of a physiologic organ is also referred to as an instance of *in situ* organ synthesis, a term used interchangeably with *in vivo* synthesis.

Experimental study of *in vivo* synthesis is routinely complicated by lack of reproducibility from one reaction site to another, nominally identical, anatomic site. The site or tissue substrate on which the reaction is taking place may vary in chemical composition, surface area, or other parameters that affect the kinetics and mechanism of the desired reaction. In the absence of such site-to-site reproducibility it is very difficult to develop results that are statistically significant without performing an inordinately large number of experiments. *In vivo* organ synthesis is potentially beset by the same set of problems, originating either in lack of reproducibility of conditions from one wound bed to another in the same animal or from a wound bed in one animal to that in another. The problem of wound-to-wound variability was dramatically minimized, almost practically eliminated, in the pioneering experiments of Billingham and Medawar (1951, 1955), who developed the concept of the anatomically constant wound bed. In their rodent models, skin was routinely excised down to the layer of muscle that lies under the dermis. With the exception of end effects, the contents of this wound bed, including the exudate that flows into it, are nearly identical from one site to the next. The precise choice of dimensions of an anatomically constant bed varies with the goal of the investigator. In experiments in which the synthesis of peripheral nerve in rats has been studied, an anatomically constant wound bed has consisted of a gap, approximately 10 mm long, along the cylindrical geometry of the nerve fiber; the ECM analog, in the form of a matrix filler inside a cylinder, has been grafted as a bridge for this gap. Studies of regeneration in the knee meniscus have also been based on a careful choice of geometry. Criteria for the selection of an anatomically well-defined wound bed have been published (Yannas, 1997).

The sequence of chemical reactions and biological interactions inside the wound bed is of great complexity. Precise knowledge of such a mechanistic sequence is necessary in order to design a regeneration template without recourse to extensive experimentation. In the absence of such information, the experimenter relies on empirical data relating the structure of the experimental device to the structure or function of the tissue or organ that is under study. An example is measurement of the moisture evaporation rate from a full-thickness skin wound bed in the guinea pig wound model that has been treated with a dermis regeneration template (DRT) seeded with keratinocytes. Following a 14-day period, which is necessary to achieve epidermal confluence over the newly synthesized dermal substrate, the new epidermis becomes keratinized and forms an effective barrier that impedes moisture evaporation from the body. Another example is the continuous measurement of the velocity of an electrical signal that is conducted by a regenerating nerve, previously treated with a nerve regeneration template (NRT). This measurement yields a virtually continuous record of the regeneration process and yields the time required for achievement of nearly physiologic values. Neither of the last two examples provides by itself definitive proof that a new, physiologically functioning organ has been synthesized; additional properties of the new organ need to be determined before its synthesis can be established. However, the noninvasive measurements of function cited above allow the investigator to monitor the progress of the synthesis from beginning to end using the same animal. The less attractive alternative is to use invasive measurements, e.g., histologic data, which provide information on only one time point per animal. Irrespective of the method of measurement, data on the degree of completion of a given property are usefully converted to a physiologic index, a measure of the closeness of a given structural or functional property of the regenerate to the intact adjacent organ.

Mammals typically possess a very small but finite potential for spontaneous regeneration of most of their organs. For example, a cylindrical defect measuring considerably less than about 1 cm in diameter in the long bone of many mammals is spontaneously refilled with apparently phys-

iologic bone (Shapiro, 1988); a gap less than about 5 mm in the transected rat sciatic nerve, previously treated by inserting the two nerve stumps into a silicone tube, is spontaneously synthesized as a fairly successful regenerate (Lundborg, 1987; Lundborg *et al.*, 1982a–d; Dahlin *et al.*, 1995). The minimum mass of dermis that can be spontaneously regenerated in adults appears to be zero (Billingham and Medawar, 1951, 1955; Madden, 1972; Peacock, 1984; Boykin and Molnar, 1992).

Organ mass that has been synthesized using the techniques described in this chapter must be corrected for organ mass that can be synthesized spontaneously at the same anatomically constant wound bed. This correction for “background” regeneration (or spontaneous regeneration) can be determined simply as the amount of organ mass synthesized in the absence of exogenous feed. Tissue or organ synthesis that has resulted from use of an exogenous feed is referred to as induced regeneration. It is clear that the net effect of the exogenous feed on a given physiologic index of the new organ cannot be quantitatively appreciated until the index has been carefully corrected for the contribution of background regeneration.

## FUNDAMENTAL DESIGN PRINCIPLES FOR TISSUE AND ORGAN REGENERATION TEMPLATES

By definition, the template essentially interacts with components of the exudate (cells and cytokines) sufficiently to modify drastically the kinetics and mechanism of the spontaneous process that normally converts exudate to scar tissue. Such an interaction requires the template surface to be adequately close and accessible to cells migrating from the exudate; migrating cells that have approached close enough require the template surface to be populated with the appropriate type and density of cell binding sites; such interaction must be allowed to proceed over the necessary time period. Finally, when the interaction has successfully modified the kinetics and mechanism of wound healing away from repair, it is required that the template remove itself even as new tissue is being synthesized adjacent to the surface of the template. Each of these steps in the function of a template must be executed, and each, in turn, must be translated into a design requirement for the template. The structural features that lend function to a regeneration template will be described separately below: features that constitute the porous network structure (scale 1–100  $\mu\text{m}$ ) will be discussed first, followed by features that describe the macromolecular network (scale 1–100 nm).

### CRITICAL CELL PATH LENGTH: MAXIMUM DIMENSION OF TEMPLATE

Host cells migrating into the template require adequate nutrition during the entire time of residence in it. For modeling purposes, the complexity of nutritional requirements of the cell are simplified by defining a critical nutrient that is required for normal cell function; such a nutrient is assumed to be metabolized by the cell at a rate  $R$  in moles/ $\text{cm}^3/\text{sec}$ . The nutrient is pictured being transported from the wound bed, where the concentration of nutrient is assumed to be a constant,  $C_0$ , over a distance  $L$  through the exudate until it reaches the cell (Fig. 15.2). In the early days following implantation of the template there is no angiogenesis and the nutrient is, therefore, transported exclusively by diffusion, which is characterized by a diffusivity  $D$  in  $\text{cm}^2/\text{sec}$ . Dimensional analysis readily yields the cell lifeline number

$$S = RL^2/DC_0, \quad (1)$$

which characterizes the relative magnitude of the rate of nutrient supply to the cell by diffusion and the rate of nutrient consumption by the cell. If the rate of consumption of the critical nutrient exceeds greatly the rate of supply,  $S \gg 1$ , and the cell must soon die. At steady state the rate of consumption of nutrient by the cell just equals the rate of transport by diffusion over the distance  $L$ . Under conditions of steady state,  $S$  is of order 1, and the value of  $L$  becomes the critical cell path length,  $L_c$ , the longest distance away from the wound bed boundary along which the cell can migrate without requiring nutrient in excess of that supplied by diffusion. For many cell nutrients of low molecular weight  $L_c$  is of order 100  $\mu\text{m}$ , a distance short enough to suggest the need for very close proximity between wound bed and implant (Yannas and Burke, 1980). The requirement for proximity is critical and suggests that a graft may not “take” unless the template has met this demanding condition of physicochemical contact.

Fig. 15.2. Model of the interface between host tissue and an implant (or the atmosphere, in the case of an unimplanted wound) adjacent to its surface. A cell from the host interface has migrated into the exudate, which flows out of host tissue. Will the cell receive sufficient nutrient by diffusion from host tissue to migrate all the way to the implant (or the atmosphere)? A critical cell nutrient is transported from the host interface, where the nutrient concentration is assumed to be equal to  $C_0$ , over a distance  $L$ , through the exudate until it reaches the migrating cell, where it is metabolized at a rate  $R$ . Angiogenesis has not yet occurred; therefore, nutrient transport takes place strictly by diffusion, characterized by a diffusivity  $D$ . Dimensional analysis allows calculation of the critical cell path length,  $L_c$ , an estimate of the maximum permissible distance of separation between the host tissue surface and the implant; it is of order  $100 \mu\text{m}$ . The value of  $L_c$  is also an estimate of the minimal thickness of exudate covering an unimplanted wound bed that is required to accommodate migrating cells through its thickness. ### UPPER AND LOWER BOUNDS OF TEMPLATE PORE DIAMETER

Having successfully migrated onto the template surface a host cell is visualized interacting with an appropriate site on the matrix and binding onto it. Cells commonly make use of cell surface receptors, e.g., the family of integrin receptors, to bind on a matrix surface; typically, each receptor binds on a specific binding site on the matrix surface. A highly detailed model of a particular interaction between a cell type and a matrix surface must specify the nature of the receptor and the binding site, as well as the number of receptors utilized per bound cell. The description of cell–matrix binding given below assumes no such specific knowledge.

We are interested in estimating the structural requirements for a porous solid that binds all or almost all of the cells of a given type in contact with it. We want to estimate the relation between the average pore diameter of a matrix and its capacity for binding cells. The surface density of bound cells can be expressed as  $\Phi_c$ , equal to the number of bound cells  $N_c$  per unit surface  $A$  of the porous template.  $\Phi_c$  is also equal to the number of bound cells per unit volume of porous template,  $\rho_c$ , divided by the specific surface of the template,  $\sigma$ . The latter is equal to the surface per unit volume of template and is expressed in units of  $\text{mm}^2/\text{cm}^3$  template:

$$\Phi_c = N_c/A = \rho_c/\sigma. \quad (2a)$$

If additional information becomes available on the nature of the binding interaction, the model can become more detailed. If  $\chi$  receptor sites are utilized per bound cell, and if each receptor is bound to one binding site, the number of binding sites per unit surface will be  $N_c\chi/A$ . Then the volume density of binding sites,  $\rho_{\text{bs}}$ , will be equal to  $\chi\rho_c$  and the surface density of binding sites will be equal to

$$\Phi_{\text{bs}} = \chi\Phi_c = \chi N_c/A = \chi\rho_c/\sigma = \rho_{\text{bs}}/\sigma. \quad (2b)$$

We will now compare the cell surface density of two matrices that have identical chemical composition but quite different average pore diameter. It is known that when other structural features, such as the pore volume fraction, remain constant, the specific surface increases with a decrease in average pore diameter. The average pore diameter as well as the pore volume fraction of a template can be controlled by careful control of the conditions of freezing prior to drying by sublimation (freeze drying or lyophilization) (Dagalakis *et al.*, 1980). In the example of a matrix that has been experimentally studied for possible template function, the average pore diameter is  $10 \mu\text{m}$  and the volume density,  $\rho_c$ , of fibroblasts that are bound on the matrix has been observed by light microscopy to be of order  $10^7$  cells/ $\text{cm}^3$  porous matrix. The number of receptors that are utilized per bound cell is not known. For this matrix, the specific surface  $\sigma$  is calculated, using a simple model that relates the shape and size of pores to their surface, to be about  $8 \times 10^4 \text{ mm}^2/\text{cm}^3$  matrix volume. According to Eq. (2a), the surface density of bound cells is equal to  $\Phi_c = 10^7/8 \times 10^4 = 125 \text{ cells}/\text{mm}^2$  for this matrix. Next we consider a matrix that has an average pore di-

iameter as large as 300  $\mu\text{m}$ . The specific surface in this case is estimated to be only about  $3 \times 10^3 \text{ mm}^2/\text{cm}^3$ . On the other hand, because both matrices have the same chemical composition, they also have the same type and density of binding sites, and it follows that the surface density of bound cells,  $\Phi_c$ , is the same in both matrices. However, the volume density of bound cells is only  $\rho_c = \Phi_c \sigma$ , or  $125 (3 \times 10^3) = 3.75 \times 10^5/\text{cm}^3$  matrix. The conclusion is that the volume density of bound cells in the matrix with the 300- $\mu\text{m}$  pore diameter is approximately 27 times lower than in the matrix with the 10- $\mu\text{m}$  pore diameter. The calculation suggests the importance of the specific surface of the porous template; if the surface is insufficiently large, an insufficient number of cells in the wound bed will be bound on the matrix. These considerations suggest a maximum pore diameter requirement for the template, solely to meet the binding needs of the cells interacting with it. In the absence of further information, the absolute magnitude of this upper bound for the pore diameter is determined by experiment.

The discussion above makes it obvious that there is also need for a minimum pore diameter, about equal to the characteristic diameter of the cells, of order 10  $\mu\text{m}$ , which must migrate inside the template volume prior to binding on specific sites on its surface. Thus, the specific surface of a regeneration template, and consequently its average pore diameter, are limited both by an upper and a lower bound, as observed experimentally (Yannas, 1998; Yannas *et al.*, 1989).

### TEMPLATE RESIDENCE TIME

The structural parameters discussed in the preceding section were required to make the cell binding sites on the template accessible to the cells in the exudate. Once such a rendezvous has been accomplished successfully, the next steps in the function of the template require the exudate–matrix interaction to be specific enough to yield new physiologic tissue and eventually the entire organ. While organ synthesis is being pursued at the wound bed the template must leave the site.

A template must be in place long enough for the specific interaction to take place but it must eventually disappear so as not to interfere with the synthetic process. These considerations are consistent with a template residence time, which has both a lower and an upper bound. The appropriate time period is approximately equal to that required for synthesizing relatively mature tissue at the specific organ site by regeneration. The latter is *a priori* unknown; it will be taken to be of the same order as that required to complete the conventional wound healing process at that anatomical site. At the expiration of this period the template is required to remove itself. Because the template is a cross-linked network it cannot diffuse away from the reaction site. The simplest design that can accomplish this disappearing act is one in which the macromolecular network undergoes degradation by enzymes of the wound bed to harmless low-molecular-weight fragments that diffuse away from the site of organ synthesis. These assumptions lead to the hypothesis of isomorphous tissue replacement (Yannas and Burke, 1980; Yannas, 1998):

$$\tau_b/\tau_h = O(1). \quad (3)$$

In Eq. (3)  $\tau_b$  denotes a characteristic time constant for degradation of the template at the tissue site where a new organ is synthesized with a time constant of  $\tau_h$ . The ratio of the two constants is on the order of one, as indicated by Eq. (3).

This hypothesis has received some experimental support from two critical observations. When the ratio in Eq. (3) was much smaller than one, indicative of a very rapidly degrading template, the wound healing process resulted in synthesis of scar, as would have been the case if the template was not there. It was also observed that when the ratio in Eq. (3) was much larger than one, the template remained in the wound bed as an intractable implant and wound closure by epithelialization did not occur (Yannas and Burke, 1980).

Adjustment of the degradation rate of the ECM analog to satisfy Eq. (3) requires adjustment of the chemical composition of the ECM analog. Assays have shown that the resistance of the network to degradation by wound bed enzymes, such as the collagenases, increases with its cross-link density (Yannas, 1981; Yannas *et al.*, 1975b). The cross-linking reaction is simply based on a process in which the water in the ECM analog is removed below  $\sim 1 \text{ wt}\%$ ; the result of drastic dehydration is formation of interchain amide bonds by condensation (Yannas and Tobolsky, 1967). The advantage of this process is that no cross-linking agent is used. Additional cross-linking can be introduced by reaction with glutaraldehyde (Yannas *et al.*, 1980); however, the cross-linked matrix must subsequently be rinsed exhaustively in order to remove traces of the toxic cross-linking

agent (Yannas *et al.*, 1989). Still a third procedure for increasing the resistance to degradation involves incorporation of a glycosaminoglycan (GAG) in the ECM analog (Yannas *et al.*, 1975a).

Use of three independent methods of adjusting the degradation rate provides substantial design flexibility. In this fashion the enzymatic degradation rate can be varied over a wide range, providing implants that, without losing their biological activity during preparation, can be designed effectively to disappear from the new organ site between a few and several days (skin) or between a few and several weeks (peripheral nerve). The time constant  $t_h$  varies greatly from one organ site to the next in the same animal species; if an ECM analog of the same composition is to be studied in a different site, the network structure must be adjusted accordingly (Yannas *et al.*, 1975a,b, 1989). There is also species-to-species variation: the half-life of the dermis regeneration template in the full-thickness (full-depth) skin wound in the swine model is 15.5 days but only 7 days in a similar type of wound in the guinea pig model (Orgill *et al.*, 1996).

## CHEMICAL COMPOSITION

The chemical composition of the ECM analogs that have induced regeneration is relatively simple. The analogs used successfully so far have been graft copolymers of type I collagen and a sulfated glycosaminoglycan. The GAG component has a dual role: on one hand, it increases the resistance to degradation (Yannas *et al.*, 1975a); on the other, specific GAG components, together with type I collagen, appear to possess specific biological activity (Shafritz *et al.*, 1994). The ratio collagen/GAG is adjusted to meet these two requirements and a covalent reaction is employed to graft the GAG chains onto the chains of the collagen substrate (Yannas *et al.*, 1980).

The mechanistic steps by which the chemical identity of collagen/GAG graft copolymers promotes regeneration are still under study; however, there is sufficient evidence to suggest a nearly complete hypothesis that is based on the observed association between inhibition of wound contraction and regeneration (Yannas, 1998).

It has long been known that the mammalian fetus is capable of regeneration whereas the adult is not (Mast *et al.*, 1992a,b). A rule of thumb suggests that the third trimester of mammalian gestation is the turning point from wound closure primarily by synthesis of physiological tissues and organs (regeneration) to closure by wound contraction and scar synthesis (repair). In amphibians, it has been known that the turning point is metamorphosis from tadpole to young adult (frog) (Wallace, 1981). Basic information on changes in wound healing behavior with development has been, however, less available in mammals, primarily due to experimental difficulties in studying wound healing in mammalian fetal models. The question was tackled in a study of the amphibian frog (*Rana catesbeiana*), in which wound closure was studied quantitatively during development from the larva (tadpole) to the young adult (frog). It was observed that, during larval development, wound contraction gradually became more important and regeneration became increasingly insignificant as a mechanism for wound closure. Following metamorphosis to the young adult, skin wounds closed by a combination of contraction and synthesis of scar tissue whereas regeneration did not contribute to wound closure (Yannas *et al.*, 1996). These observations supported the presence of an antagonistic relation between wound contraction and regeneration.

Other studies have suggested that effective inhibition of wound contraction is necessary for dermal regeneration in full-thickness skin wounds in the guinea pig (Yannas, 1981; Yannas *et al.*, 1982, 1989). In these studies it was shown that contraction was inhibited strongly by grafting the wound with an ECM analog with very specific structure (eventually named the dermal regeneration template because it was observed that it induced regeneration of a nearly physiological dermis); even slight deviations from the structure of the DRT led to strong contraction. Such data cannot be explained by hypothesizing that the DRT acted as a mechanical splint that physically hindered contraction; several other ECM analogs, differing slightly in structure and with mechanical stiffness that was either somewhat higher or lower than that of the DRT, were incapable of inhibiting contraction in the same animal model. Rather, the observations with ECM analogs support further the hypothesis that wound contraction and spontaneous regeneration are mutually exclusive phenomena (Yannas, 1998).

Wound contraction is mediated partly by migratory fibroblasts and partly by contractile fibroblasts (CFBs) (Rudolph *et al.*, 1992). An early hypothesis has suggested that the DRT inhibits contraction by disrupting the large-scale organization of the CFB population, which is involved

in formation of a three-dimensional network, capable of supporting contractile mechanical stresses across the macroscopic wound bed (Yannas, 1988; Murphy *et al.*, 1990). But how does the template interfere with formation of this hypothetical network at the scale of the cell? This question has been answered in terms of the specific cell–matrix interactions that are entered into between the CFB and the binding sites on the DRT. It is known that fibroblasts bind to naturally synthesized ECM by formation of highly specialized transmembrane links, involving integrins, which are referred to as fibronexin (Hynes, 1990). Accordingly, it has been suggested that the strong contraction-inhibiting activity of the DRT consists in establishing early connections with contractile cells of the wound bed, thereby preventing eventual formation of cell–ECM connections (fibronexin). By doing so, the DRT inhibits the function of the endogenous ECM, which is synthesized long after the DRT has been grafted, and thereby prevents the formation of an organized CFB network that is capable of contraction (Yannas, 1998). However, the identity of binding interactions between CFBs and the ECM analogs are still not well understood. Although the mechanistic hypothesis presented above has been based primarily on data from skin wounds, there is evidence that similar considerations apply in peripheral nerve wounds as well (Chamberlain *et al.*, 1998a).

## EXAMPLES OF *IN VIVO* ORGAN SYNTHESIS

### SKIN REGENERATION TEMPLATE

*In vivo* synthesis of a partly physiological skin organ using the dermis regeneration template has been demonstrated clinically with a population of massively burned patients (Burke *et al.*, 1981; Heimbach *et al.*, 1988) following extensive studies with animal models (Yannas *et al.*, 1975a,b, 1981, 1982). Patients with loss of a substantial fraction of total body surface area (TBSA) face an immediate threat to their survival, originating mainly in the loss of their epidermis. One result of this loss is an increase by an order of magnitude of the moisture evaporation rate from the body, which, if left uncorrected, leads to excessive dehydration and eventually to shock. Another result is a sharp increase in risk for massive bacterial infection, which, if allowed to progress, frequently resists treatment and leads to sepsis. Even when patients manage to survive these immediate threats there is a residual serious problem of quality of life, originating in the occurrence of crippling contractures and disfiguring scars, both of which are sequels of the normal repair process. Conventional treatment is based on use of autografting, which yields excellent results at the treatment site but which is burdened by the trauma caused at the donor site as well as by the unavailability of donor sites when the TBSA exceeds about 40–50%.

Of the two major tissue types that together comprise skin, the epidermis regenerates spontaneously provided there is a dermal substrate underneath. The dermis does not regenerate spontaneously in the adult. In clinical studies of the DRT, the latter has been used as a cell-free device and has induced regeneration of the dermis, thereby providing the essential substrate for spontaneous regeneration of the epidermis. A keratinocyte-seeded DRT that induces simultaneous formation of a dermis and an epidermis in the guinea pig model has been referred to as a skin regeneration template (SRT); however, the evidence has since suggested that the DRT does not require seeding with cells prior to grafting in order to induce regeneration of the dermis in the swine model, which is much more similar to the human than the guinea pig model. Following dermis regeneration by the unseeded DRT, epidermal cells from the wound edges migrate into the center of the wound and form a mature epidermis (Orgill *et al.*, 1996). In summary, although the seeded DRT induces simultaneous regeneration of skin in the guinea pig model, the unseeded DRT induces sequential regeneration of skin in the swine model. The kinetics of simultaneous regeneration do not depend on the size of the wound whereas those of sequential regeneration do; accordingly, the cell-seeded DRT would appear to be more useful in a clinical setting, where speed of wound closure is of essence. However, the data suggest that *in vivo* synthesis of skin does not require anything more than the DRT, and the latter directly induces synthesis of the dermis only; this explains the use of the term DRT in place of SRT.

The DRT is used as a bilayer device, consisting of an inner layer of the active ECM analog and an outer layer of elastomeric poly(dimethyl siloxane). The layer of silicone is removed about 2 weeks after grafting the device, having served the important temporary role of controlling moisture flux and bacterial invasion at the site of organ synthesis (wound bed) as well as allowing handling, including cutting and suturing, by the surgeon. The structure of the DRT comprises a col-

lagen:chondroitin 6-sulfate ratio of 98:2; lower and upper bounds of pore diameter of  $20 \pm 4 \mu\text{m}$  and  $125 \pm 35 \mu\text{m}$ , respectively; and lower and upper bounds of residence time in the wound bed of 5 and 15 days, respectively (Yannas *et al.*, 1981, 1982, 1989). Clinical use of the DRT has emphasized treatment of patients with massive burns as well as those who require resurfacing of large or small scars from burns. With wounds of relatively small characteristic dimension, e.g., 1 cm, epithelial cells migrating at speeds of order 0.5 mm/day from each wound edge can provide a confluent epidermis within 10 days. In such cases, the unseeded template fulfills all the design specifications set above for *in vivo* organ synthesis. However, the wounds incurred by a massively burned patient are typically of characteristic dimension of several centimeters, often more than 20–30 cm. These wounds are large enough to preclude formation of a new epidermis by cell migration alone within a clinically acceptable time frame, say 2 weeks. Current clinical protocol favors use of a very thin autoepidermal graft, thin enough not to leave behind a scarred donor site, to cover the neodermis (Burke *et al.*, 1981; Heimbach *et al.*, 1988; Spence, 1998).

### NERVE REGENERATION TEMPLATE

Loss of peripheral nerve function typically involves the loss of innervation in the arms, legs, or face, leading to loss of motor and sensory function (paralysis). A common cause of loss of nerve function is accidental mechanical trauma or surgery. In a well-studied experimental model of injury, the nerve trunk is cut along the entire diameter (transection) and the two stumps are inserted in a tube, usually made of silicone elastomer, other synthetic polymers, or, more recently, collagen (Lundborg, 1987; Archibald *et al.*, 1995; Valentini and Aebischer, 1997; Chamberlain *et al.*, 1998b).

The length of the gap that separates the stumps in the tubulated rat model can be adjusted and is an important experimental variable that controls the probability of success in a regeneration process (Lundborg *et al.*, 1982a). It has been observed that spontaneous elongation of the conducting fibers (axons) along the gap is complete, leading to some recovery of function, when the gap length is not much larger than about 5 mm; in contrast, the probability of regeneration is zero when the gap length is as large as 15 mm. This information allows the experimenter to estimate the extent of spontaneous (background) regeneration in the tubulated gap model at about 5 mm; therefore, any recovery of function that occurs across a gap much longer than that can be considered to result from induced regeneration. In practice, a gap length of 15 mm in the rat sciatic nerve is somewhat too large to place in the femur of the rat and, for this reason, a 10-mm gap length has been used extensively and has yielded reliable data provided that the appropriate controls have been used to separate out spontaneous from induced regeneration.

A wound in the sciatic nerve is experimentally attractive because the loss of function is limited primarily to contraction of the plantar muscle in the foot; loss of function or recovery from loss can, accordingly, be monitored by measuring the velocity or amplitude of an electric signal that is experimentally transmitted along the sciatic nerve (Madison *et al.*, 1992). Unlike currently available procedures for monitoring the recovery of skin function following full-thickness loss, this electrophysiological procedure provides for convenient and minimally invasive monitoring of the kinetics of recovery over almost the entire period of healing. Use of electrophysiological procedures has shown that recovery of peripheral nerve function following transection of the rat sciatic nerve extended to beyond 2 years. This lengthy period appears necessary for the slow turnover (remodeling) processes inside the nerve trunk that lead to increase in diameter of conducting fibers (axons) and result in slow but critical increases in conduction velocity (Chamberlain *et al.*, 1998b). On the other hand, the characteristic time constant for the short-term healing events at the site of the transection that lead to wound closure appear to extend to about 6–10 weeks, clearly longer than the time constant for healing in skin, which is about 1.5 weeks (Table 15.1).

The nerve regeneration template (NRT) has typically been studied in a wound bed formed by excising either a 10-mm or a 15-mm gap in the sciatic nerve of the rat. Early versions of the NRT inserted inside a silicone tube led to the first evidence of substantial regeneration across a gap of 15 mm in the rat sciatic nerve (Yannas *et al.*, 1987). The device incorporating the NRT is a collagen tube filled with the porous ECM analog, which has chemical composition similar to that of the DRT. The similarity between the templates ends there. The average pore diameter of the NRT is  $5 \mu\text{m}$ , an order of magnitude smaller than the middle of the range 20–120  $\mu\text{m}$  for pore diameter in the DRT. The residence time is on the order of 6–8 weeks, much shorter than

**Table 15.1. Structural properties of two regeneration templates**

Design parameter of ECM analog	Regeneration template	
	Dermis	Nerve
Residence time, weeks	1.5	6–8
Average pore diameter, $\mu\text{m}$	20–120	5
Pore channel orientation	Random	Axial

that for the DRT (about 15 days). Finally, the pore channels of the NRT are highly aligned along the tube axis rather than being randomly oriented, as with the DRT (Chang and Yannas, 1992). The differences between the two templates are highlighted in Table 15.1.

Nerves regenerated in animals with use of the NRT have shown recovery of the velocity of electric signal transmission to an extent of 70% of physiological value. However, recovery of signal amplitude has reached only between 20 and 40% of the intact tissue (Chamberlain *et al.*, 1998b). Neurological studies of performance of regenerated nerves are not complete and it is not yet possible to deduce the extent of recovery of physiological walking behavior (gait).

### REGENERATION OF THE KNEE MENISCUS

Joint stabilization and lubrication, as well as shock absorption, are the main functions of the knee meniscus. Its structure is that of fibrocartilage, distinct from that of articular cartilage, consisting primarily of type I collagen fibers populated with meniscal fibrochondrocytes. As in articular cartilage, the architecture of collagen fibers is complex. The shape of the meniscus suggests one-half a doughnut, in which the collagen fibers are arranged in a circumferential pattern that is additionally reinforced by radially placed fibers. Meniscus tearing occurs often during use, causing pain and dysfunction. The accepted treatment is partial or complete excision of torn tissue; however, the result is often unsatisfactory, because the treated meniscus has an altered shape that is incompatible with normal joint motion and stability. In the long term such incompatibility leads to joint degeneration, eventually leading to osteoarthritis, a very painful condition.

Regeneration of the surgically removed meniscus was induced following surgical deletion (excision) of the torn segment, amounting to about 80% of total mass, and implantation of a device that was based on a graft copolymer of type I collagen–chondroitin 6-sulfate copolymer (Stone *et al.*, 1989, 1990). The precise structural parameters of this matrix have not been reported in the literature, so it is not possible to discuss the results of this study in terms of possible similarities and differences with the DRT and NRT. The experimental study was based on the canine knee joint, which is particularly sensitive to alterations of structure that lead to biomechanical dysfunction. In this model, joint instabilities rapidly deteriorate to osteoarthritic changes, which can be detected experimentally. The canine meniscus regenerates poorly following excision, resulting in a biomechanically inadequate tissue that does not protect the joint from osteoarthritic changes. In one animal study, knee joints were subjected to resection of the medial meniscus and the lesion was treated either by an autograft or an ECM analog, or was not treated at all. Joint function was evaluated by studying joint stability, gait, and treadmill performance, and extended over 27 months. No evidence was presented to show that the structure of the ECM analog was optimized to deliver a maximal regenerative effect. Two-thirds of the joints implanted with the ECM analog, two-thirds of the joints that were autografted, and only one-fourth of the joints that were resected without further treatment showed regeneration of meniscal tissue. These results were interpreted to suggest that the ECM analog supported significant meniscal regeneration and provided enough biomechanical stability to minimize degenerative osteoarthritis in the canine knee joint (Stone *et al.*, 1989, 1990).

The feasibility of extending this treatment to humans was studied using patients with either an irreparable tear of the meniscal cartilage or a major loss of meniscal cartilage. Patients remained in the study for at least 36 months. Irreparably damaged meniscal tissue was first deleted and the ECM analog was implanted in its place. Regeneration of meniscal cartilage was observed at

the site of implantation with the ECM analog while the template was undergoing degradation. The results were compared with those obtained with another group of patients who had been subjected to meniscectomy (removal of damaged meniscal tissue without the treatment), during the same period of observation. Patients who were implanted with the ECM analog showed significant reduction in pain as well as greatly improved resumption of strenuous activity relative to the untreated control group (Stone *et al.*, 1997).

## SUMMARY

Studies have examined the process by which tissue and organs can be synthesized *in vivo* through use of ECM analogs; this process is also referred to as induced regeneration. Although several ECM analogs have been studied, only one of these, specified by a narrowly defined structure, has been shown to be capable of partial regeneration of skin in full-thickness skin wounds in animal models and in humans. Another ECM analog with a structure that has been specified equally narrowly has partially regenerated nerves over very large distances. The structural specificity of these templates appears to be related to the requirement for inhibition of wound contraction prior to the incidence of regeneration.

# PART IV: MODELS FOR TISSUE ENGINEERING

This Page Intentionally Left Blank

# ORGANOTYPIC AND HISTIOTYPIC MODELS OF ENGINEERED TISSUES

Eugene Bell

## INTRODUCTION

Work with intact tissues or tissue fragments in the form of organ cultures has had a long history in experimental embryology in studies devoted to causal relationships between different tissues on which the emergence of differentiated structures depend. It has been recognized that although two-dimensional cell cultures usually lose the characteristic histologic organization and most of the physiologic functions of the original tissue, organ cultures retain both, and can permit the process of development to unfold. But organ culturing in experimental embryology, unlike cell culturing, has consisted of explanting organ anlage, or pieces of intact tissue precursors, under conditions that preserved tissue integrity and discouraged cells from moving out of the explant and from engaging in DNA synthesis in preparation for cell division. Stability of the organ-cultured explant can be attributed, in large measure, to the matrix scaffolds with which the cells in tissues are associated. What cells do in organotypic explants, is for a large part, regulated by instructive scaffolds, already embedded in the extracellular matrix (ECM), and by the flow of information between different contiguous tissues through the ECM. Adequate nutrient medium and physical forces that act on scaffolds and cells may play a role in determining the maintenance and developmental potential of an explant. The disadvantages of organ cultures include their short life, their tendency to undergo central necrosis, the occurrence of vascular occlusion, and the difficulty of preparing standard models, because no two explants are identical.

An alternative approach to the study of tissues *in vitro* consists of reconstituting stable specific tissues with scaffolds, into which cells of the tissue of origin are seeded (Bell *et al.*, 1979). The key requirements for constituting standard models are the appropriate matrix scaffold and a source of cells. Signals may be provided by cells capable of generating them and/or by the addition of signals added to the scaffold or to the culture medium to induce mitogenesis, tissue morphogenesis, and differentiation. Also important may be the application of forces that tissue development requires and, insofar as they are known, the medium or media and other conditions of culture needed to promote survival *in vitro*. The result can be the fabrication of standardized models that closely resemble actual tissues in many respects.

## THE COLLAGEN GEL MODEL

A generic collagen gel model of a two-tissue, or organotypic, system is shown in Fig. 16.1. The model uses a collagen gel scaffold prepared by combining, in the cold, a neutralized 0.3–1.0 mg/ml solution of acid extracted collagen with medium, serum, and mesenchymal cells (Bell *et al.*, 1979)—dermal fibroblasts, for example, if the goal is to fabricate a skin equivalent. The bacteriological petri plate or other vessel, to which cells do not attach, into which the mix is poured, is incubated at 37°C in a 5% CO<sub>2</sub> incubator. The collagen polymerizes, when neutralized and warmed, forming a lattice of fine fibrils, 10–20 nm in size, which trap fluid. The result is a gel in

Fig. 16.1. Formation of tissue equivalent. A generic collagen gel model of a two-tissue system.

which the previously added cells are distributed. The mesenchymal cells in the gel extend and attach podial processes to the collagen fibrils and withdraw the processes with the attached fibrils toward the cell body. As the fibrils are bundled by the cells, fluid is squeezed out of the lattice. The process of gel contraction, known as syneresis, can reduce the size of the collagen lattice 30- to 40-fold, depending on the cell and collagen concentration used. The condensed gel is tissue-like in its consistency, providing a substrate on which epithelial, endothelial, or mesothelial cells may be plated. What has been described in the foregoing sequence is the formation of an untethered gel, because the tissue equivalent releases from the plate and floats. Tethered gels can be prepared by casting the initial cell–collagen–medium mix in a tissue culture plate or vessel, or, cell-seeded pregel mixes can be poured into chambers in which a peripheral grab-rail is provided, around which gels can form to provide a holdfast, limiting contraction to one dimension (Bell *et al.*, 1989; Bell, 1995a). It was found that restrained tissue equivalents were two to three times stronger than unrestrained tissues and that biosynthesis of collagen by dermal fibroblasts under restrained conditions was greater than that under unrestrained conditions, possibly related to prostaglandin  $E_2$  ( $PGE_2$ ) output by resident cells, because  $PGE_2$  inhibits collagen biosynthesis.  $PGE_2$  is produced at about half the level, by cells in restrained tissues, of that produced by cells in unrestrained tissue equivalents. Weinberg and Bell (1986) used velcro to restrain the ends of cell-seeded tubular gels that contracted only in the thickness mode.

Porter *et al.* (1998) have studied the mechanisms of gel contraction in restrained and unrestrained gels and attribute contraction in the former to cell migration through the gel. They point out that how a cell behaves in a tissue depends on the mechanical signals it receives from the matrix. The self-organization of tissue equivalents and the movement of cells within collagen gels have been reviewed (Tranquillo, 1999).

## MODELS OF CELL INTERACTIONS IN COLLAGEN LATTICES

Coculturing interactive tissue-specific subsets of cells that are combined in an appropriate scaffold will be reviewed in an exemplary way. We will focus first on the skin, because it has been used to model developmental, immunologic, and pathologic events. We will touch on other models by tissue type and discuss other forms of collagen scaffolds and techniques used, in addition to gels, for building tissue and organ models.

### THE SKIN EQUIVALENT AS A DEVELOPMENTAL MODEL

As long ago as 1963, Dodson, in Honor Fell's laboratory in Cambridge, isolated dermis from the metatarsus of 12-day chick embryos and subjected it to freeze–thaw cycles before combining it with epidermis that alone was unable to differentiate. Although it lacked living cells, the frozen–thawed dermis, constituting a structurally intact scaffold and probably rich in growth and differentiation factors, was sufficient to support keratinocyte differentiation *in vitro*. A control, consisting of heat-killed dermis, failed to promote keratinocyte differentiation. Similar combinations using adult acellular dermis and keratinocytes, made many years later (Heck *et al.*, 1985; Cuono *et al.*, 1987), were used successfully as transplants to patients requiring skin.

The first skin consisting of “living” dermis and epidermis reconstituted from cultivated cells and collagen scaffolding (Bell *et al.*, 1979, 1981, 1983) was shown to undergo virtually complete differentiation *in vitro*, lacking, however, pigment, sweat glands, neurogenic elements, a micro-

circulation, and hair follicles. The model can be reproduced faithfully and be kept alive *in vitro* for months, at least. Although collagenolytic activity is high in young dermal equivalents (Nusgens *et al.*, 1984; Rowling *et al.*, 1990), possibly associated with tissue remodeling, it has been observed that the resistance of dermal equivalents to breakdown by collagenase is greatly enhanced by 30 days of cultivation *in vitro*, suggesting that extensive cross-linking (probably by cell-secreted lysyl oxidase) of the collagen fibrils has occurred, as shown by Rowling *et al.* (1990). Continued differentiation of the model *in vitro* and the resemblance of cells in the matrix to their *in vivo* counterparts, rather than to cells grown on plastic in two dimensions, are distinguishing features (Coulomb *et al.*, 1983). Collagen processing by cells grown on two-dimensional (2D) substrates is known to be deficient in that the exported molecule retains the procollagen C- and N-terminal telopeptides normally cleaved by peptidases (Freiberger *et al.*, 1980). In the collagen lattice scaffold, processing and subsequent polymerization, for which it is a requirement, proceed normally (Nusgens *et al.*, 1984).

Populating matrix scaffolds, other than collagen lattices (gels), with dermal fibroblasts to produce dermal equivalents followed the introduction of the original work that reported the fabrication of both dermal and skin equivalents (Bell *et al.*, 1979, 1981). Materials used include nylon, Vicryl (Hansbrough *et al.*, 1993), and Biobrane (Hansbrough *et al.*, 1994). The commercial product Dermagraft (Advanced Tissue Sciences) uses the technique of seeding the Vicryl scaffold with allogeneic fibroblasts.

With the contracted dermal equivalent overlaid by keratinocytes, the time required to constitute a skin model is 14 to 21 days, in the course of which at least three different media may be used: (1) An initial medium supports the contractile activity of the mesenchymal cells (dermal fibroblasts) until an equilibrium size is attained and no further contraction occurs. The process of contraction takes about 4 days. (2) At that time a second medium is applied and keratinocytes are plated on the surface of the dermal equivalent. To promote keratinocyte proliferation, low concentrations of  $\text{Ca}^{2+}$ , epidermal growth factor (EGF), and an up-regulator of cyclic AMP are required. (3) A third medium is used during the second phase of epidermal development, calling for high  $[\text{Ca}^{2+}]$  and air-lifting to expose the epidermis to the atmosphere to induce keratinization and differentiation of a stratum corneum (Parenteau *et al.*, 1991; Bell *et al.*, 1991). The skin equivalent can be populated with melanocytes (Topol *et al.*, 1986) by plating them on the cell-populated dermal equivalent before the application of keratinocytes. Each melanocyte services about 20–30 surrounding keratinocytes, leading to skin pigmentation *in vitro*. Pigment passes into keratinocytes through a melanocyte podial process that has made contact with the keratinocyte plasma membrane.

### THE SKIN EQUIVALENT AS AN IMMUNOLOGICAL MODEL

The skin equivalent can be constituted with cultivated parenchymal cells free of any subsets of immune cells normally found in the dermis and epidermis. Using the X chromosome as a genetic marker, female cells are used to make up skin equivalents, which are then transplanted to male hosts across a major histocompatibility barrier, e.g., from Brown Norway to Fisher rats. Sher *et al.* (1983) demonstrated in the rat model, by karyotyping cells grafted in skin equivalents, that allogeneic fibroblasts were not rejected. It has been reported that clinical trials of skin equivalents made up with human allogeneic keratinocytes as well as allogeneic fibroblasts do not provoke an immune reaction in recipients (Parenteau *et al.*, 1994). The model should be a valuable tool for determining the roles played by cells of the immune system and the microcirculation in allograft rejection of actual skin. It should allow use of cells of any genotype and of human origin to study genetic abnormalities, as well as the contribution of specific genetic loci to skin development by transplanting skin equivalents to immunodeficient rodents.

### THE SKIN EQUIVALENT AS A DISEASE MODEL

Because either normal or aberrant skin cells can be incorporated into skin equivalents, models of disease states can be fabricated. A psoriasis model was fabricated to test the contribution of psoriatic dermal fibroblasts to the expression of features of the disease *in vitro* (Saiag *et al.*, 1985). A button of normal keratinocytes suspended in medium was plated in the centers of dermal equivalent disks constituted with normal human or psoriatic dermal fibroblasts, and the rate of spreading of keratinocytes over the dermal substrate was measured. It was observed that the psoriatic fi-

Fig. 16.2. Disease model. Normal keratinocytes are plated within an 8-mm-diameter circle of a 24-mm-diameter collagen lattice seeded with normal or psoriatic dermal fibroblasts. Keratinocyte growth and spreading are followed. Psoriatic fibroblasts are responsible for hyperproliferation of keratinocytes.

broblasts induced hyperproliferation and greater spreading of keratinocytes compared with the growth and spreading induced by control fibroblasts, suggesting that dermal cells may play a role in the progress of the disease (Fig. 16.2).

In addition to the study of psoriasis, and other epidermal diseases such as epidermolysis bullosa, the model should provide an *in vitro* basis for studying dermal connective tissue disorders, including dermatosparaxis and sclerosis. It is obvious that any pair of populations of mesenchymal cells and epithelial cells, of which one or both is diseased or aberrant, can be used in the three-dimensional coculturing system for studying the expression of features of the disease and testing modalities of treatment.

**THE SKIN EQUIVALENT AS A WOUND HEALING MODEL**

Two-tissue skin models can be used *in vitro* to analyze the role of dermis in epidermal wound healing (Bell and Scott, 1992). After constituting a differentiated skin equivalent in a 24-mm multiwell well-plate insert, a central disk of the skin is removed with a punch (Fig. 16.3). The acellular layer of collagen in contact with the membrane of the insert is replaced and the remainder of the gap is filled with a collagen scaffold to the level of the interface between the dermis and epidermis. The rate of overgrowth of the neodermis by keratinocytes and the development of the epidermis can be taken as measures of the effectiveness of the design of neodermis as an interacting substrate. The wound healing model can accommodate acellular dermal scaffolds with or without signals to test their effectiveness in attracting dermal fibroblasts from the surrounding matrix.

**OTHER TYPES OF EPITHELIAL–MESENCHYMAL MODELS**

A generic model for many types of epithelial–mesenchymal combinations is schematized in Fig. 16.1. Tables 16.1 and 16.2 suggest only some of the combinations for organotypic coculturing. Many others are possible. We are not suggesting that combinations need be restricted to ep-

ithelial–mesenchymal combinations. For example, interactions between populations that are coderivatives embryologically can also be modeled in a three-dimensional system *in vitro*. In the development of the nervous system both attractive and repellent signals guide the course of axons en route to end point targets (Guthrie and Pini, 1995). The authors seeded a collagen gel scaffold with two components, either ventral explants of rat hind brain or spinal cord and floor plate explants from which the former tissues were separated in the scaffold gel. It is shown that outgrowth of motor axons from aspects of hind brain or cord that faced the plate were greatly reduced, suggesting that diffusible factors from the floor plate can exclude motor axons from certain regions of the developing nervous system. The existence of chemorepellants as well as chemoattractants has been discussed (Research News, 1995). They divide into at least two families of proteins, netrins and semaphorins, responsible for growth cone guidance. It is suggested that a single factor can induce attraction or repulsion, depending on the cells involved.

## VASCULAR MODELS

### VASCULAR MODELS WITH CELLS ADDED

Vascular models that examine the effect of shear and other forces on monolayers of endothelial cells *in vitro* have been developed by Nerem *et al.* (1993), who have shown that the rate of endothelial cell proliferation is decreased by flow and that entry of cells into a cycling state is inhibited. They point out the limitations of the 2D system because the important component of cyclic stretch of basement membrane, which the endothelium normally synthesizes and on which it rests,

is absent. They suggest that a coculture system in which the endothelium is supported on smooth muscle tissue would be superior for providing a more physiologic environment. Such a system was developed by Weinberg and Bell (1986), who showed that a basal lamina was laid down between the endothelium and the contiguous smooth muscle tissue, cast in the form of a small-caliber tube *in vitro*. Fabricating the vessel was a three-step procedure. The first tissue layer cast around a small-caliber mandrel was a smooth muscle cell media, whose ends were anchored in a velcro cuff or held fast by ridges and grooves in the mandrel until radial contraction made space for bands that were secured around the ends. Hence the mechanical restraint imposed on the contracting tube allowed contraction to occur radially but not longitudinally, because each end of the vessel equivalent was held fast. The second tissue layer cast was the adventitia surrounding the smooth muscle media. To make room for it, the fluid expressed from the collagen gel scaffold was drawn out of the casting tube, and the mixture of adventitial fibroblasts suspended in medium containing neutralized collagen was introduced into the space between the media and the wall of the cylindrical casting chamber. After the adventitia had contracted radially but not longitudinally, because the media provided a frictional surface that prevented it, the mandrel was extracted, leaving a lumen of the tissue tube that was filled with a suspension of endothelial cells. The cells came to rest on the inner surface of the media as the tube was rotated.

Histologic analysis showed that the smooth muscle cells of the media were oriented in parallel with the long axis of the tissue tube that had formed, rather than circumferentially, as they dispose themselves *in vivo*. By modifying the foregoing procedure to allow the forming vessel to contract freely in its length (L'Heurex *et al.*, 1993; Hirai *et al.*, 1994), simply by eliminating the restraining ties at the ends of the mandrel, the smooth muscle cells orient circumferentially as they do *in vivo*. Similar results are obtained by applying pulsatile pressure, causing the media of the vessel to expand radially (Kanda *et al.*, 1993). Another method (Tranquillo *et al.*, 1996) is based on the observation that polymerizing collagen fibrils align in a magnetic field (Torbert and Ronziere, 1984). By orienting the model devised by Weinberg and Bell (1986), in which the ends of the developing vessel are tethered, with its long axis parallel to a strong magnetic field during fibrillogenesis, it has been shown that collagen fiber orientation is circumferential. The fiber orientation provides contact guidance for smooth muscle cells that encircle the vessel in a direction perpendicular to its length. The use of the new models in experimental animal systems should provide an opportunity to validate their design. Although the more normal organization of the cells of the media should reduce the excessive compliance of the structure that resulted from the longitudinal orientation of the smooth muscle cells, the degree of benefit is still a concern that should be resolvable in animal model trials. The collagen gel lattice may not provide the structural resistance typical of an actual artery, but other collagen scaffolds may (Bell, 1995b). It should also be possible to manipulate *in vitro* conditions by enriching scaffolds with instructive molecules able to induce differentiation of the elastic lamina normally present in arteries.

### VASCULAR MODELS WITHOUT CELLS

Vascular prostheses constructed from Dacron and other synthetics have been in use for many years but are known to elicit persistent inflammatory reactions and to become occluded. The ther-

**Table 16.3. Acellular models consisting of a matrix scaffold but expected to attract or be populated by host cells**

Cell type	Scaffold type	Ref.
Endothelial, smooth muscle, adventitial fibroblast	Submucosa, including stratum compactum of the jejunum	Sandusky <i>et al.</i> (1992)

Same as above	Poly(tetrafluoroethylene)	van der Lei <i>et al.</i> (1991), Stronck <i>et al.</i> (1992)

mosetting polymers are not biodegradable and do not integrate with host tissues, but some successes have been reported under limited conditions in experimental animals (Table 16.3). For the foregoing reasons, other acellular materials have been proposed and tried as arterial substitutes. Animal tissues that resemble arteries have been used with some success, in particular, the porcine small intestine (Sandusky *et al.*, 1992). The mucosal cells are scraped off the luminal side and the muscular layers are removed from the abluminal side, leaving the stratum compactum, a dense, highly organized fibrillar collagen matrix and the looser connective tissue of the mucosa. The material can be used as a scaffold for cells *in vitro* and has been used in animal experiments. *In vivo*, it is invaded by capillaries that contribute cells that provide an intima, whereas smooth muscle cells migrating from the anastomoses provide a media.

## SELECTION OF SCAFFOLDS OTHER THAN GELS FOR MODEL SYSTEMS

A rationale for the selection of collagen scaffolds for tissue engineering has been presented elsewhere (Bell, 1995b). Because *in vitro* models of promise usually lead to trials in experimental animals, which are costly, the argument for the use of a scaffolding material with the evolutionary success credentials of the collagen polymers is strong. Hence we focus on the variety of forms of collagen scaffolds that can be assembled in the laboratory. In addition to gels, foam, fiber, and membrane scaffolds are mentioned.

### COLLAGEN FOAM SCAFFOLDS

Collagen foams (often called sponges) were early described by Chvapil (1977). Collagen foams are fabricated by freeze-drying a solution of collagen placed in a mold of some desired configuration. The collagen concentration can be of the order of 1–5 mg/ml. Results depend on the mold design and the choice of freeze-dry cycle. The foams produced should have communicating compartments between 50 and 100  $\mu\text{m}$  in cross-section, and should be free of a surface skin, which will interfere with cell seeding. Foams made from monomeric collagen solutions are fragile, but nonetheless can be seeded with cells without having been cross-linked. Like gels, uncross-linked or mildly cross-linked foams are readily contracted by mesenchymal cells. Unlike collagen gels, they do not restrict cell division because cells in the foam compartments occupy surfaces, whereas cells in gels are completely surrounded by collagen matrix. After physical or chemical cross-linking [ultraviolet (UV) light, for example] of sufficient intensity and duration, foam scaffolds become resistant to contraction by tissue cells and exhibit decreased or increased resistance to breakdown by collagenase, depending on the cross-linking regimen. Cross-linking with aldehyde produces resilient material but destroys all biologic information intrinsic to collagen polymers.

Foams have been used for the fabrication of numerous tissue types. Sabbagh *et al.* (1998) have shown that the growth and stratification of urothelial cells occur on the collagen foam and conclude that the tissue formed is suitable for grafting. The foam scaffold seeded with bone marrow cells lends itself to medium perfusion, which improves cell survival and differentiation (Glowacki *et al.*, 1998). MacPhee *et al.* (1994) have used foams as a means of harvesting organ-derived endothelial cells by coating foams with fibroblast growth factor-1 (FGF-1) and implanting them in the skin, peritoneum, abdominal mesentery, epimysium, liver, and spleen. Single cells, of which 25% were endothelial, were obtained after collagenase digestion and further concentrated to obtain cultures of high purity. Swope *et al.* (1997) have produced skin equivalents using collagen foams as a dermal scaffold seeded with dermal fibroblasts. Scaffolds were overlaid with keratinocytes after mixing with a measured number of melanocytes determined by cell sorting.

### COLLAGEN FIBER SCAFFOLDS

Scaffolds consisting of spun collagen fibers have been manufactured at Tissue Engineering Inc. Fibers with diameters of 300 nm, as well as larger fibers (in the micrometer range) have been made on a commercial scale. They can be formed into wools by tangling (Fig. 16.4). Figure 16.5 is a scanning electron micrograph of the wool, into which cells are easily seeded (Fig. 16.6). When cross-linked by methods that do not alter the native 67-nm cross-banding, the fibers are considerably more resistant to collagenase than are foam or gel scaffolds.

*Fig. 16.4. Collagen foam-fiber wool containing fibers 30  $\mu\text{m}$  in diameter (patent pending, 09/282,088).*

### COLLAGEN MEMBRANE SCAFFOLDS

Collagen membranes can be prepared by allowing collagen in solution to dry on a surface to which it will not bind, like Teflon or polyethylene. To promote formation of fibrils the solution is neutralized and warmed to 37°C, allowing the collagen to polymerize and form the fibrils. Before it begins to gel the solution is spread on a suitable surface and allowed to dry. The thickness of the membrane can be controlled by the concentration of collagen used, and by the thickness of the gel that is allowed to form after neutralized collagen is poured into the mold in which it is dried. Membranes may be cross-linked by a variety of methods (Gorham, 1991), particularly to improve their wet strength. For example, aldehydic cross-linking will prevent cell attachment, and UV cross-linking will reduce resistance to collagenase, so that the ultimate use of the membrane will dictate the mode of cross-linking.

### CELL SIGNALING AND THE ENRICHMENT OF SCAFFOLDS

Great progress has been made in developmental and cell biology in the area of cell signaling. Its relevance for the reconstitution of prosthetic devices in tissue engineering cannot be overlooked. Whether scaffolds are seeded with cells before they are implanted, or whether they mobilize cells

*Fig. 16.5. Scanning electron micrograph of fiber-foam wool. The foam appears as irregular membranous elements between fibers that are flattened by the freeze-drying process.*

Fig. 16.6. Fiber-foam wool into which dermal fibroblasts have been seeded. By day 14 the cells are surrounded by newly synthesized extracellular matrix. Magnification: A, 100 $\times$ ; B, 320 $\times$ .

from adjacent host tissues, the cells, which become associated with a scaffold enriched with signaling molecules, must be able to respond to them in a manner that leads to the differentiation of the tissues designed to be replaced by the prosthesis. Some tissue cells are able to rebuild tissues, even *in vitro*, without the help of signals from a source other than themselves. They must, however, be combined under the right conditions, as described above. The two principal cell types of skin enjoy a paracrine relationship, providing signals for each other that are sufficient for the reconstitution of a well-differentiated two-layered skin. This relationship is expressed during development and throughout postnatal life.

Answering the general question, concerning which adult cells retain the capacity to respond to signals that were responsible for tissue differentiation in the embryo and fetus, is important for *ex vivo* tissue engineering—that is, for enriching implantable devices. For example, it has been shown that postnatal bone growth and fracture healing in mammals, in particular, endochondral ossification, is a process driven by the same molecular signals that function in the embryo. One of those signals, the protein Indian hedgehog (Ihh), is involved in regulating prenatal bone development. The Hedgehog gene family, in vertebrates, in addition to Ihh, includes Sonic hedgehog (Shh) and Desert hedgehog (Dhh), coding for proteins that play a role in a broad range of morphogenetic events in the course of development. They are thought to function by binding to and activating their specific receptors, believed to be Patched, and a seven-pass membrane protein, Smoothed. Ihh is secreted by prehypertrophic chondrocytes and in turn activates parathyroid hormone-related protein, which down-regulates the rate of chondrocyte differentiation (Vortkamp *et al.*, 1998). Further evidence that the expression of the Hedgehog family of genes is not limited to prenatal development has been provided by Traiffort *et al.* (1998), who show the presence of Ihh, Shh, and Dhh in various other adult tissues in the rat. Although Shh was found localized in the Purkinje cell layer of the adult brain, it remains to be shown what role the protein plays in that tissue.

Identifying a secreted signal that is responsible for initiating the morphogenetic and functional specialization of a developing or susceptible cell is the first step in the causal sequence leading to gene activation. The second step is the identification of the signal's receptor, and the third step is that of finding the factor or factors responsible for translocating the signal to the nucleus, where the most downstream component will act as a transcription factor. Such a sequence has at least in part been elucidated for a class of secreted signaling proteins called Wnt. The large family of Wnt genes encode proteins (rich in cysteine) that are responsible for the regulation of cell fate. They act in an autocrine or paracrine manner by redirecting the transcriptional programs of target cells. They can also form gradients and activate genes in a concentration-dependent way. The proteins of a class called Frizzled have been identified as the receptors for Wnt proteins, and  $\beta$ -catenine found downstream of Frizzled can translocate to the nucleus and act as a transcription factor (Wodarz and Nusse, 1998). It is well known that the development of tissues *in vitro* is promoted by the use of added signals such as cytokines; keeping up with the stream of newly discovered families of signaling molecules seems a necessity for the future of tissue engineering.

## GOALS AND USES OF MODEL TISSUE AND ORGAN BUILDING

One of the major goals of model tissue building is the reconstitution of three-dimensional tissue or organ equivalents that faithfully resemble actual body parts, in order to better understand

cell and tissue interactions and functions under controlled and reproducible conditions. From this point of view the model offers an opportunity to study signaling between cell populations of different embryologic origin. It is useful for analysis of disease states and for seeking remedies for them. The model can serve as a test system for toxicity, diagnostic, and cell migration assays; it can be used for the cultivation of viruses such as papilloma virus, which depend on cycling and differentiating cells. It has the advantage, if constituted with human cells, of giving responses to toxins that may be different from those given by animal cells. Cells in an organized tissue exhibit reduced susceptibility to damage as compared with cells grown on a monolayer (Bell *et al.*, 1991).

A second major goal is the development of tissue and organ models that eventually can serve as prostheses. To reach the goal, model making and *in vitro* testing go hand in hand with testing in experimental animals. Model tissues for transplantation can take many forms: (1) they can be seeded with parenchymal cells that normally populate the tissue being replaced; (2) they can be acellular but designed to mobilize cells from contiguous tissues; (3) they can be constituted with degradable biopolymer scaffolds that are permissive, with the expectation that the cells with which they are seeded or which populate them will create a tissue-specific extracellular matrix and associated scaffolding; or (4) they can be instructive, being provided with an enriched scaffold able to influence the activities of cells. If the goal of tissue engineering is the induction of regeneration, the design and selection of models must be based on their success *in vivo*.

# QUANTITATIVE ASPECTS OF TISSUE ENGINEERING: BASIC ISSUES IN KINETICS, TRANSPORT, AND MECHANICS

Alan J. Grodzinsky, Roger D. Kamm, and Douglas A. Lauffenburger

## INTRODUCTION

A chapter on quantitative aspects of tissue engineering remains difficult to write at this point in the development of tissue regeneration and cell therapy processes. Although cell functional behavior and underlying molecular mechanisms are becoming increasingly amenable to quantitative approaches, incorporating these into the complex interactions among multiple cell types in organized tissue is currently beyond the scope of feasibility. A historical parallel may be drawn to the decades-long lag between the advent of the petrochemical industry and the useful introduction of rigorous analysis in terms of fundamental physicochemical theories decades later. Thus, it is clear that today's beginning attempts in tissue engineering must be highly empirical, with design based largely on intuition and experience, much like the petrochemical industry in the 1930s.

Following this parallel, however, it can be recalled that in the 1940s the concept of unit operations appeared, in which each particular chemical production plant could be broken down into some component processes that had some similarities to processes in different types of production plants. In this way, basic principles of chemical reactors, heat exchangers, material separation equipment, and so forth were elucidated in very simple quantitative terms. It was not that mathematical models for these unit operations were immediately combined into a comprehensive quantitative description of the entire plant—which is, of course, common practice today—but instead merely that important design parameters of the components could be identified, and in some cases the direction of their manipulation for process improvement could be indicated.

This, then, appears to be the state of affairs for tissue engineering at the beginning of the twenty-first century: that key parameters governing components of the overall device or procedure might be identifiable, and some design principles for how they could be altered toward an improved device or procedure might be developed. In a manner analogous to the unit operations, simple mathematical descriptions of cell and tissue processes can be constructed for purposes of elucidating what properties matter and how they can be manipulated. Our chapter therefore provides a brief overview of how major cell and tissue properties can be described and quantified in most basic form. These properties include molecular and cell transport through tissue, molecular interactions with cells, and tissue mechanics.

## MOLECULAR INTERACTIONS WITH CELLS

There are three main classes of molecules that must be dealt with in the context of cell interactions in tissue: soluble nutrients, soluble signaling molecules, and molecules associated with the extracellular matrix. The latter two classes interact with cells primarily via cell surface receptors, whereas the former class can either bind to cell surface receptors or pass directly across the cell membrane.

### NUTRIENTS

For nutrient molecules that pass directly across the cell membrane—either by passive diffusion or via carrier proteins—such as oxygen, glucose, and amino acids, the kinetics of uptake and metabolism generally follow a Michaelis–Menten type dependence. That is, at low concentrations the rate is first order in concentration but as concentration increases the rate asymptotically approaches a constant plateau. In combination with transport rates through tissue, as described below, the consumption of nutrients can be analyzed in a fairly straightforward manner. If transport is modeled as simple diffusion through a medium in which cells are embedded as point sinks, the nutrient concentration distribution,  $L(x)$ , in the tissue is governed by the combined diffusion/reaction equation:

$$\frac{\partial L}{\partial t} = D \frac{\partial^2 L}{\partial x^2} - \frac{\rho k L}{K_M + L}, \quad (1)$$

where  $D$  is the diffusion coefficient,  $k$  is the maximal uptake rate constant per cell,  $K_M$  is the saturation constant,  $\rho$  is the cell density, and  $x$  is the spatial distance from the source. For simple nutrients, the source is typically the bloodstream. Significant depletion of nutrient, and hence possible nutrient deprivation, will occur when the ratio of uptake to diffusion becomes small. This ratio can be usefully expressed in terms of the Thiele modulus:  $\phi = (\rho k X^2 / D)^{1/2}$ , where  $X$  is the overall distance away from the source—for simple nutrients, this can be considered the mean distance between microcirculatory blood vessels. (this is an approximate expression, assuming that the uptake rate is constant with value  $k$  throughout the tissue.) When  $\phi < 1$ , the steady-state nutrient concentration becomes significantly less than the exogenous level. Transplantation of cells within a polymeric matrix can often give rise to depletion of important nutrients from levels required for sustained cell viability, when  $\rho$  is great and  $X$  is large because the implant is not adequately vascularized. Nutrient transport limitations have been examined both theoretically and experimentally for the important case of encapsulated cells (Colton, 1995).

### GROWTH FACTORS AND OTHER REGULATORY MOLECULES

Many molecules important in tissue engineering, however, cannot be dealt with quite so simply. Regulatory molecules such as growth factors, along with nutrient carriers such as iron-bearing transferrin, bind reversibly to plasma membrane receptors and are then internalized by the cell by means of invaginating membrane structures in a process known as endocytosis. The receptor/ligand complexes are carried to intracellular organelles termed endosomes, from which they are sorted to a variety of fates, including lysosomal degradation and recycling to the cell surface (see Fig. 17.1). This entire process, known as trafficking, is quite complicated, and the distribution of fates for a particular ligand can quantitatively vary as a function of its concentration as well as some of its biochemical and biophysical properties.

In the absence of trafficking, and when there is only a simple one-step reversible binding process, kinetic mass action equations can be written for the number of bound and free surface receptors and their ligands ( $L$ ). At equilibrium, the number ( $C$ ) of receptors ( $R$ ) found in the bound state is given by the expression

$$C = \frac{LR_T}{K_D + L}. \quad (2)$$

$R_T$  is the total number of surface receptors, constant only when trafficking processes are eliminated.  $K_D$  is the dissociation equilibrium constant, equal to the ratio of the receptor/ligand dissociation rate constant to the association rate constant:  $k_r/k_f$ . It is essentially the reciprocal of the receptor/ligand binding affinity. Commonly, however, ligands can bind to multiple receptors on the surface of a given cell, or receptors can be found in various states possessing different ligand

Fig. 17.1. Schematic illustration of receptor/ligand trafficking.  $L$  is intact ligand,  $L'$  is undegraded ligand;  $R_s$ ,  $C_s$ ,  $R_i$ , and  $C_i$  are cell surface and intracellular free and bound receptors;  $k_f$  and  $k_r$  are receptor/ligand association and dissociation rate constants;  $k_{eR}$  and  $k_{eC}$  are internalization rate constants for free and bound receptors;  $k_d$  and  $k_{dR}$  are degradation rate constants for ligand and receptor;  $k_x$  and  $k_{xR}$  are recycling rate constants for ligand and receptor;  $V_s$  is the receptor synthesis rate.

binding affinities. The interested reader is referred elsewhere for a detailed discussion of how to treat these more complicated situations (Lauffenburger and Linderman, 1996).

However, trafficking is almost universally present under physiological conditions, and the overall dynamics of uptake and metabolism of ligands and their receptors are strongly influenced by internalization, degradation, and recycling. Kinetic mass action equations can be written for the set of events shown in Fig. 17.1, and the dynamics of ligands and receptors in the various cell and tissue compartments can be thereby analyzed for purposes of understanding key design parameters (Lauffenburger and Linderman, 1996).

For instance, consider a molecular ligand delivered to a tissue at rate  $V_L$ . For ligands such as growth factors, the source may be other cells in the tissue—perhaps implanted cells expressing a desired growth factor—or a polymeric controlled-release device or the bloodstream. Assuming a spatially homogeneous source, the steady-state ligand concentration will be approximately given by (assuming, for simplicity, that receptor and ligand recycling are negligible) the expression

$$L = K_D \left( \frac{k_{eR}}{k_{ec}} \right) \left[ \left( \frac{\rho V'_R + k_{deg} k_{eR} / k_f}{V_L} - 1 \right) \right]^{-1}, \quad (3)$$

where  $V'_R$  is the receptor synthesis rate per cell,  $k_{eR}$  and  $k_{eC}$  are the free receptor and bound receptor internalization rate constants, respectively, and  $k_{deg}$  is a rate constant for extracellular proteolytic ligand degradation.

Following Wiley (1985), the corresponding steady-state number of receptor/ligand complexes per cell, which typically governs the functional response, is then approximately given by

$$C = \frac{LR_{max}}{K_{ss} + L}. \quad (4)$$

$R_{max}$  is equal to  $V'_R / k_{eR}$ , and  $K_{ss}$  is equal to  $k_{eC} k_f / [k_{eR} (k_r + k_{eC})]$ . Note the similarity in form to Eq. (2), which governs the number of complexes in the absence of trafficking. Thus, trafficking determines the number of available surface receptors and the effective ligand binding affinity.

When ligand concentrations are not spatially homogeneous, then the local value of  $L$  at any spatial position within the tissue must be determined by including the effects of diffusion as in Eq. (1). Here  $x$  would be the thickness of tissue away from the source. Moreover, in place of the simple metabolic uptake rate constant,  $k$ , the net dynamics of trafficking must be incorporated to account for ligand consumption.

Binding and trafficking rate constants can be measured in cell culture assays, using ligands labeled with fluorescent or radioactive tags. Descriptions of basic experimental procedures and corresponding methods of analysis can be found elsewhere (Lauffenburger and Linderman, 1996).

Extracellular matrix components can compete with cells for binding ligand, and in some circumstances may serve as a reservoir due to the reversible nature of protein/protein association. At equilibrium, this binding can be characterized using an expression analogous to Eq. (2). Extracel-

lular matrix components may exhibit binding interactions with cell surface receptors; when they are sufficiently immobilized by their linkage within the matrix, Eq. (2) again can represent these interactions in the simplest case. As with soluble ligands, though, more complicated interactions can arise with multiple receptors for different domains of a particular matrix component.

Expressions such as Eqs. (1)–(4) can be used to estimate the rate of ligand delivery required to maintain a desired level of cell surface complexes and/or free ligand concentration. The number of surface complexes typically is important for determining the cell functional response. We emphasize, though, that it is likely that the rate of ligand binding to receptors to form signaling complexes may govern cell responses as much, or more so, than the static level of complexes (Wiley, 1992). Quantification of the dependence of cell behavior on complex levels and dynamics, however, remains in its infancy at present. A small number of particular examples can be offered as guidelines, including proliferation responses of fibroblasts to epidermal growth factor (Knauer *et al.*, 1984), leading to improvements in cell level principles for growth factor design and delivery (Reddy *et al.*, 1996a,b). A further level of complication in analysis arises from the presence of autocrine ligands in a wide spectrum of tissue physiological processes, though quantitative modeling and experimental studies are now being pursued on this aspect as well (Forsten and Lauffenburger, 1992; Lauffenburger *et al.*, 1998).

## MOLECULAR AND CELL TRANSPORT THROUGH TISSUE

Movements of molecular as well as cellular species through tissue is a vital aspect of most tissue engineering processes, because the whole point of the intervention is to alter the composition of a local region from what it had been prior to the therapy. As mentioned above, transport of nutrients and regulatory factors into a cellular implant is generally required. Also, the goal of certain implanted devices is to release regulatory factors into the surrounding tissue. The synthesis of neotissues involves placing cells within a matrix composed of natural materials (e.g., collagen) or synthetic polymers (e.g., biodegradable templates). Within this environment, the cells also secrete and regulate the assembly of their own extracellular matrix composed of collagens, proteoglycans, glycoproteins, and a variety of macromolecules that are important in cell–matrix and cell–cell interactions. Solute transport through this tortuous and often dense matrix plays a critical role in the maintenance of cell viability and in the successful growth and development of the intact tissue. Moreover, colonization of implants or grafts by cultured or host cells is often desirable. And, in some cell therapies, mainly those involving immune white blood cells, the movement of cells from an injection site into certain tissue regions is essential for them to carry out their intended functions.

## MOLECULAR DIFFUSION AND CONVECTION

Cell biosynthesis requires transport of low-molecular-weight metabolites and waste products, which occurs primarily by diffusion. Many other solutes play key roles as mediators of cell behavior and in cell production and turnover of extracellular matrix, including growth factors, hormones, cytokines, and endogenous proteinases and their natural inhibitors. Transport of regulatory factors can be crucial in tissue regeneration (Perez *et al.*, 1995) and can be reduced severely by interactions with matrix (Dowd *et al.*, 1999). In addition, the assembly of a physicochemically and mechanically functional matrix requires transport of newly synthesized matrix macromolecules to appropriate locations within the extracellular space. These matrix proteins and proteoglycans (as large as several megadaltons) have such low intratissue diffusivities that even slight fluid convection within the matrix can significantly enhance macromolecular transport (Garcia *et al.*, 1996).

In general, transport depends on the size and charge of the solute, and the density (tortuosity), water content, and charge of the matrix (Garcia *et al.*, 1998) (see Fig. 17.2). Although the principal modes of transport are molecular diffusion and convection (Deen, 1987), electrostatic interactions can also affect the partitioning and transport of charged solutes into and within a charged matrix (Grodzinsky, 1983). In this regard, it is useful to note that matrix charge density at the macroscale is often associated with the content of glycosaminoglycan chains attached to proteoglycans. At the scale of the cell, the dense, negatively charged glycocalyx at the surface of many cell types can also affect transport across the cell membrane.

Each cell and tissue type presents unique challenges for providing adequate transport in tis-

Fig. 17.2. The flux of macromolecular and small solutes within a cell-seeded matrix results from diffusion, convection (fluid velocity  $U$ ), and electrical migration if the solute is charged; an electric field  $E$  exists within the tissue (caused by fluid flow or by ion concentration gradients).

sue engineering design. For example, the density of cells in liver and kidney is typically much higher than that in connective tissues such as ligament, tendon, and cartilage. On the other hand, connective tissue cells grow within a very dense, hydrated, negatively charged matrix that may be several millimeters thick but with little or no vascular or lymph supply. Some cells are best grown on surfaces whereas others require three-dimensional matrix encapsulation. The mechanical environment of cells also varies greatly: vascular cells are subjected to fluid shear and to pulsatile stresses and strains within vessel walls; cartilage, bone, and other soft connective tissue cells must sustain peak mechanical stresses as high as 10–20 MPa (100–200 atm). These dynamic stresses produce fluid flows within the matrix that can affect intratissue solute transport and the concentration of solute species at the boundaries of tissues *in vivo* (O'Hare *et al.*, 1990). Such effects must therefore be taken into account in tissue engineering design *in vitro*.

Given these diverse tissue types and geometric constructs, mathematical modeling of transport processes can be critically important in the design of tissue reactors, the basic understanding of the spatial and temporal distribution of small and large solutes in newly developing tissues, and the understanding of failure modes that might result from inadequate transport. We briefly summarize below the governing transport laws for solutes within tissues, and the boundary conditions at the tissue/media interface. These general laws may then be adapted to the particular cell and tissue types of interest.

First, the one-dimensional flux  $N_i$  of the  $i$ th species within the tissue due to diffusion, convection, and electrical migration (ohmic conduction) is described by the flux equation:

$$N_i = \phi \left( -D_i \frac{\partial c_i}{\partial x} + \frac{z_i}{|z_i|} \mu_i c_i E \right) + W_i c_i U, \quad (5)$$

where  $c_i$  is the solute concentration at the position  $x$ ,  $\phi$  is the matrix (tissue) porosity,  $z_i$  is the valence of the solute (if charged),  $U$  is the fluid velocity relative to the matrix (averaged over the total matrix area), and  $E$  is the electric field within the matrix (e.g., induced by diffusion of ionic species or by electrokinetic effects such as flow-induced streaming potentials through a charged matrix). The intrinsic transport parameters  $D_i$ ,  $\mu_i$ , and  $W_i$  represent, respectively, the intratissue diffusivity of the solute, the electrical mobility, and a hindrance factor for convection that incorporates hydrodynamic and steric interactions between solute molecules and the matrix molecules forming the “pore” walls. Even in the absence of net fluid convection, frictional hydrodynamic and steric interactions between solute, matrix, and solvent can play a critical role in transport, and may cause significant differences between the intratissue values of  $D_i$ ,  $\mu_i$ , and their corresponding values in free solution (Deen, 1987). In general, the flux Eq. (5) is general in that it applies to ionic solutes in the medium, small neutral and charged solutes (e.g., amino acids, glucose), and large neutral and charged macromolecular solutes. For small solutes,  $W \rightarrow 1$ , and the values of  $D_i$  and  $\mu_i$  may be close to their free solution values; for larger solutes,  $W < 1$ , and  $D_i$  and  $\mu_i$  as written in Eq. (5) implicitly incorporate associated hindrance factors (Deen, 1987).

It is therefore necessary to measure or estimate values for the intrinsic transport parameters  $D_i$ ,  $\mu_i$ , and  $W_i$  in order to predict solute distribution profiles within the tissue construct. To predict the spatial and temporal distribution of solutes in the neotissue, the flux equation is incorporated into the continuity law:

$$\frac{\partial c_i}{\partial t} = \frac{\partial N_i}{\partial x} + \sum_i (G_i - R_i), \quad (6)$$

where  $G_i$  and  $R_i$  represent chemical reaction rates associated with binding of solutes to cells or matrix molecules. In the absence of binding, electric migration, and convection effects, the continuity law, Eq. (6), reduces to Fick's second law for molecular diffusion. For the case of purely diffusive nutrient transport within a matrix containing cells acting as point sinks, the continuity law, Eq. (6), would reduce to the diffusion/reaction Eq. (1) above.

Electroneutrality within the tissue, including charges on all solute (i) and matrix molecules (m), requires that:

$$z_m c_m + \sum_i (z_i c_i) = 0. \quad (7)$$

Although tissues may have a high water content, the concentration of solutes within tissue water may be very different from that in the bathing medium because of size and charge effects. In general, the solute partition coefficient  $\kappa$  is defined as the ratio of the solute concentration within the tissue fluid to that in the bathing medium,  $\kappa = c^{\text{tiss}}/c^{\text{med}}$ . This partition coefficient acts as a boundary condition for the flux and continuity equations, which are written specifically in terms of solute concentrations inside the tissue. In addition, for charged solutes in the presence of a charged matrix, this partitioning is further modified due to Donnan equilibrium considerations for positively and negatively charged species, giving the Donnan partition boundary conditions (Maraudas, 1979):

$$\left( c_{i+}^{\text{med}}/c_{i+}^{\text{tiss}} \right)^{|z_+|} = \left( c_{j-}^{\text{tiss}}/c_{j-}^{\text{med}} \right)^{|z_-|}. \quad (8)$$

Finally, it is useful to recast the continuity law in terms of the dimensionless Peclet number  $\text{Pe}$ , which is defined as the ratio of solute convection plus migration fluxes to the diffusive flux (Grimshaw *et al.*, 1989):

$$\frac{\partial c_i}{\partial t} = D_i \left[ \frac{\partial^2 c_i}{\partial x^2} + \frac{\text{Pe}}{X} \left( \frac{\partial c_i}{\partial x} \right) \right], \quad (9)$$

$$\text{Pe} = X \left( \frac{W_i U + \phi \mu_i E}{\phi D_i} \right), \quad (10)$$

where  $X$  is the characteristic tissue thickness over which transport must occur. Thus, Eq. (9) takes the form of a modified Fick's second law, and puts into perspective the relative importance of the convective and electrical migration terms given values for  $X$ ,  $D_i$ ,  $W_i$ , and  $\mu_i$ . It is apparent that for solutes having small enough  $D_i$  and/or large enough fluid flow, convection may have a significant effect in determining the solute distribution within the tissue. Said another way, convection and intratissue electrokinetic (e.g., electrophoretic) effects could significantly augment the transport of nutrients and macromolecules compared to diffusion alone, over tissue dimensions  $X$ .

## CELL MIGRATION

Polymeric scaffolds are often introduced, into which it is hoped that certain cell types will migrate while others do not. For instance, regeneration of bone tissue for enhanced healing of full-thickness injuries requires that osteoprogenitor cells from surrounding tissue colonize an implanted scaffold, and that endothelial cells migrate in, to achieve neovascularization, whereas connective tissue fibroblast influx is undesirable. There are two approaches for controlling migration: (1) surface chemistry of the implanted material for selective cell adhesion interactions with the surface, influencing migratory behavior in a differential manner among various cell types, and (2) release of chemotactic attractants from within the implanted material to induce enhanced migratory responses of particular cell types.

The rate of cell population movement into a tissue can be quantified using a cell transport flux expression analogous to that for molecular diffusion and convection (Tranquillo *et al.*, 1988):

$$J_{\text{cells}} = -\mu \frac{\partial N}{\partial x} + \chi \left( \frac{\partial A}{\partial x} \right) N, \quad (11)$$

where  $\mu$  is the cell random motility coefficient, analogous to a molecular diffusion coefficient and  $\chi$  is the chemotaxis coefficient;  $\chi$  is a biphasic function of the attractant concentration,  $A$ , because

Fig. 17.3. Qualitative representation of typical dependence of cell migration speed on the ratio of cell-substratum adhesion strength to cell-generated contractile force.

chemotaxis arises from a spatial difference in the number of receptor/attractant complexes across a cell length. The first term in Eq. (11) represents cell dispersion down the spatial gradient of cell density, whereas the second term yields a directed, “convective” velocity for cell migration in the direction of an attractant concentration gradient. The values  $\mu$  and  $\chi$  can be measured in a variety of cell population assays, such as movement through a porous filter or under an agarose gel. They can alternatively be calculated from individual cell tracking assays in which cell speed, directional persistence time, and directional orientation bias are determined, because the cell population parameters are related by theory to the individual cell parameters. Details on these approaches can be found elsewhere (Lauffenburger and Linderman, 1996).

A fair amount of effort has been devoted to quantitative understanding of how substrata properties of materials affect cell migration. A central concept that is beginning to show general verification is that the speed of migration depends in biphasic manner on the strength of cell/substratum adhesiveness (see Fig. 17.3) (DiMilla *et al.*, 1991). This principle can account for a wide range of experimental observations of how migration speed varies with the density of extracellular matrix ligands immobilized on biomaterial surfaces, and for the effects of ligand affinity and competing soluble ligand (Palecek *et al.*, 1997; Wu *et al.*, 1994). This lack of monotonicity is unfortunate, of course, because it makes design of a material quite problematic; unless the full quantitative picture is well characterized one may produce a substratum either too strongly adhesive or too weakly adhesive for effective cell locomotion. Additional modulating approaches may be possible, though, by means of other parameters influencing migration speed. For instance, the dependence illustrated in Fig. 17.3 actually entails the ratio of cell/substratum adhesiveness to effective cell contractile force, so on a given substratum migration can be enhanced or inhibited by factors altering cell force generation or the substratum compliance.

## CELL AND TISSUE MECHANICS

The mechanics of a tissue or tissue substrate play a central role in many situations, ranging from the fabrication of cell-based vascular grafts to wound healing. The transmission of stresses between the extracellular matrix and cell, or between the cell membrane and its nucleus, is an important factor in controlling the biological response of the cell to its environment. Even cell motility and adhesion are influenced by the elastic characteristics of the substrate on which they are grown. To appreciate these factors requires an understanding of mechanics, both at the microscale (e.g., a single microtubule and its interaction with the actin filaments) and at the macroscale (e.g., the elastic properties of a cell-based tissue implant). Some of the basic concepts are outlined here, along with some examples of how these concepts are applied in the field of tissue engineering.

### ELASTICITY

Before dealing with some of the complexities of real biologic materials, consider first the case of a simple uniform and isotropic elastic medium. The elasticity of a material is typically characterized by its stress–strain relationship, where the stress is the force acting per unit area and the strain is the fractional change in length of the specimen, both of which are tensorial quantities. In the case of uniaxial stress, a material might exhibit a stress–strain relation of the type shown in Fig. 17.4. In this instance, the relationship is linear (or nearly so) for small strains, but becomes nonlinear as strains increase above a certain level. The elastic, or Young’s, modulus ( $E$ ) is defined as

Fig. 17.4. A plot of stress ( $\sigma$ ) vs. strain ( $\epsilon$ ), showing an initial linear region in which the Young's modulus ( $E$ ) is constant, and a nonlinear region with increasing  $E$ , leading ultimately to fracture of the specimen.

the ratio of stress to strain; in this example,  $E$  would be constant for small strains, but eventually would increase as the material experiences increasing strain.

The elastic modulus of most biologic tissues is highly nonlinear, exhibiting an increasing elastic modulus for higher strains. The fibrous elements that comprise the tissue matrix, however, are more likely to be linearly elastic over an appreciable range of strain. Elastin, for example, which can be stretched up to 300% of its initial length, has a nearly constant modulus. Table 17.1 shows the elastic moduli for several tissues and tissue components. Another important property of the material is the maximum amount of strain it can experience before it fractures, some values of which are also given in the table.

In contrast to elastic deformation in which there exists a unique relation between the applied stress and material strain, in plastic deformation, the material experiences an irreversible deformation, usually at high levels of stress, and fails to return to its original length when the stress is removed.

All the above applies to uniaxial loading. If a material is isotropic, then its elasticity is the same, regardless of the direction in which it is tested, and its mechanical properties can be completely characterized by two parameters, e.g., its elastic modulus and Poisson ratio,  $\nu$ . Anisotropic materials, however, exhibit different stress–strain characteristics along the different coordinate directions. The wall of an artery, for example, is extremely stiff in the circumferential and axial directions, but relatively compliant in the radial direction. The description of such materials can lead to considerable complexity as evidenced by the fact that in a truly anisotropic material, 21 constants analogous to the Young's modulus are required to characterize completely a material's elasticity. Intermediate between these two extremes lie materials that are transversely isotropic, that is, materials that exhibit isotropic behavior in two dimensions, but different properties in the third. Many biological materials (blood vessels, ocular sclera) can be well characterized as transversely isotropic because the primary force-supporting structures (collagen and elastin fibers) are oriented primarily in one plane.

The existence of contractile elements, such as smooth muscle cells in vessel walls or the my-

**Table 17.1. Elastic constants for a variety of biologic materials<sup>a</sup>**

Material	Elastic modulus	Yield stress	Max. strain	Ref.
Cortical bone	6–30 GPa	50–200 MPa	—	Cowin <i>et al.</i> (1987)
Collagen fibers	500 MPa	50 MPa	0.1	Kato <i>et al.</i> (1989)
Elastin	100 kPa	300 kPa	3.0	Mulcherjee <i>et al.</i> (1976)
Cartilage	10 MPa	8–20 MPa	0.7–1.2	Woo <i>et al.</i> (1987)
Skin	35 MPa	15 MPa	1.1	Yamada (1970)
Muscle fascia	340 MPa	15 MPa	1.17	Yamada (1970)
Tendon	700 MPa	60 MPa	0.10	Yamada (1970)

<sup>a</sup>Note that in many instances, the stress–strain relationship is highly nonlinear; the elastic moduli in those cases represent an approximate, characteristic value.

Fig. 17.5. (a) Stress ( $\sigma$ ; top) and strain ( $\epsilon$ ; bottom) plotted against time in a maneuver in which the stress is abruptly reduced. In a purely elastic material (dotted line), the strain immediately adjusts to a new level consistent with the new applied stress. A viscoelastic material (solid line) exhibits a further reduction in strain (creep), indicative of continued deformation following an initial elastic response. (b) The response of a cylindrical sample of cartilage subjected to a sudden compressive stress. The sample continues to compress with time as a result of water being expelled from the tissue through a porous platen. Reproduced with permission from Mow and Mak (1987).

ocardium, or actin filaments in the cytoskeleton, lends further complexity to material properties. As far as the elastic properties of the material are concerned, active constriction can be thought of as influencing both the elastic modulus of the material and the length of the sample under zero stress.

**VISCOELASTICITY AND PSEUDOELASTICITY**

Although some materials (e.g., elastin, collagen) show an immediate elastic response such that they exhibit an immediate and constant deformation following the application of stress, tissues more often respond in a time-dependent fashion (Fig. 17.5). The initial elastic response of such materials is followed by a period of additional deformation or creep, asymptotically approaching an equilibrium state at long times. Alternatively, when subjected to a periodic load, these materials display a degree of hysteresis when stress is plotted against strain. This is termed a viscoelastic response and is a result of several processes internal to the tissue. One is the transient movement of liquid through the tissue due to the nonuniform distribution of interstitial pressure that results from the application of stress. For example, if a disk or cartilage is subjected to a load as in Fig. 17.5, a gradient in fluid pressure is set up between the central regions and the edge of the specimen, which causes fluid to be expelled. The rate of deformation during this phase is clearly dependent on the permeability of the tissue.

Fig. 17.6. Pseudoelastic behavior of biological tissue. A stress–strain plot for a segment of a canine carotid artery undergoing cyclic loading; first and third cycles shown.  $T_1$  is the axial tension,  $\lambda_1$  is the axial stretch ratio, and  $L(t)/L_0$  with  $L_0$  is the relaxed length. The sample exhibits different curves for loading and unloading, which are highly reproducible. Reproduced with permission, from Lee et al. (1967).

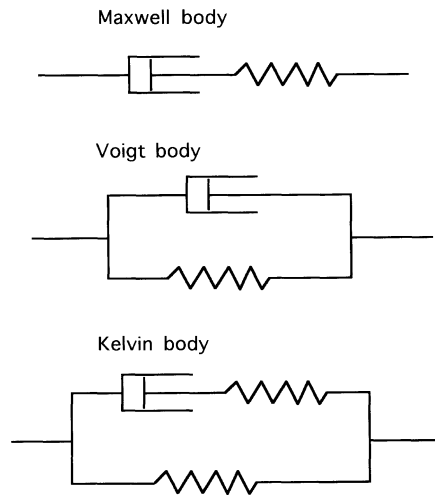

Fig. 17.7. Three commonly used models for viscoelastic behavior composed of viscous elements (dashpots) and elastic elements (springs).

Biological tissues are often referred to as pseudoelastic (Fung, 1981), in that, with periodic loading, they evolve to a stress–strain pattern that is repeatable from one cycle to the next and relatively insensitive to the strain rate. The resulting curve typically differs on extension from relaxation, exhibiting some degree of hysteresis (Fig. 17.6). By treating the loading and unloading maneuvers separately, the viscoelastic characteristics of the material can be incorporated into an otherwise elastic description of the material.

It is often necessary to simulate the true viscoelastic response of a tissue specimen, as, for example, when subjected to an abrupt increase in load (Fig. 17.5). Several simple models have been devised for this purpose. Although these make no attempt to mimic the mechanism responsible for the viscoelasticity, they are useful descriptors that can be used to represent certain viscoelastic characteristics. The most common among these models are the Maxwell, Voigt, and Kelvin models. Each is composed of a one or more springs and dashpots as shown in Fig. 17.7.

These simple models are sometimes used as a basis for constructing more complex descriptions of the material. For example, a continuum description has been used to study the mechanical characteristics of leukocytes (Schmid-Schönboin *et al.*, 1981), based on the Kelvin model of Fig. 17.7, by arranging them in various series and parallel networks. Other models for the cytoskeleton take explicit account of the fibrous microstructure (Satcher and Dewey, 1996; MacKintosh and Janmey, 1997; Stamenovic *et al.*, 1996).

### MEASUREMENT OF MECHANICAL PROPERTIES

A variety of methods have been employed to determine the mechanical characteristics of biological specimens, the method being determined by the elastic characteristics of the material, its size, and the particular property of interest.

For large-scale samples, the simplest measurement that yields the elastic modulus of a specimen is the uniaxial strain test, in which the sample is grasped at two ends and pulled while axial strain and stress are simultaneously measured. In order to minimize end effects, the sample is often necked down to a lateral dimension in the central section, smaller than the ends, and the strain is measured directly in the necked region. Because stresses in both directions perpendicular to the axial of the specimen are zero, the elastic modulus is determined by the ratio of stress to strain,  $E = \sigma_x / \epsilon_x$ . Poisson's ratio can be determined from the change of thickness of the specimen in the direction perpendicular to the applied stress. If the sample is anisotropic, additional uniaxial tests in the other two coordinate directions can be used. Alternatively, stresses can be applied in two (biaxial) or three (triaxial) dimensions simultaneously. These tests yield more information about the material, but do so at the cost of greater complexity.

These tests are most often used to measure the properties of a material in tension. The compressive characteristics are also often of interest, especially in materials such as bone and cartilage, which are often subjected to compressive loads *in vivo*. For this purpose, specimens are generally cut into the shape of a short cylinder and compressed between two platens. In the case of carti-

lage, the platens may be permeable to allow water to escape as the sample is compressed, thereby obtaining information on the permeability of the sample from the time-dependent compression following the application of a load. Both confined and unconfined compression tests are useful. The advantage of confined compression, in which the sample is placed in a rigid cylindrical chamber, typically with nonpermeable side walls, is that the stress, strain, and flow of water are purely axial and the results can be more easily interpreted.

Any of the tests just mentioned are capable of measuring nonlinearities in the stress–strain behavior of a material. As mentioned earlier, biological materials typically become stiffer as the sample is stretched. Therefore, it is important to test the material with loads in the range of those the specimen is likely to experience *in vivo*. It is equally important to know the zero-stress state of a tissue, which, as has been demonstrated for a variety of vessels, is not necessarily achieved simply by reducing the transmural pressure to zero (Liu and Fung, 1988).

All these tests require excised specimens to be cut or machined into a particular shape. Often in the case of biological tissues, it is desirable to obtain measurements from the *in vivo* state so as to avoid the artifacts that are necessarily introduced by specimen removal. Although advantageous in many respects, *in vivo* testing also limits the choice of testing methods available. Fung and Liu (1995) argued for the importance of making measurements *in vivo*, and have demonstrated how, in the case of a blood vessel, a battery of tests may be used to measure the mechanical properties of the arterial wall. Other methods—for example, the simple indentation of the material by a probe (Lai-Fook *et al.*, 1976)—can also be used.

Methods for testing the elastic and viscoelastic properties of cells and even individual molecules are rapidly becoming available. One approach, micropipette aspiration, has been used in several studies (Evans and Yeung, 1989) on various cell types. Introduced over 20 years ago to study red blood cell mechanics and later for leukocytes, the cell is partially drawn into a micropipette by means of a negative pressure. Knowing the pressures acting, and monitoring the extent of cell deformation by microscopy, allow for estimation of cell elasticity. Cell poking, a method analogous to the indentation studies just discussed, can also be applied to individual cells (Zahalak *et al.*, 1990).

Newer methods have been developed that take advantage of our ability to attach ligand-coated microspheres to cell receptors or individual molecules, and then manipulate these microspheres in a specified manner. Microsphere displacement can be controlled by the use of laser tweezers (Block *et al.*, 1989; Kuo and Sheetz, 1993; Kuo, 1995) or a magnetic trap (Glogauer and Ferrier, 1998); rotations can be produced by magnetic fields using a method termed magnetic twisting cytometry (Wang and Ingber, 1994). In these methods, both the applied forces (or torques) and displacements (or rotations) can be monitored, from which elastic and viscoelastic properties can be inferred.

# PATTERNING OF CELLS AND THEIR ENVIRONMENT

Shuichi Takayama, Robert G. Chapman, Ravi S. Kane, and George M. Whitesides

## INTRODUCTION

Control of the cell culture environment is crucial for understanding cell behavior and for engineering cell function. This chapter describes the use of a set of microfabrication techniques called “soft lithography” for patterning the substrate to which cells attach, the location and shape of the areas to which cells attach, and the fluid environment surrounding the cells, all with micrometer precision. Some examples wherein these techniques have helped to clarify problems in fundamental cell biology are summarized. The methods described are experimentally simple, inexpensive, and well suited for patterning biological materials.

How do tissues assemble *in vivo*? Once an appropriate community of cells has organized, how does it perform its functions? Answering these fundamental biological questions, and using the information thus obtained for engineering tissues, require the ability to study the behavior of cells in controlled environments. Some of the challenges in trying to control the environment experienced by individual cells lie in the size scales of the stimuli that need to be controlled (from the angstrom scale for molecular detail, through the micrometer scale for an individual cell, to the millimeter and centimeter scale for groups of cells) as well as in the number of the types of stimuli that need to be addressed (the composition of the culture media, the topography and chemical composition of the surface to which the cells attach, the nature of neighboring cells, the temperature, etc.).

Microfabrication and micropatterning using stamps or molds fabricated from elastomeric polymers (soft lithography) provide versatile methods for generating 10- to 100- $\mu\text{m}$ -sized patterns of proteins and ligands on surfaces, 50- to 500- $\mu\text{m}$ -sized culture chambers, and 10- to 100- $\mu\text{m}$ -sized laminar flows of culture media in capillaries (Xia and Whitesides, 1998). Soft lithographic methods are relatively simple and inexpensive; the elastomeric polymer most often used in these procedures—poly(dimethylsiloxane), or PDMS—has several characteristics that make it attractive for biological applications. This chapter gives an overview of the application of soft lithography to the patterning of cells, their substrates, and their fluid environment.

## SOFT LITHOGRAPHY

As the need of biologists to control and manipulate materials on the micrometer scale has increased, so has the need for new microfabrication techniques. Our laboratory has developed a set of microfabrication techniques that are useful for patterning on the scale of 0.5  $\mu\text{m}$  and larger. We call these techniques “soft lithography” because they use elastomeric (that is, soft) stamps, molds, membranes, or channels (Xia and Whitesides, 1998).

Many other techniques can and have been used to pattern cells and their environment (Hammarback *et al.*, 1985; López *et al.*, 1993a; Park *et al.*, 1998; Vaidya *et al.*, 1998). The most com-

monly used method has been photolithography. This technique has, of course, been highly developed for the microelectronics industry; it has also been adapted, with varying degrees of success, for biological studies (Hammarback *et al.*, 1985; Kleinfeld *et al.*, 1988; Ravencroft *et al.*, 1998). As useful and powerful as photolithography is (it is capable of mass production at 200-nm resolution of multilevel, registered structures), it is not always the best or only option for biological studies. It is an expensive technology; it is poorly suited for patterning nonplanar surfaces; it provides almost no control over the chemistry of the surface and hence is not very flexible in generating patterns of specific chemical functionalities or proteins on surfaces; it can generate only two-dimensional microstructures; and it is directly applicable to patterning only a limited set of photosensitive materials (e.g., photoresists).

Soft lithographic techniques are inexpensive, are procedurally simple, are applicable to the complex and delicate molecules often required in biochemistry and biology, can be used to pattern a variety of different materials, are applicable to both planar and nonplanar substrates (Jackman *et al.*, 1995), and do not require stringent control (such as a clean room environment) over the laboratory environment beyond that required for routine cell culture (Xia and Whitesides, 1998). Access to photolithographic technology is required only to create a master for casting the elastomeric stamps or membranes, and even then, the requirement for chrome masks—the preparation of which is one of the slowest and most expensive steps in conventional photolithography—can often be bypassed (Deng *et al.*, 1999; Duffy *et al.*, 1998; Grzybowski *et al.*, 1998; Qin *et al.*, 1996). Soft lithography offers special advantages for biological applications, in that the elastomer most often used (PDMS) is optically transparent and permeable to gases, is flexible and seals conformally to a variety of surfaces (including petri dishes), is biocompatible, and can be implanted if desired. The soft lithographic techniques that we will discuss include microcontact printing, patterning with microfluidic channels, and laminar flow patterning.

## SELF-ASSEMBLED MONOLAYERS

Because many of the studies involving the patterning of proteins and cells using soft lithography have been carried out on self-assembled monolayers (SAMs) of alkane thiolates on gold, we give a brief discussion of SAMs (Bain and Whitesides, 1988b; Bishop and Nuzzo, 1996; Delamarche and Michel, 1996; Dubois and Nuzzo, 1992; Merritt *et al.*, 1997; Ostuni *et al.*, 1999; Prime and Whitesides, 1993; Ulman, 1996). SAMs are organized organic monolayer films (Fig. 18.1A) that allow control at the molecular level over the chemical properties of the interface by judicious design and fabrication of derivatized alkane thiol(s) adsorbed to the surface of films of gold or silver. The ease of formation of SAMs, and their ability to present a range of chemical functionality at their interface with aqueous solution, make them particularly useful as model surfaces in studies involving biological components. Furthermore, SAMs can be easily patterned by simple methods such as microcontact printing ( $\mu$ CP) with features down to 500 nm in size and smaller (Xia and Whitesides, 1998). These features of SAMs make them the best structurally defined substrates for use in patterning proteins and cells. SAMs on gold are used for the majority of experiments requiring the patterning of proteins and cells, because they are biocompatible, easily handled, and chemically stable [for example, silver oxidizes relatively rapidly, and Ag(I) ions are cytotoxic].

## METHODS FOR PREPARING HOMOGENEOUS SAMs AND MIXED SAMs

Single-component (homogeneous) SAMs of alkanethiolates on gold are formed by exposing a surface of gold to a solution containing, or to the vapors of, an alkane thiol (RSH). The surface properties of these SAMs are determined by the nature of the terminal groups (schematically represented by half-circles at the tips of the SAMs in Figs. 18.1 and 18.2). Gold substrates are prepared on glass cover slips or silicon wafers by evaporating a thin layer of titanium (1–5 nm) to promote the adhesion of gold to the support, followed by a thin layer of gold (10–200 nm) (DiMilla *et al.*, 1994). The SAMs formed on these gold substrates are stable to the conditions used for cell culture, but care should be taken to avoid strong light and temperatures above  $\sim 70^{\circ}\text{C}$ , because both can result in degradation of the SAM (Huang and Hemminger, 1993; Ostuni *et al.*, 1999).

Mixed SAMs, or SAMs composed of two or more types of thiols adsorbed to a surface, can be formed directly by coadsorption of two or more alkane thiols from solution (Fig. 18.2A,B) (Bain

Fig. 18.1. Schematic illustration of the adsorption of proteins and the attachment of a cell to a self-assembled monolayer (SAM). The components of the SAM and the protein molecule are drawn roughly to scale; the cell is much reduced in relative size. See text for details.

and Whitesides, 1988a; Lahiri *et al.*, 1999a; Mrksich *et al.*, 1995), or by the reaction of a nucleophile, such as an amine ( $\text{H}_2\text{NR}$ ), with a preformed SAM that presents interchain carboxylic anhydride groups. The anhydride-presenting surface is an exceptionally useful one and is easily prepared by the dehydration of single-component SAMs of  $\text{HS}(\text{CH}_2)_n\text{CO}_2\text{H}$  ( $n = 10$  or  $15$ ) (Fig. 18.2C) (Yan *et al.*, 1998). The anhydride method results in mixed SAMs composed of 1:1 mixtures of terminal amide ( $-\text{COHNR}$ ) groups and carboxylic acid ( $-\text{CO}_2\text{H}/-\text{CO}_2^-$ ) groups. The surface properties of mixed SAMs are determined by contributions from the various terminal groups present—the amount of each contribution being determined, qualitatively, by the degree of exposure of that terminal group at the surface (Bain *et al.*, 1989; Bain and Whitesides, 1989). In some cases the contribution of one terminal group will predominate, especially if that terminal group is long or large enough to screen the contribution of the shorter terminal group. For example, the characteristics of mixed SAMs prepared by the interchain anhydride methods are often determined predominantly by nature of the ( $-\text{COHNR}$ ) groups, because these are longer and shield the ( $-\text{CO}_2\text{H}/-\text{CO}_2^-$ ) groups (Fig. 18.2C) (Yan *et al.*, 1997). The anhydride method makes it possible to generate mixed SAMs with a range of surface characteristics rapidly and conveniently. This method is experimentally simple, and both  $\text{HS}(\text{CH}_2)_{10}\text{CO}_2\text{H}$  and a variety of amines are commercially available. It is thus unnecessary to synthesize the alkane thiols required in the older methods of making functionalized SAMs.

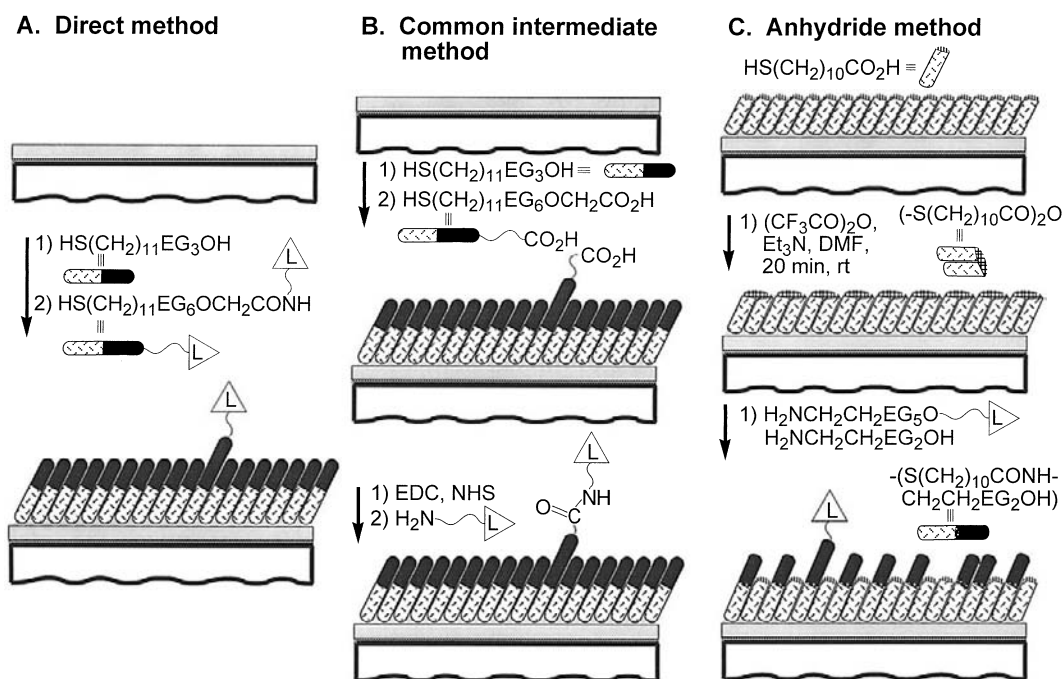

Fig. 18.2. Preparation of mixed SAMs that present a ligand by three methods: direct, common intermediate, and anhydride. These mixed SAMs are useful for the specific adsorption of the protein that binds the incorporated ligand (L). See text for details.

## PREVENTING PROTEIN ADSORPTION: INERT SURFACES

Proteins play an integral part in the adhesion of cells with surfaces: they are the glue that cements the cells to the surface. Thus, if one can control the interaction of proteins with a surface, one can begin to control the interaction of cells with that surface (Fig. 18.1). Most surfaces adsorb proteins. Thus, the main challenge in controlling the interactions of proteins and cells with surfaces lies in finding surfaces that resist nonspecific adsorption of proteins (surfaces that we call “inert,” for brevity). Inert surfaces provide the background necessary for spatially restricting protein adsorption or for preparing surfaces that bind only specific proteins, and are used in patterning proteins and cells (Merritt *et al.*, 1997), as biomaterials (Andrade *et al.*, 1987; Helmus and Hubbell, 1993), and in the construction of biosensors (Mrksich and Whitesides, 1995).

Single-component SAMs terminated in oligo(ethylene glycol) ( $EG_n$ ), oligomers longer than  $n = 3$ , resist the adsorption from solution of a variety of proteins that range in size (15–340 kDa) and charge ( $pI = 6$ –12) (Prime and Whitesides, 1991, 1993). Mixed SAMs containing as little as 50% of an  $HS(CH_2)_{11}EG_6OH$  [mixed with  $HS(CH_2)_{11}CH_3$ ] show good protein resistance, as do mixed SAMs presenting a 1:1 mixture of terminal  $-COHN(CH_2CH_2O)_nR$  ( $n = 6$ ,  $R = H$  or  $CH_3$ ) and  $-CO_2H/-CO_2^-$  groups. Other work has established that  $EG_n$  groups are not unique in their ability to resist adsorption of proteins, and, as an example, SAMs presenting  $-CH_2CH_2CH_2S(=O)-$  groups are also effective in resisting protein adsorption (Deng *et al.*, 1996). R. G. Chapman, L. Yan, S. Takayama, R. E. Holmlin, and G. M. Whitesides (unpublished results) have surveyed a large number of functional groups for their ability to resist the nonspecific adsorption of proteins, and found that polar functional groups that do not contain H-bond donors often make good components of inert surfaces. The combination of inert and adsorptive surfaces with soft lithographic techniques enables the facile patterning of proteins and cells.

## CONTROLLED PROTEIN ADSORPTION

Protein-specific mixed SAMs that present ligands for specific adsorption of a protein of interest, while resisting the nonspecific adsorption of other proteins, have been prepared by several techniques: (1) by coadsorption of a thiol that forms inert surfaces with a thiol that presents a ligand specific for a particular protein (Fig. 18.2A) (Mrksich *et al.*, 1995; Sigal *et al.*, 1996); (2) by the common intermediate method, whereby an amine terminated in a ligand is coupled to a mixed SAM presenting  $-EG_3OH$  (the inert surface component) and  $-EG_6OCH_2COOH$  (the component to which ligands are coupled) (Fig. 18.2B) (Lahiri *et al.*, 1999a); (3) by the anhydride method, whereby a mixture of two amines—one terminated with a ligand and the other with an “inert” functional group (for example,  $H_2NCH_2CH_2EG_2OH$ )—is allowed to react with a surface that presents interchain anhydride groups (Fig. 18.2C) (R. G. Chapman, L. Yan, and G. M. Whitesides, unpublished results). The common intermediate method and the anhydride method are more convenient than, and preferable to, the direct method, because they require less organic synthesis.

## MICROCONTACT PRINTING

### PATTERNING LIGANDS, PROTEINS, AND CELLS USING MICROCONTACT PRINTING

Microcontact printing is a technique that uses the relief pattern on the surface of an elastomeric PDMS stamp to form patterns on the surfaces of various substrates (Fig. 18.3A) (Xia and Whitesides, 1998). The stamp is “inked” with a solution containing the patterning component, dried, and brought into conformal contact with a surface for intervals ranging from a few seconds to minutes. The patterning component transfers to the substrate in the regions where the stamp contacts the substrate. The kinds of components used as ink for  $\mu CP$  include thiol derivatives that form SAMs on gold and silver; activated silanes that react with the SiOH groups present on the surface of silicon; various ligands (usually amine containing compounds) that react with activated SAMs (generated using the techniques described in the previous section) (Lahiri *et al.*, 1999b; Yan *et al.*, 1998); and robust proteins that can withstand drying and stamping (Bernard *et al.*, 1998; St. John *et al.*, 1998).

Although the use of proteins as the ink is limited to sturdy proteins, even the more delicate ones can be patterned utilizing microcontact printing. This patterning of proteins is accomplished

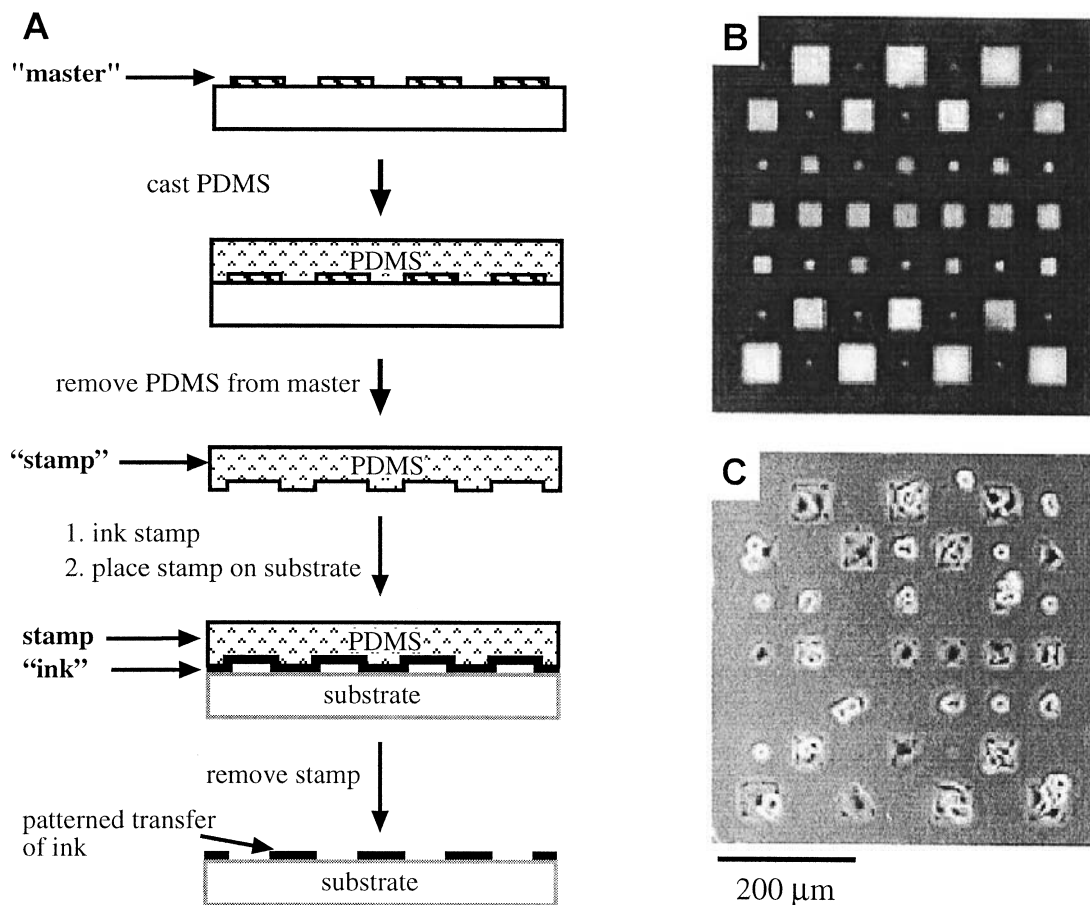

Fig. 18.3. Examples of microcontact printing experiments. (A) Typical procedure. A poly(dimethylsiloxane) (PDMS) stamp is prepared by pouring PDMS prepolymer on a “master,” curing the PDMS and removing it from the master. A solution containing the patterning component of interest (“ink”) is applied to this stamp and the solution allowed to dry. This inked stamp is placed on a substrate to allow the ink to transfer to the substrate. A patterned substrate remains after removal of the stamp. (B) Selective adsorption of fibronectin onto a surface patterned into protein-adsorptive and non-protein-adsorptive self-assembled monolayers by microcontact printing as visualized by immunostaining. (C) Patterned attachment and spreading of cells on the protein-patterned substrate in B.

by preparing areas of protein-adsorptive SAMs and allowing proteins to adsorb onto those regions from solutions. For example, López *et al.* (1993b) used microcontact printing to pattern gold surfaces into regions terminated in methyl groups, when surrounded by inert oligo(ethylene glycol) groups. Immersion of the patterned SAMs in solutions of proteins such as fibronectin, fibrinogen, pyruvate kinase, streptavidin, and immunoglobulins resulted in adsorption of the proteins on the methyl-terminated regions. The pattern of adsorbed proteins could be characterized by scanning electron microscopy; the layers of adsorbed protein appeared to be homogeneous. Alternatively, proteins can be anchored to ligands patterned onto surfaces by  $\mu$ CP. Lahiri *et al.* (1999b), for example, patterned streptavidin by  $\mu$ CP of its ligand, biotin, onto activated SAMs (using the method illustrated in Fig. 18.2B), and then allowing the protein to bind to the patterned ligand.

All eukaryotic cells, and many prokaryotic cells, are too delicate to be dried or stamped and cannot be patterned directly by  $\mu$ CP. The ability of  $\mu$ CP to create patterns of ligands and proteins, however, allows the patterning of many anchorage-dependent cells (Fig. 18.1), confining them to specific regions of a substrate; these techniques strongly influence the size and shape of the cells (Fig. 18.3C). For example, Mrksich *et al.* (1996) used microcontact printing to pattern gold or silver substrates into regions presenting oligo(ethylene glycol) groups and methyl groups. After coating the substrates with fibronectin, bovine capillary endothelial cells attached only to the methyl-

terminated, fibronectin-coated regions of the patterned SAMs. The cells remained attached in the pattern defined by the underlying SAMs for 5–7 days.  $\mu$ CP has also been used to pattern astroglial cells on silicon substrates (Craighead *et al.*, 1998). Astroglial cells attached selectively to 50- $\mu$ m-wide bars of *N*-1-[3-(trimethoxysilyl)propyl]diethylenetriamine (DETA) SAMs patterned on a silicon surface. Zhang *et al.* (1999) have synthesized oligopeptides containing a cell adhesion motif at the N terminus connected by an oligo(alanine) linker to a cysteine residue at the C terminus. The thiol group of cysteine allowed the oligopeptides to form monolayers on gold-coated surfaces. A combination of microcontact printing and these self-assembling oligopeptide monolayers was used to pattern gold surfaces into regions presenting cell adhesion motifs and oligo(ethylene glycol) groups that resist protein adsorption. Wheeler *et al.* (1999; Branch *et al.*, 1998) created patterns of covalently bound ligands and proteins on glass cover slips and used these patterns to control nerve cell growth.

### FUNDAMENTAL STUDIES IN CELL BIOLOGY USING MICROCONTACT-PRINTED SUBSTRATES

The ability to design SAMs to be either protein adsorptive or nonadsorptive, when combined with the ability of  $\mu$ CP to pattern such SAMs routinely on size scales smaller than that of a single cell (2–50  $\mu$ m), has led to new studies on the effect of patterned surface environments and cell shape on cell behavior (Table 18.1).

Singhvi *et al.* (1994) used  $\mu$ CP to prepare substrates consisting of square and rectangular islands of laminin surrounded by nonadhesive regions, and studied the behavior of rat hepatocytes on them. The cells conformed to the shape of the laminin patterns, allowing one to control cell shape independently of the extracellular matrix (ECM) ligand density. The investigators compared cells grown on various patterns and observed that cell shape, regardless of ECM ligand density, was the major determinant of cell growth and differentiation. Chen *et al.* (1997, 1999) used  $\mu$ CP to prepare substrates that presented circular cell-adhesive islands of various diameters and interisland spacings. Such patterns allowed them to control the extent of cell spreading without varying the total cell–matrix contact area. They found that the extent of spreading (the projected surface area of the cell) and not the area of the adhesive contact controlled whether the cell divided, remained in stationary phase, or entered apoptosis. Dike *et al.* (1999) used  $\mu$ CP to prepare substrates with cell-adhesive lines of varying widths. They found that bovine capillary endothelial (BCE) cells cultured on 10- $\mu$ m-wide lines underwent differentiation to capillary tubelike structures containing a central lumen. Cells cultured on wider (30  $\mu$ m) lines formed cell–cell contacts, but these cells continued to proliferate and did not form tubes. These studies indicate that cell growth, function, and differentiation can be controlled, at least in some cases, by patterning the surface of the substrate to which cells adhere.

In another study, Bailly *et al.* (1998) used micropatterned substrates in studies of the regulation of protrusion shape during chemotactic responses of mammalian carcinoma cells. They plated rat mammary carcinoma cells on gold-coated glass cover slips having 10- $\mu$ m-wide adhesive lanes. On stimulation with epidermal growth factor (EGF), the cells extended lamellipods laterally, over the nonadhesive part of the substrate. These results showed that lamellipod extension could occur independently of any contact with the substrate. Contact formation was, however, necessary for stabilizing the protrusion.

$\mu$ CP is an excellent method for patterning surfaces with complex and delicate organic groups, and it is the soft lithographic method that has been most utilized for patterning the substrate.

### MICROFLUIDIC PATTERNING

Microfluidic channels can be used to pattern surfaces by restricting the flow of fluids to desired regions of a substrate (Fig. 18.4). The patterning components—such as ligands, proteins, and cells—are deposited from the solution to create a pattern on the substrate.

Delamarche *et al.* (1997, 1998) used microfluidic patterning ( $\mu$ FP) to pattern immunoglobulins with submicron resolution on a variety of substrates, including gold, glass, and polystyrene. Only microliters of reagent were required to cover square millimeter-sized areas. Patel *et al.* (1998) developed a method to generate micron-scale patterns of any biotinylated ligand on the surface of a biodegradable polymer. These investigators prepared biotin-presenting polymer films, and patterned the films by allowing solutions of avidin to flow over them through 50- $\mu$ m channels fab-

**Table 18.1. Examples of patterning cells using microcontact printing**

Substrate	Features	Initial component patterned	Proteins patterned	Effect observed (cells patterned)	Refs.
Gold	2- to 80- $\mu\text{m}$ rectangles	Hexadecane thiol, hexa(ethylene glycol)-terminated alkane thiol	Laminin	Primary rat hepatocytes adhere and spread only on laminin-coated islands; cell shape controls cell growth and function	Singhvi <i>et al.</i> (1994)
Gold	60- $\mu\text{m}$ lines separated by 120 $\mu\text{m}$	Hexadecane thiol, tri(propylene sulfide)-terminated alkane thiol	Fibronectin	BCE cells were confined to the hexadecane thiol SAM regions for 1–2 days then started to spread into other areas	Deng <i>et al.</i> (1996)
Thin gold film (<12 nm) on polyurethane	25- to 50- $\mu\text{m}$ ridges and grooves	Hexadecane thiol, tri(ethylene glycol)-terminated alkane thiol	Fibronectin	Patterned adsorption of fibronectin; cells are confined to tri(ethylene glycol)-terminated alkane thiol SAM regions for at least 5 days	Mrksich <i>et al.</i> (1996)
Gold	3- to 40- $\mu\text{m}$ squares and circles	Hexadecane thiol, tri(ethylene glycol)-terminated alkane thiol	Fibronectin, vitronectin, collagen, anti-integrin $\beta_1$ antibody, or anti-integrin $\alpha_v\beta_3$	Extent of cell spreading (not the area of adhesive contact) controls apoptosis of bovine capillary endothelial cells	Chen <i>et al.</i> (1997, 1999)
Silicon	Features of 1 $\mu\text{m}$ and larger	Octadecyltrichlorosilane, N-1-[3-(trimethoxysilyl)propyl]diethylenetriamine, polylysine	—	LRM 55 cells (astroglial cell line) selectively attached to DETA-patterned surfaces in presence of serum-containing media; rat hippocampal neurons attach to poly(lysine)-patterned regions	Craighead <i>et al.</i> (1998)
Gold and silicon	Circles and squares of 5 to 80 $\mu\text{m}$	Hexadecane thiol, tri(ethylene glycol)-terminated alkane thiol	Fibronectin	Cell cycle progression of BCE cells were controlled by cell shape and cytoskeletal tension	Huang <i>et al.</i> (1998)
Gold	10- $\mu\text{m}$ lines	Hexadecane thiol, hexa(ethylene glycol)-terminated alkane thiol	Vitronectin	Chemotactic response of MTLn3 metastatic rat mammary adenocarcinoma cells; lamellipod extension is independent of contact with the substratum	Bailly <i>et al.</i> (1998)
Gold	Squares and lines of 20 $\mu\text{m}$ and larger	Peptides containing cell adhesion motifs and cysteine, hexa(ethylene glycol)-terminated alkane thiol	—	Human epidermoid carcinoma A431 cells, primary human embryonic kidney 293 cells, bovine aorta endothelial cells, and NIH 3T3 fibroblasts	Zhang <i>et al.</i> (1999)
Gold	10- or 30- $\mu\text{m}$ -width lines and 5- or 10- $\mu\text{m}$ squares	Hexadecane thiol, tri(ethylene glycol)-terminated alkane thiol	Fibronectin	BCE cells can be switched between growth, apoptosis, and differentiation by altering the geometry of spreading	Dike <i>et al.</i> (1999)
Glass that presents N-hydroxy-succinimide esters or aldehydes	10- $\mu\text{m}$ lines	Poly(lysine), bovine serum albumin laminin	BSA, laminin	On a patterned surface, neural somata and dendrites preferred poly(lysine) surfaces whereas axons preferred surfaces presenting laminin/poly(lysine) mixtures	Branch <i>et al.</i> (1998) Wheeler <i>et al.</i> (1999)

Fig. 18.4. Patterning substrates using microfluidic channels. (A) A poly(dimethylsiloxane) (PDMS) mold is brought into conformal contact with the surface of a substrate to form microfluidic channels. (B) The channels are filled with a solution containing patterning components. (C) The channels are washed clean of the patterning solution and the PDMS mold is removed. This sequence of steps results in generation of patterns of adsorbed proteins on the substrate.

ricated in PDMS. The avidin moieties bound to the biotin groups on the surface, and served as a bridge between the biotinylated polymer and biotinylated ligands. Patterns created with biotinylated ligands containing the RGD or IKVAV oligopeptide sequences determined the adhesion and spreading of bovine aortic endothelial cells and PC12 nerve cells. Folch and Toner (1998) and Folch *et al.* (1999) used  $\mu$ FP to produce patterns of cells on biocompatible substrates. Micropatterns of collagen or fibronectin deposited from fluids in capillaries were used to cause cells to adhere selectively to various biomedical polymers, and to heterogeneous or microtextured substrates. On removing the elastomeric stamp, the bare areas of the substrate could be seeded with more adhesive cell types such as fibroblasts. This procedure produced micropatterned cocultures. By allowing different cell suspensions to flow through different channels, patterns composed of two cell types were also generated.

The mild conditions used with  $\mu$ FP permit the patterning not only of small molecules and proteins, but also of more delicate components such as cells. By filling individual channels with different fluids, multiple components can be patterned at the same time without the need for multiple steps or the accompanying technical concerns of registration.

## LAMINAR FLOW PATTERNING

Laminar flow patterning (LFP) is a technique that can pattern surfaces, and the positions of cells on them, in useful ways. It can also pattern fluids (Takayama *et al.*, 1999) themselves. This technique utilizes a phenomenon that occurs in microfluidic systems as a result of their small dimensions—that is, low Reynolds number flow. The Reynolds number ( $Re$ ) is a nondimensional parameter describing the ratio of inertial to viscous forces in a specific flow configuration. It is a measure of the tendency of a flowing fluid to develop turbulence. The flow of liquids in capillaries often has a low  $Re$  and is laminar. Laminar flow allows two or more layers of fluid to flow next to each other without any mixing other than by diffusion of their constituent molecular and particulate components.

Figure 18.5 shows a typical setup for LFP experiments, along with images from some representative work. A network of capillaries is made by bringing a patterned PDMS slab into conformal contact with a petri dish. By flowing different patterning components from the inlets, patterns of parallel stripes are created in the main channel (Fig. 18.5A,B). The positions and environments of cells can be controlled simultaneously in several stripes in the same channel (Fig. 18.5C). Figure 18.5D shows patterning of the substrate with different proteins; Fig. 18.5E shows patterning cell position by deposition from laminar fluid flows; Fig. 18.5F illustrates the use of patterned culture media to deliver chemicals selectively to cells. In this experiment, bovine capillary endothelial cells covered the entire bottom face of the capillary; the fluorescence micrograph visualizes only those cells over which medium containing a fluorescent dye was allowed to flow. Figure 18.5G is another example of patterning the culture media. In this experiment, digestion of fibronectin on the channel surface and sequestering of calcium by ethylenediaminetetraacetic acid (EDTA) cause cells to detach and contract. When a solution of trypsin/EDTA was allowed to flow over only a portion of a cell, the treated part of the cell detached and contracted; the untreated

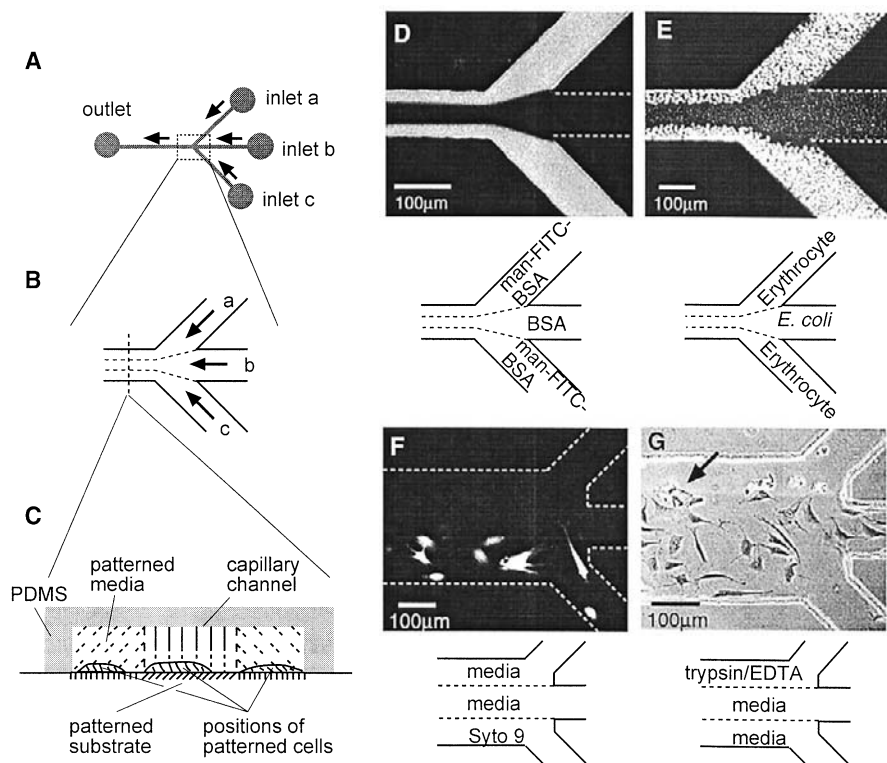

Fig. 18.5 Examples of laminar flow patterning experiments. (A) Top view of the capillary network. A poly(dimethylsiloxane) (PDMS) membrane containing micron-sized channels molded in its surface was placed on the flat surface of a petri dish to form a network of capillaries. (B) A close-up view of the junctions where the inlets converge into a single main channel. Micrographs were obtained for this area of the capillary system. (C) Cross-sectional view of the main channel, looking from the outlet toward the inlet. The patterning of the substrate, the cell positions, and the fluid environment can be controlled simultaneously in the same capillary. (D) Patterning substrate with bovine serum albumin (BSA) and BSA colabeled with mannose and fluorescein (man-FITC-BSA). (E) Patterned cell deposition. Chick erythrocytes and *Escherichia coli* were deposited selectively in their designated lanes by patterned flow of cell suspensions. Adherent cells were visualized with a fluorescent nucleic acid stain (Syto 9). (F) Using patterned media to selectively stain BCE cells. Syto 9 and media were allowed to flow from the designated inlets. (G) Using patterned media to detach bovine capillary endothelial cells selectively. Trypsin/EDTA and media were allowed to flow from the designated inlets. (D–F) Fluorescence micrographs taken from the top through PDMS. (G) Phase contrast image observed by an inverted microscope looking through the polystyrene petri dish. White dotted lines identify channels not visible with fluorescence microscopy.

part remained spread (for example, see arrow in Fig. 18.5G). Because no physical barriers are required to separate the different liquid streams, different liquids can flow over different portions of a single cell.

LFP has some features that make it complementary to other patterning techniques used for biological applications. It takes advantage of the easily generated multiphase laminar flows to pattern fluids and to deliver components for patterning. The ability to pattern the growth medium is a special feature that cannot be achieved by other processes. This method can pattern over delicate structures, such as a portion of a mammalian cell. This type of patterning is difficult by other techniques. LFP can also give simultaneous control over the surface patterns, cell positioning, and the fluid environment in the same channel.

## CONCLUSION AND FUTURE PROSPECTS

Soft lithography brings to microfabrication low-cost, simple procedures, rapid prototyping of custom-designed devices, three-dimensional capability, and biocompatibility. These techniques allow patterning of cells and their environments with great convenience and flexibility at dimensions down to micrometers. We have described three complementary soft lithographic tech-

niques—microcontact printing, patterning using fluids in microfluidic channels, and laminar flow patterning—that are useful in their ability to pattern the cell culture environment.

Microcontact printing is perhaps the simplest method for patterning surfaces and also provides the highest resolution with the greatest flexibility in the shape of the patterns generated. It is most useful when one needs to pattern two types of ligands or proteins, and when the “ink” is able to withstand drying and stamping. Microfluidic channels are well suited for patterning surfaces using delicate objects such as proteins and cells. They are also useful when multiple ligands, proteins, or cells need to be patterned. Laminar flow patterning is similar to patterning with individual microfluidic channels except that the individual flows are kept from mixing with each other by laminar flow, not by physical walls. The ability to pattern the fluid environment is the distinguishing feature of this method, and enables laminar flow to be used to pattern the distribution of different fluids over the surface of a single mammalian cell. This capability allows patterning of portions of a single cell, and remodeling of the cell culture environment, both in the presence of living cells.

The potential applications of soft lithography are just starting to be explored. There are many cell culture environments that we have not discussed in this chapter, but that can potentially be patterned utilizing soft lithographic methods. For example, topographical features created in PDMS affect cell spreading (Flemming *et al.*, 1999). Silicone polymers can sense and affect the mechanical tension within cells (Burton and Taylor, 1997; Sai *et al.*, 1999). With the availability of various three-dimensional fabrication techniques, much more work is expected in three-dimensional patterning of the cell culture substrate (Breen *et al.*, 1999; Jackman *et al.*, 1998; Terfort *et al.*, 1997). The fourth dimension, time, is also an interesting factor. Experiments such as trypsin-mediated remodeling of the exposed surfaces of cells and supports presenting adsorbed proteins using laminar flow demonstrate that real-time temporal changes in the cell culture environment are possible (Takayama *et al.*, 1999). The optical transparency of PDMS makes it possible to pattern the intensity of light in cell cultures (Paul *et al.*, 1999; Xia and Whitesides, 1998). The ability of soft lithography to pattern magnetic materials, and the nonmagnetic character of PDMS, makes it an attractive method for patterning of magnetic fields (Palacin *et al.*, 1996). The gas permeability of PDMS may be useful in patterning the gas of the surrounding cells. PDMS is electrically insulating, and the ability to mold or fabricate electrically conducting wires in it should allow patterning of electric fields (Kenis *et al.*, 1999). Gravitational fields can also be affected: microfluidic culture chambers with adherent cells can be turned upside down without loss of the culture media. Temperature, fluid shear, and other factors may also be accurately patterned.

The potential of a cell is predetermined by its genetics. Realization of that potential depends, *inter alia*, on whether the cell is exposed to the appropriate environment. Soft lithography provides tools for patterning cells and their environments with a high degree of control. This capability aids efforts to understand fundamental cell biology and advances our ability to engineer cells and tissues. The ease with which electronic components or other nonbiological components can be fabricated with soft lithography also paves the way for the engineering of cells and tissue for use in biosensors and other hybrid systems that combine living and nonliving components.

# CELL INTERACTIONS WITH POLYMERS

W. Mark Saltzman

## INTRODUCTION

Synthetic and naturally occurring polymers are an important element in new strategies for producing engineered tissue (Langer and Vacanti, 1993; Hubbell, 1995). Several classes of polymers have proved to be most useful in biomedical applications, including situations in which the polymer remains in intimate contact with cells and tissues for prolonged periods (Table 19.1). These polymers might be appropriate for tissue engineering applications, as well. But to select appropriate polymers for tissue engineering, it is necessary to understand the influence of the polymer on cell viability, growth, and function.

This chapter briefly reviews previous work on the interactions of tissue-derived cells with polymers, particularly the types of synthetic polymers that have been employed as biomaterials. In flowing blood, the interactions of cells, particularly platelets, with synthetic polymer surfaces are also an important aspect of biomaterials design, but are not considered here.

## METHODS FOR CHARACTERIZING CELL INTERACTIONS WITH POLYMERS

Cell interactions with polymers are usually studied using cell culture techniques. Although *in vitro* experiments do not reproduce the entire range of cellular responses observed following implantation of materials, the culture environment provides a level of control and quantification that cannot be easily obtained *in vivo*. To study cell interactions, cells in culture are usually plated over a polymer surface and the extent of cell adhesion and spreading on the surface is measured. By maintaining the culture for longer periods, the influence of the substrate on cell viability, function, and motility can also be determined. Because investigators use different techniques to assess cell interactions with polymers, and because the differences between experimental techniques are potentially important for interpretation of interactions, the most frequently used *in vitro* methods are reviewed in this section.

## ADHESION AND SPREADING

Most tissue-derived cells are anchorage dependent and require attachment to a solid surface for viability and growth. For this reason, the initial events that occur when a cell approaches a surface are of fundamental interest. In tissue engineering, cell adhesion to a surface is critical because adhesion precedes other events, such as cell spreading, cell migration, and, often, differentiated cell function.

A number of different techniques for quantifying the extent and strength of cell adhesion have been developed. In fact, so many different techniques are used that it is usually difficult to compare studies performed by different investigators. This situation is further complicated by the fact that cell adhesion depends on a large number of experimental parameters (Lauffenburger and Linderman, 1993), many of which are difficult to control. The simplest methods for quantifying the extent of cell adhesion to a surface involve three steps: (1) suspension of cells over a surface, (2) in-

**Table 19.1. Polymers that might be useful in tissue engineering<sup>a</sup>**

Polymer	Typical application
Polydimethylsiloxane, silicone elastomers (PDMS)	Breast, penile, and testicular prostheses, catheters, drug delivery devices, heart valves, hydrocephalus shunts, membrane oxygenators
Polyurethanes (PEUs)	Artificial hearts and ventricular assist devices, catheters, pacemaker leads
Poly(tetrafluoroethylene) (PTFE)	Heart valves, vascular grafts, facial prostheses, hydrocephalus shunts, membrane oxygenators, catheters, sutures
Polyethylene (PE)	Hip prostheses, catheters
Polysulfone (PSu)	Heart valves, penile prostheses
Poly(methyl methacrylate) (pMMA)	Fracture fixation, intraocular lenses, dentures
Poly(2-hydroxyethylmethacrylate) (pHEMA)	Contact lenses, catheters
Polyacrylonitrile (PAN)	Dialysis membranes
Polyamides	Dialysis membranes, sutures
Polypropylene (PP)	Plasmapheresis membranes, sutures
Poly(vinyl chloride) (PVC)	Plasmapheresis membranes, blood bags
Poly(ethylene–covinyl acetate)	Drug delivery devices
Poly(L-lactic acid), poly(glycolic acid), and poly(lactide–coglycolide) (PLA, PGA, and PLGA)	Drug delivery devices, sutures
Polystyrene (PS)	Tissue culture
Poly(vinyl pyrrolidone) (PVP)	Blood substitutes

<sup>a</sup>Inclusion in this list is based on past use in biomedical devices, from reviews by Peppas and Langer (1994) and Marchant and Wang (1994).

cubation of the sedimented cells in culture medium for some period of time, and (3) detachment of loosely adherent cells under controlled conditions. The extent of cell adhesion, which is a function of the conditions of the experiment, is determined by quantifying either the number of cells that remain associated with the surface (the “adherent” cells) or the number of cells that were extracted with the washes. Radiolabeled or fluorescently labeled cells can be used to permit measurement of the number of attached cells. Alternatively, the number of attached cells can be determined by direct visualization, by measurement of the concentration of an intracellular enzyme, or by binding of a dye to an intracellular component such as DNA. In many cases, the adherent cells are further categorized based on morphological differences (e.g., extent of spreading, formation of actin filament bundles, presence of focal contacts). This technique is simple, rapid, and because it requires simple equipment, it is commonly performed. Unfortunately, it is often difficult to control the force that is provided to dislodge the nonadherent cells, making it difficult to compare results obtained from different laboratories, even when they are using the same technique.

This disadvantage can be overcome by using centrifuge (McClay *et al.*, 1981) or a flowing fluid (McIntire, 1994) to provide a reproducible detachment force. In centrifugal detachment assays, the technique described above is modified slightly: following the incubation period, the plate is inverted and subjected to a controlled detachment force by centrifugation. In most flow chambers, the fluid is forced between two parallel plates (Lawrence *et al.*, 1987). Prior to applying the flow field, a cell suspension is injected into the chamber, and the cells are permitted to settle onto the surface of interest and to adhere. After some period of incubation, flow is initiated between the plates. These chambers can be used to measure the kinetics of cell attachment, detachment, and rolling on surfaces under conditions of flow. Usually, the overall flow rate is adjusted so that

the flow is laminar, and the shear stresses at the wall approximate those found in the circulatory system; however, these chambers can be used to characterize cell detachment under a wide range of conditions.

Radial flow detachment chambers have also been used to measure forces of cell detachment (Cozens-Roberts *et al.*, 1990). Because of the geometry of the radial flow chamber, in which cells are attached uniformly to a circular plate and fluid is circulated from the center to the periphery of the chamber along radial paths, the fluid shear force experienced by the attached cells decreases with radial position from the center to the periphery. Therefore, in a single experiment, the influence of a range of forces on cell adhesion can be determined. A spinning disk apparatus can be used in a similar fashion (Horbett *et al.*, 1988). Finally, micropipette techniques can be used to measure cell membrane deformability or forces of cell–cell or cell–surface adhesion (Evans, 1973; Lamoureux *et al.*, 1989; Tozeren *et al.*, 1989).

## MIGRATION

The migration of individual cells within a tissue is a critical element in the formation of the architecture of organs and organisms (Trinkhaus, 1984). Likewise, cell migration is likely to be an important phenomenon in tissue engineering, because the ability of cells to move, either in association with the surface of a material or through an ensemble of other cells, will be an essential part of new tissue formation or regeneration. Cell migration is also difficult to measure, particularly in complex environments. Fortunately, a number of useful techniques for quantifying cell migration in certain situations have been developed. As in cell adhesion, however, no technique has gained general acceptance, so it is often difficult to correlate results obtained by different techniques or different investigators.

Most experimental methods for characterizing cell motility can be divided into two categories. In visual assays, the movements of a small number of cells are observed individually (Gail and Boone, 1970; Zigmond, 1977; Allan and Wilkinson, 1978; Parkhurst and Saltzman, 1992). Population techniques, on the other hand, allow the observation of the collective movements of groups of cells; in filter chamber assays the number of cells migrating through a membrane or filter is measured (Boyden, 1962), whereas in under-agarose assays the leading front of cell movement on a surface under a block of agarose is monitored (Nelson *et al.*, 1975). The experimental details of these assays, as well as their advantages and limitations, have been reviewed (Wilkinson *et al.*, 1982). Both visual and population assays can be quantitatively analyzed, enabling the estimation of intrinsic cell motility parameters, such as the random motility coefficient and the persistence time (Gail and Boone, 1970; Dunn, 1983; Lauffenburger, 1983; Buettner *et al.*, 1989; Farrell *et al.*, 1990).

## AGGREGATION

Cell aggregates are important tools in the study of tissue development, permitting correlation of cell–cell interactions with cell differentiation, viability, and migration, as well as subsequent tissue formation. The aggregate morphology permits reestablishment of cell–cell contacts normally present in tissues; therefore, cell function and survival are often enhanced in aggregate culture (Matthieu *et al.*, 1981; Landry *et al.*, 1985; Koide *et al.*, 1989; Cirulli *et al.*, 1993; Parsons-Wingerter and Saltzman, 1993; Peshwa *et al.*, 1994). Because of this, cell aggregates may also be useful in tissue engineering, enhancing the function of cell-based hybrid artificial organs (Nyberg *et al.*, 1993) or reconstituted tissue transplants (Langer and Vacanti, 1993).

Aggregates are usually formed by incubating cells in suspension, using gentle rotational stirring to disperse the cells (Moscona, 1961). Although this method is suitable for aggregation of many cells, serum or serum proteins must be added to promote cell aggregation in many cases (Matsuda, 1988), making it difficult to characterize and control the aggregation process. Specialized techniques can be used to produce aggregates in certain cases, principally by controlling cell detachment from a solid substratum (Koide *et al.*, 1989; Parsons-Wingerter and Saltzman, 1993; Takezawa *et al.*, 1993). Synthetic polymers produced by linking cell-binding peptides (such as RGD and YIGSR) to both ends of poly(ethylene glycol) (PEG) have been used to promote aggregation of cells in suspension (Dai *et al.*, 1994).

The kinetics and extent of aggregation can be measured by a variety of techniques. Often, direct visualization of aggregate size is used to determine the extent of aggregation (Moscona, 1961).

The kinetics of aggregation can be monitored by measuring aggregate size distributions over time, which is facilitated by the use of computer image analysis techniques (Munn *et al.*, 1993; Dai *et al.*, 1994) or electronic particle counters (Orr and Roseman, 1969). Specialized aggregometers have been constructed to provide reproducible and rapid measurements of the rate of aggregation; in one such device, small-angle light scattering through rotating sample cuvettes was used to produce continuous records of aggregate growth (Thomas and Steinberg, 1980).

### CELL FUNCTION

In tissue engineering, one is usually interested in promotion of some cell-specific function. For example, protein secretion (Cima *et al.*, 1991) and detoxification (Gutsche *et al.*, 1994) are essential functions for hepatocytes. Production of extracellular matrix (ECM) proteins is important in the physiology of many cells, such as chondrocytes (Benya and Shaffer, 1982), osteoblasts (Ishaug *et al.*, 1994), and fibroblasts (Tamada and Ikada, 1994). In some cases, the important cell function involves the coordinated activity of groups of cells, such as the formation of myotubules in embryonic muscle cell cultures (Stol *et al.*, 1985) or the contraction of the matrix surrounding fibroblasts (Bell *et al.*, 1979; Barocas *et al.*, 1995). In these cases, cell function is monitored by watching for changes in the morphology in the culture.

## CELL INTERACTION WITH POLYMER SURFACES

### EFFECT OF POLYMER CHEMISTRY ON CELL BEHAVIOR

#### Synthetic polymers

For cells attached to a solid substrate, cell behavior and function depend on the characteristics of the substrate. Consider, for example, the experiments described by Folkman and Moscona (1978), in which cells were allowed to settle onto surfaces formed by coating conventional tissue culture polystyrene (TCPS) with various dilutions of poly(2-hydroxyethyl methacrylate) (pHEMA). As the amount of pHEMA added to the surface was increased, the surface became less adhesive and cell spreading decreased; spreading was quantified by measuring the average cell height on the surface. Average cell height correlated with the rate of cell growth (Fig. 19.1), suggesting that cell shape, which was determined by the adhesiveness of the surface, modulated cell proliferation. In these experiments, two simple polymers (TCPS and pHEMA) were used to produce a series of surfaces with graded adhesivity. These experiments demonstrate that the nature of a polymer surface will have important consequences for cell function, an observation of considerable significance with regard to the use of polymers in tissue engineering.

Following a similar experimental rationale, a number of groups have examined the relationship between chemical or physical characteristics of the substrate and behavior or function of attached cells. Results from a number of similar studies are summarized in Figs. 19.2 and 19.3. Cell adhesion appears to be maximized on surfaces with intermediate wettability (Fig. 19.2) (Horbett

Fig. 19.1. Cell shape and cell growth are modulated by properties of a polymer surface. Cell culture surfaces were produced by evaporating diluted solutions of pHEMA onto TCPS. The uptake of [<sup>3</sup>H]thymidine was used as a measure of proliferation. The size of the symbol represents the relative cell height; small symbols represent cells with small heights, and therefore significant spreading; large symbols represent cells with large heights, and therefore negligible spreading. Data replotted from Folkman and Moscona (1978).

Fig. 19.2. The relationship between cell adhesion and water-in-air contact angle for a variety of polymer surfaces. Data replotted from Tamada and Ikada (1994) for fibroblasts ( $\square$ ), Ikada (1994) for L cells ( $\circ$ ), Hasson *et al.* (1987) for endothelial cells ( $\Delta$ ), van Wachem *et al.* (1987) for endothelial cells ( $\bullet$ ), and Saltzman *et al.* (1991) for fibroblasts ( $\blacksquare$ ).

*et al.*, 1985; van Wachem *et al.*, 1987; Ikada, 1994; Tamada and Ikada, 1994), although there are some obvious exceptions. For most surfaces, adhesion requires the presence of serum and, therefore, this optimum is probably related to the ability of proteins, such as fibronectin (Horbett and Schway, 1988), to adsorb to the surface. In the absence of serum, adhesion is enhanced on positively charged surfaces (van Wachem *et al.*, 1987). Fibroblast spreading has been correlated with surface free energy (Fig. 19.3), but the rate of fibroblast growth on polymer surfaces appears to be relatively independent of surface chemistry (van der Valk *et al.*, 1983; Horbett *et al.*, 1985; Saltzman *et al.*, 1991). Cell viability may also be related to interactions with the surface (Ertel *et al.*, 1994). The migration of surface-attached fibroblasts (Saltzman *et al.*, 1991), endothelial cells (Hasson *et al.*, 1987), and corneal epithelial cells (Pettit *et al.*, 1994) has been measured as function of polymer surface chemistry; rates of cell migration depend on the nature of the surface, although no general trends have emerged. Collagen synthesis in fibroblasts has been correlated with contact angle, with higher rates of collagen synthesis per cell for the most hydrophobic surfaces (Tamada and Ikada, 1994).

Polymers can frequently be made more suitable for cell attachment and growth by surface modification. In fact, polystyrene (PS) substrates used for tissue culture are usually treated by glow-discharge (Amstein and Hartman, 1975) or exposure to sulfuric acid to increase the number of charged groups at the surface, which improves attachment and growth of many types of cells. Treatment of pHEMA, a nonadhesive polymer, with sulfuric acid also improved adhesion of endothelial cells and permitted cell proliferation on the surface (Hannan and McAuslan, 1987). Modification of PS or PET, poly(ethylene terephthalate), by radiofrequency plasma deposition enhanced attachment and spreading of fibroblasts and myoblasts (Chinn *et al.*, 1989). Again, many of the effects of surface modification appear to be secondary to increased adsorption of cell attachment

Fig. 19.3. The relationship between cell spreading and surface free energy for fibroblasts cultured on a variety of polymer surfaces. Data replotted from van der Valk *et al.* (1983) and Schakenraad *et al.* (1986). FEP, fluoroethylenepropylene copolymer; PE, polyethylene; PS, polystyrene; PEU, polyurethane; PSu, polysulfone; PMMA, poly(methyl methacrylate); TCPS, tissue culture polystyrene.

proteins, such as fibronectin and vitronectin, to the surface. On the other hand, some reports have identified specific chemical groups at the polymer surface [such as hydroxyl ( $-\text{OH}$ ) (Curtis *et al.*, 1983; Lydon *et al.*, 1985) or surface C—O functionalities (Chinn *et al.*, 1989)] as important factors in modulating the fate of surface-attached cells.

So far, no general principles that would allow prediction of the extent of attachment, spreading, or growth of cultured cells on different polymer surfaces have been identified. For specific cells, however, interesting correlations have been made with parameters such as the density of surface hydroxyl groups (Curtis *et al.*, 1983), density of surface sulfonic groups (Kowalczyńska and Kaminski, 1991), surface free energy (van der Valk *et al.*, 1983; Baier *et al.*, 1985; Schakenraad *et al.*, 1986), fibronectin adsorption (Chinn *et al.*, 1989), and equilibrium water content (Lydon *et al.*, 1985), but exceptions to these correlations are always found. Complete characterization of the polymer, including both bulk and surface properties, is critical to understanding the nature of the cell–polymer interactions (Tyler *et al.*, 1992).

Although the interactions of cells with implanted polymers is much more difficult to measure, the surface chemistry of polymers appears to influence cell interactions *in vivo*. For example, the ability of macrophages to form multinucleated giant cells at a hydrogel surface has been correlated with the presence of certain chemical groups at the surface: macrophage fusion decreases in the order  $(\text{CH}_3)_2\text{N}- > -\text{OH} = -\text{CO}-\text{NH}- > -\text{SO}_3\text{H} > -\text{COOH}(-\text{COONa})$  (Smetana *et al.*, 1990; Smetana, 1993). A similar hierarchy has been observed for CHO cell adhesion and growth on surfaces with grafted functional groups: CHO cell attachment and growth decreased in the order  $-\text{CH}_2\text{NH}_2 > -\text{CH}_2\text{OH} > -\text{CONH}_2 > -\text{COOH}$  (Lee *et al.*, 1994).

### Biodegradable polymers

Biodegradable polymers slowly degrade and then dissolve following implantation. This feature may be important for many tissue engineering applications, because the polymer will disappear as functional tissue regenerates (Vacanti *et al.*, 1988). Biodegradable polymers may provide an additional level of control over cell interactions: during polymer degradation, the surface of the polymer is constantly renewed, providing a dynamic substrate for cell attachment and growth.

Homopolymers and copolymers of poly(L-lactic acid), poly(glycolic acid), and poly(lactide-co-glycolide) (PLA, PGA, PLGA) have been frequently examined as cell culture substrates, because they have been used as implanted sutures for several decades (Schmitt and Polistina, 1967; Schneider, 1967; Kulkarni *et al.*, 1971; Wasserman and Levy, 1975). Chondrocytes proliferate and secrete glycosaminoglycans within porous meshes of PGA and foams of PLA (Freed *et al.*, 1993). Rat hepatocytes attach to blends of biodegradable PLGA polymers and secrete albumin for 5 days in culture (Cima *et al.*, 1991). Neonatal rat osteoblasts also attach to PLA, PGA, and PLGA substrates and synthesize collagen (Ishaug *et al.*, 1994).

Cell adhesion and function have been examined on a variety of other biodegradable polymers. When cells from an osteogenic cell line were seeded onto polyphosphazenes produced with a variety of side groups, the rate of cell growth as well as the rate of polymer degradation depended on side group chemistry (Laurencin *et al.*, 1993). Fibroblasts and hepatocytes attached to poly(phosphoesters) with a variety of side group functionalities (Saltzman *et al.*, 1991). Proliferation of fibroblasts, as well as attachment and neurite outgrowth from PC12 and dorsal root ganglia cells, have been examined on tyrosine-based polycarbonates and polyarylates (Kohn, 1994; Zhou *et al.*, 1994).

### Synthetic polymers with adsorbed proteins

Cell attachment, migration, and growth on polymer surfaces appear to be mediated by proteins, either adsorbed from the culture medium or secreted by the cultured cells. Because it is difficult to study these effects *in situ* during cell culture, often the polymer surfaces are pretreated with purified protein solutions. In this way, the investigators hope that subsequent cell behavior on the surface will represent cell behavior in the presence of a stable layer of surface-bound protein. Cell spreading, but not attachment, has been correlated with fibronectin adsorption to a variety of surfaces (Horbett and Schway, 1988; Chinn *et al.*, 1989; Pettit *et al.*, 1994). Rates of cell migration on a polymer surface have been shown to depend on the concentration of preadsorbed adhesive proteins (Calof and Lander, 1991; DiMilla *et al.*, 1993), as well as the presence of soluble inhibitors to protein-mediated cell adhesion (Wu *et al.*, 1994). It appears that the rate of mi-

gration is optimal at intermediate substrate adhesiveness, as one would expect from mathematical models of cell migration (Lauffenburger and Linderman, 1993).

### Hybrid polymers with immobilized functional groups

Surface modification techniques have been used to produce polymers for cell attachment (Ikada, 1994). For example, chemical groups can be added to change the wettability of the surface, which often influences cell adhesion (Fig. 19.2), as described above. Alternatively, whole proteins such as collagen can be immobilized to the surface, providing the cell with a substrate that more closely resembles the ECM found in tissues (Tamada and Ikada, 1994). Collagen and other ECM molecules have also been incorporated into hydrogels by either adding the protein to a reaction mixture containing monomers and initiating polymerization (Civerchia-Perez *et al.*, 1980; Carbonetto *et al.*, 1982; Woerly *et al.*, 1993), or mixing the protein with polymerized polymer, such as pHEMA, in appropriate solvents (Stol *et al.*, 1985).

To isolate certain features of ECM molecules, and to produce surfaces that are simpler and easier to characterize, smaller biologically active functional groups have been used to modify surfaces. These biologically active groups can be oligopeptides (Massia and Hubbell, 1989), saccharides (Schnaar *et al.*, 1978), or glycolipids (Blackburn and Schnaar, 1983). Certain short amino acid sequences appear to bind to receptors on cell surfaces and mediate cell adhesion. For example, the cell-binding domain of fibronectin contains the tripeptide RGD (Arg-Gly-Asp).<sup>\*</sup> Cells attach to surfaces containing adsorbed oligopeptides with the RGD sequence and soluble, synthetic peptides containing the RGD sequence reduce the cell-binding activity of fibronectin (Pierschbacher and Ruoslahti, 1984), demonstrating the importance of this sequence in adhesion of cultured cells. A large number of ECM proteins (fibronectin, collagen, vitronectin, thrombospondin, tenascin, laminin, and entactin) contain the RGD sequence. The sequences YIGSR and IKVAV in laminin also have cell-binding activity, and mediate adhesion in certain cells.

Because RGD is critical in cell adhesion to ECM, many investigators have examined the addition of this sequence to synthetic polymer substrates. Synthetic RGD-containing peptides have been immobilized to poly(tetrafluoroethylene) (PTFE) (Massia and Hubbell, 1991a), PET (Massia and Hubbell, 1991b), polyacrylamide (Brandley and Schnaar, 1988), polyurethane (PEU) (H.-B. Lin *et al.*, 1992; H. Lin *et al.*, 1994), poly(carbonate urethane) (Breuers *et al.*, 1991), PEG (Drumheller *et al.*, 1994), poly(vinyl alcohol) (PVA) (Matsuda *et al.*, 1989), PLA (Barrera *et al.*, 1993), and poly(*N*-isopropylacrylamide-co-*N*-*n*-butylacrylamide) (Miura *et al.*, 1991) substrates. The addition of RGD has induced cell adhesion, cell spreading, and focal contact formation on otherwise nonadhesive or weakly adhesive polymers (Massia and Hubbell, 1989; 1991a; Hubbell *et al.*, 1991; Lin *et al.*, 1994). Because cells contain cell adhesion receptors that recognize only certain ECM molecules, use of an appropriate cell-binding sequence has led to cell-selective surfaces as well, whereby the population of the cells that adhered to the polymer was determined by the structure of the peptide (Hubbell *et al.*, 1991).

In previous studies, the presence of serum proteins attenuated the adhesion activity of peptide-grafted PEU surfaces (Lin *et al.*, 1994), highlighting a difficulty in using these materials *in vivo*. This problem may be overcome, however, through the development of base materials that are biocompatible yet resistant to protein adsorption. One of the most successful approaches for reducing protein adsorption or cell adhesion has been production of surfaces rich in PEG (Desai and Hubbell, 1991; Merrill, 1993; Drumheller and Hubbell, 1995). For example, polymer substrates composed of PEG in highly cross-linked matrices of acrylic acid and trimethylolpropane triacrylate completely resisted protein adsorption and cell adhesion, but readily supported adhesion after derivitization with cell-binding peptides (Drumheller and Hubbell, 1994). Alternatively, matrices formed directly from synthetic polypeptides may also be useful for cell adhesion. Genes coding the  $\beta$  sheet of silkworm silk have been combined with genes coding fragments of fibronectin to produce proteins that form very stable matrices with cell adhesion domains (Pronectin

---

<sup>\*</sup> Amino acids are identified by their one letter abbreviations: A, alanine; R, arginine; N, asparagine; D, aspartic acid; B, asparagine or aspartic acid; C, cysteine; Q, glutamine; E, glutamic acid; Z, glutamine or glutamic acid; G, glycine; H, histidine; I, isoleucine; L, leucine; K, lysine; M, methionine; F, phenylalanine; P, proline; S, serine; T, threonine; W, tryptophan; Y, tyrosine; V, valine.

F; Protein Polymer Technologies, Inc.). Synthetic proteins based on peptide sequences from elastin have been used as cell culture substrates: in the presence of serum, fibroblasts and endothelial cells adhered to the surfaces of matrices formed by  $\gamma$ -irradiation cross-linking of polypeptides containing repeated sequences GGAP, GGVP, GGIP, and GVGVP (Nicol *et al.*, 1993).

In addition to cell-binding peptides, a variety of other biologically active molecules have been used to enhance cell adhesion to surfaces. For certain cells, adhesion has been enhanced by adsorption of homopolymers of basic amino acids, such as polylysine and polyornithine. Likewise, covalently bound amine groups have influenced cell attachment and growth (Kikuchi *et al.*, 1992; Massia and Hubbell, 1992). The immobilization of saccharides to polymers has also influenced cell attachment and function. Rat hepatocytes adhered, via asialoglycoprotein receptors, to surfaces derivatized with lactose and remained in a rounded morphology consistent with enhanced function in culture (Kobayashi *et al.*, 1986, 1992; Gutsche *et al.*, 1996). Similar results have been obtained with polymer surfaces derivatized with *N*-acetylglucosamine, which was recognized by a surface lectin on chicken hepatocytes (Gutsche *et al.*, 1994). A variety of carbohydrates have been immobilized on polyacrylamide disks, making them suitable for cell culture (Schnaar *et al.*, 1978).

### INFLUENCE OF SURFACE MORPHOLOGY ON CELL BEHAVIOR

The microscale texture of an implanted material can have a significant effect on the behavior of cells in the region of the implant. Fibrosarcomas developed with high frequency, approaching 50% in certain situations, around implanted Millipore filters; the tumor incidence increased with decreasing pore size in the range 450 to 50  $\mu\text{m}$  (Goldhaber, 1961, 1962). In a recent study, porous polymer membranes containing certain structural features (nominal pore size  $> 0.6 \mu\text{m}$  and fibers/strands  $< 5 \mu\text{m}$ ) were associated with enhanced new vessel growth (Brauker *et al.*, 1992).

The behavior of cultured cells on surfaces with edges, grooves, or other textures is different than behavior on smooth surfaces. In many cases, cells oriented and migrated along fibers or ridges in the surface, a phenomenon called contact guidance from early studies on neuronal cell cultures (Weiss, 1934, 1945). Fibroblasts have also been observed to orient on grooved surfaces (Brunette, 1986), particularly when the texture dimensions are 1 to 8  $\mu\text{m}$  (Dunn and Brown, 1986). The degree of cell orientation depended on both the depth (Clark *et al.*, 1991) and pitch (Dunn and Brown, 1986) of the grooves. Not all cells exhibit the same degree of contact guidance when cultured on identical surfaces: baby hamster kidney (BHK) and Madin–Darby canine kidney (MDCK) cells oriented on 100-nm-scale grooves in fused quartz, but cerebral neurons did not (Clark *et al.*, 1991). Fibroblasts, monocytes and macrophages, but not keratinocytes or neutrophils, spread when cultured on silicon oxide with grooves with a 1.2- $\mu\text{m}$  depth and a 0.9- $\mu\text{m}$  pitch (Meyle *et al.*, 1995).

Substrates with peaks and valleys also influenced the function of attached cells. Polydimethylsiloxane (PDMS) surfaces with 2- to 5- $\mu\text{m}$  texture maximized macrophage spreading (Schmidt and von Recum, 1992). Similarly, PDMS surfaces with 4- or 25- $\mu\text{m}^2$  peaks uniformly distributed on the surface provided better fibroblast growth than did 100- $\mu\text{m}^2$  peaks or 4-, 25-, or 100- $\mu\text{m}^2$  valleys (Schmidt and von Recum, 1992).

### USE OF PATTERNED SURFACES TO CONTROL CELL BEHAVIOR

A variety of techniques have been used to create chemically patterned surfaces containing cell adhesive and nonadhesive regions. These patterned surfaces have been useful for examining fundamental determinants of cell adhesion, growth, and function. For example, individual fibroblasts were attached to adhesive microislands of palladium that were patterned onto a nonadhesive pHEMA substrate using microlithographic techniques (O'Neill *et al.*, 1986). By varying the size of the microisland, the extent of spreading and hence the cell surface area were controlled. On small islands ( $\sim 500 \mu\text{m}^2$ ) cells attached but did not spread, whereas on larger islands ( $4000 \mu\text{m}^2$ ) cells spread to the same extent as in unconfined monolayer culture. Cells on large islands proliferated at the same rate as cells in conventional culture, and most cells attached to small islands proliferated at the same rate as suspended cells. For 3T3 cells, however, contact with the surface enhanced proliferation, suggesting that anchorage can stimulate cell division by simple contact with the substrate as well as by increased spreading.

A number of other studies have employed patterned surfaces in cell culture. Micrometer-scale adhesive islands of self-assembled alkane thiols were created on gold surfaces using a simple stamp-

ing procedure (Singhvi *et al.*, 1994), which served to confine cell spreading to islands. When hepatocytes were attached to these surfaces, larger islands ( $10,000 \mu\text{m}^2$ ) promoted growth, but smaller islands ( $1600 \mu\text{m}^2$ ) promoted albumin secretion. Stripes of a monoamine-derivatized surface were produced on fluorinated ethylene propylene films by radiofrequency glow discharge (Ranieri *et al.*, 1993). Because proteins adsorbed differently to the monoamine-derivatized and the untreated stripes, striped patterns of cell attachment were produced. A similar approach, using photolithography to produce hydrophilic patterns on a hydrophobic surface, produced complex patterns of neuroblastoma attachment and neurite extension (Matsuda *et al.*, 1992). A variety of substrate microgeometries, and cell attachment patterns, were created by photochemical fixation of hydrophilic polymers onto TCPS or hydrophobic polymers onto PVA through patterned photomasks: bovine endothelial cells attached and proliferated preferentially on either the TCPS surface (on TCPS/hydrophilic patterns) or the hydrophobic surface (on PVA/hydrophobic patterns) (Matsuda and Sugawara, 1995). When chemically patterned substrates were produced on self-assembled monolayer films using microlithographic techniques, neuroblastoma cells attached to and remained confined within amine-rich patterns on these substrates (Matsuzawa *et al.*, 1993).

Surfaces containing gradients of biological activity have also been useful tools in cell biology, particularly for examining haptotaxis, the directed migration of cells on surfaces with gradients of immobilized factors (Brandley and Schnaar, 1989; Brandley *et al.*, 1990).

## CELL INTERACTIONS WITH POLYMERS IN SUSPENSION

Most of the studies reviewed in the preceding section examined the growth, migration, and function of cells attached to a solid polymer surface. This is a relevant paradigm for a variety of tissue engineering applications, wherein polymers will be used as substrates for the transplantation of cells or as scaffolds to guide tissue regeneration *in situ*. Polymers may be important in other aspects of tissue engineering, as well. For example, polymer microcarriers can serve as substrates for the suspension culture of anchorage-dependent cells, and therefore might be valuable for the *in vitro* expansion of cells or cell transplantation (Demetriou *et al.*, 1986). In addition, immunoprotection of cells suspended within semipermeable polymer membranes is another important approach in tissue engineering, because these encapsulated cells may secrete locally active proteins (Emerich *et al.*, 1994) or function as small endocrine organs (Lacy *et al.*, 1991) within the body.

The idea of using polymer microspheres as particulate carriers for the suspension culture of anchorage-dependent cells was introduced by van Wezel (1967, 1985). As in planar polymer surfaces, the surface characteristics of microcarriers influence cell attachment, growth, and function. In the earliest studies, microspheres composed of diethylaminoethyl (DEAE)–dextran were used; these spheres have a positively charged surface and are routinely used as anion-exchange resins. DEAE–dextran microcarriers support the attachment and growth of both primary cells and cell lines; the best growth occurred when the surface charge was optimized (Levine *et al.*, 1979). In addition to dextran-based microcarriers, microspheres that support cell attachment have been produced from PS (Jacobson and Ryan, 1982; Fairman and Jacobson, 1983; Gutsche *et al.*, 1994), gelatin (Wissemann and Jacobson, 1985), and many of the synthetic and naturally occurring polymers described in the preceding sections. To support cell attachment and growth, the microcarrier surface has been modified chemically, or by immobilization of proteins (Jacobson and Ryan, 1982), peptides (Jacobson and Ryan, 1982) or carbohydrates (Gutsche *et al.*, 1994). Suspension culture techniques can be used to permit cell interactions with complex three-dimensional polymer formulations, as well. For example, cells seeding onto polymer fiber meshes during suspension culture resulted in more uniform cell distribution within the mesh than was obtained by inoculation in static culture (Freed and Vunjak-Novakovic, 1995).

In cell encapsulation techniques, cells are suspended within thin-walled capsules or solid matrices of polymer. Alginate forms a gel with the addition of divalent cations under very gentle conditions and, therefore, has been frequently used for cell encapsulation (Lim and Sun, 1980). Certain synthetic polymers, such as polyphosphazenes, have also been used to encapsulate cells by cation-induced gelation (Bano *et al.*, 1991). Low-melting-temperature agarose has also been studied extensively for cell encapsulation (Nilsson *et al.*, 1983). Methods for the microencapsulation of cells within hydrophilic or hydrophobic polyacrylates by interfacial precipitation have been described (Dawson *et al.*, 1987; Sefton *et al.*, 1987), although the thickness of the capsule can limit the permeation of compounds, including oxygen, through the semipermeable membrane shell. In-

terfacial polymerization has been used to produce conformal synthetic membranes on cells or cell clusters (Sawhney *et al.*, 1994), thereby providing immunoprotection while dramatically reducing the diffusional distances.

Hollow fibers are frequently used for macroencapsulation; cells and cell aggregates are suspended within thin fibers composed of a porous, semipermeable polymer. Chromaffin cells suspended within hollow fibers formed from a copolymer of vinyl chloride and acrylonitrile, which are commonly used as ultrafiltration membranes, have been studied as potential treatments for cancer patients with pain (Joseph *et al.*, 1994) or for Alzheimer's disease (Emerich *et al.*, 1994). Other materials have been added to the interior of the hollow fibers to provide a matrix that enhances cell function or growth: chitosan (Zienlinski and Aebischer, 1994), alginate (Lacy *et al.*, 1991), and agar (Sullivan *et al.*, 1991) have been used as internal matrices.

## CELL INTERACTIONS WITH THREE-DIMENSIONAL POLYMER SCAFFOLDS AND GELS

Cells within tissues encounter a complex chemical and physical environment that is quite different from commonly used cell culture conditions. *In vitro* methods for growing cells in tissue-like environments may have direct application in tissue engineering (Vacanti *et al.*, 1988; Thompson *et al.*, 1989). Previous investigators have used three-dimensional cell culture methods to simulate the chemical and physical environment of tissues (Bell *et al.*, 1979; Yang *et al.*, 1979; Schor, 1980; Schor *et al.*, 1980, 1981; Richards *et al.*, 1983; Chen *et al.*, 1985; Haston and Wilkinson, 1988; Saltzman *et al.*, 1992). White blood cells, fibroblasts, pancreatic cells, epithelial cells, and nervous tissue cells have been cultured in gels containing ECM components, and the dynamics of cell motility (Parkhurst and Saltzman, 1992; Dickinson *et al.*, 1994), aggregation (Krewson *et al.*, 1994), and force generation (Barocas *et al.*, 1995) within gels have been studied. Often, tissue-derived cells cultured in ECM gels have reformed multicellular structures that are reminiscent of tissue architecture.

Gels of agarose have also been used for three-dimensional cell culture. Chondrocytes, which dedifferentiate when cultured as monolayers, reexpressed a differentiated phenotype when cultured in agarose gels (Benya and Shaffer, 1982). When fetal striatal cells were suspended in three-dimensional gels of hydroxylated agarose, ~50% of the cells extended neurites in gels containing between 0.5 and 1.25% agarose, but no cells extended neurites at concentrations above 1.5%, an agarose concentration corresponding to an average pore radius of 150 nm (Bellamkonda *et al.*, 1995). Neurites produced by PC12 cells within agarose gels, even under optimal conditions, are much shorter and fewer in number than neurites produced in gels composed of ECM molecules, however (Krewson *et al.*, 1994).

Macroporous hydrogels have been produced from pHEMA-based materials, using either freeze-thaw or porosigen techniques (Oxley *et al.*, 1993). These materials, when seeded with chondrocytes, have been studied as cartilage replacement (Corkhill *et al.*, 1993). Similar structures have been produced from PVA by freeze-thaw cross-linking (Cascone *et al.*, 1995). Although cells adhere poorly to pHEMA and PVA surfaces, adhesion proteins can be added during the formation to encourage cell attachment and growth. Alternatively, water-soluble polymers containing adhesive peptides, such as RGDS, have been photopolymerized to form a gel matrix around vascular smooth muscle cells: cells remain viable and elongate within the gel during subsequent culture (Moghaddam and Matsuda, 1991).

Fiber meshes (Mikos *et al.*, 1993) and foams (Lo *et al.*, 1995, 1996; Thomson *et al.*, 1995) of PLGA, PLA, and PGA have been used to create three-dimensional environments for cell proliferation and function, and to provide structural scaffolds for tissue regeneration. When cultured on three-dimensional PGA fiber meshes, chondrocytes proliferated, producing glycosaminoglycans and collagen and forming structures that were histologically similar to cartilage (Puelacher *et al.*, 1994). The physical dimensions of the polymer fiber mesh influenced cell growth rate, with slower growth in thicker meshes (Freed *et al.*, 1993). Changing the fluid mechanical forces on the cells during the tissue formation also appeared to influence the development of tissue structure (Freed and Vunjak-Novakovic, 1995). A variety of techniques have been developed for the production of foams of biodegradable polymers, which may also be useful in the production of three-dimensional tissue-like structures.

# MATRIX EFFECTS

Jeffrey A. Hubbell

## INTRODUCTION

The extracellular matrix is a complex chemically and physically cross-linked network of proteins and glycosaminoglycans. The matrix serves to organize cells in space, to provide them with environmental signals to direct site-specific cellular regulation, and to separate one tissue space from another. The interaction between cells and the extracellular matrix is bidirectional and dynamic: cells are constantly accepting information on their environment from cues in the extracellular matrix, and cells are frequently remodeling their extracellular matrix. In this chapter, the proteins in the extracellular matrix and their cell surface receptors are introduced, and mechanisms by which cells transduce chemical information in their extracellular matrix are discussed. Methods for spatially displaying matrix recognition factors are described, both in the context of model systems for investigation of cellular behavior and from the perspective of creation of bioactive biomaterials for tissue engineering therapies.

The extracellular matrix serves at least three functions in its role controlling cell behavior: it provides adhesion signals, it provides growth factor binding sites, and it provides degradation sites to give way to the enzymatic activity of cells as they migrate (Roskelley *et al.*, 1995). An understanding of these interactions is important in tissue engineering, because it may be desirable to mimic the biological recognition molecules that control the relationships between cells and their natural biomaterial interface, namely, the extracellular matrix. The components of the extracellular matrix are on one level immobilized, but not necessarily irreversibly. Cell-derived enzymes, such as tissue transglutaminase, serve to cross-link chemically certain components of the extracellular matrix, such as fibronectin chains to other fibronectin chains and to fibrillar collagen chains. Other components are more transiently immobilized, such as growth factors within the extracellular matrix proteoglycan network. This network can be partially degraded, and the growth factors can be proteolytically cleaved, to mobilize the growth factors under cellular control. Not all of the signals of the extracellular matrix are biochemical in nature. A biomechanical interplay exists between cells and their extracellular matrix, and this interaction may play an important role in the functional regulation in many tissues, particular in load-bearing tissues. This chapter considers only the biochemical aspects of biological recognition; the reader is referred elsewhere for treatments of the role of the extracellular matrix as a biomechanical regulator of cell behavior (He and Grinnell, 1994; Dickenson *et al.*, 1994; Grinnell, 1999).

## EXTRACELLULAR MATRIX PROTEINS AND THEIR RECEPTORS

Interactions between cells and the extracellular matrix are mediated by cell surface glycoprotein and proteoglycan receptors interacting with proteins bound within the extracellular matrix. This section begins with an introduction of the glycoprotein receptors on cell surfaces involved in cell adhesion. The topic then turns to the extracellular matrix proteins to which those receptors bind, with a discussion of the active domains of those proteins that bind to the cell surface receptors. Finally, the role of cell surface-associated enzymes in the processing and remodeling of the extracellular matrix is addressed.

There are four major classes of glycoprotein adhesion receptors that are present on cell surfaces, three of which are involved primarily in cell–cell adhesion and one of which is involved in both cell adhesion to other cells and cell adhesion to the extracellular matrix. The first three are introduced briefly, and the fourth more extensively.

The cadherins are a family of cell surface receptors that participate in homophilic binding (i.e., the binding of a cadherin on one cell with an identical cadherin on another cell) (Takeichi, 1991; Adams and Nelson, 1998; Shapiro and Colman, 1998; Alattia *et al.*, 1999). These molecules allow a cell of one type (e.g., endothelial cells) to recognize other cells of the same type and are important in the early stages of organogenesis. These interactions depend on the presence of extracellular  $\text{Ca}^{2+}$  and may be dissociated by calcium ion chelation. Because all cadherins are present on cell surfaces, cadherins are not involved directly in cell interactions with the extracellular matrix. They may be involved indirectly, in that they may organize cell–cell contacts in concert with another receptor system that is involved in regulation of cell–extracellular matrix binding.

A second class of receptors is the selectin family (Bevilacqua *et al.*, 1991; Lasky, 1995; Vestweber and Blanks, 1999). These membrane-bound proteins are involved in heterophilic binding between blood cells and endothelial cells in a manner that depends, as the cadherins, on extracellular  $\text{Ca}^{2+}$ . These proteins contain lectinlike features and recognize branched oligosaccharide structures in their ligands, namely the sialyl Lewis X and the sialyl Lewis A structures (Varki, 1994). As with the cadherins, these receptor–ligand interactions are important primarily in cell–cell interactions, and this is particularly true in the context of inflammation.

A third class of receptors is the immunoglobulin family, proteins that are denoted as cell adhesion molecules (CAMs) (Grumet, 1991; Hunkapiller and Hood, 1989). These proteins bind their protein ligands in a manner that is independent of extracellular  $\text{Ca}^{2+}$  and they participate in both homophilic and heterophilic interactions. As with the cadherins and the selectins, they bind to other cell surface proteins and are thus primarily involved in cell–cell interactions. Selected members of the integrin class of adhesion receptors represent one class of ligand for these receptors, are as discussed below.

The fourth class of adhesion receptors is the integrin family (Ruoslahti, 1991; Hynes, 1992). Although the other three classes of receptors described briefly above are involved primarily in cell–cell recognition, the integrins are involved in both cell–cell and cell–extracellular matrix binding. The integrins are dimeric proteins, consisting of an  $\alpha$  and a  $\beta$  subunit assembled noncovalently into an active dimer. There are many known  $\alpha$  and  $\beta$  subunits, with at least 15 such  $\alpha$  subunits and 8 such  $\beta$  subunits that are capable of assembly into at least 21  $\alpha\beta$  combinations. The  $\alpha\beta$  combinations present in the  $\beta 1$ ,  $\beta 2$ , and  $\beta 3$  subclasses are shown in Table 20.1; the  $\beta 1$ ,  $\beta 2$ , and  $\beta 3$  subclasses are the most commonly expressed integrins and are thus arguably the most generally important. The  $\beta 2$  integrins are involved primarily in cell–cell recognition; for example, the integrin  $\alpha\text{L}\beta 2$  binds to two intercellular adhesion molecules (ICAM-1 and ICAM-2), both members of the immunoglobulin class of adhesion receptors described in the preceding paragraph. By contrast, the  $\beta 1$  and  $\beta 3$  integrins are primarily involved in cell–extracellular matrix interactions. The  $\beta 1$  and  $\beta 3$  integrins bind to numerous proteins present in the extracellular matrix, as illustrated in Table 20.1. These proteins include collagen, fibronectin, vitronectin, von Willebrand factor, and laminin.

Collagen is the primary structural protein of the tissues; the reader is referred elsewhere for a focused review on this extensive topic (Vanderrest and Garrone, 1991; Cremer *et al.*, 1998; Fratzl *et al.*, 1998). Many forms of collagen exist, most of which are multimeric and fibrillar. To these collagens many other adhesion proteins bind, thus collagen has the role of organizing many other proteins that interact with and organize cells. Collagen also interacts directly with integrins, primarily  $\alpha 1\beta 1$ ,  $\alpha 2\beta 1$ , and  $\alpha 3\beta 1$ .

Fibronectin is a globular protein that is present in nearly all tissues; fibronectin has been extensively reviewed elsewhere (Schwarzbauer, 1991; Miyamoto *et al.*, 1998; Magnusson and Moshier, 1998). Fibronectin also exists in many forms, depending on the site in the tissues and the regulatory state of the cell that synthesized the fibronectin. Almost all cells interact with fibronectin, primarily through the so-called fibronectin receptor  $\alpha 5\beta 1$ , and to a lesser extent through the  $\beta 3$  integrin  $\alpha \nu \beta 3$  as well as other integrins, as will be described below.

Vitronectin is a multifunctional adhesion protein found in the circulation and in many tissues (Preissner, 1991). The protein is active in promoting the adhesion of numerous cell types and

**Table 20.1. Selected members of the integrin receptor class and their ligands**

Integrin heterodimer	Ligands
$\alpha 1\beta 1$	Collagen, laminin
$\alpha 2\beta 1$	Collagen, fibronectin, laminin
$\alpha 3\beta 1$	Collagen, fibronectin, laminin
$\alpha 4\beta 1$	Fibronectin, vascular cell adhesion molecule-1
$\alpha 5\beta 1$	Fibronectin
$\alpha 6\beta 1$	Laminin
$\alpha 7\beta 1$	Laminin
$\alpha v\beta 1$	Collagen, fibrinogen, fibronectin, vitronectin, von Willebrand factor
$\alpha x\beta 2$	Complement protein C3bi, fibrinogen, factor X
$\alpha M\beta 2$	Complement protein C3bi
$\alpha L\beta 2$	Intercellular adhesion molecule-1, intercellular adhesion molecule-2
$\alpha v\beta 3$	Bone sialoprotein, fibrinogen, fibronectin, laminin, thrombospondin, vitronectin, von Willebrand factor
$\alpha IIb\beta 3$	Fibrinogen, fibronectin, laminin, thrombospondin, vitronectin, von Willebrand factor

binds primarily to the so-called vitronectin receptor,  $\alpha v\beta 3$ , as well as to  $\alpha v\beta 1$  and to the platelet receptor  $\alpha IIb\beta 3$ . von Willebrand factor is an adhesion protein that is primarily involved in the adhesion of vascular cells; the reader is referred elsewhere for a detailed review (Ruggeri, 1997; Sadler, 1998). It is synthesized by megakaryocytes, the platelet-generating cells of the bone marrow, and is stored in the  $\alpha$  granules of circulating platelets. Activation of the platelet leads to the release of the granule contents, including the von Willebrand factor. von Willebrand factor is also synthesized by and stored within the endothelial cell. A multimeric form of the protein, where tens of copies of the protein may be linked together into insoluble form, is found in the subendothelium and is involved in blood platelet adhesion to the subendothelial tissues on vascular injury.

Laminin is a very complex adhesion protein that is generally present in the basement membrane, the proteins immediately beneath epithelia and endothelia, as well as in many other tissues, as reviewed in detail elsewhere (Timpl, 1996; Timpl and Brown, 1996; Ryan *et al.*, 1996; Aumailley and Smyth, 1998). Laminin is present in a family of forms (Malinda and Kleinman, 1996; Engvall and Wewer, 1996). The classic form was purified from the extracellular matrix of Engelbreth-Holm-Swarm tumor cells and consists of a disulfide cross-linked trimer of one  $\alpha 1$  (400,000 Da), one  $\beta 1$  (210,000 Da), and one  $\gamma 1$  (200,000 Da) polypeptide chain. This form binds to the  $\beta 1$  integrins  $\alpha 1\beta 1$ ,  $\alpha 2\beta 1$ ,  $\alpha 3\beta 1$ ,  $\alpha 6\beta 1$ , and  $\alpha 7\beta 1$ , and to the  $\beta 3$  integrins  $\alpha v\beta 3$  and  $\alpha IIb\beta 3$ , as well as to other integrins. A number of other laminin forms exist, composed of  $\alpha\beta\gamma$  combinations of  $\alpha 1$ ,  $\alpha 2$ ,  $\alpha 3$ ,  $\alpha 4$ , or  $\alpha 5$ ;  $\beta 1$ ,  $\beta 2$ , or  $\beta 3$ ; and  $\gamma 1$  or  $\gamma 2$  chains. The details of the differences in function of all of the various laminin forms remain unknown, but it is clear that several of them do stimulate very different behaviors in a variety of cell types. Laminin is a particularly important component of the basal lamina, i.e., the extracellular matrix beneath monolayer structures such as epithelia, mesothelia, and endothelia (Schwarzbauer, 1999). For example, laminin contains numerous domains that bind to endothelial cells (Ponce *et al.*, 1999), and these are undoubtedly important in regulating a variety of cell type-specific functions, as discussed below.

The extracellular matrix proteins described above are very complex. They contain sites responsible for binding to collagen, for binding to glycosaminoglycans (as described below), for cross-linking to other extracellular matrix proteins via transglutaminase activity, for degradation by proteases (as described briefly below), and for binding to integrin and other adhesion receptors (as described in detail immediately below). Because the proteins must be so multifunctional, the sites that serve the singular function of binding to integrins comprise a small fraction of the protein mass. In most cases, the receptor-binding domain can be localized to an oligopeptide sequence less than 10 amino acid residues in length, and this site can be mimicked by linear or cyclic oligopeptides of identical or similar sequence as that found in the protein (Humphries, 1990; Yamada, 1991; Ruoslahti, 1991). The first such minimal sequence to be identified was the tripeptide

**Table 20.2 Selected cell binding domain sequences of extracellular matrix proteins<sup>a</sup>**

Protein	Sequence <sup>b</sup>	Role
Fibronectin	RGDS	Adhesion of most cells, via $\alpha 5\beta 1$
	LDV	Adhesion
	REDV	Adhesion
Vitronectin	RGDV	Adhesion of most cells, via $\alpha v\beta 3$
Laminin A	LRGDN	Adhesion
	SIKVAV	Neurite extension
Laminin B1	YIGSR	Adhesion of many cells, via 67-kDa laminin receptor
	PDSGR	Adhesion
Laminin B2	RNIAEIIKDI	Neurite extension
Collagen I	RGDT	Adhesion of most cells
	DGEA	Adhesion of platelets, other cells
Thrombospondin	RGD	Adhesion of most cells
	VTXG	Adhesion of platelets

<sup>b</sup>Single-letter amino acid code: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

RGD (Ruoslahti and Pierschbacher, 1987) (the single-letter amino acid abbreviation nomenclature is shown as a footnote in Table 20.2). Synthetic RGD-containing peptide, when appropriately coupled to a surface or a carrier molecule (see below), is capable of recapitulating most of the adhesive interactions of the RGD site in the protein fibronectin, including integrin binding. At least for the case of integrin binding via  $\alpha v\beta 3$ , the RGD ligand alone is capable of also inducing integrin clustering and, when the signal is presented at sufficient surface concentration, focal contact formation and cytoskeletal organization (Massia and Hubbell, 1991). It is not yet clear if this is the case for RGD binding by all integrins; e.g., in binding by  $\alpha 5\beta 1$ , it would appear that interactions with cell surface proteoglycans are also necessary (Bloom *et al.*, 1999). Many receptor-binding sequences other than the RGD tripeptide have been identified by a variety of methods, and some of these sequences are shown in Table 20.2. In these receptor-binding sequences, the affinity is highly specific to the particular ordering of the amino acids in the peptide; for example, the peptide RDG, containing the same amino acids but in a different sequence, is completely inactive in binding to integrins.

Of the adhesion peptides, one class contains the central RGD sequence. The sequence is modified by the flanking residues, modifying the receptor specificity of the receptor-binding sequence. For example, the sequence found in fibronectin is RGDS; in vitronectin, it is RGDV; in laminin, it is RGDN; and in collagen, it is RGDT. Other adhesion peptides maintain the central D residue, such as the REDV and LDV sequences of fibronectin. The REDV and LDV sequences are relatively specific in their binding and interact with the integrin  $\alpha 4\beta 1$ ; RGD peptides also bind to  $\alpha 4\beta 1$ , but the REDV and LDV sequences bind essentially only to  $\alpha 4\beta 1$ .

In addition to peptides that bind to the integrin adhesion receptors, there are other peptide sequences that bind to other nonintegrin receptors. As an example, laminin bears several such sequences, such as the YIGSR, SIKVAV, and RNIAEIIKDI peptides. The YIGSR (Graf *et al.*, 1987a,b) sequence binds to a 67-kDa monomeric nonintegrin laminin receptor (Meecham, 1991). As do the integrin receptors, this laminin receptor also interacts via its cytoplasmic domain with intracellular proteins involved with linkage to the f-actin cytoskeleton (Massia *et al.*, 1993). The YIGSR sequence is involved in the adhesion and spreading of numerous cell types (see below). The SIKVAV sequence in laminin binds to the neuronal cell surface receptor and stimulates the extension of neurites (Tashiro *et al.*, 1991).

In addition to the highly sequence-specific binding of adhesion peptides to cell surface receptors, most of the adhesion proteins also bind to cell surface components by less specific mechanisms. These proteins contain a heparin-binding domain (so called because of the use of heparin

<sup>b</sup>An X indicates a hydrophobic amino acid; basic amino acids are underlined.

affinity chromatography in purification of the protein) that binds to cell surface proteoglycans that contain heparin sulfate or chondroitin sulfate glycosaminoglycans (Wight *et al.*, 1992; Jackson *et al.*, 1991; Gallagher, 1997; Lyon and Gallagher, 1998). The peptide sequences that bind to cell surface proteoglycans are rich in cationic residues, such as arginine (R) and lysine (K), relative to their anionic residues, aspartic acid (D) and glutamic acid (E), and they also contain hydrophobic amino acids, such as alanine (A), isoleucine (I), leucine (L), proline (P), and valine (V). Several of these sequences are shown in Table 20.3. For example, the heparin-binding sequence in fibronectin bears a sequence of PRRARV, having a motif of XBBXBX, which is observed in several cell adhesion proteins, X being a hydrophobic residue and B being a basic residue, either K or R. These sites within adhesion proteins such as fibronectin and laminin bind to cell surface proteoglycan in parallel, with interaction by the integrin-binding sites to stabilize the adhesion complex (LeBaron *et al.*, 1988). Cell–cell adhesion molecules also employ cell surface proteoglycan-binding affinity, e.g., neural cell adhesion molecule (NCAM) bears the domain KHKGRDVILKKDVR, which binds to heparan sulfate and chondroitin sulfate proteoglycans (Kallapur and Akeson, 1992). The interactions with cell surface proteoglycans are much less specific than those with integrins; the binding is not as sensitive to the order of the oligopeptide sequence and moreover the effect can be mimicked simply by R or K residues immobilized on a surface, albeit certainly with a great loss in specificity (Massia and Hubbell, 1992).

The extracellular matrix is subject to dynamic remodeling under the influence of cells in contact with it. Cells seeded *in vitro* on an extracellular matrix of one composition may adhere, spread, form focal contacts, remove the initial protein, secrete a new extracellular matrix of different protein composition, and form new focal contacts (Dejana *et al.*, 1988).

Cell surface-bound and cell-derived free enzymes play an important role in this remodeling of the extracellular matrix (Mosher *et al.*, 1992). For example, cell-released protein disulfide isomerases are released from cells to cross-link protein covalently in the extracellular matrix by disulfide bridging (Mayadas and Wagner, 1992). Cell-derived transglutaminases also form an amide linkage between the  $\epsilon$ -amino group of lysine and the  $\gamma$ -carboxyl group of glutamic acid to cross-link proteins chemically in the extracellular matrix. These processes are responsible, for example, for the assembly of the globular adhesion protein fibronectin into fibrils within the extracellular matrix beneath cells.

Membrane-bound and cellularly released enzymes are also involved in degradation of the extracellular matrix to permit matrix remodeling and cell migration (Chen, 1992; Birkedall-Hansen, 1995; Blasi, 1993; Shapiro, 1998). Cell-released matrix metalloproteinases such as collagenase and gelatinase, serine proteases such as urokinase plasminogen activator and plasmin, and cathepsins are each involved in both remodeling and degradation during cell migration. Accordingly, the matrix–cell interaction should be understood to be bidirectional: the cell accepting information from the matrix, and the matrix being tailored by the cell.

One of the important roles of cell-associated enzymatic degradation of the extracellular matrix is in mobilization of growth factor activity. Because growth factors are such powerful regulators of biological function, their activity must be highly spatially regulated. One means by which

this occurs in nature is by high-affinity binding interactions between growth factors and the three-dimensional extracellular matrix in which they exist. Many such growth factors bind heparin, meaning that they, like adhesion proteins, bear domains that bind extracellular matrix heparan sulfate and chondroitin sulfate proteoglycans. For example, basic fibroblast growth factor binds heparin with high affinity (Faham *et al.*, 1996, 1998). Vascular endothelial cell growth factor is another example of a heparin-binding growth factor (Fairbrother *et al.*, 1998). These growth factors are strongly immobilized by binding to extracellular matrix proteoglycans, and they can be mobilized under local cellular activity, e.g., by degradation of these proteoglycans, or, in the case of vascular endothelial cell growth factor, by cleavage of the main chain of the growth factor away from the heparin-binding domain by plasmin activated at the surface of a nearby cell (Keyt *et al.*, 1996).

## MODEL SYSTEMS FOR STUDY OF MATRIX INTERACTIONS

Because the extracellular matrix adhesion proteins may be mimicked, at least to some degree, by small synthetic peptides, it is possible to investigate cell–substrate interactions with well-defined systems. Foundational to them all are the interactions of cells with the surface (other than with adhesion peptides intentionally endowed on the surface) that would produce cell adhesion. These so-called nonspecific interactions are between cell surface receptors and proteins that have adsorbed to the surface. Due to this role played by adsorbing proteins, some introduction to the protein and surface interactions leading to adsorption is warranted. The thermodynamic and kinetic aspects of protein adsorption have been reviewed and the reader is referred elsewhere for a more detailed treatment (Andrade and Hlady, 1986; Wojciechowski and Brash, 1991; norde and Lyklema, 1991). The primary driving force for protein adsorption is the hydrophobic effect: water near a hydrophobic surface fails to hydrogen bond with that surface and thus assumes a more highly ordered structure in which the water is more thoroughly hydrogen bonded to itself than is the case in water far away from the surface. A protein can adsorb to this surface, acting like a surfactant, and thus replace the hydrophobic surface material with a polar surface capable of hydrogen bonding with water. This releases the order in the water, with a net result of a large entropic gain. Electrostatic interactions, e.g., between charges on D, E, K, or R residues on the protein with cationic or anionic functions on the surface material, play a lesser but important role as well; because proteins generally bear a net negative charge, anionic surfaces typically adsorb less protein than do cationic surfaces. These observations, overly generalized here, guide one to examine model surfaces that are hydrophilic and nonionic, as well as being derivatizable, to permit coupling of the adhesion peptide under study.

The tendency for proteins to adsorb to material surfaces has been exploited as a method by which to immobilize peptides onto substrates for study. Ruoslahti and Pierschbacher (1986) have described the peptide Ac-GRGDSPASSKGGGGSRLLLLLR-NH<sub>2</sub> (where the Ac indicates that the N terminus is acetylated and the NH<sub>2</sub> indicates that the C terminus is amidated to block the terminal charges) for this purpose. The LLLLLL stretch is hydrophobic and adsorbs avidly to hydrophobic polymer surfaces and effectively immobilizes the cell-binding RGDS sequence from fibronectin. Nonadhesive proteins such as albumin have also been grafted with RGD peptide, e.g., by binding to amine groups on lysine residues on the albumin; adsorption of the albumin conjugate thus immobilizes the attached RGD peptide (Danilov and Juliano, 1989).

Surfaces coated with hydrophilic polymers have also been employed to graft adhesion peptides. One simple system that has been useful is glass modified with a silane, 3-glycidoxypropyl triethoxysilane; once the silane is grafted to the surface the epoxide group is hydrolyzed to produce —CH<sub>2</sub>CH(OH)CH<sub>2</sub>OH groups pendant from the surface (glycophase glass). The hydroxyl groups serve as sites for covalent immobilization of adhesion peptide, e.g., via the N-terminal primary amine (Massia and Hubbell, 1990). Titration of the surface density of grafted RGD peptides versus cell response using this system revealed quantitative information on the number density of interactions required to establish morphologically complete cell spreading (Massia and Hubbell, 1991). A surface density of approximately 10 fmol/cm<sup>2</sup> of RGD was required to induce spreading, focal contact formation, integrin  $\alpha$ v $\beta$ 3 clustering,  $\alpha$ -actinin and vinculin colocalization with  $\alpha$ v $\beta$ 3, and f-actin cytoskeletal assembly in human fibroblasts cultured on this synthetic extracellular matrix. This surface density corresponds to a spacing of roughly 140 nm between immobilized RGD sites, demonstrating that far less than monolayer coverage is sufficient to promote cell responses. Silane-modified quartz has been employed as a surface to study the role of RGD sites

and heparin-binding domains of adhesion proteins in osteoblast adhesion and mineralization, demonstrating a strong benefit for the involvement of both modes of adhesion (Rezania and Healy, 1999). The base material, glycoPhase glass, is only modestly resistant to protein adsorption and thus nonspecific cell adhesion; accordingly, it is difficult to conduct an investigation of long-term interactions, during which the adherent cells may be synthesizing and secreting their own extracellular matrix to adsorb to the synthetic one experimentally provided. This has motivated exploration with substrates that are more resistant to protein adsorption.

An enormous amount of research has been expended into grafting material surfaces with water-soluble, nonionic polymers such as poly(ethylene glycol),  $\text{HO}(\text{CH}_2\text{CH}_2\text{O})_n\text{H}$ . This vast body of research has been extensively reviewed elsewhere (Harris, 1992; Llanos and Sefton, 1993; Amiji and Park, 1993). Poly(ethylene glycol) has been immobilized on surfaces by numerous means; three particularly effective means will be addressed below.

Thiol compounds chemisorb avidly to gold surfaces (Bain and Whitesides, 1989; Lopez *et al.*, 1993). When those thiols are terminal to an alkane group,  $\text{R}-(\text{CH}_2)_n-\text{SH}$ , the group adsorbs in perfect monolayers; the thiol-gold interaction contributes about half of the energy of interaction, and the alkane-alkane van der Waals interaction contributes the other half. Accordingly, it is easy to employ alkane thiols to display, in very regular fashion, some functionality R on a gold-coated substrate (so long as the R group is not so large as to inhibit monolayer packing sterically, in which case it can be diluted with a nonfunctional alkane thiol). Using this approach, Prime and Whitesides (1993) immobilized an oligo(ethylene glycol)-containing alkane thiol,  $\text{HS}-(\text{CH}_2)_{11}(\text{OCH}_2\text{CH}_2)_n\text{OH}$ . Protein adsorption was investigated on surfaces formed with this alkane thiol and a hydrophobic coreactant,  $\text{HS}-(\text{CH}_2)_{10}\text{CH}_3$ . Degrees of polymerization ( $n$ ) as low as 4 were observed to limit dramatically the adsorption of even very large proteins, such as fibronectin. When the oligo(ethylene glycol) monolayer was incomplete, i.e., when the monolayer was mixed with the hydrophobic alkane thiol, longer oligo(ethylene glycol) functions were able to preserve the protein repulsiveness of the surface. Because the background amount of protein adsorption on these materials is so low, one would expect them to be very useful as substrates for peptide attachment for studies with model synthetic extracellular matrices, e.g., with  $\text{HS}-(\text{CH}_2)_{11}(\text{OCH}_2\text{CH}_2)_n-\text{NH}-\text{RGDS}$ .

Drumheller and Hubbell (1994a,b,c) have developed a polymeric material that was highly resistant to cell adhesion for use in peptide grafting. Materials that contain large amounts of poly(ethylene glycol) generally swell extensively, rendering material properties sometimes unsuitable for cell culture or medical devices. To circumvent this, the poly(ethylene glycol) swelling was constrained by distributing it as a network throughout a densely cross-linked network of a hydrophobic monomer, trimethylolpropane triacrylate. This yielded a material with the surface hydrophilicity of a hydrogel but with mechanical and optical properties of a glass. These materials were highly resistant to protein adsorption, even after an adsorptive challenge to the material with a very large adhesion protein, laminin, and even over multiweek durations. When the polymer network was formed with small amounts of acrylic acid as a comonomer, the polymer still remained cell nonadhesive. The carboxyl groups near the polymer surface were useful, however, as sites for derivatization with adhesion peptides such as the RGD and YIGSR sequences. Because the adsorption of proteins to those surfaces was so low, materials endowed with inactive peptides such as the RDG supported no cell adhesion.

Numerous other approaches are possible. One of particular interest, because of its ease of use, is adsorption. Block copolymers, consisting of adsorbing domains and nonadsorbing domains, can be adsorbed to material surfaces and can be used to regulate biological interactions, e.g., when the nonadsorbing domains are poly(ethylene glycol), surfaces that display very low levels of nonspecific adhesion can be generated (Amiji and Park, 1992). One convenient class of polymers includes ABA block copolymers of poly(ethylene glycol) (the A blocks) and poly(propylene glycol) (B), in which the hydrophilic and cell-repelling poly(ethylene glycol) domains flank the central hydrophobic and adsorbing poly(propylene glycol) block. The central hydrophobic block adsorbs well to hydrophobic surfaces, thus immobilizing the hydrophilic polymer and thereby resisting cell adhesion (Amiji and Park, 1992). Cell adhesion peptides can be displayed at the tips of these hydrophilic chain termini, and a very effective and simple model surface can be obtained (Neff *et al.*, 1998). Similar constructions can be designed for anionic surfaces, e.g., by using a polycationic block as a binding domain, with poly(ethylene glycol) chains attached thereto (Elbert and Hubbell, 1998).

## CELL PATTERN FORMATION BY SUBSTRATE PATTERNING

The ability to control material surface properties precisely enables the formation of designed architectures of multiple cells in culture and potentially *in vivo* as well. Large-scale architectures have been formed by patterning adhesive surfaces. Three methods for patterning have been particularly powerful—photolithography, mechanical stamping, and microfluidics.

Photolithographic methods have been employed to impart patterns on cell adhesion surfaces. Alkoxysilanes have been chemisorbed to glass surfaces (using the same grafting chemistry as with the glycoPhase glass described above), and ultraviolet light was employed to degrade the alkoxy group selectively to yield patterns of surface hydroxyl groups (Healy *et al.*, 1994). These hydroxyl groups were used as sites for reaction with a second layer of an amine-containing alkoxysilane. These aminated regions supported cell adhesion and thus formed the cell-binding regions on the patterned substrate (Kleinfeld *et al.*, 1988). Patterned amines on polymer surfaces have also been employed to induce cell patterning via adhesive domains patterned on a nonadhesive background (Ranieri *et al.*, 1993). These approaches have been combined with the bioactive peptide technology described above. For example, patterned amines have been used as grafting sites for the adhesive peptide YIGSR to pattern neurite extension on material surfaces (Ranieri *et al.*, 1994). One of the goals of this work was to create neuronal networks as a simple system in which to study communication among networks of neurons. A powerful system for such work has been provided by using adhesive aminoalkylsilanes patterned on a nonadhesive perfluoroalkylsilane background (Stenger *et al.*, 1992). Polymers have been synthesized explicitly for the purpose of attaching adhesive peptide sequences such as RGD, and these will be very useful in future studies of cell–cell interactions in neuronal and other cell systems (Herbert *et al.*, 1997). Such patterned surfaces have been formed to control cell shape and size, in order to gain deeper insight into the interplay between cell biomechanics and cell function (Thomas *et al.*, 1999). It is particularly convenient in photopatterning studies to develop photochemistries on materials specifically for the purpose of immobilizing polymers and polymer–peptide adducts (Moghaddam and Matsuda, 1993); this has been addressed, e.g., with phenylazido-derivatized surfaces (Matsuda and Sugawara, 1996; Sugawara and Matsuda, 1996).

Alkane thiols on gold have also been patterned using simple methods. Contact printing has been employed for this purpose (Kumar *et al.*, 1995). Conventional photolithographic etching of silicon was employed to make a master printing stamp, a negative of which was then formed in silicone rubber. Structures as small as 200 nm were preserved in the silicone rubber stamp. The stamp was then wetted with a cell adhesion-promoting alkane thiol,  $\text{HS}-(\text{CH}_2)_{15}-\text{CH}_3$ . Stamping a gold substrate resulted in creation of a pattern of the hydrophobic alkane group. The stamped gold substrate was then treated with the cell-resistant alkane thiol  $\text{HS}-(\text{CH}_2)_{11}(\text{OCH}_2\text{CH}_2)_6\text{OH}$ . Using this system it was possible to create adhesive patches of defined size on a very cell-nonadhesive substrate (Singhvi *et al.*, 1994). Microcontact printing can also be employed with binding approaches other than alkane thiols binding to gold, e.g., adhesion proteins such as laminin have been stamped onto reactive silane-modified surfaces to produce patterns to guide neurite outgrowth in culture (Wheeler *et al.*, 1999). This very flexible and powerful system will be useful in a wide variety of cell biological and tissue engineering applications.

A third powerful method is based on microfluidic systems, in which silicone rubber stamps are formed with silicon masters; the stamps are pressed to a surface, and the thin spaces patterned thereby are employed as capillaries to draw up fluid, containing a treatment compound, onto desired regions of the surface. The fluid can contain a soluble, adsorbing polymer with an attached adhesion peptide (Neff *et al.*, 1998), or it can contain a peptide with some affinity linker for the surface. In the practice of the latter, it is powerful to employ the very high-affinity streptavidin–biotin pair, e.g., by biotinylating the polymer at the surface and exposing, with the aid of the microfluidics channels, to peptide conjugated to streptavidin (Cannizzaro *et al.*, 1998; Patel *et al.*, 1998).

## SIGNAL TRANSDUCTION AND FUNCTIONAL REGULATION VIA THE EXTRACELLULAR MATRIX

Cell interaction with adhesive substrates is known to provide information to the cells via numerous means, and this topic has been extensively reviewed (Roskelley *et al.*, 1995; O'Toole, 1997; Katz and Yamada, 1997; Yamada, 1997; Aplin *et al.*, 1998; Sechler *et al.*, 1998; Aota and Yama-

da, 1997; Miyamoto *et al.*, 1998). The biochemical mechanisms underlying these interactions are likely numerous and have not yet been fully elucidated. One key mechanism involves the focal contact as a site for catalysis. Integrin clustering induces tyrosine phosphorylation of several proteins, many of which still have unknown function (Kornberg *et al.*, 1991; Guan, 1997). One of these proteins is a 125-kDa tyrosine that localizes, after it is tyrosine phosphorylated, at the sites of focal contacts; this protein has been accordingly named pp125 focal adhesion kinase, or pp125<sup>fak</sup> (Schaller *et al.*, 1992; Vuori, 1998; Danen *et al.*, 1998). Thus, although the cytoplasmic domain of integrins bears no direct catalytic activity, clustering of integrins is known to stimulate tyrosine phosphorylation and further specific kinases are known to assemble at the sites of clustered integrins. Interestingly, when cells were permitted to spread via a non-integrin-mediated mechanism, specifically by interaction of cell surface proteoglycans with surface-adsorbed polycations, phosphorylation of intracellular proteins did not occur (Guan *et al.*, 1991). The phosphorylation of these proteins, associated with focal contact formation, is known to be an important signal for survival of a variety of cell types (Ffrisch *et al.*, 1996; Globus *et al.*, 1998).

Cell interactions with extracellular matrix have been demonstrated to exert control over the function of the adherent cells in numerous models; examples in cell spreading and migration, hepatocyte gene expression, mammary cell differentiation, endothelial cell morphological regulation, and neurite extension from neurons will be cited as examples in the following discussions.

Cell spreading, adhesion, and migration are each related to interactions with the extracellular matrix (Huttenlocher *et al.*, 1995). The role of RGD ligand surface density in mediating adhesion morphology, e.g., the formation of focal contacts and the organization of f-actin cytoskeletal structure, was described above. Mooney *et al.* (1995) have demonstrated that the rate of hepatocyte spreading, i.e., the rate at which the hepatocyte projected area increases, was strongly dependent on the surface density of the adhesion ligand, in this case laminin. It has been demonstrated, both mathematically and experimentally, that the surface density of adhesion proteins influences the rate of cell migration (DiMilla *et al.*, 1993). Ligand density too low leads to inadequate traction and adhesion strength for cell migration, and ligand density too high may provide adhesion strength excessive for cell migration (Ward and Hammer, 1993; Palecek *et al.*, 1997). Cell migration can dramatically impact cell proliferation for cells that are contact inhibited, i.e., where cell-cell contact exerts an inhibitory effect on cell proliferation. Zygourakis *et al.* have examined both on theoretical grounds (1991a) and by experiment (1991b) that prolonged cell-cell contact in slowly migrating contact-inhibited cells dramatically limits the rate at which cells proliferate.

Hepatocytes are notoriously difficult to culture over durations extending beyond several days; they begin to lose several of their hepatocyte-specific characteristics, e.g., the synthesis and secretion of albumin (Clayton and Darnell, 1983). The loss or retention of hepatocyte-specific function may relate to interactions with the extracellular matrix. For example, when hepatocytes were permitted to spread on laminin adsorbed to surfaces at differing surface densities, the secretion of albumin was seen to be influenced substantially (Mooney *et al.*, 1995). When hepatocyte spreading was limited by seeding on patterned alkane thiol/alkane thiol-oligo(ethylene oxide) surfaces as described above, cell shape was seen to influence albumin secretion substantially. Cells were seeded on adhesive patches ranging from 1600 to 10,000  $\mu\text{m}^2$ , as well as on unpatterned surfaces. When cell spreading was limited to 1600  $\mu\text{m}^2$  by the size of the spot, albumin secretion was almost triple that of cells seeded on unpatterned substrates and allowed to spread maximally. When hepatocytes were cultured on laminin substrates, albumin expression was elevated relative to cells cultured on tissue culture plastic; moreover, this elevation of expression was specific to albumin relative to other genes (Bissell *et al.*, 1990). Hepatocytes cultured on fibronectin or laminin at protein surface densities of 1, 50, or 100  $\text{ng}/\text{cm}^2$  were seen to be switchable between differentiation (at low protein surface density) and growth (at high surface density), regardless of the identity of the extracellular matrix adhesion protein (Mooney *et al.*, 1992).

Endothelial cells have also been demonstrated to be responsive to their extracellular matrix, particularly to laminin in the basal lamina (Risau, 1995; Bischoff, 1997; Malinda *et al.*, 1999). Most of the relevant experimentation has been performed on Matrigel, reconstituted extracellular matrix from Engelbreth-Holm-Swarm tumor cells; this matrix contains large amounts of laminin of the particular form described above. When endothelial cells were cultured on tissue culture plastic, they formed a polygonal monolayer. When they were cultured on Matrigel, they formed capillary-like tubes in a complicated interconnected network. This tube formation was not inhibited

by soluble YIGSR, added to inhibit competitively the interaction of the 67-kDa laminin receptor with the YIGSR site in laminin. When soluble SIKVAV was added, however, the tubes submerged into the protein gel and formed new branches. This observation may relate to regulation of cell-associated protease activity; stimulation with SIKVAV in protein or with soluble SIKVAV increased the activity of matrix metalloproteinases (Kanemoto *et al.*, 1990; Stack *et al.*, 1990). In culture, this peptide stimulated elongation of endothelial cells (Grant *et al.*, 1992). Other receptor-mediated interactions with extracellular matrix proteins have also been shown to be important in endothelial cell functional regulation; for example, angiogenesis *in vivo* was dependent on the integrin  $\alpha\beta 3$  (Brooks *et al.*, 1994). Interestingly, purely mechanical means can also be employed to induce capillary-like tube formation; when endothelial cells were seeded on photolithographically formed thin adhesive lines, tube formation was induced (Spargo *et al.*, 1994).

The extracellular matrix has been observed to play an important role in the regulation of neuronal behavior both *in vivo* and *in vitro* (Kapfhammer and Schwab, 1992; McKerracher *et al.*, 1996). For example, neurons in culture extend more neurites on laminin than on fibronectin substrates. This activity has been localized to the active peptide regions of laminin; the sequence YIGSR appears to be involved primarily in neuronal adhesion, whereas the SIKVAV site stimulates neurite extension *in vitro*. Amines that bind to cell surface proteoglycans have also been useful in stimulating neurite outgrowth, although presumably by less specific mechanisms than with the peptides described above. Likewise, patterns on surfaces have been employed to induce and guide neurite outgrowth, e.g., with patterns between hydrophobic and hydrophilic regions (Stenger *et al.*, 1992) or with patterns of the laminin-derived peptides YIGSR and SIKVAV (Ranieri *et al.*, 1993).

## TRANSLATION TO WORKING BIOMATERIAL SYSTEMS

Although one goal of biomaterials and tissue engineering research is certainly to develop systems for the quantitative study of biological interactions, another is to develop practical novel therapeutics. Many of the concepts described above, both in terms of development of model surfaces and with regard to manipulating cellular behavior, are directly transferable; however, some cautionary comments should be made. It is not only the chemical identity of an adhesion peptide that determines its biological activity, but also its amount. This was very clearly demonstrated by Palecek *et al.* (1997), who showed that small amounts of an adhesion molecule could enhance cell migration, whereas larger amounts could inhibit it. They further demonstrated that this effect depended on, among other features, the affinity of the receptor–ligand pair, the number of receptors, and the polarization of receptors from the leading to the trailing edge of the cell. Given that many of these features depend on the state of the cell and can be modulated by the cell's biological environment, e.g., by the growth factors to which the cell is exposed (Maheshwari *et al.*, 1999), many confounding features must be considered in translation from model to practical application.

# POLYMER SCAFFOLD PROCESSING

Robert C. Thomson, Albert K. Shung, Michael J. Yaszemski,  
and Antonios G. Mikos\*

## INTRODUCTION

Polymer scaffolds must possess many key characteristics, including high porosity and surface area, structural strength, and specific three-dimensional shapes, to be useful as materials for tissue engineering. These characteristics are determined by the scaffold fabrication technique, which must be developed such that it does not adversely affect the biocompatibility of the material of construction. Novel processing techniques have been developed to manufacture scaffolds with desirable and reproducible characteristics, which have been used to demonstrate the feasibility of regenerating human tissue. These polymer scaffold fabrication techniques have been tailored to create scaffolds with particular characteristics that will satisfy the critical tissue engineering requirements of specific organs.

Restoration of organ function by utilizing tissue engineering technologies often requires the use of a temporary porous scaffold. The function of the scaffold is to direct the growth of cells migrating from surrounding tissue (tissue conduction) or the growth of cells seeded within the porous structure of the scaffold. The scaffold must therefore provide a suitable substrate for cell attachment, proliferation, differentiated function, and, in certain cases, cell migration. These critical requirements can be met by the selection of an appropriate material from which to construct the scaffold, although the suitability of the scaffold may also be affected by the processing technique. Many biocompatible materials can be potentially used to construct scaffolds. However, a biodegradable material is normally desired because the role of the scaffold is usually only a temporary one. Many natural and synthetic biodegradable polymers, such as collagen, poly( $\alpha$ -hydroxyesters), and poly(anhydrides), have been widely and successfully used as scaffold materials due to their versatility and ease of processing (Thomson *et al.*, 1995). Many researchers have used poly( $\alpha$ -hydroxyesters) as starting materials from which to fabricate scaffolds using a wide variety of processing techniques. These polymers have proved successful as temporary substrates for a number of cell types, allowing cell attachment, proliferation, and maintenance of differentiated function. Poly( $\alpha$ -hydroxyesters), such as poly(L-lactic acid) (PLLA), poly(lactic-co-glycolic acid) (PLGA) copolymers, and poly(glycolic acid) (PGA), are linear, uncross-linked polymers. These materials are biocompatible, degradable by simple hydrolysis, and are Food and Drug Administration (FDA) approved for certain clinical applications.

The major requirement of any proposed polymer processing technique is not only the utilization of biocompatible materials, but that the process should in no way affect the biocompatibility of the polymer. The processing technique should also allow the manufacture of scaffolds with controlled porosity and pore size, both important factors in organ regeneration. A highly porous scaffold is desirable to allow cell seeding or migration throughout the material. Pore size plays a critical role in both tissue ingrowth and the internal surface area available for cell attachment. A

large surface area is required so that a high number of cells, sufficient to replace or restore organ function, can be cultured.

The mechanical properties of the scaffold are often of critical importance especially when regenerating hard tissues such as cartilage and bone. Although the properties of the solid polymer and the porosity of the scaffold have a profound effect on its mechanical properties, polymer processing can also be influential in this respect. The tensile strength may, for example, be enhanced due to the crystallization of polymer chains. Alternatively, the manufacturing process may cause a reduction in the molecular weight of the polymer, resulting in a deleterious effect on mechanical properties. The shape of a hard tissue is often important to its function and in such cases the processing technique must allow the preparation of scaffolds with irregular three-dimensional geometries.

A further design consideration is the incorporation of bioactive molecules into the polymer matrix. Inactivation of bioactive molecules by exposure to high temperatures or a harsh chemical environment is the major obstacle to successful drug incorporation and delivery from a degradable scaffold. However, if localized controlled delivery of bioactive molecules to the site of growing tissue can be achieved, it would provide a powerful tool to aid in organ regeneration.

The technique used to manufacture scaffolds for tissue engineering is dependent on the properties of the polymer and its intended application. Scaffold manufacturing techniques were therefore developed using commercially available starting materials: small solid polymer chunks or in some cases long fibers. The techniques that were developed involved either heating the polymers or dissolving them in a suitable organic solvent. The viscous behavior of the polymers above their glass transition or melting temperatures and their solubility in various organic solvents were two of the more important characteristics to consider during process development.

A plethora of new fabrication methods have been investigated specifically for the purpose of tissue engineering. Several of the more established scaffold fabrication techniques are described in this chapter as well as some of the developments in polymer processing. Each technique has its advantages, but none can be considered as an ideal method of scaffold fabrication to be employed for all tissues. The choice of a fabrication technique, or the development of a new one, is dependent on the critical requirements for the tissue of interest.

## FIBER BONDING

Fibers provide a large surface area: volume ratio and are therefore desirable as scaffold materials. One of the first biomedical uses of PGA was as a degradable suture material, which is why it is commercially available in the form of long fibers. PGA fibers in the form of tassels and felts were utilized as scaffolds in organ regeneration feasibility studies (Cima *et al.*, 1991). However, these scaffolds lacked the structural stability necessary for *in vivo* use. A fiber bonding technique was therefore developed to prepare interconnecting fiber networks with different shapes for use as scaffolds in organ regeneration (Mikos *et al.*, 1993a).

PLLA is dissolved in methylene chloride, a nonsolvent for PGA, and the resulting polymer solution is cast over a nonwoven mesh of PGA fibers in a glass container. The solvent is allowed to evaporate and residual amounts are removed by vacuum drying. A composite material is thus produced consisting of nonbonded PGA fibers embedded in a PLLA matrix. The PLLA–PGA composite is then heated to a temperature above the melting point of PGA for a given time period. During heating the PGA fibers join at their cross-points as melting commences, but the two polymers do not join due to their immiscibility in the melt state. The composite is quenched to prevent any further melting of the PGA fibers during cooling. After heat treatment, the PLLA matrix of a PLLA–PGA composite membrane is selectively dissolved in methylene chloride and the resulting bonded PGA fibers are vacuum dried. Using this technique, the fibers are physically joined without any surface or bulk modification and retain their initial diameter. The PLLA matrix is required to prevent collapse of the PGA mesh and to confine the melted PGA to a fiberlike shape (Fig. 21.1). The heating time is also of critical importance because prolonged exposure to the elevated temperature results in the gradual transformation of the PGA fibers into spherical domains.

Bonded PGA fiber structures with high porosities and area:volume ratios are produced using this manufacturing method and utilize only biocompatible materials. In this respect, the structures produced are highly suitable as scaffolds for organ regeneration. In addition, they demonstrate

Fig. 21.1. A scanning electron photomicrograph of a PGA-bonded fiber mesh, prepared by a fiber bonding technique, embedded in PLLA, heated at a temperature of 195°C for 90 min and at 235°C for 5 min. From Mikos *et al.* (1993). Preparation of poly(glycolic acid) bonded fiber structures for cell attachment and transplantation. *J. Biomed. Mater. Res.* **27**, 183–189. Copyright 1993 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

structural integrity, which is lacking in the PGA tassels and felts used in organ regeneration feasibility studies. However, the stipulations concerning the choice of solvent, immiscibility of the two polymers, and their relative melting temperatures restrict the general application of this technique to other polymers. In addition, the technique does not lend itself to easy and independent control of porosity and pore size.

An alternative method of fiber bonding has been developed to fabricate tubular scaffolds useful in regeneration of tissues such as blood vessels, intestines, and ureters. This method involves coating a nonbonded mesh of PGA fibers with solutions of PLLA or PLGA (Mooney *et al.*, 1996a). The mesh is attached to a rotating Teflon cylinder and is sprayed with an atomized polymer solution. As spraying continues, a coat of PLLA (or PLGA) builds up on the PGA fibers and forms bonds at their cross-points. Longer spraying times result in thickening of the PGA fibers due to PLLA deposition. Although a bonded PGA mesh is formed by this process, the surface of the scaffold presented to transplanted cell populations is a thin coat of PLLA or PLGA. Cell attachment, growth, and function are then determined by the coating rather than by the PGA mesh. This coating may be advantageous if the mechanical properties of PGA fibers are required but the surface properties of PLLA or PLGA are more desirable for the transplanted cell population. The mechanical properties of the bonded mesh are a result of both the PGA fibers and the additional stability supplied by the PLLA or PLGA coating. Thus, if the integrity of the bond created by the coating is compromised, either through mechanical stresses or degradation of the PLLA or PLGA, the stability and mechanical properties of the bonded structure are adversely affected. Unfortunately, this method of fiber bonding does not address the problem of creating scaffolds with complex three-dimensional shapes, but it has proved successful for producing hollow tubes. This method was utilized to create tubular structures for the support of smooth muscle cells and extracellular matrix proteins (Kim *et al.*, 1998). After 7 weeks in culture, these tubes maintained their shape and structure while exhibiting high cellularity with smooth muscle cells and extracellular matrix (ECM) proteins filling the PGA pores.

## SOLVENT CASTING AND PARTICULATE LEACHING

In order to overcome some of the drawbacks associated with the fiber bonding preparation, a solvent-casting and particulate-leaching technique has been developed (Mikos *et al.*, 1994). With appropriate thermal treatment, porous constructs of synthetic biodegradable polymers can be prepared with specific porosity, surface:volume ratio, pore size, and crystallinity for different applications. The technique has been validated for PLLA and PLGA scaffolds, but can be applied to any other polymer that is soluble in a solvent such as chloroform or methylene chloride.

Fig. 21.2. A scanning electron micrograph of a 75:25 PLGA scaffold with 90% porosity, using sodium chloride of size range 300–500  $\mu\text{m}$  as a porogen. From Ishaug et al. (1997). Bone formation by three-dimensional stromal osteoblast culture in biodegradable polymer scaffolds. *J. Biomed. Mater. Res.* **36**, 17–28. Copyright 1997 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

Sieved salt particles are dispersed in a PLLA/chloroform solution and cast into a glass container. The salt particles utilized are insoluble in chloroform. The solvent is allowed to evaporate and residual amounts are removed by vacuum drying. The PLLA in the resulting PLLA/salt composite membranes is highly crystalline, but this can be controlled by one of two means depending on the desired crystallinity of the final membrane. In the first processing option, the PLLA/salt composite membranes are immersed in water to leach out the salt. This results in highly crystalline, salt-free PLLA membranes, which are then dried. The alternative option involves a heat treatment stage to produce PLLA membranes with controlled crystallinity. PLLA/salt composite membranes are heated at a temperature above the PLLA melting temperature to ensure complete melting of the polymer crystallites formed during the previous processing step. The melted PLLA membranes with dispersed salt particles are either annealed by cooling at a slow, controlled rate to produce semicrystalline membranes with specific crystallinity, or quenched, to produce amorphous membranes. Finally, the membranes are immersed in water to leach out the salt and the resulting salt-free PLLA membranes are then dried.

Highly porous membranes with porosities up to 93% and an interconnected pore structure can be produced using this solvent-casting and particulate-leaching technique (Fig. 21.2). The porosity of porous PLLA membranes can be controlled by varying the amount of salt used to construct the composite material. The pore size of the membrane can also be controlled independently of the porosity by altering the size of the salt particles. Scaffolds with pore sizes up to 500  $\mu\text{m}$  have been fabricated using this method. Membranes with high surface area:volume ratios are produced, and the ratio is dependent on both salt weight fraction and particle size. In addition, the crystallinity of PLLA membranes can be tailored to that desired for each application. These characteristics are all desirable properties of a scaffold for organ regeneration. The major disadvantage of this technique is that it can only be used to produce thin wafers or membranes (up to 2 mm in thickness). A three-dimensional scaffold cannot be directly constructed. Membrane lamination or melt molding, however, can circumvent this problem.

One of the problems associated with the aforementioned technique is that the polymer scaffolds produced are brittle and therefore inappropriate for soft tissue applications. To overcome this limitation, PLGA has been blended with poly(ethylene glycol) (PEG) and fabricated into pliable foams using the solvent-casting/particulate-leaching method (Wake et al., 1996). As the amount of PEG in the blend is increased, the pliability of the foams is increased. Thus, thick polymer membranes can be prepared with the ability to be rolled into tubes without damaging the pore structure. Using this method, foam scaffolds can be fabricated in a tubular form. These scaffolds have great potential in soft tissue engineering in a variety of applications, such as regeneration of blood vessels and the esophagus.

A concern with scaffolds made with PLLA or PLGA is the even seeding of cells, which is re-

lated to the hydrophobicity of the polymer. To counter this issue, a technique has been developed in which porous PLGA scaffolds are soaked in an aqueous solution of a hydrophilic polymer such as poly(vinyl alcohol) (PVA) (Mooney *et al.*, 1994). Hepatocytes seeded on the treated scaffolds have been shown to be present in much higher densities than in untreated scaffolds.

An alternative method to overcome the difficulty of seeding cells in PLLA or PLGA scaffolds involves the prewetting the scaffolds with ethanol (Mikos *et al.*, 1994). In this approach, porous polymer scaffold disks are soaked in ethanol for 1 hr. The scaffolds are then submersed in water to prewet them. Chondrocytes and hepatocytes seeded on the prewetted scaffolds have been shown to exhibit a uniform distribution throughout the scaffolds. This technique could also be potentially useful for seeding other types of cells as well.

## MEMBRANE LAMINATION

The construction of scaffolds with three-dimensional anatomical shapes is necessary for the regeneration of hard tissues such as cartilage and bone, whose function is partially dependent on geometry. Membrane lamination offers a means of constructing highly porous biomaterials with anatomical shapes (Mikos *et al.*, 1993b). However, the lamination procedure is useful only if it preserves the uniform porous structure of the original membranes. Also, the boundary between two layers must be indistinguishable from the bulk of the device. The methodology to process biodegradable polymer scaffolds with anatomical shapes involves the construction of a contour plot of the particular three-dimensional shape. The shapes of the contours are cut from highly porous biodegradable membranes prepared using the solvent-casting and particulate-leaching technique described above. A small quantity of chloroform is then coated onto the contacting surfaces of adjacent membranes and a bond is formed. Thus, the desired three-dimensional shape is constructed layer by layer (Fig. 21.3).

The porous structure of the PLLA and PLGA membranes used to validate the technique was unaffected by the lamination procedure, and no boundary between the layers was observed. This method can be used to prepare three-dimensional anatomically shaped PLLA and PLGA scaffolds with bulk properties identical to those of the individual membranes. This technique can not be applied to the lamination of PGA because it is soluble only in highly toxic solvents. A similar

Fig. 21.3. An example of a membrane-laminated PLLA scaffold with a nose-like shape. Reprinted from *Biomaterials* **14**, A. G. Mikos, G. Sarakinos, S. M. Leite *et al.*; *Laminated three-dimensional biodegradable foams for use in tissue engineering*, pp. 323–330. Copyright 1993, with permission from Elsevier Science.

method of membrane lamination was used to produce tubular stents (Mooney *et al.*, 1994). Flat porous scaffolds of PLGA are manufactured using the solvent-casting and particulate-leaching method. These are then wrapped around a Teflon cylinder and the overlapping edges are laminated using a small amount of chloroform to fuse the two polymer surfaces together. The Teflon tube is then removed to leave an open-ended tube, which is then capped by laminating end pieces. These constructs have been proposed as scaffolds for the regeneration of tubular tissues such as intestine.

## MELT MOLDING

Melt molding, an alternative method of constructing three-dimensional scaffolds, has many advantages over membrane lamination. PLGA scaffolds have been produced by leaching PLGA/gelatin microsphere composites formed using a molding technique (Thomson *et al.*, 1995). A fine PLGA powder is mixed with previously sieved gelatin microspheres and poured into a Teflon mold, which is heated above the glass transition temperature of the polymer. The PLGA/gelatin microsphere composite is subsequently removed from the mold and placed in distilled-deionized water. The gelatin, which is soluble in water, is leached out, leaving a porous PLGA scaffold with a geometry identical to the shape of the mold.

Using this method it is possible to construct PLGA scaffolds of any shape simply by changing the mold geometry. The porosity can be controlled by varying the amount of gelatin used to construct the composite material. The pore size of the scaffold can also be altered, independently of the porosity, by using microspheres of different diameters. In addition, because this technique does not utilize organic solvents and is carried out at relatively low temperatures, it has potential for the incorporation and controlled delivery of bioactive molecules. These molecules may be incorporated either into the polymer or into the gelatin microspheres. Gelatin has been used in the past as a vehicle for controlled delivery (Thomson *et al.*, 1995). This scaffold-manufacturing technique can also be applied to PLLA and PGA. However, higher temperatures are required because these polymers are semicrystalline and must therefore be heated above their melting temperatures. The use of higher temperatures to mold these polymers may exclude the possibility of drug incorporation. It also entails the use of a leachable component other than gelatin, because this material becomes insoluble in water after exposure to the required elevated temperatures. This manufacturing method satisfies many of the scaffold preparation design criteria and offers an extremely versatile means of scaffold preparation. Although gelatin microspheres were utilized to validate the feasibility of this technique, alternative leachable components such as salt or other polymer microspheres may be used.

## EXTRUSION

Although extrusion has been widely incorporated in the processing of industrial polymers, it has not been widely used for the fabrication of polymer scaffolds in tissue engineering applications. Widmer *et al.* (1998), however, developed an extrusion process in combination with the aforementioned solvent-casting technique to fabricate porous, biodegradable tubular conduits for the purpose of peripheral nerve regeneration (Fig. 21.4).

Briefly, PLGA or PLLA polymers are first fabricated into composite wafers with sodium chloride as a porogen by the solvent-casting technique. The wafers are cut to the desired length and placed in a customized extrusion tool. The tool is mounted on a hydraulic press and heated to the appropriate processing temperature. Pressure is then applied between the nozzle and the piston of the extrusion tool and the polymer/salt composite is extruded as a tube. After cooling, the salt is leached out by immersion in water and the entire scaffold is then vacuum dried.

The main parameter involved with the extrusion of these polymers is the extrusion temperature. The higher the extrusion temperature, the lower the pressure required to initiate extrusion. The pore morphology of the conduits is not significantly affected by this processing method unless very high extrusion temperatures are used. At high extrusion temperatures, a decrease in molecular weight is most likely caused by thermal degradation of the polymer. Pore diameter is also decreased at very high extrusion temperatures due to the increase in polymer viscosity. However, the most important variables affecting the porosity and pore size of the conduits are the salt weight fraction and salt crystal size, respectively. By varying these two parameters, the porosity and pore size can be easily tailored to incorporate the loading of cells or carriers for growth factors into the conduits.

### THREE-DIMENSIONAL PRINTING

One of the major challenges in processing polymer scaffolds for tissue engineering is creating complex three-dimensional shapes to emulate the tissue that the scaffold is designed to repair or replace. The three-dimensional printing (3DP, a trademark name) fabrication technique has been applied in an attempt to fulfill this requirement. The 3DP technique belongs to a family of fabrication techniques collectively known as solid free-form (SFF) methods, including methods such as stereolithography and laser sintering (Park *et al.*, 1998). In 3DP, a thin layer of polymer powder is spread over a piston. An inkjet printer head prints a liquid binder, usually chloroform for polymer systems, onto the powder layer. The position of the printer head is entirely controlled via a computer-assisted design and manufacture (CAD/CAM) program. The piston is dropped and the polymer powder and liquid layering steps are repeated. The previously printed liquid binder then joins this powder layer to the underlying powder layer. This process is repeated until the desired construct is complete. In this manner, intricate three-dimensional shapes can be made layer by layer with a resolution down to 300  $\mu\text{m}$ . The scaffolds can be made porous by incorporating salt in the polymer powder bed. PLLA and PLGA scaffolds have been fabricated using this technique. The strengths of 3DP-constructed polymer scaffolds using PLLA or PLGA are comparable to those fabricated by compression molding using the same base material (Giordano *et al.*, 1996).

Constructs produced with this method have been investigated for several different tissue engineering applications, including organogenesis of liver tissue (Griffith *et al.*, 1997). Surface modification of PLLA substrates for cell adhesion also has been performed using 3DP (Park *et al.*, 1998). Porous scaffolds fabricated using this process have been fashioned into cylinders with interconnected longitudinal channels for the purpose of hepatocyte transplantation (Kim *et al.*, 1998). These scaffolds show great promise in cell transplantation applications due to their branching morphology and porous structure, which may serve to promote angiogenesis and tissue ingrowth.

### GAS FOAMING

Although the process of solvent casting/particulate leaching is well established in fabricating porous polymer scaffolds, it does have some drawbacks. One major concern is the use of organic solvents during processing. Organic solvent residues left behind from the processing can have toxic effects *in vitro* and elicit an inflammatory response *in vivo*. To overcome this problem, a fabri-

cation method has been developed to create porous matrices utilizing a gas foaming technique to avoid the use of organic solvents (Mooney *et al.*, 1996b). In this method, PLGA pellets are compression molded into solid disks. After compression, the disks are exposed to high-pressure CO<sub>2</sub> to saturate the polymer. The subsequent reduction in pressure to ambient levels causes the nucleation and formation of pores in the polymer matrix from the CO<sub>2</sub> gas. However, the matrices formed have a closed pore morphology, which may be undesirable for tissue engineering applications.

In order to produce an open pore morphology using the gas foaming method, a technique has been developed to use this method in conjunction with the particulate-leaching technique (Harris *et al.*, 1998). In this process, salt particles and PLGA pellets are mixed together and compressed to form solid disks. The disks are saturated with high-pressure gas and the pressure is subsequently reduced. The salt particles are then leached out. The combination of gas foaming and particulate leaching leads to a porous polymer matrix with an open, interconnected morphology without the use of any organic solvents. Smooth muscle cells have been found to readily adhere and proliferate on scaffolds fabricated with this process. By precluding the use of organic solvents, this technique may see widespread use in cell transplantation applications of many types of cells, including hepatocytes, chondrocytes, and osteoblasts.

## FREEZE DRYING

Another method to fabricate polymer scaffolds with variable porosity and pore size utilizes an emulsion/freeze-drying process (Whang *et al.*, 1995). Water is added to a solution of PLGA in methylene chloride to create an emulsion. The mixture is then homogenized, poured into a copper mold, and quenched in liquid nitrogen. After quenching, the polymer scaffold is freeze dried to remove the water and solvent. Scaffolds with porosity of up to 90% and median pore sizes in the range of 15 to 35  $\mu\text{m}$  can be fabricated with an interconnected pore structure. In comparison to solvent casting/particulate leaching, the scaffolds produced with this method offer much higher specific pore surface area as well as the ability to make thick (>1 cm) polymer scaffolds, but the overall size of the pores is smaller.

Freeze drying has also been applied in another fashion to fabricate porous polymer foams for use in drug delivery applications (Hsu *et al.*, 1997). Scaffolds using this technique have been made with several different types of polymers, including PLLA, PLGA, PGA, and a PLGA/poly(propylene fumarate) (PPF) blend. The desired polymer is dissolved in glacial acetic acid or benzene and frozen to  $-10^{\circ}\text{C}$ . The frozen solution is then freeze dried in a lyophilizer for a week to remove the solvent. The type of polymer used has a large effect on the morphology of the resulting foams. PLGA/PPF foams typically have a leaflet morphology whereas PLLA, PLGA, and PGA foams have a capillary morphology. The type of polymer used also plays a large role in the release of drugs embedded in the polymer matrix. PLGA/PPF foams release drugs at a much faster rate than do foams made with PLGA. The lower molecular weight of the PPF allows more penetration of water into the matrix, which causes greater diffusion of drug out of the foam. Polymer foams made in this fashion, however, may not be well suited for tissue engineering applications, due to their closed pore morphologies and are limited to drug delivery use.

## PHASE SEPARATION

Phase separation has been utilized in a novel alternative method of scaffold manufacture, which has been developed primarily to address the problem of drug delivery (Lo *et al.*, 1995). The ability to deliver bioactive molecules from a degrading polymer scaffold to cells within or surrounding the scaffold is an attractive one because it could potentially allow manipulation of tissue growth and cell function. In order to achieve this goal, the scaffold manufacturing process must lend itself to incorporation of bioactive molecules and must not cause any loss of drug activity due to exposure to harsh chemical or thermal environments. Porous PLLA and poly(phosphoester) scaffolds with small hydrophilic and hydrophobic bioactive molecules have been manufactured using the following phase-separation technique. First, the polymer is dissolved in a solvent (molten phenol or naphthalene) at a low temperature ( $55^{\circ}\text{C}$  for phenol and  $85^{\circ}\text{C}$  for naphthalene). The bioactive molecule is then dissolved or dispersed in the resulting homogeneous solution, which is then cooled in a controlled fashion until liquid-liquid phase separation is induced. The resulting

bicontinuous polymer and solvent phases are then quenched to create a two-phase solid. The solidified solvent is then removed by sublimation, leaving a porous polymer scaffold with bioactive molecules incorporated within the polymer. Drug release experiments have shown that the activity of small bioactive molecules is not adversely affected by the chemical and thermal conditions utilized in this phase-separation technique. This technique has proved useful as a means of incorporating small molecules into polymer scaffolds. However, incorporating and releasing drugs with large protein structures without loss of activity remain a challenge.

## POLYMER/CERAMIC COMPOSITE FOAMS

Bone regeneration presents some interesting and unique challenges to engineers and scientists interested in scaffold design. First, because almost all bone defects are irregularly shaped, any proposed scaffold processing technique must be sufficiently versatile to allow the formation of porous polymer-based materials with irregular three-dimensional shapes. Second, the scaffold must have high strength to replace the structural function of bone temporarily until it is regenerated. Although poly( $\alpha$ -hydroxyesters) have been used in a solid form for many orthopedic applications, the compressive strength of foam scaffolds constructed of these materials rapidly declines with increasing porosity (Thomson *et al.*, 1995).

In order to improve the mechanical properties of these foams, short hydroxyapatite fibers were incorporated into the poly( $\alpha$ -hydroxyester) framework in order to reinforce the scaffold (Thomson *et al.*, 1998). A melt-molding technique such as the one previously described would be desirable as a means to produce a three-dimensional scaffold. Unfortunately, melt molding is not suited to the manufacture of a composite foam. The reinforcing effect of fibers within a polymer matrix is effective only if the fibers can be evenly distributed throughout the polymer such that the degree of fiber-polymer contact is maximized and fiber-fiber contact is held to a minimum. Because achieving an even fiber distribution by attempting to mix two solid phases (polymer and fiber) prior to molding is extremely difficult, a solvent-casting technique is employed.

Hydroxyapatite short fibers and a porogen (either gelatin microspheres or salt particles) are first dispersed in a PLGA/dichloromethane solution. The result, after solvent evaporation and drying, is a composite material consisting of hydroxyapatite fibers and a porogen embedded in a PLGA polymer membrane. The required three-dimensional shape is then achieved by compression molding the composite material. Subsequent leaching of the porogen then leaves a porous composite scaffold of PLGA reinforced with short hydroxyapatite fibers (Fig. 21.5). Within a range of fiber contents, these scaffolds have superior compressive strength compared to nonreinforced PLGA scaffolds of the same porosity.

Another process that utilizes hydroxyapatite to reinforce PLGA foams involves the use of particulate hydroxyapatite rather than the use of fibers (Devin *et al.*, 1996). This technique utilizes an emulsion to create the porous scaffold. The NaCl and the particulate hydroxyapatite are first suspended in a PLGA solution in chloroform. An aqueous PVA solution is then added to the suspension to form an emulsion. The emulsion is cast into cylindrical molds and then vacuum dried. The dried matrices are then submerged in water to leach out the salt and form the porous scaffolds. The concentration of the PVA solution and the diameter of the salt crystals both control the diameter of the pores formed, which range from 18 to 150  $\mu\text{m}$  in diameter. Increasing the weight-percent of hydroxyapatite particles in the initial polymer suspension increases the compressive strength of the final matrix. The compressive properties of the composite scaffold are of the same order of magnitude as those of cancellous bone.

An alternative method to formulate polymer/ceramic composites has been proposed using a novel phase transition technique (Zhang and Ma, 1999). In this process, hydroxyapatite powder is added to a PLGA/dioxane solution. The mixture is frozen for several hours to induce phase separation and then freeze dried to sublimate the solvent. The formed composite foams exhibit an interconnected irregular pore morphology with a polymer/hydroxyapatite skeleton. The compressive strength of these foams is significantly higher than that of foams made from pure PLGA. The porosity, pore size, and pore structure can all be controlled by changing the polymer concentration, hydroxyapatite amount, solvent type, and phase-separation temperature. Composite foams with porosity of up to 95% and pore size in the range of 30 to 100  $\mu\text{m}$  can be fabricated with this method.

Fig. 21.5. Scanning electron photomicrographs of highly porous composite scaffolds constructed of PLGA and hydroxyapatite short fibers using a solvent-casting and melt-molding technique. Sodium chloride particles of size ranging from 300 to 500  $\mu\text{m}$  were used as a porogen with an original weight-percent of (a) 70% and (b) 90%. Reprinted from *Biomaterials* **19**, R. C. ### IN SITU POLYMERIZATION

All of the polymer-processing techniques discussed thus far have described methods to manufacture prefabricated scaffolds, which may then be used to regenerate the appropriate tissue. Prefabricated scaffolds are suitable for most tissues engineering applications; however, there are many instances in orthopedic surgery when mechanical stability must be restored immediately. In such cases, a nondegradable bone cement, usually poly(methyl methacrylate) (PMMA), is used to fill the bone defect and provide mechanical stability. A degradable, poly(propylene fumarate)(PPF)-based bone cement has been developed to provide the same function but on a temporary basis (Yaszemski *et al.*, 1996; Peter *et al.*, 1999a). PPF is an unsaturated linear polyester and is a viscous liquid at room temperature. It can be cross-linked at the time of surgery to form a solid degradable bone cement via an addition polymerization with *N*-vinyl pyrrolidone (*N*-VP). As the cross-linking reaction proceeds, the PPF is transformed from a viscous liquid to a puttylike state before finally solidifying. During its liquid and putty states, the cement can be injected or molded into the bone defect. It is therefore well suited for this application because many bone injuries result in defects that are relatively inaccessible without further surgical exposure and are geometrically ill

defined. Most addition polymerization reactions are exothermic and generate large quantities of heat. In the case of PMMA, which is polymerized *in situ*, this is sufficient to cause some local tissue necrosis. In contrast, much less heat is generated by the cross-linking reaction between PPF and *N*-VP (Peter *et al.*, 1999b), and no local tissue necrosis has been noted in *in vivo* studies (Yaszemski *et al.*, 1996). Two other components are incorporated into the PPF cement at the time of cross-linking. The first is NaCl, which leaches out to provide pores into which new bone can grow, and the second is  $\beta$ -tricalcium phosphate, which is an osteoconductive material that facilitates new bone growth. Incorporation of  $\beta$ -tricalcium phosphate also enhances the mechanical properties of the cement. By using high-molecular-weight PPF and incorporating  $\beta$ -tricalcium phosphate, the mechanical properties of the scaffold can be closely matched to that of human trabecular bone (Peter *et al.*, 1997, 1998). In this manner, a temporary osteoconductive scaffold may be formed *in situ* to replace the mechanical function of bone until new bone, stimulated to form in the scaffold pores, can assume this structural role.

## CONCLUSIONS

The diversity of organ structure and function is such that the design requirements of scaffolds for tissue engineering are specific to the tissue of interest. Consequently, the processing technique employed to manufacture a polymer scaffold with the desired characteristics must be chosen or developed appropriately. Several novel manufacturing techniques have been developed to process synthetic polymers into porous scaffolds with large void volumes for cell seeding and sufficient surface area for cell attachment. Each technique has particular advantages, such as ease of fabrication, superior structural strength, or the ability to incorporate and deliver bioactive molecules, but none can be considered as an ideal method of scaffold fabrication to be employed for all tissues. The choice of a scaffold fabrication technique is therefore a question of setting priorities to determine the critical requirements. Future challenges in polymer scaffold processing include the fabrication of high-strength scaffolds for hard tissue replacement at load-bearing sites and the ability to incorporate and deliver proteins and growth factors without loss of activity. All of the methods discussed in this chapter are viable and promising ways to produce polymer scaffolds for tissue regeneration and repair.

# BIODEGRADABLE POLYMERS

James M. Pachence and Joachim Kohn

## INTRODUCTION

The design and development of tissue-engineered products has benefited from many years of clinical utilization of a wide range of biodegradable polymers. Newly developed biodegradable polymers and novel modifications of previously developed biodegradable polymers have enhanced the tools available to create clinically important tissue engineering applications. The increased demands placed on biomaterials for novel sophisticated medical implants such as tissue engineering constructs continues to fuel the interest in improving the performance of existing medical-grade polymers and in developing new synthetic polymers. This chapter surveys those biologically derived and synthetic biodegradable polymers that have been used or are under consideration for use in tissue engineering applications. The polymers are described in terms of their chemical composition, breakdown products, mechanism of breakdown, mechanical properties, and clinical limitations. Also discussed are product design considerations in processing of biomaterials into a final form (e.g., gel, membrane, matrix) that will effect the desired tissue response.

## BIODEGRADABLE POLYMER SELECTION CRITERIA

The selection of biomaterials plays a key role in the design and development of tissue engineering product development. Although the classical selection criterion for a safe, stable implant dictated choosing a passive, “inert” material, it is now understood that any such device will elicit a cellular response (Peppas and Langer, 1994). Therefore, it is now widely accepted that a biomaterial must interact with tissue to repair, rather than act simply as a static replacement. Furthermore, biomaterials used directly in tissue repair or replacement applications (e.g., artificial skin) must be more than biocompatible: they must elicit a desirable cellular response. Consequently, a major focus of biomaterials for tissue engineering applications centers around harnessing control over cellular interactions with biomaterials, often including components to manipulate cellular response within the supporting biomaterial as a key design component. It is important for the tissue engineering product developer to have several biomaterials options available, because each application calls for a unique environment for cell–cell interactions. Such applications include (1) support for new tissue growth (wherein cell–cell communication and cell availability to nutrients, growth factors, and pharmaceutically active agents must be maximized); (2) prevention of cellular activity (when tissue growth, such as in surgically induced adhesions, is undesirable); (3) guided tissue response (enhancing a particular cellular response while inhibiting others); (4) enhancement of cell attachment and subsequent cellular activation (e.g., fibroblast attachment, proliferation, and production of an extracellular matrix of dermis repair); (5) inhibition of cellular attachment and/or activation (e.g., platelet attachment to a vascular graft); and (6) prevention of a biological response (e.g., blocking antibodies against homograft or xenograft cells used in organ replacement therapies).

Biodegradable polymers are applicable to those tissue engineering products for which tissue repair or remodeling is the goal, but not where long-term materials stability is required. Biodegradable polymers must also possess (1) manufacturing feasibility, including sufficient commercial

quantities of the bulk polymer; (2) the capability to form the polymer into the final product design; (3) mechanical properties that adequately address short-term function and do not interfere with long-term function; (3) low or negligible toxicity of degradation products, in terms of both local tissue response and systemic response; and (4) drug delivery compatibility in applications that call for release or attachment of active compounds.

## BIOLOGICALLY DERIVED BIORESORBABLES

### TYPE I COLLAGEN

Collagen is the major component of mammalian connective tissue, animal protein, accounting for approximately 30% of all protein in the human body. It is found in every major tissue that requires strength and flexibility (e.g., skin, bone). Fourteen types of collagens have been identified, the most abundant being type I (van der Rest *et al.*, 1990). Because of its abundance (it makes up more than 90% of all fibrous proteins) and its unique physical and biological properties, type I collagen has been used extensively in the formulation of biomedical materials (Pachence *et al.*, 1987; Pachence, 1996). Type I collagen is found in high concentrations in tendon, skin, bone, and fascia, which are consequently convenient and abundant sources for isolation of this natural polymer.

The structure, function, and synthesis of type I collagen have been thoroughly investigated (Piez, 1984; Tanzer and Kimura, 1988). Collagen proteins, by definition, are characterized by a unique triple-helix formation extending over a large portion of the molecule. The three peptide subunits that make up the triple helix of collagen have similar amino acid composition, each chain comprising approximately 1050 amino acid residues. The length of each subunit is  $\sim 300$  nm, and the diameter of the triple helix is  $\sim 1.5$  nm. The primary structure of collagen (with its high content of proline and hydroxyproline, and with every third amino acid being glycine) shows a strong sequence homology across a genus and the adjacent family line. Because of its phylogenetically well-conserved primary sequence and its helical structure, collagen is only mildly immunoreactive (De Lusto *et al.*, 1987; Anselme *et al.*, 1990). The individual collagen molecules will spontaneously polymerize *in vitro* into strong fibers that can be subsequently formed into larger organized structures (Piez, 1984). The collagen may be further modified to form intra- and intermolecular cross-links, which aid in the formation of collagen fibers, fibrils, and then macroscopic bundles that are used to form tissue (Nimni and Harkness, 1988). For example, tendon and ligaments are composed mainly of oriented type I collagen fibrils, which are extensively cross-linked in the extracellular space. Added strength via *in vivo* cross-linking is imparted onto the collagen fibers by several enzymatic (such as lysyl oxidase) and nonenzymatic reactions; the most extensive cross-linking occurs at the telopeptide portion of the molecule.

Collagen cross-linking can be enhanced after isolation through a number of well-described physical or chemical techniques (Pachence *et al.*, 1987). Increasing the intermolecular crosslinks (1) increases biodegradation time, by making collagen less susceptible to enzymatic degradation; (2) decreases the capacity of collagen to absorb water; (3) decreases its solubility; and (4) increases the tensile strength of collagen fibers. The free  $\epsilon$ -amines on lysine residues on collagen can be utilized for cross-linking, or can similarly be modified to link or sequester active agents. These simple chemical modifications provide a variety of processing possibilities and consequently the potential for a wide range of tissue engineering applications using type I collagen.

It has long been recognized that substrate attachment sites are necessary for growth, differentiation, replication, and metabolic activity of most cell types in culture. Collagen and its integrin-binding domains (e.g., RGD sequences) assist in the maintenance of such attachment-dependent cell types in culture. For example, fibroblasts grown on collagen matrices appear to differentiate in ways that mimic *in vivo* cellular activity and exhibit nearly identical morphology and metabolism (Silver and Pins, 1992). Chondrocytes can also retain their phenotype and cellular activity when cultured on collagen (Toolan *et al.*, 1996). Such results suggest that type I collagen can serve as tissue regeneration scaffolds for any number of cellular constructs.

The recognition that collagen matrices could support new tissue growth was exploited to develop the original formulations of artificial extracellular matrices for dermal replacements (Yannas and Burke, 1980; Yannas *et al.*, 1980; Burke *et al.*, 1981). Yannas and Burke were the first to show that the rational design and construction of an artificial dermis could lead to the synthesis of a der-

mislike structure with physical properties that “would resemble dermis more than they resembled scar” (Burke *et al.*, 1981). They created a collagen–chondroitin sulfate composite matrix with a well-described pore structure and cross-linking density that optimizes regrowth while minimizing scar formation (Dagalakis *et al.*, 1980). The reported clinical evidence and its simplicity of concept make this device an important potential tool for the treatment of severely burned patients (Heimbach *et al.*, 1988).

Collagen gels were used by Bell at the Massachusetts Institute of Technology to create a cell-based system for dermal replacement (Bell *et al.*, 1991; Parenteau, 1999). This living skin equivalent (commercially known as Alpligraf) is composed of a mixture of live human fibroblasts and soluble collagen in the form of a contracted gel, which is then seeded with keratinocytes. A number of clinical investigators have tested such cell-based collagen dressings for use as a skin graft substitute for chronic wounds and burn patients.

### GLYCOSAMINOGLYCANS

Glycosaminoglycans (GAGs), which consist of repeating disaccharide units in linear arrangement, usually include a uronic acid component (such as glucuronic acid) and a hexosamine component (such as *n*-acetyl-*d*-glucosamine). The predominant types of GAGs attached to naturally occurring core proteins of proteoglycans include chondroitin sulfate, dermatan sulfate, keratan sulfate, and heparan sulfate (Heinegard and Paulsson, 1980; Naeme and Barry, 1993). The GAGs are attached to the core protein by specific carbohydrate sequences containing three or four monosaccharides.

The largest GAG, hyaluronic acid (hyaluronan), is an anionic polysaccharide with repeating disaccharide units of *n*-acetylglucosamine and glucuronic acid, with unbranched units ranging from 500 to several thousand. Hyaluronic acid can be isolated from natural sources (e.g., rooster combs) or via microbial fermentation (Balazs, 1983). Because of its water-binding capacity, dilute solutions of hyaluronic acid are viscous.

Like collagen, hyaluronic acid can be easily chemically modified, as by esterification of the carboxyl moieties, which reduces its water solubility and increases its viscosity (Balazs, 1983; Sung and Topp, 1994). Hyaluronic acid can be cross-linked to form molecular weight complexes in the range 8 to  $24 \times 10^6$  or to form an infinite molecular network (gels). In one method, hyaluronic acid is cross-linked using aldehydes and small proteins to form bonds between the C—OH groups of the polysaccharide and the amino to imino groups of the protein, thus yielding high-molecular-weight complexes (Balazs and Leshchiner, 1986). Other cross-linking techniques include the use of vinyl sulfone, which reacts to form an infinite network through sulfonyl–bis-ethyl cross-links (Balazs and Leshchiner, 1985). The resultant infinite-network gels can be formed into sheaths, membranes, tubes, sleeves, and particles of various shapes and sizes. No species variations have been found in the chemical and physical structure of hyaluronic acid. The fact that it is not antigenic, eliciting no inflammatory or foreign body reaction, makes it desirable as a biomaterial. Its main drawbacks in this respect are its residence time and the limited range of its mechanical properties.

Because of its relative ease of isolation and modification and its superior ability in forming solid structures, hyaluronic acid has become the preferred GAG in medical device development. It has been used as a viscoelastic during eye surgery since 1976 and has undergone clinical testing as a means of relieving arthritic joints (Weiss and Balazs, 1987). In addition, gels and films made from hyaluronic acid have shown clinical utility to prevent postsurgical adhesion formation (Urmann *et al.*, 1991; Holzman *et al.*, 1994; Medina *et al.*, 1995).

### CHITOSAN

Chitosan is a biosynthetic polysaccharide that is the deacetylated derivative of chitin. Chitin is a naturally occurring polysaccharide that can be extracted from crustacean exoskeletons or generated via fungal fermentation processes. Chitosan is a  $\beta$ -1,4-linked polymer of 2-amino-2-deoxy-*d*-glucose; it thus carries a positive charge from amine groups (Kaplan *et al.*, 1994). It is hypothesized that the major path for chitin and chitosan breakdown *in vivo* is through lysozyme, which acts slowly to depolymerize the polysaccharide (Taravel and Domard, 1993). The biodegradation rate of the polymer is determined by the amount of residual acetyl content, a parameter that can easily be varied. Chemical modification of chitosan produces materials with a variety of physical

and mechanical properties (Muzzarelli *et al.*, 1988; Wang *et al.*, 1988; Laleg and Pikulik, 1991). For example, chitosan films and fibers can be formed utilizing cross-linking chemistries and adapted techniques for altering from other polysaccharides, such as treatment of amylose with epichlorohydrin (Wei *et al.*, 1977). Like hyaluronic acid, chitosan is not antigenic and is a well-tolerated implanted material (Malette *et al.*, 1986).

Chitosan has been formed into membranes and matrices suitable for several tissue engineering applications (Hirano, 1989; Sandford, 1989; Byrom, 1991). Chitosan matrix manipulation can be accomplished using the inherent electrostatic properties of the molecule. At low ionic strength, the chitosan chains are extended via the electrostatic interaction between amine groups, whereupon orientation occurs. As ionic strength is increased, chain-chain spacing is diminished; the consequent increase in the junction zone and stiffness of the matrix result in increased average pore size. Chitosan gels, powders, films, and fibers have been formed and tested for applications such as encapsulation, membrane barriers, contact lens materials, cell culture, and inhibitors of blood coagulations (East *et al.*, 1989).

### POLYHYDROXYALKANOATES

Polyhydroxyalkanoate (PHA) polyesters are degradable, biocompatible, thermoplastic materials made by several microorganisms (Miller and Williams, 1987; Gogolewski *et al.*, 1993). They are intracellular storage polymers whose function is to provide a reserve of carbon and energy (Dawes and Senior, 1973). Depending on growth conditions, bacterial strain, and carbon source, the molecular weights of these polyesters can range from tens into the hundreds of thousands. Although the structures of PHAs can contain a variety of *n*-alkyl side chain substituents (see Structure 1), the most extensively studied PHA is the simplest: poly(3-hydroxybutyrate) (PHB).

Imperial Chemical Industries (ICI; London, United Kingdom) developed a biosynthetic process for the manufacture of PHB, based on the fermentation of sugars by the bacterium *Alcaligenes eutrophus*. PHB homopolymers, like all other PHA homopolymers, are highly crystalline, extremely brittle, and relatively hydrophobic. Consequently, the PHA homopolymers have degradation times *in vivo* on the order of years (Holland *et al.*, 1987; Miller and Williams, 1987). The copolymers of PHB with hydroxyvaleric acid are less crystalline, more flexible, and more readily processible, but suffer from the same disadvantage of being too hydrolytically stable to be useful in short-term applications when resorption of the degradable polymer within less than 1 year is desirable.

PHB and its copolymers with up to 30% of 3-hydroxyvaleric acid are now commercially available under the trade name Biopol. It was found previously that a PHA copolymer of 3-hydroxybutyrate and 3-hydroxyvalerate, with a 3-hydroxyvalerate content of about 11%, may have an optimum balance of strength and toughness for a wide range of possible applications. PHB has been found to have low toxicity, in part due to the fact that it degrades *in vivo* to *d*-3-hydroxybutyric acid, a normal constituent of human blood. Applications of these polymers previously tested or now under development include controlled drug release, sutures, and artificial skin as well as industrial applications such as paramedical disposables (Yasin *et al.*, 1989; Doi *et al.*, 1990).

### EXPERIMENTAL BIOLOGICALLY DERIVED BIORESORBABLES

Synthetic biomolecules are beginning to find a place in the repertoire of biomaterials for medical applications. Model synthetic proteins structurally similar to elastin have been formulated by Urry and co-workers (Nicol *et al.*, 1992; Urry, 1995). Using a combination of solid-phase peptide chemistry and genetically engineered bacteria, they synthesized several polymers having homologies to the elastin repeat sequences of valine-proline-glycine-valine-glycine repeat (VPGVG). The

Structure 1. Poly( $\beta$ -hydroxybutyrate) and copolymers with hydroxyvaleric acid. For a homopolymer of HB,  $Y = 0$ ; commonly used copolymer ratios are 7, 11, and 22 mol% of hydroxyvaleric acid.

constructed amino acid polymers were formed into films and then cross-linked. The resultant films have intriguing mechanical responses, such as a reverse-phase transition: when a film is heated, its internal order increases, translating into substantial contraction with increasing temperature (Urry, 1995). The films can be mechanically cycled many times, and the phase transition of the polymers can be varied by amino acid substitution. Copolymers of VPGVG and VPGXG have been constructed (where X is the substitution) that have been shown to have a wide range of transition temperatures (Urry, 1995). Several medical applications are under consideration for this system, including musculoskeletal repair mechanisms, ophthalmic devices, and mechanical and/or electrically stimulated drug delivery.

Other investigators, notably Tirrell and Cappello, have combined techniques from molecular and fermentation biology to create novel protein-based-biomaterials (Cappello, 1992; Anderson *et al.*, 1994; Tirrell *et al.*, 1994). These protein polymers are based on repeat oligomeric peptide units, which can be controlled via the genetic information inserted into the producing bacteria. It has been shown that the mechanical properties and the biological activities of these protein polymers can be programmed, suggesting a large number of potential biomedical applications (Krejchi *et al.*, 1994).

Another approach to elicit an appropriate cellular response to a biomaterial is to graft active peptides to the surface of a biodegradable polymer. For example, peptides containing the RGD sequence have been grafted to various biodegradable polymers to provide active cell-binding surfaces (Hubbell, 1995).

## SYNTHETIC POLYMERS

From the beginnings of the study of materials sciences, the development of highly stable materials has been a major research challenge. Today, many polymers are available that are virtually nondestructible in biological systems, e.g., Teflon, Kevlar, or poly(ether-ether-ketone). On the other hand, the development of degradable biomaterials is a relatively new area of research. The variety of available, degradable biomaterials is still too limited to cover a wide enough range of diverse material properties. Thus, the design and synthesis of new, degradable biomaterials is currently an important research challenge.

Due to the efforts of a wide range of research groups, a large number of different polymeric compositions and structures have been suggested as degradable biomaterials. However, in most cases no attempts have been made to develop these new materials for specific medical applications. Thus, detailed toxicological studies *in vivo*, investigations of degradation rate and mechanism, and careful evaluations of the physicochemical properties have so far been published for only a very small fraction of those polymers. This leaves the tissue engineer with only a relatively limited number of promising polymeric compositions to choose from. The following section is limited to a review of the most commonly investigated classes of biodegradable, synthetic polymers.

### Poly( $\alpha$ -hydroxy acids)

Naturally occurring hydroxy acids, such as glycolic, lactic, and  $\epsilon$ -caproic acids, have been utilized to synthesize an array of useful biodegradable polymers for a variety of medical product applications. As an example, bioresorbable surgical sutures made from poly( $\alpha$ -hydroxy acids) have been in clinical use since 1970; other implantable devices made from these versatile polymers (e.g., internal fixation devices for orthopedic repair) are becoming part of standard surgical protocol (Helmus and Hubbell, 1993; Shalaby and Johnson, 1994; Hubbell, 1995).

The ester bonds of the poly(hydroxy acids) are cleaved by hydrolysis, which results in a decrease in the polymer molecular weight (but not mass) of the implant (Vert and Li, 1992). This initial degradation occurs until the molecular weight is less than 5000, at which point cellular degradation takes over. The final degradation and resorption of the poly(hydroxy acid) implants involve inflammatory cells (such as macrophages, lymphocytes, and neutrophils). Although this late-stage inflammatory response can have a deleterious effect on some healing events, these polymers have been successfully employed as matrices for cell transplantation and tissue regeneration (Freed *et al.*, 1994a,b). The degradation rate of these polymers is determined by initial molecular weight, exposed surface area, crystallinity, and (in the case of copolymers) ratio of the hydroxy acid monomers.

The poly(hydroxy acid) polymers have a modest range of mechanical properties and a corre-

spondingly modest range of processing conditions. Nevertheless, these thermoplastics can generally be formed into films, tubes, and matrices using such standard processing techniques as molding, extrusion, solvent casting, and spin casting. Ordered fibers, meshes, and open-cell foams have been formed to fulfill the surface area and cellular requirements of a variety of tissue engineering constructs (Helmus and Hubbell, 1993; Freed *et al.*, 1994b; Hubbell, 1995; Wintermantel *et al.*, 1996). The poly(hydroxy acid) polymers have also been combined with other materials, e.g., poly(ethylene glycol), to modify the cellular response elicited by the implant and its degradation products (Sawhney *et al.*, 1993).

### Poly(glycolic acid), poly(lactic acid), and their copolymers

Poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and their copolymers are the most widely used synthetic degradable polymers in medicine. Of this family of linear aliphatic polyesters, PGA has the simplest structure (see Structure 2) and consequently enjoys the largest associated literature base. Because PGA is highly crystalline, it has a high melting point and low solubility in organic solvents. PGA was used in the development of the first totally synthetic absorbable suture (Frazza and Schmitt, 1971). The crystallinity of PGA in surgical sutures is typically in the range 46–52% (Gilding and Reed, 1979). Due to its hydrophilic nature, surgical sutures made of PGA tend to lose their mechanical strength rapidly, typically over a period of 2 to 4 weeks postimplantation (Reed and Gilding, 1981).

In order to adapt the materials properties of PGA to a wider range of possible applications, researchers undertook an intensive investigation of copolymers of PGA with the more hydrophobic poly(lactic acid). Alternative sutures composed of copolymers of glycolic acid and lactic acid are currently marketed under the trade names Vicryl and Polyglactin 910. Due to the presence of an extra methyl group in lactic acid, PLA (Structure 3) is more hydrophobic than PGA. The hydrophobicity of high-molecular-weight PLA limits the water uptake of thin films to about 2% (Gilding and Reed, 1979) and results in a rate of backbone hydrolysis lower than that of PGA (Reed and Gilding, 1981). In addition, PLA is more soluble in organic solvents than is PGA.

It is noteworthy that there is no linear relationship between the ratio of glycolic acid to lactic acid and the physicomechanical properties of their copolymers. Whereas PGA is highly crystalline, crystallinity is rapidly lost in PGA–PLA copolymers. These morphological changes lead to an increase in the rates of hydration and hydrolysis. Thus, copolymers tend to degrade more rapidly compared with either PGA or PLA (Gilding and Reed, 1979; Reed and Gilding, 1981).

Because lactic acid is a chiral molecule, it exists in two stereoisomeric forms that give rise to four morphologically distinct polymers. *d*-PLA and *l*-PLA are the two stereoregular polymers, *d,l*-PLA is the racemic polymer obtained from a mixture of *d*- and *l*-lactic acid, and meso-PLA can be obtained from *d,l*-lactide. The polymers derived from the optically active *d* and *l* monomers are semicrystalline materials, whereas the optically inactive *d,l*-PLA is always amorphous. Generally, *l*-PLA is more frequently employed than *d*-PLA, because the hydrolysis of *l*-PLA yields *l*(+)-lactic acid, which is the naturally occurring stereoisomer of lactic acid.

The differences in the crystallinity of *d,l*-PLA and *l*-PLA have important practical ramifications: because *d,l*-PLA is an amorphous polymer, it is usually considered for applications such as drug delivery, where it is important to have a homogeneous dispersion of the active species within a monophasic matrix. On the other hand, the semicrystalline *l*-PLA is preferred in applications where high mechanical strength and toughness are required—for example, sutures and orthopedic devices (Christel *et al.*, 1982; Leenstag *et al.*, 1987; Vainionpää *et al.*, 1987). PLA, PGA, and their copolymers are also being intensively investigated for a large number of drug delivery applications. This research effort has been comprehensively reviewed by Lewis (1990).

Structure 3. The extra methyl group confers hydrophobicity.

Some controversy surrounds the use of these materials for orthopedic applications. According to one review of short- and long-term response to resorbable pins made from either PGA or PGA:PLA copolymer, in over 500 patients, 1.2% required reoperation due to device failure, 1.7% suffered from bacterial infection of the operative wound, and 7.9% developed a late noninfectious inflammatory response that warranted operative drainage (Böstman, 1991). Subsequently it has become evident that the delayed inflammatory reaction represents the most serious complication of the use of the currently available degradable fixation devices. The mean interval between fixation and the clinical manifestation of this reaction is 12 weeks for PGA and can be as long as 3 years for the more slowly degrading PLA (Böstman, 1991). Whether avoiding reoperation to remove a metal implant outweighs an approximately 8% risk of severe inflammatory reaction is a difficult question; in any event, an increasing number of trauma centers have suspended the use of these degradable fixation devices. It has been suggested that the release of acidic degradation products (glycolic acid for PGA, lactic acid for PLA, and glyoxylic acid for polydioxanone) contributes to the observed inflammatory reaction. Thus, the late inflammatory response appears to be a direct consequence of the chemical composition of the polymer degradation products, for which there is currently no prophylactic measure (Böstman, 1991). A solution to these problems for orthopedic (and perhaps other) applications requires the development of a polymer that is more hydrophobic than PGA or PLA, degrades somewhat more slowly, and does not release acidic degradation products on hydrolysis.

### Polydioxanone

The poly(ether-ester) polydioxanone (PDS) is prepared by a ring-opening polymerization of *p*-dioxanone. PDS has gained increasing interest in the medical field and pharmaceutical field due to its degradation to low-toxicity monomers *in vivo*. PDS has a lower modulus than does PLA or PGA, thus it became the first degradable polymer to be used to make a monofilament suture. PDS has also been introduced to the market as a suture clip as well as a bone pin marketed under the name ORTHOSRB in the United States and Ethipin in Europe (Ray *et al.*, 1981; Greisler *et al.*, 1987; Mäkelä *et al.*, 1989).

### Poly( $\epsilon$ -caprolactone)

Poly( $\epsilon$ -caprolactone) (PCL) (Structure 4) is an aliphatic polyester that has been intensively investigated as a biomaterial (Pitt, 1990). The discovery that PCL can be degraded by microorganisms led to evaluation of PCL as a biodegradable packaging material (Pitt, 1990). Later, it was discovered that PCL can also be degraded by a hydrolytic mechanism under physiologic conditions (Pitt *et al.*, 1981a). Under certain circumstances, cross-linked PCL, can be degraded enzymatically, leading to "enzymatic surface erosion" (Pitt *et al.*, 1981b). Low-molecular-weight fragments of PCL are reportedly taken up by macrophages and degraded intracellularly, with a tissue reaction similar to that to the other poly(hydroxy acids) (Pitt *et al.*, 1984). Compared with PGA

Poly( $\epsilon$ -caprolactone)

Structure 4. An aliphatic polyester that can be degraded hydrolytically under physiologic conditions.

or PLA, the degradation of PCL is significantly slower. PCL is therefore most suitable for the design of long-term, implantable systems such as Capronor, a 1-year implantable contraceptive device (Pitt, 1990).

Poly( $\epsilon$ -caprolactone) exhibits several unusual properties not found among the other aliphatic polyesters. Most noteworthy are its exceptionally low glass transition temperature of  $-62^{\circ}\text{C}$  and its low melting temperature of  $57^{\circ}\text{C}$ . Another unusual property of poly( $\epsilon$ -caprolactone) is its high thermal stability. Whereas other tested aliphatic polyesters had decomposition temperatures ( $T_d$ ) between  $235$  and  $255^{\circ}\text{C}$ , poly( $\epsilon$ -caprolactone) has a  $T_d$  of  $350^{\circ}\text{C}$ , which is more typical of poly(ortho esters) than aliphatic polyesters (Engelberg and Kohn, 1991). PCL is a semicrystalline polymer with a low glass transition temperature of about  $-60^{\circ}\text{C}$ . Thus, PCL is always in a rubbery state at room temperature. Among the more common aliphatic polyesters, this is an unusual property, which undoubtedly contributes to the very high permeability of PCL for many therapeutic drugs (Pitt *et al.*, 1987).

Another interesting property of PCL is its propensity to form compatible blends with a wide range of other polymers (Koleske, 1978). In addition,  $\epsilon$ -caprolactone can be copolymerized with numerous other monomers (e.g., ethylene oxide, chloroprene, tetrahydrofuran, *d*-valerolactone, 4-vinylanisole, styrene, methyl methacrylate, vinylacetate). Particularly noteworthy are copolymers of  $\epsilon$ -caprolactone and lactic acid that have been studied extensively (Pitt *et al.*, 1981a; Feng *et al.*, 1983). The toxicology of PCL has been extensively studied as part of the evaluation of Capronor. Based on a large number of tests, the monomer,  $\epsilon$ -caprolactone, and the polymer, PCL, are currently regarded as nontoxic and tissue-compatible materials. Consequently, the Capronor system has undergone Food and Drug Administration (FDA)-approved phase I and phase II clinical trials (Pitt, 1990).

It is interesting to note that in spite of its versatility, PCL has so far been predominantly considered for controlled-release drug delivery applications. In Europe, PCL is being used as a biodegradable staple, and it stands to reason that PCL (or blends and copolymers with PCL) will find additional medical applications in the future. The most comprehensive review of the status of PCL has been by Pitt (1990).

### Poly(ortho esters)

Poly(ortho esters) are a family of synthetic degradable polymers that have been under development for several years (Heller *et al.*, 1990). Devices made of poly(ortho esters) can be formulated in such a way that the device undergoes "surface erosion"—that is, the polymeric device degrades at its surface only and will thus tend to become thinner over time rather than crumbling into pieces. Because surface-eroding, slablike devices tend to release drugs embedded within the polymer at a constant rate, poly(ortho esters) appear to be particularly useful for controlled-release drug delivery (Heller, 1988); this interest is reflected by the many descriptions of these applications in the literature (Heller and Daniels, 1994).

There are two major types of poly(ortho esters). Originally, poly(ortho esters) were prepared by the condensation of 2,2-diethoxytetrahydrofuran and a dialcohol (Cho and Heller, 1978) and marketed under the trade names Chronomer and Alzamer. On hydrolysis, these polymers release acidic by-products that autocatalyze the degradation process, resulting in degradation rates that increase with time. Later, Heller *et al.* (1980) synthesized a new type of poly(ortho ester) based on the reaction of 3,9-bis(ethylidene-2,4,8,10-tetraoxaspiro{5,5}undecane) (DETOSU) (see Structure 5) with various dialcohols. These poly(ortho esters) do not release acidic by-products on hydrolysis and thus do not exhibit autocatalytically increasing degradation rates.

Structure 5. Poly(ortho esters). The specific composition shown here is a terpolymer of hexadecanol (1,6-HD), *trans*-cyclohexyldimethanol (*t*-CDM), and DETOSU.

Structure 6. Poly(SA-HDA anhydride). This composition represents one of many polyanhydrides that have been explored. The clinically relevant polyanhydrides are copolymers of sebacic acid and *p*-carboxyphenoxy propane.

### Polyanhydrides

Polyanhydrides were first investigated in detail by Hill and Carothers (1932) and were considered in the 1950s for possible applications as textile fibers (Conix, 1958). Their low hydrolytic stability, their major limitation for industrial applications, was later recognized as a potential advantage by Langer *et al.* (see Rosen *et al.*, 1983), who suggested the use of polyanhydrides as degradable biomaterials. A study of the synthesis of high-molecular-weight polyanhydrides has been published by Domb *et al.* (1989, 1994).

A comprehensive evaluation of the toxicity of the polyanhydrides showed that, in general, the polyanhydrides possessed excellent *in vivo* biocompatibility (Laurencin *et al.*, 1990). The most immediate applications for polyanhydrides are in the field of drug delivery. Drug-loaded devices are best prepared by compression molding or microencapsulation (Mathiowitz *et al.*, 1988). A wide variety of drugs and proteins, including insulin, bovine growth factors, angiogenesis inhibitors (e.g., heparin and cortisone), enzymes (e.g., alkaline phosphatase and  $\beta$ -galactosidase), and anesthetics, have been incorporated into polyanhydride matrices and their *in vitro* and *in vivo* release characteristics have been evaluated (Chasin *et al.*, 1990). One of the most aggressively investigated uses of the polyanhydrides is for the delivery of chemotherapeutic agents. One particular example of this application is the delivery of bis-chloroethylnitrosourea (BCNU) to the brain for the treatment of glioblastoma multiforme, a universally fatal brain cancer (Langer, 1990). For this application, polyanhydrides derived from bis-(*p*-carboxyphenoxy propane) and sebacic acid (see Structure 6) received FDA regulatory clearance in the fall of 1996 and are currently being marketed under the name Gliadel.

### Polyphosphazenes

Polyphosphazenes consist of an inorganic phosphorous–nitrogen backbone (see Structure 7), in contrast to the commonly employed hydrocarbon-based polymers (Scopelianos, 1994). Consequently, the phosphazene backbone undergoes hydrolysis to phosphate and ammonium salts, with the concomitant release of the side group. Of the numerous polyphosphazenes that have been synthesized, those that have some potential use for medical products are substituted with amines of low  $pK_a$  and those with activated alcohol moieties (Allcock, 1990; Crommen *et al.*, 1992; Laurencin *et al.*, 1993). The most extensively studied polyphosphazenes are hydrophobic, having fluoroalkoxy side groups. In part, these materials are of interest because of their expected minimal tissue interaction, which is similar to Teflon.

Aryloxyphosphazenes and closely related derivatives have also been extensively studied. One such polymer can be cross-linked with dissolved cations such as calcium to form a hydrogel matrix because of its polyelectrolytic nature (Allcock and Kwon, 1989). Using methods similar to alginate encapsulation, microspheres of aryloxyphosphazene have been used to encapsulate hybridoma cells without affecting their viability or their capacity to produce antibodies. Interaction

Structure 7. Polyphosphazene. Shown here is a polymer containing an amino acid ester attached to the phosphazene backbone.

Structure 8. A poly(amide carbonate) derived from desaminotyrosyl tyrosine alkyl esters. This is an example for a group of new, amino acid-derived polymers.

with poly(L-lysine) produced a semipermeable membrane. Similar materials have been synthesized that show promise in blood contacting and in novel drug delivery applications.

### Poly(amino acids) and pseudo-poly(amino acids)

Because proteins are composed of amino acids, many researchers have tried to develop synthetic polymers derived from amino acids to serve as models for structural, biologic, and immunologic studies (see Structure 8). In addition, many different types of poly(amino acids) have been investigated for use in biomedical applications (Anderson *et al.*, 1985). Poly(amino acids) are usually prepared by the ring-opening polymerization of the corresponding *N*-carboxy anhydrides that are obtained by reaction of the amino acid with phosgene (Bamford *et al.*, 1956).

Poly(amino acids) have several potential advantages as biomaterials. A large number of polymers and copolymers can be prepared from a variety of amino acids. The side chains offer sites for the attachment of small peptides, drugs, cross-linking agents, or pendant groups that can be used to modify the physicochemical properties of the polymer. Because these polymers release naturally occurring amino acids as the primary products of polymer backbone cleavage, their degradation products may be expected to show a low level of systemic toxicity.

Poly(amino acids) have been investigated as suture materials (Spira *et al.*, 1969), as artificial skin substitutes (Aiba *et al.*, 1985), and as drug delivery systems (Mitra *et al.*, 1979; McCormick-Thomson and Duncan, 1989). Various drugs have been attached to the side chains of poly(amino acids), usually via a spacer unit that distances the drug from the backbone. Poly(amino acid)-drug combinations investigated include poly(L-lysine) with methotrexate and pepstatin (Campbell *et al.*, 1980), and poly(glutamic acid) with adriamycin and norethindrone (van Heeswijk *et al.*, 1985).

Despite their apparent potential as biomaterials, poly(amino acids) have actually found few practical applications. The *N*-carboxy anhydrides, the starting materials, are expensive to make and difficult to handle because of their high reactivity and moisture sensitivity. Most poly(amino acids) are highly insoluble and nonprocessable materials. Because poly(amino acids) degrade via enzymatic hydrolysis of the amide bond, it is difficult to reproduce and control their degradation *in vivo* because the level of enzymatic activity varies from person to person. Furthermore, the antigenicity of polymers containing three or more amino acids excludes their use in biomedical applications (Anderson *et al.*, 1985). Because of these difficulties, only a few poly(amino acids), usually derivatives of poly(glutamic acid) carrying various pendant chains at the  $\gamma$ -carboxylic acid group, are currently being investigated as implant materials (Lescure *et al.*, 1989).

As an alternative approach, James and Kohn (1997) and Kemnitzer and Kohn (1997) have

replaced the peptide bonds in the backbone of synthetic poly(amino acids) by a variety of such “nonamide” linkages as ester, iminocarbonate, urethane, and carbonate bonds. The term “pseudo-poly(amino acid)” is used to denote this new family of polymers in which naturally occurring amino acids are linked together by nonamide bonds.

The use of such backbone-modified pseudo-poly(amino acids) as biomaterials was first suggested in 1984 (Kohn and Langer, 1984). The first pseudo-poly(amino acids) investigated were a polyester from *N*-protected *trans*-4-hydroxy-L-proline and a poly(iminocarbonate) from tyrosine dipeptide (Kohn and Langer, 1985, 1987). Several studies indicate that the backbone modification of conventional poly(amino acids) in general improves their physicochemical properties (Ertel and Kohn, 1994; Fiordeliso *et al.*, 1994; James and Kohn, 1997). This approach is applicable to, among other materials, serine, hydroxyproline, threonine, tyrosine, cysteine, glutamic acid, and lysine; it is only limited by the requirement that the nonamide backbone linkages give rise to polymers with desirable material properties. Additional pseudo-poly(amino acids) can be obtained by considering dipeptides as monomeric starting materials. Hydroxyproline-derived polyesters (Kohn and Langer, 1987; Yu *et al.*, 1987; Yu-Kwon and Langer, 1989), serine-derived polyesters (Zhou and Kohn, 1990), and tyrosine-derived polyiminocarbonates (Pulapura *et al.*, 1990) and polycarbonates (Pulapura and Kohn, 1992) represent specific embodiments of these synthetic concepts.

## CREATING MATERIALS FOR TISSUE-ENGINEERED PRODUCTS

As described in this chapter, the bulk polymer properties and the cellular response to biomaterials are important selection criteria for the design of a tissue-engineered product. In addition, the ability to mold the biomaterial into the appropriate cellular-level architecture must be considered, and such architecture must be compatible with the desired tissue response. Hubbell classified approaches to choosing biomaterials for various tissue engineering applications according to type of tissue response sought: (1) conducting tissue responses and architectures, (2) inducing tissue responses and architectures, and (3) blocking tissue responses (Hubbell, 1995; Wintermantel *et al.*, 1996). Implicit in this consideration is that the specific material architecture (e.g., membrane, gel, matrix, tube) is critical to the tissue engineering product design and thus influences the choice of biomaterials.

### BARRIERS: MEMBRANES AND TUBES

Design formats requiring cell activity on one surface of a device while precluding transverse movement of surrounding cells onto that surface call for a barrier material. For example, peripheral nerve regeneration must allow for axonal growth and at the same time preclude fibroblast activity that could produce neural-inhibiting connective tissue. Structures such as collagen tubes can be fabricated to yield a structure dense enough to inhibit connective tissue formation along the path of repair while allowing axonal growth through the lumen (Li *et al.*, 1992). Similarly, collagen membranes for periodontal repair provide an environment for periodontal ligament regrowth and attachment while preventing epithelial ingrowth into the healing site (van Swol *et al.*, 1993). Antiadhesion formulations using hyaluronic acid, which prevent ingrowth of connective tissue at a surgically repaired site, also work on this concept (Urmann *et al.*, 1991).

### GELS

Gels are used to provide a hydrogel scaffold, to encapsulate, or to provide a specialized environment for isolated cells. For example, collagen gels for tissue engineering were first used to maintain fibroblasts, which were the basis of a living skin equivalent (Parenteau, 1999). Gels have also been used for the maintenance and immunoprotection of xenograft and homograft cells such as hepatocytes, chondrocytes, and islets of Langerhans used for transplantation (Sullivan *et al.*, 1991; Chang, 1992; Lacy, 1995). Semipermeable gels have been created to limit cell–cell communication and interaction with surrounding tissue, and to minimize movement of peptide factors and nutrients through the implant. In general, nondegradable materials are used for cell encapsulation to maximize long-term stability of the implant. In the future, however, it may be possible to formulate novel “smart” gels in which biodegradation is triggered by a specific cellular response instead of simple hydrolysis.

## MATRICES

It has been recognized since the mid-1970s that three-dimensional structures are an important component of engineered tissue development (Yannas and Burke, 1980; Yannas *et al.*, 1980). Yannas and co-workers were the first to show that pore size, pore orientation, and fiber structure are important characteristics in the design of cell scaffolds. Several techniques have subsequently been developed to form well-defined matrices from synthetic and biologically derived polymers, and the physical characteristics of these matrices are routinely varied to maximize cellular and tissue responses (Fenkel *et al.*, 1997; Langer and Vacanti, 1993). These engineered matrices have led to several resorbable templates for tissue regeneration.

## CONCLUSION

Research in the use of currently available biomaterials and in developing novel bioresorbable polymers has helped to drive the establishment of the field of tissue engineering. Despite a wide range of possible choices, there is a tendency to choose those bioresorbable polymers that have a history of regulatory approval instead of letting the application guide the choice of material. The latter approach, moreover, may require lengthy and costly polymer development work. Nonetheless, in order to gain the sort of precise control over cell response and cell interactions with surrounding tissues that is expected of tissue engineering applications, continued research on new bioresorbable polymers will be necessary.

# APPROACHES TO TRANSPLANTING ENGINEERED CELLS AND TISSUES

Janet Hardin-Young, Jeffrey Teumer, Robert N. Ross, and Nancy L. Parenteau

## INTRODUCTION

Approaches to the use of living cells in tissue engineering is dictated by the primary purpose of the implant, be it metabolic or structural and the availability of a suitable cell source. Whatever the intended mode of action of tissue-engineered grafts, the function is provided either directly or indirectly by the cellular component. Determining where these cells will come from plays a pivotal role. Cellularization of an implant can be achieved through recruitment of host cells *in vivo*, directed *in vivo* tissue formation, *ex vivo* cell propagation, and *in vitro* organotypic tissue culture. Tissue scaffolds and living tissue implants are by no means static devices once inside the body. Therefore the inflammatory response of the host plays a key role in determining the persistence, long-term structure, and functionality of the engineered implant. Another important parameter is the immunologic response when using cells not from the host. Fortunately, certain allogeneic human cells may be transplanted successfully with little or no immune response. However, special measures such as immune therapy, genetic modification, or encapsulation must be taken to introduce xenogeneic cells. Reagents and methods used in the culture of cells should be screened and validated for safety to guard against untoward changes in the cell population or introduction of adventitious agents during processing. This is true regardless of the cell source.

The ultimate goal of tissue engineering is to replace, repair, or enhance biological function in the event of damaged, absent, or dysfunctional elements, often at the scale of a tissue or an organ. Engineered tissues are achieved by using cells that are manipulated through their extracellular environment to develop living biological substitutes for cells and tissues that are lacking. Many different strategies may be used to accomplish this goal, but they all have in common the enlistment of living cells for therapeutic use.

Among the chief factors that dictate the best strategy for developing and utilizing engineered tissues are technical feasibility, required properties of the implant, and the interaction of the host with the graft. This chapter is a general discussion of such factors, and the possible approaches that can be used to transplant cells and reestablish tissues. Specific applications of transplanting engineered cells and tissues will be covered in more detail in subsequent chapters.

## DEVELOPING WORKABLE STRATEGIES

Successful development of an engineered biologic substitute depends on contributions from such diverse fields as cell biology, extracellular matrix biochemistry, biomaterials science, biomedical engineering, biochemistry, immunology, cell culture technology, chemical engineering, and physiology. Having identified a clinical need, the decision to go forward with the development of a particular tissue-engineered product is based on a careful evaluation of available scientific knowledge and an assessment of present and near-term technical capabilities. The concept is then tested in the laboratory for its overall scientific merit and for proof of principle. After laboratory evi-

dence suggests proof of principle, the approach is refined and modified by further *in vitro* and animal experimentation, and eventually by clinical trials.

Reproducibility of results is a critical consideration. No tissue engineering process can succeed without the high probability that the product will consistently have the desired characteristics. Reproducibility of the product is achieved through standardization of protocols that are built on a substantial foundation of fundamental technical knowledge, the deepest possible understanding of the basic mechanisms involved, careful experimentation, and direct technical experience. Without these things, the target tissues to be modeled, the laboratory and manufacturing techniques required to develop the product, and the native tissue all remain essentially black boxes. Such unknowns are the antithesis of reproducible results. For *ex vivo* expansion of most cells types, precise regulation of pH, oxygen tension, seeding density, growth factors, and nutrients is required. The development of commercial processes to provide a living cell-based product depends on a thorough understanding of the metabolic and physical requirements of the specific cells and on the technical expertise to provide them in quantities large enough to support a commercially viable enterprise.

The final test of the clinical applicability of a tissue-engineered product is the ability to provide sufficient quantities of reliably reproducible product at a reasonable cost. Even the most promising ideas fail as commercial products if they are proved unfeasible as a result of irreproducibility, cost, unavailability of cell source, or inability to direct the host response to the implant. How an implant is expected to function determines the features that must be designed into it (Table 23.1) and the industrial plan for how it is to be produced. Design approaches range from the relatively simple use of cultured cells (Green *et al.*, 1979; Brittberg *et al.*, 1994) to the use of what could be termed organ equivalents, in which there is an attempt to replicate both structure and function (Parenteau *et al.*, 1992; Bilbo *et al.*, 1993; Wilkins *et al.*, 1994).

The best approach is not always obvious and must often be arrived at through experimentation, including clinical trials. For example, the repair of articular cartilage is being investigated using undifferentiated cultured chondrocytes (Brittberg *et al.*, 1994), chondrocyte precursors in collagen, matrix alone (Reddi, 1994; Speer *et al.*, 1979; von Schroeder *et al.*, 1991; Wakitani *et al.*, 1994), and differentiated cartilage analogs (Vacanti *et al.*, 1991; Freed *et al.*, 1993, 1994a,b). Cartilagenous matrix forms readily *in vitro* and *in vivo*, but its long-term phenotype is difficult to control. Isolated human chondrocytes from a small biopsy seeded on bioresorbable polymer (Cao *et al.*, 1998) have been expanded in an attempt to provide custom-engineered autologous cartilage transplants for the reconstruction of the nose or outer ear (Naumann *et al.*, 1998).

Use of differentiated cartilage analogs for articular cartilage repair has faced problems of inadequate tissue integration with adjacent host cartilage. The difficulties stem from the biology of the host articular cartilage, which is a relatively acellular, avascular, dense matrix that undergoes little interstitial remodeling. Only empirical data will determine which of these is the best approach. The best therapy will be the one that reproducibly forms articular cartilage, effect long-term repair, and is cost effective.

**Table 23.1. Types of engineered tissues**

Type of tissue	Graft role	Example
Physical	Primarily biomechanical	Bone (Habal and Reddi, 1994; Thomson <i>et al.</i> , 1995)
Physiological	Physiological	Blood vessels (Termin <i>et al.</i> , 1994) Liver (Dunn <i>et al.</i> , 1989; Sussman <i>et al.</i> , 1994) Kidney (Humes, 1995)
Chemical	Produce soluble, diffusible component	Pancreatic islets (Mikos <i>et al.</i> , 1994) Neuroendocrine substance (Aebischer <i>et al.</i> , 1994)
Combination	Multiple	Skin (Sabolinski <i>et al.</i> , 1996)

In the case of organotypic analogs of skin, such as the Apligraf human skin equivalent (HSE), the situation of tissue response is quite different from that of cartilage. The development of an organotypic HSE is particularly important because these *in vitro* three-dimensional skin constructs show morphologic and biochemical profiles expressed in living skin. This serves as a benefit rather than a hindrance. Formation of an organotypic analog results in a robust multifunctional tissue that, unlike cartilage, is able to interact and integrate with the wound to affect healing on multiple levels (see Chapter 65).

Tissue structure, whether only minimally achieved prior to implantation or more completely developed in culture, must be achieved quickly *in vivo* for optimum cell function. A vascular implant, for example, must serve immediately as an efficient conduit for blood and not trigger the formation of thrombi. Not only should the implant not be rejected by the host, but the implant should foster the migration of native cells to the site. Implantation must not interfere with normal function of the existing tissue or of the organ. A bone graft must not significantly weaken the site around the implant. Finally, the implant must become, as much as possible, a fully functional analog of the native tissue in the implantation site.

### MODE OF ACTION—AN IMPORTANT DESIGN CONSIDERATION

The desired mode of action of a graft dictates the type of implant necessary and determines important functional and mechanical requirements of the graft. Engineered tissue implants presently in use or under investigation can be grouped into four general categories that focus on its primary function (Table 24.1): physical, chemical, physiologic, and a combination of graft roles. These modes of action are discussed below.

#### PHYSICAL GRAFTS

The primary mode of action of physical grafts (e.g., ligament, cartilage, or vascular replacements) is to perform a biomechanical structural role. The biomechanics depend heavily on the extracellular component of the graft and on the capacity for living cells of the graft (attracted to the site of the graft or implanted with the graft) to maintain that structure. This, however, may be too simplistic a view for tissue engineering. For example, physical properties are of acute concern on implantation of a vascular graft. The surface of the graft must not elicit a thrombogenic response and the structure must be able to withstand arterial pressure without threat of aneurysm. In addition, the material must have more than adequate suture retention characteristics. Therefore, it is obvious to focus on the initial physical properties and short-term effects of the grafts. Although this is a necessary first step, and there has been some exciting progress in this area (see Chapter 34), unlike an inert device, a tissue graft, whether cellular or noncellular, will be expected to interact with the body. Because of this, the biology and physiology of the cells become increasingly important postimplant and will ultimately determine the long-term patency of the grafts, just as they can in autologous saphenous vein grafts. This general concept of the physical structure ultimately depending on cell biology and physiology is likely true for most physical tissue-engineered grafts.

There are clinical situations in which a relatively large tissue mass is required physically to fill the space of tissue lost as a result of surgical resection (e.g., tissue replacement after mastectomy) (Eiselt *et al.*, 1998). Living tissues for “bulking” applications are limited by the ability to vascularize the tissue. Problems to solve in designing such a tissue-engineered product with such a mode of action include designing an acellular structural framework to fill the space, providing a suitable matrix for the localization of transplanted cells, and promoting vascularization of the forming tissue. One approach has been to allow a scaffold to prevascularize prior to seeding with functional cells (Wake *et al.*, 1995). Attempts have been made to enhance this process by seeding the matrix with polymer microspheres containing a potent angiogenic molecule [vascular endothelial growth factor (VEGF)] for controlled release to promote vascularization at the site of tissue formation (Eiselt *et al.*, 1998).

#### PHYSIOLOGIC OR CHEMICAL GRAFTS

In grafts that are intended to have a physiologic or chemical mode of action, the biological or biochemical properties of the graft are more important than the physical structure or mechanical properties of the graft. Products of the constituent cells are of greater concern than properties of the extracellular component of the graft.

A variety of tissue-engineered implants with physiologic or chemical function are under development. For example, biodegradable polymer scaffolds have been developed to support the growth of hepatocytes on implantable microcarriers (Davis and Vacanti, 1996). Biologic function of these hepatocyte transplants has been demonstrated in animal models by production of albumin and other liver products, and by clearing bilirubin and urea metabolites. Pancreatic islet cell transplants are likewise under investigation (Hayashi *et al.*, 1998).

Even in the design of physiologic and chemical grafts, however, the contribution of an extracellular matrix component and mechanical properties must be understood, because they may be important for cell regulation. The function of cultured rat hepatocytes, for example, is improved when cells are cultivated between two collagen layers that provide extracellular matrix contact and permit proper cell polarization (Dunn *et al.*, 1992; Ezzell *et al.*, 1993).

### COMBINATION

There are instances in which several aspects of the implant are key elements to its effectiveness. Certain types of grafts are intended to perform two or more equally important functions. For example, cultured human skin has important physical structure and biologic function. The graft skin is a distinct physical structure that covers a physical defect. The stratum corneum serves as an immediate barrier to water loss and infection while the living layers promote wound healing through their biologic interaction with the host wound bed.

### ROLE OF THE HOST

It should be clear that the host interaction with the tissue-engineered product is an important consideration. The success of the implant depends on working with the host response in such a way that the metabolic requirements and appropriate regulatory signals are provided by and to the implant. An initial inflammatory response is followed by vascularization and migration of mesenchymal cells into the graft (Kemp *et al.*, 1995). Unlike normal wound healing, however, there seems to be a well-defined period of 5 to 10 weeks during which the host response to an implant can be directed toward integration or toward inflammation and “rejection” of the implant. If the process is not directed toward tissue integration by this time, inflammatory mechanisms of the foreign body reaction are mobilized, and the body attempts to eliminate or isolate the implant. This is an innate, nonspecific immune response. Strategies to avoid this destruction therefore become major design considerations.

It is thought by some that the inflammatory response to an implant is not only beneficial but necessary for the recruitment of host cells. Our experience both in animals and in the clinic suggests that directed tissue integration through signals other than those of acute inflammation might be sufficient and more desirable. Inflammation, when unchecked, can lead to fibrosis, and in some cases, destruction of the implant architecture and/or encapsulation of the implant.

The degree of graft remodeling and cell replacement by the host tissue varies by type of implant. If the graft is to replace a lost or deficient function, the implanted cells should naturally be designed to persist and function for a long time. Premature loss of implanted cells through turnover, lack of ability for self-propagation and/or maintenance, and an inflammatory or immune response by the host would undermine the goals of the therapy. In other cases, however, population by the host cells and remodeling of the structure may be requirements for achieving proper function. In bone grafts, for example, cell population or repopulation and remodeling of the extracellular matrix are important for achieving stable mechanical properties. Another example of this is the host cellularization and remodeling of a small-caliber vascular graft made of collagen (discussed in Chapter 33).

In the case of cultured skin, which will be used in a variety of acute and chronic wounds, flexibility of the implant's response, durability of the engineered tissue, and its ability to direct a positive host response are key to its effectiveness. Remodeling of cultured skin is advantageous and results in improved function and appearance in the dermatologic surgery patient (Eaglstein *et al.*, 1991). The persistence and remodeling of Apligraf (Graftskin) (Apligraf is a registered trademark of Novartis) human skin equivalent, for example, is dependent on the type of application (see Chapter 67). Contribution from the host varies depending on the wound environment and the biology, biochemistry, and physiology of both the cellular elements and the extracellular matrix of the graft.

Whatever the intended mode of action of tissue-engineered grafts, the function is provided either directly or indirectly by the cellular component. Therefore, determining where these cells will come from plays a pivotal role.

## SOURCE OF CELLS

Tissue engineering requires a reliable source of viable cells for processing. Which source of cells is best used for a tissue-engineered product depends on many factors, including the functional requirements of the implant as well as the feasibility of collecting, processing, and storing these cells and the tissue-engineered product. Timing is an issue. For example, an off-the-shelf product is more likely to be used in a timely manner compared with a product that requires custom production. Economic considerations are also important. The cost of finding source material, cultivating it, and manipulating some cell types often limits what can be accomplished in tissue engineering.

If the implant relies on *in vivo* cell growth after reimplantation, *in vitro* expansion of cells is less critical. An example of this is bone marrow transplantation, because marrow cells have the potential to reconstitute the recipient's hematopoietic tissue without significant prior *in vitro* culture and expansion. In most cases, however, it is necessary to expand the cell number by some *in vitro* method prior to implantation. Success of the process therefore depends on the ability to scale up the culture system without altering the desirable characteristics of the cultivated cells.

Currently, only a few cell types (e.g., keratinocytes, fibroblasts, chondrocytes, and myoblasts) can be expanded in significant numbers in culture. For other cell types (e.g., normal hepatic, neural, or pancreatic islet cells), it is not currently possible to expand in culture a sufficient number of normal cells for clinical use. For such cell types, alternative strategies (e.g., genetic modification or the use of cultivated cell lines) are being explored. Sources of cells may be autologous (obtained from the same individual for whom the graft is intended), allogeneic (obtained from an individual of the same species who is genetically distinct from the individual for whom the graft is intended), or xenogeneic (obtained from an individual of a species different from the species of individual for whom the graft is intended).

## AUTOLOGOUS CELLS

The most direct source of cells for transplant is autologous tissue. The use of autologous tissue obviates the difficulties of overcoming noncompatibility with the host's immune system, which is a challenge in grafting any nonhost material into an immunocompetent host. Cell number can be increased from autologous sources in two ways: (1) autologous cell expansion or (2) autologous cell recruitment. In autologous cell expansion, cells are harvested from a patient biopsy, grown in culture to the desired number, and then reimplanted into the body. In autologous cell recruitment, *in vivo* conditions are manipulated to foster migration of the desired cell population to the site.

For autologous cells to be useful, cultivation of the cell type must permit expansion of the population to a number sufficient to meet the functional need of the implant within a time frame that suits the needs of the patients. The time required to harvest tissue from the patient, expand the cells in culture, and construct the implant can be a critical limitation of autologous material. If the tissue is needed to sustain life, the time needed to manufacture the implant may not be consistent with patient survival. In addition, healthy tissue may be sparse or unavailable. The cost and inherent variability of each autologous, custom-made device may limit clinical feasibility and must be considered in comparison with alternatives that are likely to be available. Cost and variability may be partially alleviated by providing an automated, controlled means of processing patient tissue, which can be placed directly in the hospital laboratories. This strategy is being used for the cultivation of patients' hematopoietic cells (Koller *et al.*, 1993; Van Zant *et al.*, 1994).

Cultured autologous cells were the first clinical application of cellular tissue engineering. Autologous keratinocytes were grown in culture and grafted onto burn victims (Gallico *et al.*, 1984). In this procedure, a small biopsy of skin is taken from an uninjured area of a burn patient. The keratinocytes of the epidermis are then isolated from this biopsy, and their number is increased in tissue culture (Rheinwald and Green, 1975). These cultured keratinocytes are then grafted to the patient as confluent sheets of cells after having been expanded as much as 2000-fold from the initial biopsy (Epicel, Genzyme Tissue Repair, Cambridge, MA) (Green *et al.*, 1979).

Autologous cultured chondrocytes (Carticel, Genzyme Tissue Repair, Cambridge, MA) are

being used to treat articular cartilage injuries in humans. Chondrocytes are harvested from an uninvolved area of the injured knee, expanded in culture, and then surgically seeded into the articular defect and held in place with a piece of periosteal sheath, also harvested from the patient. Arthroscopic examination has shown smooth-surfaced articular cartilage regenerated in the site of the original lesions in patients followed for up to 5.5 years after implantation (Brittberg *et al.*, 1994).

### **Autologous cell recruitment**

Recruitment of autologous cells to restore or enhance tissue function can also be achieved *in vivo* by providing an appropriate acellular scaffold designed to foster cell infiltration. Such implants are designed to guide cell migration and thus enable cells recruited from the patient's population of cells to differentiate and replace the implanted regeneration scaffold with a functional, living tissue. The matrix components of the implant are resorbed and eventually replaced by new, host-derived, extracellular matrix. Implanted scaffolds may also contain chemical factors that stimulate chemotaxis and cell differentiation. For example, acellular bone grafts are cellularized by cells recruited from the marrow, blood, or periosteum and are most likely stimulated by bone morphogenic proteins bound to the bone matrix (Reddi and Anderson, 1976).

Because regeneration scaffolds do not contain live cells at the time of implantation, production and storage of the product are simplified. These advantages are balanced by the disadvantage that the clinical success of regeneration scaffolds is totally dependent on appropriate cellular recruitment from the host. In some cases, critical steps in cellular recruitment may be either inadequate or lacking entirely. Recruitment may be aided by the use of bound growth factors or concomitant gene therapy such as the use of VEGF (Takeshita *et al.*, 1996) or other angiogenic or chemotactic factors.

In some cases, the scaffold must provide immediate physical functionality during the early acellular stage and must also induce host regeneration of new tissue. Many such regeneration scaffolds have been produced from components of the natural extracellular matrix. Scaffold grafts in the form of bone powders are used routinely in facial bone repair. Composite scaffolds of controlled porosity and physical characteristics are being developed to direct bone formation (Thomson *et al.*, 1998). Matrix scaffolds have also shown promise in the repair of dermis (Burke *et al.*, 1981; Yannas *et al.*, 1982, 1989; Livesey *et al.*, 1995), tendons (Goldstein *et al.*, 1989; Kato *et al.*, 1991), nerves (Chang and Yannas, 1992), meniscus (Stone *et al.*, 1990), and blood vessels (see Chapter 32).

### **ALLOGENEIC CELLS**

One way of minimizing the limitations of supply inherent in strategies that rely on autologous cells is the development of tissue-engineered products from allogeneic cells. The use of allogeneic cells allows banking of cells. This permits safety and functional performance screening. Moreover, because allogeneic material can be free from the variability associated with patient-dependent autologous sources, it permits the development of a consistently reproducible and cost-effective product. Such standardized allogeneic cell sources also allow the construction of complex tissues (Wilkins *et al.*, 1994) that would otherwise be prohibitively expensive in time, money, and effort if they were to be produced by custom manufacture from autologous sources.

An example of this is the formation of the Apligraf HSE. A method for cultivating human keratinocytes from neonatal foreskin, using a minimally supplemented basal medium (MSBM), was reported in 1992 (Johnson *et al.*, 1992). Three passages in culture provide approximately  $10^{10}$  cells for cryostorage as a cell bank. Subsequent culture of these cells for one passage results in an additional 10-fold increase in cell number, which is then sufficient to produce approximately 100–200 m<sup>2</sup> of HSE constructs from a single source. This allogeneic skin equivalent provides both the advantages of a skin graft without the need for harvesting tissue and the production of large quantities of consistent material.

### **IMMORTALIZED CELL LINES**

Cell lines may be derived from cells that have undergone certain genetic changes that permit them indefinite proliferation as long as their metabolic requirements are satisfied. Such immor-

talized cell lines can be used to overcome some of the source limitations of current cell culture technology. The genetic changes that immortalize these cell lines are usually accompanied by some loss of differentiated structure and function, however. Although this dedifferentiation may make these cells significantly different from their native counterparts, because these cells remain somewhat plastic, such cell lines are more amenable to gene transfer. Specific properties can thus be engineered into them to produce desired therapeutic proteins, perform selected cell functions, or overcome host immune reaction.

Safety is a concern when using cell lines, however, because immortalized cells exhibit some of the properties of neoplastically transformed cells. Such cell lines are thus considered to be partially transformed cells with a predisposition to become fully neoplastic cells capable of forming tumors in the recipient. Tissue engineering strategies that use cell lines can take this danger into account in a variety of ways. Techniques of encapsulation of the cell line, extracorporeal use, or control of immortalization using conditions that select against gene expression such as temperature or drug sensitivity can limit the cells and risk to the patient. A hepatocyte cell line has been used in an extracorporeal system to treat acute liver failure (Sussman *et al.*, 1994).

### XENOGENEIC SOURCES

For some cell types, the tissue demand cannot be met through the use of autologous or allogeneic sources. This has led to strategies that employ xenogeneic tissues. Technology employing cell encapsulation, immune protection, extracorporeal systems, and genetic manipulation is being developed to enable the use of xenogeneic tissues and organs, because one need only breed enough animals to meet demand. The use of xenogeneic tissue requires extra attention to the problem of rejection by the patient's immune system. Xenogeneic cells are feasible only if the tissues can be used effectively. For example, porcine pancreatic islet transplantation will have limited feasibility if the tissue remains difficult to harvest and requires a number of animals for each treatment. Cost and quality-control issues associated with islet preparation could be restrictive.

Microencapsulation techniques have been used to permit transgenic implants (Basic *et al.*, 1996). In general, however, the problem remains unsolved of designing membranes that selectively restrict permeation by some effector molecules of the immune system but permit, or even facilitate, permeation by other biologically active molecules of roughly equivalent size (Edge *et al.*, 1998).

### THE IMMUNOLOGY OF NONAUTOLOGOUS CELLS

Although there are significant differences in the mechanisms of allograft and xenograft rejection, there are important common features. Destruction of implanted tissues by the patient's immune system is a hurdle when nonautologous cells are used. These are acquired immune responses, the mechanisms of true graft rejection. For example, the mitigation of complement-mediated rejection is believed to be a major hurdle for the transplantation of xenogeneic cells (Schilling *et al.*, 1976). Once the hyperacute rejection is prevented, transplantation of xenogeneic cells will face many of the same problems associated with allograft rejection.

Allograft rejection is primarily a T cell-mediated immune response. In conventional organ transplantation, cytotoxic T cells (cytotoxic T lymphocytes, CTLs) specific for alloantigens present on the endothelial cells attack the vasculature of the grafted organ, which leads to destruction of the graft (Adams *et al.*, 1994; Pober *et al.*, 1986). Passenger leukocytes contributes to the response by stimulating the expansion of donor-reactive T helper cells, which are necessary for the generation of CTLs.

Not all cell types are equal in their ability to elicit a host immune response. Donor cells can be classified on the basis of their ability to act as target cells for effector CTLs, and their expression of histocompatibility leukocyte antigen (HLA) proteins. Some cell populations (e.g., leukocytes and endothelial cells) are strongly allostimulatory. These professional antigen-presenting cells (APCs) constitutively express major histocompatibility complex (MHC) class I, class II, and costimulatory proteins (e.g., B7 and CD40), are capable of stimulating naive T cells, resulting in the expansion of alloreactive T helper cells, and serve as targets for effector CTLs. Other cell types classified as nonprofessional APCs are less allostimulatory (e.g., keratinocytes, smooth muscle cells, and fibroblasts) (Murray *et al.*, 1995; Laning *et al.*, 1997). Nonprofessional APCs do not constitutively express MHC class II proteins (Gaspari and Katz, 1988) and are unable to induce the ac-

tivation and expansion of required T helper cells because they lack the functioning costimulatory molecules necessary for proper T cell activation.

One approach to using allogeneic cells in tissue engineering has been to use pure populations of allogeneic nonprofessional APC cells that are weakly or nonallostimulatory and do not contain endothelial cells or passenger leukocytes. The Apligraf HSE, an allogeneic construct containing only human fibroblasts and keratinocytes, is an example of such an engineered graft (Wilkins *et al.*, 1994). This skin construct contains both purified keratinocyte and fibroblast populations and has been shown in both preclinical (Theobald *et al.*, 1993; Laning *et al.*, 1999; Moulton *et al.*, 1999) and clinical (Falanga *et al.*, 1998) studies not to sensitize recipients.

In situations in which the donor cells are strongly allostimulatory, there are several approaches that might be used to control the host immune response, including traditional therapies used in solid organ transplants. Host immune response is not only determined by the allogenicity of the individual cell types that comprise the graft but also by the accessibility to the graft by the host immune system. Developing appropriate animal models to investigate the allogenicity of a graft is critical. Immunocompromised mice such as the severe combined immunodeficient (SCID) mouse lack functioning immune systems, which allows them to accept human tissue transplants. A number of humanized SCID mouse models have been developed to assess the antigenicity of both organ grafts and engineered tissue grafts. For example, SCID mice humanized with human white blood cells reject allogeneic human skin but not an allogeneic HSE (Briscoe *et al.*, 1999).

In most cases, tissue engineered grafts will be avascular when transplanted. Because endothelial cells are a primary target of graft rejection, the absence of allogeneic endothelium in an engineered graft is an important element for the immunologic success of the engineered grafts. In addition, the lack of an established vasculature may beneficially limit the initial interaction between the host immune system and the graft cells.

In summary, the use of allogeneic and xenogeneic cells in tissue engineering provides alternatives to the use of autologous cells in some circumstances. The specific types of cells used in the graft will determine the degree of immunoreactivity of the graft and will therefore determine the immunologic approach used to obtain graft acceptance. In some cases the alloreactivity of the graft will be negligible, so that no special treatment is necessary for graft acceptance. The use of allogeneic or xenogeneic cells does entail particular safety considerations.

## SAFETY CONSIDERATIONS

Reagents and methods used in the culture of autologous cells should be screened and validated for safety to guard against untoward changes in the cell population or introduction of adventitious agents during processing. This is true regardless of the cell source. Each autologous sample must be kept isolated throughout the process to avoid possible exposure to cells or tissues from other individuals. This becomes a primary limitation to achieving economies of scale in process, because each tissue must be treated on a "custom" basis (Schaeffer *et al.*, 1999). With allogeneic sources, sufficient safeguards must be in place to minimize the possibility of transmitting an infectious agent from the donor to the host. Although allogeneic sources must be carefully screened to guard against transmission of such infectious diseases as human immune deficiency and hepatitis viruses, there is adequate time and access to the cells permitting thorough screening of cell banks for adventitious agents, abnormal karyotype, tumorigenicity, and phenotypic changes, even well beyond their point of use. This can yield a product with less risk than traditional blood and organ transplants, which already have an excellent safety record. Because the need for batch isolation is eliminated, this permits a scalable process using prescreened material.

The use of xenogeneic cells present a special safety consideration, the possibility of introducing into the human population viruses that are not known or understood, and that might be pathogenic in humans. Therefore animal tissues must be thoroughly screened (Fishman, 1998) and would likely come from tightly controlled, closed animal herds.

## CONCLUSION

From this overview, we can see there are many options to consider in the design and production of an engineered tissue grafts. The cultivation and manipulation of cells for the practical purposes of producing functional tissue present a number of formidable but rewarding challenges to both the biologist and the engineer.

# CRYOPRESERVATION

Jens O. M. Karlsson and Mehmet Toner

## INTRODUCTION

Cold has the power to preserve and the power to destroy. Consider, for instance, the woolly mammoth finds in Siberia—the tissues of these late Pleistocene animals have been sufficiently well preserved to make possible the isolation of intact protein (Prager *et al.*, 1980) and DNA (Johnson *et al.*, 1985) after as much as 50,000 years of frozen storage. On the other hand, the destructive effects of cold temperatures are also well known: frostbite destroys skin tissue, and frost damage to plants causes major crop losses every year. Scientists have exploited the deleterious effects of low temperatures: freeze–thaw cycles are routinely used by biologists to deliberately lyse cells; in cryosurgery, liquid-nitrogen-cooled probes are used to ablate cancerous tissue. In order to also harness the preservative powers of cold, making possible the storage of living biological materials in a state of “suspended animation,” it is necessary to prevent cell and tissue damage during the potentially destructive procedures of freezing and thawing. Although the challenges presented by this problem are sometimes daunting, the potential benefits of cryopreservation to medicine and biotechnology are great.

A significant body of knowledge has been accumulated about the mechanisms of freezing-related damage to cells, the key component of bioartificial organs and tissues (Mazur, 1984). Mathematical models have made possible the prediction of the physicochemical response of cells to freezing (Pitt, 1992; Toner, 1993) and the rational design of cell freezing protocols by computer-aided optimization (Karlsson *et al.*, 1996). Although the progress in developing cryopreservation procedures for cells is encouraging, the scale and complexity of tissues and organs present additional problems that must be overcome before cryopreservation can become widely used for these systems (Karlsson and Toner, 1996). Thus, cryopreservation technology is currently evolving in parallel with the field of tissue engineering as a whole: significant advances have been made to date, but many challenges remain. In this chapter, we present an overview of the principles of cryobiology as they apply to both cells and tissues, emphasizing the use of mathematical models to guide the design and optimization of cryopreservation procedures.

## APPLICATIONS OF CRYOPRESERVATION TECHNOLOGY IN TISSUE ENGINEERING

Cryobiology is becoming a focus of research in tissue engineering, because preservation is a core technology in bringing cell-based medical devices to market. Effective preservation procedures are required at the following critical steps in the tissue engineering production cycle:

1. Screening of source cells: Nonautologous source cells must be extensively tested for adventitious agents. Such validation can require months of time (Bell and Rosenberg, 1990), during which the source cell pool must be preserved in order to prevent contamination or genotypic changes.
2. Cell banking: To ensure reproducibility in the manufacturing process, the United States

Food and Drug Administration requires the establishment of Master and Working Cell Banks, which must be preserved under conditions that assure genetic stability (Wiebe and May, 1990).

3. Inventory control: Adequate preservation technology is a prerequisite to maintaining a product inventory in order to meet end-user demand. Because cell expansion over several weeks may be necessary to populate a tissue-engineered device (Green *et al.*, 1979), just-in-time manufacturing approaches can be difficult to implement. Thus, the lead time for product delivery may be unacceptably long if long-term storage is not possible.

4. Quality control: Cryopreservation of cell or tissue samples at each step of production can be used for subsequent quality-control testing, and for creating cell and tissue archives documenting the manufacture of each lot of tissue. Because regulation of tissue-engineered devices is still an evolving area, such archives may become necessary for validation of the manufacturing process.

5. Biological manipulations: Freeze-thaw protocols can be used to effect desirable biological changes in tissue. By selectively destroying or impairing immunostimulatory cells, the cryopreservation process can reduce tissue immunogenicity (Taylor *et al.*, 1987; Ingham *et al.*, 1993). In skin grafting applications, freezing can be used to reduce the metabolic activity of fresh tissue to therapeutically optimal levels (Naughton *et al.*, 1997; Naughton, 1999).

6. Product distribution: Shipping of tissue-engineered products from the manufacturing plant to the end-user requires product stability in transit. Adequate technologies for long-term tissue preservation are especially critical for companies with a single manufacturing facility, because constraints on product distribution caused by shelf life limitations will impede access to geographically distant markets.

7. Tissue banking: The need for tissue or organ replacements in hospitals is variable and inherently unpredictable. Thus, to ensure immediate availability of tissue-engineered devices, it will be necessary to establish clinical tissue banks.

Compared with other methods of storing cells and tissue (refrigeration, chemical preservation, *in vitro* culture), freezing to cryogenic temperatures has the benefits of affording long shelf lives with assured genetic stability, virtually no risk of microbial contamination during storage, and improved cost effectiveness (as an illustrative example, the cost of liquid nitrogen used for cryogenic storage is approximately \$1/gallon, whereas serum required to maintain a tissue in culture costs well over \$1000/gallon). Thus, cryopreservation is currently the most viable approach to meet the requirements of production, distribution, and end-use of tissue-engineered products.

## CHALLENGES IN CRYOPRESERVATION PROTOCOL DEVELOPMENT

The cryopreservation process causes significant changes in the thermal, chemical, and physical environment in the tissue, with attendant risks of biological damage. Temperature changes are mainly due to heat-transfer boundary conditions imposed by the freezing and warming methods, but can also be affected by the latent heat of fusion of ice in the tissue. The chemical environment may be altered prior to freezing by addition of cryoprotectant agents, but it is also modulated by the formation of ice in the suspending medium. The growth of this ice phase removes water from the remaining unfrozen solution, thus enriching the medium in solutes, and lowering the chemical potential of the unfrozen water. In addition to effecting these chemical changes, the presence of ice also modifies the physical environment in the tissue, causing alterations in tissue structure. Furthermore, mechanical forces may arise in the tissue due to thermal stress phenomena. Every change imposed on the tissue during cryopreservation disrupts homeostasis, and has the potential to cause irreversible damage.

In order to minimize tissue destruction during freezing and thawing, methods for chemical and thermal processing must be optimized. Chemical manipulations are typically limited to the introduction of one or more cryoprotectant additives into the tissue before freezing, and removal of these additives after thawing. One must choose the types of cryoprotectant to use, and develop a protocol for adding and removing these chemicals with a minimum of deleterious effects to the tissue. Addition and dilution protocols typically involve one or more steps of bathing the tissue in a solution of specified composition and temperature, for a given amount of time (i.e., three parameters must be specified for each step). Thermal processing methods are usually specified in terms

of the temperature versus time profile  $T(t)$  to be imposed at the boundary of the tissue, because our ability to control the spatial temperature in the tissue interior is limited. The temperature history  $T(t)$  may be linear or nonlinear, but for design purposes it is customarily divided into piecewise linear segments, each of which is defined by a constant rate of temperature change, and a limit temperature (or time) at which the next segments begins (thus two parameters must be specified for each segment).

Consider now the development of a cryopreservation procedure. If there are  $n$  steps in the chemical-processing protocol, and  $m$  steps in the temperature profile, there will be at least  $p = 3n + 2m$  protocol parameters to optimize. Because there is interaction between the various processing steps (e.g., the effect of cooling rate depends on the cryoprotectant concentration; the effect of the warming procedure depends on the preceding freezing protocol), all  $p$  parameters should be simultaneously optimized. Whereas in the simplest case,  $n = 2$  (a single cryoprotectant addition step and a single dilution step) and  $m = 2$  (linear cooling and linear warming), optimization using a full factorial design with only two levels for each parameter would require  $2^p = 1024$  experiments. Clearly, the number of experiments required for rigorous optimization of cryopreservation procedures is prohibitively large, even for the simplest class of protocols. Thus, it is common practice to optimize sequentially individual parameters in the protocol, using as few as  $p + 1$  experiments (for two levels per parameter) to yield a pseudooptimal solution that will be strongly dependent on the initial values used in the search. As a result of the shortcomings of experimental protocol optimization, the empirical development of cryopreservation procedures has been limited to systems that are relatively robust, or those in which damage can be tolerated (McGrath, 1985). The successful design of cryopreservation procedures for complex tissues, however, will probably require the use of theoretical models and computer-aided optimization methods. Thus, the mechanisms of tissue damage during freezing and thawing must be understood, and appropriate mathematical models developed.

## CRYOBIOLOGY OF CELLS

### BACKGROUND AND HISTORICAL PERSPECTIVE

The study of the behavior of individual cells during freezing and thawing provides a starting point for analysis of tissue damage during cryopreservation. Cells are usually the key component of an engineered tissue, providing the tissue-specific bioactivity required to achieve a therapeutic effect. Even in tissues designed to have a purely biomechanical function (e.g., heart valves), the presence of a viable cell population will reduce the risk of postimplantation graft failure (McNally and McCaa, 1988). Thus, even though there are multiple modes of injury to tissue during cryopreservation, minimizing cell damage must be a major goal in designing protocols for the freezing and thawing of tissue, as well as for cryoprotectant addition and removal.

The first reports of low-temperature biological research are found in the writings of Sir Robert Boyle (1693). However, significant progress toward development of successful cryopreservation protocols was not made until the twentieth century, when two major breakthroughs were achieved. First, the 1949 discovery of the cryoprotective properties of glycerol led to the now ubiquitous and successful use of cryoprotectant additives in freezing media (Polge *et al.*, 1949). Second, the use of mathematical models to predict the behavior of cells during freezing was pioneered by Mazur (1963), and paved the way for subsequent successes in predicting cell damage due to intracellular ice formation (reviewed by Karlsson *et al.*, 1993b). In what follows, an overview of the principles of cell cryobiology and the mathematical models describing the governing phenomena will be given, after which we will turn to the problem of tissue preservation.

### EXPERIMENTAL OBSERVATIONS OF CELL FREEZING

The response of the cell to the freezing process can be observed using a cryomicroscope, a microscope fitted with a low-temperature stage. Modern cryomicroscope designs use digital feedback control systems to achieve precise temperature regulation, and include a video camera for quantitative image analysis (Diller, 1982). As can be seen in Fig. 24.1, the cell response depends on the method of freezing, and, in particular, the cooling rate is a critical parameter in determining the outcome of the freezing protocol. When the extracellular ice forms, a chemical potential difference across cell membranes results, driving water out of the cell by osmosis. However, the plasma

Fig. 24.1. Behavior of cells during freezing, observed using a cryomicroscope. Three separate freezing experiments are shown, in which rat hepatocytes were cooled at different rates:  $10^{\circ}\text{C}/\text{min}$  (A, B),  $100^{\circ}\text{C}/\text{min}$  (C, D), and  $400^{\circ}\text{C}/\text{min}$  (E, F). Cells are shown after seeding of extracellular ice at  $-1^{\circ}\text{C}$  (A, C, E) and after cooling to  $-40^{\circ}\text{C}$  (B, D, F).

membrane has a finite permeability to water, the magnitude of which determines the rate of water efflux and the corresponding time scale of cell dehydration. Thus, if the rate of cooling is sufficiently slow to allow the intracellular solution to equilibrate with its external environment by expressing water through the cell membrane, the cell will dehydrate extensively with decreasing temperature (see A and B, Fig. 24.1). On the other hand, if the cooling rate is fast compared with

the rate of water efflux, low temperatures are reached before significant dehydration can occur. In this latter case, the cell remains largely undeformed, but there is a very high probability of ice formation in the cell, inasmuch as the intracellular solution is in a supercooled nonequilibrium state. Because cryomicroscopes use transmitted light, intracellular ice formation appears as a darkening of the cytoplasm, due to scattering of light by ice crystals in the cell (E and F, Fig. 24.1). At intermediate cooling rates, cells are partially dehydrated, and thus near equilibrium. However, there is still some supercooling of the cytoplasm, and therefore intracellular ice crystals may form in some cells (C and D, Fig. 24.1).

If one measures the survival of cells frozen using various cooling rates, one finds that post-thaw viability decreases with increasing rate of cooling (Mazur *et al.*, 1972). The cooling rate at which the probability of cell survival drops to 50% also corresponds to the cooling rate at which 50% of cells are observed to form intracellular ice (Toner, 1993). However, at very low rates of cooling, a drop-off in survival is seen with *decreasing* rates of cooling (Fig. 24.2). Based on experimental observations of the cooling rate dependence of cell survival, Mazur *et al.* (1972) proposed the two-factor hypothesis of cell freezing injury, which posits that two distinct mechanisms are responsible for cell damage during cryopreservation.

One mode of injury is dominant at high cooling rates, and is associated with intracellular ice formation. The mechanism of damage has not been fully elucidated, but is thought to be due to mechanical disruption of the plasma membrane and/or other structures by intracellular ice crystals (Karlsson *et al.*, 1993b). A dissenting theory holds that the cell membrane is damaged by osmotic stresses arising from intracellular supercooling, and that extracellular ice crystals grow into the cytoplasm following membrane rupture (Muldrew and McGann, 1994). In either case, the extent of damage will be higher with increasing supercooling, and thus the probability of cell survival decreases with increasing cooling rate.

A second mode of injury, unrelated to intracellular ice formation, is hypothesized to be active at low cooling rates. This mechanism of cell damage is usually referred to as “solution effects” injury and is believed to be related to cell dehydration, mechanical deformation of the cell, and/or the prolonged exposure to high intra- and extracellular concentrations of electrolytes and cryoprotectants (Mazur *et al.*, 1972). Because the extent of cell dehydration and the time of exposure to these deleterious conditions both increase with decreasing cooling rate, cell damage due to solution effects should decrease at increasing rates of cooling.

Thus, as shown in Fig. 24.2, there is an optimum cooling rate at which the two mechanisms of damage are balanced, and the probability of cell survival reaches a maximum. Optimal values of other protocol parameters (e.g., in multistep freezing procedures) can similarly be explained in terms of a balance between solution effects and intracellular ice formation (Karlsson *et al.*, 1996). Although the experimental evidence supports the universality of the two-factor hypothesis as a qualitative explanation of cell damage during freezing, the optimum cryopreservation method is known to differ from cell type to cell type (Mazur *et al.*, 1972). This is a result not only of variable sensitivity to freezing injury, but also of variations in cell biophysical properties such as the water permeability of the plasma membrane and the activity of ice nucleating catalytic sites in the

Fig. 24.2. Effect of cooling rate on cell survival. According to the two-factor hypothesis, cell damage at low cooling rates is due to cell dehydration and attendant exposure to concentrated solutions, whereas cell injury at high rates of cooling is due to intracellular ice formation.

cell, which affect the rate of dehydration and the probability of intracellular ice formation, respectively (McGrath, 1988; Toner, 1993). Thus, every cell type requires its own cryopreservation protocol to be developed and optimized, a fact that has spurred efforts to develop rational design methods for the optimization of freezing and warming procedures (Karlsson *et al.*, 1996). Such computer-aided design techniques require theoretical models of the behavior of cells at low temperatures.

### MATHEMATICAL MODELING OF THE CELLULAR RESPONSE TO CRYOPRESERVATION

The use of mathematical models to predict the effect of cryopreservation on cells was pioneered by Mazur (1963), who developed the first models of water transport during freezing. Though useful for advancing our understanding of the qualitative behavior of cells during cryopreservation, these early models were unable to predict the probability of intracellular ice formation. This problem was subsequently addressed by Pitt and co-workers, who developed a series of phenomenological models based on fitting probability distributions to the experimental data (Pitt, 1992), and by Cravalho and co-workers, who initiated an effort to develop a mechanistic thermodynamic model of the intracellular water-ice phase transition (Cravalho, 1976; Karlsson *et al.*, 1993b). The latter effort culminated with the development of a mechanistic, fully integrated model of water transport, intracellular ice nucleation, and crystal growth in the presence of cryoprotectants (Karlsson *et al.*, 1994), based in part on the earlier work of Toner and colleagues (1990), in which classical nucleation theory was successfully used to predict the probability of intracellular ice nucleation in the absence of cryoprotectants. The essential model equations are described below.

The description of cell dehydration is based on the original two-compartment, membrane-limited transport model of Mazur (1963), modified here to take into account the presence of cryoprotectants:

$$\frac{dV}{dt} = \left( \frac{L_{pg}A}{v_w} \right) \exp \left[ \left( \frac{E_{Lp}}{R} \right) \left( \frac{1}{T_0} - \frac{1}{T} \right) \right] \left[ \Delta H_f \left( \frac{T}{T_0} - 1 \right) - RT \ln \left[ \frac{V - \phi_s V_0}{V + (\Pi_s v_w - \phi_s) V_0} \right] \right], \quad (1)$$

where  $V$  is the volume of the cell cytoplasm;  $V_0$ , the initial value of  $V$ ;  $A$ , the cell membrane surface area;  $t$ , time;  $\phi_s$  and  $\Pi_s$ , the initial values of the volume fraction and osmolarity of intracellular solutes (native electrolytes and cryoprotectant additives), respectively;  $T$ , temperature;  $T_0$ , the equilibrium melting temperature of water;  $\Delta H_f$ , the specific heat of fusion of water;  $v_w$ , the specific volume of water;  $L_{pg}$ , the membrane water permeability at  $T_0$ ;  $E_{Lp}$ , the activation energy for water transport; and  $R$ , the gas constant. The main assumptions of this model are that the intracellular solution is ideal and well mixed, and that the cell membrane is impermeable to all species except water. Equation (1) can be solved numerically for a given cooling protocol  $T(t)$  to yield predictions of cell volume, water content, solute content, and cytoplasmic supercooling (Fig. 24.3). These parameters are required in order to predict the probability of ice formation in the cell. Figure 24.3 shows predicted values of water content, cryoprotectant concentration, and cell supercooling for rat hepatocytes frozen using various cooling rates. If cooling is fast, the water content and intracellular cryoprotectant concentration remain approximately constant during freezing. As a result, the cytoplasmic supercooling increases almost linearly with decreasing temperature, dramatically increasing the probability of intracellular ice formation. In contrast, for slow cooling rates, the cell dehydrates extensively, allowing the intracellular solution to remain in thermodynamic equilibrium (no supercooling) for temperatures as low as  $-40^\circ\text{C}$ . Thus, the probability of intracellular ice formation will be very small. On the other hand, the loss of cell water caused by slow freezing results in significant increase in the intracellular concentration of cryoprotectant and electrolytes, possibly reaching cytotoxic levels.

The intracellular ice nucleation model is based on classical nucleation theory (Christian, 1975; Turnbull and Fisher, 1949), first applied to intracellular ice formation predictions by Toner (Toner *et al.*, 1990). This model has subsequently been extended to incorporate the effects of cryoprotectant additives on the rate of ice nucleation (Karlsson *et al.*, 1993a, 1994). The total rate of formation of ice nuclei inside one cell is given by

$$J = I_O V + I_S A + I_V V, \quad (2)$$

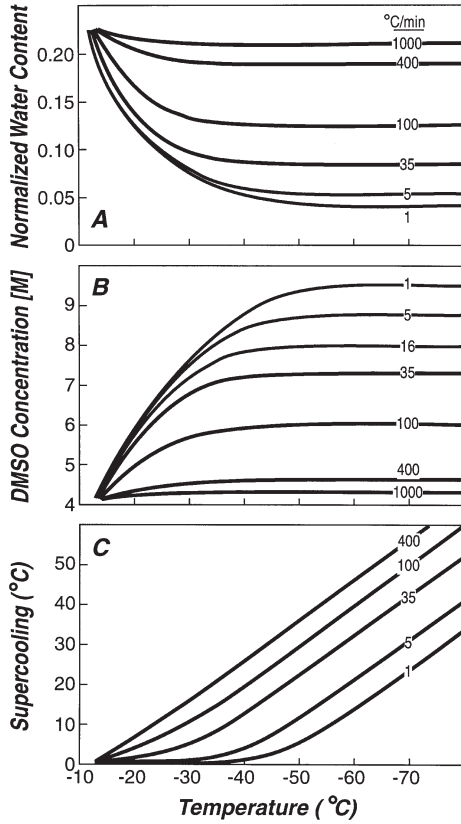

Fig. 24.3. Predicted temperature dependence of intracellular water content (A), DMSO concentration (B), and supercooling (C), during freezing of rat hepatocytes at the indicated cooling rates. Adapted from Karlsson *et al.* (1993a), with permission from the Biophysical Society.

where  $J$  is the nucleation rate per cell;  $I_O$ ,  $I_S$ , and  $I_V$  are specific nucleation rates corresponding to three different mechanisms: homogeneous nucleation ( $I_O$ ), and heterogeneous nucleation mediated by catalytic sites on the cell surface ( $I_S$ ) or inside the cell volume ( $I_V$ ), respectively. According to classical nucleation theory, the rate of homogeneous nucleation has a temperature dependence of the form

$$I_O = \Omega_O \exp[-\kappa_O \Delta T^{-2} T^{-3}], \quad (3)$$

where  $\Delta T$  is the extent of supercooling of the solution, and  $\Omega_O$  and  $\kappa_O$  are the kinetic and thermodynamic nucleation rate parameters, respectively. The coefficients  $\Omega_O$  and  $\kappa_O$  are dependent on temperature and on the chemical composition of the solution (Karlsson *et al.*, 1994). The rates of heterogeneous nucleation can be determined as follows (Karlsson *et al.*, 1993a):

$$I_S = w_S \Omega_O \exp[-k_S \kappa_O \Delta T^{-2} T^{-3}], \quad (4)$$

$$I_V = w_V \Omega_O \exp[-k_V \kappa_O \Delta T^{-2} T^{-3}], \quad (5)$$

where  $w_S$ ,  $k_S$ ,  $w_V$ , and  $k_V$  are kinetic and thermodynamic coefficient scaling factors for surface-catalyzed and volume-catalyzed nucleation, respectively, and are constants that can be determined experimentally (Karlsson *et al.*, 1993a).

The crystal growth model assumes that ice nuclei grow spherically, and that growth is rate limited by diffusion of water monomers to the ice–liquid interface. The total volume of ice forming inside a cell during freezing is given by

$$V_{\text{ice}} = \frac{4\pi}{3} \sum_{i=1}^N \left[ \int_{t_i}^t \alpha^2 D dt \right]^{3/2}, \quad (6)$$

where  $N$  is the number of intracellular ice nuclei;  $t_i$ , the time of nucleation event  $i$ ;  $\alpha$ , a non-dimensional crystal growth parameter; and  $D$ , the effective diffusivity of water in the cytoplasm.  $N$

Fig. 24.4. Predicted volume fraction of intracellular ice during freezing of mouse oocytes at the indicated cooling rates. The cells were equilibrated with 2 M (A) or 8 M (B) glycerol prior to freezing. For simplicity, homogeneous nucleation ( $I_O$ ) was the only ice formation mechanism included in these simulations. Reprinted with permission from Karlsson *et al.* (1994), *J. Appl. Phys.* 75(9), Fig. 4, p. 4448. Copyright 1994, American Institute of Physics.

and  $t_i$  can be determined from Eq. (2); the calculation of  $\alpha$  and  $D$  has been previously described by Karlsson *et al.* (1994).

Figure 24.4 illustrates the effects of cooling rate and cryoprotectant concentration on ice formation in mouse oocytes. When freezing the cells in 2 M glycerol, the cell volume crystallizes completely on appearance of the first ice nucleus. However, the nucleation temperature can be depressed either by using slow cooling to dehydrate the cell, or by using ultrarapid cooling to lower the ice formation temperature kinetically (Karlsson *et al.*, 1994). When 8 M glycerol is used, ice crystal growth is arrested before the volume of intracellular ice reaches damaging levels, for all cooling rates. This effect is due to the lowering of the water diffusivity  $D$  by highly concentrated cryoprotectant solutions, and is the basis for vitrification technology (Fahy *et al.*, 1984). Innocuous levels of intracellular ice formation can also be achieved with lower, nontoxic concentrations of cryoprotectant, by using a multistep temperature profile with an initial slow cooling step to dehydrate the cell, and a subsequent rapid cooling step to suppress ice nucleation kinetically (Karlsson *et al.*, 1996). Mathematical models are essential in designing and optimizing such protocols.

### CRYOPROTECTANT ADDITIVES

Polge and co-workers discovered in 1949 that addition of glycerol to a suspension of spermatozoa prior to freezing resulted in a dramatic increase in the number of viable cells recovered after thawing (Polge *et al.*, 1949). Many other chemicals have since been found to have cryoprotective properties, but glycerol and dimethyl sulfoxide (DMSO) remain the most commonly used to date. Cryoprotectants are typically categorized into two groups according to their ability to enter the cell. Examples of permeating cryoprotectants include glycerol, DMSO, ethylene glycol, and 1,2-propanediol. Nonpermeating cryoprotectants include polyvinyl pyrrolidone, hydroxyethyl starch, and various sugars (e.g., trehalose). The mechanism of cryoprotection by these chemicals is not fully understood. However, both permeating and nonpermeating cryoprotectants reduce the concentration of intracellular water, thus reducing the rate at which the remaining water molecules can form damaging ice crystals. Furthermore, permeating cryoprotectants act as a solvent, diluting the intracellular electrolyte solution when water is removed from the cell during freezing, and thus protecting the cell from damage due to solution effects (Mazur, 1984). There is also evidence that cryoprotectants may directly interact with the plasma membrane and cell proteins to stabilize these structures (Timasheff, 1982; Anchordoguy *et al.*, 1991). Nonetheless, cryoprotectant chemicals may also be cytotoxic, in particular if the time of exposure is long, or if they are used in high concentrations (Fahy, 1986). Cell damage may also occur during the preeeze addi-

Fig. 24.5. Shrink–swell behavior of cells during exposure to a penetrating cryoprotectant additive (CPA). The cell volume initially decreases due to osmotically driven water loss, then increases as cryoprotectant and water enter the cell. Cell damage can result if the transient volume change is too large.

tion and postthaw removal of cryoprotectant, as a result of osmotic stresses (Levin and Miller, 1981). Thus, care must be taken in choosing the type of additive to use, determining the minimum concentration that will result in effective cryoprotection, and designing protocols for addition and removal of the cryoprotectant.

Because the cell membrane is usually more permeable to water than to cryoprotectants, addition of a cryoprotective chemical to a cell suspension will result in the characteristic “shrink–swell” behavior shown in Fig. 24.5. Assuming the cell is initially suspended in an isotonic solution, the addition of cryoprotectant will create a hypertonic environment. Water will be removed from the cell by osmosis, faster than the rate at which the cryoprotectant can diffuse into the cell, and thus the cell shrinks. The rate of water transport decreases as the cell dehydrates, because the increased intracellular tonicity reduces the osmotic pressure difference across the membrane. When the rate of water efflux equals the rate of cryoprotectant influx, the cell volume is at an extremum, after which cryoprotectant permeation will dominate the transport, and the cell will slowly increase in volume as cryoprotectant diffuses into the cell. During this swelling phase, water also reenters the cell, driven by the osmotic pressure difference generated by the intracellular cryoprotectant.

To effect cryoprotectant removal after thawing, the cell suspension is diluted, resulting in dynamics opposite to those observed during cryoprotectant addition. The cells initially swell as water rapidly enters, then slowly shrink as the cryoprotectant diffuses out. The cell volume reaches its maximum when the water and cryoprotectant fluxes balance each other.

Conditions that cause large excursions of cell volume are deleterious (Gao *et al.*, 1995b). There is thought to be a critical minimum cell volume below which cells are damaged (Meryman, 1970). Similarly, if the cell volume becomes too large, lysis may result. Thus, it is important to predict the volumetric response of cells during cryoprotectant loading and dilution, in order to prevent osmotic damage. The coupled transport of cryoprotectant and water across the cell membrane is often modeled using the Kedem–Katchalsky formalism (Kedem and Katchalsky, 1958), but can be adequately described by a two-parameter model (Kleinhans, 1998): The volume flux of cryoprotectant entering the cell is

$$J_a = P v_a (\Pi_a^{\text{ex}} - \Pi_a^{\text{in}}), \quad (7)$$

where  $P$  is the permeability of the membrane to the cryoprotectant;  $v_a$ , the specific volume of the cryoprotectant agent; and  $\Pi_a^{\text{ex}}$  and  $\Pi_a^{\text{in}}$ , the cryoprotectant osmolarity in the extracellular and intracellular solution, respectively. The water flux into the cell is given by

$$J_w = -L_p RT [(\Pi_e^{\text{ex}} + \Pi_a^{\text{ex}}) - (\Pi_e^{\text{in}} + \Pi_a^{\text{in}})], \quad (8)$$

where  $L_p$  is the membrane water permeability and  $\Pi_e^{\text{ex}}$  and  $\Pi_e^{\text{in}}$  are the electrolyte osmolarity in the extracellular and intracellular solution, respectively. The rate of change of the cell volume is then equal to the sum of these two fluxes, multiplied by the instantaneous cell area. The resulting differential equation can be solved numerically (Kleinhans, 1998).

In order to predict the excursions of the cell volume during cryoprotectant loading and removal, the permeability parameters  $L_p$  and  $P$  must be known. They can be determined using stan-

dard parameter estimation techniques by fitting the model equations to measurements of cell volume during a shrink–swell experiment. These measurements can be obtained by video microscopy using specially designed microdiffusion or microperfusion stages, or using electronic particle size counters with large numbers of cells (McGrath, 1997).

If the permeability parameters are known, computer simulations can be used to design protocols for adding and removing cryoprotectant (Levin and Miller, 1981; Arnaud and Pegg, 1990; Gao *et al.*, 1995b). Typically, cryoprotectants are added and removed in multiple steps, in which cells are exposed to a series of solutions, the compositions of which have been optimized to minimize cell volume transients. Furthermore, the time of exposure must be chosen to ensure that cells have fully equilibrated with the solution. A third parameter is the temperature, because cryoprotectant toxicity usually decreases with decreasing temperature. However, whereas the membrane permeability also decreases at low temperatures, there is a trade-off between reduced toxicity and the longer equilibration times required.

## CRYOBIOLOGY OF TISSUE

### TRANSPORT PROCESSES: SIZE EFFECTS

Although the principles of cell cryobiology provide a starting point for the design and optimization of cryopreservation procedures for living tissue and organs, the additional challenges presented by the scale of engineered tissues and organs must be considered (Karlsson and Toner, 1996). On the microscopic length scale of a single biological cell, gradients in temperature, pressure, and solute concentration can typically be neglected; i.e., these quantities can be assumed to be spatially uniform in the cell (Mazur, 1963). However, due to the macroscopic dimensions of tissue, significant spatial variations in the thermal, chemical, and mechanical state of the system are expected. Moreover, because desired changes in flux of mass (i.e., cryoprotectant addition and dilution) and heat (i.e., cooling and warming) can be imposed only at the boundary conditions of the system, our ability to control the state of the tissue during cryopreservation is limited.

The rate of cryoprotectant loading into tissues prior to freezing, and removal after thawing, will be limited by diffusion through the matrix. Cryoprotectant transport kinetics in various types of tissue have been quantified by nuclear magnetic resonance spectroscopy (Fuller *et al.*, 1989), high-performance liquid chromatography (Carpenter and Dawson, 1991), and osmometry (Borel Rinkes *et al.*, 1992a). Typical values for the diffusion coefficient of DMSO in the extracellular matrix are on the order of  $D = 10^{-5}$  cm<sup>2</sup>/sec. For simple tissue geometries, the permeation of cryoprotectant into or out of the tissue can be calculated from solutions of the diffusion equation subject to appropriate boundary conditions (Crank, 1975). In many cases, the penetration depth ( $\lambda$ ) of cryoprotectant into the tissue can be approximated by the equation

$$\lambda \approx \sqrt{Dt}. \quad (9)$$

Thus, DMSO penetrates a tissue to a depth of approximately 1 mm after 15 min, and 2 mm after 1 hr. Equilibration of a 1-cm-thick tissue with cryoprotectant should require overnight incubation. Whereas these time scales are often impractical, and may result in cell damage due to excessive exposure to cryoprotectant, incubation times used in practice often result in incomplete equilibration, with low cryoprotectant concentration in the tissue interior (Hu and Wolfenbarger, 1994).

Mass transport in tissue during freezing and thawing also gives rise to nonuniform concentration distributions; their analysis often requires consideration of coupled heat-transfer and phase-transformation processes, in addition to diffusive transport. Cooling and solidification of tissue can be described by a Stefan-like energy equation (Viskanta *et al.*, 1997): during freezing, the preferential exclusion of solutes from the ice lattice lowers the chemical potential of the unfrozen water, creating a driving force for water transport. Models for the ensuing solute redistribution (Körber, 1988) and cell dehydration (Levin *et al.*, 1977; Rubinsky, 1989) have been derived. Because local thermodynamic equilibrium is assumed at the interface between the growing ice crystals and the unfrozen solution, the energy equation and mass transport models are coupled via the phase diagram of the solution (Viskanta *et al.*, 1997); i.e., not only does the rate of cooling affect the distribution of water and solute in the tissue, but the rate of mass diffusion in the unfrozen liquid affects the temperature distribution in the system. Numerical solutions of the equations governing

tissue freezing indicate that significant gradients in temperature and solution composition result (Rubinsky, 1989; Viskanta *et al.*, 1997).

We know from cell cryobiology that the cooling rate is a major determinant of the outcome of the cryopreservation procedure (see previous discussion of experimental observations of cell freezing). Due in part to the phase change in the tissue, in part to the low thermal conductivity and high heat capacity of biological materials, the local rate of temperature change experienced by a cell will depend on its location within the tissue (Diller, 1992). Thus, localized cell damage may result in sections of tissue in which the rates of cooling and warming are significantly different from the optimal treatment. Thermal gradients may be significant even in cryopreservation of thin tissues such as skin, due to packaging requirements. There are two possible strategies for minimizing heat-transfer-related problems in tissue cryopreservation. The first is to reduce the sensitivity of cell survival to the rate of change of temperature: it is known that cryoprotectants broaden the “survival signature” (Fig. 24.2), increasing the range of survivable cooling rates (Mazur, 1984). The second approach is to improve the rate of heat transfer within the tissue in order to reduce thermal gradients: one promising method is the use of electromagnetic radiation for warming of cryopreserved tissue (Bai *et al.*, 1992).

### DAMAGE MECHANISMS

Cells are the vital element of engineered organs and tissue, and their survival must be a priority in the design of cryopreservation procedures. However, the effects of freezing and thawing on other tissue components, such as extracellular matrix and synthetic elements, must also be considered. Due to the complex structure of organized tissue, there is a larger number of possible damage mechanisms for tissue than for isolated cells (Karlsson and Toner, 1996). The major modes of injury to tissue during cryopreservation are discussed below.

The cooling rate dependence of the survival of cells in cryopreserved tissue is qualitatively similar to the classic survival signature for cells in suspension (Fig. 24.2), indicating that the two-factor hypothesis of freezing injury is also valid for cells in tissue (Borel Rinkes *et al.*, 1992b; Muldrew *et al.*, 1994). However, there are important quantitative differences between cells in tissue culture and isolated cells, and these affect the design of freezing and thawing protocols. For example, corneal keratocytes cultured in monolayers are more sensitive to the cooling rate but less sensitive to cryoprotectant than are disaggregated keratocytes, and the optimal cryopreservation protocols for the cultured and isolated cells are significantly different (Armitage and Juss, 1996). *In vitro* culture has been observed to affect the behavior of other cell types during cryopreservation, typically increasing the probability of intracellular ice formation compared with isolated cells (Karlsson and Toner, 1996). These effects may be due to a number of factors, including facilitation of intracellular ice formation via gap junctions or other cell–cell interactions (Berger and Uhrig, 1996), changes in the biophysical properties of cell membranes by cell isolation procedures or by phenotypic changes in tissue culture (Sandler and Andersson, 1984; Yarmush *et al.*, 1992), and sensitivity to injury dependent on the state of cell adhesion (Hetzl *et al.*, 1973; Hornung *et al.*, 1996).

In addition to these differences between cells in a tissue environment and cells in isolation, there can be differences between cells within the tissue. An obvious but important example is that of tissue in which two or more distinct cell types exist in coculture, such as keratinocytes and fibroblasts in skin (Wilkins *et al.*, 1994) or hepatocytes and fibroblasts in liver (Bhatia *et al.*, 1997). Because the optimal cooling rate (and by extension, the optimal value of other processing parameters) may differ significantly between dissimilar cell types (Karlsson *et al.*, 1993b), development of cryopreservation techniques for tissues with multiple cell species is particularly difficult. Even for a tissue populated with a single cell species, the effective low-temperature response of the cells can depend on their location within the tissue. This effect results from the fact that cell dehydration during freezing and thawing is driven by the low chemical potential of extracellular ice: the larger the distance of a cell from the ice phase, the larger the effective resistance to water transport (Levin *et al.*, 1977; Diller and Raymond, 1990). Thus, in tissues with multiple cell layers, interior cells will retain more water during freezing. Furthermore, physical separation of interior cells from the extracellular ice phase may inhibit surface-catalyzed nucleation of intracellular ice in these cells (Toner, 1993). These factors will give rise to spatially varying requirements for optimal cell survival.

Besides direct injury to cells, cryopreservation procedures may cause damage to molecular

structures critical to tissue function. For example, there is evidence that cryoprotectant additives, osmotic stress, and low temperatures adversely affect intercellular tight junctions in epithelial monolayers (Armitage *et al.*, 1995). Furthermore, cell–substrate attachment points may be a target of cryoinjury, resulting in detachment and loss of cells after freezing and thawing (Hornung *et al.*, 1996). The extracellular matrix is deformed by ice crystals during freezing (Persidsky and Luyet, 1975), and is exposed to hypertonic concentrations of electrolytes and cryoprotectant. Nonetheless, the mechanical properties of tissues such as cartilage and skin do not appear to be significantly affected by the cryopreservation procedure (Arnoczky *et al.*, 1988; Foutz *et al.*, 1992).

Last, we must consider damage to the macroscopic tissue structure. One such mode of injury has been identified in tissues with significant luminal spaces, a common example being a vascularized organ. During the freezing process, ice forms first in the vasculature, causing dehydration of the surrounding tissue (Rubinsky, 1989). If cooling is slow, a significant volume of water will then accumulate and solidify in the vascular space, exerting potentially damaging pressure on tissue structures. In liver tissue, overdistention and rupture of blood vessels and sinusoids by this mechanism is an important mode of cryoinjury (Rubinsky *et al.*, 1990). Potential solutions to this problem can be learned from freezing-resistant and freeze-tolerant organisms such as the wood frog *Rana sylvatica* and the winter flounder *Pseudopleuronectes americanus*, which can survive freezing temperatures by secreting glucose (acting as a cryoprotectant) and antifreeze glycoproteins (which bind the surfaces of ice crystals) into their circulation, respectively, in order to control ice growth in the vasculature (Duman and De Vries, 1974; Storey *et al.*, 1992). Such strategies have met with limited success *in vitro* (Rubinsky *et al.*, 1994).

The macroscopic structure of an organ or tissue may also be compromised by fractures formed in the solidified tissue during freezing and thawing. Due in part to thermal gradients in the specimen, in part to volumetric expansion resulting from the water–ice phase transition, significant stress develops during cooling and warming. These mechanical stresses can exceed the strength of the frozen material, causing fractures in the tissue. Such fractures have proved problematic in the cryopreservation of arteries, because grafts must be intact to be useful clinically (Pegg *et al.*, 1997). Likewise, attempts to preserve more complex organs are hampered by structural damage caused by gross fractures (Fahy *et al.*, 1990; Rabin *et al.*, 1997). Current approaches to mitigate mechanical damage include the use of cryoprotectants, which appear to reduce thermal stress in aqueous solutions (Gao *et al.*, 1995a), and the use of slow warming rates to reduce thermal gradients until glassy regions in the tissue undergo softening (Pegg *et al.*, 1997). Advances in mathematical modeling of thermal stresses during freezing and thawing will make possible the design of cryopreservation procedures that minimize the probability of tissue fracture (Rabin and Steif, 1998).

## SUMMARY AND FUTURE DIRECTIONS

The challenge in development of cryopreservation technology for living biological systems is twofold. The first challenge is to determine the optimal (minimally damaging) protocol among an essentially infinite number of possibilities. The diversity of potential pathways for damage during freezing, thawing, and the loading and removal of cryoprotectant makes it difficult to find a successful procedure. Thus, theoretical modeling of the dominant damage mechanisms is often required to make the optimization problem tenable. Models of cell damage during freezing are now sufficiently advanced to make possible the rational design of cooling procedures using computer simulations. However, although the mechanisms of damage to tissue during cryopreservation are also becoming better understood, adequate models are not yet available for all relevant processes. The second challenge lies in implementation of the cryopreservation protocol determined to be optimal. Due to the macroscopic dimensions and unfavorable transport properties of biological tissue, it is often impossible to impose the designed chemical and thermal profiles uniformly in the tissue, resulting in suboptimal processing. In addition, differences in the optimal protocols for dissimilar tissue components may lead to conflicting requirements in heterogeneous tissue.

Future research efforts toward the development of cryopreservation methods for tissue engineering must therefore focus on the two problems described above. Fundamental experimental and theoretical research is required to elucidate the mechanisms of damage during cryopreservation, and to develop predictive models of these deleterious processes. Likewise, techniques for accurate measurement of the biophysical properties of tissues must be developed in order to obtain necessary model parameters. Strategies toward enabling implementation of optimal protocols in-

clude minimizing temperature and concentration gradients, and improving robustness by decreasing system sensitivity to variations in protocol parameters. Although some of these goals may be achieved by novel technology (e.g., electromagnetic heating to reduce thermal gradients), a complementary approach should be the consideration of cryopreservation requirements in the design of engineered tissues and organs. By suitable choice of device geometry, material properties, and cells, it will be possible to increase system robustness during the chemical and thermal processing required for cryopreservation.

The critical need for effective cryopreservation technology in tissue engineering is an impetus for accelerated efforts toward solving the fundamental problems described in this chapter. Although the remaining scientific and technological challenges are formidable, significant progress has been achieved to date through interdisciplinary research activities, and prospects for the future are bright.

# IMMUNOMODULATION

Denise Faustman

## INTRODUCTION

The application of novel basic science concepts to transplantation may permit a broader and improved therapeutic use of cellular and whole organ transplantation therapies in humans. One embodiment of this concept involves the elimination of immunosuppressive drugs and treatment in the host. For instance, genetically engineered or modified donor cells may be rendered less immunogenic and the host could potentially receive either no immunosuppressive drugs or decreased dosages of drugs. Advances, especially for cellular transplants have allowed novel therapies to progress to human trials. Furthermore, improvements in the immunomodulations of the donor cells, to render them resistant to graft rejection, have identified previously new immune barriers, such as recurrent disease in immunoprotected islet cells due to type I diabetes. In this chapter, the barriers yet to be overcome will be highlighted, especially as they relate to the specific challenges of each clinical setting. The promise of transplantation therapy will be highlighted as it relates to preliminary human trials, even in the setting of cross-species transplants.

A long-standing goal of the transplant community has been to overcome immunologic rejection of transplanted tissues and organs. Although much of the research has been devoted to identifying new immunosuppressive agents and new combinations of existing agents for allotransplantation, immunosuppression still carries significant short-term side effects, especially enhanced susceptibility to infection. For xenografts, even stronger immunosuppressive regimens are expected to be necessary. One solution to xenograft acceptance may reside in novel therapeutic strategies that strive to prevent the need for immunosuppression.

Our laboratory has attempted to avert transplant rejection by immunologically intervening at a new attack point in the rejection cascade. Tissues and cells were treated before transplantation to conceal or eliminate the antigens that summon immune rejection. This technology is sometimes referred to as “donor antigen modification” or, more stylistically, “designer tissue and organs” (Faustman and Coe, 1991). Our intention was to modify the graft at the molecular level in order to avoid immunosuppression of the host. Earlier efforts at modifying the graft at the cellular level by elimination of donor lymphoid cell populations were successful in mice in the allograft setting, but ineffective for whole organ survival in even lower species or in cellular transplants in higher species or across species barriers. Designer tissues and organs modified at the molecular level offered greater selectivity and latitude in tailoring the graft to escape immune detection. Donor antigen modification contrasts with a protocol of bone marrow chimerism (i.e., a bone marrow transplant and a solid organ transplant from the same donor to ensure acceptance of the organ), whereby host immune manipulations are employed.

Without the risks of systemic immunosuppression, designer tissues and organs could be therapeutic for a broad range of chronic conditions that are not life threatening. They also could be offered to conventional organ transplant patients at earlier stages of their disease when patients are healthier and better able to withstand surgical intervention. The main risk with designer tissues and organs is that the modified donor tissue could be rejected, a risk commonly encountered with

any transplant. Because designer tissue can be potentially rendered safer and may ultimately avoid host intervention with toxic drugs, a broader spectrum of diseases could be treated and at earlier time points without induced morbidity.

The purpose of this chapter is to describe the evolution of research on designer tissues and to trace its contribution to a growing body of transplant research. Research in murine hosts demonstrated the successful transplantation of xenogeneic cells and tissues modified at the molecular level without immunosuppression. Transplant success of cells across species by donor antigen modification allowed the extension of these concepts to the genetic level. The ability to modify antigens either at the DNA, RNA, or protein level offers tremendous latitude in the development of new biological therapies. Variations on the designer tissue concept are being probed in animal models of diabetes, solid organ failure, and neurological diseases. A concept launched in the laboratory in the early 1990s has already culminated in landmark human clinical trials for Parkinson's and Huntington's disease using donor-modified pig neurons into humans.

The wide range of applications of designer tissues and organs for allo- and xenotransplantation is readily apparent; modified donor cells, tissues, and organs can be considered potential therapies for an almost limitless number of conditions as long as the dominant antigens are identified and then effectively shielded or eliminated prior to implantation.

## ORIGIN OF THE DESIGNER TISSUE CONCEPT

Our idea of targeting donor antigens instead of modifying the host immune system was stimulated by research on the molecular events surrounding the killing of target cells by cytotoxic T lymphocytes (CTLs; hereinafter referred to as T cells). In an elegant study, Spits and co-workers (1986) identified the sequential stages of T cell destruction of the target cell. In contrast to earlier research, which focussed primarily on the T cell, they examined the roles of cell surface markers on both the T cell and the target cell. By using antibodies against different cell surface markers to block distinct stages, they were able to tease apart *in vitro* the interactions between molecules on the T cell and the target cell. They were among the first to identify three stages in T cell cytotoxicity: (1) adhesion between T cell and target cell, (2) T cell receptor activation, and, (3) T cell lysis of the target cell.

A critical finding was that one of the major classes of histocompatibility antigens on the surface of the target cell—the major histocompatibility complex (MHC) class I molecules—was involved in both adhesion to, and activation of, the T cell. Class I antigens and other classes of antigens encoded by the MHC complex serve to distinguish “self” from “non-self” because they differ across species and between members of the same species. Class I antigens have long been eliciting T cell cytotoxicity, but this study offered more detailed insight into their pivotal role. What this study also demonstrated was that antibodies to class I antigens could prevent T cell adhesion and activation, thereby interfering with lysis.

Spits and co-workers crystallized the importance of class I antigens in immune rejection of tumors. With this study's goal centering on enhancing tumor rejection, we departed on the idea of a central role of target class I antigens as pivotal in tumor escape, and perhaps similarly focused on an opposing role for manipulation in transplantation. As a test antigen, we chose to mask class I on donor cells with antibody fragments, and then transplant the donor antigen-modified cells into nonimmunosuppressed hosts.

## FIRST DEMONSTRATION OF THE CONCEPT

Using a xenogeneic model, the first successful demonstration of the designer tissue concept was demonstrated (Faustman and Coe, 1991). We found that when we coated the graft with antibody fragments to conceal class I antigens, the graft eluded the host immune system indefinitely and functioned normally. The host developed tolerance to the treated graft because secondary transplants of untreated tissue were later accepted. The mechanism of donor-specific tolerance is still not fully defined, but may involve induction of T cell anergy through altered donor class I density. Altered class I density may be pivotal in T cell shaping in both the periphery as well as the thymus, as defined by Pestano *et al.* (1999).

The graft consisted of purified human cadaveric islets that had been incubated with antibody fragments before being implanted into nonimmunosuppressed mice. We decided to produce very

pure antibody fragments because they lacked the portion of the antibody molecule that binds complement, the Fc fragment. When the Fc fragment is enzymatically cleaved from the  $F(ab')_2$  fragment, the purified  $F(ab')_2$  fragment binds to the graft for several days without fixing complement, which would have destroyed the graft. Grafts survived for 200 days and functioned appropriately, as determined by assays for human C' peptide, a proinsulin processing product. Finally, human liver cells similarly treated with antibody fragments also survived for an extended period.

Treatment with whole antibodies to class I antigens failed to prolong graft survival, as did treatment with whole antibodies and antibody fragments to CD29. CD29 is an antigen uniquely expressed on the passenger lymphocytes that accompany the graft because they cannot be entirely eliminated during the purification process. Finally, treatment of the graft with polyclonal antibody fragments to all antigenic determinants on human islets prolonged graft survival until the point when class I antibody fragments were removed from the mixture. Graft rejection ensued at a slower rate, attesting to the critical role of class I antigens as pivotal for this transplantation barrier, although recognizing the possible importance of other antigens in additional immune responses.

For the sake of rigor, we selected a xenogeneic instead of an allogenic model to test the designer tissue concept. If designer tissues could succeed in the demanding case across a species barrier, then they could be considered for simpler antigenic models. In other respects, however, our xenogeneic model represented the height of simplicity. First, the tissue contained only one dominant antigen that needed to be masked. We found that human islet tissue highly expressed class I antigens, while displaying only minimal expression of two adhesion molecules, intercellular adhesion molecule-1 (ICAM-1), and lymphocyte function-associated antigen-3 (LFA-3) (which in other tissues are thought to stabilize binding and to contribute to T cell activation). Second, the vasculature could be separated from the tissue to avoid hyperacute rejection, the earliest and most formidable barrier to discordant xenograft acceptance. Third, our model targeted antigens at the protein level rather than at the genetic level. Our goal was to conceal protein antigens that already appeared on the surface of graft cells. Other approaches, discussed later in this chapter, targeted antigens not at the protein level, but at the DNA and RNA level. The use of more sophisticated transgenic and antisense technology, respectively, can similarly prevent antigen expression and validated the donor antigens as a target for the immune response.

In summary, this tough xenogeneic model confirmed the paramount role of class I antigens in islet cell rejection. By providing a challenging test of the designer tissue concept, it also helped to launch a novel therapeutic strategy.

## EXPANSION OF RESEARCH ON DESIGNER TISSUES

After our study was published, our laboratory and others began to probe the potential of designer tissues, using a variety of donor antigen modifications techniques as well as masking antigens with protein fragments in varying transplantation settings. The body of early research, in part summarized in Table 25.1, can be classified in four distinct groups based on the technique used to modify the donor tissue. The techniques currently employed for donor antigen modification are presented in Table 25.1 as it relates to the level of interference utilized to prevent normal cell surface protein expression. The methods include antibody masking, gene ablation, gene addition, and RNA ablation.

### ANTIBODY MASKING

Antibody masking of xenogeneic tissue is the first of the donor antigen modification techniques to progress to primate and human trials. Pancreatic islet cells and neurons are the most common types of donor cells to be camouflaged with antibody masking, although any type of tissue can theoretically be treated once the dominant antigens have been identified. All of the studies cited below targeted class I antigens using antibody fragments.

Islet cell masking for the treatment of diabetes was early on pursued with mixed results. Osorio and colleagues (1994b) targeted class I antigens in a mouse allograft model. To approximate a diabetic state, the mice first were treated with a drug that chemically induced hyperglycemia. Then they received islet allografts that had been pretreated with antibody fragments. Graft survival was prolonged relative to controls, but within one month the grafts were eventually rejected.

**Table 25.1. Designer donor tissues<sup>a</sup>**

Technique/tissue	Allo/xeno	Donor/recipient	Target	Ref.
<b>Masking antibody</b>				
Islets	Xeno	Human/mouse	Class I	Faustman and Coe (1991)

<sup>b</sup>Human serum *in vitro*.

Investigators attributed eventual allograft rejection to a variety of possibilities, including the absence of sufficient quantities of F(ab')<sub>2</sub> fragments, antiidiotypic antibodies against the F(ab')<sub>2</sub> fragment, and an immune pathway independent of class I activation of T cells.

Steele and colleagues (1994) investigated islet cell transplants in a primate model. Cynomolgus monkeys received either allogeneic or xenogeneic (human) islets. The grafts were pretreated with antibody fragments to class I antigens. Histologic evidence of donor islets were present months after transplantation into nonimmunosuppressed monkeys.

Neuronal xenografts with antibody masking have been investigated for Huntington's disease (Pakzaban *et al.*, 1995) and Parkinson's disease (Burns *et al.*, 1994). In the first study, fetal pig striatal cells were implanted into rats whose striatum had been lesioned 1 week earlier with injections of quinolinic acid. These injections destroy striatal neurons in an attempt to stimulate the dysfunction present in Huntington's disease. Rats received either untreated tissue or tissue pretreated with F(ab')<sub>2</sub> fragments against porcine class I antigens. Of the control rats receiving untreated tissue, some were immunosuppressed with cyclosporin A (CsA) whereas others were not. Three to

four months later, graft survival was found to be prolonged in animals given F(ab')<sub>2</sub>-treated grafts and in the CsA-treated animals given unaltered grafts. Grafts did not survive in nonimmunosuppressed controls. Graft volume, determined histologically with the aid of computer image analysis, was significantly larger in the CsA group compared with the F(ab')<sub>2</sub> group. Yet in both of these groups, immunohistochemistry revealed graft cytoarchitecture to be well organized and graft axons to have grown correctly in the direction of their target nuclei. It was encouraging that pig neurons appeared to be capable of locating their target.

In a similar study design, Burns and co-workers (1994) applied antibody masking to a primate model of Parkinson's disease. Porcine mesencephalic neuroblasts were implanted into monkeys with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced Parkinsonism. Measures of locomotor activity and dopamine fiber density in the host striatum confirmed that pretreatment of donor tissue with F(ab')<sub>2</sub> fragments succeeded in restoring motor function and replenishing dopamine fibers at the site of implantation. A control animal, maintained on CsA after receiving untreated cells, showed similar improvement. A nonimmunosuppressed control showed no improvement after transplantation, suggesting graft rejection.

The studies described in this section highlight the range of potential applications of antibody masking in both allo- and xenotransplants. Islet cell masking has encountered unexpected hurdles in the application of type I diabetes. However, neuronal cell masking has been sufficiently effective to usher in human clinical trials.

## GENE ABLATION

Gene ablation, or gene "knockout" technology, offers another vehicle to modify donor tissue and organs. With gene ablation, the gene or genes encoding protein antigens can be permanently deleted, thereby eliminating antigen expression in all cells. In one common method of gene ablation, the target gene is inactivated in cultured embryonic stem cells via homologous recombination; a target vector containing an inactive version of the gene recombines with, and thereby replaces, the wild-type gene. Through reintroduction of the embryonic cells into a foster mother and through selective breeding, progeny can be produced that are homozygous for the mutation. Rejection by the host immune system is expected to be avoided when the targeted gene encodes a protein antigen slated for expression on the surface of donor cells.

The major advantage of gene ablation over protein modification of donor tissue is that the antigen is permanently eliminated in all cells, tissues, and organs in which it is expressed. The major limitation is that it is available only in mice, which are too phylogenetically distant from humans to be considered as suitable donors. The permanent nature of the modification also can sometimes be a limitation, especially when the protein encoded by the gene has additional functions. Inactivation of the gene might lead to physiological changes that compromise the utility of the donor tissue. Gene ablation can also target genes that encode proteins essential for the target protein expression.

Several transplantation laboratories have exploited the availability of knockout mice deficient in  $\beta_2$ -microglobulin.  $\beta_2$ -Microglobulin is a peptide that performs a chaperone function as part of the class I molecule and is necessary for its assembly and expression. Mice homozygous for the  $\beta_2$ -microglobulin mutation fail to display class I antigens on the cell surface, a feature that makes them highly desirable for transplantation studies. Although much of the research described below has focused on islet cell and liver cell xenotransplants, one project examined whole organ allografts. Coffman and co-workers (1993) found that kidneys from  $\beta_2$ -microglobulin-deficient mice functioned significantly better in allogeneic recipients than did kidneys from normal mice.

The fate of pancreatic islet transplants from  $\beta_2$ -microglobulin-deficient mice has been explored in several studies. The islets showed prolonged survival when implanted into a normal mouse strain (Markmann *et al.*, 1992; Osorio *et al.*, 1993). Most grafts survived indefinitely (>80% beyond 100 days) and were capable of reversing hyperglycemia that had been chemically induced prior to transplantation. Investigators attributed the few instances of graft rejection to three possibilities. First, some surface expression of class I antigens can occur in the absence of  $\beta_2$ -microglobulin. The presence of even a fraction of the total number of class I antigens may be sufficient for T cell recognition and lysis. Second,  $\beta_2$ -microglobulin circulating in the serum of the recipient can be used to reconstitute class I antigens on the donor tissue (because  $\beta_2$ -microglobulin is a highly conserved protein not encoded by genes at the MHC locus). Third, rejection of the

tissue from  $\beta_2$ -microglobulin-deficient donors may be mediated by other immune pathways, such as by natural killer cells. Support for the second and third possibilities was presented by Li and Faustman (1993) in their study of liver cell allo- and xenografts.

### MECHANISMS OF GRAFT SURVIVAL AFTER CLASS I DONOR ABLATION OR ANTIBODY MASKING

The performance of highly divergent cross-species transplants has allowed the  $\beta_2$ -microglobulin-deficient donor model to be more closely studied. First, as the donor and recipient diverge phylogenetically, so does the homology of the  $\beta_2$ -microglobulin proteins, and donor grafts have slower reconstitution of surface class I with host  $\beta_2$ -microglobulin. These highly divergent cross-species transplants demonstrate delayed  $\beta_2$ -microglobulin reconstitution of surface class I from the serum from host animals. Unfortunately, these grafts demonstrate shortened survival times, suggesting some donor class I antigen expression is beneficial after the transplant is established.

The reconstitution of donor surface class I with host  $\beta_2$ -microglobulin in the gene ablation model or even in the antibody masking model has a marked advantage. The grafts in the majority of cases survive indefinitely. Furthermore, the primary grafts permit secondary nongenetically manipulated or non-antibody-masked grafts to survive similarly if from the same donor (Faustman and Coe, 1991). The data in total suggest donor-specific tolerance occurs in these transplant models.

This important demonstration of tolerance induction was studied by the use of gene ablation models with more permanent class I ablation. With the thought that a little is good so more should be better, other gene ablation models, such as the ablation of other class I assembly genes, were tested, i.e., genes *Tap1*, *Tap2*, *Lmp2*, *Lmp7*, etc. Often these donor gene ablation models were used as F<sub>1</sub> donor mice with two sequential class I processing steps interrupted. Uniformly, these cellular transplants from these donors performed less well and the hosts never developed secondary tolerance sufficient for secondary same-donor transplants (D. Faustman, personal communication).

Insights into the mechanisms of T cell tolerance in hosts receiving class I-ablated grafts may have recently been clarified. In a publication by the Cantor laboratory, peripheral CD8 T cell tolerance was mechanistically characterized from the viewpoint of peripheral tolerance maintenance (Pestano *et al.*, 1999). It has been recognized for years that the persistence of peripheral class I-expressing cells is necessary for peripheral CD8<sup>+</sup> T cell tolerance (Vidal-Puig and Faustman, 1994). Using  $\beta_2$ -microglobulin-deficient hosts, transferred and potentially cytotoxic and mature CD8 T cells were transferred into the mutant host. The transferred T cells then failed to engage their T cell receptors. The CD8 cells down-regulated their CD8 gene expression and underwent apoptosis. Thus inhibition or interference of the T cell receptor and CD8 binding to host class I triggered these CD8 cells into a pathway of cell death. This is an extremely important observation and probably underlies the reason why  $\beta_2$ -microglobulin or class I-masked donor cellular transplants escape T cell death. The lack of class I expression immediately after transplantation eliminated potential T cell killing. As the graft gradually reexpresses class I, it is protected from the next layer of the immune response, natural killer cell lysis of totally class I-negative transplants.

### PREVENTION OF GRAFT REJECTION DOES NOT PREVENT RECURRENT DISEASE: THE CHALLENGE OF CELLULAR TRANSPLANTS IN TYPE I DIABETES

The fate of pancreatic islet transplants from  $\beta_2$ -microglobulin-deficient mice has been explored in several studies. The islets show prolonged survival when implanted into allogeneic mouse strains (Markmann *et al.*, 1992; Osorio *et al.*, 1993). Graft rejection of donor antigen-modified islets almost invariably occurs when the recipients are already nonobese diabetic (NOD) mice (Markmann *et al.*, 1992). This recurrent disease process is a barrier that is not overcome by xenografts. Soon after implantation, NOD mice, at a slightly delayed rate, reject islet allografts from  $\beta_2$ -microglobulin-deficient mice or class I-masked xenogeneic islets. This is in contrast to the success with recipients whose diabetes is chemically induced. NOD mice, unlike those with chemically induced diabetes, spontaneously develop an autoimmune form of diabetes that destroys the grafts. In this respect, NOD mice more closely resemble humans with type I diabetes.

Previous reports have published many effective therapies that prevent autoimmune diabetes development in animal models. The list is long and experiments are not always consistent, making it difficult to identify therapies that are effective at preventing NOD disease. In contrast to the

<sup>c</sup>Recipients were prediabetic NOD mice and grafts were xenografts of pig origin.

long list of “cures” for the not-yet diabetic NOD mouse, the list of “cures” for the already diabetic NOD mouse is short (Table 25.2). The transplant barrier of achieving long-term islet survival in diabetic NOD mice is a significant problem that largely stands unconquered.

Since 1992, two research groups have published new therapies for diabetic NOD and BB rodents, combining them with syngeneic islet transplantation. The data are limited and in most cases the work was unsuccessful, except for some approaches utilizing tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) or direct inducers or mimics of TNF- $\alpha$  such as the bacillus of Calmette–Guerin (BCG), lipopolysaccharide (LPS), or interleukin-1 (IL-1). As Table 25.2 shows, TNF- $\alpha$  or TNF- $\alpha$  stimulants retard the recurrent and very brisk autoimmune destruction of syngeneic islets. It should be stressed the isogeneic islet survival is not permanent. A histologic examination of the syngeneic grafts in NOD mice reveals that TNF- $\alpha$ -treated mice have transplanted islets surrounded by large clusters of mononuclear lymphocytes and, with extended transplantation times, invading lymphocytes, thus explaining that syngeneic islet survival is prolonged and rarely permanent.

Table 26.2 highlights the next significant problem, i.e., the allograft survival data. If the data are extended to the more clinically relevant allograft islet transplant barrier, islets are uniformly rejected when transplanted into already diabetic NOD mice. In fact, an inspection of the peer-re-

viewed literature indicates a remarkable paucity of success, other than a single report of a non-clinically applicable approach (lymph node irradiation with bone marrow transplantation) and encapsulation data published frequently as meeting abstracts and a report using islets with ablated glutamic acid decarboxylase (GAD). The lack of success of islet allografts and xenografts in diabetic NOD or BB rodents still allowed the launching of many of these same new approaches in human clinical trials in type I diabetic patients. Ideally, islet allograft methods should work in relevant autoimmune animal models prior to human clinical trials. As Table 26.2 demonstrates, most if not all of the major islet transplant strategies have been tested in NOD mice or BB rats and failed to demonstrate efficacy. Again, Li and colleagues demonstrated prolonged islet allograft survival in already diabetic NOD mice, but this involved total-body irradiation with bone marrow transplantation (Li *et al.*, 1995).

Graft rejection almost invariably occurs, however, when the recipients are NOD mice (Markmann *et al.*, 1992; Osorio *et al.*, 1994a). Islet allografts from  $\beta_2$ -microglobulin-deficient mice are rejected by NOD mice at a slightly delayed rate, but still soon after implantation. This is in contrast to the success with recipients whose diabetes is chemically induced. NOD mice, unlike those with chemically induced diabetes, spontaneously develop an autoimmune form of diabetes that destroys the graft because it displays a variety of antigens identical to autoantigens. In this respect, NOD mice more closely resemble humans with type I diabetes. These findings suggest that elimination of class I antigens alone will not be sufficient for the treatment of humans with type I diabetes. One of the many directions for future research is to pinpoint on the graft the autoantigens that induce autoimmune rejection.

Elimination of class I antigens also may be insufficient for selected tissues and selected combinations of donor and host species. Liver cells from  $\beta_2$ -microglobulin-deficient donors were implanted into allogeneic recipients and two different of xenogeneic recipients (Li and Faustman, 1993). The allotransplants and the xenotransplants into guinea pigs were not effective. In contrast, xenotransplants of mouse cells into frog recipients survived; when liver cells were transplanted from humans to mice in antibody-masking experiments, they were accepted (Faustman and Coe, 1991). These studies show the results of class I antigen removal to varying extents, according to the species combination of donor and host.

Gene ablation experiments have demonstrated the advantages and limitations of eliminating class I antigens. There are clearly dominant antigens on islet cells and neurons in some allogeneic and xenogeneic combinations. However, class I antigens may play a secondary role depending on the type of donor tissue, the species combination, and/or the disease state of the recipient. In these cases, other dominant antigens need to be identified and targeted.

## THE LAUNCHING OF XENOGENEIC HUMAN CLINICAL TRIALS IN THE UNITED STATES USING IMMUNOMODULATION

Few cross-species transplantation technologies have progressed to human clinical trials. In part this has been due to primate models showing minimal efficiency. Also, early whole organ human clinical trials in the 1970s demonstrated minimal success, even with massive dosages of immunosuppression. Finally, some segments of the medical community have been concerned about cross-species infections, therefore necessitating new technologies to avoid the use of donor species closely related to humans, i.e., baboons. The testing of novel transplantation approaches needs to avoid the limitation of a severely compromised host immune system with decreased resistance to fight infections.

Clinically close primate and rat models are available for neurological diseases such as Parkinson's disease. Using the masking class I antibody fragment approach, animal studies show promise for porcine neurons for spinal cord injuries in rat models and porcine liver cells for transient liver failure from hypotension or infection. Fetal neuronal xenografts with antibody masking have been investigated for Huntington's disease and Parkinson's disease (Deacon *et al.*, 1997). In the first study, fetal pig striatal cells were implanted into rats whose striatum had been lesioned 1 week earlier with injections of quinolinic acid. These injections destroy striatal neurons, and attempt to stimulate the dysfunction present in Huntington's disease. Rats received either untreated tissue or tissue pretreated with F(ab')<sub>2</sub> fragments against porcine class I antigens. Of the control rats receiving untreated tissue, some were immunosuppressed with CSA and others were nonimmunosuppressed. Graft volume, determined histologically with the aid of computer image analysis, was

significantly larger and well-organized, and graft axons were correctly grown in the direction of their target nuclei. It was encouraging that pig neurons appeared to be capable of locating their target. Also, because of the use of fetal tissue, the transplanted mass was significantly enlarged at the time of autopsy, demonstrating posttransplantation survival as well as growth of the transplant. Six Parkinson's patients have now been treated with fetal pig neurons masked with class I antibody fragments and have reported long-term survival (>2 years), with patients demonstrating mild to marked functional improvements. Six more patients were similarly treated with fetal pig neurons and CSA. These patients showed less clinical improvement but still had function exceeding base line. At 8 months, one of these patients died of a thromboembolic event and an autopsy was performed. As reported by Deacon *et al.* (1997), similar to the primate studies performed before clinical trials, the fetal pig neurons survived and correctly produced axons over long distances in the brain toward their target nuclei. This confirmed the optimism of the suitability of using pig tissue in this transplant setting, and the masking approach to decrease tissue immunogenicity.

Additional clinical trials of masked neuron transplants have continued in the United States. To date, an additional 11 patients in a Food and Drug Administration (FDA)-scrutinized clinical trial have been enrolled in a phase II/III trial using pig cells for Parkinson's disease. The FDA has approved 36 patients for 18 months in this blinded human study for safety and efficacy. The advantages of the donor antigen modifications methods include the lack of host interventions, thus allowing a broader audience for applications of cellular transplants for disease treatments.

## GENE ADDITION

Gene addition is a technique especially promising for transplantation of solid organs, the most challenging type of transplant, and represents another form of donor antigen modification. Solid organs are particularly troublesome from the point of view of transplantation and they are subject to hyperacute rejection. Hyperacute rejection, the first wave of assault against discordant xenografts, results in rapid rejection within minutes to hours. The vascular endothelium, which cannot be removed prior to transplant, expresses the epitope, the target of hyperacute rejection (Platt, 1994). Preformed antibodies that bind to  $\alpha$ -Gal activate complement, resulting in loss of vascular integrity, hemorrhage, ischemia, and necrosis.

Gene addition involves the insertion of a foreign gene (or transgene) early in development. The desired gene is microinjected into the nucleus of a fertilized egg, thereby giving rise to a mature animal with the transgene incorporated into the genome of each cell. The desired gene or genes used thus far in xenograft research encode proteins designed to inhibit hyperacute rejection. Gene addition is advantageous because it can be readily undertaken in many kinds of donor animals, particularly swine. Swine are among favored donor animals for solid organ transplants because of their ease of breeding and domestication, low maintenance costs, similarities to humans in organ size and physiology, and fewer ethical objections. The other advantages of gene addition, like those for gene ablation, are permanence and versatility. Many sections of this book highlight these approaches and are discussed in detail in other chapters.

## RNA ABLATION

RNA ablation is another promising strategy that strives to prevent antigen expression at the RNA level by blocking transcription or translation. RNA ablation can be achieved through the creation of oligodeoxynucleotides that are complementary to, and hybridize with, DNA or RNA sequences to inhibit transcription or translation, respectively.

RNA ablation in the transplant field has been less frequently pursued to date. For example, Ramanathan and co-workers identified an oligodeoxynucleotide that inhibited induction of class I and ICAM expression by interferon- $\gamma$  (Ramanathan *et al.*, 1994). The studies were performed *in vitro* in a cell line, K562, that normally has low-level expression of class I antigens. They first postulated that the oligodeoxynucleotide acted in the early stages of interferon- $\gamma$  induction rather than posttranslationally. In their follow-up study, they showed that the oligodeoxynucleotide acted even earlier via a novel mechanism—it inhibited binding of interferon- $\gamma$  to the cell surface (Ramanathan *et al.*, 1994; Ramakrishnan and Houston, 1984). This may be an unusual mechanism for an oligodeoxynucleotide, but it only enhances the possibilities for xenotransplant research. What these studies provide is yet another means of blocking expression of class I antigens or other transplantation antigens.

## COMMENT

Designer tissues and organs through donor antigen modification hold tremendous promise for xenotransplantation. Research in animal models has already demonstrated that long-term xenograft survival can be achieved without immunosuppression. This achievement has galvanized the transplantation community, for it shows that an overwhelming obstacle to xenograft acceptance can be alleviated in select settings. Immune rejection need not occur if graft antigens can be immunologically masked or genetically eliminated. Researchers now have at their disposal a battery of techniques that operate at the DNA, RNA, or protein level to remove or conceal antigens. Xenotransplantation is within reach, not just for patients with life-threatening conditions, but also for patients with chronic conditions. As testimony to widespread applications for chronic conditions, the first clinical trial of designer tissues is for patients with Parkinson's disease.

The successes with cellular and tissue xenografts still are not the final solution for the far more difficult task of whole organ xenotransplantation or recurrent autoimmune disease. Solid organs have a multiplicity of antigens, particularly those which elicit hyperacute rejection. Once all of the dominant antigens are identified, the therapeutic strategy for whole organs and tissues is conceptually identical—modify the donor, not the host. The barriers for recurrent autoimmunity still stand, but it is hoped that donor antigen modification is beneficial.

# IMMUNOISOLATION

Beth A. Zielinski and Michael J. Lysaght

## INTRODUCTION

Serious investigative efforts in the field of immunisolated cell therapy began in the late 1970s and early 1980s. Since then, cellular encapsulation has evolved into a broad-based approach for the delivery of gene products for treating diseases or conditions that respond to sustained release of biotherapeutic substances. This review chronicles the technological developments underlying the progress and evolution in cell therapy and summarizes results available from the initial clinical evaluations of this approach.

Two decades ago, Chick *et al.* (1977) and later Lim and Sun (1980) successfully maintained glucose homeostasis in chemically induced diabetic rats using encapsulated allogeneic islets. Efforts to develop the artificial pancreas have continued and have fostered the development of an expanding array of device formats relying on a large repository of biomaterials. Cell encapsulation technology has also expanded to the treatment of chronic pain (Sagen *et al.*, 1993; Joseph *et al.*, 1994; Decostard *et al.*, 1998) and to neurodegenerative diseases, including Parkinson's disease (Tresco *et al.*, 1992a,b; Aebischer *et al.*, 1994a; Tseng *et al.*, 1997; Sautter *et al.*, 1998), Alzheimer's (Hoffman *et al.*, 1993) and amyotrophic lateral sclerosis (ALS) (Sagot *et al.*, 1995; Tan *et al.*, 1996). Other disorders that have been addressed with this type of therapy include hypocalcemia (Aebischer *et al.*, 1986), dwarfism (Chang *et al.*, 1993), anemia (Koo and Chang, 1993; Rinsch *et al.*, 1997), hemophilia (Colton, 1996; Brauker *et al.*, 1998), and cancer (Geller *et al.*, 1997a,b). Human trials have been initiated for diabetes (Soon-Shiong *et al.*, 1994; Scharp *et al.*, 1994), chronic pain (Aebischer *et al.*, 1994b; Buscher *et al.*, 1996), and ALS (Ezzell, 1995; Aebischer *et al.*, 1996).

## TECHNOLOGY

Encapsulation is based on the premise that cells, once sequestered within a semipermeable membrane, are isolated from the immune system and therefore cannot be recognized and/or destroyed by normal host defenses. The membrane also presents a barrier to any potential outgrowth of cells into the host parenchyma, thus permitting the use of mitotically active cell lines. Bidirectional diffusion through the membrane of small-molecular-weight molecules such as oxygen, glucose, cellular secretogues, and bioactive cellular products allows for continued maintenance of encapsulated cell viability and sustained release of the molecules of interest. Species such as host complement, antibodies, and immune effector cells may be inhibited from passing through the membrane (Fig. 26.1). Available barriers range from tight (approximately 30-kDa molecular-weight cutoff, semipermeable) to open (up to about 0.6- $\mu$ m pore size, microporous). Immunogenicity of the encapsulated cell population plays a key role in governing the selection of a membrane with the appropriate molecular-weight cutoff (Colton, 1996). Microporous membranes are increasingly being investigated for encapsulated allogeneic cells, i.e., cells isolated from and implanted into members of the same species. Relevant mechanisms of host recognition and immunoreactivity appear cellular in nature and therefore may require only the exclusion of host ef-

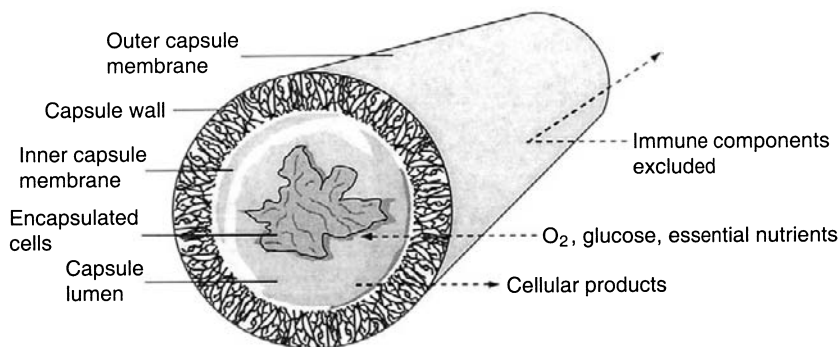

Fig. 26.1. A cross-sectional view of cells encapsulated in a polymer hollow-fiber macrocapsule. Diameter is typically 600 to 1200  $\mu\text{m}$ . Wall thickness is approximately 10% of diameter. Cells grow within the lumen of the hollow fiber and are protected from host immune destruction by the semipermeable polymer membrane. Low-molecular-weight species such as cellular secretogues, oxygen, glucose, and other essential nutrients pass through the membrane freely, thus maintaining cell viability and allowing for continuous release of bioactive cellular products. Depending on the selectivity of the encapsulating membrane, host antibodies and complement components may be wholly or partially excluded from the capsule lumen. Host immune effector cells are always prevented from passing through immunoisulatory membranes.

factor cells. Tighter membranes, although potentially more restrictive to diffusion of nutrients and secreted product, seem preferable when encapsulating xenogeneic cell types, i.e., cells isolated from tissue derived from a member of a species other than that of the implanted recipient. Membranes of this type include those having lower molecular-weight cutoffs and those alternatively designed to trap host immune complexes and prevent their entry into the capsule lumen (Colton, 1996; Wang, 1998). Xenogeneic cells may induce cellular and humoral immune responses based on immunoreactive secretogues and appear vulnerable to natural and elicited antibodies and to host complement. In addition, transfer of xenogeneic virus from transplant to host is also a concern. Thus, tighter membranes not only provide protection against cellular attack but may also confer protection against immune rejection mediated by macromolecules and retard xenogeneic viral transfer (Colton, 1996; Morris, 1996).

Several capsule formats have been studied. Biohybrid implants directly anastomosed to host vasculature have been examined in both rodents and pancreatectomized diabetic dogs (Sullivan *et al.*, 1991; Maki *et al.*, 1993). Vascular implants have waned in popularity as a result of their intrinsic complexity and the need for long-term anticoagulation when using blood-contacting devices. Nonvascular devices include spherical microcapsules, cylindrical hollow-fiber macrocapsules, flat sheet devices (Geller *et al.*, 1997b), and planar macrocapsules (Ezzell, 1995). Microcapsule implants can be formed by interfacial coacervation of weak polyelectrolytes such as sodium alginate and poly(L-lysine) (Lim and Sun, 1980) or chitosan and carboxymethylcellulose (Yoshio-ka *et al.*, 1990). In one popular approach, droplets of cells suspended in sodium alginate are dripped into a bath of calcium chloride, resulting in formation around the droplet of an interfacial film of insoluble calcium alginate. The droplets can subsequently be overcoated with several alternating layers of poly(L-lysine) and alginate. In a related technique, water-insoluble polyacrylates can also be formed into microcapsule walls by interfacial precipitation (Boag and Sefton, 1987; Dawson *et al.*, 1987; Sugamori and Sefton, 1989; Mallabone *et al.*, 1989; Crooks *et al.*, 1990; Broughton and Sefton, 1990). Here, cells are suspended in a polymer solution and extruded into a precipitating bath of nonsolvent. Viability of encapsulated cells in this system, however, appears to be marginal possibly because of contact with organic solvent during preparation or because of inadequate diffusive properties of the polymeric membrane (Crooks *et al.*, 1990). A single spherical bead typically contains only a few hundred cells or a single islet, and tens or hundreds of thousands are required to provide a full therapeutic dosage. In contrast, macrocapsules employ much larger depots to contain the full therapeutic dosage in one or a few implants. Macrocapsules are shaped as cylinders or planes and typically one dimension is held below 1 mm. Macrocapsules are fabricated from preformed hollow-fiber or planar membranes prepared by phase inversion of

water-insoluble polymers quenched in a nonsolvent bath. Molecular-weight cutoff of the membrane depends on conditions of fabrication and formulation and may be selected to be in a range from 30 kDa to over  $10^6$  Da. The resulting membranes are then filled with cell suspension and sealed appropriately. In contrast to spherical microcapsules, lumens of macrocapsule implants are usually completely empty prior to cell loading and therefore require the addition of a supportive matrix for optimal cell viability. Both natural and synthetic luminal matrices have been investigated. Natural matrices include polysaccharides such as alginate and chitosan and cross-linked proteins such as collagen (Lanza *et al.*, 1992; Zielinski and Aebischer, 1994). All are hydrogels with low (2–5%) solid content and hence offer little resistance to diffusive transport. Investigation of synthetic matrices has included the use of poly(vinyl alcohol) (PVA) foams (Li *et al.*, 1998).

Three types of cells may be employed for encapsulation: primary postmitotic cells, mitotically active cell lines, and engineered cell lines (Colton, 1996). Postmitotic cell types, particularly islets of Langerhans, dominate early literature (Chick *et al.*, 1977; Lim and Sun, 1980; Sullivan *et al.*, 1991; Lacy *et al.*, 1991; Lanza *et al.*, 1992, 1993; Gerasimidi-Vazeou *et al.*, 1992; Soon-Shiong *et al.*, 1993; Maki *et al.*, 1993). Primary cells are isolated from excised glands of donor animals. The cells are enzymatically digested, adapted to *in vitro* tissue culture conditions, and then encapsulated. Primary cells are advantageous when regulated release or the secretion of multiple cellular products is desired. Postmitotic cells also adequately provide initial insight into therapeutic efficacy, although isolated tissue may not be available in sufficient quantity to keep up with demands of most applications in large animal studies or human applications. Both allogeneic and xenogeneic sources have been investigated. Both have been successful in small-animal models; however, xenogeneic cells in large-animal hosts appear to require tighter membranes and more stringent immunoisolatory measures than do their allogeneic counterparts. Inappropriate choice of encapsulating membrane resulting in a lack of immunoprotection and sensitization of the host may explain early problems associated with xenogeneic cell viability.

Mitotically active cell lines provide an alternative to the use of primary cells. Cell lines are easier to maintain in tissue culture and serve as a continuous source of graftable cells. By their very nature, cell lines possess the ability to proliferate within the capsule; however, growth may be constrained by contact inhibition and metabolic factors (Lysaght *et al.*, 1994). Dividing cell lines can also be genetically engineered to produce the desired gene product (Chang *et al.*, 1993; Tan *et al.*, 1996; Rinsch *et al.*, 1997; Sautter *et al.*, 1998). Cell lines of both xenogeneic and allogeneic origin have been successfully encapsulated. Use of mitotically active cell lines for encapsulated cell therapy, although advantageous, requires careful attention to patient safety in the unlikely event of capsule rupture. Allogeneic cell lines, due to similarities in their genetic profile and the profile of the implanted recipient, may possess the ability to proliferate outside the capsule without provoking immunological recognition. Risk of immune evasion may even be greater in immunoprivileged sites such as the central nervous system (CNS) (Morris, 1996). Allogeneic cell lines would almost certainly need to be transfected with suicide genes prior to encapsulation and implantation, although studies showing the effectiveness of this approach are not yet available. Xenogeneic cell lines are more immunogenic than allogeneic lines and therefore are more susceptible to destruction by a host in the event that they escape the capsule. In studies conducted to date, both peripherally located xenogeneic cells and those transplanted into the CNS have been shown to be recognized and completely destroyed by the host immune system (Fuchs and Bullard, 1988; Somerville and d'Apice, 1993). Cited studies are not exhaustive, nevertheless many investigators believe xenogeneic cell lines may be a wiser choice for encapsulation and implantation.

## CLINICAL

The first clinical trials of immunoisolation were initiated in 1993 (Soon-Shiong *et al.*, 1994). By April of 1999, five phase I clinical trials had been reported for diabetes, chronic pain, and ALS (Soon-Shiong *et al.*, 1994; Scharp *et al.*, 1994; Aebischer *et al.*, 1994b; Ezzell, 1995; Buscher *et al.*, 1996), and phase II clinical trials were being initiated for chronic pain in the United States. The trials are summarized in Table 26.1. Trials involving encapsulated allogeneic islets for the treatment of diabetes were initiated to provide proof of principle for encapsulation technology. Those investigations involving chronic pain and ALS have advanced to the next step, which involves the evaluation of human-relevant devices and protocols. If such studies prove successful, this technology may then move directly into large-scale regulatory trials and thence to clinical practice.

**Table 26.1. Current clinical trials using cell encapsulation therapy**

Application	Investigator/country/year	Device/polymer/cell type	Brief results
Chronic pain	Aebischer <i>et al.</i> (Cytotherapeutics)/ Switzerland/1994	Hollow fiber/acrylic, 50 kDa/ calf adrenal chromaffin cells	<i>n</i> = 10; histologic and biochemical evidence of cell viability and functionality following explant at 45–155 days; no evidence of complications due to implantation
Chronic pain	Aebischer <i>et al.</i> (Cytotherapeutics)/ United States/1995 (Phase I); 1999 (Phase IIA trials being initiated)	Hollow fiber/acrylic, <100 kDa/ calf adrenal chromaffin cells	<i>n</i> = 15; histologic and biochemical evidence of cell viability and functionality following explant at 200 days; no evidence of complications due to implantation
ALS	Aebischer <i>et al.</i> (Cytotherapeutics)/ Switzerland/1995	Hollow fiber/Polysulfone, 280 kDa/engineered baby hamster kidney cells	<i>n</i> = 6; nanogram quantities of CNTF measured in patient CSF up to 17 weeks postimplantation; evidence of cell viability following retrieval
Diabetes	Soon-Shiong <i>et al.</i> /United States/ 1994	Microcapsule/alginate, <100 kDa/allogeneic islets	<i>n</i> = 1; (immunosuppressed); adequate regulation of patient glucose at 9 months
Diabetes	Scharp <i>et al.</i> (Neocrin)/United States/1994	Hollow fiber/acrylic, 65 kDa/ allogeneic islets	<i>n</i> = 9; good biocompatibility; no immune complications; cell viability and stimulated insulin release shown following explant at 2 weeks

Based on the previous success of encapsulated islet transplants in rodent and dog models, Soon-Shiong *et al.* (1994) and Scharp *et al.* (1994) have conducted clinical investigations involving type I and type II diabetic patients. The two investigative groups, however, have used very different methods. Soon-Shiong *et al.* implanted modified islet-containing alginate microcapsules into the peritoneum of a 38-year-old diabetic male. The patient, immunosuppressed with 50 mg/day of cyclosporin for a preexisting kidney transplant, received a total dose of  $>10^6$  pooled allogeneic islets administered at two separate time intervals. Soon-Shiong *et al.* utilized purified alginate microcapsules with a high guluronic acid content, which his earlier studies had identified as possibly having improved biocompatibility and increased mechanical strength compared to standard alginate capsules (Otterlei *et al.*, 1991; Soon-Shiong *et al.*, 1991). Insulin secretion from the encapsulated islets was noted 24 hr following implantation of 700,000 microcapsules. Exogenous insulin administration was decreased during this period. Following a supplemental dose of 350,000 encapsulated islets, insulin administration further decreased and at 9 months postimplantation, exogenous insulin administration was discontinued for 1 month then resumed. Peripheral neuropathy, a common complication associated with diabetes and experienced by this patient, was reported to be alleviated posttransplant. Results are difficult to evaluate because other investigators have achieved similar or better results using unencapsulated islets in immunosuppressed recipients. At best this preliminary clinical trial demonstrated that the encapsulation procedure did not adversely affect cell viability or function relative to unencapsulated islets. It offers little insight into the extent of immunoprotection provided by this approach.

Scharp's clinical trial was designed to investigate whether immunoisolation protects against the autoimmune challenge of type I diabetes. This is an important issue because autoimmune rejection of transplanted islets normally destroys unencapsulated islets in a nonimmunosuppressed host. Islets were encapsulated in semipermeable hollow-fiber macrocapsules having a nominal molecular-weight cutoff of approximately 65 kDa. The islets, isolated from a single donor, were suspended in 1% sodium alginate and then loaded into preformed acrylic copolymer capsules. Approximately 50 islets were loaded into each capsule. Four capsules, three containing islets and alginate and one containing just alginate, were implanted subcutaneously into each type I and type

II diabetic patient and nondiabetic control subjects. The net dosage of islets (150) is about  $4000\times$  less than would be required for therapeutic implant. During the 2-week implant period, blood glucose levels of all three groups appeared to be unchanged from preimplant values. On retrieval of the capsules, *in vitro* analysis revealed differences in glucose responsiveness between the cell-loaded explants of the diabetic groups and those of the control group. Explanted capsules from the control group responded appropriately to both glucose and theophylline challenges. Those from the experimental groups, on the other hand, responded only to stimulation with theophylline. Differences in responsiveness were attributed to chronic hyperglycemia in the diabetic patients, which likely stressed the islets and impaired insulin secretion. Histologic analysis of retrieved capsules showed substantial cell viability and minimal host tissue reaction in all cases. The investigators conclude that this trial demonstrated the short-term biocompatibility and acute immunoprotective capacity of semipermeable membranes under immunologically challenging conditions. Longer duration studies are planned.

In addition to diabetes, clinical trials involving chronic pain were conducted in Switzerland and the United States by Aebischer and Goddard (Aebischer *et al.*, 1994a; Buscher *et al.*, 1996). These trials flow from earlier collaboration with Sagen *et al.* demonstrating reduction of chronic pain by the implantation of encapsulated bovine adrenal chromaffin cells in rodents. Studies in larger animals confirmed the immunoisolatory properties of the membrane and were used to develop and validate an implant suitable for intrathecal implantation in humans (Joseph *et al.*, 1994). The first clinical trial conducted in Switzerland involved 10 end-stage cancer patients suffering from intractable pain. Results have been reported for the entire series and published for the 7 of the 10 patients (Buscher *et al.*, 1996). Each of the 10 patients received a 5-cm-long tethered device, having a molecular-weight cutoff of approximately 50 kDa, which contained approximately 2 million cells suspended in a supportive alginate matrix. The device was implanted in the lumbar subarachnoid space through a series of expanding catheters during a minimally invasive surgical procedure very analogous to a spinal tap. The silicone tether located at one end of the device allowed for simple withdrawal of the implant if necessary or desirable. Capsules were retrieved for analysis in some patients and recovered postmortem in others. Implant duration ranged from 41 to 172 days. Cell survival in all evaluable cases was confirmed by histology, by catecholamine release postretrieval, and in selected cases by immunohistochemistry. Patients in the open-label study showed a decline in intake of narcotics and reduction in pain ratings. Although preliminary, this protocol represents the first successful clinical trial of a human-relevant immunoisolation device and confirms the immunoprotective function of semipermeable membranes in nonimmunosuppressed xenogeneic hosts.

Based on the results obtained from the Swiss trials, FDA-approved phase I clinical trials were initiated in the United States by Cytotherapeutics (Providence, RI). These trials were designed to test the safety of intrathecal implantation of encapsulating devices into end-stage cancer patients suffering from chronic pain. In addition, survival of the encapsulated xenogeneic bovine chromaffin cells was evaluated following device retrieval. Fifteen patients were enrolled in the trial. Trial protocol paralleled that implemented in the initial clinical trials conducted in Switzerland. No clinically significant safety issues associated with the implantation procedure were observed in any of the patients enrolled. Following retrieval and histologic and biochemical analysis, devices were shown to contain viable and functional encapsulated bovine chromaffin cells for up to 200 days postimplantation. As a result of the success of this phase I trial, phase IIA clinical trials were initiated by Cytotherapeutics and Astra AB of Sweden, and patient enrollment was completed in January, 1999. The trial is being conducted at four clinical sites in the United States and Europe.

A second clinical trial underway in Switzerland involves the delivery of ciliary neurotrophic factor (CNTF) for treatment of amyotrophic lateral sclerosis (Ezzell, 1995; Aebischer *et al.*, 1996). ALS, often called Lou Gehrig's disease in the United States, is characterized by the progressive degeneration of motor neurons, resulting in movement disorder and eventual respiratory failure due to loss of neurons innervating the chest wall and diaphragm. Administration of neurotrophic factors such as CNTF has been shown *in vitro* and in small animal models to protect against death of motor neurons. Systemic delivery of CNTF is unfavorable because of rapid clearance in the serum and toxicity of high doses of purified CNTF. Sagot *et al.* (1995) and Tan *et al.* (1996) have demonstrated efficacy with encapsulated baby hamster kidney (BHK) cells releasing recombinant CNTF in a mouse model of ALS. In studies conducted by Sagot *et al.*, BHK cells, after transfec-

tion with the gene for mouse CNTF, produced 100 ng of CNTF per million cells per day in this study. After encapsulation and subcutaneous implantation, the transfected cells prolonged the lives of diseased mice by 40% relative to controls and improved motor function on several behavioral assays. In addition, the phrenic nerves of experimental mice, which innervate the diaphragm, were also shown to contain 50% more myelinated motor neurons than controls. Clinical trials based on these studies were initiated by Aebischer *et al.* (1996) using cells transfected with the gene for human CNTF. Six ALS patients were implanted with polymer capsules containing BHK cells genetically engineered to secrete human CNTF. Encapsulating devices and surgical procedures were modeled after those used for clinical trials involving implantation of encapsulated bovine chromaffin cells for the alleviation of chronic pain (Aebischer *et al.*, 1994a; Buscher *et al.*, 1996). Prior to implantation, devices were shown to release approximately 0.5  $\mu\text{g}$  of human CNTF per day *in vitro*. Following intrathecal implantation, 170–6200 pg/ml of CNTF were measured within the patients' cerebrospinal fluid for at least 17 weeks postimplantation (Aebischer *et al.*, 1996). CNTF levels were undetectable in all patients prior to implantation. On retrieval, all devices showed good viability and CNTF output. This trial represents the first clinical combination of immunoisolation and gene therapy.

## FUTURE DIRECTIONS

Future progress of immunoisolated cell therapy will result from both the aggressive clinical application of existing technology and the continued development of new generations of capsules, cells, and clinical application. Techniques may be developed that allow capsule membranes to be modified so as to enhance encapsulated cell viability. Microvascularization of the external portion of the capsule membrane has been suggested by researchers at Baxter Healthcare Corp. as a means of improving the performance of their encapsulation devices for insulin-secreting cells (Brauker *et al.*, 1992, 1995; Danheiser, 1995). Promoting the growth of blood vessels in close proximity to the membrane may increase bidirectional diffusion of essential nutrients and cellular secretagogues, thus enhancing viability and function of the encapsulated cell population. Other modifications in membrane fabrication and capsule design involve the use of biodegradable hydrogel microspheres (Lanza and Chick, 1997). Researchers at Biohybrid Technologies propose the development of biodegradable cell microcapsules that remain intact only for the life cycle of the encapsulated cell population (Danheiser, 1995; Lanza and Chick, 1997). Following degradation of the protective capsule, remains of the grafted cells would be phagocytosed by the host immune system. A new batch of microspheres could be injected or treatment could be ceased. Host sensitization remains a potential problem with this procedure; induction of host tolerance is a potential upside. Other technological advancements include the use of photopolymerized conformal coatings that entrap individual cells or small cell clusters and the use of systems that combine different polyanionic and polycationic moieties to encapsulate cells (Basta *et al.*, 1996; Tun *et al.*, 1996; Wang *et al.*, 1997; Hill *et al.*, 1997).

The future of cell encapsulation is closely entwined with that of human gene therapy. The span of therapeutic applications will increase as cells are tailored to release any of the variety of bioactive molecules whose genes are being identified. In addition, cell lines might be engineered to adapt to an encapsulated environment by incorporation of genes that induce mitotic arrest following exogenous administration of appropriate agents. Other cell types, such as genetically engineered myoblasts, may prove useful as progenitor cells that spontaneously differentiate following tubule formation (Deglon *et al.*, 1996; Rinsch *et al.*, 1997). Such approaches permit cell growth within the capsule but circumvent problems associated with unrestrained cell proliferation. Alternatively, it may be possible to induce quiescent cell lines to proliferate within the capsule when the cell population declines. Modifications of cell lines in these ways, along with optimization of luminal supportive matrices, have the potential to create capsules possessing an indefinite supply of cells that will not require replacement or reloading.

Future applications of encapsulated cell therapy are likely to include to other CNS disorders such as Huntington's and Alzheimer's disease and a variety of non-CNS related diseases, including hemophilia and malignant cancer (Emerich and Sandberg, 1994; Emerich *et al.*, 1994; Danheiser, 1995; Geller *et al.*, 1997a,b). Emerich *et al.* investigated an animal model of Huntington's disease and its response to encapsulated cell therapy. Kordower *et al.* (1995) reported that poly-

# ENGINEERING CHALLENGES IN IMMUNOISOLATION DEVICE DEVELOPMENT

Efstathios S. Avgoustiniatos, Haiyan Wu, and Clark K. Colton

## INTRODUCTION

One approach to minimizing or eliminating systemic immunosuppression in cell therapies is the use of tissue-engineered implantable immunobarrier (also called immunoisolation) devices, in which the tissue is protected from immune rejection by enclosure within a semipermeable membrane or encapsulant. This chapter deals with those factors that influence the performance and engineering design of immunobarrier devices: (1) tissue supply from primary or cell culture sources, (2) protection from immune rejection, in light of the mechanisms thought to operate in the presence of a semipermeable membrane, the properties of that membrane, and the implications for biology and device design, and (3) maintenance of cell viability and function, its relationship to device design, and the role of, and factors affecting, oxygen-supply limitations. Emphasis is given to the third area dealing with oxygen-supply limitations and its effect on viability and function. After reviewing recent work in this area, a detailed example is provided of how engineering analysis can be applied to the problem of enhancing oxygen supply by *in situ* oxygen generation.

Immunoisolation is the enclosure of transplanted tissue in a semipermeable membrane in order to protect it from immune rejection, thereby creating an implantable biohybrid artificial organ. Immunobarrier devices of this type are under study for the treatment of a variety of diseases. Biohybrid artificial organs have previously been reviewed extensively (Colton and Avgoustiniatos, 1991; Lanza *et al.*, 1992a; Aebischer *et al.*, 1993; Christenson *et al.*, 1993; Bellamkonda and Aebischer, 1994; Lanza and Chick, 1994, 1995a,b; Lysaght *et al.*, 1994; Mikos *et al.*, 1994; Aebischer and Lysaght, 1995; Colton, 1995, 1996). Many of the topics discussed in this chapter have previously been presented in great detail (Colton, 1995). This article focuses on the engineering challenges involved in the attempt to make implantable immunoisolation devices a clinical reality. These challenges are examined largely in the context of a biohybrid artificial pancreas for treatment of diabetes, but the problems and general principles are applicable to other uses of cell therapy as well.

## ENGINEERING CHALLENGES

The essential elements of an implanted device that incorporates encapsulated cells are shown in Fig. 27.1, which illustrates the case of a biohybrid artificial pancreas. The implanted tissues are separated from the host by an immunoisolation membrane. Cells can be encapsulated at a high tissuelike density, as illustrated in Fig. 27.1, or dispersed in an extracellular gel matrix, such as agar, alginate, or chitosan. The membrane prevents or retards access of cellular and humoral immune components to the transplanted tissue but permits passage of the secreted product (insulin). At the

Fig. 27.1. Essential elements of an implanted device that incorporates encapsulated cells, illustrating the case of a biohybrid artificial pancreas. Reproduced, with permission, from Colton (1995).

same time there must be sufficient access to nutrients, such as glucose and oxygen, and removal of secreted metabolic waste products, such as lactic acid, carbon dioxide, and hydrogen ions. Transplanted cells must be supplied with nutrients by diffusion from the nearest blood supply, through surrounding tissue, the immunoisolation membrane, and the graft tissue itself.

Engineering challenges exist in three areas: (1) supply of tissue, (2) protection from immune rejection, and (3) maintenance of cell viability and function.

### SUPPLY OF TISSUE

The amount of tissue required for transplantation in an immunoisolation device is determined by the secretion rate of the desired agent per cell and the amount of the active agent required by the body (Colton, 1995); it depends on the specific medical application (Avgoustiniatos and Colton, 1997a) and ranges from about  $10^6$  in central nervous system applications to about  $10^9$  cells in diabetes. The complexity and difficulty of all aspects of the problem increase with the volume of implanted tissue required. Thus, it is not surprising that some central nervous system applications, which require the least amount of transplanted tissue (Avgoustiniatos and Colton, 1997a) are the first to advance to clinical testing (Aebischer and Lysaght, 1995).

There are various sources of tissue. Most common is primary tissue (terminally differentiated, postmitotic cells) used immediately after isolation or following culture. Cultured, dividing cell lines, either native or genetically modified with recombinant DNA, have been studied and are attractive from the standpoints of harvesting large volumes of cells and of meeting regulatory standards of uniformity, sterility, and safety. In the case of primary tissue, only xenogeneic sources are practical because of the limited supply of human tissue. With cultured cell lines, as with primary tissue, immunoisolation is easier to accomplish with allogeneic than with xenogeneic cells. However, some investigators prefer xenogeneic cell lines because such cells would be rejected by the host if the device broke and released unencapsulated cells (Aebischer and Lysaght, 1995), whereas allogeneic cells might not be so easily rejected, especially if they were tumorigenic.

In applications in which tissue requirements are high, such as for the treatment of diabetes, supplying the required amount of tissue will represent the largest cost component for manufacture of the implant. A cell line that secretes insulin at a sufficiently high rate and that regulates the concentration of glucose in the plasma at the physiological set-point for humans is needed. In the meantime, effort has gone into isolating porcine islets of Langerhans, because porcine insulin has been used in humans for years and the islets regulate the glucose concentration to an appropriate level. Current processes are based on laboratory-scale methodology involving pancreas digestion

by collagenase, followed by centrifugation with Ficoll density gradients. Innovative improvements are needed for the development of an economical large-scale process for producing large numbers of viable and functioning islets with high yield.

### PREVENTING IMMUNE REJECTION

Possible rejection pathways elicited by immunoisolation are shown in Fig. 27.2. The process may begin with diffusion across the immunobarrier of immunogenic tissue antigens that have been shed from the cell surface, secreted by live cells, or liberated from dead cells. Recognition and display of these antigens by host antigen-presenting cells initiate the cellular and humoral immune responses. The former response leads to activation of cytotoxic cells, macrophages, and other immune cells. Prevention of cells entering the tissue compartment is easily achieved using microporous membranes. This may be the only requirement for immunoisolation of allogeneic tissue, at least for periods up to several months (Korsgren and Jansson, 1994). With xenografts, keeping out components of the humoral immune response is more difficult to accomplish. Such components include cytokines and lymphokines (e.g., interleukin-1), which can have deleterious effects on  $\beta$  cells, as well as newly formed antibodies to immunogenic antigens that have leaked across the barrier. In addition, there may be naturally occurring antibodies, most likely IgM, to cell surface antigens. Antibodies produced during preexisting autoimmune disease, such as type I diabetes, might also bind to cell surface antigens. Last, macrophages and certain other immune cells can secrete low-molecular-weight reactive metabolites of oxygen and nitrogen, including free radicals, hydrogen peroxide, and nitric oxide, which are toxic to cells in a nonspecific fashion. The extent to which these agents may play a role in causing rejection of immunoisolated tissue depends on how far they can diffuse before they are inactivated by chemical reactions.

Cytotoxic events occur if antibodies and complement components pass through the membrane. Binding of the first component (C1q) to an IgM, or two or more IgG molecules, initiates a cascade that culminates in the formation of the membrane attack complex, which can lyse a single cell. IgM (910 kDa) and C1q (410 kDa) are both larger than IgG, so if host IgM and C1q can

Fig. 27.2. Possible pathways for immune rejection mechanisms with encapsulated cells. Reproduced, with permission, from Colton (1995).

be prevented from crossing the barrier, then a specific, antibody-mediated attack on the islet cell should be averted. If the alternative complement pathway is activated and not inhibited by the implanted tissue, then passage of C3 (200 kDa) across the membrane must also be prevented. Small complement breakdown products, such as C5a (10 kDa), may also pose a problem (Chang, 1998). Both IgM and C1q have a smallest dimension of about 30 nm and should be completely retained by a membrane with a maximum pore diameter of 30 nm. The pores of a hydrophobic membrane in contact with extracellular fluid are likely to be coated with a monolayer of protein ~10 nm thick. Thus, pores with diameters of about 50 nm would be needed to allow C1q and IgM to pass through. Amicon PM30 polysulfone membranes with nominal cutoff of 30 kDa (Hagihara *et al.*, 1997) as well as Nucleopore membranes with 0.1- $\mu$ m pore size (Ohgawara *et al.*, 1998) have been reported to prevent the permeation of C1q and smaller complement components.

The precise mechanism(s) that may play a role in rejection of encapsulated tissue are, in general, incompletely understood, and probably depend on the specific types of cells present, the species and its phylogenetic distance from humans, and the concentration of humoral immune molecules to which the implanted tissue is exposed. The latter depends on the transport properties of the immunoisolation membrane, as well as on the total mass of cells implanted (which affects the magnitude of the immune response), the tissue density, and the diffusion distances between tissue and immunoisolation membrane (which affect access of the humoral components generated to the graft tissue). If free radicals and other reactive oxygen and nitrogen species pose a significant problem, no passive membrane barrier will be able to provide immunoisolation, and some other approach (e.g., scavenging of free radicals, immunomodulation of transplanted tissue, local suppression of host immune response) will be necessary. However, even if this preceding issue is not a problem, if complete retention of IgG (or even C1q and IgM) coupled with passage of albumin and iron-carrying transferrin (81 kDa) is required, there remains a problem because of the size discrimination properties of membranes in which there is invariably a wide distribution of pore sizes. If cytokine transport must also be prevented, the problem is even more difficult. However, some surprising results suggest it is not hopeless. Alginate poly(lysine) microcapsules, found to be impermeable to IgG (150 kDa) and permeable to the cytokine IL-1b (17.5 kDa), could be made permeable to transferrin but remained impermeable to the lower molecular-weight cytokine tumor necrosis factor (TNF; 51 kDa) by increasing their guluronic acid content (Kulseng *et al.*, 1997). The suggested explanation for this result is that TNF in its active form is a bell-shaped trimeric molecule consisting of three identical subunits (17 kDa), in contrast to transferrin, which consists of one single polypeptide chain, resulting in the trimeric TNF having a more expanded tridimensional structure.

### CELL VIABILITY AND FUNCTION

Maintenance of cell viability and function is essential and is limited by the supply of nutrients and oxygen. Diffusion limitations of oxygen in tissue *in vivo* are far more severe than those of glucose because the concentration of glucose in tissue is many fold higher (Tannock, 1972). The requirements of specific tissues for other small molecules and for macromolecules are poorly understood or have not yet been quantified; transport limitations for large molecules are highly dependent on immunoisolation membrane properties, whereas oxygen limitations are always serious. If the local oxygen concentration drops to sufficiently low levels, the cells will die. Hypoxia at levels high enough to keep cells alive can nonetheless have deleterious effects on cell functions that require high cellular ATP concentrations—for example, ATP-dependent insulin secretion (Dionne *et al.*, 1993).

Oxygen supply to encapsulated cells depends in a complicated way on a variety of factors, including (1) the site of implantation and the local oxygen partial pressure ( $pO_2$ ) in the blood, (2) the spatial distribution of host blood vessels in the vicinity of the implant surface, (3) the oxygen permeability of the membrane or encapsulant, (4) the oxygen consumption rate of the encapsulated cells, (5) the geometric characteristics of the implant device, and (6) the tissue density and spatial arrangement of the encapsulated cells or tissues. The original concept of a biohybrid artificial organ (Colton, 1995), and the design that has received the most extensive study in large animals, is an intravascular arteriovenous shunt in the form of a semipermeable membrane tube through which arterial blood flows and on the outside of which the implanted tissue is contained in a housing. This approach provides the best physiologic oxygen supply ( $pO_2 = 100$  mmHg) but suffers from the

need to break the cardiovascular system and may be limited to a small fraction of patients. One alternative is an extravascular device in the form of a planar or cylindrical diffusion chamber implanted, for example, in subcutaneous tissue or intraperitoneally. Such devices are exposed to the mean  $pO_2$  of the microvasculature, around 40 mmHg. Implantation in soft tissue is further disadvantaged if a foreign body response occurs, producing an avascular layer adjacent to the membrane, typically on the order of 100  $\mu\text{m}$  thick. This fibrotic tissue increases the distance between blood vessels and implant, and the fibroblasts in that layer consume oxygen. Discovery of a class of microporous membranes that induce neovascularization at the material–tissue interface by virtue of the membrane microarchitecture (Brauker *et al.*, 1995) may ameliorate the severity of this problem. The angiogenic process takes 2–3 weeks (Padera and Colton, 1996) for completion, and the vascular structures remain indefinitely. By bringing some blood vessels close to the implant, oxygen delivery is improved. Another alternative for an extravascular implant is spherical microcapsules, implanted, for example, in the peritoneal space. The spherical geometry is advantageous from the standpoint of mass transfer, but the large volume of microcapsules employed, and the tendency for most to attach permanently to peritoneal surfaces, may lead to clinical problems.

Despite encouraging results with various tissues and applications (Aebischer and Lysaght, 1995; Colton, 1995), the problem of oxygen transport limitations is one of the major hurdles that remain. The maximum  $pO_2$  (about 40 mmHg for the microvasculature) available for extravascular devices limits the steady-state thickness of viable tissue that can be supported. Potentially even more severe than these steady-state limitations is the hypoxic environment surrounding the device during the first few days after implantation. This situation is ameliorated only as new blood vessels grow toward the device–host tissue interface. During this period, anoxia likely exists within regions of the device, leading to death of a substantial fraction of the initially implanted tissue.

Islets are particularly prone to oxygen supply limitations because they have a relatively high oxygen consumption rate (Dionne, 1990). In the normal physiologic state they are highly vascularized and are supplied with blood at arterial  $pO_2$ . When cultured *in vitro* under ambient normoxic conditions, islets develop a necrotic core, the size of which increases with increasing islet size, as is to be expected as a result of oxygen diffusion and consumption within the islet (Dionne, 1990). Despite the extensive literature on immunoisolation of islets (Colton and Avgoustiniatos, 1991; Colton, 1995), only scant attention has been paid to the issue of islet viability within implanted immunobarrier devices. What is clear from these collective studies is that all attempts to support larger volumes of islet tissue in high density within the device (i.e., conditions wherein all or most of the internal device volume is occupied by viable islet tissue) have led to massive islet necrosis, invariably in regions furthest from the oxygen source. With few exceptions, only by suspending islets in an extracellular gel matrix at very low islet volume fractions (e.g., 1–5%), which greatly increases the size of the implanted device, have investigators been able to maintain the viability of initially loaded islets. However, use of such low tissue density puts undesirable constraints on the maximum number of islets that can be supported in a device of a size suitable for surgical implantation. There are some reports about the function and morphologic appearance of islets contained within such devices (Altman *et al.*, 1988; Brunetti *et al.*, 1991; Colton and Avgoustiniatos, 1991; Lacy *et al.*, 1991; Brauker *et al.*, 1992; Hill *et al.*, 1992; Lanza *et al.*, 1992a,b, 1993; Scharp *et al.*, 1994; Colton, 1995). Critical parameters such as the number and volume of viable islets that could be supported, as well as the development of islet necrosis and fibrosis, are being examined (Suzuki *et al.*, 1998a,b, 1999). In one study (Suzuki *et al.*, 1998b) with syngeneic transplantation of islets in a titanium ring chamber into streptozotocin (STZ)-induced diabetic mice, devices containing 250 implanted islets were rarely successful in normalizing blood glucose concentration at 4 weeks after transplantation, whereas the success rates were comparable using devices loaded with 500, 750, and 1000 islets. The highest success rate was obtained by implanting two devices, each loaded with 500 islets. The number of viable islets that remained at explantation between 1 and 12 weeks postimplantation was consistent with the notions that (1) the volume of viable islet tissue that can be supported by a particular device configuration is determined primarily by the rate of supply of oxygen to the tissue contained therein, and (2) most of the loss of viable  $\beta$  cell mass occurs during the first few days after transplantation as a result of the hypoxic environment around the immunobarrier device, which presents the most severe oxygen-supply limitations.

This problem has been observed in naked transplantation (Davalli *et al.*, 1996) in a study in

which syngeneic islets were transplanted under the kidney capsule of normal and diabetic mice. In grafts harvested 1 and 3 days after transplantation, islets had undergone substantial damage, as evidenced by the presence of apoptotic nuclei, large fused masses with central necrosis, and reduced graft insulin content. Tissue remodeling was evident after 7 days, and good vascularization and oxygenation of the remaining islets were achieved at day 14. The association of apoptosis with the loss of transplanted islets has also been observed by others (Paraskevas *et al.*, 1997) and may be a general response to severe hypoxia as well as perhaps other factors such as conditions of isolation and culture, glycemic state, and the nonspecific inflammatory reaction associated with the transplantation procedure. In any event, the hypoxic environment for several days following transplantation is a problem common to both naked and immunobARRIER transplantation.

## OXYGEN-SUPPLY LIMITATIONS

Although supply of high-molecular-weight nutrients and waste elimination may be important factors in immunoisolation, work cited in the previous section suggests that the most critical factors affecting viability and function are the limitations imposed on oxygen supply to tissues in immunobARRIER devices. It is therefore not surprising that this area has attracted increased attention over the past few years, and work has been reported in several areas aimed at enhancing oxygen supply or reducing the impact of these limitations.

## IMPLANTATION SITE

Gel-encapsulated tissues are often implanted intraperitoneally. The peritoneal cavity provides a large surface area and offers the advantage of insulin delivery in the neighborhood of the portal vein, which is more physiologic than peripheral insulin delivery obtained, for example, by subcutaneous implantation. However, the peritoneal cavity has several disadvantages (Leblond *et al.*, 1999), including delayed and reduced insulin absorption; high peritoneal macrophage population (85% of peritoneal fluid cells), which may induce a fibrotic reaction; high mechanical stress because of continuous movement; possibility of severe pain if a peritoneal reaction occurs; clumping of microcapsules, especially likely in large animals and humans because of the higher number of capsules that have to be implanted; and poor cell oxygenation. The available oxygen partial pressure in the peritoneal cavity is about 40 mmHg, roughly the same as in the microvasculature. This latter factor led investigators to hypothesize that the intrapleural cavity may be a more suitable site for cell implantation (Kaur and Vacanti, 1996) because the oxygen partial pressure of fluids in the pleural cavity is a direct reflection of that in the inspired gas as a result of direct oxygen diffusion across the alveoli to the intrapleural space.

The most successful site for implantation of nonencapsulated islets of Langerhans, particularly in large animals and humans, is the liver, which also has a higher oxygen partial pressure. Large microcapsules (above 700  $\mu\text{m}$  in diameter) can cause large increases in portal vein pressure, which has caused death of animal subjects. However, the use of small microcapsules, about 300  $\mu\text{m}$  in diameter, was found safe and appropriate for intraportal implantation (Leblond *et al.*, 1999). On the other hand, the physiologic suitability of the intrahepatic site for islet transplantation has been questioned (Guan *et al.*, 1998).

## IMPLANT-HOST TISSUE INTERFACE

The biologic response to the implant by the host tissue can play an important role in affecting oxygen supply to the transplanted tissue. The details of that response depend in part on the implantation site.

The presence of numerous macrophages adhered to the outer surface of various polymeric hollow-fiber (Hunter *et al.*, 1999) and planar (Jesser *et al.*, 1996) membranes implanted in the peritoneal cavity of rats or mice has been reported. These macrophages may exacerbate oxygen-supply limitations by virtue of their own oxygen consumption, and they have been associated with rat islet graft disintegration or morphologic alteration (Jesser *et al.*, 1996), leading to the suggestion that these membranes are not entirely suitable for immunoisolation in the peritoneal cavity. However, this phenomenon has also been observed with alginate microcapsules. In one study, subcutaneous administration of a macrophage inhibitor eliminated the recurrent hyperglycemia observed in streptozotocin-induced diabetic mice that had been treated with intraperitoneal trans-

plantation of alginate–poly(L-lysine)–alginate-microencapsulated rat islets (Hsu *et al.*, 1999). Those findings are indicative of the detrimental effects associated with macrophage adherence to intraperitoneal implants.

The presence of blood vessels in the vicinity of a device is especially important when implanted subcutaneously because it minimizes the diffusion distance for oxygen. This principle can be illustrated by the results of calculations we presented previously (Avgoustiniatos and Colton, 1997b). We analyzed oxygen diffusion and consumption in a planar diffusion chamber consisting of dense islet tissue encapsulated between composite microporous membranes. We examined two cases: (A) The outer membrane surface is overlaid with a 100- $\mu\text{m}$ -thick avascular fibrotic capsule containing a 10% volume fraction of respiring cells. Blood vessels of the microvasculature are present outside of this layer. (B) Neovascularization is induced to occur at the membrane–host tissue interface, and the outer membrane surface is taken to be uniformly exposed to the 40 mmHg oxygen partial pressure of the microvasculature. In case A, the fibrotic capsule accounts for a 34 mmHg partial pressure drop, 22 mmHg caused by the diffusion resistance of the tissue and 12 mmHg associated with oxygen consumption by the cells in the fibrotic layer. Another 5 mmHg drop occurs across the 30- $\mu\text{m}$ -thick membrane, leaving only about 1 mmHg for support of viable tissue, which amounts to only an 18- $\mu\text{m}$ -thick slab (assuming oxygen is supplied from both sides). A device containing 1 ml of islet tissue for restoring normoglycemia in a human would require an *en face* (surface) area of about 550  $\text{cm}^2$ , most likely too large to be practical. In case B, the oxygen partial pressure at the outer surface of the transplanted tissue layer increases from 1 to 15 mmHg, and the thickness of supportable tissue increases from 18 to 70  $\mu\text{m}$ . The required surface area decreases to about 140  $\text{cm}^2$ , a more feasible size.

The aforementioned discovery by Brauker *et al.* (1995) of membrane materials that induce neovascularization leads to the presence of blood vessels in closer proximity to the transplanted tissue than is the case with fibrotic tissue. A strategy of implantation involving prevascularization of an immunoisolation device fabricated from such materials has been suggested (Padera and Colton, 1996) in order to prevent the extreme hypoxia that immediately follows implantation. However, it is not known whether the resulting spatial distribution of vessels, especially the density of vascular structures close to the membrane, attained by prevascularization is sufficient to support any particular thickness of tissue that is added to the device. It has been suggested (Vasir *et al.*, 1998) that local hypoxia partially regulates neovascularization of grafted naked islets via up-regulation of expression of vascular endothelial growth factor (VEGF), a potent angiogenic stimulus. VEGF is presumably also secreted by islet tissue in immunoisolation devices, thereby further increasing the extent of neovascularization. However, the critical issue is whether the oxygen supply available to the tissue at the time of implantation is sufficient to maintain all of the tissue in a viable state.

To further enhance the extent of prevascularization, several studies have investigated use of VEGF. In one study (Trivedi *et al.*, 1999) using ported devices fabricated with vascularizing membranes, VEGF in solution was infused at a very low rate through the device into the surrounding tissue for 10 days. Histologic examination revealed a marked increase in vascular structures within 15  $\mu\text{m}$  of the membrane as well as farther away. Two days after infusion ceased, an insulin bolus was infused into the device and its plasma concentration was followed with time. The rate of insulin release into the bloodstream from the device with VEGF infusion was higher than that from control devices (without VEGF) but lower than that resulting from subcutaneous injection. These results are consistent with those of microdialysis studies with a similar device implanted subcutaneously but without angiogenic factor infusion (Rafael *et al.*, 1999). Exchange of glucose with the microcirculation following intravenous glucose injection was poorer when the microdialysis probe was placed within the device than when placed directly in the subcutaneous fat until 3 months after implantation, at which point they became similar.

In another study (Hunter *et al.*, 1999), VEGF (referred to as endothelial cell growth factor; ECGF) was incorporated into calcium alginate that filled the lumen of hollow-fiber membranes (having either a continuous, smooth or a broken, rough outer surface), which were implanted either subcutaneously or intraperitoneally for 65 days. The subcutaneous implant with the discontinuous outer surface displayed marked neovascularization. The others did not. Nonetheless, results from both of these studies suggest that release of angiogenic factors into the surrounding host tissue can increase the neovascularization around the device.

## PROPERTIES OF TRANSPLANTED TISSUE

Characterization of metabolic and secretory properties, such as oxygen consumption and insulin secretion rate per unit volume of tissue, by cell lines as well as islet tissue from different donor species is important for improving the performance of biohybrid artificial pancreas devices. One source of insulin-secreting tissue is insulinoma cell lines, which offer the advantage of virtually unlimited uniform tissue. Genetic engineering could be used to modify the insulin secretion and glucose sensing so as to mimic that of native islets while maintaining or imparting new desirable properties, such as a lower oxygen consumption rate per unit volume and less susceptibility to hypoxic conditions, for example, by the action of antiapoptotic genes. Extensive studies with various encapsulated cell lines, such as the  $\beta$ TC3, MIN6, and NOD-RIP-Tag mouse insulinoma cell lines, have been performed for the purpose of characterizing relevant properties (Mukundan *et al.*, 1995; Papas *et al.*, 1996; Benson *et al.*, 1997; Kawakami *et al.*, 1997; Ohgawara *et al.*, 1998; Loudovaris *et al.*, 1999).

Another approach is use of primary tissue that is naturally hypoxia resistant. Tilapia, a tropical teleost fish, have large, anatomically discrete islets that are easily harvested. A study by Wright *et al.* (1998) demonstrated that these tilapia islets are much less sensitive to hypoxia than are mammalian islets. For example, culturing under conditions of bulk medium oxygen partial pressure around 25 mmHg resulted in uniform fragmentation and near-total necrosis of rat islets in less than 24 hr but caused only central necrosis in fish islets at up to 1 week. Fish islet grafts exposed to hypoxic culture for 72 hr prior to transplantation produced normoglycemia in diabetic nude mice for various periods of time. The authors reported starting production of tilapia with “humanized” tilapia insulin genes, which should result in islets that secrete humanized insulin.

## *In Situ* OXYGEN GENERATION

It is now established that limitations of oxygen supply may result in substantial viability loss, especially immediately after implantation, such as observed in isogeneic islets in a planar diffusion immunobarrier device implanted into diabetic mice (Suzuki *et al.*, 1998a,b). One approach to overcome the oxygen limitation problem is to supply implanted tissue with oxygen generated *in situ* adjacent to one side of the immunobarrier device (Wu *et al.*, 1999). On the other side, the exterior of the device is exposed to either culture medium for *in vitro* studies or the host tissue for *in vivo* conditions.

We have previously described *in situ* oxygen generation by electrolytic decomposition of water in an electrolyzer (Wu *et al.*, 1999). The electrolyzer is in the form of a thin, multilayer sheet, within which electrolysis reactions take place on the anode and the cathode to form oxygen and hydrogen, respectively (Erickson and Russell, 1977). The anode side is placed in close contact with the immunobarrier device, which provides a continuous supply of oxygen to the implanted tissue. The oxygen flux  $N_e$  (mol/cm<sup>2</sup>·sec) generated by the electrolyzer is related to the current  $I$  (amperes) applied between the electrodes by

$$I = nFA_e N_e, \quad (1)$$

where  $n = 4$  is the number of electrons required to make one molecule of oxygen,  $F$  is Faraday's constant (96,500 A·sec/equivalent), and  $A_e$  is the cross-sectional area through which oxygen diffuses to the implanted tissue. The oxygen flux can be set at any desired level by appropriate control of the current. In the remainder of this chapter, we show how a theoretical model can be used to analyze oxygen transport in a device of the type we previously employed (Wu *et al.*, 1999). The theoretical model provides estimates of the oxygen profiles in the tissue. In specific numerical examples applicable to *in vivo* conditions, we examine the effects of tissue thickness, oxygen flux, and external partial pressure on oxygen profile characteristics, and on the maximum and minimum oxygen partial pressures to which the tissue is exposed. We define different regimes of operation, depending on the direction of oxygen flux between the exterior and the device and the presence or absence of a nonrespiring region in the middle of the tissue caused by oxygen limitations, and we formulate the oxygen flux requirement to avoid the development of such a region. The results of this analysis can be used to improve the design of experiments for the study of the effectiveness of *in situ* electrochemical oxygen generation by providing estimates for the appropriate value of imposed oxygen flux and the maximum possible viable tissue thickness.

Fig. 27.3. Schematic diagram of a system, corresponding to an immunobarrier device with *in situ* oxygen electrochemical generation. The heavy curve is the oxygen partial pressure profile. Membranes 1 (M1) and 2 (M2) constitute a laminated composite membrane (Wu et al., 1999). A host tissue layer or a mass-transfer boundary layer (not shown) can be present outside M2.  $P_{ext}$  is the external oxygen partial pressure.  $P_{Sm}$  and  $P_{Se}$  are the oxygen partial pressures at the membrane-tissue interface opposite ( $x = -L/2$ ) and nearest ( $x = L/2$ ) the electrolyzer, respectively.  $P_C$  is the critical oxygen partial pressure below which hypoxic damage occurs and respiration ceases,  $N_e$  is the oxygen flux generated by the electrolyzer,  $L$  is the thickness of the implanted tissue,  $L_m$  is the maximum tissue thickness that can be supported by  $P_{ext}$ , and  $L_e$  is the maximum tissue thickness that can be supported by  $N_e$ . Three alternative coordinate systems,  $x$ ,  $y$ , and  $z$ , used in our analysis, are also shown.

## THEORETICAL ANALYSIS OF *IN SITU* OXYGEN GENERATION

### PROBLEM FORMULATION

We consider one-dimensional oxygen diffusion in Cartesian coordinates through a series of layers (Fig. 27.3). Three different coordinates are used in this analysis:  $x$  is the distance from the midplane of the implanted tissue space of thickness  $L$  (centimeters), considered positive in the direction toward the electrolyzer;  $y$  and  $z$  are the distances from the interfaces between the implanted tissue and membrane 1 and between the implanted tissue and the electrolyzer outer membrane, respectively, both positive in the direction toward the implanted tissue layer.

The species conservation equation for oxygen in layer  $i$  is

$$D_i \frac{d^2 c_i}{dx^2} = V_i, \quad (2)$$

where  $D_i$  ( $\text{cm}^2/\text{sec}$ ) is the effective diffusion coefficient of oxygen in layer  $i$ , and  $V_i$  ( $\text{mol}/\text{cm}^3 \cdot \text{sec}$ ) is the local oxygen consumption rate per unit volume in layer  $i$ . The local concentration of oxygen  $c_i$  ( $\text{mol}/\text{cm}^3$ ) is linearly related to the local oxygen partial pressure  $P_i$  (mmHg) in phase  $i$  by

$$c_i = \alpha_i P_i, \quad (3)$$

where  $\alpha_i$  is the Bunsen solubility coefficient of oxygen in that phase ( $\text{mol}/\text{cm}^3 \cdot \text{mmHg}$ ). Combination of Eqs. (2) and (3) yields the species conservation equation for oxygen in phase  $i$  in terms of the partial pressure  $P_i$ :

$$(D\alpha)_i \frac{d^2 P_i}{dx^2} = V_i. \quad (4)$$

Use of partial pressures instead of concentrations eliminates need for partition coefficients between adjacent phases because the partial pressures at equilibrium are equal across an interface.

Except as noted, we focus on the implanted tissue in this study, and for simplicity we will omit the subscript for this layer. With this simplification, the species conservation equation for oxygen in the live implanted tissue within the chamber becomes

$$D\alpha \frac{d^2 P}{dx^2} = V. \quad (5)$$

Oxygen consumption rate per unit volume  $V$  is assumed to follow Michaelis–Menten kinetics,

$$V = V_{\max}(1 - \epsilon) \frac{P}{K_m + P}, \quad (6)$$

for  $P > P_C$ , where  $V_{\max}$  is the maximum oxygen consumption rate per unit volume of tissue,  $1 - \epsilon$  is the live tissue volume fraction in the tissue layer,  $K_m$  is the Michaelis–Menten constant, and  $P_C$  is the critical value of  $P$  below which oxygen consumption ceases.

Equation (4) must be solved simultaneously in all layers. At each interface between adjacent layers  $i$  and  $j$ , there is equality in each phase between the oxygen partial pressure

$$P_i = P_j \quad (7)$$

and oxygen flux

$$(D\alpha)_i \frac{dP_i}{dx} = (D\alpha)_j \frac{dP_j}{dx}. \quad (8)$$

Equations (7) and (8) supply two boundary conditions necessary to solve Eq. (4) in all internal layers. Two specified external conditions necessary to solve Eq. (4) everywhere are, at  $x = L/2$ ,

$$D\alpha \frac{dP}{dx} = N_e, \quad (9)$$

and, at  $x = -(L/2 + L_{\text{ext}})$ ,

$$P = P_{\text{ext}}, \quad (10)$$

where  $N_e$ , the oxygen flux imposed by the electrolyzer, is taken to be positive in the negative  $x$  direction;  $L_{\text{ext}}$  is the sum of the layer thicknesses external to the tissue chamber at the side opposite to the electrolyzer; and  $P_{\text{ext}}$  is the external oxygen partial pressure, i.e., that in the microvasculature for *in vivo* implantation or that of the bulk medium for *in vitro* culture.

We present here the analytical solution to Eq. (5) using zero-order kinetics [ $K_m$  set equal to 0,  $V = V_{\max}(1 - \epsilon) = \text{constant}$ ]. With  $P_C = 0.1$  mmHg (Anundi and De Groot, 1989; Chance *et al.*, 1973; Silver, 1973), the difference between this solution and that obtained with numerical methods using the nonlinear Michaelis–Menten kinetics is negligible here because of the high values of  $P/K_m$  attained (Avgoustiniatos and Colton, 1997a; Wu *et al.*, 1999).

For pedagogical reasons, we choose to focus initially on the implanted tissue layer as an isolated problem. In this case, the boundary conditions for the implanted tissue layer are expressed in terms of the oxygen partial pressures  $P_{\text{Se}}$  and  $P_{\text{Sm}}$  at the two tissue–membrane interfaces nearest the electrolyzer and nearest the external host tissue or medium side, respectively:

at  $x = L/2$ ,

$$P = P_{\text{Se}}, \quad (11)$$

and, at  $x = -L/2$ ,

$$P = P_{\text{Sm}}, \quad (12)$$

$P_{\text{Se}}$  and  $P_{\text{Sm}}$ , neither of which is known *a priori*, are shown in Fig. 27.3. Because the problem is not symmetric about  $x = 0$ ,  $P_{\text{Se}} \neq P_{\text{Sm}}$  in general.

Two relations are needed in order to relate  $P_{\text{Se}}$  and  $P_{\text{Sm}}$  to the known quantities  $N_e$  and  $P_{\text{ext}}$ , a flux boundary condition at  $x = L/2$ , Eq. (9), and a flux boundary condition at  $x = -L/2$ ,

$$D\alpha \frac{dP}{dx} = N_m, \quad (13)$$

where  $N_m$  is the oxygen flux across the tissue–membrane interface farthest from the electrolyzer, also positive in the negative  $x$  direction. An oxygen balance around the tissue layer yields

$$N_m = N_e - VL; \quad (14)$$

$N_m$  can be viewed as the unused portion of the  $N_e$  passing through the tissue layer.

If no oxygen consumption occurs external to the implanted tissue, then the oxygen profile between  $P_{\text{ext}}$  and  $P_{\text{Sm}}$ , derived using the internal boundary conditions Eqs. (7) and (8), is composed of linear segments, and the flux can be expressed by

$$N_m = \frac{P_{\text{Sm}} - P_{\text{ext}}}{R_{\text{ext}}}, \quad (15)$$

where  $R_{\text{ext}}$  is the sum of the diffusive mass transfer resistances in series external to the tissue. In an *in vitro* experiment,  $R_{\text{ext}}$  is associated with each of the two components of the membrane laminate and the mass transfer boundary layer in the medium:

$$R_{\text{ext}} = \frac{1}{k_c \alpha_{\text{med}}} + \left( \frac{L}{D\alpha} \right)_{M2} + \left( \frac{L}{D\alpha} \right)_{M1}, \quad (16)$$

where M1 and M2 refer to the cell retentive and vascularizing membranes, respectively,  $k_c = D_{\text{med}} / \delta_c$  is the boundary layer mass transfer coefficient between the stirred medium and membrane M2, and  $\delta_c$  is the concentration boundary layer thickness (Wu *et al.*, 1999). If the device is implanted, the expression equivalent to Eq. (16) would be

$$R_{\text{ext}} = \left( \frac{L}{D\alpha} \right)_{\text{host tissue}} + \left( \frac{L}{D\alpha} \right)_{M2} + \left( \frac{L}{D\alpha} \right)_{M1}, \quad (17)$$

where the first term on the right-hand side is the diffusional resistance imposed by a host tissue layer between M2 and the closest blood vessels (Avgoustiniatos and Colton, 1997b).

If the external layers contain respiring cells, as is the case with the host tissue layer and with the vascularizing membrane M2 when infiltrated by cells, the effect on oxygen profiles can be consolidated into a correction to  $P_{\text{ext}}$ :

$$\left( P_{\text{ext}} \right)_{\text{corrected}} = P_{\text{ext}} - \sum_{i=2}^m \Delta P_{Vi} \quad (18)$$

where  $\Delta P_{Vi}$  is the oxygen partial pressure drop through all layers caused by oxygen consumption in layer  $i$ ,  $m$  is the number of layers, and  $i = 1$  refers to the live implanted tissue. This problem has been analyzed elsewhere (Avgoustiniatos and Colton, 1997b). Oxygen consumption by cells infiltrating the outer vascularizing membrane layer causes a negligible oxygen partial pressure drop. Hence, the only nonnegligible term in the sum in Eq. (18) is that arising from respiration in the host tissue layer found between the outer membrane and the nearest blood vessels,

$$\left( P_{\text{ext}} \right)_{\text{corrected}} = P_{\text{ext}} - \left( \frac{VL^2}{2D\alpha} \right)_{\text{host tissue}} \quad (19)$$

for the typical situation where the host tissue is exposed to  $P \gg K_m$  so that the local oxygen consumption is independent of partial pressure.

### OXYGEN PARTIAL PRESSURE PROFILE

Assuming that all the tissue layer is exposed to  $P > P_C$ , Eq. (5) can be solved with boundary conditions, Eqs. (11) and (12), to give

$$P(x) = \frac{P_{Se} + P_{Sm}}{2} + (P_{Se} - P_{Sm}) \frac{x}{L} - \frac{V}{2D\alpha} \left[ \left( \frac{L}{2} \right)^2 - x^2 \right]. \quad (20)$$

The first two terms on the right-hand side of Eq. (20) represent the oxygen profile in the absence of reaction but with the same surface partial pressures  $P_{Se}$  and  $P_{Sm}$ , and the last term represents the symmetrical reduction in local partial pressure resulting from oxygen consumption. These terms are superimposable because  $V$  is taken as independent of  $P$ .

By differentiating Eq. (20) with respect to  $x$  and substituting the result into Eq. (9), we obtain a relationship between  $P_{Se}$  and  $P_{Sm}$ :

$$P_{Se} - P_{Sm} = N_c \frac{L}{D\alpha} - \frac{VL^2}{2D\alpha}. \quad (21)$$

The first term on the right-hand side of Eq. (21) represents the partial pressure drop in the absence of reaction (i.e., the entire flux  $N_c$  passes unchanged through the tissue layer), and the second term represents the reduction in this partial pressure drop arising from oxygen consumption. Alternatively, expressing  $N_c$  in Eq. (21) in terms of  $N_m$  using Eq. (14) leads to

$$P_{Se} - P_{Sm} = N_m \frac{L}{D\alpha} + \frac{VL^2}{2D\alpha}. \quad (22)$$

The first term on the right-hand side of Eq. (22) represents the partial pressure drop caused by the unused flux  $N_m$  passing through the tissue layer, and the second term represents the additional drop resulting from consumption. We can also eliminate  $V$  from Eq. (21) by expressing it in terms of  $N_c$  and  $N_m$  using Eq. (14), which leads to

$$P_{Se} - P_{Sm} = \frac{L}{D\alpha} \frac{N_c + N_m}{2}. \quad (23)$$

Equation (23) shows that the net pressure drop between the two tissue–membrane boundaries is equal to the tissue diffusion resistance multiplied by the average of the flux (a linear function of  $x$ ) at the two boundaries.

We can also express both  $P_{Sm}$  and  $P_{Se}$  in terms of the known external oxygen partial pressure  $P_{ext}$ . By rewriting Eq. (15) in terms of  $P_{Sm}$  and using Eq. (14) we obtain

$$P_{Sm} = P_{ext} - V \left( L - \frac{N_c}{V} \right) R_{ext}. \quad (24)$$

Then, combining Eqs. (21) and (24) we also obtain

$$P_{Se} = P_{ext} - V \left( L - \frac{N_c}{V} \right) \left( \frac{L}{D\alpha} + R_{ext} \right) + \frac{VL^2}{2D\alpha}. \quad (25)$$

By substituting Eqs. (24) and (25) into Eq. (20), we obtain an expression for the oxygen partial pressure profile in terms of  $N_c$  and  $P_{ext}$ :

$$P(x) = P_{ext} - V \left( L - \frac{N_c}{V} \right) R_{ext} - \frac{V}{2D\alpha} \left[ \left( L - \frac{N_c}{V} \right)^2 - \left( \frac{L}{2} - x - \frac{N_c}{V} \right)^2 \right]. \quad (26)$$

When oxygen enters the device from both sides, a minimum in the oxygen partial pressure profile should exist. The position of the minimum can be calculated by differentiating Eq. (26) with respect to  $x$  and setting the derivative equal to 0, at  $x = x_{min}$ ,

$$\frac{dP}{dx} = 0 \quad (27)$$

to obtain

$$x_{\min} = \frac{L}{2} - \frac{N_e}{V}. \quad (28)$$

A minimum exists when  $x_{\min} > -L/2$ , when  $L > N_e/V$ , from Eq. (28), or when  $N_m < 0$ , from Eq. (14). Substituting Eq. (28) into Eq. (26) leads to the minimum oxygen partial pressure  $P_{\min}$ ,

$$P_{\min} = P_{\text{ext}} - V \left( L - \frac{N_e}{V} \right) R_{\text{ext}} - \frac{V}{2D\alpha} \left( L - \frac{N_e}{V} \right)^2. \quad (29)$$

The second term on the right-hand side of Eq. (29) represents the oxygen partial pressure drop through the external layers, and the third term represents the drop through the tissue layer that is supported from the host tissue or culture medium side. By substituting Eqs. (28) and (29) into Eq. (26), a simpler equation for the oxygen profile in terms of  $P_{\min}$  and  $x_{\min}$  can be obtained:

$$P(x) = P_{\min} + \frac{V}{2D\alpha} (x - x_{\min})^2. \quad (30)$$

Equation (30) implies that the profile is symmetrical around the minimum. However, the profile extends to different lengths,  $N_e/V$  and  $L - N_e/V$  at the electrolyzer and external sides of the minimum, respectively. Using Eq. (28), we can apply Eq. (30) at the tissue–electrolyzer membrane interface ( $x = L/2$ ) to obtain a relationship between  $P_{\text{Se}}$  and  $P_{\min}$ ,

$$P_{\text{Se}} - P_{\min} = \frac{N_e^2}{2VD\alpha}. \quad (31)$$

## MAXIMUM SUPPORTABLE TISSUE THICKNESS

### Single layer of live tissue

The maximum thickness of viable tissue  $L_{\max}$  that can be supported in the device is

$$L_{\max} = L_e + L_m, \quad (32)$$

where  $L_e$  and  $L_m$  are, respectively, the maximum tissue thickness that can be supported by the imposed oxygen flux,  $N_e$ , on one side and by oxygen diffusion from the host tissue or culture medium on the other (Fig. 27.3). If  $N_m$  is positive, then, from Eq. (14),  $N_e$  is more than large enough to sustain oxygen consumption by all tissue, and there is a positive flux left that exits the device. If  $N_m$  is negative, then  $N_e$  is not large enough to sustain oxygen consumption by all tissue, and it is complemented by an influx from the opposite side of the device. Setting  $N_m = 0$  in Eq. (14) leads to the maximum tissue thickness  $L_e$  supportable from  $N_e$ :

$$L_e = \frac{N_e}{V} \quad (33)$$

The maximum tissue thickness supportable by diffusion from the exterior of the device,  $L_m$ , may be determined by noting that when

$$L = L_{\max} = \frac{N_e}{V} + L_m, \quad (34)$$

the equations leading to Eq. (30) are still applicable along with

$$P_{\min} = P_C. \quad (35)$$

Substitution of Eqs. (34) and (35) into Eq. (29) results in a quadratic expression in  $L_m$ ,

$$\left(\frac{V}{2D\alpha}\right)L_m^2 - (VR_{\text{ext}})L_m - (P_{\text{ext}} - P_C) = 0, \quad (36)$$

the positive root of which is

$$L_m = -D\alpha R_{\text{ext}} + \left[ (D\alpha R_{\text{ext}})^2 + \frac{2D\alpha}{V}(P_{\text{ext}} - P_C) \right]^{1/2}; \quad (37)$$

$L_m$ , the tissue thickness that can be supported from  $P_{\text{ext}}$ , is independent of the oxygen flux  $N_e$ . In order to have  $P > P_C$  everywhere, it is necessary to satisfy

$$L < L_{\text{max}} = \frac{N_e}{V} + L_m, \quad (38)$$

or, in terms of the adjustable oxygen flux  $N_e$ ,

$$N_e > V(L - L_m), \quad (39)$$

where  $L_m$  is given by Eq. (37). If the implanted tissue is proliferating, leading to an increase of  $L$  with time, the minimum oxygen flux  $N_e$  necessary to prevent tissue death also increases.

### Presence of nonrespiring tissue

Up to this point, we have considered only  $L \leq L_{\text{max}}$ , in which case there is a single layer of live tissue. If  $L > L_{\text{max}}$ , there must exist a nonrespiring region between  $x = -L/2 + L_m$  and  $x = L/2 - L_e$  in which  $P = P_C$  and  $V = 0$ . Equation (20) cannot be applied in this case because it was derived assuming a constant  $V$  throughout the tissue layer. Instead, we break the solution domain into two parts. For convenience, the origin of the coordinate system is placed on one or the other implanted tissue–membrane interface.

At the electrolyzer side, the origin is at  $z = 0$ , where  $z = L/2 - x$ . Equation (5) retains the same form in terms of  $z$ , and the boundary conditions and associated relationships at  $z = 0$  and  $z = L_e$  are analogous to their previous form. With  $P_{\text{min}} = P_C$ , the solution becomes

$$P(z) = P_C + \frac{V}{2D\alpha}(L_e - z)^2. \quad (40)$$

$P_{\text{Se}}$  can be calculated by setting  $z = 0$  in Eq. (40):

$$P_{\text{Se}} = P_C + \frac{VL_e^2}{2D\alpha}. \quad (41)$$

Taking the derivative of Eq. (40) with respect to  $z$  and applying Eq. (9) leads to Eq. (33), which defines  $L_e$  in terms of the known parameters  $N_e$  and  $V$ . Equation (40) represents a special case ( $P_{\text{min}} = P_C$ ) of an alternative form of Eq. (30).

At the other side of the device, we solve Eq. (5) in an analogous way in terms of the distance from the tissue–membrane interface,  $y = L/2 + x$ , in the domain between  $y = 0$  and  $y = L_m$ . The solution for the partial pressure becomes

$$P(y) = P_C + \frac{V}{2D\alpha}(L_m - y)^2; \quad (42)$$

$P_{\text{Sm}}$  can be calculated by setting  $y = 0$  in Eq. (42):

$$P_{\text{Sm}} = P_C + \frac{VL_m^2}{2D\alpha}. \quad (43)$$

Taking the derivative of Eq. (42) with respect to  $y$  and applying Eqs. (13) and (15) leads to

$$P_{Sm} = P_{ext} - VL_m R_{ext} \tag{44}$$

When nonrespiring tissue is present,  $P_{Sm}$  is always less than  $P_{ext}$ , as shown by Eq. (44), because oxygen diffuses from the exterior into the device. In contrast,  $P_{Sm}$  calculated from Eq. (24) can be lower, equal to, or higher than  $P_{ext}$  in the absence of nonrespiring tissue. Combination of Eqs. (43) and (44) leads to the same quadratic expression, Eq. (36), whose positive root is the physical solution for  $L_m$  given by Eq. (37).

### CALCULATIONS

Using the equations derived in the previous section, we calculate oxygen profiles in immunoisolation devices supplied with oxygen by *in situ* oxygen generation. We use  $V_{max} = 2.76 \times 10^{-8}$  mol/cm<sup>3</sup>·sec, applicable to  $\beta$ TC3 cells (Mukundan *et al.*, 1995), tissue density  $1 - \epsilon = 0.75$ , characteristic of devices seeded with  $\beta$ TC3 cells and examined after *in vitro* culture (Wu *et al.*, 1999),  $D\alpha = 1.70 \times 10^{-14}$  mol/cm·sec·mmHg,  $(D\alpha)_{M1} = 1.95 \times 10^{-14}$  mol/cm·sec·mmHg,  $(D\alpha)_{M2} = 2.79 \times 10^{-14}$  mol/cm·sec·mmHg,  $L_{M1} = 30 \mu\text{m}$ ,  $L_{M2} = 15 \mu\text{m}$  (Avgoustiniatos and Colton, 1997b; Wu *et al.*, 1999), and  $P_C = 0.1$  mmHg (Anundi and De Groot, 1989; Chance *et al.*, 1973; Silver, 1973). We assume  $P_{ext} = 40$  mmHg for our base case, corresponding to the oxygen partial pressure of the microvasculature being present on the surface of the outer membrane M2 with  $L_{ext} = L_{M1} + L_{M2}$ , and we ignore the negligible effect of cells infiltrating M2 (Avgoustiniatos and Colton, 1997b). Using Eq. (6) with  $K_m = 0$ , we calculate that  $V = 2.07 \times 10^{-8}$  mol/cm<sup>3</sup>·sec, and using Eq. (17) we calculate that  $R_{ext} = 2.07 \times 10^{11}$  mmHg/(mol/cm<sup>2</sup>·sec).

### EFFECT OF IMPOSED OXYGEN FLUX $N_e$

Figure 27.4 depicts oxygen partial pressure  $P$  for different values of the imposed oxygen flux  $N_e$  with a fixed implanted tissue layer thickness  $L = 200 \mu\text{m}$ . Using Eq. (37),  $L_m = 53 \mu\text{m}$  in all cases. The five curves correspond to different types of behavior (Table 27.1). For  $N_e = 5 \times 10^{-10}$  mol/cm<sup>2</sup>·sec,  $L < L_e$ ,  $P$  increases monotonically in the  $y$  direction, the oxygen generated is sufficient to sustain consumption by all tissue, and there is still some left that exits to the device exterior through the membranes. As  $N_e$  decreases,  $P_{Se}$  does also. This is consistent with the first derivative of  $P_{Se}$  with respect to  $N_e$ , as given by Eq. (25) or Eq. (41), always being positive. At  $N_e = 4.14 \times 10^{-10}$  mol/cm<sup>2</sup>·sec,  $L = L_e$ , and the oxygen generated is just enough to sustain consumption by all tissue.  $P$  increases monotonically with  $y$ , and there is no net oxygen transport through the external membrane layers, where  $dP/dy = 0$ . At  $N_e = 3.5 \times 10^{-10}$  mol/cm<sup>2</sup>·sec,  $L_e < L < L_{max}$ , and oxygen supplied by the electrolyzer is not enough to support all tissue; oxygen enters the tissue layer from both sides, resulting in a minimum in the oxygen profile ( $P_{min} = 21$

Fig. 27.4. Oxygen partial pressure  $P$  as a function of the distance  $y$  from the M1–tissue interface for different values of the oxygen flux  $N_e$  generated by the electrolyzer. The five curves correspond to five different types of behavior, delineated in Table 27.1. In all cases  $P_{ext} = 40$  mmHg,  $L_m = 53 \mu\text{m}$ , and  $L = 200 \mu\text{m}$ .

Table 27.1. Characteristics of curves in Figs. 27.4–27.6

	2.5	121	53	200	$L > L_e + L_m$	40	17	0.1	89

<sup>a</sup> $L_e$ ,  $L_m$ , and  $L^*$  are given by Eqs. (33), (37), and (45), respectively.

<sup>b</sup> $P_{Sm}$ ,  $P_{min}$ , and  $P_{Se}$  are given by Eqs. (24), (29), and (25), respectively.

mmHg) at  $y = L - L_e = 31 \mu\text{m}$ . At  $N_e = 3.04 \times 10^{-10} \text{ mol/cm}^2 \cdot \text{sec}$ , the tissue thickness is exactly the maximum that can be supported from both sides,  $L = L_{max}$ , all the tissue is still viable, and  $P_{min}$  drops to  $P_C$  at a single point,  $y = L_m = L - L_e$ . At the lowest flux,  $2 \times 10^{-10} \text{ mol/cm}^2 \cdot \text{sec}$ , for which  $L > L_{max}$ , the combination of  $N_e$  and  $N_m$  is insufficient to sustain consumption throughout the entire tissue thickness, and a nonrespiring region develops between  $y = L_m = 53 \mu\text{m}$  and  $y = L - L_e = 103 \mu\text{m}$ , all of which is exposed to  $P = P_C$ . The latter two profiles are identical at the host side of the device, whereas they differ by a displacement in the  $y$  direction at the electrolyzer side. This occurs because, once  $P_{min}$  falls to  $P_C$ , a nonrespiring region develops, and oxygen transport at the two sides of this region is decoupled.

For a device with fixed  $L = 200 \mu\text{m}$  having the entire space filled with tissue and alginate ( $1 - \epsilon = 0.75$ ),  $N_e = 3.04 \times 10^{-10} \text{ mol/cm}^2 \cdot \text{sec}$  corresponds to the minimum oxygen flux that prevents development of a nonrespiring region. If the formation of such a region must be avoided,  $N_e$  should be adjusted higher. If a cell line is used, its proliferation must be controlled. Assuming that other nutrients or metabolic factors are not restrictive, uncontrollable proliferation should eventually lead to the presence of two layers of live tissue next to the membranes of the device, one supplied with oxygen by the electrolyzer and the other from the exterior of the device, with a layer of nonrespiring tissue in between. Histologic sections of tissue having these characteristics have indeed been described (Colton, 1995) in devices implanted without *in situ* oxygen generation. In general, one should expect proliferation to continue where  $P$  is high, and the nonrespiring region to expand where  $P$  is lowest, in the middle section of the device, until such time as proliferation is shut off by biological means or the buildup of internal mechanical forces leads to cessation of proliferation or destruction of the device.

### EFFECT OF TISSUE THICKNESS $L$

Variation of the tissue thickness  $L$  is examined in Fig. 27.5 for  $N_e = 3.5 \times 10^{-10} \text{ mol/cm}^2 \cdot \text{sec}$ , corresponding to the middle profile in Fig. 27.4. In this case,  $L_e = 169$ ,  $L_m = 53$ , and  $L_{max} = 222 \mu\text{m}$  for all curves. For  $L < 169 \mu\text{m} = L_e$ ,  $P$  increases monotonically in the  $y$  direction, the oxygen generated is sufficient to sustain oxygen consumption by all tissue, and there is still some oxygen left that exits to the device exterior through the membrane. This applies to the curves for the four smallest thicknesses shown in Fig. 27.5. The remaining curves correspond to

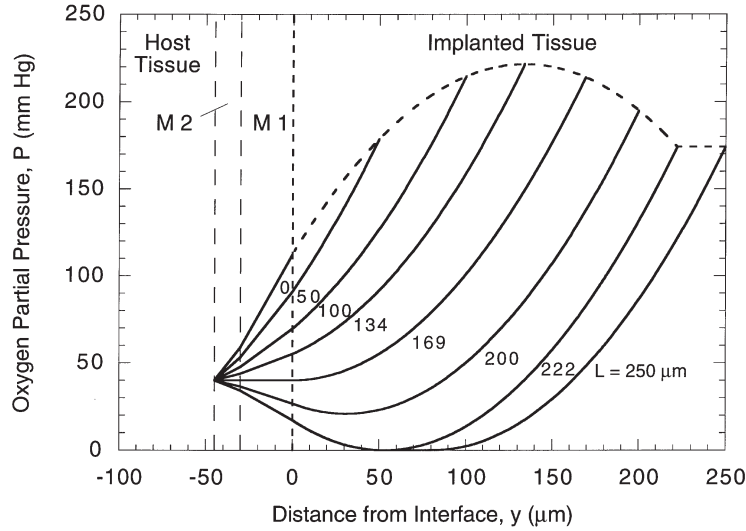

Fig. 27.5. Oxygen partial pressure  $P$  as a function of the distance  $y$  from the M1–tissue interface, for different values of the tissue thickness  $L$ . The characteristics of the curves are delineated in Table 27.1. The dashed line connecting the highest points of each oxygen profile is a plot of  $P_{Se}$  as a function of  $L$ . In all cases  $P_{ext} = 40$  mmHg,  $L_m = 53$   $\mu\text{m}$ ,  $N_e = 3.5 \times 10^{-10}$  mol/cm<sup>2</sup>·sec, and  $L_e = 169$   $\mu\text{m}$ .

other types of behavior (see Table 27.1). For  $L = 169$   $\mu\text{m} = L_e$ ,  $P$  increases monotonically with  $y$ , and there is no net oxygen transport through the external membrane layers, where  $dP/dy = 0$ . For  $L_e < L = 200$   $\mu\text{m} < L_{max}$ , oxygen supplied by the electrolyzer is not enough to support all tissue. Oxygen enters the tissue layer from both sides, resulting in a minimum ( $P_{min} = 21$  mmHg) in the oxygen profile where the two fronts meet at  $y = L - L_e = 31$   $\mu\text{m}$ . This curve is identical to the middle curve in Fig. 27.4. For  $L = 222$   $\mu\text{m} = L_{max}$ , the tissue thickness is exactly the maximum that can be supported from both sides. All the tissue is still viable, and  $P_{min}$  drops to  $P_c$  at a single point,  $y = L_m = L - L_e$ . At  $250$   $\mu\text{m}$ , for which  $L > L_{max}$ , the combined oxygen flux from each side is insufficient to sustain consumption throughout the entire tissue thickness, and a nonrespiring region develops between  $y = L_m = 53$   $\mu\text{m}$  and  $y = L - L_e = 81$   $\mu\text{m}$ . In analogy to curves in Fig. 27.4, the latter two profiles are identical at the host side of the device, while they differ by a displacement in the  $y$  direction at the electrolyzer side.

In contrast to Fig. 27.4, where  $P_{Se}$  decreased monotonically with  $N_e$ , Fig. 27.5 shows that  $P_{Se}$  goes through a maximum as  $L$  increases. That maximum must occur for  $L \leq L_{max}$ , because  $P_{Se}$  does not vary with  $L$  when  $L \geq L_{max}$ . The value of this maximum partial pressure can be obtained by differentiating Eq. (25) with respect to  $L$  and setting the derivative equal to 0, which yields the length  $L^*$  at which  $P_{Se}$  is maximized:

$$L^* = L_e - D\alpha R_{ext}. \quad (45)$$

If  $L^* \leq 0$ , the maximum in  $P_{Se}$  occurs as  $L \rightarrow 0$  and, from Eq. (25), is equal to  $P_{ext} + N_e R_{ext}$ . Substituting  $L^*$  for  $L$  in Eq. (25) gives, for  $L^* > 0$ ,

$$(P_{Se})_{max} = P_{ext} + \frac{VD\alpha R_{ext}^2}{2} + \frac{N_e^2}{2VD\alpha}. \quad (46)$$

For the conditions applying to Fig. 27.5, Eqs. (45) and (46) give  $L^* = 134$   $\mu\text{m}$  and  $(P_{Se})_{max} = 222$  mmHg, the curve for which is plotted in Fig. 27.5. The dashed line in Fig. 27.5 connects the highest points of all oxygen profiles and is therefore a plot of  $P_{Se}$  as a function of  $L$ .

The existence of this maximum can be understood by rewriting Eq. (25) as

$$P_{Se} = P_{ext} + N_e \left( \frac{L}{D\alpha} + R_{ext} \right) - VL \left( \frac{L}{2D\alpha} + R_{ext} \right). \quad (47)$$

The second term on the right-hand side of Eq. (47) is the partial pressure drop associated with the imposed oxygen flux  $N_e$  in the absence of reaction, and the third term is the reduction in this partial pressure drop associated with oxygen consumption. For  $L < L^*$ , as  $L$  increases, the term associated with  $N_e$  increases faster than the term associated with consumption, and  $P_{Se}$  increases. For

Fig. 27.6. Oxygen partial pressure  $P$  as a function of the distance  $y$  from the M1-tissue interface for different values of the external oxygen partial pressure  $P_{\text{ext}}$ . The three curves correspond to three different types of behavior, delineated in Table 27.1. In all cases  $N_e = 2.5 \times 10^{-10}$  mol/cm<sup>2</sup>·sec,  $L_e = 121$   $\mu\text{m}$ , and  $L = 200$   $\mu\text{m}$ .

$L > L^*$ , the second-order dependence on  $L$  in the consumption term prevails and  $P_{S_c}$  drops with increasing  $L$ , until  $L$  reaches  $L_{\text{max}}$ , beyond which point  $P_{S_c}$  remains constant.

### EFFECT OF EXTERNAL OXYGEN PARTIAL PRESSURE $P_{\text{ext}}$

Figure 27.6 shows the effect of  $P_{\text{ext}}$  on oxygen profiles for a device with  $L = 200$   $\mu\text{m}$  and  $N_e = 2.5 \times 10^{-10}$  mol/cm<sup>2</sup>·sec.  $L_e = 121$   $\mu\text{m}$  for all curves, but  $L_m$  varies because it depends on  $P_{\text{ext}}$ , as shown by Eq. (37). The three curves shown correspond to different types of behavior (see Table 27.1). For  $P_{\text{ext}} = 100$  mmHg, corresponding to the oxygen partial pressure in arterial blood,  $L_m = 98$   $\mu\text{m}$ ,  $L_e < L < L_{\text{max}}$ , and the two fronts of oxygen entering the device from both sides meet, resulting in a minimum ( $P_{\text{min}} = 27$  mmHg) at  $y = L - L_e = 79$   $\mu\text{m}$ . For  $P_{\text{ext}} = 72.3$  mmHg,  $L_m = 79$   $\mu\text{m}$ , the tissue thickness is the maximum that can be supported from both sides,  $L = L_{\text{max}}$ , and  $P_{\text{min}} = P_C$  at one point,  $y = L_m = L - L_e$ . At 40 mmHg,  $L_m = 53$   $\mu\text{m}$ , and  $L > L_{\text{max}}$ . The combined oxygen flux from each side is insufficient to sustain consumption by all tissue, and a nonrespiring region develops between  $y = L_m = 53$   $\mu\text{m}$  and  $y = L - L_e = 79$   $\mu\text{m}$ .

### CONCLUDING REMARKS

Our analysis provides estimates of oxygen profiles in implanted tissue within a planar immunobarrier device with *in situ* electrochemical generation for different values of the adjustable oxygen flux  $N_e$ , the tissue thickness  $L$ , and the external oxygen partial pressure  $P_{\text{ext}}$ . It can also be used to predict the effects of other parameters, for example, the tissue density  $1 - \epsilon$  and the maximum oxygen consumption rate per unit volume of the implanted tissue,  $V_{\text{max}}$ . Evaluation of oxygen profile characteristics, including the minimum and maximum values of oxygen partial pressure within the tissue, allows for the appropriate selection of the oxygen flux  $N_e$  and the tissue thickness  $L$  so as to avoid the loss of tissue viability and function associated with the development of a nonrespiring region. If a proliferating cell line is used, its proliferation must be controlled to avoid the development of such a region. The results of this analysis can be extended to study the possible development of damaging hyperoxic conditions and to assist in the prediction of the secretory function of the implanted tissue.

PART VII: FETAL TISSUE  
ENGINEERING

# FETAL TISSUE ENGINEERING

Dario O. Fauza

## INTRODUCTION

The first reported transplantation of human fetal tissue took place in 1922, when a fetal adrenal graft was transplanted into a patient with Addison's disease (Hurst *et al.*, 1922). A few years later, in 1928, fetal pancreatic cells were transplanted in an attempt to treat diabetes mellitus (Fichera, 1928). In 1957, a fetal bone marrow transplantation program was first undertaken (Thomas *et al.*, 1957). All of those initial experiments involving human fetal tissue transplantation failed, and it is only in the past two decades that fetal tissue transplantation in humans has started to yield favorable outcomes. A number of therapeutic applications of fetal tissue have already been explored, with variable results. Nonetheless, to date, the vast majority of studies have involved simply fetal cell, tissue, or organ transplantation, without any tissue engineering *sensu strictu*.

Fetal tissue has also been utilized as a valuable investigational tool in biomedical science since the 1930s. Embryologists, anatomists, and physiologists have studied fetal metabolism, fetoplacental unit function, premature life support, and brain activity in preivable fetuses (Klopper and Diczfalusy, 1969; Diczfalusy, 1974). *In vitro* applications of fetal tissue are well established and somewhat common. Cultures of different fetal cell lines, as well as commercial preparations of human fetal tissue, have been routinely used in the study of normal human development and neoplasias, in genetic diagnosis, in viral isolation and culture, and to produce vaccines (Haase, 1987; Lehrman, 1988; American Medical Association, 1990). Biotechnology, pharmaceutical, and cosmetic companies have employed fetal cells and extraembryonic structures such as placenta, amnion, and the umbilical cord to develop new products and to screen them for toxicity, teratogenicity, and carcinogenicity (Hansen and Sladek, 1989; Vawter *et al.*, 1990). Fetal tissue banks have been operating in the United States and abroad for many years as sources of various fetal cell lines for research (Rojansky and Schenker, 1993).

Considering that a large body of data has emerged from research involving fetal cells or tissues and that attempts at engineering virtually every mammalian tissue have already taken place, it is highly surprising that most fetal cell lines are yet to be explored for actual tissue engineering purposes. The true engineering of fetal tissue, through culture and placement of fetal cells into matrices or membranes, or through other *in vitro* manipulations prior to implantation, has barely begun to be investigated. Human studies are yet to be performed and very few animal experiments have been reported thus far (Vacanti *et al.*, 1988; Cusik *et al.*, 1995; Fauza *et al.*, 1998a,b). Fetal cells were first used experimentally in engineered constructs by Vacanti *et al.* (1988). Interestingly, this investigation was part of the introductory study on selective cell transplantation using bioabsorbable, synthetic polymers as matrices. This same group performed another study involving fetal cells in 1995 (Cusik *et al.*, 1995). Both experiments, in rats, did not include structural replacement or functional studies. The use of fetal constructs as a means of structural and functional replacement in large animal models was first reported experimentally only in 1997 (Fauza *et al.*, 1998a,b). This chapter starts to explore the still exceedingly new field of fetal tissue engineering, along with a general overview of fetal cell and tissue transplantation.

## GENERAL CHARACTERISTICS OF FETAL CELLS

Immunologic rejection (in nonautologous applications), growth limitations, differentiation and function restraints, incorporation barriers, and cell/tissue delivery difficulties are well-known complications of tissue engineering. Likely, many of those problems could be better managed, if not totally prevented, if fetal tissue was used. Due to their properties both *in vitro* and *in vivo*, fetal cells are, potentially, an excellent “raw material” for tissue engineering.

### *In Vitro*

Compared with cells harvested postnatally, most fetal cells multiply more rapidly and more often in culture (Vacanti *et al.*, 1988; Fine, 1994; Cusik *et al.*, 1995; Qu *et al.*, 1996; Fauza *et al.*, 1998a,b). Depending on the cell line considered, however, this increased proliferation is more or less pronounced, or, in a few cases, not evident at all (Vacanti *et al.*, 1988; Fauza *et al.*, 1998a,b, 2000).

Because they are very plastic in their differentiation potential, fetal cells respond better than mature cells to environmental cues (Fine, 1994). Limited data from fetal myoblasts and osteoblasts suggest that purposeful manipulations in culture or in a bioreactor can be designed to steer fetal cells to produce improved constructs (Qu *et al.*, 1996; Fauza *et al.*, 2000). Fetal cells can survive at lower oxygen tensions than those tolerated by mature cells and are therefore more resistant to ischemia during *in vitro* manipulations (Wong, 1988). They also commonly lack long extensions and strong intercellular adhesions (Wong, 1988; Dekel *et al.*, 1997). Probably because of those characteristics, fetal cells display better survival after refrigeration and cryopreservation protocols when compared with adult cells (Groscurth *et al.*, 1986; Wong, 1988; Fine, 1994). This enhanced endurance during cryopreservation, however, seems to be tissue specific. For instance, data from primates and humans have shown that fetal hematopoietic stem cells, as well as fetal lung, kidney, intestine, thyroid, and brain tissues, can be well preserved at low temperatures, whereas non-hematopoietic liver and spleen tissues can also be cryopreserved, but not as easily [Gage *et al.*, 1985; Groscurth *et al.*, 1986; National Institutes of Health (NIH), 1988; Crombleholme *et al.*, 1991; Andreoletti *et al.*, 1997; Mychaliska *et al.*, 1998; Surbek *et al.*, 1998].

### *In Vivo*

The expression of major histocompatibility complex (H-2) antigens in the fetus, and hence, fetal allograft survival in immunocompetent recipients, are age and tissue specific (Garvey *et al.*, 1980; Kirkwood and Billington, 1981; Statter *et al.*, 1988; Strong, 1991; Edwards, 1992; Foglia *et al.*, 1986a,b; Bakay *et al.*, 1998). The same applies to fetal allograft growth, maturation, and function (Gonet and Renold, 1965; Mullen *et al.*, 1977; Foglia *et al.*, 1986a; Guvenc *et al.*, 1997). At least in fetal mice, the precise gestational time of detection of H-2 antigen expression and the proportion of cells expressing these determinants depend on inbred strain, specific haplotype, tissue of origin, and antiserum batch employed (Kirkwood and Billington, 1981). Nevertheless, the precise factors governing the timing and tissue-specificity of H-2 antigen expression are yet to be determined in most species, including humans.

In addition to H-2 antigen expression, other mechanisms also seem to govern fetal immunogenicity. A study in mice suggests that, by catabolizing tryptophan, the mammalian conceptus suppresses T cell activity and defends itself against rejection by the mother (Munn *et al.*, 1998). In humans, fetal cells can be found in the maternal circulation in most pregnancies and fetal progenitor cells have been found to persist in the circulation of women many years after childbirth (Artlett *et al.*, 1998; Nelson *et al.*, 1998). These preliminary data allow us to suppose that engineered constructs made with fetal cells should be less susceptible to rejection in allogeneous applications. Xenograft implantations may also become viable, because initial studies suggest that fetal and embryonic cells are also better tolerated in cross-species transplantations, including in humans (Borlongan *et al.*, 1996; Deacon *et al.*, 1997; Dekel *et al.*, 1997; Ourednick *et al.*, 1998; Reinholt *et al.*, 1998). On the other hand, while less immunogenic, some fetal cells may be too immature and functionally limited, if harvested too early (Hullett *et al.*, 1987; Laferty, 1988). Yet, experimental models of fetal islet pancreatic cell transplantation have shown that, with time, the initially immature and functionally limited cells will grow, develop, and eventually function normally (Hullett *et al.*, 1987). Conversely, however, certain cells, such as those from rat striatum, actually func-

tion better after implantation if harvested early, as opposed to late, in gestation (Fricker *et al.*, 1997).

Fetal cells may produce high levels of angiogenic and trophic factors that enhance their ability to grow once grafted (Bjorklund *et al.*, 1987). By the same token, those factors may also facilitate regeneration of surrounding host tissues (Bjorklund *et al.*, 1987). Interestingly, significant clinical and hematologic improvements have been described following fetal liver stem cell transplantation in humans, even when there is no evidence of engraftment (Amos and Gordon, 1995). These improvements have been attributed to regeneration of autologous hematopoiesis and inhibition of tumor cell growth promoted by the infused cells, through mechanisms yet to be determined (Thomas, 1993). The underdifferentiated state of fetal cells also optimizes engraftment, by allowing them to grow, elongate, migrate, and establish functional connections with other cells (Fine, 1994).

### Applications

Because of all the general benefits derived from the use of fetal cells, along with others specific to each cell line, several types of fetal cellular transplantation have been investigated experimentally or employed in humans for decades now. Clinically, fetal cells have been useful in a number of different conditions, including Parkinson's and Huntington's diseases (Hoffer *et al.*, 1988; Lindvall *et al.*, 1990; Kopyov *et al.*, 1998; Tabbal *et al.*, 1998), diabetes mellitus (Laferty, 1988; Lehrman, 1988), aplastic anemia (Kansal *et al.*, 1979; Harousseau *et al.*, 1980; Lucarelli *et al.*, 1980; Kochupillai *et al.*, 1987a; Lehrman, 1988; Han *et al.*, 1990), Wiskott–Aldrich syndrome (Broxmeyer *et al.*, 1994; Wagner *et al.*, 1995; Lu *et al.*, 1996), thymic aplasia (DiGeorge syndrome) and thymic hypoplasia with abnormal immunoglobulin syndrome (Nezelof syndrome) (Harboe *et al.*, 1966; August *et al.*, 1968; Cleveland *et al.*, 1968; Ammann *et al.*, 1975; NIH, 1988), thalassemia (Fine, 1994), Fanconi anemia (Gluckman *et al.*, 1989); acute myelogenous and lymphoblastic leukemias (Lucarelli *et al.*, 1980; Kochupillai *et al.*, 1987b; NIH, 1988; Vilmer *et al.*, 1992; Wagner *et al.*, 1995), Philadelphia chromosome-positive chronic myeloid leukemia (Bogdanic *et al.*, 1993), X-linked lymphoproliferative syndrome (Vowels *et al.*, 1993; Lu *et al.*, 1996), neuroblastoma (Wagner *et al.*, 1992, 1995; Lu *et al.*, 1996), severe combined immunodeficiency syndrome (Githens *et al.*, 1973; Buckley *et al.*, 1976; O'Reilly *et al.*, 1980; Loudon and Thompson, 1988; NIH, 1988), hemophilia (Fine, 1994), skin reconstruction (Fine, 1994), and neurosensory hypoacusis (Magomedov, 1998). Fetal cells have also been applied to treat inborn errors of metabolism, including Gaucher's disease, Fabry's disease, fucosidosis, Hurler's syndrome, metachromatic leukodystrophy, Hunter's syndrome, glycogenosis, Sanfilippo's syndrome, Morquio syndrome type B, and Niemann–Pick disease (Touraine, 1983, 1989; Touraine *et al.*, 1991; Fine, 1994). Experimentally, fetal cell and organ transplantation has been studied in an ever-expanding array of diseases (Crombleholme and Harrison, 1990; Nozawa *et al.*, 1991; Czech and Sagen, 1995; Fine, 1994; Borlongan *et al.*, 1997; Khan *et al.*, 1997; Scorsin *et al.*, 1997; Winkler *et al.*, 1998). Nonetheless, actual fetal tissue engineering as a therapeutic means has barely started to be explored, with very few studies undertaken thus far; these will be discussed later in more detail (Fauza *et al.*, 1998a,b, 2000; D. O. Fauza, J. Sperling, and J. P. Vacanti, unpublished data, 1999).

### THE FETUS AS A TRANSPLANTATION HOST

Although there has been no account yet of a fetus receiving an engineered construct *in utero*, one could envision a number of advantages of such a procedure, not only from a theoretical perspective, but also from clinical and experimental evidence derived from intrauterine cellular transplantation studies already reported. Those potential advantages encompass induction of graft tolerance in the fetus, due to its immunologic immaturity; induction of donor-specific tolerance in the fetus by concurrent or previous intrauterine transplantation of hematopoietic progenitor cells; a completely sterile environment; the presence of hormones, cytokines, and other intercellular signaling factors that may enhance graft survival and development; the unique wound healing properties of the fetus; and early prevention of clinical manifestations of disease, before they can cause irreversible damage. Most of those advantages should be more or less evident, depending on the gestational timing of transplantation.

## FETAL IMMUNE DEVELOPMENT

Among the potential benefits of *in utero* transplantation, the singularity of the fetal immune system deserves special attention. In that respect, basic research on fetal development, as well as studies involving pre- and postnatal transplantation of lymphohematopoietic fetal cells, have contributed to a better understanding of the fetal immune response.

Fetal tolerance resulting in permanent chimerism has been shown to occur in nature in non-identical twins with shared placental circulation (Lillie, 1916; Owen, 1945). Little is known, however, about precisely when and by what mechanism this tolerance is lost. During fetal development, the precursors of the hematopoietic stem cells arise in the yolk sac, migrate to the fetal liver, and then migrate to the thymus, spleen, and bone marrow (Metcalf and Moore, 1971). The fetal liver has its highest concentration of hematopoietic stem cells between weeks 4 and the 20 of gestation (Gale, 1987). Because of their cellular immunologic "immaturity," the fetal liver and, to a lesser extent, the fetal thymus have been studied as potential sources of hematopoietic stem cells for major histocompatibility complex-incompatible bone marrow transplantation for almost four decades now (Uphoff, 1958; Bodley *et al.*, 1961; Amos and Gordon, 1995). Umbilical cord blood can also be a source of hematopoietic stem cells, but it has been applied mostly between relatives, although some success with unrelated, mismatched cord blood has also been reported (Gluckman *et al.*, 1989; Vilmer *et al.*, 1992; Wagner *et al.*, 1992; Bogdanic *et al.*, 1993; Vowels *et al.*, 1993; Wengler *et al.*, 1996).

Lymphocytes capable of eliciting graft-versus-host disease (GVHD) are found in the thymus by week 14 of gestation, but are not detectable in the liver until week 18 (O'Reilly *et al.*, 1983). Despite considerable numbers of granulocyte-macrophage colony-forming cells, there is an almost complete absence of mature T cells up to week 14 in human fetal livers (Phan *et al.*, 1989). During gestation, B cell development takes place mostly in the liver and T cell development occurs predominantly in the thymus. This specificity is probably the reason why fetal liver cells are immunoincompetent for cell-mediated and T cell-supported humoral reactions, such as graft rejections and GVHD. Thus, in principle, tissue matching is not necessary in fetal liver transplantation, if the harvest occurs up to a certain point in gestation. In a number of animal models, studies have shown that fetal liver cells induce no or merely moderate GVHD in histoincompatible donor/recipient pairs (Uphoff, 1958; Porter, 1959; Van-Putten *et al.*, 1968; Bortin and Saltztein, 1969; Perryman *et al.*, 1988; Prümmer *et al.*, 1985).

Umbilical cord blood and placental blood, on the other hand, although rich in hematopoietic progenitor cells, contain alloreactive lymphocytes (Clement *et al.*, 1990; Deadcock *et al.*, 1992; Fischer *et al.*, 1992; Harris *et al.*, 1992; Rabian-Herzog *et al.*, 1992; Amos and Gordon, 1995). These lymphocytes are also immature, but it is unclear whether they are more or less reactive than adult ones. Compared with those from adult blood, the proportions of activated T cells and helper-inducer subsets (CD4/29) are significantly reduced, whereas the helper-suppressor (CD4/45A) subset is significantly increased (Amos and Gordon, 1995). Cord blood natural killer cell activity is low or similar to that in adult blood, but lymphokine-activated killer cell activity may be higher (Keever, 1993; Gaddy *et al.*, 1995).

Although fetal liver stem cells should not cause GVHD, they could still be subject to rejection. Because of that, fetal liver stem cell transplantation has been attempted in the clinical setting mainly in patients with depressed immune function, such as in immunodeficiencies, replacement therapy during bone marrow compromise, and during fetal life (*in utero* transplantation). The same principle applies to the use of fetal thymus. No fatal cases of GVHD have been reported in patients who received fetal liver stem cells harvested before week 14 of gestation (Amos and Gordon, 1995). This complication, however, has been reported in a patient who received liver cells from a 16-week-old fetus (Lucarelli *et al.*, 1979). With umbilical cord blood stem cell transplantation, the incidence of GVHD has been minimal (Gluckman *et al.*, 1989; Vilmer *et al.*, 1992; Wagner *et al.*, 1992; Bogdanic *et al.*, 1993; Vowels *et al.*, 1993; Broxmeyer *et al.*, 1994; Lu *et al.*, 1996; Wengler *et al.*, 1996).

## Applications of *in utero* transplantation

Cellular intrauterine transplantation has been employed clinically to treat lymphohematopoietic diseases, inborn errors of metabolism, and genetic disorders, with some success (Simpson and Golbus, 1985; Slavin *et al.*, 1989; Touraine *et al.*, 1989, 1991, 1992; Touraine, 1991,

1996; Raudrant *et al.*, 1992; Wengler *et al.*, 1996; Zanjani *et al.*, 1997; Hayward *et al.*, 1998). Determination of the optimal gestational age for transplantation, along with cell selection, route of cell administration, and postinterventional tocolysis, are still evolving (Metcalf and Moore, 1971; Crombleholme *et al.*, 1991; Flake and Harrison, 1995; Zanjani *et al.*, 1997; Fauza *et al.*, 1999).

Through *in utero* transplantation of hematopoietic progenitor cells, both allogeneic and xenogeneic chimerisms have been induced in animal models and allogeneic chimerism has been achieved in humans (Billingham *et al.*, 1953; Binns, 1967; Zanjani *et al.*, 1995; Wengler *et al.*, 1996; Yuh *et al.*, 1997; Hayward *et al.*, 1998; Tanaka *et al.*, 1998). Animal studies have shown induction of donor-specific allogeneic and xenogeneic tolerance in the fetus by intrauterine transplantation of hematopoietic stem cells, improving survival of other grafts later in life (West *et al.*, 1994; Yuh *et al.*, 1997; Tanaka *et al.*, 1998). Tolerance, or lack thereof, of allogeneic or xenogeneic intrauterine implantation of engineered constructs remains to be determined, however. Likewise, potential therapeutical benefits of prenatal autologous implantation of engineered tissue, as well as likely advantages stemming from the commonly scarless fetal wound healing, are yet to be explored.

## FETAL TISSUE ENGINEERING

Vacanti *et al.* (1988) were the first to make use of fetal cells in engineered constructs. The experiment, in rats, used fetal cells from the liver, intestine, and pancreas, which were cultured, seeded on bioabsorbable matrices, and later implanted. The fetal constructs were implanted in heterologous fashion and heterotopically, namely, in the interscapular fat, omentum, and mesentery, with no structural replacement. They were removed for histologic analysis no later than 2 weeks after implantation. Successful engraftment was observed in some animals that received hepatic and intestinal constructs, but in none that received pancreatic ones.

Only in 1995 was a second study performed, by the same group, involving fetal liver constructs, also implanted in heterologous and heterotopic fashion in rats (Cusick *et al.*, 1995). Fetal hepatocytes were shown to proliferate to a greater extent than adult ones in culture and to yield higher cross-sectional cell area at the implant. As in the first experiment, neither structural replacement nor functional studies were included. Fetal constructs as a means of structural and functional replacement, in autologous fashion, in large-animal models, were first reported experimentally in 1997 (Fauza *et al.*, 1998a,b). Those studies, which involved treatment of surgically created congenital anomalies with fetal-engineered tissue, are discussed below.

## CONGENITAL ANOMALIES

Major congenital anomalies are present in approximately 3% of all newborns (McKusick, 1990). Those diseases are responsible for nearly 20% of deaths occurring in the neonatal period and even higher morbidity rates during childhood (Anonymous, 1989). By definition, birth defects entail loss and/or malformation of tissues or organs. Treatment of many of those congenital anomalies is often hindered by the scarce availability of normal tissues or organs, either in autologous or allogeneic fashion, mainly at birth. Autologous grafting is frequently not an option in newborns due to donor site size limitations, and the well-known severe donor shortage observed in practically all areas of transplantation is even more critical during the neonatal period.

A novel concept in perinatal surgery has been introduced, involving minimally invasive harvest of fetal tissue, which is then engineered *in vitro* in parallel to the remainder of gestation, so that an infant with a prenatally diagnosed birth defect can benefit from having autologous, expanded tissue readily available for surgical implantation in the neonatal period (Fig. 28.1). (Fauza *et al.*, 1998a,b, 2000). Three studies utilizing this concept have been reported at this time (Fauza *et al.*, 1998a,b, 2000). Each study involved a different model of a congenital anomaly, namely, bladder exstrophy, skin, and diaphragmatic defects. In all experiments, harvest of fetal tissue was by videofetoscopy (Figs. 28.2 and 28.3).

In the bladder reconstruction study, fetal lambs underwent surgical creation of a bladder exstrophy defect. One group of animals had their bladder exstrophy primarily closed and another group underwent bladder augmentation with engineered, autologous fetal bladder tissue at birth. Fetal detrusor cells proliferated in culture significantly faster than adult ones (up to fourfold) (Fig. 28.4). Fetal urothelial cells proliferated at expected postnatal rates. The engineered bladders were radiologically normal at 3 weeks postimplantation (Fig. 28.5). At 2 months postopera-

Fig. 28.1. Diagram representing the concept of fetal tissue engineering for surgical treatment of birth defects. A fetus with a prenatally diagnosed congenital anomaly undergoes tissue harvest, preferably through minimally invasive technique. The tissue is then processed and engineered *in vitro* while pregnancy continues, so that the newborn can benefit from having autologous, expanded tissue promptly available for reconstruction at birth.

tively, after the synthetic matrix had already been reabsorbed, the engineered bladders were more compliant than those primarily closed (Fig. 28.6). Histologic analysis of the engineered tissue showed a multilayered, pseudostratified urothelial lining (transitional epithelium) on its luminal side and overlying layers of smooth muscle cells surrounded by connective tissue. The microscopic architecture of the engineered mucosa was distinct from, but resembled that of, native bladder (Fig. 28.7). The muscular layer was hypertrophied in the exstrophic bladders primarily closed, as expected, but normal in the engineered bladders (Fig. 28.8).

In the skin replacement study, animals were their own controls, each with two experimental skin defects treated either with an engineered, autologous fetal skin tissue, or with an acellular biodegradable scaffold equal to the one used for the engineered skin. Fetal dermal fibroblasts multiplied significantly faster *in vitro* (approximately fivefold) than the same cells harvested postnatally. Fetal keratinocytes multiplied at expected postnatal rates. The engineered skin grafts induced faster epithelization of the wound (partial at 1 week and complete between 2 and 3 weeks postoperatively) compared with the acellular ones (partial at 3 weeks and complete between 3 and 4 weeks postoperatively) (Fig. 28.9). Time-matched histologic analysis of skin architecture showed a higher level of epidermal/dermal organization, richer vascularization, and less dermal scarring in the wounds that received the engineered skin, compared with those that received the acellular matrices (Fig. 28.9). Normal skin annexes were not observed in any grafted area up to 2 months postoperatively, albeit some areas that received engineered skin showed an architectural pattern compatible with ongoing adnexal development at 8 weeks postimplantation (Fig. 28.9).

Given the limitations of autologous grafting and transplantation during the neonatal period, autologous fetal tissue engineering may well become the only alternative for the treatment of a number of life-threatening congenital anomalies in which new tissue is needed to repair a defect

Fig. 28.2. Diagram representing the surgical setup for video-fetoscopic (minimally invasive) harvest of tissue from fetal lambs. Semiflexible, balloon-tipped cannulas are used through the access ports to the uterus in order to prevent dissection of the gestational membranes from the myometrium. Continuous warmed saline amnioinfusion is necessary for proper visualization of the operating field.

Fig. 28.3. Videofetoscopic view of the harvest of a fetal lamb's bladder specimen for tissue engineering purposes. *B*, Exstrophic bladder; *S*, bladder specimen; *U*, umbilical cord. The arrows point toward titanium clips placed on the harvested bed of the bladder to prevent fetal evisceration. Reproduced with permission from Fauza et al. (1998a).

Fig. 28.4. Phase microscopy view of fetal detrusor cells completely filling the culture plate only 3 days after harvest ( $\times 100$ ). Reproduced with permission from Fauza et al. (1998a).

Fig. 28.5. Contrast cystograms performed 3 weeks postoperatively after primary closure of an exstrophic bladder (A) and after augmentation of an exstrophic bladder with autologous engineered fetal tissue (B). Reproduced with permission from Fauza *et al.* (1998a).

at birth. In many severe but non-life-threatening conditions, this therapeutic concept may also become first choice, as suggested by the functional results of the bladder augmentation study (Fauza *et al.*, 1998a). This concept can be applied to virtually any cell line. It can also include *in utero* implantation of the engineered construct, as well as different forms of cell manipulation *in vitro*, prior to implantation (Fauza *et al.*, 2000; D. O. Fauza, J. Sperling, and J. P. Vacanti, unpublished data, 1999). Fetal cells can also be frozen, stored, and implanted later in life, either in autologous or allogous fashion (D. O. Fauza *et al.*, unpublished data, 2000). All those possibilities are currently being further pursued.

### ETHICAL CONSIDERATIONS

The use of fetal tissue has always been the object of intense ethical debate. The ethical controversies primarily arise from the fact that the primary source of fetal tissue is induced abortion. Spontaneous abortion usually does not raise many moral issues. The National Institutes of Health, the American Obstetrical and Gynecological Society, and the American Fertility Society, in accordance with the provisions that control the use of adult human tissue, regulate the use of fetal spec-

Fig. 28.6. Bladder compliance curves obtained 60 days after either engineered bladder augmentation or primary closure of experimental exstrophic bladders. Reproduced with permission from Fauza et al. (1998a).

Fig. 28.7. Microscopic view of mucosa from an exstrophic bladder primarily closed (A) and from an engineered fetal bladder tissue (B), 60 days postoperatively (hematoxylin and eosin stain) ( $\times 100$ ). Reproduced with permission from Fauza et al. (1998a).

Fig. 28.8. Microscopic view of the muscular layer from an exstrophic bladder primarily closed (A) and from an engineered fetal bladder tissue (B), 60 days postoperatively. Notice the evident hypertrophy of muscular bundles in the exstrophic bladder closed primarily, as expected. Muscular hypertrophy was not observed in the engineered bladders (hematoxylin and eosin stain) ( $\times 100$ ). Reproduced with permission from Fauza *et al.* (1998a).

imens from this latter source (NIH, 1988; Annas and Elias, 1989; Greeley *et al.*, 1989; Gershon, 1991). However, spontaneous abortion generally yields unsuitable fetal tissue, because it is frequently compromised by pathology such as chromosomal abnormalities, infections, and/or anoxia (NIH, 1988; Annas and Elias, 1989). Arguments on the use of fetal tissue from induced abortion are largely based on somewhat limited scientific evidence, along with clashing religious and customary beliefs about the beginning of life. Not surprisingly, despite the efforts of numerous national and international ethical committees and governmental bodies, a consensus has not yet been reached. In the United States, in spite (or perhaps because) of a recent moratorium on federal funding for fetal tissue transplantation research, an agreement on this issue seems to be slowly forming, although a stable solution may still be years away (Gershon, 1991; Strong, 1991).

This polemic notwithstanding, tissue engineering, as a novel development in fetal tissue processing, adds a new dimension to the discussion concerning the use of fetal tissue for therapeutic or research purposes. If specimens from a live, diseased fetus are to be used for the engineering of tissue, which in turn is to be implanted in autologous fashion, no ethical objections should be anticipated, as long as the procedure is a valid therapeutic choice for a given perinatal condition. In that case scenario, ethical considerations are the very same that apply to any fetal intervention. On the other hand, if fetal engineered tissue is to be implanted in heterologous fashion, ethical issues are analogous to the ones involving fetal tissue/organ transplantation, regardless of whether the original specimen comes from a live or deceased fetus. The distinction between autologous and heterologous implantation of engineered fetal tissue is a critical one in that, again, no condemnation of autologous use could be ethically justified.

Fig. 28.9. Comparative neoskin histologies from engineered (a) and acellular (b) sites at different times postimplantation, in weeks. Notice the faster epithelization time and higher level of organization of the engineered specimens (hematoxylin and eosin stain) ( $\times 100$ ). Reproduced with permission from Fauza *et al.* (1998b).

## FUTURE PERSPECTIVES

Fetal tissue engineering is one of the newest developments of the still immature fields of tissue engineering and fetal surgery. As such, it is but a very promising concept that has hardly started to be explored, with many questions yet to be answered and numerous evolutionary paths, including unsuspected ones, yet to be pursued. Most fetal cell lines are yet to be studied for tissue engineering purposes. The optimal timing for harvest of each kind of fetal cell remains to be determined, along with their growth, differentiation, cryopreservation, and antigenic properties. At the same time, models for a better determination of embryonic and fetal age are only starting to be determined (Evtouchenko *et al.*, 1996). The whole subfield of *in utero* implantation of engineered tissue awaits examination. Banks of diverse fetal cell lines, either for autologous, allogous, or maybe even xenologous applications, are beginning to be optimized (Borel Rinkes *et al.*, 1992; Gluckman *et al.*, 1992, 1993; Rubinstein, 1993; Mychaliska *et al.*, 1998).

Fetal tissue engineering will benefit from the progress expected for tissue engineering in gen-

eral, which should include several aspects of this multidisciplinary field. For instance, genetic engineering could maximize or modify certain specialized fetal cell functions (Ekhterae *et al.*, 1990). Fetal cells are ideal targets for gene transfer due to their proliferation and differentiation capacities (Johnson *et al.*, 1989; Karson and Anderson, 1990). Cell surface modulation techniques currently under investigation, including, but not restricted to, gene manipulation, could delete immunogenic sites and prevent immunorecognition, maximizing the naturally "permissive" allogeneous and possibly xenogeneous implantation of different cryopreserved fetal cells (Pollok and Vacanti, 1996). Methods for studying interfaces between cell and different biomaterials, along with mathematical models and *in vitro* systems that can predict *in vivo* events, should be adapted to fetal cells (Nerem and Girard, 1990; Lauffenberger, 1991; Parkhurst and Saltzman, 1992; Guido and Tranquillo, 1993; Hsieh *et al.*, 1993; Ratner, 1995). Finally, fetal cell and construct manipulation at zero gravity should be examined as tissue engineering in space starts to be explored (Saltzman, 1997).

As a component of the general promise of tissue engineering, fetal tissue engineering may well become the only perinatal alternative for treatment of a number of life-threatening birth defects in the future. As long as progress is made in the ethical debate over the use of fetal cells, its reach, nonetheless, will likely go beyond the perinatal period, offering unique novel perspectives to various aspects of surgery.

# PLURIPOTENT STEM CELLS

Michael J. Shamblott, Brian E. Edwards, and John D. Gearhart

## INTRODUCTION

Pluripotent stem cells, cells that can replicate in culture but also form many or most of the cells comprising the body, have been described. In the mouse and a few other species, embryonic stem and embryonic germ cells can be derived from the inner cell mass of a blastocyst, and from primordial germ cells, respectively. These cells differentiate *in vitro* into a mixture of cell types, including heart muscle cells, blood cells, neural cells, and vascular cells. This repertoire can be greatly expanded by using powerful enrichment and selection strategies, and purified populations of differentiated cells can be generated. Reports of human embryonic stem and germ cells have received significant attention in both the scientific and popular press. The capacity of these cells to differentiate *in vitro* into a wide variety of cell types suggests their eventual use in the generation of cells for tissue engineering and transplantation therapies.

## DEFINITION OF A STEM CELL

A stem cell can replicate itself and produce cells that take on more specialized functions. The breadth of function adopted by the more differentiated daughter cells and their progeny is commonly referred to as the developmental potential, or potency, of the stem cell. Stem cells that give rise to only one type of differentiated cell are termed unipotent. In common usage, the relative terms oligopotent, multipotent, and pluripotent represent an increase in the number of differentiated cell types from few to many or most. A totipotent cell is one that can generate the totality of cell types that comprise the organism. In practice, these few terms poorly describe a continuum of possibilities.

The ability to form a wide variety of cell types makes pluripotent stem cells a promising resource for tissue engineering and transplantation. Through the use of enrichment, selection, expression, and sorting technologies, *in vitro* differentiation of stem cells will certainly contribute to future transplantation therapies.

## DEVELOPMENTAL POTENTIAL

In order to describe more fully the potential of a stem cell, one must consider the process by which a fertilized egg develops into a complex multicellular organism. Within several days following fertilization, the processes of cell cleavage, compaction, and cavitation generate a mass of cells called the blastocyst. The blastocyst consists of two cell populations, an outer layer of cells surrounding a fluid-filled cavity and a mass of cells within the cavity. The outer cells (trophoblast) contribute to the placenta but not the embryo proper. The inner cell mass (ICM) cells further differentiate during gastrulation to form the three germ layers of the embryo: ectoderm, mesoderm, and endoderm. Cells of the germ layers generate all the tissues of the embryo. During gastrulation, cells that will go on to form the germ cells (eggs and sperm) are also allocated.

## TYPES OF PLURIPOTENT STEM CELLS

There are only a few stem cell types that can be cultured and qualify for true pluripotent/totipotent status. These include embryonal carcinoma (EC), embryonic stem (ES), and embry-

onic germ (EG) cells. EC cells were first described as the stem cell component of teratocarcinomas that arose following the transfer of a mouse postimplantation embryo or embryonic gonad to an ectopic site (Stevens, 1958). Later, similar stem cells were derived from spontaneous teratocarcinomas formed in both mouse (mouse EC cells) and humans (human EC cell). EC cultures are heteroploid and some are multipotent.

Pluripotent/totipotent stem cells have been derived from two embryonic sources. ES cells are derived from the ICM of preimplantation embryos (Evans and Kaufman, 1981; Martin, 1981), whereas EG cells are derived from primordial germ cells (PGCs) that (during normal development) migrate to and colonize the gonad, eventually forming eggs and sperm (Matsui *et al.*, 1991; Resnick *et al.*, 1992). Both mouse ES and EG cells demonstrate germ-line transmission in experimentally produced chimeras (Labosky *et al.*, 1994; Stewart *et al.*, 1994). Mouse ES and EG cells share several morphological characteristics such as high levels of alkaline phosphatase (AP) activity and the presence of some specific cell surface antigens. Other important shared characteristics include growth as multicellular colonies, normal and stable karyotypes, the ability to be continuously passaged, and the capability to differentiate into cells derived from all three embryonic germ layers. Pluripotent stem cell lines that share most of these characteristics have also been reported for chicken (Pain *et al.*, 1996), mink (Sukoyan *et al.*, 1993), hamster (Doetschman *et al.*, 1988), pig (Shim *et al.*, 1997; Wheeler, 1994), rhesus monkey (Thomson *et al.*, 1995), and common marmoset (Thomson *et al.*, 1996). Human pluripotent stem cells derived from PGCs (Shamblott *et al.*, 1998) and ICM (Thomson *et al.*, 1998) have been described.

Multipotent stem cells can be cultured from a number of fetal and adult sources. Perhaps the best known source is bone marrow, which contains both hematopoietic stem cells (Civin *et al.*, 1984) and mesenchymal stem cells (Caplan, 1991; Pittenger *et al.*, 1999), some of which can apparently also form hepatocytes (Petersen *et al.*, 1999). Neural stem cells have also been cultured from the ependymal cells lining the brain ventricles (Johansson *et al.*, 1999) and cells found in the cerebellum (Snyder *et al.*, 1995). It is likely that of the many lineage-restricted stem cell populations that exist *in vivo*, some will be amenable to *in vitro* growth and analysis.

## METHODS OF ASSAY

Histologic, immunocytochemical, and molecular markers have been used to indirectly assess pluripotency. These include high levels of AP and presentation of specific cell surface glycolipids (Kannagi *et al.*, 1983; Solter and Knowles, 1978) and glycoproteins (Andrews *et al.*, 1984). These properties are characteristic of pluripotent stem cells, but are neither necessary nor sufficient as a definition.

The only direct measure of developmental potential is the analysis of cell differentiation. There are both *in vitro* and *in vivo* methods to establish broad developmental potential. For example, some types of stem cells can be observed (and even directed to some extent) to differentiate in culture. When differentiation occurs, structures termed embryoid bodies (EBs) are formed; these were initially described as arising in human (Peyron, 1939) and mouse (Stevens, 1958, 1959, 1970) germ cell tumors called teratomas and teratocarcinomas.\* These cell aggregates range from a cluster of pluripotent stem cells enclosed by a layer of endoderm to complex structures in which inductive and stochastic developmental processes lead to a seemingly haphazard array of cell types, including representatives of all three germ layers. The presence of differentiated cell types within EBs has been used as evidence of cell pluripotency, as a means to study some early events in development, and as a source of differentiated cells (Doetschman *et al.*, 1985; Evans and Kaufman, 1981). Although useful in the production of cells for tissue engineering and transplantation, the *in vitro* differentiation of pluripotent stem cells is limited by our understanding of the genes, molecules, and physical events involved and cannot easily rival *in vivo* differentiation.

When some types of stem cells are implanted at ectopic sites within an isogenic or immunologically compromised mouse, teratomas and teratocarcinomas form. The complex physiological milieu of the tumor provides a wide but difficult to control array of stimuli. Analysis of the vari-

---

\* Teratocarcinomas are malignant tumors arising from relatively undifferentiated germ cells. A wide variety of highly differentiated cells and structures can be found within the tumor, including gut and respiratory epithelia, nerves, muscle, cartilage, and bone. The presence of stem cells within the tumor distinguishes teratocarcinomas from teratomas

ety of cell types that comprise the tumor can be used as a measure of developmental potential. If cells that derive from all three germ layers are identified, the term pluripotent can be used. This property alone may not be a definitive test of stem cell pluripotency, because it has been demonstrated that visceral endoderm (yolk sac) of the rat and mouse is capable of forming highly differentiated teratomas containing cells of all three embryonic germ layers (Sobis *et al.*, 1991, 1993). The ultimate and definitive test of developmental potency is the generation of chimeric animals. Under the least restrictive definition, only a stem cell that can contribute to all the tissues of the embryonic and adult organism can be said to be totipotent. This test can be performed for only a few species, mainly the mouse.

In practice, the assignment of pluripotent and totipotent status is more difficult than the analysis of differentiation. Bone marrow and peripheral blood contain hematopoietic stem cells that generate all of the types of blood cells. These cells are often referred to simply as pluripotent stem cells, in acknowledgment of their capacity to form cells of erythroid, lymphoid, and myeloid lineages. This usage does not allow for stem cells that can be demonstrated to form representatives of all three germ layers, but where totipotency cannot be established.

Totipotency is also a problematic term. ICM cells are capable of generating every cell of the embryonic and adult organism, but have lost the capability to form trophoblasts and therefore cannot entirely reconstitute a conceptus. Therefore, the ICM and stem cells derived from it are only totipotent with respect to the embryo. Another important consideration in the use of the term totipotent is that it is sometimes used to describe the capacity of cells form an embryo, that is, that the cells are capable of self-organization into an organism. No known stem cell possesses this property, so under this definition, stem cells are at best pluripotent.

A resolution to these nomenclature dilemmas is a matter of preference and will certainly be a subject for honest debate. Under the strictest definitions, only fertilized eggs and early blastomeres (2–4 cell stage) qualify as totipotent; however, they are not stem cells because they cannot continuously replicate. Stem cells with the demonstrated ability to form representatives of all three germ layers are pluripotent, with special acknowledgment for cells such as mouse ES and EG cells, which can be demonstrated to form all of the cells of the embryonic and adult organism.

## DIFFERENTIATION *IN VITRO*

### BASIC TECHNIQUES

*In vitro* culture and differentiation of stem cells offer the hope of precise control of the process and the products, but require responsibility for its direction. Most ES and EG cells require leukemia inhibitory factor (LIF; ~1000 U/ml) to proliferate and remain pluripotent.<sup>†</sup> The simple withdrawal of LIF from the growth media enables differentiation, albeit within a relatively narrow range of cell types produced. The formation of EBs has been the most common and successful paradigm for more complex and varied differentiation of pluripotent stem cells. Although EBs are spontaneously formed in mouse and human ES/EG cell cultures, their formation can be enhanced by withdrawing LIF from the media then plating cells in an environment conducive to aggregation, rather than adhesion to a substrate. This is achieved by plating cells in suspension culture in bacteriologic petri dishes or in hanging drops. A viscosity-increasing agent such as methylcellulose is often added to the culture media to promote EB aggregation. After several days of growth and influence by added factors and compounds, EBs are disaggregated and plated onto an adhesive substrate and allowed to grow and further differentiate. With the proper combinations of growth and differentiation factors, mouse ES (Keller *et al.*, 1993; Wiles and Keller, 1991) and EG (unpublished results) cell cultures can generate cells of the hematopoietic lineage and cardiomyocytes (Klug *et al.*, 1995; Rohwedel *et al.*, 1996). In addition, mouse ES cells have been used to generate *in vitro* cultures of neurons (Bain *et al.*, 1995), skeletal muscle (Rohwedel *et al.*, 1994), vascular endothelial cells (Rohwedel *et al.*, 1994), adipocytes (Dani *et al.*, 1997), and visceral endoderm (Abe *et al.*, 1996; Doetschman *et al.*, 1985), which is the precursor to structures such as the pancreas, liver, and lung.

<sup>†</sup> LIF is a member of a cytokine family that heterodimerizes with the gp130 molecule. Other members of the family, such as oncostatin M, or strategies that directly activate gp130-mediated signal transduction, can replace LIF.

## TARGET CELL ENRICHMENT

A number of exogenous factors have been used to direct EB differentiation. The most commonly used chemical reagents are retinoic acid (RA), dimethyl sulfoxide (DMSO), hexamethyl bisacetamide (HMBA), and reagents that elevate intracellular cAMP levels, such as dibutyl-cAMP (db-cAMP), forskolin, and 3-isobutyl-1-methyl-xanthine (IBMX). RA, cAMP elevators, and HMBA have been used to influence the formation of neurons from EC and ES cells (Andrews *et al.*, 1986; McBurney *et al.*, 1982). DMSO has been used to enhance the production of mesodermal derivatives such as muscle cells (Habara-Ohkubo, 1996; McBurney *et al.*, 1982) and endodermal derivatives (Edwards and Adamson, 1986). The modes of action by which RA and DMSO act are not fully understood, although it is clear that the effects of RA are mediated through RA receptors and this receptor impacts the regulation of genes that contain RA-responsive elements.

Growth factors have been used in the differentiation of pluripotent stem cells. The most sophisticated application of growth factors is in the derivation of hematopoietic cells from mouse ES cells. Included are stem cell factor (known as c-kit ligand, SCF, steel factor, and mast cell factor), vascular endothelial growth factor (VEGF), erythropoitin (EPO), interleukin-1 (IL-1), IL-3, IL-6, IL-11, macrophage colony-stimulating factor (M-CSF), granulocyte colony-stimulating factor (G-CSF), granulocyte—macrophage colony-stimulating factor (GM-CSF), and bone morphogenic protein 4 (BMP4) (Biesecker and Emerson, 1993; Keller *et al.*, 1993; Keller, 1995; Kennedy *et al.*, 1997; Palacios *et al.*, 1995).

The exact component(s) that cause a desired differentiation effect are often unknown, except for their activity in a bioassay. Typically, these factors are secreted by a support or feeder culture. These feeder cultures “condition” the media in which they grow. These media are then harvested (and sometimes concentrated) and used as a growth supplement. One example is the use of bone marrow stromal cell conditioned medium (CM) as a component of hematopoietic cell differentiation. This CM is required for eventual production and long-term repopulation of the lymphoid, myeloid, and erythroid lineages (Palacios *et al.*, 1995).

## SELECTIVE MATRICES

The nature of the surface a cell attaches to can have a profound impact on its characteristics. Most ES and EG cells grow best on a feeder layer of mouse embryonic fibroblasts (primary mouse embryo fibroblasts or STO fibroblasts) that have been irradiated or treated with mitomycin C to make them mitotically inactive. Instead of live cells, the extracellular matrix (ECM) of these fibroblasts or a layer of gelatin will suffice, but often with suboptimal performance. Several adhesion matrices have been employed in the growth of stem cell-derived cells. Collagens I and IV have been used to promote adhesion and cell division in a number of cell types, including vascular endothelial cells (Hirashima *et al.*, 1999), and laminin has been shown to promote neurite outgrowth in many neuronal culture systems, including ES cell-derived neuronal cells (Bain *et al.*, 1995). Cell-derived extracellular matrices such as Matrigel and human ECM (Collaborative Biomedical Products) have been used to support the differentiation of various cell types.

Deposition of growth factors within extracellular matrices and basement membranes is a critical phenomenon of development. Signals deposited by one cell type are subsequently read by naive cells that grow in contact with the conditioned ECM or degrade a conditioned basement membrane. It is likely that complex differentiation and tissue engineering will benefit from the use of these types of inductive processes.

## GENETIC SELECTION

Genetic selection is a powerful strategy for generating pure or nearly pure populations of differentiated cell types. In order to develop this strategy, a gene that is expressed specifically in the desired cell type must be identified. This gene can be specific to a terminally differentiated cell type or to a lineage-restricted stem cell. The promoter of the specific gene is then joined to a gene that encodes resistance to an antibiotic drug such as neomycin (G418), hygromycin, bleomycin, or zeocin. This construct is transfected into stem cells that are then caused to differentiate. If the differentiating cells are treated with the antibiotic drug, all cells that cannot express the fusion gene construct will die (Fig. 29.1). An example of genetic selection is the production of a highly pure (>99%) population of cardiomyocytes from differentiated mouse ES cells using the  $\alpha$ -cardiac myosin heavy chain promoter joined to a cDNA coding for neomycin resistance (Klug *et al.*, 1996).

Fig. 29.1. Genetic selection used to obtain a specific population of differentiated cells. A target cell-specific promoter requiring a transcription factor ( $\circ$ ) is joined to a gene imparting drug resistance ( $\square$ ) and transferred into pluripotent stem cells. When the stem cells differentiate, only cells that can activate, transcribe, and translate (dashed arrow) the target cell-specific promoter along with their cell-specific genes ( $\text{▨}$ ) are resistant to the antibiotic ( $\nabla$ ) and survive.

### TRANSCRIPTION FACTOR EXPRESSION

Another genetic strategy is to transfect pluripotent stem cells with a construct that causes the expression of a factor known (or thought) to play an important role in the commitment to a desired lineage. Usually, these are transcription factors. As commitment decisions are usually hierarchical, it is beneficial to choose a transcription factor that is influential in the earliest stages. The promoter driving the expression can be a strong constitutive promoter, a tissue-specific promoter, or an exogenously regulated promoter such as the commercially available tetracycline (Clontech) and ecdysone (Invitrogen) expression systems. Examples of ES cell differentiation influenced by transcription factor expression are the generation of skeletal muscle cells following the constitutive expression of MyoD1 (Dekel *et al.*, 1992; Shani *et al.*, 1992) and the generation of neurons following the constitutive expression of neuroD2 or neuroD3 (O'Shea *et al.*, 1997).

### FLUORESCENCE-ACTIVATED CELL SORTING

Fluorescence-activated cell sorting (FACS) is a powerful method to physically select a subset of target cells from a mixed population. This strategy is used when the target cell expresses a specific cell surface molecule.<sup>‡</sup> The molecules can be receptors or protein, glycoprotein, or lipid surface antigens. An antibody that is specific to the surface molecule is used to identify the target cell in solution. This antibody is then tagged with a fluorophore. Target cells that fluoresce are physically segregated and saved. Negative cells are washed away or collected separately. One or more antibody/fluorophore combination(s) can be used to impose highly selective criteria, allowing fine-tuning of cell populations or the ability to recover extremely rare cell types. One complication with FACS is that adherent cell types need to be effectively disaggregated prior to sorting. Special precaution must be taken during this process to retain the specific surface molecule(s). Damage caused by enzymatic treatment such as trypsin digestion must be minimized and should be followed by a period of cellular recovery and resynthesis. FACS has been used as both an analytical and a preparative tool to select many cell types. One example of its use is in the study and preparation of ES cell-derived hematopoietic stem cells prior to mouse immune system repopulation experiments (Palacios *et al.*, 1995).

### MARKERS OF DIFFERENTIATION

Markers are used to monitor the process of differentiation. Markers can be specific proteins, glycoproteins, glycolipids, or other metabolites made by the target cell of interest. Methods of detection include histologic analysis using dyes; immunoreactivity of cells or cell homogenates to specific antibodies; and mRNA expression by using Northern blot analysis, reverse transcriptase and polymerase chain reaction (RT-PCR), or RNase protection assay. The loss of markers of pluripotency can also be used to monitor differentiation. The mouse transcription factor Oct3/4<sup>§</sup>

<sup>‡</sup> Cells can also be loaded with enzyme substrates that fluoresce when acted on by specific endogenous enzymes or reporter enzymes such as  $\beta$ -galactosidase (Metzger *et al.*, 1996).

<sup>§</sup> A commonly used abbreviation for mouse Oct3 (GenBank Accession No. MUSOCT3) and Oct4 (MMOCT4P), although their reported nucleotide and predicted amino acid sequences are not identical.

is expressed in unfertilized eggs, ICM, PGCs, and pluripotent stem cells. The loss of Oct3 expression or other markers such as AP or SSEA-3 (Andrews, 1984) can be used to gauge the effectiveness and progress of differentiation schemes.

## EXAMPLES OF *IN VITRO* DIFFERENTIATION AND MARKERS

### HEMATOPOEISIS

Through the use of the selective growth media, exogenously added compounds and growth factors, selective growth matrices, and genetic strategies, a number of different cell types have been derived from mouse pluripotent stem cells. These include hematopoietic cells, vascular endothelium, muscle cells, neurons, and visceral endoderm (Fig. 29.2).

Hematopoiesis within EBs was one of the first differentiation phenomena observed, and remains one of the most thoroughly studied. Mouse ES cells are grown in a standard media containing LIF. The cells are then removed from the plates by incubation in trypsin, then plated into bacteriologic dishes and grown in 1% methylcellulose in the presence of various cytokines and other factors. After 3 days EBs form and are allowed to grow for about 2 weeks. During this time, erythroblasts accumulate in endothelium-lined channels or cysts, forming blood islands that are red due to the presence of hemoglobin. EBs are then disaggregated using trypsin or other enzymes and plated onto adhesive tissue culture plates or are harvested for analysis. Through the use of specific markers such as GATA-1, *c-myb*, SCL, and embryonic and adult globin, it has been shown that most, if not all, of the hematopoietic lineages are represented among the differentiated cells produced (Keller *et al.*, 1993). Not unexpectedly, hematopoietic stem cells are produced by this process, because EB-derived cells can be used to repopulate the hematopoietic system of a mouse that has had its own immune system damaged or destroyed by radiation (Palacios *et al.*, 1995).

### VASCULAR ENDOTHELIUM

Hematopoiesis and the development of a vascular system are developmentally connected. Both are mesodermal derivatives, and are colocalized in the developing aorta–gonad–mesonephros (AGM) region of embryo (Medvinsky and Dzierzak, 1996). It is not clear however, if there is a common precursor (hemangioiblast) or if erythropoiesis requires endothelial cells (Kennedy *et al.*, 1997). Vascular endothelium is effectively produced in mouse EBs using standard culture condi-

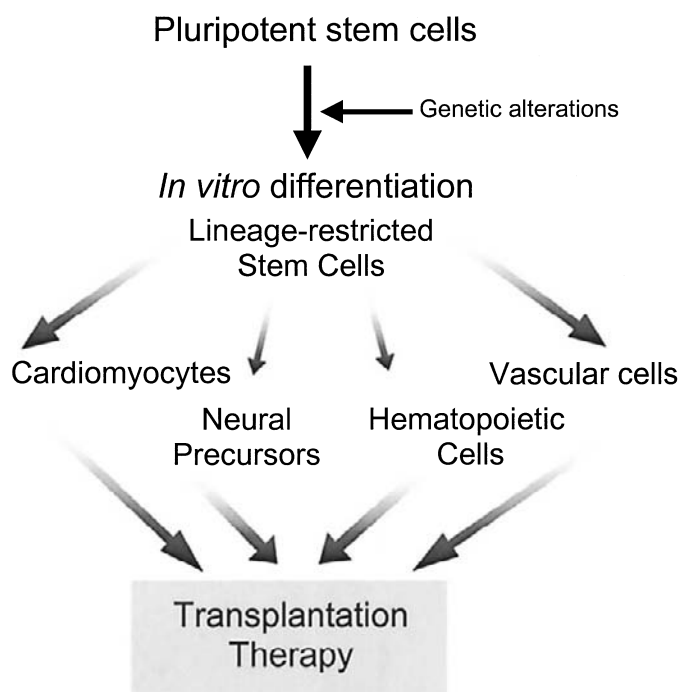

Fig. 29.2. Some uses of pluripotent stem cells in transplantation therapy. Pluripotent stem cells such as embryonic stem and embryonic germ cells can be genetically manipulated. Pluripotent stem cells are then allowed to differentiate *in vitro* into embryoid bodies that contain many different cell types, including lineage-restricted stem cells, precursor cells, and terminally differentiated cells. Through the use of selection, enrichment, and sorting, pure cell populations can be generated. These cells are then transplanted directly or used to engineer tissues with more complex architectural requirements.

tions, and can organize into vessel-like channels filled with blood cells. This process can apparently be enhanced through the expression of transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1) (Zhang *et al.*, 1998). Vascular endothelial cells can be grown out from disaggregated EBs onto collagen-coated surfaces and studied or selected by using antibodies to CD34, platelet-endothelial cell adhesion molecule (PECAM), VEGF receptor (flk-1), VE-cadherin and von Willebrand factor (vWf), as well as by binding of acetylated low-density lipoprotein (Ac-LDL) (Hirashima *et al.*, 1999; Wang *et al.*, 1992).

## MUSCLE

The spontaneous contraction of ES cell-derived cardiomyocytes (heart muscle cells) is one of the most visually and conceptually striking examples of ES cell differentiation *in vitro*. The rhythmic contractile movements seen in these cultures suggest a great deal of specialized differentiation and cellular organization. It is surprising, therefore, that this occurs when LIF is withdrawn from the culture medium for  $\sim$ 10 days. The time course of muscle-specific structural gene expression in these cells roughly parallels that seen in the embryo. Sarcomeres with functional gap junctions and  $\text{Ca}^{2+}$  channels, as well as organized myofibrils, are formed (T. Doetschman *et al.*, 1993; T. C. Doetschman *et al.*, 1985; Rohwedel *et al.*, 1994; Westfall *et al.*, 1997). Cardiomyocytes, which precede skeletal and smooth muscle developmentally, are formed in the greatest abundance in EBs and have been identified through the use of specific markers such as myosin light chain, myosin heavy chain, muscle-specific actin, and myogenin (Robbins *et al.*, 1990). Furthermore, ventricular specification of EB-derived cells occurs, as evidenced by ventricular myosin light chain-2 (Miller-Hance *et al.*, 1993). DMSO, RA, db-cAMP, and expression of the muscle-specific transcription factor MyoD have been used to enhance the production of smooth and skeletal muscle (Dinsmore *et al.*, 1996; Drab *et al.*, 1997). Expression of the M-twist transcription factor has the opposite effect, to inhibit myogenic differentiation (Rohwedel *et al.*, 1995).

## NEURAL DIFFERENTIATION

ES cells (Bain *et al.*, 1995; Fraichard *et al.*, 1995) and some EC cells (Andrews, 1984; Lang *et al.*, 1989; Pleasure and Lee, 1993) are readily differentiated into neuroectodermal derivatives such as neurons and glia. Typically, ES cells are used to form EBs in the presence of RA. The EBs are then disaggregated (or plated directly as EBs) and plated onto an adherent plastic, laminin, or poly(D-lysine)-coated surface, where mixed populations can then be further identified and selected for. General markers such as neurofilament heavy and light isoforms, microtubule-associated protein (MAP), Tau, and  $\beta$ -tubulin III have been used to identify neuronal cells, and Pax-6 and nestin have been used to identify early neuroepithelial cells. Distinct morphological characteristics such as neurite elongation and dendrite formation, and more specific markers including tyrosine hydroxylase (TH), 5-hydroxytryptamine (5-HT), synaptophysin, Mash1, Math4a, neurotransmitters, and neurocan have been used to refine neuronal identification. Patch clamping has also been used for functional identification.

The general identification of glial cells can be done by examining cells for the expression of glial fibrillary acidic protein (GFAP). Specific identification of astrocytes can be made by using the marker OP-4, whereas oligodendroglial cells can be identified by the markers GalC and O4.

Several different approaches have been used to influence the outcome of RA-induced EB differentiation. Nerve growth factor (NGF) has been used to accelerate the formation of neurons within an EB (Wobus *et al.*, 1988), and expression of the transcription factor Noggin (O'Shea and Gratsch, 1998) and neuroD2 and neuroD3 (O'Shea *et al.*, 1997) lead to significant enhancement of neuronal production. Genetic selection using an early neuroepithelial-specific transcription factor (Sox2) promoter to drive neomycin resistance resulted in efficient purification of neuroepithelial progenitor cells that can then differentiate into neurons (Li *et al.*, 1998).

## VISCERAL ENDODERM

Visceral endodermal cells give rise to a number of cell and tissue types, including the epithelial lining of the digestive tract, respiratory tracts, and bladder, as well as the parenchyma of the liver, pancreas, thyroid gland, and parathyroid gland. Visceral endoderm is generated in RA-treated mouse EC cell aggregates (Hogan *et al.*, 1981) and EBs derived from mouse (Doetschman *et al.*, 1985) and human (Shamblott *et al.*, 1998) pluripotent stem cells. Mouse EB-derived visceral

endoderm has been shown to express many genes in common with liver, including transcription factors such as hepatocyte nuclear factor-1 (HNF-1), HNF-3, and HNF-4 forms; enzymes such as aldolase B (ALDO-B) and liver-type pyruvate kinase (L-PK), as well as the serum proteins  $\alpha$ -fetoprotein (AFP), transthyretin (TTR), albumin, and several apolipoproteins (Abe *et al.*, 1996; Duncan *et al.*, 1997, 1998). This extensive representation of metabolic and regulatory molecules suggests that visceral endoderm may be a useful cell type for the generation of several target tissues, including liver and pancreas.

## IN VIVO APPLICATIONS

### CURRENT THERAPEUTIC MODELS

Several reports of stem cell therapy have energized and encouraged the entire field of stem cell biology. Most of the work to date has attempted to use lineage-restricted or multipotent stem cells rather than pluripotent stem cells. Some of this work may have a profound effect on our compartmentalized notions of germ layer origins. One outstanding example of stem cell-derived cell therapy is the engrafting of neurons generated from human EC cells (NTERA-2) to rat cerebrum damaged by induced transient ischemia (Borlongan *et al.*, 1998). The significant cellular integration and functional recovery observed in these rats suggest the potential use of these cells to treat stroke, Parkinson's disease, and other human neurodegenerative disorders. Importantly, grafts of postmitotic neurons generated from RA-treated NTERA-2 into the CNS of rodents do not lead to tumors (>1 year of observation) (Trojanowski *et al.*, 1997).

Multipotent neural stem cell (NSC) cultures derived from neonatal mouse cerebellum (clone C17.2) have a broad capacity to participate in the development of the brain when implanted (Snyder *et al.*, 1995). It has been reported that intracerebroventricular injection of these cells can result in widespread engraftment and correction of dysmyelination caused by a genetic lack of myelin basic protein (MBP) in *shiverer* mice (Yandava *et al.*, 1999). One of the most important aspects of these two transplantation studies is that cells placed at one location migrated widely and correctly to the desired location and engrafted in a way that led to the amelioration of a neuropathologic condition.

Cells of the central nervous system are of ectodermal origin, and, it was thought, are capable of repopulating cells of this dermal type only. However, this developmental exclusivity has been brought into question (Tajbakhsh *et al.*, 1994). The demonstration that NSCs derived from mouse forebrain striata engraft into the hematopoietic system (which is of mesodermal origin) of sublethally irradiated mice suggests a greater developmental plasticity than is commonly afforded multipotent stem cells (Bjornson *et al.*, 1999).

A similar suggestion has been made concerning bone marrow stem cells. These cells develop into hematopoietic and mesenchymal lineages, both of which are of mesodermal origin. Demonstration that these stem cells can also form liver cells, which are of endodermal origin, may further exemplify the ability of some cell types to cross dermal-origin boundaries (Petersen *et al.*, 1999).

The use of pluripotent stem cells as a source of cells for transplantation holds great promise due not only to the breadth of cells that could potentially be generated, but also to the ability to manipulate the cells genetically prior to differentiation. The risks inherent with their use must also be considered, however. As described earlier, grafting of undifferentiated mouse pluripotent stem cells to various sites such as the mouse testis, kidney capsule, or brain leads to the formation of a tumor. Transplantation models and eventual therapies will have to ensure that pluripotent stem cells have been eliminated from the implant.

### GENETIC MANIPULATION

One significant advantage of the use of pluripotent stem cells in developmental studies or in transplantation paradigms is the ease with which they can be genetically manipulated. Mouse ES and EG cells are easily and routinely cultured and are capable of continuous passage, so tremendous cell expansion is possible. This is not the case for most nontransformed euploid (chromosomally normal) differentiated mouse cell lines. The human pluripotent stem cell cultures to date are not as easily grown as their mouse counterparts, and there are no examples of the successful introduction of foreign DNA into them. Fortunately, many nontransformed euploid differentiated cell lines have the capacity for extensive cell division, so genetic alterations and selections may be

carried out on lineage-restricted and/or differentiated human cells that are derived from pluripotent stem cells.

Mouse pluripotent stem cells, and to a lesser extent human EC cells, are amenable to most routine methods of transfection. Electroporation, lipofection, and chemically mediated and virally mediated gene delivery have all been used successfully on mouse ES cells. These methods and novel viral/retroviral approaches are currently being investigated for use on human pluripotent stem cells.

Mouse ES cells have been the most extensively manipulated pluripotent stem cell type. Gene “knockout” and disruption experiments require gene targeting and homologous recombination, both of which are routine. Adding genes and artificial genetic constructs is also easily achievable. As described above, these strategies have been used successfully to select cell populations genetically or to direct differentiation by expression of transcription factors. In future stem cell differentiation experiments, combinations of gene disruption and the addition of novel gene function may be used to create truly customized cell populations and cells that are particularly amenable to the assembly and function of organ structures.

## CELL DELIVERY

### Developmental potential of transplanted cells

If cell or organ transplantation is the goal of a pluripotent stem cell differentiation experiment, the issues of which cells to deliver, the method of delivery, and the location of delivery will eventually arise. The type of cell to deliver may not be obvious, however. Fully differentiated and post-mitotic cells are the most predictable and probably the safest choice, as they have function(s) that can be defined and characterized *in vitro*. The finite capacity of these cells to repopulate and the need to create many narrowly defined cell classes limits the usefulness of this approach. At the other end of the spectrum are undifferentiated pluripotent stem cells, with an enormous capacity to repopulate and differentiate. The high probability of tumor formation will certainly limit the medical application of this approach. The most obvious middle ground is the use of lineage-restricted stem cells. Current efforts detailed above using multipotent stem cells are an excellent first approximation of this approach. Future uses may include the selection or enrichment for stem cells that can repopulate and form several different terminally differentiated cell types. Future practices may include the design of fully repopulating organs.

### Method and location of delivery

The optimal method and location of cell delivery are dependent on several factors, including target location, desired function, ease of access, and patient safety. Cells can be introduced as a suspension or implanted as a pellet or tissue-engineered organoid. These cells and structures can be implanted within a damaged organ or at an ectopic site.

## IMMUNORECOGNITION AND REJECTION

Immune rejection is one of the most important issues in allogeneic transplantation therapy, whether it is whole organ, tissue, or cellular transplantation. At its most basic level, immune rejection is simply the result of the recognition of the graft as different from the host. Strategies to counteract rejection involve either ways to prevent the recognition of the graft as non-self or to prevent the physiologic reaction to the alloantigens present on the graft.

Currently, there are several pharmacologic means to prevent immune rejection. These chemicals tend to depress the entire immune response pathway, leading to negative side effects, namely, an increased risk of infection. There are areas of immune privilege such as the CNS, seminiferous tubule, or the eye. Transplantation into these regions may lessen the need for immunosuppressive agents.

Other alternative methods to prevent graft rejection include genetic modification of the graft tissue. In these scenarios, genes involved in antigen presentation can be disrupted, modified, or added to in pluripotent stem cells. This strategy has been attempted with mouse ES cells. Major histocompatibility complex (MHC) class I recognition molecules are found on all nucleated cells and require  $\beta_2$ -microglobulin to function. Genetic disruption of this gene highly reduces class I antigen presentation and cytotoxic T cell response (Zijlstra *et al.*, 1989). MHC class II molecules

are constitutively expressed in immune cells but only rarely and weakly in nonimmune cells. Disruption of several  $\alpha$  and  $\beta$  genes in mouse ES cells has been used to generate mice with limited MHC class II antigen presentation (Cosgrove *et al.*, 1991; Grusby *et al.*, 1991). By combining these disrupted alleles, class I- and II-deficient mice have been created (Grusby *et al.*, 1993). However, grafts derived from these mice have been subject to rejection following transplantation, though at a slower rate than normal controls. Minor histocompatibility antigens, tissue-specific antigens, and hybrid histocompatibility antigens are also capable of causing cell-mediated graft rejection and may require modification before some pluripotent stem cell-derived cells can be used for transplantation.

A technically feasible method of preventing graft rejection is to use autologous tissue. In some cases, lineage-restricted stem cells collected from the patient, such as those found in bone marrow, may be useful. Autologous pluripotent stem cell lines may be generated through therapeutic cloning (Solter and Gearhart, 1999), which involves somatic cell nuclear transfer technology, similar to the technique used in the production of the famous cloned sheep, Dolly (Wilmut *et al.*, 1997). A somatic nucleus would be taken from the patient and introduced into an enucleated oocyte. Pluripotent stem cells would then be derived from the resulting blastocyst. The resulting stem cell line could then be transplanted without rejection. This may be the most straightforward method to prevent graft rejection, although it would require somatic cell nuclear transplantation for every patient.

## SUMMARY AND FUTURE PROSPECTS

### STATUS AND CHALLENGES

Since the first reports of human pluripotent stem cells, research emphasis has been placed on the isolation and characterization of lineage-restricted human cells that comprise EBs. Scientific and political challenges lie ahead with respect to this research. If these stem cells are to be of general use in tissue engineering and transplantation, genes and factors involved in developmental and differentiation processes will need to be elucidated and utilized. Differentiation cascades will also have to be defined in order to generate cells that are appropriately restricted in developmental potential. For pluripotent stem cell-derived tissue engineering to be practical, the above challenges must be overcome, but will also be augmented by difficult issues of tissue architecture. In a more practical, but no less important, sense, we must develop improved techniques for pluripotent stem cell colony disaggregation and growth.

Pluripotent stem cell research faces political challenges as well, due to the origin of the cells. Federal funding of the research, which is currently being debated, would be necessary to realize rapidly the therapeutic potential of these cells. Our current system of peer review and governmental oversight of scientific research funding has served scientific research well. The open communication and sharing of technologies and reagents that are possible with governmental funding stimulates and encourages vigorous research. Oversight provided by the federal funding agencies can serve to set guidelines for the pursuance of the work. There is also a place for the biotechnology industry in this equation, with their ability to focus considerable financial resources on practical and profitable approaches.

Significant progress has been made in mouse and human pluripotent stem cell growth, differentiation, and transplantation. The challenges ahead are difficult but will eventually provide rewards by uncovering developmental mechanisms and providing cells and tissues for transplantation.

This Page Intentionally Left Blank

# GENE-BASED THERAPEUTICS

Lee G. Fradkin, J. Dezz Ropp, and John F. Warner

## INTRODUCTION

Many inherited and acquired disease processes, characterized at the genetic level, are known to be due to protein deficiencies or defects. Potential gene-based therapeutic strategies can now be designed to address these diseases. The initial premise of gene therapy was to correct heritable genetic disorders through gene replacement. However, the true potential of gene-based therapies can now be viewed in a broader context of biologics delivery for applications involving cancer, vaccines, genetic and metabolic disorders, viral infections, as well as cardiovascular and other organ-based interventions. The basic goal of gene-based therapeutics is the safe and effective delivery of genes to the disease site with subsequent expression, under physiologic conditions, of a therapeutic protein.

Biotechnology, in existence for approximately two decades, has traditionally focused on the production of therapeutic proteins. This industry was formed on the concept that synthetic (i.e., *in vitro*) manufacture of therapeutic proteins offers safety, control, and cost savings over isolation from natural sources. The diverse biologic activities provided by therapeutic proteins present great opportunities for the treatment of disease. Despite the immense advances in this field, the individual qualities of recombinant therapeutic proteins also present obstacles in their development, manufacture, and utilization. The concept of gene-based therapeutics arises from a desire to minimize the complexity presented by utilizing protein as the delivered therapeutic and to capitalize, instead, on the manufacture and delivery of a more generic molecule, namely, DNA encoding the therapeutic protein. Although the protein is still the therapeutic entity per se, delivery of genes requires the development of a single manufacturing process for the gene delivery vehicle that should be generally applicable to similar vehicles bearing different genes. As with any novel technology, however, the theory of gene-based therapeutics is more straightforward than its application. This chapter will identify advances and current shortcomings in the technology, with highlights from recent literature. Throughout the text the reader is referred to other recent specific reviews to avoid their repetition. Rather than a comprehensive review of the literature, the focus of this chapter is on those areas in which advancement is required to bring gene-based therapeutics to fruition.

The large number of genes for which the sequence has been determined through recent advances in genomics research presents a staggering potential for the future of gene-based therapeutics. Further work on determining the functional activities of many of these new gene candidates is necessary; however, in all cases, well-understood, robust gene delivery systems are required. Despite the infancy of gene-based therapeutics, over 300 clinical trials have been initiated in the past decade. The maturation of this therapeutic approach will come about through the results of these clinical trials, preclinical experimentation, and basic research in the fields of virology, cell biology, and molecular biology.

The primary considerations for successful gene transfer technologies are manufacture of the gene delivery vehicle, its delivery to the target tissue and cell surface, cellular internalization, intracellular trafficking, nuclear uptake, and functional gene expression with appropriate, controlled

levels of duration. In addition, safety of the delivery system, the expressed gene product, and associated immune responses are potential issues requiring evaluation. As the field of gene-based therapeutics establishes a more solid footing, in part through addressing the issues discussed below, the full potential of gene-based therapeutics in the treatment of human disease will be realized.

## GENE DELIVERY

Although the various viral- and plasmid-based gene delivery vehicles differ in composition and function, their ultimate goal is the production of a therapeutic protein in sufficient quantity at the appropriate site to elicit the desired biological responses. Viral delivery systems consist of modified, usually nonreplicating, viral genomes carrying a specific transgene. Plasmid-based gene delivery systems utilize a variety of agents (lipids, polymers, peptides) complexed with DNA encoding a transgene or utilize the “naked” DNA alone (reviewed in Maurer *et al.*, 1999; Rolland, 1998, and references therein). The most commonly used complexing agents are cationic liposomes and condensing agents such as poly(ethyleneimine) (PEI) and poly(L-lysine). Gene delivery vehicles must successfully traverse multiple barriers as they transit from the site of administration to their final destination, the nucleus of target cells (Mahato *et al.*, 1997a,b). Layered over these delivery barriers is the added complexity that each class of vehicle (adenoviral, retroviral, plasmid-based, etc.) has its own advantages and disadvantages that affect these potentially rate-limiting steps. To generate functional gene-based therapeutics, there must be a clear understanding of the requirements pertinent to the route of administration and the capabilities (as well as limitations) of the chosen delivery vehicle.

Although the barriers encountered along the gene delivery development path differ greatly depending on the route of administration, issues of gene delivery can be dissected temporally and spatially into three steps: (1) extracellular trafficking, (2) uptake into target cells, and (3) intracellular trafficking. Although the relative needs will vary by application, all delivery vehicles will require the ability to function at each of these steps. For instance, highly efficient DNA transport through the cytoplasm and into the nucleus is of little consequence if the delivery vehicle never reaches the target cells. Work in all categories of gene-based delivery has focused, therefore, more on a mechanistic understanding of delivery and the requisite improvements necessary to overcome these delivery barriers (Deshmukh and Huang, 1997; Lee and Huang, 1997; Meyer *et al.*, 1997; Onodera *et al.*, 1999; Palsson and Andreadis, 1997). Consequently, a more thorough understanding of current gene delivery system capabilities has begun to emerge. In this section we address some of the considerations regarding current gene delivery systems and outline some strategies employed to overcome these barriers.

## EXTRACELLULAR TRAFFICKING

On administration to the patient, gene delivery vehicles will encounter a physiologic milieu quite different from that presented under *in vitro* conditions. For example, systemic intravenous (IV) administration, perhaps the most challenging route of administration, presents several extracellular trafficking barriers that are a major limitation for this delivery route. Delivery systems will require stability within a complex array of serum proteins as well as an ability to avoid clearance by the phagocytic cells of the reticuloendothelial system (RES). Immune clearance presents further considerations more specific for viral systems (Anderson, 1998; Kuriyama *et al.*, 1998; Worgall *et al.*, 1997). Poly(ethylene glycol) (PEG) and lipids conjugated to adenovirus abrogate the effect of neutralizing antibodies *in vitro* and *in vivo* (Chillon *et al.*, 1998; O’Riordan *et al.*, 1999). In the case of plasmid-based systems, serum affects the biophysical and biochemical properties of lipid–DNA complexes by altering both size and charge, leading to an increase in complex disintegration, DNA release, and ultimately degradation (S. Li *et al.*, 1999). It is likely that the delivery vehicles that arrive at the target site could differ substantially from that originally formulated and administered to the patient. The composition of lipids in plasmid-based delivery systems affects the transfection efficiency (S. Li *et al.*, 1998; Zhao *et al.*, 1997). Data suggest the lipid composition is also an important factor in the recruitment of serum proteins (S. Li *et al.*, 1998, 1999). There is likely a direct relationship between the serum stability of lipid–DNA-based systems and their relative transfection efficiency (S. Li *et al.*, 1999). In general, there is a clear need for understanding the subtle balance of aggregation, disassembly, and DNA degradation that are critical for gene delivery.

Although the interaction of plasmid delivery systems with serum components is unavoidable following IV administration, the ultimate effect in practical terms is less obvious. Complement depletion in mice prior to IV injection of cationic lipid–DNA complexes suggests that, although the complexes interact with serum complement proteins, the interactions do not influence the transfection efficiency or systemic distribution of the complexes (Barron *et al.*, 1998). Clearly, we need to develop a better understanding of the array of interactions delivery vehicles encounter in order to optimize their IV administration. Serum interaction and stability studies are obviously an important part of developing new plasmid-based delivery systems and further exploration may lead to predictive models for *in vivo* activity (Goula *et al.*, 1998; Vitiello *et al.*, 1998; Yang and Huang, 1997, 1998).

Retroviruses are also sensitive to opsonization and inactivation by serum components following systemic delivery (Agrawal *et al.*, 1999; Rother *et al.*, 1995; Takeuchi *et al.*, 1994, and references therein). Furthermore, packaging cell line origin can impact immune response activation and profoundly affect viral clearance and stability (reviewed in Anderson, 1998). Strategies designed to minimize immune response activation by utilizing alternate packaging cell lines are currently ongoing (Forestell *et al.*, 1997; Pensiero *et al.*, 1996; Rigg *et al.*, 1996). These issues of *in vivo* stability are partially responsible for limiting the primary usage of retroviruses in humans to *ex vivo* applications. However, direct *in vivo* intratumoral administration of retroviral vectors has been accomplished using the p53 gene in the treatment of non-small-cell lung cancer (Roth *et al.*, 1996) and the interferon- $\gamma$  (IFN- $\gamma$ ) gene for metastatic melanoma (Nemunaitis *et al.*, 1999). Overall aspects of retroviral delivery have been reviewed (Anderson, 1998; Onodera *et al.*, 1999; Robbins *et al.*, 1998).

Targeting a specific disease requires knowledge of the appropriate tissue and cell types necessary to express the therapeutic protein as well as an understanding of the delivery system and route of delivery that will achieve the clinical goal. Biodistribution studies have provided a foundation for IV delivery of lipid–DNA complexes (Mahato *et al.*, 1998; McLean *et al.*, 1997; Niven *et al.*, 1998; Osaka *et al.*, 1996). A detailed comparison of IV versus intratracheal (IT) plasmid-based delivery of the cystic fibrosis transductance regulator (CFTR) gene (Griesenbach *et al.*, 1998) provides an elegant demonstration of differential uptake and expression based on the delivery route. Following IV administration of a cationic lipid-based delivery system, DNA was delivered to distal lung in the alveolar region, including alveolar type II epithelial cells, whereas, following IT administration, DNA was found in the epithelial lining of the bronchioles (i.e., clara cells) (Griesenbach *et al.*, 1998).

Differences in gene expression profiles based on delivery route highlight another major issue confounding development of gene-based delivery vehicles, namely, the lack of *in vitro* to *in vivo* correlation with available models. The relevance of the *in vitro* model to the *in vivo* situation is essential. As in the case of differences in expression pattern for IT versus IV delivery, the extracellular barriers differ immensely for each route of administration and ideally should be reflected in the model. The extracellular barriers presented by blood components for IV delivery are quite different from those presented by mucus, which is relevant for IT or aerosol lung delivery. The latter is likely the delivery route of choice for the CFTR gene (McDonald *et al.*, 1998), and the CF sputum presents its own unique delivery barriers (Kitson *et al.*, 1999; Stern *et al.*, 1998).

In an attempt to quantitate the barriers for airway delivery, investigators (Kitson *et al.*, 1999) have developed an *ex vivo* sheep tracheal epithelium model to analyze directly lipid- and adenoviral-based extra- and intracellular barriers. Overall, the results suggest that extracellular barriers are a major impediment to pulmonary delivery for both lipid-based and adenoviral systems. Normal mucus is a barrier for plasmid-based gene delivery, with a 25-fold increase in expression following its removal; no effect of normal mucus removal was observed for adenovirus infectivity (Kitson *et al.*, 1999). Expression following both adenovirus and plasmid-based gene delivery was significantly reduced in the presence of fresh CF sputum. These results suggested that the extracellular and plasma membrane barrier issues should be the primary focus for increased delivery efficiency of airway tissue. Once lipid–DNA complexes have traversed the apical surface of the respiratory epithelial membrane, however, it was suggested that the intracellular barriers are likely similar for *in vivo* and *in vitro* systems.

Previous attempts have been made to overcome the extracellular barrier presented by CF sputum by applying surface active agents (Parsons *et al.*, 1998) or DNase (Stern *et al.*, 1998) to the airway passages for enhanced transfection by adenoviral and lipidic delivery systems. Such “assist-

ed delivery” by coadministration of an agent to provide a more hospitable environment for the delivery system is an attractive option for airway delivery due to ease of administration. The combined use of traditional pharmaceuticals or biologics and gene-based therapeutics could potentially provide a greater benefit in such applications.

Several delivery strategies have been employed to avoid the potentially deleterious extracellular barriers of IV and IT delivery through direct administration of the gene delivery vehicle to the tissue of interest. Examples include intratumoral injection (e.g., Nomura *et al.*, 1999), intramuscular (IM) injection (e.g., Kessler *et al.*, 1996; Marshall and Leiden, 1998; Monahan *et al.*, 1998), and particle bombardment (i.e., gene gun) (e.g., Mahvi *et al.*, 1997; Rakhmilevich *et al.*, 1999). Delivery by the IM route can be accompanied by electroporation to enhance transfection efficiency (Mir *et al.*, 1999). Moreover, other invasive direct application strategies such as direct instillation of adenovirus within the pericardial sac are in development (Lamping *et al.*, 1997; March *et al.*, 1999). While minimizing the extracellular barriers the delivery vehicles are required to overcome, the downstream barriers beginning with cell uptake still exist.

### CELLULAR UPTAKE

The identification of the coxsackie and adenovirus receptor (CAR) (Bergelson *et al.*, 1997) as the receptor for adenovirus serotypes A, C, D, E, and F (Roelvink *et al.*, 1998) has furthered our understanding of the requirements for adenovirus infection. Decisions for adenoviral gene delivery strategies can now be based on a critical assessment of receptor levels in target tissues. The importance of receptor levels was highlighted by analyses demonstrating the variability seen in gene expression levels (Y. Li *et al.*, 1999) and distribution of adenovirus receptors (Hemmi *et al.*, 1998; Nalbantoglu *et al.*, 1999; Walters *et al.*, 1999). Variability in receptor availability could profoundly affect the outcome of adenovirus-based gene delivery and therefore should be a primary consideration in developing gene delivery strategies.

The increasing ability to overcome CAR deficiency by modification of adenovirus fiber proteins to provide alternative cell-binding epitopes (i.e., retargeting viral infectivity) should help to alleviate limitations of viral delivery based solely on receptor availability (Hidaka *et al.*, 1999; Sandig and Strauss, 1996). Retargeting strategies, in addition to potentially overcoming the lack of a receptor, provide an opportunity to generate the desired specificity for target cells. Without specificity, all cells possessing the CAR will be transduced by adenovirus. This leads to potential toxicities due to the increased dosing needed to overcome this lack of specific targeting as well as potentially dangerous side effects due to the expression of the therapeutic gene in an inappropriate cell population. Specific targeting is especially desired for the delivery of therapeutic genes preferentially into tumor cells (reviewed in Bilbao *et al.*, 1998). Several strategies aimed at eliminating natural viral tropism while providing novel interaction, typically through antibodies (or fragments thereof), have shown promise in proof-of-principle studies for adenovirus as well as adeno-associated virus (AAV) (Bartlett *et al.*, 1999; Douglas and Curiel, 1997; Goldman *et al.*, 1997; Miller *et al.*, 1998; Rogers *et al.*, 1997). These strategies also effect an enhancement in transfection in cases in which the CAR is limiting, and consequently reduce toxicity associated with the high levels of adenovirus required to achieve a therapeutic effect (Rancourt *et al.*, 1998). As with any secondary modification, manufacture of these viral-antibody hybrids will present yet another challenge to overcome before the full utility of this approach is recognized. Similarly, genetic manipulation of the critical fiber knob, by adding alternate binding epitopes directly during viral production, presents its own manufacturing concerns related to producer cell line specificity (Dmitriev *et al.*, 1998; Douglas and Curiel, 1997; Krasnykh *et al.*, 1998). In addition, potential immune recognition will be a concern for any retargeting strategy.

Retroviral vectors, based on the prototype murine leukemia virus (MuLV), possess a natural tropism based on receptor levels as well. Cells competent for retroviral transduction present the natural MuLV (amphotropic) receptor and are actively dividing. Although cell division is required for retroviral transduction (Miller *et al.*, 1990), rapid proliferation alone is not sufficient for transduction efficiency. Transduction may also be limited at the receptor level (Bauer *et al.*, 1995; Movassagh *et al.*, 1998; Orlic *et al.*, 1996; Sabatino *et al.*, 1997). As with adenovirus, there is a requirement for high-level expression of the appropriate viral receptor. Increasing the *Pit2* receptor level from 18,000 to 150,000 per cell increased the MuLV transduction efficiency from 10 to 50% in rat 208F embryo fibroblasts (Kurre *et al.*, 1999). Retargeting strategies for retroviral gene de-

livery have been the subject of reviews (Anderson, 1998; Gunzburg and Salmons, 1996; Sandig and Strauss, 1996).

In addition to the more standard reengineering of genetic and biochemical functionalities of retrovirus, novel analyses have emerged that focus more on the physicochemical forces involved in retroviral–cell interaction (Palsson and Andreadis, 1997). This study explored the physicochemical forces that determine the binding of the retroviral vector to the target cell and the kinetic interplay between cell cycle and retroviral life cycle, events that determine the intracellular fate of the virus and ultimately constrain the efficiency of the gene transfer process (Palsson and Andreadis, 1997).

Plasmid-based systems rely on ionic charge-based interactions for initial cell binding and subsequent endocytosis (Hope *et al.*, 1998, and references therein). Direct membrane fusion is the likely alternate route for cationic lipid–DNA-based systems; however, the relative contribution of these two pathways to nuclear delivery is unknown at this time. The differences in serum interactions and transfection efficiency from one lipid formulation to another make it difficult to generalize regarding uptake mechanisms (S. Li *et al.*, 1998, 1999; Zhao *et al.*, 1997). Furthermore, polymer-based systems display behaviors that differ from lipid systems. Consequently, much of the plasmid-based formulation technology development to date has relied on empirical assessments. Future formulation development will require evaluation in well-defined therapeutic models.

Targeting strategies have been employed for plasmid-based systems in an attempt to increase efficiency and specificity of delivery (e.g., Cristiano, 1998; Erbacher *et al.*, 1999; Harbottle *et al.*, 1998; Hung *et al.*, 1998; Kawakami *et al.*, 1998; Mohr *et al.*, 1999). Although the addition of targeting elements or other protein components to plasmid-based systems is an attempt to mimic the positive qualities of viral gene delivery systems, some of the negative consequences, such as increased immunogenicity, may become more apparent. Overall, a variety of strategies and considerations exist to improve the cellular uptake efficiency of gene-based therapeutics.

## INTRACELLULAR TRAFFICKING

The viral systems have naturally evolved highly efficient intracellular trafficking mechanisms and for this reason have been exploited for gene delivery with minimal attempts to modify their inherent functionality. Detailed understanding of the intracellular trafficking pathway for adenovirus has continued to evolve, however, in order to capitalize fully on this gene delivery workhorse (Leopold *et al.*, 1998; E. Li *et al.*, 1998; Miyazawa *et al.*, 1999; Suomalainen *et al.*, 1999; K. Wang *et al.*, 1998). Understanding the multiple functions afforded by the coat proteins of adenovirus in the intracellular phase of its infection cycle (Greber and Kasamatsu, 1996; Greber *et al.*, 1993, 1994) has provided a foundation on which to build plasmid-based delivery systems. Engineering of plasmid-based systems has focused on overcoming intracellular trafficking barriers such as endosomal entrapment and nuclear uptake (reviewed in Meyer *et al.*, 1997; Wagner, 1998).

It is difficult to generalize regarding the intracellular trafficking barriers and approaches for plasmid-based systems due to the multitude of lipids, polymers, and peptides employed. Reviews (Hope *et al.*, 1998; Meyer *et al.*, 1997) have covered this subject, and therefore the present discussion will be limited to common trafficking barriers (Zabner *et al.*, 1995) and strategies to overcome them. Endosomal release and nuclear uptake are the primary foci for improvement in transfection efficiency (i.e., expression) following entry into the cell for plasmid-based delivery. Decomplexation and cytoplasmic transport are perceived as the most likely secondary barriers that need to be addressed. Increased efficiency of intracellular trafficking will result in an improved therapeutic index and, consequently, allow reduced dosing of the plasmid delivery system to obtain the desired biologic response. Such improvements should also minimize potential toxicities related to high dosing.

Although endosomal entrapment may or may not practically limit expression (Brisson *et al.*, 1999; El Ouahabi *et al.*, 1997; Laurent *et al.*, 1999; Meyer *et al.*, 1997; Mizuguchi *et al.*, 1997; Zabner *et al.*, 1995), several endosomolytic agents (mostly modeled after viral elements) have been incorporated into plasmid-based systems (Baru *et al.*, 1998; Wagner, 1998). A body of evidence has begun to emerge suggesting that plasmid-based systems, analogous to retroviral systems (Miller *et al.*, 1990), require cell proliferation for successful transfection (Fasbender *et al.*, 1997; Mortimer *et al.*, 1999; Ropp, 1999; Tseng *et al.*, 1999; Wilke *et al.*, 1996). The prevailing hypothesis is that nuclear membrane breakdown during mitosis is required for uptake of plasmid DNA into the nucle-

us. In contrast, adenoviral vectors are able to transduce nondividing cells (Greber and Kasamatsu, 1996), suggesting that the viral genome has evolved a means to pass through the nuclear membrane.

A number of strategies to overcome the nuclear membrane are currently in development for plasmid-based systems. Incorporation of peptide nuclear localization signals (NLSs) into plasmid delivery systems to transport plasmid into the nucleus of quiescent cells has produced mixed results to date (Ludtke *et al.*, 1999; Meyer *et al.*, 1997; Sebestyen *et al.*, 1998; Zanta *et al.*, 1999). Further development of such approaches will focus on appropriate presentation of the NLSs as well as feasibility of scale-up and production. Alternatively, a nuclear transport cis-acting DNA element from SV40 may prove useful in plasmid-based systems (Dean, 1997; Graessmann *et al.*, 1989). An approach that circumvents the need for nuclear transport utilizes cytoplasmic expression via the T7 polymerase system (reviewed in Meyer *et al.*, 1997). Increased expression of a marker gene in mouse brain tumors (Mizuguchi *et al.*, 1997) and direct intratumoral injection of the *T7/tk* gene (Chen *et al.*, 1998) have illustrated the potential for this approach. *In vivo* utility of such strategies may be limited, however, due to potential immunogenicity issues related to the use of a xenogenic protein (e.g., phage T7 polymerase).

The cytoplasm of the cell presents transport and stability barriers to gene delivery independent of whether expression is nuclear or cytoplasmic. Lechardeur *et al.* (1999), for example, demonstrated the potential negative impact of DNA instability within the cytoplasm for plasmid-based systems. Clearly, an important role for the gene delivery agent, therefore, is protecting the stability and integrity of the nucleic acid cargo during all stages of delivery. Aside from DNA loss due to nucleases and other degradative enzymes, the cytoplasm is a viscous environment, which limits free diffusion of plasmid-sized molecules (Luby-Phelps, 1994; and reviewed in Meyer *et al.*, 1997). Adenovirus overcomes this environment by utilizing specific endogenous cellular molecular motors to facilitate transport through the cytoplasm (Suomalainen *et al.*, 1999). The understanding of plasmid-based transport through the cytoplasm is, however, relatively unexplored. Only recently has the potential involvement or exploitation of cytoskeletal components for enhancement of plasmid-based gene delivery been addressed (Hamm-Alvarez, 1999; Kitson *et al.*, 1999). Understanding the intracellular trafficking of DNA from cellular uptake through delivery into the nucleus should allow increases in the efficiencies of gene transfer. Increased efficiency of delivery and expression will ultimately affect dosing regimens, therapeutic indices, and safety profiles.

## PERSISTENT GENE EXPRESSION

The duration of gene expression and the impact of immunologic responses directed against the vector and/or gene product are important considerations for gene-based therapeutics. The desired level of persistence of therapeutic gene expression varies with each specific therapeutic application. Expression of rapidly acting agents with known systemic toxicities, such as cytokines, would be preferentially expressed in a controlled short-term manner. Therapeutic or prophylactic vaccination, similarly, may not benefit from long-term expression of an antigen due to the potential danger of inducing immune tolerance to an organismal or tumor epitope. A study by Ochsenbein *et al.* (1999) indicates, however, the need for sustained or repeated immunization in the treatment of established tumors.

Germ-line gene therapies, theoretically capable of stably directing appropriate tissue-specific expression of therapeutic proteins prior to the onset of disease, are the subject of ongoing ethical and legislative debate and are unlikely to be pursued vigorously in the near future. Short-term expression (i.e., several days to months) is within the capability of several gene delivery approaches. The following section will focus on the technical aspects of achieving sustained gene expression and begins by defining those treatments that will benefit from persistent expression.

## THERAPEUTIC APPLICATIONS

Therapeutic applications requiring prolonged gene expression include both gene replacement by somatic cell gene therapy and sustained, but nonpermanent, expression of a gene product whose therapeutic window is restricted to its duration of expression. Although the gene replacement types of applications represent the "holy grail" of gene therapy, e.g., the introduction of the CFTR gene into cystic fibrosis patients to effect remission of disease, this type of treatment is unlikely to represent the first generation of significant successes in somatic cell gene therapy. There are several

factors that make it unlikely that the initial successes in gene therapy will occur through replacement of a missing or defective chromosomal gene (the exception of genes encoding secreted proteins is discussed below): (1) the current gene transfer technologies may not be efficient enough to transduce a sufficiently high percentage of affected cells in a single tissue to restore function, (2) many diseases affect multiple organs and may require widespread gene transfer throughout the patient's body, (3) it is unclear whether gene replacement will reverse long-established symptoms presented by the patient, and (4) the technologies for transferring large segments of DNA capable of bearing appropriately regulated promoters are only beginning to be developed. Such regulation may be necessary to restrict expression to the desired tissues. The current lack of a safe and reproducible means by which to express stably a newly introduced gene over the human life-span by either single or multiple doses of a vector is also an important consideration for replacement-type applications.

Gene replacement approaches based on the transient expression of a secreted protein, however, are likely to come to fruition in the near future. Secreted proteins act both on transduced and nontransduced cells, therefore the requirement for a high percentage of cells to be transduced is reduced. In some cases, these diseases have been treated successfully with systemically administered human- or animal-derived protein therapeutics as well as recombinant protein therapies (reviewed in Buckel, 1996). Recombinant production of proteins has reduced reliance on naturally derived proteins for a number of therapeutics, thus alleviating the risks of associated adventitious agents. However, the relatively short duration of protein activity presents practical limitations and, hence, provides a potential need for longer duration protein production at the disease site via gene-based approaches. Although significant progress has been made toward increasing the effective circulating time of recombinant proteins through derivatization with agents such as PEG (Francis *et al.*, 1998), the effective half-lives of stabilized proteins may not allow sufficiently infrequent treatment schedules to reduce significantly the cost or patient burden of frequent administration in some cases. The use of slow-release matrix-protein complexes could be promising in this regard (e.g., Putney and Burke, 1998).

Current gene-based therapeutics technologies appear adequate to allow the moderately sustained expression and, in some cases, infrequent repetitive delivery needed to ameliorate certain genetic diseases. Although direct comparisons of the therapeutic efficacies of protein-based versus gene-based approaches have not yet been extensively pursued, there are indications that protein production from a newly introduced gene may be more physiologically relevant, and hence effective in some cases (Morsy *et al.*, 1998b; Rakhmilevich *et al.*, 1999). Among the approaches being pursued are expression of factors VIII and IX for the treatment of hemophilia (reviewed in Herzog and High, 1998),  $\alpha$ 1-Antitrypsin for the treatment of emphysema and liver cirrhosis (reviewed in Geddes and Beckles, 1995), leptin for the treatment of obesity (Morsy *et al.*, 1998b), and apo A-1 for the treatment of atherosclerosis (Benoit *et al.*, 1999, and references therein).

A second type of therapeutic applications requiring relatively persistent gene expression includes those involving the treatment of diseases not necessarily caused by the absence of a protein, but which can be treated through expression of a therapeutic protein. These therapeutic proteins are often normally expressed in tissue- and/or condition-specific manners. Use of a gene-based approach allows expression of a therapeutic protein in a controlled spatial and temporal manner. The applications of both protein- and gene-based approaches to deliver antiangiogenic factors to established tumors to effect regression by reducing their vascularization provide examples of this type of approach.

The antiangiogenic protein, angiostatin, a proteolytic fragment of plasminogen, was initially laboriously purified from the urine and serum of tumor-bearing mice (O'Reilly *et al.*, 1994), but is now produced as a recombinant protein in quantities adequate for clinical trials. Through mechanisms not yet clear, angiostatin suppresses the angiogenesis necessary for tumor growth beyond  $\sim 1$  mm (Folkman, 1972), while apparently leaving normal angiogenic processes sufficiently intact to preclude systemic toxicity. The activities of angiostatin and the unrelated antiangiogenic protein, endostatin (O'Reilly *et al.*, 1997), require the continued presence of the therapeutic protein for efficacy; cessation of therapy leads to outgrowth of residual tumor cells.

Several reports have demonstrated the successful use of angiostatin and endostatin gene-based therapeutics in mice (Blezinger *et al.*, 1999; Cao *et al.*, 1998; Griscelli *et al.*, 1998; Liu *et al.*, 1999; Nguyen *et al.*, 1998; Tanaka *et al.*, 1998). Because expression of angiostatin or endostatin causes

regression of tumors to micrometastatic states without completely eradicating tumor cells, both protein and gene therapeutic approaches may benefit from the inclusion of adjuvant therapies such as radiation (Gorski *et al.*, 1998; Mauceri *et al.*, 1998) or chemotherapy (Harris, 1998). Of particular interest will be whether vector-mediated antiangiogenic protein expression *in situ* differs from systemic administration of recombinant proteins with respect to efficacy, toxicity, and cost.

### CURRENT APPROACHES FOR PERSISTENCE

Persistent therapeutic protein gene expression can be achieved in one of two general ways: (1) a single dose of a persistently expressing vector or (2) repeated delivery of a less persistently expressing vector. Retroviral, adenoviral, adeno-associated viral, and plasmid-based gene delivery systems are the principal vectors being evaluated in a variety of animal and clinical models for their ability to express therapeutic proteins following administration by several different routes. Current considerations regarding these delivery systems involve their persistence of expression, mechanisms limiting that persistence, and the ability to administer repeat doses.

Immediately after infection, innate immune responses play a role in eliminating the vast majority of recombinant adenovirus (Ad) virions (Worgall *et al.*, 1997). However, the onset of antigen-driven immunity directed against the viral open reading frames (ORFs) remaining in the first generation (E1-deleted or E1/E3-deleted) replication-deficient adenoviral vectors is chiefly responsible for limiting their duration of expression (e.g., Tripathy *et al.*, 1996, Y. Yang *et al.*, 1994a, 1996a). Loss of expression generally occurs by 1 month posttransduction and can be ameliorated by codelivery of pharmacologic and vector-encoded immunosuppressive agents (Bouvet *et al.*, 1998; Cassivi *et al.*, 1999; Cichon and Strauss, 1998; Elshami *et al.*, 1995; Ilan *et al.*, 1997; Jani *et al.*, 1999; Jooss *et al.*, 1998; Kaplan and Smith, 1997; Kay *et al.*, 1997; Lochmuller *et al.*, 1996; T. A. Smith *et al.*, 1996; Vilquin *et al.*, 1995; Yap *et al.*, 1997) or by infection of immunodeficient strains of mice (Barr *et al.*, 1995; Dai *et al.*, 1995; Elshami *et al.*, 1995; Schowalter *et al.*, 1999; Yang *et al.*, 1994b; Zsengeller *et al.*, 1995). Although the potential safety issues regarding the use of immunosuppressive agents in human gene-based therapeutics have not yet been addressed, these approaches have been important in determining the mechanisms limiting the duration of gene expression and the ability to deliver vectors repetitively.

Partially, in an attempt to generate more persistent expression by reducing vector immunogenicity, the so-called “gutless” or “helper-dependent” adenovirus vectors have recently been developed (reviewed in Morsy and Caskey, 1999). All viral ORFs are deleted from these viral vectors, leaving only the transgene, the viral terminal repeats required for replication in packaging cells, a packaging sequence, and “stuffer” DNA to increase the genome to sufficient length for packaging into viral capsids. Recombinant virus is generally produced by cocultivation of a plasmid of the recombinant genome and a helper virus expressing all required trans-acting replication and packaging factors. Although contaminating helper virus remains an issue, studies using these vectors demonstrate improved performance with respect to immunogenicity, safety, and duration of expression (Chen *et al.*, 1997; Morsy *et al.*, 1998a; Schiedner *et al.*, 1998).

Adeno-associated viral (AAV) vectors have been “gutless” since their inception, bearing only the transgene flanked by the viral inverted terminal repeats necessary for replication and packaging (reviewed in Carter, 2000; Hallek and Wendtner, 1996; Rabinowitz and Samulski, 1998). Plasmids containing the recombinant viral genome or the replication and packaging proteins are coinjected into tissue culture cells by transient or stable transfection. These cells are then infected with adenovirus or transfected with appropriate Ad gene expression plasmids to provide the helper functions necessary to initiate and sustain the replication and packaging of AAV virions. The duration of expression of AAV vectors introduced into the muscle of nonimmunosuppressed animals can be in excess of several months (e.g., Snyder *et al.*, 1997).

Similar to the helper-dependent Ad and AAV recombinant vectors, plasmid-based vehicles encode only the desired therapeutic gene. Additionally, most lack protein components, reducing the likelihood of antigen-specific immune responses that potentially shorten the duration of expression. However, in a manner essentially independent of the specific type of plasmid-based gene delivery vehicle employed, expression declines precipitously from a peak level 8–12 hr following IV administration to undetectable levels after 2 to 3 days (e.g., Liu *et al.*, 1997).

The majority of plasmid-based systems utilize the human cytomegalovirus immediate-early (hCMV-IE) promoter–enhancer due to its relative lack of cell type specificity and high activity.

Although extensive evaluation of a variety of cell type-specific and viral promoters has been reported (reviewed in Miller and Whelan, 1997; Walther and Stein, 1996), it has not become apparent that other promoters express more persistently than the hCMV-IE promoter–enhancer. This sequence is also commonly used to express transgenes in recombinant adenoviral vectors when expression becomes lost due to cell-mediated immune responses at approximately 1 month post-IV administration. The discrepancy between hCMV-IE promoter–enhancer persistence in plasmid-based and adenoviral contexts may reflect different cellular responses to these vehicles and suggests that the promoter is capable of persistent expression in some heterologous constructs. Presumably, some as yet undefined aspect of the viral genome structure, not shared by most plasmids, facilitates persistence.

Plasmid-based gene delivery using the IM route of administration is notably different from that of IV administration in its degree of persistent expression. Introduction of uncomplexed, “naked”, or complexed DNAs by IM administration can result in prolonged expression (i.e., greater than 1 year) (e.g., Wolff *et al.*, 1992). The mechanism by which muscle fibers persistently express newly introduced transgenes is not yet clear. The route provides a simple means of systemically expressing therapeutic proteins, but may not be suitable for all applications. For example, IM administration of the vascular endothelial growth factor (VEGF) gene resulted in substantial gene-dependent injury at the site of injection (Springer *et al.*, 1998). Comparisons of IM route-dependent toxicity or pathology at the site of introduction should therefore be made for each therapeutic protein-encoding vector.

To achieve persistent gene expression, several groups have focused on the incorporation of cis- and trans-acting viral DNA elements into plasmid vectors. Sequences derived from viral replication origins and trans-acting origin binding factor ORFs derived from the Epstein–Barr Virus (EBV) (Guanghuan *et al.*, 1999; and reviewed in Scimmenti and Calos, 1998) and bovine papilloma virus (BPV) (Pirsoo *et al.*, 1996, and references therein) genomes have been used. These plasmid vectors are prevented from replicating by deletion of part of the replication origin necessary for the initiation of DNA synthesis. The relative persistence of these vectors is thought to involve the interaction of the origin binding protein with both the plasmid-born replication origin sequence and the host cell chromatin, tethering the plasmid and preventing its loss during cell division (Calos, 1998). Although this model predicts that the effect of the viral elements should be manifest predominantly in dividing cells, this has not yet been tested. An unresolved potential safety issue arises from the epidemiological association of EBV with several human cancers (Rickinson and Kieff, 1996) and the demonstration that B cell-directed expression of the EBV origin binding protein, EBNA-1, in transgenic mice results in the development of lymphomas (Wilson *et al.*, 1996). Sufficiently detailed structure–function analyses may allow the generation of mutant EBNA-1 species that facilitate nuclear persistence while lacking oncogenic potential, if these two activities are indeed separable.

Persistent therapeutic gene expression may be achievable through use of replicating vectors. In general, however, their use has been avoided due to the safety issues associated with uncontrolled *in vivo* viral replication. A modified replicating SV40-based plasmid system (Cooper *et al.*, 1997) is under development. The introduction of a specific set of mutations that reduce the oncogenicity of large T antigen, without blocking its ability to bind to the origin, potentially reduce the risk of tumorigenesis. If sufficiently limited distribution can be maintained, for example, by direct intratumoral injection or by engineering cell type-specific replication, certain therapeutic applications may be achievable.

The IM route of administration has proved to result in relatively persistent *in vivo* expression with both plasmid-based and viral gene delivery systems. Additionally, the use of viral elements in plasmid-based vectors shows promise for long-term expression by other routes. With these promising advances comes the concern that expression needs to be controlled to avoid adverse responses associated with prolonged expression. Ideally, vector transcription could be regulated in a positive manner by administration of a short-lived nontoxic drug (Clackson, 1997; Harvey and Caskey, 1998; Rossi and Blau, 1998). In the absence of the inducer, little or no expression of the therapeutic gene would occur and, in this manner, gene expression can be modulated. Several such systems have been described: regulation of transcription through use of the antibiotic tetracycline (reviewed in Blau and Rossi, 1999), the immunosuppressive rapamycin (Magari *et al.*, 1997; Rivera *et al.*, 1996; Ye *et al.*, 1999), the insect hormone ecdysone (No *et al.*, 1996), and the antiprogestins

(Burcin *et al.*, 1999, and references therein). Although promising, current outstanding issues include limited *in vivo* demonstration of efficacy, high basal levels of transcription in the absence of inducer, and the possibility that these prokaryotic or chimeric repressor proteins may prove immunogenic, precluding repeat delivery. However, the perceived need for regulated gene expression is, in part, an acknowledgment of the substantial progress that has been made regarding the levels and persistence of gene expression systems.

### REPEAT ADMINISTRATION AND IMMUNE REACTIVITY

Prolonged therapeutic expression of proteins *in vivo* may also be accomplished by repetitive delivery of vectors. Unfortunately, the impact of the innate and adaptive immune responses following administration of either viral or plasmid-based gene delivery particles on the effectiveness of subsequent doses is becoming more apparent. Adenoviral (Benihoud *et al.*, 1998; Dong *et al.*, 1996; Kagami *et al.*, 1998; T. A. Smith *et al.*, 1996; Yang *et al.*, 1996b; Yei *et al.*, 1994) and AAV (Halbert *et al.*, 1998; Manning *et al.*, 1998) delivery systems express efficiently on repeated administration only in mice lacking functional adaptive immune systems [e.g., nude or severe combined immunodeficient (SCID) mice] or immunocompetent mice tolerized or transiently immunosuppressed by pharmacologic or vector-encoded agents. Although the “gutless” Ad vectors have been designed to avoid elicitation of adaptive immune responses by elimination of viral ORFs, the inability to deliver repetitively AAV vectors, which lack all viral ORFs, to nonimmunosuppressed animals bodes poorly for this approach with respect to repeat delivery. Furthermore, a study has demonstrated that prior administration of an Ad vector rendered transcriptionally inactive by UV irradiation precluded expression from a subsequently administered Ad vector, suggesting that the capsid proteins associated with the incoming viral genomes are sufficient to generate a neutralizing immune response (Kafri *et al.*, 1998).

Another means by which to avoid the adaptive immune responses that may block secondary delivery is “serotype switching,” which involves the alternating use of recombinant viruses that are genetically divergent so as to not elicit cross-neutralizing immune responses. Such an approach has been reported for both Ad (Kass-Eisler *et al.*, 1996; Mack *et al.*, 1997; Mastrangeli *et al.*, 1996; Roy *et al.*, 1998) and AAV (Rutledge *et al.*, 1998; Xiao *et al.*, 1999). Applications are likely to be restricted, however, due to the limited number of Ad and AAV serotypes available in cloned form.

The ability to deliver repetitively plasmid-based gene expression constructs differs from the viral systems in that the innate (i.e., cytokine release) immune system, rather than the adaptive (i.e., T and B cell activation) immune system, appears to mediate interference. Productive IV delivery of a second plasmid-based construct after prior delivery of a first was shown to require a delay of 9–11 days (Song *et al.*, 1997). This “refractory period,” the length of time required between doses for productive secondary transfection, is dependent on the amount of the first treatment dose (Fradkin *et al.*, 2000). When the interval between IV doses was arbitrarily set as 3 days, the initial dose had to be reduced from a typical dose of 50  $\mu\text{g}$  to 0.5–5  $\mu\text{g}$  of liposome-complexed DNA per mouse to allow subsequent gene expression. Delivery of liposome-complexed DNA via intraperitoneal injection also showed a refractory period (Vernachio *et al.*, unpublished data). Induction of the refractory period does not require expression of a protein or mRNA by the first vector, e.g., a promoterless plasmid effectively induces a refractory period of length similar to that of an expressing plasmid. Administration of liposome-complexed plasmid by the IV route elicits rapid IFN- $\gamma$ , type I IFN, TNF- $\alpha$ , IL-6, and IL-12 expression (Dow *et al.*, 1999; Dow *et al.*, unpublished data; Whitmore *et al.*, 1999), similar to that seen following immunostimulation by oligonucleotides containing hypomethylated CpG motifs (reviewed in Krieg, 1996; Pisetsky, 1996). Further studies have implicated the interferon pathway in establishment of the refractory period (Fradkin *et al.*, 2000). Thus, the innate immune responses to lipid–DNA complexes *in vivo* appear to have a profound impact on repeat gene expression.

### SAFETY CONSIDERATIONS FOR GENE-BASED THERAPEUTICS

One of the primary issues surrounding any new emerging medical technology, particularly one involving gene transfer, is safety. The development of safe and effective gene-based therapeutics will require the careful choice and design of vectors for particular therapeutic applications, the controlled assessment of toxicology in compliance with good laboratory practices, and validated manufacturing processes following current good manufacturing practices. Regulatory groups will

need to address certain environmental release issues due to the technology's use of genetically modified organisms, pathogenicity of the delivery agents (e.g., viral systems), and characterization and quality assurance of the master seed banks and vector stocks (K. T. Smith *et al.*, 1996). Moreover, gene transfer has potential safety and toxicity considerations associated with the delivery system and expression of the delivered gene within cells. These considerations are all part of normal drug development and are a sign of the maturation of gene-based therapeutics from a research technology to clinical utility.

The basic nature of gene-based therapeutic strategies to deliver and express therapeutic proteins at the disease site under physiologically relevant conditions defines a new pharmacology compared to more established small-molecule and recombinant protein drug treatments. Thus, novel evaluation technologies will be employed to measure these new pharmacologic parameters to establish proper dosing regimens. For example, therapeutic proteins produced at the disease site may be undetectable using current expression detection systems, although the biologic effect occurs. Therefore, our sense of appropriate quantitative potency specifications to ensure biologic activity may need to be redefined. Although numerous clinical trials have been completed or are underway, no gene-based therapeutics have yet been approved for commercial clinical use. Hence, with limited published preclinical data available, pharmacologists and toxicologists will be challenged to design relevant treatment regimens using predictive models to identify potential acute and long-term adverse effects. However, guideline documents dealing with the preclinical safety evaluation of biotechnology-derived products (International Conference on Harmonization, 1998) and safety aspects of gene therapy products (CPMP/SWP, 1998) have been released. Furthermore, preclinical safety requirements for human somatic cell therapy and gene therapy products have been defined by the Food and Drug Administration (FDA) (1998). Thus, initial safety guidelines are in place to direct the safe development of gene-based therapeutics.

In spite of the tremendous potential of gene-based therapeutics to treat a variety of disease conditions, there remain a number of safety and scientific concerns regarding the technology (Verdier and Descotes, 1999). Some key safety considerations for gene-based therapeutics include the toxicity associated with the delivery systems employed, the expression of novel genes in new tissue types, interactions of the vectors with host genetic sequences, and the impact of host immune responses (i.e., innate and adaptive) directed against the delivery vehicle and/or the gene product.

The sequelae of host inflammatory and immune responses activated by any gene delivery particle (i.e., viral or plasmid-based) may play an important role in toxicity as well as impact the functional duration of the therapy. The induction of various cytokines could likely contribute to different degrees of acute toxicity depending on the gene delivery system employed and species evaluated, particularly with viral gene delivery (Muruve *et al.*, 1999). Toxicity issues may be more pronounced on systemic administration of vehicles compared to regional (e.g., intratumoral) delivery strategies. Although limited, preliminary studies would suggest that some gene therapeutics can be administered safely with appropriate dosing.

Safety issues concerning activation of protooncogenes through insertional mutagenesis or inactivation of tumor suppressor genes are important considerations, depending on the particular delivery system employed. Concerns regarding generation of replication-competent viruses and gene integration into germ-line tissue must be addressed. Because most viral delivery systems have been designed to be replication defective for safety purposes, replication-competent species potentially arising during manufacture must be detected. The *cis*- or *trans*-complementation of defective functions inherent in the vector by either viral or cellular gene products is an additional consideration for possible vector mobilization within the host. In the case of retroviral gene delivery, no replication-competent retrovirus (RCR) has been detected clinically following single or multiple intratumoral injections (Nemunaitis *et al.*, 1999). Through appropriate vector and packaging cell construction, it is hoped that recombination events leading to the generation of some of these species can be minimized.

The variety of gene delivery systems each provides a unique set of tissue specificities and properties that have advantages and disadvantages, dependent on the therapeutic application. The development of any new therapeutic technology needs to evolve through thorough demonstrations of preclinical safety. Although animal models can provide a certain level of safety evaluation, the critical safety profiles need to be defined through well-designed human studies.

## LARGE-SCALE PRODUCTION ISSUES

The successful development of gene-based therapeutic approaches for treating human disease requires progression through a well-defined set of clinical trials. Through each stage of clinical testing (i.e., phases I, II, and III) larger and more diverse patient populations are required. As a result, increasing amounts of gene-based product, processed under stringently controlled current good manufacturing practices, will be required. The safe application of gene-based therapeutics necessitates that production conditions be clearly defined with assurances that the manufacturing process can be validated and the reagent components can be certified for safety and conformity.

There are a number of issues that have arisen in the large-scale manufacture of these novel viral and plasmid-based gene therapeutics. Viral vectors must be produced in tissue culture packaging cells and are therefore subject to several specific considerations. Tissue culture cell lines used for manufacturing vectors need to be tested for infectious agents and any growth medium components (e.g., serum or growth factors) certified to be free of adventitious agents. Purification schemes must be appropriate for the removal of potential contaminants or product interference, e.g., retroviral transduction is adversely affected by proteoglycans secreted by producer cells in the preparation of viral stocks (Le Doux *et al.*, 1996, 1998).

Recombinant viruses are generally produced in tissue culture cells that have either been stably transfected or are transiently transfected with plasmid constructs expressing the viral ORFs required for viral DNA replication and packaging. Stably introduced expression constructs are generally maintained through drug selection of a contemporaneously introduced drug resistance gene. The gene-based therapeutic should be purified in such a manner as to render it demonstrably free of the selective drug. Ideally, the stability of the viral ORF under drug selection should be monitored over time to ensure homogeneity in production. The use of transient transfection into unmodified tissue culture cells reduces the burden of cell line stability characterization. However, although adequate to generate materials necessary for preclinical and phase I/II trials, transient transfection protocols have not yet been reported to be scaled up to yield the amounts of vector required for later stage trials and commercialization.

Another issue in the large-scale manufacture of viral vectors is the variability in the number of useful vector particles generated, i.e., the particle-to-infectivity (P:I) ratio, and their subsequent stability on storage. These variabilities can render production lots differentially efficacious for gene transfer and therapeutic effect. Most aspects of viral packaging are poorly understood and the P:I ratio cannot therefore be controlled or manipulated. Additionally, titers used to calculate infectivity ratios are generally determined using tissue culture cells under conditions optimized for *in vitro* infection; the relevant *in vivo* potencies are not well characterized (e.g., Forestell *et al.*, 1995). Methodologies to reduce P:I ratios should actively be sought because undesired inflammatory responses to both viral and plasmid-based particles are likely a function of total particle numbers delivered.

The generation of replication-competent virus (RCV) arising during vector production from the recombination of the vector genome and the viral replication protein encoding ORFs has been problematic for most viral-based gene delivery systems. Generation of RCV has been reported for adenovirus (Lochmuller *et al.*, 1994; Zhu *et al.*, 1999), AAV (Allen *et al.*, 1997; X. S. Wang *et al.*, 1998), and retrovirus vectors (Chong *et al.*, 1998; Miller and Buttimore, 1986, and references therein). Replication-competent retrovirus arising during manufacture was found to be responsible for the onset of lymphomas in vector-treated primates (Donahue *et al.*, 1992), demonstrating the reality of the dangers associated with RCVs. Although the possibility of recombination can be reduced by elimination of regions of homology between the vector genome and viral ORFs (Fallaux *et al.*, 1998), evidence that AAV replication-competent virus can arise through nonhomologous recombination has been presented (Allen *et al.*, 1997). The large amounts of actively replicating DNAs in packaging cells may preclude complete prevention of the generation of RCV, particularly during large-scale production. Acceptable safe limits, if any, of such contaminants may need to be established through rigorous preclinical testing.

Plasmid-based gene delivery vectors, due to their *in vitro* formulation from small-molecule compounds (e.g., cationic lipids), do not necessarily require animal-derived growth products in their manufacture. However, manufacturing issues exist for this class of delivery system as well. Some aspects of plasmid DNA preparation can involve the utilization of animal-derived reagents, i.e., the bovine pancreatic RNase often used to degrade contaminating *Escherichia coli* RNA in

plasmid preparations. These components can be purified from animals free from known adventitious agents; however, other unknown biologic agents may be present. A current problem in the manufacture of plasmid-based gene delivery vehicles is our limited understanding about the *in vivo* transfection-active species of formulated DNA. This has rendered the development of physical assays for ascertaining batch-to-batch variation difficult. The performance of vectors *in vitro* has proved to be a poor predictor of their *in vivo* function; different barriers to their activity are likely to exist in the *in vivo* environment. Issues involving the manufacture of gene-based products will be resolved as the technology and its product development continue to evolve.

## CONCLUSION

The use of proteins or biologics for the therapeutic treatment of various diseases is well established. Gene-based therapeutics provides an alternative, and potentially superior, means of delivering therapeutic proteins to diseased sites. Although gene-based therapeutics has tremendous potential for treating a variety of diseases, there are a number of issues arising from preclinical and clinical studies remaining to be addressed before clinical products are approved for routine use in humans.

With the availability of varied types of gene delivery systems, the challenge will be to understand the most appropriate delivery vehicle for each therapeutic application. Suitable manufacturing processes, compliant with regulatory guidelines, and well-designed clinical studies with clear end points need to be implemented. In addition, the safety profiles need to be clearly delineated. In particular, toxicities associated with the different delivery systems (i.e., viral and plasmid-based), novel gene expression in tissues, and host immune responses directed against the delivery vehicles and/or gene products need to be fully understood. Preliminary indications of safety and efficacy can be derived from preclinical studies utilizing inbred mice and rabbits. Relatively more outbred animals, e.g., nonhuman primates and companion animals, provide models potentially more closely related to the human with respect to dosing regimens, toxicity, and immune responses. Evaluation of the safety and efficacy of human gene therapeutics, however, can be achieved only through human clinical trials.

A greater understanding of cell biology, virology, immunology, and molecular biology is required to achieve the full potential of gene-based therapeutics. Fortunately, ongoing advances in these fields of basic scientific inquiry are mirroring the challenges arising in the development of gene-based therapeutics. Additionally, through a well-defined clinical development process, a great deal of knowledge will be gained regarding various pragmatic aspects in the utilization of gene-based therapeutics. The research technology of gene-based therapeutics is now positioned to move to the next stage, intervention in human disease.

## ACKNOWLEDGMENTS

L.G.F. and J.D.R. made equal contributions in the writing of this chapter. We wish to thank Denny Liggitt, Qing Wang, Meg Snowden, Steve Dow, and Rodney Pearlman for their comments on the manuscript and encouragement. We also thank our colleagues at Valentis, Inc., current and past, in particular, John Vernachio and Jeff Fairman, for their contributions and discussions. We apologize to the many scientists whose work was not cited due to space limitations.

# BREAST RECONSTRUCTION

Kuen Yong Lee, Craig R. Halberstadt, Walter D. Holder, and David J. Mooney

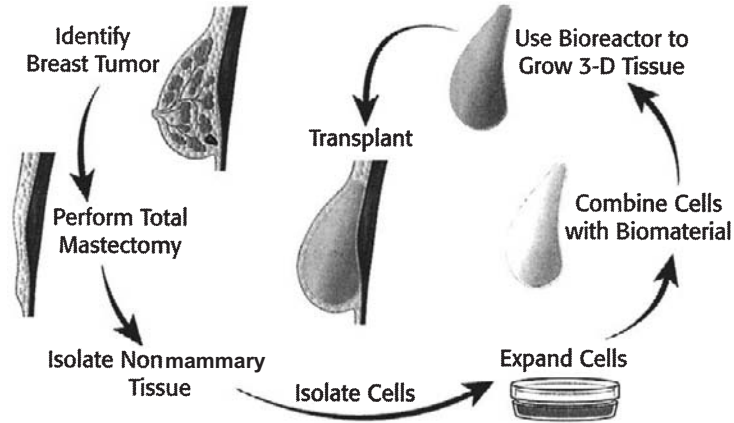

## INTRODUCTION

There are many patients who need reconstructive surgery after mastectomy or lumpectomy due to breast cancer. Tissue engineering may provide an approach to create new soft tissue masses for these applications. Various cell types can be used for breast reconstruction, including preadipocytes, fibroblasts, smooth muscle cells, muscle myocytes, and chondrocytes. To introduce cell-polymer constructs into the body, proper selection of polymeric materials should provide three-dimensional support for engineered new tissue. There are two strategies for introducing the cell-polymer constructs into the body. The first is to surgically implant and the second approach is to deliver in a minimally invasive manner using injectable forms of materials. A critical challenge to engineer large tissue masses is vascularization, and approaches to optimize this process include delivery of angiogenic molecules or endothelial cells.

There is a significant need for breast reconstruction due to cancer; the American Cancer Society estimates that approximately 182,000 new cases of breast cancer are reported each year. Direct medical costs for treating new and existing cases approach \$6 billion each year, according to the National Cancer Institute (American Cancer Society, 1997). Historically, breast cancer was treated with radical mastectomy. This procedure removed the breast, underlying pectoral muscles, and axillary lymph nodes. Radical breast surgery was developed at a time when breast cancers typically were very large before detection and were thus often unresectable by current standards. With the advent of mammography and a rising awareness of the importance of breast self-examination programs, earlier and smaller breast cancers are detected and do not warrant radical surgery. Radical mastectomy was abandoned for most patients when it became increasingly apparent that equivalent survival occurred after modified radical mastectomy, which preserved the pectoral muscles and removed less skin and fewer lymph nodes. During the past 30 years the National Surgical Adjuvant Breast Program (NSABP) has conducted numerous randomized prospective clinical trials that have explored newer and less deforming treatments for breast cancer (Harris *et al.*, 1997). These studies have unequivocally demonstrated that for most women with small breast cancers, simple excision (lumpectomy) of the breast cancer with sampling of the axillary lymph nodes followed by radiation is equivalent in survival to modified radical mastectomy. However, in some women mastectomy remains the best treatment due to extensive tumor involvement within the breast such that removal of all or most of the breast tissue is required.

The current approaches to reconstruct breast tissue include reconstructive surgery utilizing autologous tissue flaps, or implants of synthetic materials. Complex flap reconstructions using transversus rectus abdominal myocutaneous (TRAM) flaps, latissimus dorsi flaps, or muscle-free flaps from the buttock or thigh are used to reconstruct large volumes of lost breast tissue. These are very extensive procedures with long recovery periods, and require the harvest of tissue from another site in the body with its attendant side effects and complications. The advantage of this approach is that a patient's own tissues are utilized, and the use of a tissue results in a more natural tactile tissue quality. A more commonly used procedure involves the use of synthetic materials. In

Fig. 31.1. Schematic of the approach to engineer a soft tissue replacement for women with breast cancer. The first steps include identification and removal of the breast tissue, then isolation and multiplication *in vitro* of appropriate cells derived from another site in the body. These cells are then combined with a biodegradable polymer matrix and implanted into the body to recreate a soft tissue that emulates the lost breast tissue.

this process a tissue expander is placed, usually beneath the pectoral muscles, and is gradually inflated over several weeks to the desired size. It is subsequently removed by a relatively simple procedure and a saline-filled permanent silastic implant is placed in the cavity. Because the implant is a foreign body there may be a substantial inflammatory response producing fibrosis, thickening, and an unnatural shape and tactile quality. Also, implants may leak and require replacement. Silicone-filled implants are now rarely used due to a possible induction of autoimmune disease caused by the leakage of silicone.

Tissue engineering is potentially a potent approach to treat the loss of tissues or organs (Langer and Vacanti, 1993; Mooney and Mikos, 1999), and could find wide utility in breast tissue reconstruction. Tissues can be engineered with a number of different strategies, but a particularly appealing approach for breast reconstruction utilizes a combination of a patient's own cells combined with a polymeric scaffold. In this approach, tissue-specific cells are isolated from a small tissue biopsy and expanded *in vitro*. The cells are subsequently placed onto polymeric scaffolds, which act as synthetic extracellular matrices. These scaffolds deliver the cells to the desired site in body, define a space for tissue formation, and potentially control the structure and function of the engineered tissue (Putnam and Mooney, 1996; Kim and Mooney, 1998a). Utilization of biodegradable polymer scaffolds leads ultimately to a new tissue mass with no permanent synthetic element. New soft tissues, which can be transplanted into a patient and reconstruct lost breast tissue, can potentially be created with this process (Fig. 31.1). This approach may circumvent the main limitations of reconstruction of breast tissue using tissue transplantation, while eliminating the need for the permanent implantation of synthetic prosthetic materials.

In this chapter, we summarize the various cell types that may be useful for breast reconstruction, the polymers that can potentially be utilized in this tissue engineering approach, and the development of suitable animal models that allow one to test this concept for breast reconstruction. In addition, we review approaches being developed to promote vascularization of the engineered tissue, because this will be a critical challenge to engineer a large mass of soft tissue with cell transplantation.

## CELL TYPES FOR SOFT TISSUE ENGINEERING

Many considerations must be addressed when choosing which cell type(s) to be used in human breast tissue engineering. The first consideration is that there is substantial variability in the size, shape, and consistency of the breast. All three factors change over time, with a tendency for breast parenchyma (glands and ducts) to involute or regress as a woman ages, after pregnancy, and particularly after menopause, and to be replaced by fat. Also, comparing breast tissue among women of any given age, there is considerable variability in size, shape, tactile, elastic, and tensile characteristics of the tissue. The tensile and elastic characteristics of the breast are produced by three major factors: (1) the amount and quality of fat in the breast, (2) the amount and quality of glandular and duct tissue in the breast, and (3) the mechanical characteristics of the fibrous support structures of the breast (Cooper's ligaments). In breast reconstruction, the creation of a functional breast with lactational ability is not needed and, in fact, may add to a woman's breast can-

cer risk by introducing mammary epithelial cells that may be predisposed to cancer development. The major goal of breast reconstruction is to produce a breast mound with all of the aesthetic properties of a normal breast. A major concern for a woman undergoing breast reconstruction for cancer or augmentation is that the right side should match the left side and that the reconstruction should be aesthetically correct. Also, it is important to understand that there is considerable variability in the expectations of women who undergo reconstructive or augmentation breast surgery in terms of the desired size, shape, and elastic and tactile qualities of the breast reconstruction. With these observations, a projection can be made that fat cells would need to be a major part of the tissue-engineered construct and other cell types (e.g., muscle) would be needed to contribute appropriate conformational, tensile, elastic, and tactile characteristics of the construct. Also, due to the variability in normal breast, some individual manipulation of these constituents may be required.

A major cell type comprising normal breast tissue, and likely the engineered replacement, is the adipocyte. Lipid-laden fat cells (adipocytes) are terminally differentiated and will not divide further *in vivo* or under cell culture conditions. If these cells are to be used, they would have to be harvested from fat in an equivalent volume required for the construct (Nguyen *et al.*, 1990; Kononas *et al.*, 1993; Hang-Fu *et al.*, 1995). Alternatively, preadipocytes could be used for engineering soft tissue (Patrick *et al.*, 1999), because these cells can potentially be expanded in culture. These cells are fibroblast-like in structure and often contain small lipid droplets. More research is required to best determine how to maintain the preadipocyte phenotype with growth factors or growth medium supplementation to optimally expand and maintain these cells.

Because breast tissue is more than fat alone in most cases, additional cell types must be considered to contribute to the shape, tactile, elastic, and tensile characteristics of a breast reconstructed by tissue engineering methods. Possible other cell types include smooth muscle cells, fibroblasts, skeletal muscle, and elastic cartilage. Fibroblasts contribute greatly to the support structure of the breast by laying down bands of collagen that connect the breast tissue to the skin and to the pectoral muscle, as well as helping maintain the overall shape. Fibroblasts are an integral component of tissue-engineered skin products, and transplantation of fibroblast-containing tissues has been demonstrated successfully to replace lost skin tissue in several situations (Landeem *et al.*, 1992; Eaglstein and Falanga, 1998). The density and firmness of the breast are primary effects of the glandular epithelium and ductal structure. Tissues that have similar tactile and elastic properties are almost exclusively muscle. Smooth muscle cells can be readily isolated from a number of organs and expanded in culture. Techniques have been developed to seed these cells efficiently onto three-dimensional scaffolds fabricated from various polymers (Kim *et al.*, 1998), and to grow new tissues from these cell-polymer constructs with a defined size and shape (Kim and Mooney, 1998b). Implantation of smooth muscle-containing polymers can lead to the reformation of significant tissue masses, with reorganization of the smooth muscle tissue into appropriate three-dimensional structures (Oberpenning *et al.*, 1999). Muscle myocytes can also be greatly expanded *in vitro*, and have been demonstrated to reform functional tissue masses under appropriate conditions (Vandenburg and Kaufman, 1979; Vandenburg *et al.*, 1991). However, it remains to be demonstrated that smooth or skeletal muscle myocytes will maintain a tissue mass over long periods of time without neural stimulation. An alternative approach is to utilize chondrocytes as a component of an engineered breast tissue. Elastic cartilage has many of the mechanical properties of glandular breast tissue that are potentially important for tissue engineering of breast (e.g., elasticity). Chondrocytes can be readily expanded in culture and are able to survive in low oxygen tensions. Chondrocytes have been used extensively in tissue engineering to engineer a variety of tissue constructs both *in vitro* and *in vivo* (Atala *et al.*, 1994; Breinan *et al.*, 1998; Wakitani *et al.*, 1998).

A number of issues must be ultimately addressed in relation to cell expansion for breast tissue reconstruction. In considering the number of cell types that may potentially be used, it is very likely that a variety of growth factors will be needed for the *in vitro* expansion of cells. Implanted cell-bearing polymers may also need to be created to provide the short- or long-term stimulation of growth factors and other substances to enhance vascularization, or to provide or sustain a local milieu that will maintain a stable, healthy tissue mass in an area that may be foreign to the tissue (Mooney *et al.*, 1996c; Peters *et al.*, 1999a; Sheridan *et al.*, 2000). Standard isolation and expansion protocols must also be developed, and critical factors include aseptic technique in the harvest,

routine quality control testing of all cultures, and long-term cell storage. It may also be possible to isolate all the cell types required for breast tissue engineering from a single tissue source. For example, fat contains, in addition to adipocytes, a large vascular network, composed primarily of capillary endothelial cells and some vascular smooth muscle cells as well as a collagen stromal structure produced by fibroblasts (Williams *et al.*, 1994). Hence, multiple cell types can potentially be obtained from this tissue. In attempting to produce fat tissue, it may be beneficial to purify and expand the cellular components of fat without isolating each component. This may be particularly important if, as suggested by several authors, vascular endothelial cells and others exhibit organ specificity (Bassenge, 1996; Craig *et al.*, 1998; Murphy *et al.*, 1998).

## MATERIALS

There are two general strategies for introducing the cell–polymer constructs back into the body in order to engineer tissues. The constructs can be implanted using an open surgical procedure (implantable material), or introduced in a minimally invasive manner utilizing syringes or endoscopic delivery (injectable materials). Implantable forms of materials are typically foams, sponges, films, and other solid devices. The typical injectable forms of materials include hydrogels and microbeads. Most synthetic polymers, such as aliphatic polyesters, polyanhydrides, poly(amino acids), and poly(ortho esters), are suitable for fabrication of implantable devices. On the other hand, natural polymers, including alginate, chitosan, hyaluronic acid, and collagen, are good examples of injectable materials. Hydrogels are highly attractive injectable forms due to the potential to implant into the body in a minimally invasive manner. Their properties can be engineered for biocompatibility, selective permeability, mechanical and chemical stability, and other requirements as specified by the application (Jen *et al.*, 1996). Certain polymers such as the polyanhydrides and collagen can be used in both types of applications (Anseth *et al.*, 1999; Doillon *et al.*, 1994).

### IMPLANTABLE MATERIALS

A variety of polymers can be utilized to form solid or macroporous scaffolds for tissue engineering applications (Fig. 31.2). Aliphatic polyesters of poly(glycolic acid) (PGA) and poly(lactic acid) (PLA) are well-characterized synthetic biodegradable polymers that have been widely applied to the biomedical field generally, and to the tissue engineering arena specifically (Wong and Mooney, 1997). PGA has a high crystallinity, a high melting temperature, and low solubility in organic solvents. PLA has a much more hydrophobic character than PGA due to the introduction of the methyl group. PLA has low water uptake and its ester bond is less labile to hydrolysis owing to steric hindrance of the methyl group. Therefore, PLA degrades more slowly and has higher solubility in organic solvents compared with PGA. Copolymers of PLA and PGA (PLGA) can be readily synthesized and their physical properties are regulated by the ratio of glycolic acid to lactic acid. This enables these copolymers to be used in various applications as biodegradable matrices in tissue engineering (Mooney *et al.*, 1995).

These aliphatic polyesters can be readily processed into various physical forms appropriate for tissue engineering applications. A number of techniques have been proposed to generate highly porous scaffolds, including solvent casting/particulate leaching (Mikos *et al.*, 1994), phase separation (Lo *et al.*, 1995), emulsion freeze drying (Whang *et al.*, 1995), fiber extrusion and fabric formation (Freed *et al.*, 1994), and gas foaming (Mooney *et al.*, 1996b; Harris *et al.*, 1998). Nonwoven fabrics of PGA, stabilized by spraying with PLA or PLGA solution, thus providing significant resistance to compressional forces, were successfully used to culture smooth muscle cells (Kim and Mooney, 1998b), even with a tubular structure (Mooney *et al.*, 1996a). Gas foaming and particulate leaching techniques have proved efficient for generating open pore structures (Fig. 31.3), and because the gas foaming process does not require any organic solvents or high temperature, biologically active molecules can be incorporated into these matrices without denaturation (Shea *et al.*, 2000; Sheridan *et al.*, 2000). Implantation of porous polymer scaffolds leads to host tissue ingrowth and formation of granulation tissue throughout the scaffold (Fig. 31.4).

A number of other synthetic polymers can also be utilized to fabricate scaffolds for breast tissue reconstruction. These include polycaprolactone, polyanhydrides, poly(amino acids), and poly(ortho esters). Polycaprolactone (PCL) is also one of the aliphatic polyesters. PCL is a semi-crystalline polymer with high solubility in organic solvents and low melting temperature. Because

**Poly(glycolic acid)****Poly(lactic acid)****Polycaprolactone****Poly(amino acid)****Polyanhydride****Poly(ortho ester)****Alginic acid****Chitosan****Hyaluronic acid**

Fig. 31.2. Chemical structures of various implantable and injectable materials for tissue engineering scaffolds.

the degradation rate of PCL is much slower than that of PGA or PLA, it has been used as a long-term drug delivery carrier (Pitt, 1990). The biocompatibility of PCL has been investigated in rat (Yamada *et al.*, 1997) and rabbit models (Lowry *et al.*, 1997). Polyanhydrides are usually copolymers of aromatic diacids and aliphatic diacids. They usually degrade by surface erosion, and their degradation rate can be controlled, depending on the choice of diacids (Domb *et al.*, 1989). The degradation rates of polyanhydrides are much faster than those of poly(ortho esters) in the absence of any additives. Therefore, polyanhydrides have been widely used as biodegradable implants for local drug delivery of cefazolin, bupivacaine (Park *et al.*, 1998), methotrexate (Dang *et al.*, 1994), and taxol (Fung *et al.*, 1998). Poly[bis(*p*-carboxyphenoxy)propane-sebacic acid] was approved by the FDA for clinical trials (Engelberg and Kohn, 1991). It is biocompatible and nontoxic, even in the rat brain, when compared to standard neurosurgical implants (Tamargo *et al.*, 1989). Poly(amino acids) have been studied due to their similarity to proteins, and have been widely investigated for biomedical applications such as sutures and artificial skin (Anderson *et al.*, 1985). Poly(amino acids) are usually polymerized by ring-opening of *N*-carboxyanhydrides, and versatile copolymers can be prepared from various combinations of amino acids. However, due to their highly insoluble and nonprocessable properties, “pseudo”-poly(amino acids) have been also devel-

Fig. 31.3. (a) Scanning electron photomicrograph of the surface of a PLGA matrix formed with the gas foaming/particulate leaching methods. (b) Photomicrograph of hematoxylin- and eosin-stained cross-section of new tissue formed by smooth muscle cells on the matrix shown in a after 2 weeks in culture ( $\times 400$ ). Fig. 31.4. Formation of new three-dimensional tissue following implantation of a highly porous biodegradable polymer matrix. Rat adipocytes were seeded for 24 hr onto a 13-mm-diameter, 3-mm-thick PLA matrix and then implanted into the subcutaneous space of a female Lewis rat. The implants were harvested 4 weeks postimplantation, fixed in formalin, embedded and 4- $\mu$ m sections were stained with hematoxylin and eosin. A  $\times 2.5$  magnification of the graft is shown. A well-defined tissue is present throughout the implant site, with the establishment of a vascular bed, and the matrix size and shape predetermine the size and shape of the engineered tissue mass. Unpublished data from W. D. Holder and C. R. Halberstadt.

oped by Kohn and Langer (1987). It was also reported that poly(amino acids) containing L-arginine, L-lysine, or L-ornithine caused endothelium-dependent relaxation of bovine intrapulmonary artery and vein, and stimulated the formation and/or release of an endothelium-derived relaxing factor identified as nitric oxide (Ignarro *et al.*, 1989). Poly(ortho esters) are biodegradable polymers that degrade by gradual surface erosion and have been known as useful materials for controlled drug delivery. Poly(ortho ester) membranes containing indomethacin (Solheim *et al.*, 1992), gentamycin (Pinholt *et al.*, 1992), or insulin-like growth factor (Busch *et al.*, 1996) have been prepared and implanted into rats without any noticeable inflammation after degradation.

### INJECTABLE MATERIALS

A number of polymers, mainly naturally derived, can be utilized in an injectable form (Fig. 32.2). Alginate has found the widest use to date as an injectable scaffold material for tissue engineering (Atala *et al.*, 1994) due to its simple gelation properties when ionically cross-linked with divalent cations such as  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Ba}^{2+}$ , and  $\text{Sr}^{2+}$  (Fig. 31.5a). Because of favorable properties, including biocompatibility, nonimmunogenicity, hydrophilicity, and relatively low cost, there have been many attempts to utilize this material as wound dressings, dental impressions, immobilization matrices, and scaffolds for cultured and transplanted cells (Klock *et al.*, 1997; Shapiro and Cohen, 1997; Gombotz and Wee, 1998). Alginate can be used in an injectable form either by being preformed into small beads or by injection before or during the solidifying process. Due to the ease of implantation in a minimally invasive manner, alginate beads have been prepared and used for transplantation of chondrocytes (Lemare *et al.*, 1998; Gregory *et al.*, 1999) or hepatocytes (Joly *et al.*, 1997).

Alginate is not an ideal material for a tissue engineering approach because it loses divalent ions into the surrounding medium, and then dissolves. This process is uncontrollable and unpredictable. In addition, the molecular weight of many alginates is typically above the renal clearance threshold of the kidney (Al-Shamkhani and Duncan, 1995). Alginate is also known to discourage protein adsorption due to its hydrophilic character, and this may decrease the survival of many cell types in alginate hydrogels (Smentana, 1993). Hydrolytically degradable covalently cross-linked hydrogels derived from alginate have been reported (Bouhadir *et al.*, 1999). To avoid the degradation problem of alginate, polyguluronate blocks with molecular masses of 6000 Da were isolated from alginate, oxidized, and covalently cross-linked with adipic dihydrazide. The gelling of these polymers could be readily controlled, and their mechanical properties depended on the cross-linking density. An RGD-containing cell adhesion ligand has also been covalently coupled to enhance the cellular interaction with alginate hydrogels (Rowley *et al.*, 1999). These modified alginate hydrogels provided for adhesion, proliferation, and expression of a differentiated phenotype of mouse skeletal myoblasts (Fig. 31.5b).

Fig. 31.5. (a) Alginate hydrogel, ionically cross-linked with  $\text{Ca}^{2+}$ , as an injectable material for the tissue engineering approach. From K. H. Bouhadir and D. J. Mooney (unpublished). (b) Photograph of myoblasts cultured on GRGDY-modified alginate hydrogel surfaces for 3 days. Reprinted from *Biomaterials* **20**; J. A. Rowley, G. Madlambayan, and D. J. Mooney; "Alginate hydrogels as synthetic extracellular matrix materials," pp. 45–53. Copyright 1999, with permission from Elsevier Science.

Other naturally occurring polymers can also be utilized as an injectable material to achieve breast tissue reconstruction. These include chitosan, hyaluronic acid, and collagen. Chitosan is the second most plentiful biomass, and various derivatives of chitosan have been formed by coupling various molecules to the reactive amino groups in the backbone (Muzzarelli, 1983; Lee *et al.*, 1995). Chitosan has been known to be biocompatible and biodegradable and has a low toxicity (Chandy and Sharma, 1990; Tomihata and Ikada, 1997). This enables chitosan to be useful for versatile biomedical applications such as plastic surgery (Biagini *et al.*, 1991) and wound healing (Muzzarelli *et al.*, 1993). Chitosan matrices were fabricated and proposed as cell substrates for bovine chromaffin cells and porcine hepatocytes due to their structural similarity to glycosaminoglycans (Eser-Elcin *et al.*, 1998; Elcin *et al.*, 1999). Hyaluronic acid is known to be one of the glycosaminoglycan components of the extracellular matrix and plays a significant role in wound heal-

ing and cell proliferation. Hyaluronic acid is degraded by hyaluronidase, which exists in cells and serum (Afify *et al.*, 1993). Hyaluronic acid and its derivatives have been used as a drug delivery system (Larsen and Balazs, 1991). Hydrogels of hyaluronic acid have also been prepared by covalent cross-linking with various kinds of hydrazides (Vercruyse *et al.*, 1997). Human fibroblasts and keratinocytes were cultured on hyaluronic acid-derived biomaterials (Zacchi *et al.*, 1998) and cross-linked nonanimal hyaluronic acid gel was used for facial intradermal implants (Duranti *et al.*, 1998). Collagen is the best known tissue-derived natural polymer. It is the main component of all mammalian tissues, including skin, bone, cartilage, tendon, and ligament. Collagen has been used as a tissue culture scaffold or artificial skin due to the easy attachment to it by many different cell types. However, collagen offers a limited range of physical properties, and can be expensive (Pulapura and Kohn, 1992). The attachment of cells to collagen can be altered by chemical modification and incorporation of either fibronectin, chondroitin sulfate, or low levels of hyaluronic acid into the collagen matrix (Srivastava *et al.*, 1990).

## ANIMAL MODELS

A primary problem with the development of tissue-engineered human breast reconstruction or augmentation is that there are no similar animal models. Human beings are the only animals to have developed breasts. Other primates may have small breast mounds, particularly when lactating, but these are inadequate for developing large tissue constructs for partial or complete mastectomy equivalents to what occurs in human patients. Cattle and goats have udders that have no structural or functional similarity to humans. Rats and mice have multiple teats along mammary lines extending from the neck to the inguinal region, with small mammary glands beneath each teat. Pigs, dogs, and sheep similarly have subcutaneous mammary glands that are inconspicuous unless the animal is lactating. Despite the lack of an ideal model, major development of concepts can be achieved and important research questions answered using several animal models.

There has been excellent success using inbred female Lewis rats as a small animal for the development of transplantable tissues on absorbable polymers such as PGA, PLA, PGLA, and alginate (Holder *et al.*, 1998). This model allows for transplantation of cells between individuals without concern for immunologic rejection, which parallels the likely autologous nature of cell transplantation for breast engineering. In addition, the Lewis rat is larger than many other strains and allows for the testing of larger (1–2 cm) or multiple constructs in the same animal. In order to prevent migration of implanted materials and control the local formation of the engineered tissue, a “purse-string” technique has been developed to secure implants at specific sites (Roland *et al.*, 1998). Briefly, a single nonabsorbable suture is passed in and out of the skin to form a circle. The skin is lifted with a forcep, forming a pocket, and the implant is placed into the subcutaneous tissue in the center of the circle through a small incision that is then sutured together. The purse-string suture is then tightened to hold the implant in place. The suture may be removed 2 weeks later and the implant will remain in place.

Another attractive animal model that allows for the transplantation of human-derived cells is Nude (*nu/nu*) mice or severe combined immunodeficient (SCID) mice. These animals have a compromised immune systems to the extent that they will often accept xenogeneically transplanted tissues, and these mice have been particularly useful for transplantation and immunologic studies of human tumors, bone marrow, skin, and other tissues (Mortensen *et al.*, 1976; Lopez-Valle *et al.*, 1996; Ullmann *et al.*, 1998). They are potential models for evaluating various polymer constructs with and without human cells *in vivo* without the adverse effects of a major immunologic reaction. Further, basic questions about human cells and polymers *in vivo* may be answered without going to human trials prematurely. Development of these models may not be straightforward, because there are subtle differences between strains regarding acceptance of various tissues and growth of the implanted tissues in different sites (e.g., a tissue may grow in one mouse strain but not another or grow in a subcutaneous site but not in an internal location). Nude mice basically lack a T lymphocyte response whereas SCID mice lack both T and B lymphocyte responses. However, both types have natural killer cells that may interact with some transplanted materials. These mouse colonies must be monitored closely for changes in the immune status of the mice, which at times occur spontaneously. Human cells must be routinely screened for human immunodeficiency virus (HIV), hepatitis, and mycoplasma before transplanting into immunosuppressed mice to assure the safety of the animals and workers, and the validity of the experiments.

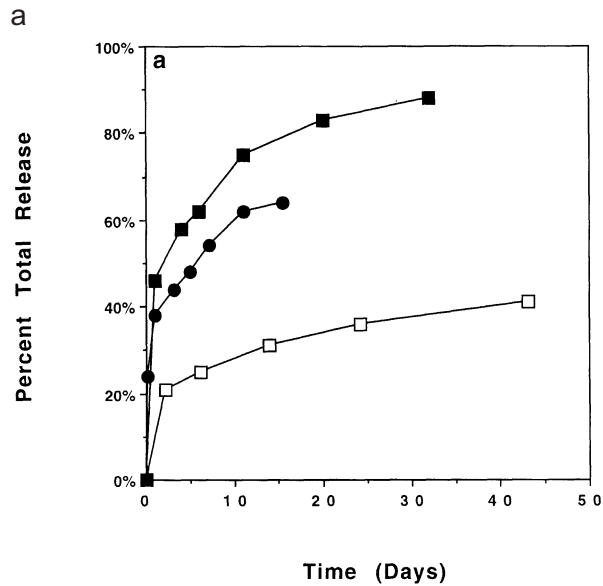

Fig. 31.6. (a) Release of  $^{125}\text{I}$ -labeled growth factors ( $\square$ , VEGF;  $\bullet$ , FGF-2;  $\blacksquare$ , EGF) from PLGA matrices formed with the gas foaming/particulate leaching methods. From Peters et al. (1999a). Photomicrographs of tissue cross-section after 4 weeks of implantation into Lewis rats for a matrix-releasing (b) plasmid-encoding PDGF ( $\times 100$ ) and (c) control plasmid ( $\times 400$ ). Photomicrographs have labels for adipose tissue (A), polymer (P), and vessel (V). From Shea et al. (2000).

In evaluating larger animals as models for breast tissue engineering, animals with skin and subcutaneous tissues that are similar to those of humans are required in order to evaluate larger constructs in the subcutaneous position. For this reason, the same animal must be used as a tissue donor and recipient. Dogs generally have little fat and very loose skin and present many of the problems of the rat in terms of migration of implanted materials. Pig skin and subcutaneous tissues are very similar to human skin and tissues, but most pigs continue to undergo rapid gain weight throughout their lives, which makes monitoring implants very difficult. We have had success with adult miniature Yucatan pigs that tend to maintain their size without massive weight gain (C. R. Halberstadt and W. D. Holder, unpublished data). Implanted materials can be readily monitored and sites easily marked with a skin tattoo. These animals have a pectoral musculature similar to that in humans so that subpectoral muscle sites may also be used. Primates, although relat-

Fig. 31.6.c

ed to humans, anatomically do not have any particular advantage over sheep or pigs as a model. Further research and development will be required to establish a technology for biopsies and cellular construct implantation that is efficient, technically straightforward, and minimally invasive in any of these large animal models.

### STRATEGIES TO ENHANCE THE VASCULARIZATION OF ENGINEERED TISSUE

A critical challenge to engineer breast tissue, or any tissue of significant thickness, is to develop a vascular network that can support the metabolic needs of the engineered tissue and integrate it with the rest of the body. The need for a vascular network has been strikingly demonstrated in studies of hepatocyte transplantation, in which over 90% of the cells transplanted even on relatively thin (3mm thick) scaffolds died within days following implantation (Mooney *et al.*, 1997). This finding of significant cell death prior to tissue vascularization is not unique to hepatocytes, but has also been noted in smooth muscle cell transplantation as well (Cohn *et al.*, 1997), and is likely a general finding in all efforts to engineer tissues (Colton, 1995). The presence of vascularized networks in natural metabolic organs results in a short diffusion distance between the nutrient source and the cells (Thomson *et al.*, 1995), and these vascular networks must be created in engineered tissues as well.

There are three general approaches taken to date to promote angiogenesis in engineered tissues. The first relies on vascularization, which accompanies the inflammatory response to any implanted foreign material. Optimization of the porosity and pore size of tissue engineering scaffolds can increase the rate of granulation tissue formation in engineered tissues (Mikos *et al.*, 1993; Mooney *et al.*, 1994). However, the blood vessel ingrowth occurs slowly with this approach, and will likely not be sufficient to engineer large tissue volumes. The second two approaches attempt actively to modulate the vascularization process by either delivering angiogenic molecules or blood vessel-forming cells (endothelial cells) to the site at which the tissue is being engineered.

Site-specific delivery of angiogenic molecules may provide an efficient means of stimulating localized vessel formation. Controlled and sustained release of angiogenic molecules from the tissue engineering scaffolds may allow one to optimize this process (Eiselt *et al.*, 1998; Peters *et al.*, 1999b; Sheridan *et al.*, 2000). Various growth factors, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (FGF-2), and epidermal growth factor (EGF), could be incorporated into a polymeric matrix and released at a controlled and sustained rate for an extended period of time (Fig. 31.6a). Alternatively, delivery of plasmid DNA encoding the angio-

genic proteins may be another approach to generate the vascular networks in engineered tissues (Shea *et al.*, 2000). PLGA scaffolds containing a plasmid encoding for platelet-derived growth factor (PDGF), a potent angiogenesis promoter, greatly increased the number of blood vessels and granulation tissue that formed compared to scaffolds, which did not deliver the plasmid DNA (Fig. 31.6, b and c).

Another potential approach to enhance angiogenesis in engineered tissues is to cotransplant endothelial cells along with the primary cell type of interest. This approach is suggested by the observation that endothelial cells will spontaneously form capillary-like structures *in vitro* if cultured in an appropriate environment (Ingber and Folkman, 1989; Pepper *et al.*, 1992). Endothelial cells seeded into a tissue engineering scaffold may be able to form capillaries, or capillary-like structures, which then can merge with capillaries growing into the scaffold from the host tissue. This possibility is supported by our previous finding that transplantation of syngeneic endothelial cells on polymer scaffolds led to a statistically significant enhancement in the density of blood vessels in the scaffolds following 2 weeks implantation into rats (Holder *et al.*, 1997). In addition, we have demonstrated that the new capillaries that form in these scaffolds are composed of both the transplanted endothelial cells and the ingrowing cells from the host (Nör *et al.*, 1999).

One attractive approach to engineering tissues in these models is to deliver cellular constructs that are approximately 500  $\mu\text{m}$  in thickness or less. This may optimize diffusional transport of nutrients to the cells while each small cell-polymer unit becomes vascularized. We have taken this approach by designing porous alginate-RGD beads (500  $\mu\text{m}$  to 3mm in diameter) for cell transplantation. Because the beads are macroporous, the vascular endothelial cells can migrate into the beads and establish a three-dimensional vascular bed in a short time. This approach can potentially be combined with angiogenic factors and cells to enhance the timing of endothelialization to promote the survival of the transplanted cells.

## CONCLUDING REMARKS

Tissue engineering may provide a new therapy to reconstruct breast tissue for woman undergoing lumpectomy or mastectomy. A number of cell types and polymeric materials may be useful to reconstruct breast tissue. In addition, it is clear that optimization of vascularization is critical to engineer large tissues. This approach may ultimately allow one to engineer and reconstruct breast tissue in the future with less pain and less invasive methods than those currently utilized clinically.

Lian Xue and Howard P. Greisler

## INTRODUCTION

Tissue-engineered blood vessels have a long history, beginning with early developments in polymeric vascular graft technology and in cell and tissue transplantation. More recent biologic manipulation is geared toward modulating the tissue reaction to implants and to thereby impacting on the common failure modes of thrombosis and intimal hyperplasia. This chapter reviews the biologic reactions elicited by commercially available and by experimental vascular grafts and discusses various strategies designed to induce endothelialization and/or to inhibit intimal hyperplasia. These strategies include endothelial cell seeding, impregnation with slow-release cytokines and growth factors, and the use of bioresorbable polymers. Novel techniques for the *in vitro* production of totally tissue-engineered blood vessels are addressed. A better understanding of physiologic and pathologic processes occurring after implantation of prosthetic grafts, combined with the development of novel technologies, will lead the road toward the development of ideal vascular substitutes.

The search for artificial vascular grafts dates back to 1952, when Voorhees developed Vinyon N, the first fabric graft (Voorhees *et al.*, 1952). The 550,000 vascular bypass surgeries performed annually in the United States make the development of vascular substitutes a continuing priority.

Initial graft research was directed at developing inert materials that passively transported blood and minimally interacted with blood and tissue. Poly(ethylene terephthalate) (Dacron) and expanded poly(tetrafluoroethylene) (e-PTFE) are the products of this research and are currently the most widely used prosthetic vascular grafts. However, the development of completely nonreactive substances has proved unrealistic. Both Dacron and e-PTFE react with blood components and perigraft tissues in both beneficial and detrimental fashions. An extraordinary expansion of our knowledge of mechanisms of vascular response to physiologic and pathologic conditions and the concomitant advance in the field of biomaterials have led to a more sophisticated strategy, optimizing tissue–biomaterial reactions to elicit desirable results. Synthetic grafts can be coated with proteins, anticoagulants, and antibiotics to potentially improve graft function. Similarly, synthetic polymers or biologically derived structural proteins can be bonded to various bioactive cytokines and growth factors to induce a favorable host response. Resorbable polymers comprise another type of graft in which extensive *in vivo* tissue ingrowth provides the biomechanical and functional integrity of the vascular conduit. Following over two decades of intensive research, a better understanding of the clinical value of endothelial cell (EC) seeding is starting to emerge. The use of tissue engineering techniques to construct a biologically viable vascular substitute is becoming feasible. Genetic manipulation of vascular cells may enhance the potential function of these biologic grafts (Conte, 1998).

The efficacy of vascular grafts depends on the intrinsic properties of the graft and the hemodynamic environment in which the graft is placed, as well as patient variables such as clinical indication, outflow resistance, progress of primary disease, and comorbidities. An understanding of graft pathophysiologic processes and failure modes will lay the basis for enhancement of long-term patency rates and development of more efficacious vascular substitutes.

## GRAFT HEALING

All grafts, regardless of their composition and structure, evoke complex but predictable host responses. Blood–biomaterial surface reactions start immediately after restoration of circulation. The cellular and humoral responses to synthetic materials include the deposition of plasma proteins and platelets, the infiltration of neutrophils and monocytes, and the migration and proliferation of endothelial and smooth muscle cells. Even the most inert substances thus far developed are still recognized as “foreign.” The tissue/graft/blood interfaces are highly complex microenvironments that are ultimately responsible for graft patency.

## PROTEIN ADSORPTION

Serum proteins—such as albumin, fibrinogen, and immunoglobulin G (IgG), the most abundant serum proteins—adsorb to the graft almost instantaneously following exposure to the systemic circulation. Then, according to the Vroman effect, there is a redistribution of proteins regulated by each protein's relative biochemical and electrical affinity for the graft surface and by its relative abundance (Vroman, 1987). Because platelets and blood cells interact predominantly with the bound proteins and not with the prosthetic material, the constitution and concentration of bound protein largely determine the interaction of blood and graft and therefore affect graft survival. For example, fibrinogen, laminin, fibronectin, and vitronectin have an RGD sequence (Arg-Gly-Asp) region that binds to the glycoprotein gIIb/IIIa receptor complex on platelet membranes. Thus, platelet deposition and activation are influenced by prior protein adsorption. The binding of RGD sequence to  $\beta_2$  integrins expressed on the cell surface also mediates the recruitment of the circulating leukocyte to the graft. The neutrophils bound to immobilized IgG and fibrinogen express a deficiency in their ability to kill bacteria, which may be partly responsible for the susceptibility of grafts to infections (De La Cruz *et al.*, 1998). Additional plasma proteins, including complement components, can be activated directly by synthetic surfaces to varying degrees. The generation of complement C5a, a monocyte chemoattractant, is greater following implantation of Dacron compared to e-PTFE grafts in an animal model (Shepard *et al.*, 1984). In addition, the rapid accumulation of coagulant proteins such as thrombin and factor Xa on the luminal surface after implantation contributes to the graft-associated procoagulant activity (Toursarkissian *et al.*, 1997).

## PLATELET DEPOSITION

Early platelet disposition occurs primarily via receptor-mediated interactions with adsorbed proteins and, to a lesser extent, by direct adherence to the graft. The platelet/protein complex is mediated through von Willebrand factor and platelet membrane glycoproteins. After adherence, the platelets undergo conformational changes and degranulate, thereby releasing a variety of bioactive substances, including serotonin, epinephrine, ADP, and thromboxane A<sub>2</sub> (TXA<sub>2</sub>), which activate additional platelets and increase thrombin production. Activated platelets also release growth factors, including platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and transforming growth factor  $\beta$  (TGF- $\beta$ ), which modulate smooth muscle cell (SMC) migration and proliferation and extracellular matrix synthesis and degradation. In addition, platelets release monocyte chemoattractants such as platelet factor 4 and  $\beta$ -thromboglobulin, which mediate the recruitment of monocytes to the graft. Platelet deposition and activation continue chronically after graft implantation. Animal experiments demonstrate increased levels of thromboxane and decreased systemic platelet counts 1 year after Dacron graft implantation (Ito *et al.*, 1990). Human studies have also revealed an increase in In-<sup>111</sup> labeled platelet adhesion to grafts at late times following implantation (McCollum *et al.*, 1981; Stratton *et al.*, 1982, 1983).

Because the deposition and activation of platelets elicit a cascade of histopathologic events, the thrombogenic nature of the synthetic graft surface is therefore a major determinant of both early and late graft patency. A myriad of interventions have been tried in order to attenuate platelet deposition, aggregation, and activation. Antiplatelet agents directly targeting platelet/graft-binding molecules, such as platelet surface glycoprotein IIb/IIIa ( $\alpha$ IIb $\beta$ 3 integrin) and different functional domains of thrombin, have been shown to at least transiently decrease the platelets on Dacron grafts (Kelly *et al.*, 1992; Mazur *et al.*, 1994). A variety of techniques used to alter surface thrombogenicity have been studied experimentally, including the application of antiplatelet or anticoagulant substances to biomaterial surfaces, the alteration of surface electronegativity, and the radio frequency glow discharge of plasma-polymerized monomers to surfaces, in the hope of enhancing surface thromboresistance without alteration of the material's bulk properties.

## NEUTROPHIL AND MONOCYTE INFILTRATION

The acute inflammatory response is mediated through potent chemoattractants such as C5a and leukotriene B4 (LTB4), which draw neutrophils to the synthetic graft surface. Neutrophils are attracted to the fibrin coagulum of the inner and outer capsules of the graft. The neutrophil binds to fibrinogen deposited on the graft surface by  $\beta 2$  integrins, mainly CD11b/CD18, which then mediate adhesion-dependent functions such as chemotaxis and promote transmigration. IgG, another protein deposited on the graft surface, is also important for neutrophil function. IgG can bind to Fc $\gamma$  receptors expressed on neutrophils. Normally, this binding triggers a series of effector functions. However, the recruitment of phagocytic cells around prosthetic grafts does not sufficiently increase infection resistance. On the contrary, neutrophils adherent to biomaterials express a deficiency in their ability to kill and phagocytose bacteria. It has been proposed that Fc receptor ligation by immobilized IgG on graft surface may account for this deficiency (De La Cruz *et al.*, 1998). Neutrophils can also interact with other deposited proteins, such as C3bi and factor X.

Neutrophils adhere to the endothelial cells in the perianastomatic region through selectin- and integrin-mediated mechanisms. L-Selectin is thought to modulate neutrophil/endothelial cell interactions by presenting neutrophil ligands to the E-selectin and P-selectin on the vascular endothelium. Selectin-carbohydrate bonds are important in initial contact whereas integrin-peptide bonds are responsible for firm adhesion and transmigration of neutrophils (Jones *et al.*, 1996). Both intercellular adhesion molecular-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on the endothelial cell (EC) surface can bind integrins. ECs up-regulate ICAM-1 and are induced to express VCAM-1 when stimulated by agonists such as interleukin 1 (IL-1) tumor necrosis factor (TNF), lipopolysaccharide, and thrombin (Bevilacqua *et al.*, 1985; Gamble *et al.*, 1985). Activated neutrophils release oxygen free radicals and various proteases, resulting in matrix degradation and possible inhibition of complete endothelialization and tissue incorporation of the vascular graft.

Circulating monocytes are also attracted to areas of injured or regenerating endothelium, especially in areas preactivated by IL-1 and TNF. There are many plasma monocyte recruitment and activating factors, including LTB4, platelet factor 4, and PDGF (Ford-Hutchinson *et al.*, 1980; Deuel *et al.*, 1981). In the presence of these plasma activating factors, monocytes differentiate into macrophages and become the major participant in the body's chronic inflammatory response. Macrophages release proteases and oxygen free radicals, which have long-term effects on the tissue/graft/blood interface.

A variety of cytokines are released from inflammatory cells activated by biomaterials. When cultured in the presence of polygalactin, a bioresorbable material phagocytized both *in vivo* and *in vitro* by macrophages, macrophages release into the culture media mitogens capable of stimulating the proliferation of quiescent smooth muscle cells, endothelial cells, and fibroblasts as compared to similar macrophages cultured in the presence of Dacron (Greisler *et al.*, 1991b). This mitogenic activity appears to be related to the secretion of fibroblast growth factor-2 (FGF-2) because pretreatment of the culture media with a neutralizing anti-FGF-2 antibody diminishes the stimulatory effect on smooth muscle cell growth (Greisler *et al.*, 1991b, 1996b). Cultured monocytes and macrophages incubated with Dacron and e-PTFE have been demonstrated to produce different amounts of IL-1 $\beta$ , IL-6, and TNF- $\alpha$ , concentrations being higher with Dacron than with e-PTFE (Swartbol *et al.*, 1997). TNF- $\alpha$  is one of the factors that may contribute to the enhanced proliferation of SMCs caused by a leukocyte-biomaterial interaction, and IL-1 may be partly responsible for the increased SMC proliferation caused by the leukocyte-EC reaction (Mattana *et al.*, 1997). IL-1 induces up-regulation of the expression of IGF-1 by ECs (Glazebrook *et al.*, 1998). Coincubation of polymorphonuclear leukocytes and IL-1 $\beta$ -treated human vascular endothelial cells (HUVECs) dramatically increased PDGF release (Totani *et al.*, 1998). Because the inflammatory reaction elicits a cascade of growth processes, it has been proposed that approaches attenuating the initial inflammatory reaction may improve the long-term patency of graft.

## ENDOTHELIAL AND SMOOTH MUSCLE CELL INGROWTH

Native uninjured blood vessels possess an endothelial lining that constantly secretes bioactive substances; these factors inhibit thrombosis, promote fibrinolysis, and inhibit SMC proliferation to help maintain normal blood flow. After graft implantation, tissue ingrowth originates primarily from the cut edge of the adjacent artery. Unlike most animal models, in which there is often complete endothelialization of synthetic grafts, currently available grafts implanted into humans

manifest only limited endothelial cell ingrowth, not extending beyond 1–2 cm of both anastomoses. However, endothelial islands have been described in the midportions of grafts at significant distances from the anastomosis, which suggests that other EC sources for graft endothelialization may exist. Interstitial tissue ingrowth accompanied by microvessels from the perigraft tissue is another major source for graft flow surface endothelialization on high-porosity e-PTFE and on bioresorbable prostheses (Clowes *et al.*, 1986; Golden *et al.*, 1990; Greisler *et al.*, 1988; Onuki *et al.*, 1998). There is also a possibility of circulating endothelial cell or stem cell deposition and proliferation based on the observation of scattered islands of endothelial cells isolated from pannus and unaccompanied by transmural microvessel ingrowth, present on impervious Dacron grafts in a canine model and also observed in a 24-month human Dacron graft explant (Shi *et al.*, 1994; Kouchi *et al.*, 1998; Wu *et al.*, 1995).

The ECs growing onto prosthetic graft surfaces undergo phenotypic modulation. These phenotypically altered “activated” cells may secrete bioactive substances that promote thrombogenesis and SMC growth. Activated ECs increase their PDGF synthesis and secretion, and subintimal smooth muscle cell proliferation occurs predominantly in the areas with an endothelial lining, i.e., the perianastomotic region, providing a link between endothelial cell turnover and intimal thickening (Greisler, 1996). This perianastomotic region is highly complex with chronic endothelial cell injury and has complex biomechanical characteristics and chronic inflammation. Although the time course may differ among species, in most animal models SMC proliferation starts as early as 2 days, peaks by 2 weeks after implantation of the graft, and thereafter diminishes. But neointimal volume keeps increasing by extracellular matrix synthesis and ultimately may form a stenotic lesion (Hamdan *et al.*, 1996).

SMCs found within the pseudointima of prosthetic grafts are also functionally altered. These SMCs produce significantly higher amounts of PDGF than do those of the adjacent vessel, which may contribute to the development of intimal hyperplasia (Pitsch *et al.*, 1997). In addition to SMCs, inflammatory mononuclear phagocytes and foreign body giant cells produce a variety of growth-modulating substances, including PDGF, FGF, and TGF- $\beta$ , which perpetuate SMC proliferation and production of extracellular matrix components.

### GRAFT FAILURE AND PATENCY RATES

A variety of mechanisms can lead to vascular graft occlusion. Immediate graft failure is usually the result of technical problems during surgery or may be due to the host's hypercoagulable status. Failure in the first month following graft placement is most likely the result of thrombosis in the face of high distal resistance. Anastomotic pseudointimal hyperplasia is the most common reason for graft failure from 6 months to 3 years after graft insertion. Late graft occlusions are frequently secondary to the progression of distal atherosclerotic disease. Thus, thrombogenicity and intimal hyperplasia represent the most common “intrinsic” causes of graft failure amenable to intervention by manipulation of graft construction, composition, and/or induced alterations in blood and tissue reactions to the implanted graft.

Clinical restenosis and patency rates reflect these “intrinsic” problems of synthetic grafts. Aortic reconstruction involves the placement of large-caliber Dacron or e-PTFE grafts. Because of the relatively high flow rates and low outflow resistance, these grafts have an 85–95% 5-year patency rate (Lind *et al.*, 1982; Moore *et al.*, 1968). When synthetic grafts are used in the infrainguinal, and especially the infrapopliteal, positions, the results are less than optimal. The 1- and 3-year patency rates for e-PTFE grafts used in infrapopliteal bypasses are 43 and 30%, respectively (Veith *et al.*, 1986). These small-caliber grafts are especially susceptible to anastomotic intimal hyperplasia and are more prone to early thrombosis because of lower flow rates and higher resistance outflow vessels.

### Graft infection

Vascular graft infection occurs in only 1–5% of implanted grafts (Leikweg and Greenfield, 1977; Szilagyi *et al.*, 1972). However, the catastrophic effects of graft infection resulting in a 50% amputation rate and a 25–75% mortality rate justify experimental attempts aimed at increasing prosthetic material resistance to bacterial infection (Goldstone and Moore, 1974). Penicillins and cephalosporins have been noncovalently bound to Dacron and e-PTFE surfaces with subsequent increased resistance to *Staphylococcus aureus* infection in animal models. Rifampin-bonded gelatin-

sealed Dacron grafts have also been shown *in vitro* to provide increased protection against bacterial colonization (Goeau-Brissoniere *et al.*, 1994; Vicaretti *et al.*, 1998).

### GRAFT CHARACTERISTICS AFFECTING VASCULAR HEALING

Chemical composition, construction parameters, and biomechanics are the intrinsic characteristics of a vascular graft that predominantly influence its interaction with its host and, in turn, determine its fate.

#### Porosity

The rate of tissue ingrowth is dependent on graft porosity or permeability (over limited ranges that differ in various graft type). Clowes has shown, in a baboon model, enhanced tissue ingrowth with complete reendothelialization in e-PTFE grafts with a 60- or 90- $\mu\text{m}$  internodal distance (Clowes *et al.*, 1986). Transinterstitial capillary ingrowth was not seen with the more commonly used 30- $\mu\text{m}$  internodal distance in e-PTFE. In a canine study, 90- $\mu\text{m}$  internodal e-PTFE grafts also demonstrated greater endothelial coverage and higher patency rates than similarly treated 30- $\mu\text{m}$  internodal distance e-PTFE grafts (Cameron *et al.*, 1993). However, human trials using this more widely expanded e-PTFE have failed to show any advantage in platelet disposition as compared to standard 30- $\mu\text{m}$  internodal distance e-PTFE grafts (Clowes and Kohler, 1991). In addition, transinterstitial ingrowth may differ when comparing two materials with equal porosity, e.g., PGA and Dacron (Greisler *et al.*, 1985). Greisler (Greisler *et al.*, 1987a, 1988a) has demonstrated significantly greater transinterstitial capillary ingrowth resulting in reendothelialization in lactide/glycolide woven prostheses as compared to Dacron prostheses when implanted into both rabbit and canine models. High-porosity grafts require preclotting.

#### Compliance

The compliance mismatch between arteries and grafts causes flow disruption, which has been thought to influence anastomotic pseudointimal hyperplasia (Abbott and Cambria, 1982). There have been attempts to design more compliant grafts, including the use of more flexible materials or by changing construction parameters. It is reported that grafts made of polyurethane may possess better compliance than e-PTFE (Stansby *et al.*, 1994). Surgeons have reported improved patency by interposing a piece of vein between the synthetic graft and artery at the distal anastomosis, a type of composite graft that may increase compliance at the distal anastomosis. Animal experiments have demonstrated a decreased neointimal thickness in composite grafts at the perianastomotic area (Gentile *et al.*, 1998). This method is now used by some as an alternative choice for femopopliteal arterial reconstruction, especially below-knee, when sufficient autologous vein is not available, although the benefit remains controversial. The value of more compliant grafts, however, is unclear.

Difficulties arise from the fact that there is great variability in the arterial tree in that the distal small-caliber arteries are often less compliant than the larger more central arteries. With progressive disease, wall thickening and calcification can occur throughout the arteries of atherosclerotic individuals. Another issue is that even experimental, relatively elastic grafts become less compliant over time because of the fibroplastic reaction that occurs following implantation. Even if a compliance match were possible, a final complicating factor may be the development of a hypercompliant zone in the region of the artery near the anastomosis (Hasson *et al.*, 1985).

#### Flow surface characteristics

The interface reaction between blood and the graft surface is dependent on surface chemical and physical properties such as surface charge, surface energy, and the degree of roughness. For example, a negative surface charge attenuates platelet adhesion and a positive charge promotes it. Heterogeneity of charge density distribution is also thought to be thrombogenic. A myriad of approaches have been made to stabilize and/or passivate the thrombotic reaction, including modification of surface properties, incorporation of antiplatelet or anticoagulant substances onto the graft, and endothelialization of the blood-contacting surface.

#### ANGIOGENESIS

ECs have only limited capacity for regeneration. After about 70 cell cycles, ECs can no longer divide. In order to achieve complete reendothelialization of the large surface areas required clini-

cally, it is likely necessary to recruit ECs from other than an adjacent artery. In response to local angiogenic stimuli, ECs preexisting in capillaries in perigraft tissue become activated and move toward stimuli in a process that involves secretion of proteases, degradation of basement membrane and extracellular matrix, migration and proliferation of ECs, and reconstruction of tubular structures.

The platelet disposition and the inflammatory reaction around the graft result in release of a number of cytokines and proteolytic enzymes, which in turn incite secretion of a cascade of growth factors. Among these factors, some are angiogenic, such as tissue factor, vascular endothelial growth factor (VEGF), and FGFs, and some are angiogenic inhibitors, such as platelet factor 4, interferons, and thrombospondin; some exhibit biphasic activities, such as TNF- $\alpha$  and TGF- $\beta$ . All of these bioactive substances create a microenvironment in which angiogenesis is a function of balance between positive and negative regulators. In addition, another balance between proteases and proteolytic inhibitors, such as plasminogen activator/plasminogen activator inhibitor (PA/PAI), is involved in cell migration and angiogenesis (Pepper, 1997). Exogenous intervention may change these balances so as to facilitate the endothelialization of prosthetic graft.

Local delivery of exogenous angiogenic factors may induce transmural capillary ingrowth *in vivo* and stimulate endothelialization of prosthetic grafts. In this context, a matrixlike fibrin providing spatial support is essential and can be used as a reservoir from which exogenous cytokines and growth factors can be released into the local microenvironment. Bioresorbable grafts may also facilitate local angiogenesis by stimulating macrophage release of endogenous angiogenic factors (see below).

Analogous strategies have been used to stimulate the development of collateral blood flow into ischemic tissue. In animal models, systemic or local applications of exogenous angiogenic factors, including VEGF, aFGF, and bFGF, may increase the capillary density of ischemic myocardial or limb tissue, prompt development of collateral circulation, and improve tissue hypoxia. A gleam of hope may be ahead for those severe ischemic extremities with no runoff channels for bypass surgery, a frustrating situation that usually ends with amputation.

## STRATEGIES FOR THE DEVELOPMENT OF VASCULAR GRAFTS

To improve the long-term patency rate of arterial substitutes, especially in small-caliber arterial and venous systems, the following approaches have been pursued: (1) modification of the blood contact surface to obviate the thrombogenicity of synthetic grafts, (2) manipulation of graft-induced *in vivo* responses by controlled delivery of bioactive substances, (3) development of bioresorbable vascular prostheses, (4) endothelialization of the graft blood-contacting surface, and (5) development of completely tissue-engineered vascular substitutes.

### SURFACE MODIFICATIONS

The simplest modification is to coat the graft with an inert polymer. Carbon coating, first done in the 1960s, has been found to decrease surface thrombosis, conjectured to be due to its negative charge and hydrophobic nature. The alternative carbon-impregnated prosthetic graft was also found experimentally to reduce platelet disposition. However, the advantage of these grafts is not confirmed by clinical comparative studies (Bacourt, 1997; Tsuchida *et al.*, 1992). A prospective multicenter clinical study of 81 carbon-impregnated e-PTFE and 79 standard e-PTFE grafts for below-knee popliteal and distal bypass showed no difference in patency rate between the two groups at up to 12 months after implantation. Silicone polymer coating, which produces a smooth surface that is devoid of the usual e-PTFE graft permeability and texture, followed by plasma glow discharge polymerization, effectively abolished pannus tissue ingrowth and graft surface neointimal hyperplasia in a baboon arterial interposition graft model and in a canine arteriovenous graft model (Lumsden *et al.*, 1996). Nojiri *et al.* (1995) have developed a three-layered graft consisting of Dacron for the outer layer (to promote perigraft tissue incorporation), nonporous polyurethane in the middle layer (to obtain a smooth surface), and a 2-hydroxyethyl methacrylate and styrene (HEMA-st) copolymer coating for the inner layer (to establish a nonthrombogenic blood interface). These grafts, with an inner diameter of 3 mm, were implanted in canine carotid arteries and remained patent for over 1 year. Only a monolayer of adsorbed proteins was found on the luminal surface of the grafts, with no pannus ingrowth from the adjacent artery, no thrombus, and no endothelial lining or neointimal formation.

Another approach is to cover the flow surface with proteins. Protein coating was originally introduced to decrease the initial porosity of Dacron grafts as an alternative to preclotting with blood. When the impregnated protein is degraded, the graft undergoes tissue ingrowth (Quarmby *et al.*, 1998). The compounds most often used have been albumin, gelatin, and collagen. Knitted Dacron prostheses coated with albumin, gelatin, and collagen have been available for clinical use. The albumin coating, created in the 1970s, was found in animal models to diminish platelet and leukocyte adhesion. In the canine thoracoabdominal aortic model, knitted Dacron grafts impregnated with carbodiimide cross-linked human albumin were compared to identical Dacron grafts with the recipients' blood preclotting. Albumin-impregnated grafts displayed less transinterstitial blood loss at implantation, and significantly thinner inner capsules at 20 weeks (Kang *et al.*, 1997).

Native collagen is intrinsically thrombogenic, whereas cross-linking of collagen is thought to diminish its thrombogenicity. In addition, collagen coating establishes a good matrix for cell ingrowth and induces neointimal formation, thereby potentially improving graft long-term patency. Promising results have been demonstrated by several groups (Bos *et al.*, 1998). But another clinical study reported that there was no appreciable difference in graft patency between woven and collagen-impregnated knitted Dacron aortoiliac grafts (Quarmby *et al.*, 1998).

Gelatin is a derivative of collagen but is more easily degraded when applied as a graft coating. Modification of coating techniques could control the degradation time (Bos *et al.*, 1998). Various techniques have been utilized in protein impregnation processes, including alkylation, plasma discharge, nonspecific cross-linking and covalent binding, and the application of thin polymer films (Dempsey *et al.*, 1998; Eberhart *et al.*, 1987; Ishikawa *et al.*, 1984; Kottke-Marchant *et al.*, 1989; Phaneuf *et al.*, 1998; Rumisek *et al.*, 1986; Tsai *et al.*, 1990).

Antithrombogenic substances have been affixed experimentally to synthetic grafts. For example, heparin binding to Dacron prostheses transiently reduces its thrombogenicity in some models (Mohamed *et al.*, 1998). In canine studies, heparin coupled to polyurethane and poly(dimethylsiloxane) surfaces improved graft patency rates (Park *et al.*, 1988). Thrombolytic substances, such as urokinase, have also been affixed to synthetic surfaces with promising results. Relatively little is known considering the long-term efficacy of these modifications because the duration of effective release is limited (Nojiri *et al.*, 1996).

### MANIPULATING *In Vivo* HEALING PROCESSES

Tissue incorporation is an unavoidable and desirable process for implanted prostheses. But excessive cell proliferation as well as extracellular matrix deposition result in intimal hyperplasia, leading to vascular graft failure. The ideal healing process of vascular grafts would be rapid endothelialization of blood-contacting surfaces, spatially and temporally limited subendothelial SMC growth, followed by phenotypic and functional differentiation of cell components, as well as controlled remodeling of the extracellular matrix. The recent expansion of knowledge concerning mechanisms responsible for the migration and proliferation of ECs and SMCs, angiogenesis, extracellular matrix deposition and remodeling, and physiologic parameters provides the possibility of manipulating the healing process by optimizing the microenvironments of graft and perigraft tissue.

Fibroblast growth factors, notably FGF-1 (acidic FGF) and FGF-2 (basic FGF), known as strong mitogens for mesenchymal and neuroectodermal cells, also possess potent angiogenic activities. Both FGFs have been experimentally applied to grafts in combination with heparin, which potentiates their mitogenic activity and protects them from proteolytic degradation. In order to achieve a controlled healing response, it is important to have a defined delivery system with which to apply bioactive substances to the graft and predictably release them locally, with bioactivities preserved for a desired period. Greisler has evaluated the affixation of FGF-1 to synthetic surfaces. In early attempts, FGF-1 was applied to various synthetic grafts by means of sequential application of fibronectin, heparin, FGF-1, and a second heparin layer, utilizing known binding affinities between successively applied agents. Using [<sup>125</sup>I]FGF-1, the retention of the growth factor was quantitated. After 1 week in an animal model, retention was 44% in Dacron grafts and 23% in polydioxanone (PDS) grafts (Greisler *et al.*, 1986a, 1987b). After graft explantation, the FGF-1 was eluted and was shown to have retained its mitogenic activity on quiescent murine lung capillary endothelial cells. However, this technique failed to enhance endothelialization *in vivo*. It was proposed based on *in vitro* studies that FGF-1 bound to immobilized heparin did not possess mi-

togenic activity until the bond between the FGF-1 and heparin or between the heparin and fibronectin was broken (Greisler *et al.*, 1996a).

Further studies developed a method in which FGF-1 and heparin were delivered by fibrin glue (FG), fibrinogen polymerized by thrombin. *In vivo* release kinetics were quantitated using [<sup>125</sup>I]FGF-1 and heparin impregnated into e-PTFE grafts implanted into rabbit infrarenal aortas. There was 13% retention of FGF-1 on the surface following 1 week of circulation, diminishing to 4% after 1 month. Equal distribution of the [<sup>125</sup>I]FGF-1 throughout the walls of the prostheses was achieved (Greisler *et al.*, 1992a). Since fibrin glue is potentially a thrombogenic substance, the acute thrombogenicity of this FG/FGF-1/heparin-treated e-PTFE graft was assessed in canine aortoiliac model using autologous platelets radiolabeled with <sup>111</sup>In. Compared to untreated grafts, there was no difference in platelet disposition at 5 and 30 min after implantation, but there was significantly less platelet deposition in the FG/FGF-1/heparin-treated grafts at 120 min (Gosselin *et al.*, 1995). There was also no differential deposition of platelets on the anastomotic versus middle graft segments over time. Later *in vitro* studies have shown a decreased platelet adherence on either FG- or FG/FGF-1/heparin-treated grafts when compared to blood-preclotted e-PTFE grafts. The orientation and state of polymerization likely alter the affinity of fibrin to platelet adherence (Zarge *et al.*, 1997).

Utilizing the FG delivery system, FGF-1- and heparin-impregnated e-PTFE grafts, 60  $\mu$ m internodal distance, have been evaluated in both canine aortoiliac and thoracoabdominal aortic models. When compared to FG-treated (no FGF-1) e-PTFE grafts or uncoated e-PTFE grafts, the FG/FGF-1/heparin graft treatment resulted in a significant increase in endothelial cell proliferation as assayed by *en face* autoradiography, with a more rapid development of a confluent factor VIII-positive endothelial blood-contacting surface, fully confluent in 28 days (Gray *et al.*, 1994; Greisler *et al.*, 1992a). There was also extensive transinterstitial capillary ingrowth observed throughout the graft wall. Cross-sectional autoradiography showed a similar significant increase in subendothelial myofibroblast proliferation within FG/FGF-1/heparin-treated grafts at 1 month, returning to base line at later times. When analyzed at 140 days, the FG/FGF-1/heparin grafts had developed significantly thicker inner capsules consisting of myofibroblasts and collagen compared to both untreated and FG/heparin-treated grafts.

Coimmobilization of FGF-2 and heparin in a microporous polyurethane graft by cross-linked gelatin gel has been demonstrated to accelerate tissue regeneration on synthetic grafts, associated with a greater extent of endothelialization via perianastomotic and transmural capillary ingrowth, in a rat aortic grafting model (Doi and Matsuda, 1997). A consistent "neointima" approximately 40  $\mu$ m thick, with intermittent endothelialization as well as SMCs and fibroblasts underneath the luminal surface, was observed in the middle portion of treatment grafts, compared to the control grafts covered with only a fibrin layer. In response to exogenous stimuli, ECs, SMCs, and fibroblasts turn over and enter the cell cycle. Transformed cells achieve the ability of dividing, synthesizing ECM, and producing growth factors by autocrine and paracrine mechanisms. A number of growth factors and cell-cycling proteins are involved in this process. Intimal hyperplasia caused by excessive cellular and ECM proliferation could be a sequela of such intervention. The key point is fine control of this proliferation process. Although studies to date indicate that the induced cell proliferation is transient, the incorporation of a later released inhibitor aimed at cessation of cell cycling could be beneficial.

## BIORESORBABLE GIFTS

Current clinically available synthetic vascular grafts, made of either e-PTFE or Dacron, are permanent prostheses within the host after implantation. Theoretically, it is possible to stimulate a rapid and controlled ingrowth of tissue to assume the load bearing sufficient to resist dilation, and including cellular and extracellular components with desirable physiologic characteristics, forming a "neoartery." The synthetic material may no longer be necessary following tissue ingrowth. Another strategy in the design of vascular grafts therefore is the use of bioresorbable materials.

Wesolowski *et al.* (1963) and Ruderman *et al.* (1972) were the first to describe the concept that a slowly absorbable vascular graft could induce a host regenerative process, producing a "new" functional artery. These early partially resorbable grafts were composed of Dacron and catgut yarns or Dacron and polylactide yarns. The first published report of a fully bioresorbable grafting was

by Bowald in 1979 and described the use of a rolled sheet of Vicryl (a copolymer of polyglycolide and polylactide) (Bowald *et al.*, 1979, 1980). These early grafts were prone to aneurysmal dilation and rupture.

Early studies done by Greisler (1982) and Greisler *et al.* (1985) evaluated woven poly(glycolic acid) (PGA) grafts in a rabbit model. Four weeks after implantation, these 24-mm by 4-mm grafts contained an inner capsule composed of a confluent layer of endothelial cells and smooth musclelike myofibroblasts amid dense collagen fibers. Similarly constructed and implanted Dacron grafts demonstrated an inner capsule containing solely fibrin coagulum, with minimal cellularity. Macrophage infiltration and phagocytosis were in parallel with the resorption of the PGA, which was totally resorbed by 3 months. In this initial experiment, 10% of the PGA grafts showed aneurysmal dilation, with no difference in the incidence of dilation between 1 and 3 months and 3 and 12 months, suggesting that the critical time for the development of aneurysms is during prosthetic resorption before the ingrowth of tissue with adequate strength to resist hemodynamic pressures. Later studies evaluated grafts composed of polydioxanone, a more slowly resorbed compound. These grafts showed similar endothelialization of the regenerated luminal surface and produced prostacyclin and thromboxane in concentrations similar to those in control rabbit aorta. PDS remained present up to 6 months. Only 1/28 PDS grafts exhibited aneurysmal dilation, with explant times as late as 1 year. The explanted specimens of these PDS grafts demonstrated some biomechanical characteristics similar to native arteries and were able to withstand static bursting pressures of 6000 and 2000 mmHg mean pressure without fatigue (Greisler *et al.*, 1987a).

Additional experiments were done with a variety of resorbable materials, some combined with Dacron (Greisler *et al.*, 1986). The results demonstrated that transanastomotic pannus ingrowth is not a critical source of cells replacing bioresorbable vascular prostheses but rather transinterstitial ingrowth of myofibroblasts, capillaries, and endothelial cells in the principal mechanism (Fig. 32.1). In addition, tissue ingrowth was observed to parallel the kinetics of macrophage phagocytosis and prosthetic resorption (Greisler *et al.*, 1987a, 1988a). *In vivo*, the rate of cell proliferation and collagen deposition in the inner capsule parallels the kinetics of macrophage-mediated prosthetic resorption (Greisler *et al.*, 1991a, 1993b). These studies also confirmed the inhibitory effect of Dacron and the stimulatory effect of Polyglactin 910 (PG910) on tissue ingrowth and inner capsule cellularity. As described earlier in this chapter, activated macrophages release a variety of growth factors, including PDGF, interleukin-1, basic FGF, TGF- $\beta$ , and tumor necrosis factor. The phagocytosis of various biomaterials can lead to macrophage activation. Rabbit peritoneal macrophages were cultured in the presence of PG910, Dacron, or neither, and the mitogenic activity in the resulting conditioned media was compared using growth assays of quiescent BALB/c 3T3 fibroblasts, rabbit aortic SMCs, and murine capillary ECs. The media of the macrophages grown in the presence of the bioresorbable polymer stimulated significantly more proliferation in all cell types than did the media of the macrophages grown in the absence of the material or in the presence of Dacron (Greisler, 1991; Greisler *et al.*, 1993a, 1996b). Preincubation of the conditioned media with neutralizing antibody against FGF-2 blocked 50–80% of that mitogenic activity.

A bioresorbable graft must regenerate a tissue complex of efficient strength prior to loss of prosthetic integrity so as to minimize the possibility of aneurysmal dilation. There are several theoretical ways to obviate this problem. One is to compound the bioresorbable material with a non-resorbable material that remains behind as a mechanical strut. Another solution involves the combination of two or more bioresorbable materials with different resorption rates so that the more rapidly resorbed material evokes a rapid tissue ingrowth while the second material provides temporary structural integrity to the graft. Third, growth factors, chemoattractants, and/or cells can be applied to the graft to enhance tissue ingrowth and organization.

Partially resorbable grafts have also been investigated in our laboratory. Dacron was found to inhibit the macrophage-mediated arterial regeneration stimulated by the resorbable component PG910. Polypropylene was then chosen as the nonresorbable component because of its high tensile strength, low fatigability, low degradation *in vivo*, and minimal inhibitory effect on cellular regeneration of grafts (Greisler *et al.*, 1992b). The composite grafts constructed from yarns containing 69% PG910 and 31% polypropylene were implanted into rabbit and dog arteries. One year after implantation, these grafts showed 100% patency with no aneurysms (Greisler *et al.*, 1987c). In a different study, totally bioresorbable composite grafts woven from yarns of 74%

Fig. 32.1. Midportion of a polydioxanone prosthesis/tissue complex explanted after 2 months, showing capillaries invading the inner capsule, with one capillary communicating with the luminal surface (hematoxylin and eosin;  $\times 25$ ). From *Arch. Surg.*, 1987, **122**, 715–721. Copyrighted 1987, American Medical Association.

PG910 and 26% PDS also demonstrated a 100% 1-year patency with no aneurysms in the rabbit aorta model (Greisler *et al.*, 1988b). The PG910 was totally resorbed by 2 months and the PDS by 6 months. The regenerated arteries withstood 800 mmHg of pulsatile systolic pressure *ex vivo* without bursting. A confluent, functional, von Willebrand factor (vWF)-positive endothelial cell layer over circumferentially oriented smooth musclelike myofibroblasts was present in the inner capsule of both these grafts.

Galletti *et al.* (1988) at Brown University used Vicryl prostheses coated with retardant polyesters to protect the Vicryl temporarily from hydrolytic and cellular degradation. When implanted into the canine aorta, prosthetic resorption was noticed at 4 weeks and was complete by 24 weeks. No coated grafts developed aneurysmal dilatation, whereas one of the uncoated grafts ruptured. It was theorized that the low pH generated in the microenvironment of the degrading bioresorbable polymers (polyglycolide and polylactide) stimulated macrophages to secrete growth factors that induce fibroblast proliferation. In separate experiments, another group in The Netherlands evaluated grafts prepared from a mixture of 95% polyurethane and 5% polylactide (van der Lei *et al.*, 1987; Yue *et al.*, 1988). They found that only relatively compliant grafts that induced circumferential smooth muscle development contained elastin and remained mechanically stable without dilating. They concluded that modifications of the graft preparation, including smooth muscle cell seeding, may help enhance optimal orientation of the smooth muscle cells and prevent aneurysm formation.

With further research, a small-diameter, totally resorbable vascular graft may be able to improve the current dismal long-term patency rates of small-caliber e-PTFE grafts.

### ENDOTHELIAL CELL SEEDING

Normally, endothelial cells perform a variety of physiologic functions, among them being the promotion of thromboresistance. Endothelial cells possess a negative outer charge that repels platelet adherence. They also produce glycosaminoglycans that bind antithrombin III, and produce prostacyclins and tissue plasminogen activator, all of which facilitate the anticoagulant and fibrinolytic activities of endothelial cells. Theoretically, the presence of a confluent monolayer of endothelial cells could improve graft thromboresistance. In addition, a confluent EC monolayer may also prevent the development of pseudointimal hyperplasia by preventing the deposition of platelets, which release bioactive factors responsible for SMC migration, proliferation, and production of ECM, and by assuming a quiescent phenotype in which ECs may release SMC growth inhibitors.

In 1978, Herring (Herring *et al.*, 1978) first reported that endothelial cell seeding onto a graft surface enhanced graft survival. Since then, this subject has been intensively investigated. Considerable progress has been achieved, especially related to technical problems. Initial difficulties in cell harvesting, cell seeding, cell adhesion, and prevention of desquamation have all been largely overcome (Graham *et al.*, 1982; Jarrell and Williams, 1991). The ideal seeded grafts should have a confluent endothelial cell lining at the time of implantation and the cells should be able to resist shear stress after the restoration of circulation, with the more desirable of their physiologic function intact. One of the difficulties is the relatively low cell density initially applied to the graft. The cell density of the endothelial cell lining on a normal vein is approximately  $10^3$  ECs/mm<sup>2</sup> (Sipehia *et al.*, 1996). In a completely lined vascular graft, cell density has to approach this value. The initial attachment of at least  $5 \times 10^3$  ECs/mm<sup>2</sup> is required for immediate confluent human EC coverage of a small-caliber vascular graft, because some of the cells will be washed off after exposure to the flow. To maximize immediate cell inoculation density, a two-stage seeding procedure is often performed in which endothelial cells are harvested, allowed to proliferate *in vitro*, and then seeded and grown to confluence on the vascular graft prior to implantation (Prendiville *et al.*, 1991; Sentissi *et al.*, 1986; Shindo *et al.*, 1987). Disadvantages of this technique are the potential for infection, the alterations of EC phenotype and function, the requirement of a waiting period of 3–4 weeks for expansion of cell population, and the necessity for two operative procedures. An alternative method involves the use of microvascular endothelial cells. Small-diameter Dacron grafts seeded with enzymatically harvested omental microvascular cells in a single-stage technique showed confluent endothelial linings, larger thrombus-free surface area, and improved patency rates at 1 year in a canine model (Pasic *et al.*, 1994).

Another technical issue related to EC seeding is cell adhesion and retention. Endothelial cells adhere very poorly to synthetic graft materials. Many adhesive proteins, such as fibronectin, collagen, fibrin, laminin, RGD-containing peptides, and plasma, have been applied to the graft surface to improve the seeding efficiency. Nitrogen-containing plasma treatment, a novel surface modification technique, generates basic groups on the graft surface and enhances EC resistance to shear stress-induced desquamation (Sipehia *et al.*, 1996; Tseng and Edelman, 1998). The studies on the kinetics of EC seeding showed that at least 20% of initially adherent cells were lost during the first hour and even 60% within the first 24 hr (Rosenman *et al.*, 1985b; Schneider *et al.*, 1988; Vohra *et al.*, 1991). Prolongation of incubation time before exposure to flow has been suggested to allow maturation of the cytoskeleton so as to improve the cell retention on the graft surface (Miyata *et al.*, 1991; Prendiville *et al.*, 1991; Sugawara *et al.*, 1997). Preconditioning the seeded EC monolayer with graded shear stress promotes reorganization of the EC cytoskeleton and production of extracellular matrix, which in turn enhances the EC retention at flow exposure (Ott and Ballermann, 1995). The properties of prostheses affect EC attachment. Dacron expressed higher and easier cell attachment compared to e-PTFE when both grafts were coated with the same matrix (Sugawara *et al.*, 1997; Vohra *et al.*, 1990). Polyurethane also showed better cell attachment than e-PTFE (Giudiceandrea *et al.*, 1998). PTFE has a negative surface charge, which is an important property against platelet deposition. Meanwhile, the negative charges also obstruct the negatively charged ECs from accessing the graft surface because of natural repulsive forces. A technique called electrostatic transplantation has been developed to induce a temporary positive, or less negative,

graft luminal surface charge, entailing EC attraction to the graft surface and accelerating their morphologic maturation. Using this technique, Bowlin *et al.* (1998) achieved no cell loss after a 30-min exposure to 15 dynes/cm<sup>2</sup> shear stress *in vitro* compared to 30% cell loss of control grafts and a cell density of  $78,420 \pm 6274$  cells/cm<sup>2</sup>, which was 2.3 times more than control after 120 min of physiologic shear stress exposure. The seeded cells maintained the ratio of prostacyclin/TXA<sub>2</sub> production. A theoretical advantage of this technique is that when the graft is removed from the device, the luminal surface charge immediately reverts to its natural negative state, rendering any nonendothelialized areas less thrombogenic. This overcomes the limitation of adhesive protein coating, which may allow exposure of thrombogenic surfaces to flow when ECs do not reach complete confluence or desquamate from the surface. Another desirable aspect of this technique is its simplicity, which may further bring EC seeding time to a clinically acceptable range.

Zilla demonstrated a considerable cell loss 9 days after the implantation into baboons of EC-seeded e-PTFE grafts using fibrin glue coating for cell attachment, but the endothelium was kept confluent by compensatory overspreading of the remaining cells (Zilla *et al.*, 1994b). Animal studies have suggested that endothelial cell-seeded Dacron and e-PTFE grafts elicit decreased platelet deposition and increased patency rates (Allen *et al.*, 1984; Graham *et al.*, 1985; Stanley *et al.*, 1982; Wakefield *et al.*, 1986; Whitehouse *et al.*, 1983). Endothelial cell-seeded grafts have also been shown to be more resistant to bacterial contamination (Rosenman *et al.*, 1985a). However, the seeded grafts have not been reproducibly shown to reduce anastomotic pseudointimal hyperplasia significantly (Graham *et al.*, 1991).

Although a myriad of encouraging results have been achieved experimentally, the clinical data have been limited and have shown mixed results. Herring *et al.* (1989) reported an increased 1-year patency rate for endothelial-seeded e-PTFE femoral–popliteal grafts as compared to unseeded grafts in the nonsmoking population. But some later studies using the same single-staged endothelial seeding technique have failed to show a long-term advantage of the seeded grafts (Jensen *et al.*, 1994). Magometschnigg *et al.* (1992) showed a twofold increase in early patency and a twofold decrease in late amputation rates using cultured endothelial cells seeded onto fibrin glue-coated e-PTFE grafts placed as infrapopliteal (femoral–tibial) bypasses. Utilizing a similar two-stage endothelial cell-seeding technique, Zilla *et al.* (1994a) demonstrated increased patency and decreased platelet deposition in clinically implanted endothelial cell-seeded e-PTFE femoropopliteal bypass grafts over 3 years as compared to unseeded grafts. This group reported (Meinhart *et al.*, 1997) very encouraging long-term results in a clinical follow-up study involving 108 *in vitro* endothelialized e-PTFE grafts, 107 of which were implanted in the infrainguinal position. In their initial randomized study, the primary patency rates were 84.7% for endothelialized grafts and 55.4% for control e-PTFE grafts after 3 years, 73.8 versus 31.3% after 5 years, and 73.8 versus 0% after 7 years. Combining these data with their more recent additional patients, who received EC-seeded grafts, the overall 7-year patency was 66% for 107 of endothelialized femoropopliteal e-PTFE grafts.

A major concern with EC-seeded grafts in humans is the potential for intimal thickening, supported by histopathologic observations from two separate case reports. In one case with bilateral above-knee grafts seeded with cephalic vein ECs, one of the grafts developed stenosis and had to be replaced 41 months after implantation. The central part of this graft was explanted and investigated. The graft had a confluent endothelium lining on a collagen IV-positive basement membrane with subintimal tissue of  $1.21 \pm 0.19$  mm thickness (Deutsch *et al.*, 1997). The unusually thick subendothelial layer has also been found in another case in which a microvascular EC-seeded Dacron graft was placed as a mesoatrial bypass and had to be resected because of external mechanical stricture 9 months after implantation (Park *et al.*, 1990).

Besides technical problems, concern exists as to the ultimate function of those endothelial cells on the graft surface, the cells having been injured by the process of manipulation and/or chronic exposure to an unphysiologic environment. Injured endothelial cells produce a variety of procoagulants, such as von Willebrand factor, plasminogen activator inhibitor, thrombospondin, and collagen. Higher levels of PDGF and bFGF have been measured in endothelial-seeded grafts, which is of particular concern given their potential role in stimulating the migration and proliferation of SMCs, and thereby stimulating the development of pseudointimal hyperplasia (Graham and Fox, 1991; Sapienza *et al.*, 1998).

Advances in molecular biology have provided the possibility of applying genetically modified

endothelial cells with desired functions to synthetic grafts. The first application of this technology to vascular grafting was reported by Wilson *et al.* (1989). In this initial study, Dacron grafts seeded with retrovirally transduced ECs containing a *lacZ* marker gene were implanted into canine carotid artery. Gene expression from modified ECs on the graft surface was identified for a period of 5 weeks. Tissue plasminogen activator (tPA) has been successfully transfected into endothelial cells (Dichek *et al.*, 1991). These modified cells effectively express this fibrinolytic agent after being seeded onto synthetic graft surfaces (Shayani *et al.*, 1994). It may also be possible to transfect endothelial cells so that they oversecrete growth factors and growth inhibitors in order to encourage further endothelial cell proliferation and migration and to prevent smooth muscle cell hyperplasia.

Gene transduction is, however, a developing technology. The effects of gene transduction and of the vector employed on EC biological behavior and on the host response introduce new variables to EC seeding, which remain to be elucidated. Controversial results have been reported in the literature related to the proliferation, adhesion, and retention of genetically modified ECs on the surface of synthetic grafts. Brothers *et al.* (1990) observed a lower proliferation rate of *lacZ* and Tn5 gene transduced canine ECs versus wild type. In contrast, Jaklitsh *et al.* (1993) and Huber *et al.* (1995) separately reported that there were no changes in the proliferation rate of tPA retrovirally transduced ECs, but the migration of cells was decreased. A major concern is that modified ECs express poor retention on graft surfaces *in vivo*. A significantly lower percentage of surface endothelialization was detected at 6 weeks on canine thoracoabdominal aortic e-PTFE grafts seeded with *lacZ*-transduced ECs compared with those seeded with nontransduced control ECs (Baer *et al.*, 1996; Podrazik *et al.*, 1993). Dunn *et al.* (1996) reported only 6% retention of ECs that had been tPA transduced on Dacron grafts after 2 hr of exposure to the flow *in vivo*. The similar poor retention of tPA-transduced ECs on e-PTFE grafts has been described by other groups (Falk *et al.*, 1998; Huber *et al.*, 1995). For this reason, little has been documented so far concerning the long-term benefit of genetically modified EC-seeded grafts *in vivo*.

The introduction of genetic engineering offers considerable potential to manipulate the function of seeded cells on graft surface and of perigraft cells, which may in turn further augment the efficiency of EC seeding. It merits consideration for the development of a new generation of vascular grafts in the future.

### TOTALLY TISSUE-ENGINEERED VASCULAR GRAFTS

In addition to the continuing emphasis on the endothelialization of the flow surface, the function of other cell types in the vascular wall has attracted more and more attention. It has been suggested that ECs by themselves cannot produce a stable intima without SMCs or fibroblasts underneath. Tissue fragments containing multiple cell types, including venous tissue, adipose tissue, and bone marrow, have been seeded onto grafts and were found to accelerate the graft healing process (Noishiki *et al.*, 1998). Interestingly, bone marrow cell seeding was reported to induce an abundant capillary ingrowth in the graft wall and a rapid, complete endothelialization of the inner surface without intimal hyperplasia. The primitive stem cells in the bone marrow, having the ability to differentiate in response to their microenvironment and to proliferate as well as to secrete cytokines for supporting their survival, may provide a useful cell source for tissue engineering.

Driven by the desire to develop an ideal vascular substitute, attempts to construct a neoartery have been carried out. Vascular cells are seeded into a three-dimensional ECM or onto polymer scaffolds. After implantation, these cells proliferate and produce ECM while the scaffolds degrade, and eventually are replaced by self-tissue. The newly formed conduits are viable vessels with the ability to remodel to fit the hemodynamic environment and maintain many of the normal functions of the cell components.

SMCs seeded onto biodegradable grafts composed of 95% polyurethane and 5% poly(L-lactic acid) were demonstrated to result in fast and uniform neointima development (Yue *et al.*, 1988). Shinoka *et al.* (1998) generated a graft from autologous mixed vascular cells expanded *in vitro* by culture of carotid artery segments and then seeded onto polygalactin or PGA scaffolds. After 7 days of *in vitro* culture, the grafts were implanted as pulmonary artery interpositions in lambs. The scaffolds no longer existed at 11 weeks, and the newly generated resembled native artery architecture, with ECs lining the luminal surface and with the development of ECM, including collagen and elastin fibers. However, an increase in the diameter of the grafts was noticed. Niklason *et al.*

(1999) reported encouraging results with a similar graft produced by seeding SMCs onto PGA scaffolds that were sodium hydroxide-modified to endure better cell attachment, and the graft was cultured in an *in vitro* pulsatile radial stress environment for 8 weeks before implantation. Engineered grafts showed contractile responses to serotonin, endothelin-1, and prostaglandin  $F_{2\alpha}$  and expressed the SMC differentiation marker myosin heavy chain. The grafts cultured under pulsatile condition produced more collagen than those grown without pulsatile stress and exhibited a mechanical strength comparable to native human saphenous veins (ruptured at  $2150 \pm 909$  mmHg versus  $1680 \pm 307$  mmHg). Autologous ECs were seeded onto the luminal surface and were cultured for another 3 days before implantation. Four of the grafts were implanted into swine saphenous arteries, of which two were generated under pulsatile stress and two under static conditions. Two pulsed grafts remained patent up to 24–28 days without dilation or rupture, and two non-pulsed grafts remained open for 3 weeks and then developed thrombosis. The polymer remnants were no longer visible at 4 weeks.

When using bioresorbable polymers as scaffolds, in parallel to the resorption of polymer is an inflammatory process, which not only may play a major role in inducing tissue ingrowth but may also provide a pathologic microenvironment for all cell components. The complete understanding and fine control of this process will be the key point for the success of this kind of graft.

The first attempt to create totally biologic vascular structures *in vitro* without synthetic polymers was made by Weinberg and Bell (1986). They constructed a three-layered blood vessel model with a collagen matrix as a scaffold for ECs, SMCs, and fibroblasts. Similar efforts have been made by other groups (Langer and Vacanti, 1993; L'Heureux *et al.*, 1993; Ziegler and Nerem, 1994). However, this model failed to yield requisite mechanical strength, and later grafts were reinforced with Dacron meshes. This weakness is presumed to be, at least in part, a result of lack of organization of the ECM. As an alternative, L'Heureux *et al.* (1998), rather than use exogenous ECM components, generated a vessel exclusively from cultured vascular cells in a well-defined environment; ECM was produced, with the organization resembling that in natural vessels. SMCs were cultured *in vitro* to form a cellular sheet, then wrapped around a tubular support to produce the “media,” and subsequently a similar sheet of fibroblasts was placed around the media to provide the “adventitia.” After maturation, the tubular support was removed and ECs were seeded onto the luminal surface. This constructed “vessel” displayed a burst strength over 2000 mmHg. The SMCs expressed circumferential and longitudinal orientations with a differentiation marker, desmin, and even showed contractile responses when challenged with vasocative agonists. Abundant ultrastructurally organized collagen and elastin fibers were present in the ECM. However, in short-term studies, after these vessels were implanted in canine femoral arteries, intramural blood infiltration was noticed. Although many more efforts will be required to conquer technical obstacles and optimize the manufacturing system, and as well examine the long-term efficacy, the possibility is open for creating novel viable substitutes for vascular replacement.

### ENDOVASCULAR STENTS AND STENT GRAFTS

The progress in vascular surgery and interventional radiology has led to the birth of intravascular interventions for vascular disease. Stents and stent grafts are the products of this developing technique, which minimizes invasive procedures and thus especially benefits high-risk patients.

Endovascular stents were initially designed to provide structural support following angioplasty, originally described by Dotter in 1969 (Dotter, 1969), but have become clinically widespread. There are three basic types of stents: balloon-expandable stents, which need balloon inflation to expand the stent into the arterial wall; self-expanding stents, allowing delivery in a collapsed form with the stent expanding to its predetermined size after release from the delivery device; and thermal-expanding stents, made by a shape-memory metal alloy that is in an easily manipulated form that assumes a memorized shape at a certain transition temperature. All these stents have been successfully used in pelvic arteries with a 2-year patency of approximately 84% (Müller-Hülsbeck *et al.*, 1998).

The stent graft is a combination in which a prosthetic graft is fixed to the arterial wall by an intravascular stent. The graft is usually either Dacron or e-PTFE and is combined with different stents. The primary indications for endovascular grafting are arterial aneurysm, arterial-venous fistulae, and vascular trauma. There have been numerous attempts to extend this technique to the treatment of arterial occlusive disease. Theoretically, the graft creates a barrier to exclude diseased arterial wall and provides a smooth flow conduit, while the stent support affixes the graft and may

enhance luminal patency by resisting external compression. Although the short-term results show promise in carefully selected cases (Allen *et al.*, 1998), little is known about the long-term consequences of this new technology.

There are limited data regarding the pathologic and hemodynamic influences of the stent or stent graft anchored to the arterial wall. It has been reported that stent placement may cause a variety of flow disturbances (Müller-Hülsbeck *et al.*, 1998). The stent components may stimulate a nonspecific inflammatory reaction and induce neointimal formation (Müller-Hülsbeck *et al.*, 1997; Schürmann *et al.*, 1996). Stent grafts possess even more complexities in respect to the healing process, which is different from either the stent or the graft. Obvious compliance changes between stent/unsupported graft/artery interfaces yield a remarkable hemodynamic disturbance. Delivery procedures, such as balloon dilation, which may alter graft intrinsic characteristics such as porosity, wall thickness, etc., as well as create mechanical injury to the surrounding artery, should also be taken into account (Salzmann *et al.*, 1997, 1998). In addition, unlike conventional bypass, the endovascular graft is placed into luminal arteries with perigraft exposure to diseased arterial intima or to thrombus. All these factors change the healing characteristics of prostheses. An inflammatory reaction and progressive thickening of neointima have been observed in both e-PTFE- and Dacron-based stent grafts (Hussain *et al.*, 1998; Yee *et al.*, 1998). A controlled study in the canine iliac artery model showed that endovascular stent grafts, composed of e-PTFE grafts and balloon-expandable stents, resulted in both greater endothelialization and an approximately five times thicker neointima in the midportion of the graft and a higher percentage of stenosis at the distal anastomosis, when compared to conventional e-PTFE grafts. Yee *et al.* investigated a similar stent graft in the porcine iliac artery and concluded that intravascular placement dramatically altered the healing of this type of graft (Ohki *et al.*, 1997).

Endovascular intervention alleviates surgical morbidity and mortality, thus having considerable clinical potential. The accumulation of experience, optimization of devices, and a better understanding of resultant pathologic processes will enhance their efficacy.

# SMALL-DIAMETER VASCULAR GRAFTS

Susan J. Sullivan and Kelvin G. M. Brockbank

## INTRODUCTION

Surgical treatment of vascular disease is now a common medical procedure. However, to date the use of synthetic materials is limited to grafts larger than 5 mm due to the frequency of occlusion observed with synthetic vessels of smaller diameter. Consequently, significant efforts in the past 15 years have focused on the development of a small-diameter blood vessel equivalent using tissue engineering. The seeding of synthetic grafts with endothelial cells has been investigated as a means to increase patency, but has been limited by the challenges associated with maintaining effective surface coverage. As an alternative to the use of synthetic materials, two approaches have been taken to create a blood vessel using cell and matrix components. Several groups have established techniques for creating a cellular vessel through coculture of smooth muscle cells with collagen or other matrix proteins and lining the lumen with endothelial cells. The second approach is designed to provide a graft constructed of a material, such as collagen, that would provide the required mechanical properties on implant but would also facilitate remodeling and infiltration of host cells into a cellular vessel. Our group has evaluated an acellular construct composed of porcine intestinal collagen matrix that provides the requisite mechanical properties, can be remodeled *in vivo*, and has shown promising patency in the rabbit carotid model.

In the early 1900s, clinicians began investigating the use of vein segments as arterial bypass grafts, but these procedures did not gain popular acceptance until the development of contrast angiography and the introduction of heparin as an anticoagulant (Carrell, 1910; Schloss and Shumacker, 1949; Charles and Scott, 1933; Murray and Jones, 1940). Arterial replacement is now a common treatment for vascular disease, with over 400,000 autologous coronary grafts (either arteries or veins) and over 200,000 vein grafts into peripheral arteries performed each year. A marketing analysis has shown that at least 300,000 coronary artery bypass procedures are performed annually in the United States involving in excess of 1 million vascular grafts (Frost and Sullivan, 1997). Autogenous vessels, particularly internal mammary arteries and saphenous veins, remain the “gold standard” for coronary grafting. However, many patients do not have veins suitable for grafting due to preexisting vascular disease, vein stripping, or vein harvesting in prior vascular procedures. Studies estimates that as many as 30% of the patients who require arterial bypass procedures will have saphenous veins unsuitable for use in vascular reconstruction (Edwards *et al.*, 1996). In addition, it has been shown that 2–5% of saphenous veins considered for bypass procedures were unusable on the basis of gross pathology and that up to 12% were subsequently classified as diseased, a classification that was associated with patency rates less than half that of nondiseased veins (Panetta *et al.*, 1992). Finally, significant morbidity and surgical costs are associated with the harvest of autologous vessels. All of these factors contribute to a widely recognized clinical need for a readily available, small-diameter vascular graft.

Chemically cross-linked xenogeneic and allogeneic blood vessels have been assessed as vascular grafts. Early attempts to use bovine arterial grafts failed due to aneurysmal degeneration and infection (Rosenberg *et al.*, 1970). Cross-linked human umbilical vein grafts are still in use clini-

cally despite the need for routine monitoring for early detection of aneurysms and poor patency rates in more challenging graft positions, such as across and below the knee (Brewster *et al.*, 1983; Edwards and Mulherin, 1980).

## SYNTHETIC GRAFTS

The use of synthetic materials to fabricate a blood vessel substitute began in the 1950s and has led to vascular prostheses made from a wide variety of materials, including nylon, Teflon, Orlon, Dacron, polyethylene, and polyurethane (Greisler, 1991). Expanded poly(tetrafluoroethylene) (e-PTFE) was introduced about 20 years ago, and Dacron and PTFE remain the most widely used synthetic materials. Both of these materials have been very successful in applications requiring large-diameter (greater than 5–6 mm) vascular substitutes in areas of high blood flow (Pratt, 1984). However, in low flow or smaller diameter applications such as peripheral vascular repair below the knee or coronary bypass, these grafts are not effective and there are no Food and Drug Administration (FDA)-approved products for such applications. Possis Medical, Inc., has received a humanitarian-use investigational device exemption (IDE) for an e-PTFE graft that acts as an arteriovenous shunt running from the aorta to the vena cava. When this graft is employed, coronary anastomoses are made in a side-to-side manner and pressure is maintained by placement of a Venturi flow restrictor near the vena cava. The Venturi flow restriction maintains blood flow through the graft at 500–600 ml/min and back pressure is maintained between the Venturi restriction and the aorta. Previous e-PTFE grafts often failed as a result of anastomotic hyperplasia, which leads to stenosis, and Dacron grafts were susceptible to thrombosis (Callow, 1983; O'Donnell *et al.*, 1984; Stephen *et al.*, 1977). Composite devices that incorporate biological substances into the synthetic graft in order to modulate the host response and help prevent graft failure have also been developed. Synthetic grafts have been impregnated with biodegradable components such as albumin, collagen, gelatin, elastin, and fibrin (Gundry and Behrendt, 1987; Kottke-Marchant *et al.*, 1989) designed to decrease the surface reactivity to platelets; however, long-term efficacy has not been achieved using this approach. Agents that are known to inhibit thrombogenesis or promote anticoagulation, such as heparin, prostaglandin E<sub>1</sub> (PGE<sub>1</sub>), hirudin, and aspirin, have also been bound to the lumen of the synthetic vessels but have met with limited success (Park *et al.*, 1988; Phaneuf *et al.*, 1998).

## IN VITRO BLOOD VESSEL TISSUE ENGINEERING

Initial attempts at tissue engineering a blood vessel substitute involved seeding the lumen of a synthetic graft with endothelial cells. Modifying the prosthetic graft surface with a monolayer of autologous endothelial cells was initially suggested by Herring *et al.* (1987) as a means to provide a more biocompatible surface with the potential to decrease thrombosis and intimal hyperplasia. Some advances have been made as a result of extensive experimentation in endothelialization of grafts (Williams *et al.*, 1994; Pasic *et al.*, 1994; Meinhart *et al.*, 1997). Progress was initially limited by the challenges associated with the harvest and culture of endothelial cells. However, human umbilical vein endothelial cells are now commonly used as a model for vascular endothelial cells in studies evaluating methods for graft seeding. In addition to the issues of cell sourcing, defining techniques for establishing a confluent layer of cells on the luminal surface has also been challenging. Unfortunately, methods that promote endothelial cell adhesion can, in turn, lead to a more thrombogenic surface. If the surface is not completely covered or some cells are lost on exposure to flow, the patency rates would be reduced rather than improved. Results from Bowlin and Rittgers (1997) suggest that electrostatic methods used to endothelialize e-PTFE grafts may be a promising approach. In this process, the surface is induced to become positively charged, which promotes endothelial cell adhesion. Once the seeding process is complete, however, the graft reverts to its original, highly negatively charged state so that any exposed areas will no longer promote cell adhesion. Endothelialization of synthetic grafts has shown some feasibility in animal models, but clinical trials have not shown significant differences in patency as a result of endothelialization, and the source of cells for widespread clinical application remains problematic (Meinhart *et al.*, 1977; Welch *et al.*, 1992).

Another approach to a tissue-engineered blood vessel is based on the coculture of cells with natural biologic and/or synthetic materials in order to “grow” a cellular vessel. Weinberg and Bell (1986) demonstrated *in vitro* development of a model blood vessel with three layers, correspond-

ing to an intima, media, and adventitia. A confluent layer of endothelial cells was grown in culture onto the lumen of a tubular collagen construct consisting of an outer layer of fibroblasts and a middle layer of smooth muscle cells. In this study, the cells and matrix were cast in an annular mold and an external Dacron mesh was used to provide additional mechanical support. The model grossly resembled a muscular artery, except for the Dacron mesh; electron microscopy demonstrated well-differentiated bipolar smooth muscle cells. Endothelial cells formed a monolayer of flattened cells interconnected by cellular junctions with numerous cytoplasmic vesicles, Weibel–Palade bodies, and patches of basement membrane. In addition to mechanical properties that necessitated the use of a support mesh, there were a number of differences between the model and normal arteries. A major difference was that elastin, the principal arterial tissue matrix protein besides collagen, was not present in the model. Matsuda and Miwa (1995) also created a hybrid construct using an artificial scaffold of polyurethane seeded with smooth muscle and endothelial cells. This construct was shown to remodel *in vivo* such that the endothelial cells on the lumen became oriented in parallel to the direction of blood flow, and the smooth muscle cells in the medial layer redistributed and became circumferentially oriented. Implants were successful in the canine model for up to 1 year.

The constructs of Weinberg and Matsuda used a composite approach to reinforce the strength of the cellular layers. A key challenge in the development of a cellular model blood vessel was to create a construct with the required mechanical properties. Auger and colleagues (L'Heureux *et al.*, 1993) expanded on this coculture approach and were able to produce a vessel equivalent using human cells and collagen without using any synthetic supports. L'Heureux *et al.* (1998) have now demonstrated that their construct could mature in culture into a vessel with excellent mechanical properties. This construct had a burst strength exceeding 2000 mmHg. Umbilical cord-derived smooth muscle and skin-derived fibroblast cells were cultured separately in the presence of ascorbic acid and were formed into a vessel by wrapping successive layers around a mandrel. Constructs that were lined with umbilical cord-derived endothelial cells demonstrated feasibility in short-term studies in a xenogeneic model. Others, particularly the laboratory groups of Nerem at Georgia Tech and Tranquillo at the University of Minnesota (Ziegler *et al.*, 1995; Tranquillo *et al.*, 1996), have investigated the effect of culture conditions and *in vitro* mechanical forces on the development of cellularized constructs. Girton *et al.* (1999) have generated blood vessel medial layer equivalents with smooth muscle cells and collagen and have shown that the mechanical strength can be enhanced by nonenzymatic cross-linking of proteins with reducing sugars such as glucose and ribose. This glycation of the media equivalents significantly increased both stiffness and tensile strength of the constructs. The work at Georgia Tech has focused on the development of a cellular construct with a confluent endothelium and has evaluated the physiological responses of the smooth muscle and endothelial cells to shear and mechanical stresses associated with flow conditions.

Bovine vessels containing vascular biopsy-derived smooth muscle and endothelial cells have now been cultured on tubes of partially hydrolyzed poly(glycolic acid) under pulsatile conditions (Niklason *et al.*, 1999). These vessels also had burst strengths greater than 2000 mmHg and exhibited the beginnings of vascular contractile responses. Four engineered arteries were implanted in the saphenous arteries of miniature swine; both of the vessels exposed to pulsatile conditions *in vitro* prior to implantation were patent for up to 24 days postimplantation, whereas both control vessels that were not exposed to pulsatile conditions were occluded within 3 weeks. It is interesting to note that, just as in the studies of Weinberg and Bell more than a decade ago, these constructs were notably lacking in elastin content.

These advances in the development of cellular blood vessel equivalents through *in vitro* tissue engineering are promising. However, generating a blood vessel equivalent composed of autologous cells requires harvesting the patient's cells months in advance of the required graft procedure and extensive culture time, and would be a difficult technology to commercialize.

### **IN VIVO TISSUE ENGINEERING OF BLOOD VESSELS**

An alternative to generating a cellularized vascular construct *in vitro* is to construct a prosthesis that is remodeled *in vivo*. Zarge *et al.* (1997) reviewed progress in the development of bioresorbable synthetic grafts that induce tissue ingrowth and remodeling after implantation to form a "neoartery." The clinical efficacy of such grafts depend on a balance between rapid graft resorption during tissue ingrowth and slower degradation rates for maintenance of structural stability.

Structural stability may also be maintained by incorporation of a nonresorbable material that acts as a mechanical strut or combinations of materials with different resorption rates. Bioresorbable graft performance may also be modified by incorporation of growth factors, chemoattractants, or cells within or on the graft.

There have also been efforts to develop resorbable grafts composed of naturally occurring materials. Collagen and collagen-based materials have been increasingly used in a variety of medical products since the mid-1960s. However, in general, the collagen constructs were designed to be similar to the synthetic polymer prostheses in terms of their ability to persist. Consequently, purification and cross-linking methods were developed to optimize mechanical strength and enhance the stability of the collagen *in vivo* (Sabelman, 1985; Khor, 1997). In these cases, the material is seen as a foreign body and is essentially encapsulated by inflammatory cells and organized scar tissue rather than being integrated into the surrounding tissue.

Wilson *et al.* (1990) investigated the use of a collagen-based biomaterial as a vascular prosthesis. In these studies, canine iliac and carotid arteries were processed using a multistep detergent and enzymatic extraction method. This method generated an acellular matrix of collagen, elastin, and some glycosaminoglycans. These acellular matrix allografts were also used in coronary artery bypass and compared with autogenous saphenous veins (Wilson *et al.*, 1995). The patency rates were 44% (4 of 9) for the matrix allografts and 57% (4 of 7) for the saphenous vein grafts. Implantation of these acellular prostheses into the carotid and femoral arteries in dogs demonstrated over 90% patency without administration of postoperative anticoagulants. The implants were followed for up to 4 years and showed no evidence of aneurysm formation or dystrophic calcification. Even after 4 years, however, the collagen remained intact and there was no significant cellular infiltration. Inhibition of cellular infiltration may have been attributable to the presence of residual sodium dodecylsulfate remaining in the graft after processing.

In contrast, investigators at Organogenesis have developed methods for using the intestinal collagen layer derived from the submucosa of the small intestine as a biomaterial with the potential for true integration by remodeling. Over 30 years ago, the submucosal layer of the small intestine was proposed as a vascular substitute (Lawler *et al.*, 1971; Egusa, 1968; Matsumoto *et al.*, 1966). This collagenous material was initially of interest because of its inherent mechanical strength and natural intubation. The studies employed inverted segments of autologous small intestine submucosa (SIS) to replace portions of the inferior vena cava or aorta and demonstrated over 80% patency in a small series of dogs. Badylak and colleagues (1989) extended these studies using autogenous SIS as a large-diameter (10-mm) vascular graft in the canine infrarenal aorta. Grafts were prepared by inverting the intestine, removing the serosal and muscularis layers by manual abrasion, and then returning the tube to its original orientation. The luminal diameter was adjusted to match that of the recipient blood vessel by inserting a glass mandrel of the desired diameter and suturing to gather any excess SIS. Of the 12 grafts, 11 remained patent until explant, at times ranging from 1 week to 1 year postimplant. Using similar methods for constructing the grafts, Badylak's group also investigated an autogenous, small-diameter SIS graft in the canine carotid and femoral positions and reported patency of 75%. In these studies, however, all the dogs received both aspirin and warfarin for the first 8 weeks postsurgery (Lantz *et al.*, 1990). Histological evaluation of the explanted grafts suggested that the SIS was remodeled and Badylak's research group has also pursued SIS applications in soft tissue repair and orthopedics (Badylak, 1993).

In our early studies exploring the use of this material in soft tissue repair and vascular prosthetics, the submucosal layer was obtained after mechanical cleaning using a customized, commercial gut-cleaning machine. Our results with 4-mm vascular grafts indicated that without aggressive anticoagulant therapy, the grafts were thrombogenic when evaluated in a canine *ex vivo* shunt or implanted as an aortic graft in rabbits (Termin *et al.*, 1993). In subsequent grafts, the luminal surface was modified by treatment with a benzalkonium chloride/heparin complex to reduce thrombogenicity, and these grafts showed promise when implanted in the infrarenal rabbit aorta (Termin *et al.*, 1994). In addition, we demonstrated that this material could be minimally cross-linked with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC), a water-soluble carbodiimide, and sterilized with peracetic acid. Unlike the more traditional methods that used fixatives such as glutaraldehyde, this process reduced antigenicity without preventing cell ingrowth *in vivo* (Hardin-Young *et al.*, 1996). In addition, using a water-soluble carbodiimide also eliminates the problems associated with the residual toxicity seen with aldehyde fixation of biomaterials.

Fig. 33.1. Effect of chemically cleaning the ICL.

Although these studies were promising, it also became clear that the SIS material obtained after mechanical cleaning was quite heterogeneous (Fig. 33.1). The amount of residual cellular material in the submucosal layer varied between preparations from different donor pigs as well as within different sections of the small intestine. This variability complicated graft fabrication and *in vitro* characterization as well as analysis of *in vivo* results. Consequently, extensive efforts at Organogenesis in the past 2 years have focused on material processing and characterization. Mechanical and chemical cleaning of the proximal porcine jejunum using a proprietary process that removes cells and cellular debris while maintaining the native collagen structure generates the intestinal collagen layer (ICL), a sheet of predominantly type I collagen.

ICL is prepared from the intestines of swine (about 450 lb) obtained from a closed herd (Parsons Farm, Hadley, MA). The mesenteric layer is manually removed from the small intestine prior to mechanical stripping of the mucosal and membranous layers. It is mechanically processed through three series of rollers on the Ernest Bitterling Model M34 (Nottingham, England) under a constant flow of water. The remaining submucosal collagen layer is longitudinally slit between the lymphatic tags and cut into 6-inch lengths, which are then processed to remove any residual cells. The chemical cleaning of the intestinal collagen layer is a proprietary process involving several washes in chelators and salts at specific pH ranges. Once the process is complete, the ICL is stored at  $-80^{\circ}\text{C}$  until use. All lots of material are tested for sterility and residual endotoxin levels prior to release. In related work, an ICL laminate has been shown to be effective in hernia repair in animal models. This construct, GraftPatch, received premarket approval [known as 510(k) clearance] from the FDA in 1998 for use in soft tissue repair (see the FDA web site, <http://www.fda.gov/cdrh/manual/idemanul.html>). Unlike the synthetic mesh products traditionally used for hernia repair, GraftPatch became well-integrated into the surrounding abdominal wall tissue and developed a vascularized, mesothelial-like layer on the luminal surface that presumably contributes to the resistance of the patch to adhesion formation (Abraham *et al.*, 1999).

Having developed methods for producing a material that can be made reproducibly and could be used in a commercial product, we are currently evaluating the *in vivo* efficacy of 4-mm vascular grafts constructed from the ICL. To manufacture a vascular graft, the ICL is aseptically entubated using a mandrel of the desired diameter. In contrast to the suturing method used in the Lantz studies (1990), the collagen tube is created by dehydration and cross-linking of the ICL wrapped around the mandrel. A thin layer of bovine collagen is deposited on the graft lumen followed by cross-linking in a 1 mM 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride. After rinsing to remove all residual cross-linker, the grafts are sterilized overnight with 0.1% peracetic acid. The grafts are rinsed again with sterile water and subsequently coated with heparin (benzalkonium chloride complex) in isopropanol.

In using the ICL as a vascular graft, the goal is to process the tissue so that native collagen structure is retained while ensuring that the necessary mechanical properties are provided. For a vascular conduit, it is critical that the material can be sutured and has sufficient burst strength to withstand physiologic blood pressure. In addition, the porosity of the material should allow cellular infiltration from the adventitial side while maintaining hemostasis. The protocol developed for graft fabrication was designed to identify the lowest amount of chemical cross-linking that provided the requisite mechanical characteristics. Thus, in contrast to synthetic polymers or highly cross-linked biomaterials, the ICL graft fulfills the hemodynamic and hemostasis requirements while still having the potential to be remodeled by the host tissue. The graft characteristics are summarized in Table 33.1 ( $n = 25$ ).

Having determined that the grafts had the requisite mechanical properties for a vascular graft, the *in vivo* efficacy was evaluated using a small animal model in collaboration with Dr. Otto Hagen at Duke University Medical Center (Davies and Hagen, 1995). Through a right cervical

**Table 33.1. Mechanical analysis of ICL grafts**

Mechanical test	Result
Suture retention test	3.7 ± 0.5 Newtons
Burst test	12.4 ± 5.5 psi
Porosity	4.26 × 10 <sup>-3</sup> ml/cm <sup>2</sup> /min
Compliance (change between 80 and 120 mmHg × 10 <sup>-2</sup> )	5.0%

oblique incision, the jugular vein of New Zealand White rabbits (2.0 to 2.5 kg) was mobilized, ligated, and divided to expose the carotid artery. Following complete mobilization of the right carotid artery and prior to arterial clamping, heparin (200 IU/kg) was given intravenously. Atraumatic arterial clamps were placed proximal and distal to the arteriotomy sites to occlude flow prior to the proximal arteriotomy. An end-to-side proximal anastomosis of artery to graft was done with 10-0 Ethilon sutures and the distal anastomosis was done in a similar manner. The segment of carotid artery between anastomoses was excised, leaving an interposition graft 3–4 cm long. No postoperative anticoagulants were used and the animals were monitored for 1 to 3 months prior to explant. All animal care and handling was in compliance with the “Principles of Laboratory Animal Care” as formulated by the National Society for Medical Research (1996) and the “Guide for the Care and Use of Laboratory Animals” published by the National Research Council (National Academy Press, 1996).

The ICL vascular grafts showed excellent patency in this pilot study, with all 20 grafts patent on explant after 14 ( $n = 2$ ), 28 ( $n = 9$ ), 53 ( $n = 4$ ), or 90 ( $n = 5$ ) days. Preliminary histological evaluation has shown that the graft does undergo remodeling by host cells and studies are underway to identify the cells infiltrating the graft as well as the changes in those populations as a function of time of implant. These studies will also investigate how the mechanical properties of the graft are affected by *in vivo* remodeling. Although short-term patency is highly dependent on the luminal surface properties, long-term patency is equally dependent on mechanical properties of the graft. It is increasingly evident that remodeling of blood vessels is strongly affected by the loading and deformation to which they are subjected. For example, the remodeling of veins used in arterial bypass is modulated by distension and shear stress, both of which are a function of the graft mechanical properties (Dobrin, 1995).

Ideally, the ICL grafts will provide a collagen scaffold that is remodeled *in vivo* into a functional neovessel, as illustrated in Fig. 33.2. The use of an acellular vascular prosthesis would provide an “off the shelf” option to address the clinical need for a small-caliber graft. These data are

Fig. 33.2. Schematic diagram of *in vivo* remodeling of an ICL graft.

very encouraging, but much more work will be needed to determine the long-term efficacy of the ICL grafts in large animal models.

## SUMMARY

Surgical treatment of vascular disease is now a common medical procedure. However, to date, the use of synthetic materials is limited to grafts larger than 5–6 mm due to the frequency of occlusion observed with synthetic vessels of smaller diameter. Significant progress has been made during the past 10 years in the development of blood vessel equivalents using tissue engineering. The first approach is designed to produce constructs that are cellularized *in vitro*. Cocultures of smooth muscle cells with matrices such as collagen under a variety of conditions have been used to optimize the cellular orientation and mechanical properties of these cellular constructs. An alternative method that would have the advantage of being a more readily available commercial product is to produce a vascular graft that is cellularized *in vivo*. In our studies, the intestinal collagen layer has shown promise as an acellular graft that will remodel over time. ICL was used to form 4-mm vascular grafts with appropriate mechanical properties for blood vessels *in vivo* and initial studies employing heparinized ICL tubes as carotid interposition bypass grafts in rabbits have demonstrated 100% patency after periods ranging from 1 to 3 months.

Although several approaches to the tissue engineering of a small-diameter vascular graft have begun to show feasibility, demonstrating potential clinical efficacy will require much more data from long-term implant studies. Clearly, the grafts will be influenced by the interaction with the host tissue and the remodeling will be dependent on a number of factors, including the hemodynamic environment, the degree of cellular infiltration and graft endothelialization, and the potential for development of cellular hyperplasia. The requirement for a construct with sufficient mechanical strength, a nonthrombogenic surface, long-term resistance to hyperplasia and aneurysm formation, as well as compatibility with the host tissue, remains a major challenge for tissue engineering.

## INTRODUCTION

At the time of writing this chapter, in 1999, the treatment of symptomatic valvular heart disease is based on two different methodologies, the use of mechanical devices and prostheses or the use of tissue, for repair or replacement of diseased native heart valves. This chapter focuses on the applications of tissue for such treatment, but it is important to mention, in passing, mechanical devices and prostheses, because they are used more widely than tissue prostheses. The major reason for the dominance of mechanical devices and prostheses is their greater durability. Investigators working in the field must be aware of the limitations of tissue methods and devices in order to advance the design and performance of tissue in the treatment of valvular heart disease.

Although there were clever and ingenious indirect attempts to treat valvular heart disease before 1960, success proved to be elusive until it was possible to repair or replace valves in their orthotopic locations. The achievement that made possible a direct approach to the diseased heart valve was the development of the heart–lung machine in 1953. In that year, Professor John Gibbon of Philadelphia performed the world's first open-heart operation on a patient with congenital heart disease. His machine, the culmination of 17 years of research and development, gave the surgeon the ability to divert, or bypass, the blood around the heart and lungs so that the heart could be opened and repaired under direct vision. The original Gibbon heart–lung machine was large and unwieldy, and required large amounts of donor blood to prime the circuit, but it was a start. Great improvements in technology for pumping and oxygenating blood followed rapidly. The first operations for valvular heart disease in which the valves were exposed within the heart were performed in 1960. Those first operations, in Boston, Massachusetts, and Portland, Oregon, were performed by Dwight Harken and Albert Starr, respectively. Harken and Starr replaced diseased valves with mechanical, ball-in-cage prostheses of their own design. Two years later, Åke Senning in Zurich began repairing and replacing diseased aortic valves with free-hand techniques using the patients' own (autologous) fascia lata (Senning, 1967), and Ross (1962) in London replaced a diseased aortic valve with a cadaveric human aortic valve. Figures 34.1 and 34.2 show Senning's methods for replacing and repairing aortic valves with fresh, untreated autologous fascia lata. Out of this pioneering work by men of genius and determination sprang the modern era of successful treatment of valvular heart disease. Throughout the world in 1999, mechanical valvular prostheses are more widely used than are tissue prostheses, in spite of significant drawbacks to their use. The drawbacks include noise, nonphysiologic flow patterns, catastrophic failure modes, and the need for lifelong anticoagulant therapy. It can be argued that the ideal treatment for repair or replacement of diseased human heart valves should be based on tissue technology rather than on the use of mechanical devices. Tissue valves are quiet and are associated with physiologic flow patterns, typically have slowly developing rather than catastrophic failure modes, and usually do not require anticoagulant therapy. The major, unsolved problem with tissue heart valves is their limited durability, generally 5 to 15 years. If the durability problem can be solved, tissue valves will be the clear choice for treatment of valvular heart disease. To clarify the issue, it is necessary to say something about the varieties of tissue valves and techniques that have been used for the past 35 years.

Cardiovasc. Surg.* 54, 465–470, with permission from Mosby, Inc.

### A SHORT HISTORY OF TISSUE HEART VALVES

As noted above, the first tissue heart valves were made of human tissue from autologous and homologous sources. Autologous tissue was an obvious first choice, to avoid an immune response. Unfortunately, fresh, untreated autologous tissues, both fascia lata and pericardium, were found to undergo shrinkage and thickening when used for valve repair or replacement. Figure 34.3 is a photograph of one of Senning's fascia lata valves explanted after 6 years, showing the shrinkage and thickening that occurred. That early finding of the fate of fresh, untreated autologous tissue has been reconfirmed by Kumar *et al.* (1995). These changes occurred within months or years, although Senning had some patients who survived up to 20 years with their autologous tissue fascia lata valves. One unanswered question is why Senning could have long-term success with some patients but not with all patients. There was a different outcome with homologous, cadaveric human aortic valves transplanted to the aortic position of host patients. Those valves did not under-

Yorke Medical Books, New York.

go shrinkage and thickening, but they were also found to have limited durability. The surgical procedure for implanting cadaveric aortic valves can be performed with variations, but all of the variations require a level of surgical expertise that has discouraged many surgeons from using them (Love, 1993).

The problems encountered with both autologous and homologous tissue valves led surgeons in the United States and Europe to consider the use of animal, or heterologous, tissue valves. Looking back on the history of tissue valves, one is tempted to question the logic of a progression from autologous to homologous to heterologous tissue valves; the reverse sequence would seem to have been more reasonable from an immunologic point of view. In simplest terms, the determination of surgeons to use tissue valves, combined with the apparent failure of autologous tissue valves, and the difficulties of both supply and implantation of homologous tissue valves, led to this development. The first recorded use of animal tissue valves was by French surgeons who implanted valves taken from the abattoir and implanted without treatment, other than attempted sterilization with antibiotic solutions (Binet *et al.*, 1965). The results were, predictably, unsatisfactory, and caused most of the first users to abandon the use of animal tissue valves.

One of the pioneers from that early work persisted with the concept of making animal tissue valves suitable for use in human patients. Carpentier in Paris explored different chemical treatments of animal tissue valves, and settled on an agent from the leather-tanning industry, glutaraldehyde (Carpentier *et al.*, 1969). Glutaraldehyde was found to reduce the immunogenicity of the untreated animal tissue by producing collagen cross-links that reduced solubility, and thus the immune stimulus to the host. Tanning with glutaraldehyde renders the tissue stiffer than it is in the untreated state. From 1968 to the present, heterologous tissue valves have occupied an important place in the cardiac surgeon's armamentarium for treating valvular heart disease. Carpentier, with engineers from the Baxter Edwards company, took porcine aortic valves from the slaughterhouse, tanned them with glutaraldehyde, and mounted them on stents made of Elgiloy wire covered with Dacron fabric for implantation in humans, and in so doing launched the bioprosthetic industry. An American engineer/entrepreneur, Warren Hancock, worked in parallel with Carpentier and founded his own company to manufacture porcine bioprostheses.

Another type of heterograft bioprosthesis was introduced in 1974 by Ionescu of Romania, while he was working in Leeds (Bartek *et al.*, 1974). He used bovine pericardium mounted on a stent machined from titanium covered with Dacron fabric. One of his valves is shown in Fig. 34.4. Initially, his valve was well received, primarily because it had low gradients in even the smallest sizes, in contrast to the porcine bioprostheses. The pig aortic valve has a ridge of muscle across one leaflet that becomes an impediment to flow in the smaller sizes, after the tissue has been stiffened by glutaraldehyde. However, the rigid titanium stent of the Ionescu valve was a design flaw. In the early days of bioprosthetic development, it became apparent that a flexible stent, whether made of

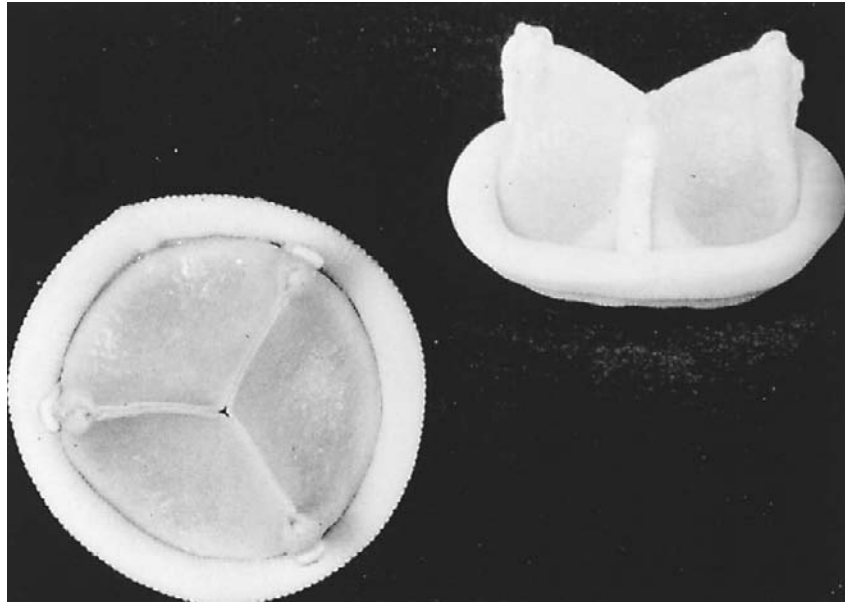

Fig. 34.4. The Ionescu–Shiley bovine pericardial bioprosthesis.

wire as in the Carpentier valve or of thermoplastic as in the Hancock valve, was an essential component of a successful bioprosthesis. The tissue is prone to mechanical failure when mounted on a rigid stent (Reis *et al.*, 1971; Christie and Barratt-Boyes, 1991). The Ionescu valve had another problem, a suture at each of the three leaflet commissures that proved to be another point of tissue failure due to stress. The bad experience with the Ionescu valve caused some investigators to think that the problem was the tissue, not the stent. However, bovine pericardium tanned with glutaraldehyde and mounted on a flexible stent performs as well, or better than, porcine aortic valves (Marchand *et al.*, 1998; Frater *et al.*, 1998).

The use of cadaveric homograft valves, pioneered by Ross in London, has had two devoted proponents from the earliest days to the present. They are Brian Barrett-Boyes of Auckland, New Zealand, and Mark O'Brien of Brisbane, Australia. Their persistence kept the concept alive for three decades until it became more widely accepted. A key factor important for the wider acceptance of the concept was the founding of the CryoLife Company in Marietta, Georgia. CryoLife began its existence as a company devoted to the harvesting and the preservation of cadaveric aortic roots and valves that could be used for the homograft operation. Before CryoLife, surgeons wanting to use homograft valves needed to have their own tissue banks in their medical centers. Those surgeons were required to harvest the valves from the autopsy suite, sterilize the valves, and preserve them until they were used. That burden undoubtedly contributed to the lack of early acceptance of the homograft operation. Another factor that was important for wider acceptance was the evidence provided by O'Brien that cryopreserved homografts might retain viability after implantation (O'Brien *et al.*, 1991). Although the matter has provoked significant controversy and skepticism, the debate has focused attention on the possibility of a viable replacement valve that might have the property of self-repair. That dream comes closer to the ideal replacement valve. Homograft valves appear in some series to have better durability than heterograft valves, but the difference has not been of an order of magnitude, in even the best reported results. Homograft valves have shown superior performance in the subset of patients with infective endocarditis. Stent-mounted bioprosthetic valves do not fare well in the presence of infection, whereas the unstented homograft valve can be expected to survive in the presence of infection. It is the presence or absence of the stent that probably makes the difference; foreign body material has long been known to require removal when surrounded by infection. However, there are downsides to the homograft valve. The problem of supply, once a severe limitation, has been greatly eased by the CryoLife technology. There is a small but real concern for the possibility of transmission of the autoimmune deficiency syndrome (AIDS) virus. Perhaps the biggest problem with the homograft valve is that it can be used only in the aortic or pulmonary position. Work is in progress to mount homograft

valves on stents to make them available for use in the atrioventricular position, but this is not routinely possible.

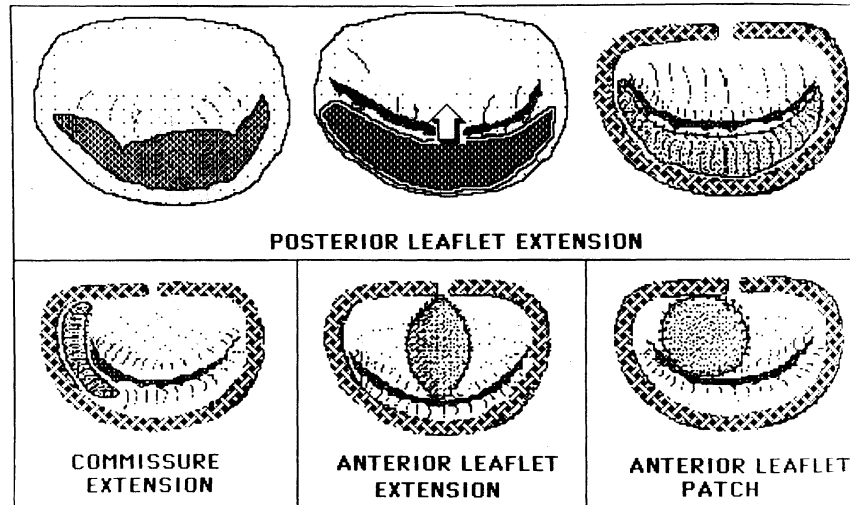

### THE STATUS OF TISSUE VALVES IN 1999

Following this brief history of tissue valves, the status of tissue valves in 1999 can be described. Commercially available tissue valves in 1999 include heterografts, homografts, and autografts. The heterograft valves are of two kinds, porcine and bovine, both tanned with glutaraldehyde. The porcine heterografts are aortic valves from slaughterhouse pigs, and they are available both stent mounted and unstented. The bovine heterograft is available as a stent-mounted pericardial bioprosthesis, with glutaraldehyde-tanned bovine pericardium from slaughterhouse material. Homograft valves are available commercially and are also implanted in some centers from tissue banks maintained at those centers. The tissue is treated with antibiotic solution, but is not tanned with glutaraldehyde. One company, Autogenics, has marketed a stent-mounted autograft, a bioprosthesis made in the operating room at the time of the valve replacement operation with the patient's own pericardium prepared, cut, and mounted on a stent system in 10 min. The pericardium is immersed for 10 min in 0.625% glutaraldehyde solutions buffered to pH 7.4 with phosphate. The rationale for using glutaraldehyde with the autograft is quite different than it is with heterograft tissue. The heterograft tissue is clearly immunogenic without tanning, and it is completely tanned for more than a week to produce collagen cross-linking to minimize solubility. The tanning was found by Carpentier to greatly attenuate, but not eliminate, immunogenicity of the tissue. With the autograft, there is no concern for immunogenicity; the light tanning is done to make the tissue stiffer and thus easier to use in the fabrication process. The investigators who developed this valve also reported that the lightly tanned autologous tissue did not display the thickening and shrinkage that had been noted by early investigators who used fresh, untreated tissue (Love *et al.*, 1992).

Limited durability has been the drawback to all of the tissue valves used for the past 25 years. Heterograft and homograft valves are subject to a usually gradual deterioration from a process known as calcific degeneration. As the process continues, there is an associated loss of tensile strength of the tissue. Tissue valves fail over time either because of excessive stiffening of the tissue, leading to stenosis and regurgitation, or from primary tissue failure with tearing. The autograft valve has been in clinical use for over 6 years, and it is not yet clear if it will prove to have superior durability and freedom from calcific degeneration and primary tissue failure. The inventors of the autograft valve believe that the immune response to heterograft and homograft tissue plays a role, perhaps the major role, in determining the fate of the tissue valve (Love, 1993). This point of view is not widely accepted in 1999, and only longer follow-up of the clinical series will show if the autograft is a superior tissue valve. There is one piece of intriguing evidence from long-term follow-up of a clinical series of porcine heterograft bioprostheses that may support the concept of immune response as a determinant of the fate of those valves. Jamieson has reported the durability of porcine valves related to the age of the patient at the time of implantation (Jamieson *et al.*, 1994). His data are displayed as a family of curves that confirm what has long been known, that durability is directly proportional to the patient's age at the time of implantation. Porcine valves, which are known to fail early in young patients, may last 10 to 15 years in older patients. The durability of the heterograft valve in children and adolescents is so unacceptable that such valves are used in that age cohort only when no other kind of valve can be used. Several interpretations can be made of Jamieson's data, but one possible explanation is that a more active immune response can be expected in young patients contrasted with older patients.

There is an accepted animal model for studying the fate of tissue valves, and data on the performance of tissue valves in that animal model are required by the U.S. Food and Drug Administration for approval. If a heterograft tissue valve is implanted in a juvenile weanling sheep, defined as one less than 6 months of age and generally less than 30 kg in weight, the heterograft valve is typically heavily calcified in 3 to 5 months (Barnhart *et al.*, 1982a,b). The calcification seen in the juvenile sheep model is apparently identical to the same process seen in humans over a period of several years. The model has been widely used to investigate the efficacy of anticalcification treatments that have been proposed by valve manufacturers. It has been reported that the autologous tissue heart valve shows minimal to no calcification in that model (Love *et al.*, 1994). That evidence is the primary reason for the expectation that the autograft will prove to be a more durable

Fig. 34.5. Carpentier's techniques, using pericardium, for patching the mitral valve. From S. Chauvaud, V. Jebara, J.-C. Chachques, B. E. Asmar, S. Mihaileanu, P. Perier, G. Dreyfus, J. Relland, J.-P. Couetil, and A. Carpentier (1991). Valve extension with glutaraldehyde-preserved autologous pericardium. *J. Thorac. Cardiovasc. Surg.* **102**, 171–178, with permission from Mosby, Inc.

bioprosthesis, less subject to calcific degeneration and primary tissue failure in humans. A study correlating the immune response in juvenile sheep to heterograft, homograft, and autograft valves is waiting to be done. Such a study could settle the issue of the importance of the immune response in determining the fate of the tissue valve.

The author of this chapter has been one of the pioneer investigators of the autograft valve. His group, along with four other groups in different parts of the world, has provided evidence that the autograft valve may behave differently than heterograft and homograft valves. In 1967, Ross in London transplanted the autologous pulmonary valve of a child to the aortic position to treat aortic valve disease. That operation has become known as the Ross procedure, or the pulmonary switch operation, and is currently enjoying a wave of popularity because of the remarkable durability of the transplanted autologous pulmonary valve. Patients have survived more than 25 years with no evidence of degeneration in their transplanted valves. The concept of this operation was developed in the animal laboratory at Stanford University; Ross applied the concept to the clinical setting. The downside to the Ross procedure is that there is only one pulmonary valve that can be transplanted, it can only be used in the aortic position, and when it has been moved to the aortic position, it must be replaced with an imperfect bioprosthesis. For the sake of this discussion, it is important to remember that this most perfect of all tissue valves to date is an autologous valve. Since 1980, Carpentier in Paris has used autologous pericardium treated with a brief immersion in glutaraldehyde for the repair of mitral valve leaflets damaged mainly by rheumatic endocarditis (Chauvaud *et al.*, 1991); the techniques are shown in Fig. 34.5. He and his colleagues have reported that autologous pericardial patches used for leaflet extension procedures have shown no calcific degeneration for more than 10 years. Using autologous pericardium for patching or leaflet extension is, admittedly, different from using that material to construct an entire valve, but the excellent long-term behavior of lightly tanned autologous pericardium is further evidence for the superiority of autologous tissue.

Duran, a Spanish surgeon working in Saudi Arabia, and most recently in the United States, resurrected Senning's original concepts for repair and replacement of aortic valves, using autologous pericardium treated with a brief immersion in glutaraldehyde, as shown in Fig. 34.6. He initially used tanned bovine pericardium, but switched to autologous pericardium when other groups began reporting better results with the autologous tissue. His method is essentially a free-hand technique that requires a significant element of surgical skill. He has reported his medium-term follow-up of 51 patients, mean age 31.2 years, observed up to 5 years with an impressive lack of degenerative changes (Duran *et al.*, 1995). Duran's work constitutes yet another piece of evidence for the superiority of autologous tissue for valve repair or replacement.

Deac in Romania has an interesting clinical series in progress that adds further support to the use of autologous tissue. He modified a technique described by Mickleborough for intraoperative

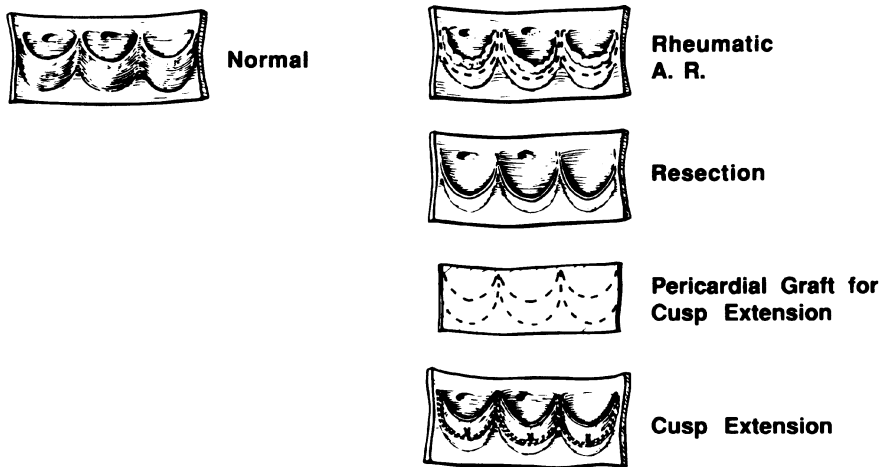

Fig. 34.6. Duran's methods for aortic valve reconstruction with pericardium. Reprinted with permission from the Society of Thoracic Surgeons (*The Annals of Thoracic Surgery*, 1991, Vol. 52, pp. 447–454).

construction of a stentless atrioventricular valve, mitral or tricuspid (Deac *et al.*, 1995). Mickleborough's method is shown in Fig. 34.7. Whereas Mickleborough used tanned bovine pericardium, Deac has used lightly tanned autologous pericardium. Deac's results with 18 patients, mean age 42 years, from 1989 to 1994, are encouraging. It is especially noteworthy that he, too, has not seen evidence of calcific degeneration in any of his patients.

Finally, the work of this author and his group with a stent-mounted bioprosthesis made in the operating room at the time of valve replacement was encouraging in both the animal laboratory model and early clinical experience since the first human implant in 1992 (Fabiani *et al.*, 1995). An Autogenics valve, made with autologous pericardium treated with a brief immersion in glutaraldehyde, is seen in Fig. 34.8. The valve could be made within 10 min with disposable, single-use instruments, in the operating room at the time of the valve replacement operation. Love (1993) has given a detailed account of early work on the autologous pericardial valve. The Autogenics valve is not being marketed in 1999.

### THE ISSUE OF WHETHER TO USE A STENT

Another issue that must be considered by investigators of tissue valves is whether to mount the tissue on a stent. With mechanical valves, this is not an issue because, by definition, the me-

Fig. 34.7. Mickleborough's experimental method for constructing a stentless mitral valve from tanned bovine pericardium. Deac has modified her method and used lightly tanned autologous pericardium in a growing clinical series. Pericardium is wrapped around a cylinder of the appropriate diameter. Total length of the leaflets equals  $\frac{1}{2}\pi d$ . A single suture line is needed to construct the valve. Triangular portions of the pericardium are removed, as shown, leaving chordal tips of the prosthesis. From Mickleborough *et al.* (1988).

Fig. 34.8. The autologous tissue cardiac valve (ATCV) made in the operating room at the time of valve replacement.

chanical valve is made entirely of metal and plastic and fabric, part of which is a stent. With tissue, however, a decision can be made to use or not to use a stent. There are arguments that can be made for both sides of the issue. A stent confers precise dimensions to the bioprosthesis, and the implantation of stent-mounted valves is a relatively straightforward surgical procedure, well within the capabilities of most cardiac surgeons. Stentless valves, on the other hand, whether heterograft, homograft, or autograft, generally require a higher level of surgical skill for their successful implantation. Dimensions are less precise, and more subjective judgments must be made in choosing and implanting the valve. It is a perfect example of the old surgical saw that good results come from experience, and experience comes from bad results. Those surgeons in 1999 who are able to report the best results with stentless valves are surgeons of extensive experience. Pediatric cardiac surgeons argue for stentless tissue valves for another reason. A stent, no matter how cleverly designed, occupies part of the valve orifice, and thus reduces the effective orifice area, and eliminates any potential for growth. These are important considerations because reduction of effective orifice area increases the transvalvular pressure gradient or energy loss, and a stent retains its fixed dimensions. For infants and children who require valve replacement, growth must be considered. A stented valve of fixed dimensions cannot grow with the patient, and the valve must be replaced one or more times as a child with a stented valve matures. There is some early evidence from both clinical and laboratory experience that the transplanted autologous pulmonary valve retains viability and can grow with the patient. If this proves to be the case, it will be a powerful argument in favor of the pulmonary switch operation, and the use of any other kind of unstented autologous tissue valve that might be expected to retain viability and the capacity for growth.

It should be noted that what are being marketed as stentless valves are not really stentless. The heterograft and allograft stentless valve both have stents, i.e., the biologic stents of the donor. They are stentless in the sense that neither has a rigid, mechanical stent.

Whether to use a stent is a more debatable issue for aortic or pulmonic valve repair than it is for a mitral or tricuspid repair. That is because the aortic and pulmonic valves have their own native stents from their attachments to the aorta and pulmonary artery, respectively, whereas the atrioventricular valves gain support from the chordal apparatus that attaches the leaflets to the papillary muscles of the interior ventricular walls. No entirely satisfactory bioprosthetic replacement valve has been found to mimic the unique and delicate chordal apparatus. Deac's work with a stentless valve, which substitutes two tongues of leaflet tissue for the chordae tendineae, is an attempt to solve this problem. Following animal implants in the laboratory, he is reporting success in a clinical series underway in Tirgu-Mures, Romania (Deac *et al.*, 1995). Deac uses autologous pericardium treated with a brief immersion in glutaraldehyde for his valve.

## THE ISSUE OF REPAIR VERSUS REPLACEMENT

The use of tissue of any kind to treat valvular heart disease involves another consideration and choice, whether to repair or replace a damaged valve. As noted at the beginning of this chapter, the earliest work with tissue to treat valvular heart disease involved techniques for both repair and replacement. Senning's seminal paper of 1967, written after 7 years of work with fascia lata for both repair and replacement of aortic valves, should be consulted for an introduction to, and discussion of, this issue. He was a surgeon of uncommon skill and great imagination who led the way for many who followed, and he should be acknowledged as one of the key figures in the treatment of valvular heart disease. After his pioneering work beginning in 1962, there were many groups around the world that used untreated autologous fascia lata to make valves. All of those groups, including Senning, abandoned the work because of early failures and unpredictable results. It should be remembered, however, that Senning (1984) was able to report a group of his patients with normally functioning valves 12 to 20 years postoperatively.

Carpentier revisited the concept of repair and replacement with his repairs of mitral valves damaged by rheumatic heart disease and degenerative processes. As noted earlier in this chapter, he evolved his methods along several different lines, which include plastic procedures on the valve leaflets and chordae, the use of annuloplasty rings to repair dilated annuli, and the use of gusset patches to increase the area and mobility of scarred leaflets. For this latter work, he used fully tanned bovine pericardium initially, but in 1980 he switched to the use of autologous pericardium treated with a brief immersion in glutaraldehyde (Chauvaud *et al.*, 1991). His vast experience with repair techniques, disseminated to the current generation of cardiac surgeons, has established the principle that it is always preferable to repair a diseased heart valve, whenever possible, rather than to replace that valve. That principle derives from *a priori* thinking that a natural valve is better than any man-made substitute, from the knowledge that there is no perfect prosthetic heart valve, either tissue or mechanical, and now from accumulated clinical experience showing better clinical results in series of valve repairs compared with valve replacements.

Duran has provided additional evidence for the superiority of repair over replacement with his work in Saudi Arabia treating aortic valvular heart disease in a population of primarily young patients afflicted with rheumatic heart disease. Like Carpentier, he initially used fully tanned bovine pericardium for his aortic valve repairs, but switched to autologous pericardium treated with a brief immersion in glutaraldehyde because of evidence for the superiority of the autologous tissue (Duran *et al.*, 1995).

The issue is still being debated in 1999, but there is mounting evidence to support the view that repair should always be performed whenever possible, and that replacement should be reserved for those patients who are not candidates for repair with current techniques.

## SPECULATION ABOUT THE FUTURE
