With regard to the use of tissue for heart valve repair or replacement, it is necessary to consider which tissue to use. The source of the tissue is one issue, and the specific tissue is another issue. The sources in 1999 are domestic animals (cattle and pigs), human cadavers, and autologous tissue taken from the host. The specific tissues available in 1999 are either natural valves or pericardium used to make valves. The natural valves used commercially are either porcine aortic valves, fully tanned with glutaraldehyde and stent mounted, or untanned human cadaver valves for aortic replacement, with or without accompanying aortic root replacement. Bovine pericardium, fully tanned with glutaraldehyde, is used for replacement when fashioned into stent-mounted or stentless bioprostheses, or for repair purposes. Autologous pericardium treated with a brief immersion in glutaraldehyde is being used for repair of mitral valves by Carpentier, for repair of aortic valves by Duran, and for mitral replacements by Deac. The Autogenics stented autologous tissue bioprosthesis has been used for aortic and mitral replacement. It is not yet clear which tissue, from which source, will prove to be the tissue of choice. Nor is it clear how the tissue will be best used, either for repair techniques or for replacement techniques, with or without a stent.

In discussing the use of tissue for repair or replacement of diseased heart valves, it is germane to consider disease transmission with animal or cadaveric tissue. The risk is extremely small, but definite and proved. With animal tissue, there is concern for the transmission of what have come to be known as the prion diseases. Bovine spongiform encephalopathy, or BSE, is the manifestation of prion disease in cattle. In sheep, it is known as scrapie. There is no known equivalent in domestic pigs, and thus the porcine heterograft is not known to carry the risk of prion transmis-

sion. The prion diseases, although fortunately rare, are formidable afflictions. There is no *in vivo* test for the diseases, there is no known treatment, and the diseases are uniformly fatal. Prion disease has been epidemic among domestic sheep and cattle in Europe, but it is not clear if the diseases have appeared in North American animals. Transmission from animals to man has been documented from the use of animal tissue products. The extensive review by Prusiner (1995), who coined the term "prion," should be consulted for details.

With cadaveric tissue, the rare but definite risk is transmission of the human immunodeficiency virus (HIV), leading to AIDS. Donors can be tested for HIV, but the problem is the window of unknown length that can exist between infection and development of a positive test for the virus. One case has been documented of a donor who tested negative for the virus, whose organs transmitted the virus to multiple recipients of his heart, liver, kidneys, and bone (Simonds *et al.*, 1992). Apart from the problem of the window between infection and test positivity, another aspect of the risk of HIV transmission is the imperfect sensitivity and specificity of the test for HIV antibodies. Until a more reliable, early test for HIV is developed, or until there is an effective treatment for AIDS, the use of cadaveric tissue will carry risk of transmission of the disease.

Autologous tissue carries no risk of disease transmission, and that fact must be recognized as a strong argument for its use whenever possible. From the standpoint of disease transmission alone, it may be speculated that autologous tissue will be more widely used for both repair and replacement of diseased heart valves in the future. Patients will always demand that risks of all kinds associated with surgical treatments be minimized. In the very litigious environment that exists in the United States, risk minimization is a major consideration for physicians.

Autologous tissue can be used for repair or replacement, and autologous tissue replacement valves can be either stent mounted or unstented. The use of autologous tissue for both repair and replacement of diseased heart valves is an old idea, unsuccessful when first tried with fresh, untreated tissue, and now successful with tissue that has been treated with a brief immersion in glutaraldehyde. To date, the only autologous tissue that has been used successfully is pericardium. Pericardium, both fully tanned bovine and lightly tanned autologous, now has a proved record of successful use for valve repair and replacement. Patients having second or third cardiac operations may not have suitable pericardium available, and it thus becomes important to consider other candidate tissues. Further, materials scientists are concerned about isotropy and anisotropy in tissues used for valve repair or replacement. Valvular leaflets are anisotropic, whereas pericardium is isotropic (Zioupos *et al.*, 1994). Fascia lata, used by Senning, should be reevaluated as a candidate tissue. Venous tissue, peritoneum, and rectus fascia have all been used or suggested for use in the past as fresh, untreated tissue (Love, 1993). These tissues should also be reexamined for use after light tanning with glutaraldehyde. A tissue other than pericardium could prove to be best for valvular applications.

Another topic of speculation about the future is the potential for development of techniques for repairing or replacing heart valves nonsurgically. The potential is for techniques that would enable the treating physician, surgeon or cardiologist, to introduce a folded valve by way of a catheter into the heart or great vessels, there to unfold and attach the valve in the orthotopic position by fixation means yet to be developed. With constantly improving catheter technology and imaging techniques, it is not beyond the realm of near possibility that nonsurgical treatment of valvular heart disease may become feasible. It is obvious that only a tissue valve could be used in this way; mechanical valves cannot be compressed in size and thus could not be used this way.

## RECENT DEVELOPMENTS

In the most literal sense of the phrase "tissue engineering," it is now possible to grow heart valve leaflets *in vitro*, and then implant them in experimental animals. This impressive achievement has been reported by a team from the Harvard Medical School and the Massachusetts Institute of Technology in a series of presentations and articles since 1995. The concept was introduced at a meeting of the European Association for Cardiothoracic Surgery in 1995, and subsequently published in 1997 (Zund *et al.*, 1997). Fibroblast and endothelial cell cultures derived from human, bovine, and ovine sources were seeded on biodegradable poly(glycolic acid) meshes to create valve leaflets. Xenograft leaflets made of human fibroblasts and bovine endothelial cells, and allograft leaflets made of ovine cells, were engineered *in vitro*. The authors found that elastin and collagen production by the fibroblasts was a function of how long the biodegradable mesh survived.

In another study, ovine endothelial cells and fibroblasts were isolated from arteries, cultured, and then seeded onto biodegradable scaffolds of poly(glycolic acid). Both allograft and autograft leaflets were grown by this method and were used to replace one leaflet of the pulmonary valve in lambs (Shinoka *et al.*, 1995). An inflammatory response was seen with the implanted allograft leaflets that was not seen with the autograft leaflets. Evidence based on cell labeling suggested that the cells seeded *in vitro* persisted in the leaflets up to 11 weeks postoperatively (Shinoka *et al.*, 1996). Tensile strength of the leaflets increased with time, and was comparable to that of the native leaflets after 9–10 weeks. Additionally, the authors compared fibroblasts of dermal origin with those of femoral arterial wall origin to determine which would provide tissue more like normal valve leaflets (Shinoka *et al.*, 1997). Based on measurement of collagen and elastin content, and tensile strength, the arterial wall fibroblasts provided tissue sheets more like normal valve leaflets. The seminal work of this group of investigators is bringing us ever closer to the possibility of growing whole valves *in vitro* that could be used to replace diseased heart valves. It is interesting that these investigators have found that autologous cells are better accepted *in vivo* than are allogeneic cells.

The quest for more durable xenograft valves continues. A group in Hanover, Germany, has reported the use of a solvent to remove cells from the porcine aortic valve (Gratzer *et al.*, 1998). An acellular matrix was produced, onto which cultured human endothelial cells were seeded. The authors did not study the tensile strength of their modified porcine valves, nor did they implant any valves in animals. Their untanned, modified valves contain xenograft collagen and allograft endothelium, and it can be questioned if such a valve could be expected to be more durable than a glutaraldehyde-tanned xenograft.

Love (1998) has described methods and instruments that can be used to reconstruct diseased semilunar heart valves with lightly tanned autologous pericardium, without the use of a stent. The key to the method is the use of a precisely sized and cut unitary trefoil tissue pattern, and instruments to hold the tissue in anatomical orientation while the reconstruction is being performed. By eliminating the stent, the patient is left with only a piece of his or her own tissue and the sutures used to accomplish the reconstruction. There is tissue-to-tissue interface at the line of attachment, which allows firm healing, and full effective valve orifice area. Love and colleagues have optimized the geometry of the trefoil with computer-assisted design, and they are validating the geometry with finite-element analysis. Additionally, they are developing an instrument for preuse intraoperative testing of tissue that provides measurements of thickness, strength, and isotropy/anisotropy. The system has been tested in experimental animals and is being readied for clinical use.

## THE IDEAL VALVE REPAIR OR REPLACEMENT

By way of summing up the foregoing discussion, it may be useful to describe some of the design goals for the ideal repair or replacement in the light of 39 years of experience with surgery for valvular heart disease. Mechanical prostheses have enjoyed great success in the treatment of valvular heart disease, and it cannot be disputed that hundreds of thousands of lives have been saved and extended by their use. Mechanical devices cannot be used to repair valve leaflets; only tissue will serve that purpose, unless a synthetic material becomes available. No synthetic material has proved to have the properties needed to endure bidirectional flexing some 40 million times a year without failing or producing thrombosis. The limited durability of currently available tissue valves has restricted their use. It seems clear that a tissue valve with better durability would more closely approach the ideal replacement valve. The reasons for this are given in the beginning of this chapter. Better, more durable tissue is clearly needed for valve repair or reconstruction. Tissue-engineered heart valves grown *in vitro* with autologous cells are on the horizon, and may be a near-perfect solution to the need for more durable tissue valves. It may be that lightly tanned autologous pericardium will prove to have better durability and freedom from calcific degeneration. If so, it may qualify as a preferred tissue for use with both repair and replacement techniques. Manufacturers of heterograft bioprostheses have used a variety of chemical treatments, many proprietary and unpublished, to prevent the calcific degeneration of porcine and bovine tissue valves. One is reminded of the old adage that it is not possible to make a silk purse from a sow's ear. A chemical treatment of autologous tissue that prevented the thickening and shrinkage of the fresh, untreated tissue, but allowed the tissue to remain viable and self-repairing, would be a great advance in tissue engineering.

The argument has been made that valve repair is always preferable to valve replacement. An extension of that argument is the use of extensive repair techniques, such as those used by Duran, that blur the distinction between repair and replacement. Such extensive repairs accomplish the goal of giving the patient an essentially new valve, while avoiding the need for a stent, with the disadvantages imposed by the stent. The goal is near achievement with operations on aortic and pulmonic valves, but more elusive with operations on mitral and tricuspid valves because of their complicated anatomy, including the chordal apparatus. Deac's method is a noteworthy approach, but may not lend itself to the kind of reproducibility that is required for widespread acceptance by the surgical community.

It should be clear that many opportunities exist for tissue engineering in the field of cardiac valvular repairs and prostheses. The needs are for ways to treat existing tissue to make it suitable for valvular applications, or for growing valvular tissue *in vitro*, and for designs of improved techniques and methods for repairing and replacing valves that eliminate or minimize the use of stents. Nonsurgical methodology for treating valvular heart disease, such as valve delivery and placement by a catheter, is another opportunity for tissue engineering.

# CORNEA

Vickery Trinkaus-Randall

## INTRODUCTION

The cornea is an excellent candidate for tissue engineering; however, the biologic constraints that impose restrictions on alterations of corneal shape or curvature, or on the placement of a prosthesis, make the tissue very challenging to engineer. Devices to alter corneal curvature to improve vision are much in demand, although some procedures have resulted in major structural changes to the eye, actually causing damage. Attention to the biology of the cornea is necessary for such interventions to succeed. On the other hand, the need for synthetic corneas is real and the effort to develop a keratoprosthesis has come a long way in the past 5 years. To date several intact models are being evaluated at various levels of stringency. The replacement of a human cornea requires an interdisciplinary approach, where the goal of the materials scientists is to design materials that are accepted and ultimately integrated by the cornea. There is a great need in underdeveloped countries for synthetic corneas because, for cultural or medical reasons, transplants are not feasible.

The cornea has two major functions: (1) to protect the intraocular contents of the eye and (2) to serve as the principal optical element (i.e., refract light). The elasticity and thickness of the cornea allow it to maintain the intraocular pressure (IOP) within the eye. The cornea comprises one-sixth of the outer wall of the eye and junctures with the sclera, imparting an oval appearance to the anterior surface of the cornea (Fig. 35.1A).

To function as the major optical element the cornea must remain transparent, allowing for the formation of an image on the retina. In addition, light scatter can alter the ability of the retina to obtain a clear image. Therefore any opacity in the cornea occurring from disease or trauma can scatter light and degrade the image. To provide or improve vision, the development of synthetic corneas and of other devices and procedures that alter the refractive properties of the cornea has been evaluated. The cornea appears on the surface to be a simple tissue, but the development of synthetic models has been quite challenging. For example, the cornea is avascular and must remain that way; its thickness is regulated by a series of pumps and cell junctions. If the integrity of the latter is lost, the eye becomes edematous. In addition, the corneal matrix may be altered by components from the tears and/or from the aqueous humor located posterior to the endothelium. All of these limitations are compounded by the observation that the cornea is one of the most highly innervated tissues and that repair is impeded in the absence of innervation.

When diseases or trauma render the cornea opaque, the cornea loses its ability to refract light. This disability can be treated with surgery, called a “penetrating keratoplasty,” whereby the cornea is replaced with a donor cornea. When corneal transplants have failed repeatedly, synthetic corneas have been sutured in place in an attempt to restore some vision. The goal of this chapter is to address the progress that investigators have made in creating a synthetic cornea and in reshaping the cornea. We will follow the course of history, from designing prosthetic devices that were intended merely to provide vision, to developing models that are designed to be biocompatible. The first part of the chapter describes the morphology and function of the cornea to help elucidate what is required in engineering the cornea and what are the limitations of the tissue. The latter part of the chapter examines various methods of modifying the cornea.

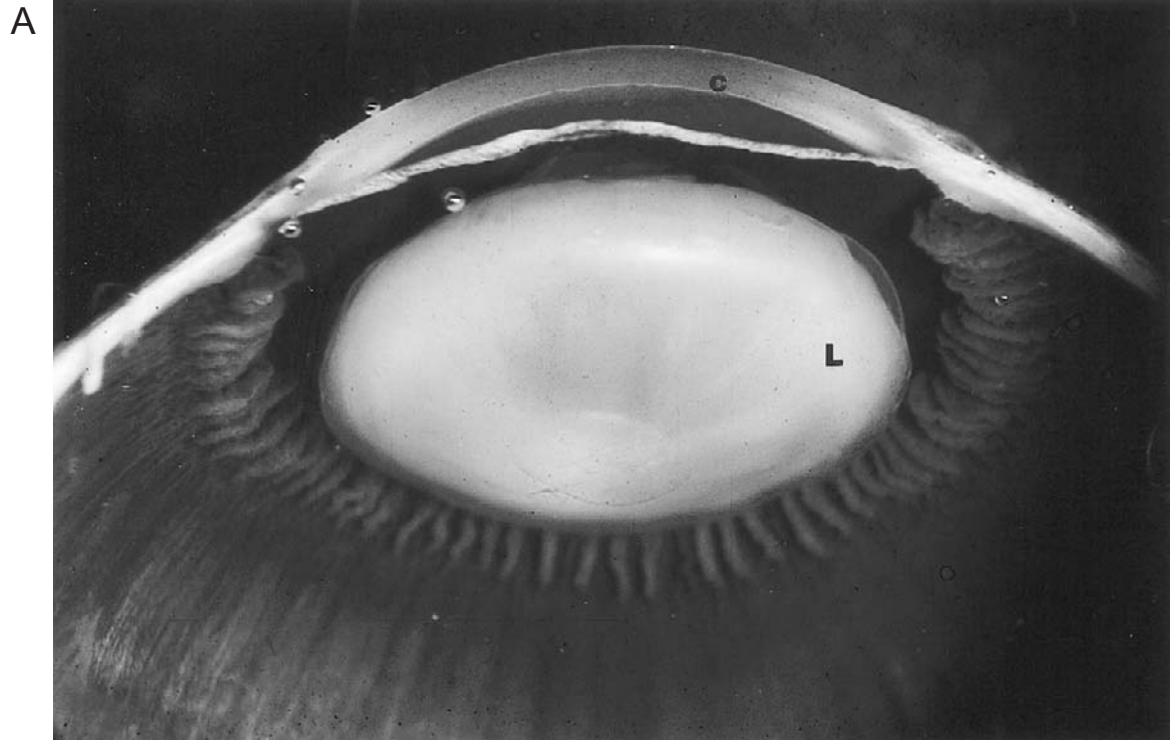

Fig. 35.1. (A) A cross-section of the eye illustrates the curvature of the cornea (C). The endothelium is anterior to the aqueous humor, and the cornea is anterior to the lens (L). (B) A schematic illustrating the three regions of the cornea. The epithelium is most anterior and is composed of five to seven layers. Bowman's membrane is an acellular domain in between the epithelium and the stroma. The stroma is the major structural component and is populated by stromal keratocytes. The endothelium is not represented in this diagram.

The cornea is divided into three regions. It is characterized by five to seven layers of epithelium on the anterior surface, a stroma (which is the major structural component), and comprises an extensive matrix located between the two basal laminae and a single layer of endothelial cells on the posterior side of Descemet's membrane (Fig. 35.1B) (Poise and Mandell, 1970). All re-

gions of the cornea obtain  $O_2$  from tears through the anterior corneal surface. Other nutrients, such as glucose, amino acids, carbohydrates, and lipids, are derived from the aqueous humor. Growth factors are both endogenous and supplied by the aqueous humor via the posterior corneal surface and the tears. The limbal vessels also play a minor role in supplying nutrients.  $CO_2$  is eliminated from the anterior surface whereas the waste product, lactate, is removed mainly via diffusion across the stroma and endothelium into the aqueous humor. Regulation of lactate concentration is essential because an excess can cause edema of the stroma, resulting in opacity.

The transparency of the cornea depends in part on maintenance of the structure and integrity of cells and the surrounding proteoglycans and collagen. In addition, the cornea must regulate the diffusion of water and ions into the stroma. The normal cornea is 78%  $H_2O$  by weight. The epithelium prevents swelling by inhibiting the diffusion of water and ions from the tears across tight junctions. The endothelium uses both a barrier function consisting of tight junctions and a metabolic pump located in the basolateral membrane to prevent swelling of the stroma. The stroma, composed of highly charged proteoglycans, must in turn remain relatively dehydrated. When excess water enters the stroma, glycosaminoglycans take up water. The consequence is an increase in corneal thickness (edema), a disruption in the alignment of collagen fibrils, and ultimately interference with light transmission through the cornea. The latter are all critical components of transparency because edema alters the corneal refractive power, which is determined by both the index of refraction and the radius of curvature of the cornea. The index of refraction in a normal cornea is 1.376 and the radius of curvature averages 7.7 mm on the central anterior surface. The shorter the radius of curvature, the steeper the cornea and the more refracting power it has. Clinically the term “diopters” (corneal power) is used rather than corneal shape (millimeters radii). About 75% of the dioptric power of the eye depends on the interface of the cornea and the surrounding air.

Another critical component of vision is glare. The healthy cornea has the ability to absorb UV radiation (280–300 nm), which protects the posterior part of the eye. Glare is produced by bright light that is scattered within the eye, causing discomfort and decreased vision. As a consequence, opacities may decrease the visual acuity, not only by disrupting the geometric image but also by producing light scatter within the globe. The light scatter reduces the ability to discriminate images on the retina (Miller and Benedek, 1973). This loss may occur when a person has cataracts. In this case a person can see images without loss of acuity in dim light but is bothered by bright light. Light scatter can also occur when the stroma is injured or when inflammation lies within or near the visual axis. Because the cornea is absent in synthetic corneas, the choice of materials or UV blockers is an important component in the design of a synthetic cornea.

Corneal topography is a critical component of vision. To best understand the design of a cornea, consider topographic maps of a mountain. An aspheric surface is composed of compound curves that differ in various meridians. The cornea flattens across the center and periphery, increasing the radius of curvature about 2 mm paracentrally and about 4 mm peripherally. The change is more dramatic along the nasal portion of the cornea than along the temporal portion. This is an important aspect to clinicians who are interested in reshaping the cornea by performing refractive surgery or by placing optics or rings within the cornea to alter the curvature. Persons from outside the field of ophthalmology should be aware that the most commonly corrected corneal property is a change of curvature. Compensation for subtle alterations in curvature and corneal power (diopters) has in the past been performed using eye glasses. It remains the least invasive methodology for correcting vision.

## BIOLOGY OF THE CORNEA

### EPITHELIUM AND ADHESION STRUCTURES

The role of the corneal epithelium is threefold: (1) it must act as a mechanical barrier to foreign organisms, (2) it should have a smooth, transparent optical surface caused by adsorption of the tear film, and (3) it must mediate the diffusion of water, solutes, and drugs on the anterior surface. The epithelium of a healthy normal cornea is not keratinized and is composed of five to seven layers. There is a single layer of basal columnar cells, two to three layers of wing-shaped cells, and two to three layers of superficial cells. The predominantly mitotically active cell layer is the basal layer and the resulting daughter cells move apically and are ultimately sloughed into the tear

Fig. 35.2. (A) An electron micrograph of hemidesmosomes along the basal lamina of a cornea. Note the electron-dense areas on the cytoplasmic face of the cell and the anchoring fibrils (arrowheads) extending into the anterior stroma. Hemidesmosomes are shown within the rectangle. (B) Hemidesmosomes fail to form in the presence of inhibitors of tyrosine phosphorylation.

film (Lavker *et al.*, 1991). Cell turnover is low and only 5% of the basal cells mitose at any one time. A small number of the basal cells become apoptotic. Because the epithelium is subject to large shear forces caused both by blinking and by the movement of the eye during blinking, epithelial cells must remain tightly adherent to neighboring cells via specialized cell–cell junctions (i.e., desmosomes, zonula adherens, tight junctions, and gap junctions). They must also remain adherent to the basal lamina via cell–substrate junctions (hemidesmosomes) (Fig. 35.2A).

Hemidesmosomes can be thought of as the root system of the basal epithelial cells and in intact corneas the entire complex penetrates the basal lamina and terminates in the anterior stroma in the form of anchoring fibrils. It has been shown that the complete formation of hemidesmosomes requires phosphorylation of tyrosine residues. In the absence of phosphorylation, filaments penetrate the lamina lucida of the basal lamina, but the adhesion complex, including intermediate filaments, is not detected (Fig. 35.2B). The highly organized complex is disrupted in disease (i.e., Bullous pemphigoid), trauma (chemical burn or wound), or after surgery, because the cells become motile, using other junctions to migrate along the basal lamina to repair the wound. During wound repair the genomic expression is altered, with some proteins becoming down-regulated (i.e., Bullous pemphigoid antigen) and others up-regulated (i.e., vinculin) (Zieske *et al.*, 1989). It is also known that these proteins are components of signal transduction pathways. A more in-depth discussion of this process can be found in reviews by Gipson and Sugrue (1949) and Trinkaus-Randall *et al.* (1998).

The surface or basal lamina to which the epithelial cells adhere changes with age and/or disease, causing a decrease in adherence of cells and a change in the expression of epithelial adhesion proteins. The distribution of  $\alpha 6$  and  $\beta 4$  integrin subunits along the basal surface of the cells is altered with age, indicating that the basal lamina no longer adequately supports the tissue. In fact, when these cells are cultured *in vitro* under enriched conditions, the proteins are synthesized normally (Trinkaus-Randall *et al.*, 1993). Another example of change occurs when the basal lamina is thickened in diabetes, leading to a decrease in the ability of anchoring fibrils to penetrate (Kenyon, 1983). These morphologic and biochemical changes may explain why the epithelium is often disrupted following vitrectomy surgery. These findings illustrate the importance of the surface chemistry of the basal lamina. Any design for a synthetic device requires that the surface chemistry of the anterior surface support the adherence and proliferation of epithelial cells and the deposition of extracellular matrix proteins. In contrast, the posterior surface should possess a surface chemistry that discourages cellular attachment and epithelial downgrowth.

A discussion on the epithelium is incomplete without at least a mention of the tear film. The plasma membrane of superficial epithelial cells consists of a hydrophobic lipid bilayer, which if unaltered would prevent the tear film from coating the apical cells evenly. However, mucin secreted by goblet cells of the conjunctiva, and glycoproteins secreted by epithelial cells, coat the epithelium, decrease the surface tension, and render it wettable (Rismondo *et al.*, 1989). As a result the

tears spread over the apical epithelium and maintain an intact tear film for 20–30 sec between blinking. Abnormalities of the mucin–glycoprotein layer cause the tear film to break up into dry spots after resurfacing. In addition, the precocular tear film is hypertonic in comparison to the extracellular fluid within the corneal stroma, and when the epithelium is intact the fluid is drawn from the stroma. When the endothelial barrier function is compromised, the tear film may actually play a role in corneal dehydration.

## STROMA

The stroma is the major structural component of the cornea and is composed of an extracellular matrix rich in collagen and sulfated proteoglycans. The distribution of proteins is not uniform from anterior to posterior, and the anterior part of the stroma contains less water than the posterior region (3.04 mg H<sub>2</sub>O/mg dry weight vs. 3.85% mg H<sub>2</sub>O/mg dry weight) (Castoro *et al.*, 1988). The change in hydration plays a role in corneal edema (Kangas *et al.*, 1994). The major cells of the stroma, keratocytes, are fibroblast-like and are dispersed throughout the stroma, contacting each other via gap junctions. These cells become myofibroblast-like after injury and express  $\alpha$ -smooth muscle actin (Jester *et al.*, 1995). This cell phenotype can be “turned on” by high concentrations of transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1), suggesting that the bioavailability of growth factors in the stroma changes with injury and repair. Other evidence suggests that a fibroblast growth factor (FGF-2) and TGF- $\beta$  are present transiently at the wound (Trinkaus-Randall and Nugent, 1998). *In vitro* experiments demonstrate that receptor binding and the TGF- $\beta$ 1 mRNA level are enhanced at the migrating cells along the wound margin (Song *et al.*, 1999). FGF-2, TGF- $\beta$ 1, and epidermal growth factor (EGF) mRNAs have been detected in the human stroma and in the aqueous humor (McAvoy and Charlain, 1990).

The major collagens of the stroma are types I, V, and VI, and XII (Cintron *et al.*, 1981; Poschi and Klaus, 1980; Doane *et al.*, 1991). The main collagens (type I collagen) are stacked in orderly sheets that form lamellae and regulate the fibril diameter of type V collagen and the elongation of type I collagen. The orthogonal array in the posterior cornea is caused by fibrils in one lamella running at right angles to an adjacent lamella. The lamellae in the anterior stroma display an oblique orientation, with bundles of fibrils interdigitating from one lamella to the next fibril. Proteoglycans, the other major component, maintain the spacing between collagen fibrils. The glycosaminoglycan (GAG) chains on the protein cores are sulfated and play a role in maintaining the cornea in a hydrated state. The two major proteoglycans are decorin, which contains chondroitin/dermatan sulfate side chains, and lumican, which possesses keratan sulfate side chains. Keratocan is another keratan sulfate proteoglycan that is cornea and sclera specific. Decorin binds to collagen fibrils and is hypothesized to act as a spacer of type I collagen fibrils. Furthermore, deletional analysis and computer modeling have shown that fibril organization is disrupted in the absence of decorin (Midura *et al.*, 1989; Cintron *et al.*, 1990; Funderburgh and Chandler, 1989; Weber *et al.*, 1996). Changes in the relative biochemical composition of the GAGs occur in response to injury. The change is seen as an increase in the relative synthesis of dermatan sulfate compared to that of keratan sulfate (Cintron *et al.*, 1981; Brown *et al.*, 1995). There is an accompanying change in sulfation and hydration, resulting in an alteration in the alignment of fibrils, leading to haze.

## ENDOTHELIUM

Endothelial dysfunction can occur when there is an increase in the hydration of GAGs. The most clinically significant corneal edema occurs in the posterior stroma, where the ability to absorb H<sub>2</sub>O is greater than that in the anterior stroma due to the higher concentration of keratan sulfate. In the posterior stroma the H<sub>2</sub>O is not bound as tightly and consequently is easily released. On the other hand, the H<sub>2</sub>O absorbed by the anterior stroma is bound more tightly, potentially explaining why anterior stromal edema is more persistent. The force required to prevent the stroma from swelling is called the swelling pressure (SP) and at a normal hydration the SP = 80 g/cm<sup>2</sup>, or 55 mmHg (Hedsby and Dohlman, 1963). A healthy, intact endothelium counteracts the tendency toward hydrophilicity and maintains transparency by (1) possessing a barrier function that decreases the flow of H<sub>2</sub>O into the stroma and (2) possessing a metabolic pump that transports ions from the stroma to the aqueous humor, with H<sub>2</sub>O following by diffusion. Under normal conditions there is a balance between the pump and endothelial functions that maintains a stromal hydration of 78% and a stromal thickness of  $0.52 \pm 0.002$  mm.

**Table 35.1 Chemical composition of human aqueous humor and basic salt solution<sup>a</sup>**

Component	Concentration (mmoles/liter)	
	Aqueous humor	Basic salt solution
Sodium	162.9	155.7
Potassium	2.2–3.9	10.1
Calcium	1.8	3.3
Magnesium	1.1	1.5
Chloride	131.6	128.9
Bicarbonate	20.15	—
Phosphate	0.62	—
Lactate	2.5	—
Glucose	2.7–3.7	—
Ascorbate	1.06	—
Glutathione	0.002	—
Citrate	—	5.8
Acetate	—	28.6
pH	7.38	7.6
Osmolality (mOsm)	304	298

<sup>a</sup>As an irrigating solution.

Endothelial cells are present as a single layer of cells adherent to the posterior basal lamina, called Descemet's membrane (Waring *et al.*, 1982). Endothelial cell number is monitored clinically using a specular microscope and is thought to decrease with age or trauma (Laing *et al.*, 1976). When cells are lost, the remaining cells reorganize by changing their shape while continuing to maintain a tight apposition with adjacent cells. This barrier function is composed of endothelial cells attached via discontinuous tight junctions located at the apical portion of the lateral plasma membrane. Gap junctions are located at the lateral plasma membranes. When there is a major loss in cell number the barrier becomes leaky and water from the aqueous humor passes into the stroma (Rao *et al.*, 1982; Yee *et al.*, 1985; O'Neal and Poise, 1986; Carlson and Bourne, 1988). The driving force of the metabolic pump is controlled by Na<sup>+</sup>,K<sup>+</sup>-ATPase, which is located in the lateral membranes and transports Na<sup>+</sup> from the stroma to the aqueous humor (McCartney *et al.*, 1987; Gersoki *et al.*, 1985). The tight junctions prevent bulk flow of fluid by keeping the Na<sup>+</sup>,K<sup>+</sup>-ATPase site located along the lateral membranes.

The function of the junctions can be evaluated clinically by measuring fluorescein permeability (Carlson and Bourne, 1988). Drugs and irrigating solutions applied to the eye have been shown to compromise the barrier function because the junctions are pH and Ca<sup>2+</sup> dependent. Preservatives that function as antimicrobials or antioxidants that are found in solutions of epinephrine can harm the junctions when administered at high concentrations (Edelhauser *et al.*, 1976; Green *et al.*, 1977). This explains the importance of selecting irrigating solutions that resemble the aqueous humor (McDermott *et al.*, 1988) (see Table 35.1). This system of junctions and pumps may seem inefficient, but most nutrients necessary for the cornea are derived from the aqueous humor and must diffuse across. Therefore flexibility in the system is necessary.

## REFRACTION

Different regions of the eye are composed of different materials (i.e., possess different indices of refraction), thus it is highly surprising that the cornea is transparent, because the light must strike tissue of varied structure and density, increasing the potential for light scatter. However, there is evidence that suggests that refractile elements (<2000 Å) of small dimensions, compared to the wavelength of light (<2000 Å), do not scatter light extensively (Farrell, 1994). In fact, investigators have demonstrated that only 1% of the incident light is scattered in the cornea. Transparen-

cy is regulated by the arrangement of collagen fibrils (the diameter of collagen fibrils is 300 Å and the fibrils are uniformly spaced 550 Å apart) and the transparency of keratocytes is due to cytoplasmic crystallin proteins. In addition, the changes in the refractive index that take place within the cornea occur over a distance less than half the wavelength of light. This evidence refutes the older hypothesis that light scatter was cancelled by destructive interference (Benedek, 1971).

## SUMMARY

In summary, our goal is to explain why the cornea is an excellent candidate for tissue engineering and why the biologic constraints that impose restrictions on alterations of corneal shape and curvature, or the placement of a prosthesis, make the tissue very challenging to engineer. The need for synthetic corneas is real in all parts of the world.

## CRITERIA FOR KERATOPROSTHESES

The transplantation of human donor corneal grafts is performed for patients needing a replacement cornea due to degenerated, scarred, or opacified corneas. As will be discussed later, as early as the 1700s synthetic corneas were designed and implanted in persons who had bilateral loss of eyesight such that the patients regained “finger-counting” vision. These surgeries were conducted prior to the era when corneas were available for performing corneal transplants. Modern techniques now allow donor corneal transplants, but in some countries transplantation of tissue remains culturally unacceptable or tissue is unavailable. Although transplantation or replacement of corneas (penetrating keratoplasty) has a high success rate, there remain problems. Persons affected by specific conditions, such as chemical burns, ocular pemphigoid, Stevens–Johnson syndrome, or recurrent graft rejections, have a poor level of success, with the donor cornea losing its transparency. Transmission of disease has also become a factor, although it is a rare occurrence (Duffy *et al.*, 1974; Hort *et al.*, 1988). These factors have led to a recent increase in research and development of synthetic corneas. The first devices were designed to give a patient vision without consideration to biologic compatibility or aesthetics. Currently, the biologic constraints of the tissue are considered in the design and shape of the device.

Laboratories working on the design of synthetic devices have arrived at a series of criteria (Leibowitz *et al.*, 1994; Chirila, 1994a,b). To date the three major criteria agreed on by both clinicians and scientists are (1) that the device must remain stable in the eye for extended periods of time and must not act as an inflammatory or immunologic stimulus; (2) that the central optic must remain transparent and form a high-quality image at or near the retina, and (3) that the peripheral component must allow for the ingrowth of stromal keratocytes, the subsequent deposition of extracellular matrix proteins, and ultimately be “permanently anchored” in place. There are several additional criteria that should result in the development of a device that would require minimal clinical follow-up. The interface of the cells and material must remain colonized to develop sufficient tensile strength to maintain the device in place. The continuity will prevent aqueous humor leakage and inhibit epithelial downgrowth and eventual extrusion. The peripheral component must not become encapsulated and diffusion of nutrients must occur. A small number of investigators have additional goals in the development of the optimal device. The most important additional goal is to create an anterior surface that will be covered by a continuous confluent sheet of epithelium. The resulting epithelium must remain stable and capable of recovering the surface if it is injured. Ultimately coverage is thought to prevent epithelial downgrowth and enzymatic digestion. Methods to achieve this surface will be discussed. Epithelial surface covering is an additional goal and has been one of the most difficult challenges. As a result, many groups have decided alternatively to clean the anterior surface periodically to prevent protein deposits and epithelial downgrowth. Another goal is the modification of the surface chemistry of the posterior surface so that cells or protein do not attach to the posterior surface. Failure to modify the surface chemistry has resulted in the failure of several synthetic epikeratoplasty models.

One difference in the design of a synthetic cornea from that of prostheses intended for skin or other vascular tissue is the lack of use of biodegradable polymers. Although these polymers have certain advantages, to date they have not been able to fit within the biologic constraints imposed by the cornea. Many of the mechanisms of repair are similar to those of skin and other ectodermally derived tissues, but the cornea must remain avascular to be transparent. Because the center must remain transparent, there are no known techniques to ensure that the central transparent ma-

terial can be held in place if the peripheral porous skirt material degrades and fails to hold the device in place. The only potential porous material is that used by Legeais's group; the material they use becomes translucent after fibroplasia or when the spaces between fibers are filled with fluid (Legeais *et al.*, 1994).

## DEVELOPMENT OF THE KERATOPROSTHESIS

The successful development of a synthetic cornea (keratoprosthesis) has been a difficult goal to accomplish. The major reason for the failure of keratoprostheses was extrusion (the spontaneous removal of a device from the cornea). This was generally preceded by erosion, necrosis of adjacent tissue, inflammation, and epithelialization of the device. Other complications that arose were secondary glaucoma, retroprosthetic membranes, retinal detachment, and ultimately poor visual acuity (Dohlman *et al.*, 1974). Unfortunately, the development of the device has met with many setbacks and its advances have been separated by some 50 years. The recent advance is correlated with an increase in the understanding of the biology of the eye and developments in polymer science.

In the late 1700s one of the first documented efforts at inserting a device was performed by Pellier de Quengsy (1789). A glass plate was inserted into an opaque eye. The insertion of glass plates into corneas was also reported in the 1800s. As one would predict, the glass plate was not stable and quickly extruded. Over time, efforts were made to stabilize the central optic with celluloid plates and egg membranes (Dimmer, 1891). Plexiglass and acrylate (Binder and Binder, 1956; Gyorffy, 1951), or supporting plates of solid or fenestrated poly(methyl methacrylate) (PMMA) (Castroviejo *et al.*, 1969). At that time, although an effort was made to support the central optic, there was no effort made to achieve the correct refractive index or to optimize the corneal curvature. The peripheral constructs were not biocompatible but increased the surface area available to secure the cornea to the device. As a consequence, cellular ingrowth into the device did not occur and the device was not anchored. These initial prostheses led to the development by Cardona (1964) of "through and through" devices.

Cardona was a pioneer in the development of keratoprostheses and demonstrated that highly purified and polymerized materials could be maintained in the cornea. The materials first used by him were rigid and impermeable and were secured with sutures. Neither keratocyte ingrowth nor deposition of matrix proteins was reported. In fact, some of the devices that he designed protruded through the eyelid and used the surrounding tissue for stabilization. Devices of this style are currently used when lubrication of the cornea is minimal. Consequently the device never "healed in place." More importantly, the devices often gave the person "finger-counting" vision. The more current Cardona devices are complex and include a PMMA optic surrounded by a perforated skirt of poly(tetrafluoroethylene) (PTFE) reinforced with a mesh composed of poly(ethylene terephthalate) (Dacron) and autologous tissue.

The complexity of the device is matched by the surgery—the device is inserted through the eyelid, often requiring the removal of the lens, iris, and ocular muscles. Because there is no UV-absorbing tissue remaining, the optic is tinted to absorb UV irradiation. After all of this, the device often gives no more than 30° of visual field. The two-compartment model, consisting of a core and a peripheral skirt, was designed to reduce extrusion, but the devices continued to be extruded. One of the underlying reasons was that the material did not encourage cellular ingrowth and the synthesis of matrix proteins. In contrast, the free edge permitted necrosis and allowed for epithelial downgrowth. The latter occurs because epithelium preferentially follows the stroma (rather than migrate onto the anterior surface), resulting in extrusion. Attempts to achieve the interpenetration or anchoring of the material biologically in place led to the development of both the osteo-odontoprosthesis and other porous polymers for the outer rim by Strampelli and Marchi (1970).

The premise of the Italian group was that a biologic material would be more easily tolerated than a synthetic material. To manufacture their device, an acrylic optical core was embedded within the core of a tooth. The insertion of the device was complicated and was often accompanied by infiltration with vascularization, abscess formation, and extrusion. Blencke *et al.* (1978) altered the osteo-odontoprosthesis by replacing the tooth portion with a glass ceramic. Caizza *et al.* (1990) implanted a modified device using bone. The main concern regarding these devices is the high potential for bone resorption that diminishes not only the strength of the device but also the tensile strength between the device and surrounding tissue. One device examined 12 years after implan-

tation did suffer from extensive bone resorption. Although the concerns are valid, these devices are surgically implanted into humans. Taloni and his collaborators (1995) in Italy have altered the complexity of the operation and followed the central vision function in patients with these devices. To date there is no reported long-term follow-up *in vivo*. Although this is an interesting concept there are major drawbacks as to the long-term durability of the device and the extensiveness of the surgery.

### RECENT DEVELOPMENTS OF POROUS MATERIAL

By the 1980s investigators proposed that acceptance of the device and lack of extrusion depended on the ability of stromal fibroblasts to migrate into the device and deposit a matrix. Fibrovascular ingrowth into Proplast was demonstrated by Barber *et al.* (1980), into a melt-blown poly(butylene):poly(propylene) web by Trinkaus-Randall *et al.* (1991), and into expanded poly(tetrafluoroethylene) (Impra) by Neel (1983). Kain (1990) developed a model in which carbon fibers projected from the optic haptic as rays and demonstrated that keratocytes migrated along the fiber. However, the carbon fibers were friable. Barber *et al.* (1980) were the first to evaluate the biologic response of the cornea to Proplast, which ranges in pore size from 100 to 500  $\mu\text{m}$ . Severe inflammation was not detected over a period of 4 months *in vitro*. Although collagen was identified in histologic specimens, extrusion from interlamellar pockets occurred unless conjunctival flaps were used. In fact, when Proplast was used as the skirt material for intact devices there was an 18% extrusion rate from corneas after 6 months. White and Gona (1988) developed a similar keratoprosthesis with a central cylinder of poly(methyl methacrylate) and a periphery of Proplast, with pore sizes ranging from 80 to 400  $\mu\text{m}$ . The two materials were joined by either cyanoacrylate or by "screwing" the PMMA into the trephined Proplast disk. They, too, reported a high extrusion rate, indicating that the device was not anchored within the stroma. The use of Proplast was discontinued because of its inflammatory responses when used in other devices.

The development of the poly(butylene):poly(propylene) web by Trinkaus-Randall *et al.* (1990) was based on surgical mesh fabrics used in skin, muscle, and arterial wall (Beahan and Hull, 1982). The optimal pore size determined in these tissues was used as the base line for determining the optimal pore size in the cornea (Bobyne *et al.*, 1982; Pourdeyhimi, 1989; Cook *et al.*, 1989). Trinkaus-Randall *et al.* (1990, 1991) evaluated fibroblast ingrowth into many webs with different pore and fiber sizes. A fiber diameter that ranged from 2 to 12  $\mu\text{m}$  with a void volume of 88% was found to be optimal in *in vitro* and *in vivo* studies (Fig. 35.3A). Scanning electron micrographs demonstrated that keratocytes migrated into the interstitial spaces and along the fibers (Fig. 35.3B) (Trinkaus-Randall *et al.*, 1990, 1991). To achieve the optimal stability *in vivo* the polyolefinic webs (3M; St. Paul, MN) were modified with antioxidants to prevent the breakdown of fibers and maintain the strength and resiliency of the stroma-device interface so that the implantation of the device would not weaken the strength of the cornea (Trinkaus-Randall *et al.*, 1992). The porous material was placed in intrastromal pockets and evaluated over 2 years and neither degradation nor extrusion was detected. Several years later Legeais *et al.* (1994) evaluated a skirt material fabricated from a porous PTFE (Impra) (pore size of 18–22  $\mu\text{m}$ ) that permitted fibroplasia. To date this group has evaluated the retention of a synthetic cornea in human patients (skirt, 200  $\mu\text{m}$  thick; pore size, 80  $\mu\text{m}$ ) (Legeais *et al.*, 1995a).

Trinkaus-Randall's group took a different approach and characterized and quantitated the biologic response to each material separately under *in vitro* and *in vivo* conditions. As a consequence the biologic response of the cornea was analyzed and the biochemical composition of the stroma and epithelium was studied in normal and wounded conditions. Using these parameters we have been able to determine whether the tissue responded as predicted under normal trauma or if there was a change in the regulation of proteins. There are now several groups extending this approach and the data will help enhance the overall understanding of the response of the cornea to synthetic materials.

Evaluating the response to the porous skirt material was performed using an intrastromal pocket whereby the cells migrate into the disk at its anterior, posterior, and lateral edges (Fig. 35.4). This requires cells to move into an empty zone (unlike a wound bed) and deposit a matrix. Fibroplasia is assessed using a combination of phase-contrast and fluorescent microscopy and biochemical analysis. To evaluate the deposition of collagen and proteoglycans, both the accumulated matrix and the matrix synthesized at various times up to 3 months was determined. Type I

Fig. 35.3. (A) A scanning electron micrograph of the porous material [a poly(butylene):poly(propylene) melt-blown web, 80:20] used in the construct. (B) A scanning electron micrograph of fibroblasts migrating along and between fibers (arrowheads).

collagen was determined from amino acid analysis of acid hydrolysates of the disks at various times and compared to intact and wounded corneas (Trinkaus-Randall *et al.*, 1991). The collagen, calculated as a ratio of hydroxyproline to proline, was standardized to total protein. Trinkaus-Randall *et al.* (1991) demonstrated that the collagen deposited in the disk did not increase significantly until day 21.

Fig. 35.4. Phase-contrast micrograph of the porous construct inserted between collagen lamellae and evaluated after 42 days. The micrograph is a cross-section of the cornea. Note that the endothelium (E) is intact. The porous material is white. Cells have migrated from the posterior stroma (open arrowheads) and have deposited an extracellular matrix. Open holes indicate regions where deposition of matrix is incomplete.

These investigators also analyzed the optimum pretreatment regimes of the porous materials and found that by day 28 there was less edema and 5.5-fold more collagen deposited when the disks were preseeded with keratocytes, compared to untreated disks. The change could not be attributed to the collagen present at the time of implantation, because the values of collagen in all cases (no pretreatment, 0.05 mg/disk; collagen type I, 0.07 mg/disk; preseeding of cells, 0.04 mg/disk; collagen type I and preseeding of cells, 0.05 mg/disk) were negligible at 8 days (Trinkaus-Randall *et al.*, 1994). When the deposition and synthesis of glycosaminoglycans were evaluated

Fig. 35.5. Immunofluorescent micrograph of a cross-section of the stroma where the porous construct has been inserted. Frozen sections of the cornea were stained with antibodies to (A) FGF-2 and (B) TGF- $\beta$ . Note that the growth factors were detected at the margin between the disk and the stroma (white arrows).

they found that the migration of cells into the disks mimics the scenario of wound repair, but took longer to occur (Brown *et al.*, 1995). The change in dermatan sulfate into an iduronate form and the decrease in the relative amount of keratan sulfate are hallmarks of stromal repair (Funderburgh and Chandler, 1989; Cintron *et al.*, 1990). Interestingly, heparan sulfate, which is absent in control corneas, was detected, indicating that growth factors (such as FGF-2, which binds heparan sulfate) may play a role in stromal wound repair. Specifically, Trinkaus-Randall and Nugent (1998) demonstrated that although FGF-2 was not detected immunohistochemically in unwounded stroma, it was present transiently at the margin between the disks and stroma (Fig. 35.5). Other developers of synthetic corneas have begun to assess the biological response using similar criteria. Legeais's group (Legeais *et al.*, 1994) examined fibroplasia using electron microscopy and Drubaix (Drubaix *et al.*, 1995) reported changes in collagen types after insertion of synthetic material into the stroma. Chirila's group has been examining the production of collagen in hydrogel sponges and reported that the hydrogel sponge did not possess a high enough tensile strength until cellular ingrowth occurred (Chirila *et al.*, 1993).

### RECENT DEVELOPMENTS OF OPTIC MATERIAL

The development of optic material has had a long and laborious history. As mentioned previously, the use of glass and other polymers has been attempted. The material used for the central optical material must allow light transmission in the visible range. However, to protect the retina from ultraviolet damage the material needs to be modified to absorb light at wavelengths below 300 nm. This is even more critical in devices in which the lens has been removed. Optimally, the optic should have tensile properties similar to that of a cornea and allow for continuous reshaping of both anterior and posterior curvatures. The material must either be impermeable to keratocytes or the index of refraction must not be altered. The optic must support the diffusivity of nutrients and should either support epithelial cells or be capable of being modified to support and maintain epithelial cells.

The most commonly used material, PMMA, has both advantages and disadvantages. It transmits light, has been made in ultraviolet-absorbing forms for intraocular lenses, can be shaped, retains clarity with age, exhibits low toxicity, and is well tolerated as long as polymerization has been carried to completion. Its disadvantages include its rigidity and hydrophobicity, its lack of diffusivity, and the subsequent potential lack of supporting epithelial cells.

One of the earlier materials that continued to be used by Van Andel *et al.* (1988) is glass held in place with a platinum holder. The material was designed as a low-cost device. Glass has many of the same advantages and disadvantages as PMMA yet requires more frequent clinical follow-up.

Another polymer, silicone, was used in temporary devices by Duncker and Eckardt (1988) and in designs intended for permanent devices by Kain (1990). In the latter design the silicon optic was supported by peripheral carbon fibers. Legeais *et al.* (1994) discussed the use of a silicon optic coated with poly(vinylpyrrolidone) (PVP). Their evaluation of the model did not include any mention of reepithelialization. However, this group has made advances in shaping the optic.

Other potential candidates are the hydrogels, which eliminate many of the disadvantages of PMMA. Hydrogels are elastic and can be manufactured to have a high tensile strength. They allow for the diffusivity of nutrients, maintain transparency, and can be modified to support epithelial cell growth by coating, by altering the composition of the hydrogel, or by chemically modifying the surface (Trinkaus-Randall *et al.*, 1994; Rosen, 1976; Wu *et al.*, 1994; Laskany *et al.*, 1997). Poly(2-hydroxyethyl methacrylate) (pHEMA) has been used extensively in soft contact lenses. The laboratory of Chirila (1994a,b) developed a device in which both components were cross-linked polymers of HEMA. The central optic was a HEMA-2-ethoxyethyl methacrylate acrylamide. Epithelial downgrowth was observed along with stromal necrosis in these devices, so, unfortunately, the device did not support epithelialization. Tensile strength was not increased above the strength of the homopolymer when the HEMA was copolymerized with 4-*t*-butyl-2-hydroxycyclohexyl methacrylate (Chirila *et al.*, 1995). More recently, there have been advances in the development of intact devices, which will be discussed later.

A poly(vinyl alcohol) hydrogel (refractive index, 1.42) was developed for use as an optic by Trinkaus-Randall *et al.* (1988). The hydrogel was prepared from a poly(vinyltrifluoroacetate) precursor (Ofstead and Posner, 1987). The precursor was molded and attached to the porous component using either thermal fusion or a solvent adhesive. After conversion to a poly(vinyl alcohol), the

hydrogel retained the shape of the precursor. This hydrogel possessed a higher elasticity (436 vs. 15%) and tensile strength (110 vs. 35 kg/cm<sup>2</sup>) than that of the intact cornea. It possessed a water content around 70%, which is similar to the water content of the cornea (79%). The high water content and the structure of the hydrogel allow for the diffusivity of ions and glucose through the material. The elasticity is important, because it is critical that the material reseals after passage of a suture. When ultraviolet absorbers (phenylbenzotriazole and a benzophenone derivative) were copolymerized, transmission of ultraviolet light was not detected below 340 nm. (Tsuk *et al.*, 1997). The surface of the poly(vinyl alcohol) hydrogel also has the ability to be modified to support epithelial cell growth and maintenance. Trinkaus-Randall and co-workers (Wu *et al.*, 1994; Latkany *et al.*, 1997) and Laroche *et al.* (1989) studied the response of epithelial cells to hydrogels. In the laboratory of Trinkaus-Randall, when the surfaces were coated with extracellular matrix proteins and the epithelium was cultured, the cells became confluent, multilayered, displayed typical cytoarchitecture, showed a basal–apical polarity, and synthesized a typical repertoire of adhesion proteins (Fig. 35.6). However, when the disks were implanted *in vivo* the apical surface of the cultured cells was altered, with the shearing force associated with blinking (Fig. 35.7, A and B).

Techniques have been used to modify the surface chemistry of the poly(vinyl alcohol) hydrogels with argon radio frequency (RF) plasma treatments. This treatment repeatedly enhanced cell adhesion and proliferation *in vitro* and *ex vivo*, and limbal epithelium migrated over the treated surfaces of implanted devices (Fig. 35.8) (Latkany *et al.*, 1997). This was an exciting observation but the long-term prognosis *in vivo* is not known at this time.

The hydrogel evaluated by Laroche *et al.* (1989) *in vitro* has a refractive index of 1.368, is oxygen permeable, and also demonstrated diffusivity of nutrients. Their group conducted preliminary

Fig. 35.6. Transmission electron micrograph of epithelial cells cultured on a hydrogel, with the surface treated with matrix proteins. The cells are multilayered and the apical cells have characteristic microvilli (arrowheads).

Fig. 35.7. (A) Phase-contrast micrographs of confluent cells cultured on HEMA modified with plasma treatments. Cells maintain typical epithelial cytoarchitecture. (B) HEMA constructs sutured into corneas as a keratoplasty, demonstrating the roughening of the apical surface that occurs in the absence of tear film.

experiments using the adhesion peptide, RGD; however, no results have been described *in vivo*. The use of the adhesion peptide has been shown to be successful *in vitro* by Massia and Hubbell (1991), with cells showing varied morphologic responses to small concentrations of peptide. These elegant studies helped to explain the cell surface interaction *in vitro*, but they do not ensure adhesivity and/or maintain cytoarchitecture *in vivo*. This has continued to be one of the most challenging tasks in the development of keratoprostheses.

### EVALUATION OF INTACT DEVICES

Although some groups have evaluated the material components of the devices separately, other groups have fabricated intact devices and sutured them *in vivo*. The devices from many laboratories all have peripheral skirts, but the material, the method of bonding, and the surface treatment differ. The criteria for success in these devices are that they (1) have sufficient strength and resiliency to permit surgical manipulation, (2) remain intact without any degradation at the interface between the porous and transparent haptics, (3) can be anchored in place via cellular ingrowth and protein deposition, (4) are not susceptible to enzymatic degradation, and (5) remain transparent over an extended time period. To date very little work has been conducted on molding the devices to achieve an optimal curvature or on attempting to correct vision by altering the refracting power of the optic. Instead, the advancements have been in the manufacture of a device that is retained in the cornea for extended periods of time and that does not result in epithelial downgrowth and stromal necrosis.

Fig. 35.8. HEMA constructs (radio frequency plasma modified) sutured into corneas ex vivo and cultured for 3 weeks on a rotating surface. Epithelia are seen migrating onto the HEMA. Epithelia are labeled with fluorescein isothiocyanate—phalloidin, staining F-actin filaments.

The results from Legeais' group are well worth reporting. The porous material is 200  $\mu\text{m}$  thick with a pore size ranging from 50 to 80  $\mu\text{m}$  (Legeais *et al.*, 1995a,b). Legeais reports that the PTFE porous peripheral skirt became translucent on fibroplasia. However, it has been observed that translucency of Impra is achieved when the pores of the material are filled with fluid and that any solvent can render the PTFE (Impra) translucent. The device was implanted in 24 human patients and five failures were reported in the first 6 months. The haptic was inserted into lamellar pockets and the optic was positioned through a hole made in the central cornea. The devices gave the patients a visual field of 110–130°, far superior to the earlier models. In a second model reported from this group the optic was silicon coated with PVP and the junction between the two polymers was produced chemically. They found that after implantation in rabbits the silicon remained hydrophilic and the IOP could be measured with a Goldman tonometer. Their studies lasted for 3 months. Unfortunately, the design of the device is not available for examination. Several other designs have been developed and implanted, and these aim to enhance fibroplasia and minimize downgrowth. These devices have been implanted in eyes with dystrophy, pseudophakic edema, pemphigus, and burns. Unfortunately, signs of decolonization 9–12 months after implantation have been noted. Dohlman, who has been instrumental in the development of keratoprotheses, has reevaluated which conditions have the best prognosis and what factors can be used as predictors of outcome (Dohlman, 1997). Dohlman has continued to use a plastic device that is not colonized; however, he has demonstrated that with meticulous follow-up the patients can have an excellent outcome (Table 35.2). He found that eyes with graft failure had the best outcome, whereas those with chemical burn and Steven–Johnson syndrome had the worst outcome. Patients with pemphigus ranged in the middle in terms of predictability of outcome. In addition, Dohlman has demonstrated that in some dry-eye patients the device must be implanted through the lid.

Another laboratory in China (Chang *et al.*, 1995) used a silicone membrane altered by plasma-induced graft copolymerization-treated HEMA. Chang's device was sutured in place using the same procedure used in corneal transplantation (penetrating keratoplasty). They found that the graft did not remain in the place of the host cornea and was extruded by 3 months. It is likely that stromal downgrowth occurred, i.e., the fibroblasts grew under and essentially formed a second cornea, gradually extruding the cornea. It is also possible that epithelial downgrowth occurred, aiding in the extrusion of the device. No other reports from this group can be found, so it is difficult to do more than hypothesize about the reasons for failure.

Chirila's group has employed an exciting idea whereby both the peripheral rim and the central optic are cross-linked polymers of HEMA, with the advantage that both are chemically similar. In this model the periphery was made from a hydrogel sponge produced by phase-separation polymerization in aqueous solution. The sponge has a high water content (80% w/w), facilitating

Fig. 35.9. (A) Design of a synthetic corneal construct to be sutured into the cornea as a full-thickness device, showing optical and porous regions. (B) Side view of device placed into the cornea and held in place with single sutures around the circumference of the device until the porous region (white) is anchored, after keratocyte invasion and matrix deposition.

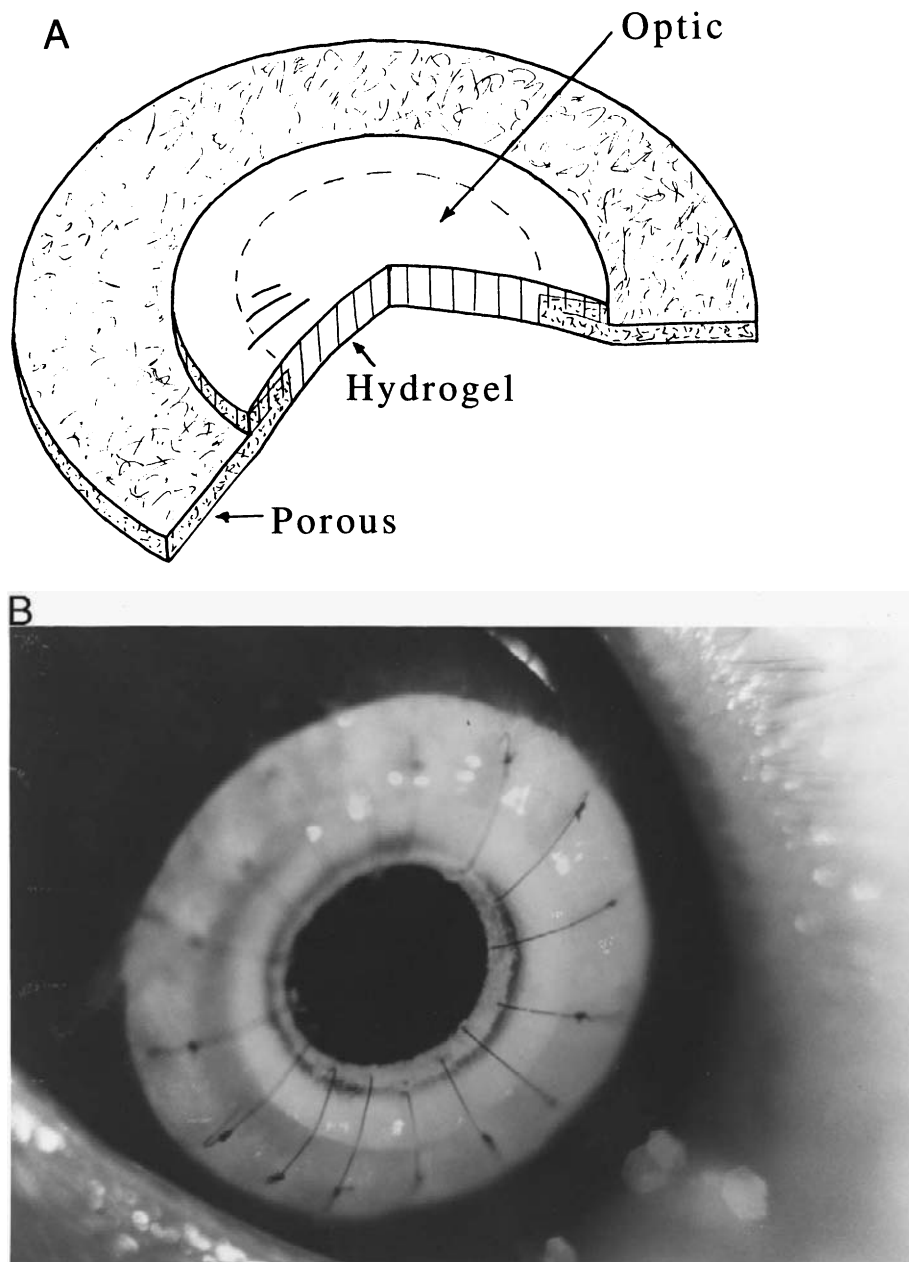

Fig. 35.10. (A) Schematic of a construct to be sutured into the cornea as a partial-thickness device. Note the flange of the porous material that extends into the stroma between lamellae. (B) View of a partial-thickness device placed into a stromal bed and secured in the cornea with a series of individual sutures. Fibroplasia occurs more rapidly in this model and inflammation is less, compared to the full-thickness device.

diffusivity through the material. Fibroplasia was detected when the devices were pretreated with type I collagen (Chirila *et al.*, 1993; Chirila, 1994a,b). More recently they have detected ingrowth of keratocytes in compromised corneal models; however, epithelialization remains a challenge.

We have produced several models, varying in size (4.5–9 mm) and design (Trinkaus-Randall *et al.*, 1997). The devices were evaluated in rabbits using both penetrating keratoplasty and lamellar keratoplasty models, whereby the device was implanted leaving Descemet's membrane intact. The time course of fibroplasia depended on the model and on the size of the porous skirt. The response to the device sutured in as a penetrating keratoplasty was the least successful. In this model the device has no flanges to increase the surface area for fibroplasia (Fig. 35.9). In the models in which Descemet's membrane was left intact, the device was placed as posteriorly as possible in the stromal lamellar bed and the flanges were inserted into the stromal lamellae (Fig. 35.10). Fibroplasia was detected as early as 15 days after surgery and as late as 21 days, the difference being the diameter of the skirt. Although fibroplasia occurred earlier when the area of the skirt was increased,

Fig. 35.11. Epithelialization occurs in the partial-thickness models (Fig. 35.10). It is generally seen after 3 weeks. The epithelium that has migrated from the limbus has been stained with fluorescein isothiocyanate—phalloidin, staining F-actin, and delineates epithelial cytoarchitecture.

the cornea could not support the device in the long term, because there was less diffusivity of nutrients. Smaller models (7 mm in diameter) have been retained in rabbit corneas for a minimum of 1 year with epithelialization in some of the cases (Fig. 35.11). Collagen types III and VI were detected after 6 weeks using immunohistochemical techniques.

Interestingly, heparan sulfate absent in the unwounded stroma was detected and coincided with the appearance of growth factors. The appearance of heparan sulfate suggested that proteoglycans might modulate activity of growth factors so that those cells would become responsive to FGF-2 (Trinkaus-Randall and Nugent, 1998). In all of these models the anterior chamber remained intact and no signs of leakage was detected.

These observations led us to develop methods of control release to enhance the rate of fibroplasia and wound repair. Experiments were conducted to demonstrate that small volumes of sodium alginate injected into the stroma without cytokines did not elicit an inflammatory response over a period of 14 days (a typical time for response in a rabbit cornea). There was also no long-term perturbation of collagen lamellae. Injection of FGF-2 elicited vascularization whereas TGF- $\beta$  did not. Release of  $^{125}\text{I}$ -labelled FGF-2 and TGF- $\beta$  from alginate gels was measured in *ex vivo* and *in vivo* experiments and a first-order release was detected for a period of 3–5 days. However, there was a large vascularization response. Poly(lactic-co-glycolic acid) (PLGA) microspheres were also used and we demonstrated that 1.3% of the encapsulated TGF- $\beta$  was released/day and the release persisted with nearly linear kinetics for 4 weeks. The released growth factor possessed biologic activity. Our goal is to place PLGA capsules containing TGF- $\beta$  into porous materials and insert them into the stromas and evaluate the release. This would allow us to understand the degradation in PLGA, release of growth factor, and change in diffusivity that occurs within the stroma (Trinkaus-Randall and Nugent, 1998).

The advances in the past 5 years have accelerated our level of knowledge and resulted in several models that are currently being evaluated *in vivo*. Long-term studies are needed to follow fibroplasia of the porous material and epithelialization of the anterior surface in the models that have been described.

## OTHER DEVICES USED TO CHANGE THE CURVATURE OF THE CORNEA

To date many technologies have been developed to change the curvature of the cornea. The scope of the field is too vast to cover in this chapter. Briefly, the recent procedures that are commonly used are laser *in situ* keratomileusis (LASIK) and the insertion of rings into the stroma. These developments stem from the radial keratotomy developed in Russia and subsequent excimer laser radial keratotomy and photoreactive radial keratotomy to correct severe myopic patients (as reviewed by Waring and the PERK) (Brint *et al.*, 1994; Waring, 1992, 1998; Nizam *et al.*, 1992; Sastry *et al.*, 1993). Laser *in situ* keratomileusis combines several techniques, but changes the curvature without removing the epithelium or Bowman's membrane. The goal is to avoid epithelial hyperplasia and haze, which have been typical sequelae of these procedures. This procedure is now considered an acceptable treatment after a corneal transplant when vision cannot be rehabilitated with eyeglasses or contact lenses (Ophthalmology Times, 1999). A more reversible procedure to alter curvature is the insertion of intrastromal corneal ring segments. The rings are fabricated from PMMA and are inserted into the lamellae. The advantages of these devices are that they can be removed and the cornea has not been reshaped in the procedure.

### ACKNOWLEDGMENTS

Departmental grants have been received from Research to Prevent Blindness and Lion's Eye Research Foundation and NIH-EY-06000. I would also like to thank Dan Orlow for his schematic drawing of the cornea, and all of the present and past members in my laboratory and Matthew Nugent, for their work, insight, and critical discussions.

# BIOARTIFICIAL PANCREAS

Taylor G. Wang and Robert P. Lanza

## INTRODUCTION

The World Health Organization (WHO) estimates that over 143 million people suffer from diabetes mellitus worldwide, and that number will more than double by the year 2025. In patients with insulin-dependent diabetes mellitus (IDDM), there is a marked decrease in the number of insulin-producing islet cells in the pancreas. In the past, animal or recombinant human sources of insulin have provided the replacement therapy required by these patients. Unfortunately, injected insulin cannot precisely mimic the ability of the normal pancreas to regulate blood glucose concentrations. The concentration of insulin in the blood is normally closely linked to the blood glucose concentration. The moment-to-moment adjustments in insulin secretion by the beta cells of the pancreatic islets, which serve to control blood glucose concentrations, depend on a complex series of biochemical pathways in the living beta cell. These adjustments are extremely difficult or impossible to simulate by insulin injections. The results of the Diabetes Control and Complications Trial (DCCT) suggest that failure to achieve physiologic glucose control with injected insulin is responsible for the serious complications of this disease, including diabetic nephropathy, retinopathy, and neuropathy (Diabetes Control and Complication Trial Research Group, 1993).

There is hope that transplantation of islets of Langerhans will eliminate the need for daily insulin injections, and will prove effective in preventing or retarding the development of complications associated with diabetes. Restoration of normal glucose metabolism has already been achieved in several patients with IDDM by islet transplantation (Bretzel *et al.*, 1996; Hering *et al.*, 1996; Sutherland *et al.*, 1994). Success, unfortunately, has been sporadic, and the requirements for immunosuppressive drugs expose these patients to a wide variety of serious complications (Fung *et al.*, 1992; Kahan, 1989). In addition, many of these immunosuppressive drugs, including glucocorticoids and cyclosporin, have dose-dependent deleterious effects on glucose homeostasis and beta cell function (Alejandro *et al.*, 1989; Gunnarsson *et al.*, 1983; Schlump *et al.*, 1986; Van Schilfgaarde *et al.*, 1986). A number of immunoisolation systems have been developed and refined during the past several years in which the transplanted tissue can be separated from the immune system of the host by a selectively permeable membrane. Low-molecular-weight substances such as nutrients, electrolytes, oxygen, and bioactive secretory products are exchanged across the membrane while immunocytes, antibodies, and other transplant rejection effector mechanisms are excluded (Darquy and Reach, 1985; Soon-Shiong *et al.*, 1990). This approach has the potential not only to allow allogeneic transplantation of cells and tissues without immunosuppression, but also to permit the use of xenografts. The latter, by most accounts, will be essential before any immunoisolation device can be applied on a wide scale.

Like other human organs, donor pancreases are in very short supply. In the United States, it is estimated that only approximately 1000 pancreases are recovered each year. Even with improved procurement of human organs, the supply of donor tissue would remain quite inadequate if pancreatic islet transplantation were to be developed as an effective therapy. For the immediate future, the logical alternative is to use nonhuman donor islets. For example, methods have been devel-

oped to isolate pancreatic islets from porcine and bovine glands; insulins from these animals are fully active in humans and have been used to treat diabetics for over 70 years. Pig and cow islets are an attractive option because they are readily available and the amino acid sequences of these insulins are similar to those in human insulin. Further, herds of specific pathogen-free (SPF) animals would be available as a potential safeguard against the transfer of infectious organisms to human islet recipients.

Although fundamental advances in our understanding of the human immune system and the immune rejection process may eventually lead to means for developing technologies to overcome the vigorous humoral and cellular immune responses associated with transplantation of xenogeneic tissues, these solutions are likely to be decades in the future. In the meantime, encapsulation may be the only way to establish prolonged survival of cell and tissue transplants in patients with diseases caused by the loss of specific vital metabolic functions. In addition to diabetes, encapsulation has broad application to treating major diseases such as cancer and autoimmune deficiency syndrome (AIDS) and a wide range of other disorders resulting from functional defects of native cell systems (Lanza and Chick, 1995). Applications include the use of cells such as hepatocytes for the treatment of liver failure and enzymatic defects (Cai *et al.*, 1989; Eguchi *et al.*, 1996; Hori, 1988; Makowka *et al.*, 1980; Mito and Sawa, 1996; Sun *et al.*, 1986, 1987); adrenal cells in Parkinson's disease (Freed, 1996; Sagen, 1996; Widner *et al.*, 1991); cells to produce nerve growth factors in Alzheimer's disease (Hefti and Knusel, 1988; Phelps *et al.*, 1989a,b), epilepsy, Lou Gehrig's disease, Huntington's disease (Frim *et al.*, 1993; Schumacher *et al.*, 1991; Winn *et al.*, 1994), spinal cord injuries (Tessler, 1996), and strokes; cells to produce clotting factors VIII and IX in hemophilia (Hellman *et al.*, 1989; Roberts, 1989); and endocrine cells in other disorders resulting from hormone deficiency (Fu and Sun, 1989; Lanza *et al.*, 1992). Moreover, by using recombinant DNA and cell engineering technologies in conjunction with encapsulation technologies, it should also prove possible to treat patients suffering from chronic pain (Sagen, 1996), Kaposi's sarcoma, and various hematologic disorders.

To date, most of the research in the area of encapsulated cell transplantation has been carried out with pancreatic islets. There are several reasons for this: (1) diabetes is a leading cause of morbidity and mortality in the world, at an annual cost of approximately \$134 billion in the United States alone; (2) pancreatic islets, which comprise only 1–2% of the human adult pancreatic volume, can be isolated from animal sources; and (3) the quantity of differentiated islet tissue to be transplanted is within a reasonable range (less than 1 g).

Many types of encapsulation systems have been studied. These include devices anastomosed to the vascular system as arteriovenous shunts, diffusion chambers (both hollow fibers and wider-bore tubular membranes), and spherical micro- and macrocapsules (Fig. 36.1). Results in diabet-

Fig. 36.1. Biohybrid artificial devices. In the form of a vascular implant, islets can be distributed in a chamber surrounding a permselective membrane, and the device implanted as a shunt in the vascular system. Alternatively, islets can be immunoisolated within membrane diffusion chambers or microcapsules and placed intraperitoneally, intramuscularly, subcutaneously or in other sites. The islets within these biohybrid devices are generally immobilized in hydrogels such as alginate or agar. One of the important functions of these gels is to provide more uniform islet distribution by preventing settling and subsequent aggregation of the islets into larger, necrotic masses. From Lanza and Chick (1995), with permission.

ic rodents and dogs indicate that these systems can function for periods of several months to more than 1 year. Currently, spherical micro- and macrocapsules appear to have the highest therapeutic potential.

## THEORETICAL BACKGROUND

Over the past decade, several methods for encapsulating islets have been investigated. Micro- and macrocapsules offer a number of distinct advantages over the use of other biohybrid devices, including (1) greater surface-to-volume ratio, (2) ease of implantation (can simply be injected), and (3) retrievability by lavage and needle aspiration (or alternatively, fabrication from biodegradable materials).

### IMMUNOISOLATION

The effectiveness of immunoisolation of a polymer capsule is closely tied to its membrane's permeability, or more precisely, the pore size of the capsule membrane. It has been suggested, and argued forcefully, that with proper selection of a cutoff pore size, the polymer membrane can serve as a gatekeeper (Fig. 36.2), keeping the higher molecular weight (MW) components of immune system out, and allowing the smaller MW molecules such as oxygen and hormones to pass through without much impedance.

Although most of the current polymer capsule designs are based on this principle (De Vos *et al.*, 1993; Goosen, 1994; Lim and Sun, 1980; Soon-Shiong *et al.*, 1993), there is a fundamental weakness in this model. Pore sizes of polymer membranes are not homogeneous by nature, but rather consist of a broad spectrum of sizes and have very long tails. This flaw was first suggested by Colton as early as 1991, but was largely ignored by capsule designers (Colton and Avgoustiniatos, 1991). Ignoring this may have contributed to inconsistent conclusions in the literature (Brissova *et al.*, 1998; Cole *et al.*, 1992; Fan *et al.*, 1990; Iwata *et al.*, 1994; Lanza and Chick, 1994; Lacik *et al.*, 1998; Lum *et al.*, 1992). For the capsule to provide total immunoprotection for living cells, the polymer membrane must not have pores larger than the antibody complement component (Colton and Avgoustiniatos, 1991). This suggests that unless a gatekeeper capsule has a step function cutoff at less than 300 Å in pore diameter and is defect free, the effectiveness of the capsule as an immunoisolation device will be compromised.

A new mathematical model incorporating the pore size distribution for immunoisolation of living cells has been proposed (Wang, 1997). In this new model, the pore size distributions of the membrane are taken into consideration, the capsule wall is thicker, and the pores are bigger than in the gatekeeper model. Figure 36.3 is the schematic drawing of the new model. The large pores will allow the nutrients, proteins, and immune system components to enter the membrane. However, the small pores inside the membrane will prevent or delay most of the immune system components from passing all the way through to the inner volume of the capsule, where the cells reside. The capsule membrane operates more as an immune system barrier than as a gatekeeper. In calculations, we will focus on preventing the antibody-mediated attack on living cells. We assume the immune system density is very diluted, and antibodies and complement components pass

Fig. 36.2. Gatekeeper model. The immune system is excluded from entering the capsule, yet nutrients, oxygen, and proteins pass through without impedance.

Fig. 36.3. Barrier model. In the barrier model, the capsule wall is thicker and the pores are bigger than in the gatekeeper model. This allows the immune system components to enter the membrane. However, sufficiently smaller pores inside the membrane act as barriers to prevent or delay most of the immune system components from passing all the way through to the inner volume of the capsule, where the islet resides.

through the immunoisolation membrane as a result of “random walk motion.” For the sake of simplicity, we shall study the motion in one dimension, and assume the probability to go forward and backward an equal number of steps is the same. After a total of  $N$  such steps, the probability of finding the immune system at a position  $m$  steps away from the origin is

$$P_N(m) = \frac{N!}{\left(\frac{N+m}{2}\right)! \left(\frac{N-m}{2}\right)!} \left(\frac{1}{2}\right)^N, \tag{1}$$

where  $m = n_f - n_b$  and  $N = n_f + n_b$ ;  $n_f$  represents the step forward,  $n_b$  the step backward. This is a Gaussian distribution curve centered at zero. The root-mean-square displacement,  $\sqrt{(\delta x)^2}$ , of the immune system after  $N$  steps is found to be

$$\sqrt{(\delta x)^2} = \sqrt{(\delta m)^2} R = \sqrt{NR}, \tag{2}$$

where  $\delta x = x - \bar{x}$  and  $\delta m = m - \bar{m}$ . Here  $R$  is the average step size and can be approximated to be the average pore size. If we assume the immune system is originally located at the surface of the capsule, and the root-mean-square distance needed to travel is the membrane thickness  $d$ . Eq. (2) can be rewritten as

$$\frac{d^2}{R^2} = N. \tag{3}$$

We can now write the immunisation time,  $\Gamma$ , defined as the time required for the immune system to pass through the membrane with a thickness  $d$  as

$$\Gamma = \frac{d^2}{R^2} f\tau. \tag{4}$$

Using equipartition theorem, the random-walk motion in three dimensions can be written as

$$\Gamma = 3 \frac{d^2}{R^2} f\tau, \tag{5}$$

where the  $f$  is the ratio between surface areas of small pores and large pores, and  $\tau$  is the time that the immune system can be trapped by the small pores in each collision. The value  $f$  can be determined quantitatively from the pore surface area distribution, and the value  $\tau$  for different immune systems can be estimated qualitatively from the dextran size exclusion chromatography (SEC) retention time.

Using an antibody complement component as an example, the estimated immunoisolation

time for the sodium alginate/poly(lysine)/sodium alginate capsule (110-kDa pore size by dextran standard, 2- $\mu\text{m}$  wall thickness) is on the order of days. This calculated value is in agreement with many of the experimental observations on how long islets encapsulated inside the capsule can survive after transplantation into presensitized animal models, such as NOD mice. More importantly, this model might suggest that the current capsule will have limited success in treating type I diabetic disease in humans.

### MASS TRANSPORT

To maintain the viability of islets inside an immunoisolation capsule, the nutrient and oxygen must be allowed to diffuse in, and the insulin out. This is a convective diffusive process. Mass transport across a random network structure is an extremely complicated system. Any attempt to undertake a rigorous calculation of this system is beyond the scope of this chapter. Here, the intent is to examine the order of magnitude power dependence of capsule membrane parameters on the steady-state mass transport rate across a capsule membrane. The diffusion mass transport flux,  $Q$ , across the membrane is proportional to the concentration gradient, and membrane porosity.

$$Q \propto \frac{D}{d} \Delta c A_{\text{eff}}, \quad (6)$$

where  $D$  is the diffusion coefficient,  $d$  is the thickness of the membrane, and  $\Delta c$  is the mass concentration difference; here  $A_{\text{eff}}$  is the effective capsule surface area that participates in mass transport. The diffusion of biomaterial in liquids is under a nonslip condition;  $D$  is proportional to the temperature,  $T$ , and inversely proportional to the fluid viscosity,  $\eta$ , and the particle radius,  $r$ . This is usually called the Stokes velocity. It represents the diffusion of large spherical biomaterial in an open system. To account for the effect of capsule membrane porosity on mass transport, we need to calculate  $A_{\text{eff}}$ . This problem can be simplified by modeling the polymer membrane as a bundle of interwoven pipes. Those pipes have inner diameters,  $R$ , which approximate average pore sizes. The capsule surface area participating in diffusion is  $NR^2$ , and  $N$  is the number of pipes per unit surface area. The mass flow inside a pipe has a velocity profile of  $R^2$ . Thus, the effective diffusive mass flow passing through a cross-section of the pipe per unit of time is proportional to the fourth power of the radius of the pipes. Equation (6) can then be rewritten as

$$Q \propto \frac{R^4 T}{r \eta d} \Delta c N. \quad (7)$$

Equation (7) is phenomenological. However, it might provide some valuable insight on the capsule design optimization.

### MECHANICAL STRENGTH

Many immunoisolation devices fail inside animal and/or human hosts because of capsule breakage. This exposes unprotected living cells to the host's immune system. At best, the cells are destroyed; at worst, an immunoreaction can be triggered. Therefore, if the immunoisolation devices are to be used for the long-term cure of hormone deficiency diseases in humans, the mechanical strength of the capsules must be sufficiently great to survive the constant pressure exerted.

Examine the case of a spherical capsule with a radius of  $R$ . Under unidirectional pressure,  $P_x$ , the capsule distorts the shape to compensate the pressure:

$$P_x = Yd \left( \frac{2}{R_2} - \frac{2}{R_1} \right), \quad (8)$$

where  $Y$  is Young's modulus,  $d$  is the thickness, and  $R_1$  and  $R_2$  are major and minor axes of the deformed capsule. If the distortion is small, we can approximate  $R_1 = R + \delta r$  and  $R_2 = R - \delta r$ . Equation (8) can be rewritten as

$$\frac{\delta r}{R} = \frac{R}{4Yd} P_x. \quad (9)$$

Equation (9) shows the advantages that a smaller capsule and a thicker membrane have on resisting deformation,  $\delta r/R$ , under pressure,  $P_x$ .

Equations (5), (7), and (9) clearly show that if the capsule parameters cannot be adjusted independently, it will be very difficult to satisfy all the dichotomy requirements of immunoisolation, mass transport, and mechanical strength.

## EXPERIMENT

### BIOCOMPATIBILITY

Experiments have demonstrated the feasibility of long-term immunoisolation of islets by artificial poly(acrylonitrile)/poly(vinylchloride) membranes and the long-term biocompatibility of the membrane versus the graft and versus the recipient (Lanza *et al.*, 1991, 1992). Data indicate that islet implants can provide correction of hyperglycemia in dogs and rodents for periods of several months to more than 1 year without the use of immunosuppressive drugs. Diffusion chambers fabricated from permselective acrylic membranes showed little or no evidence of an inflammatory response when implanted intraperitoneally in either spontaneously or streptozotocin-induced diabetic rats (Lanza *et al.*, 1992, 1993). Complications such as abscess formation or intestinal adhesions, which have been observed with other technologies (Andersson, 1979), were not observed with these implants. These studies have been extended to implantation in the peritoneal cavity of a large animal, the dog, with surgically induced diabetes. Histologic examination of the chambers revealed that they were biocompatible. The outer surface showed only scattered foci of macrophages and lymphocytes. Intactness and sterility of the chambers, however, was a crucial factor in the success of the implants. In addition to loss of islet viability, damaged or contaminated membranes were often encapsulated by fibrous tissue that exhibited an interstitial acute and/or chronic inflammatory reaction, and development of granulation tissue was observed. Most of these transplants ultimately failed because of membrane breakage.

### BLOOD GLUCOSE CONTROL

The motivation for islet transplantation is to provide physiologic control of blood glucose concentration. *In vitro* and *in vivo* experiments have demonstrated only moderately delayed changes (lag time <10 min) in insulin secretion in response to changes in glucose concentration. Perfusion of encapsulated islets with glucose elicited an approximately fourfold average increase from the basal insulin secretion (Wang *et al.*, 1997; Lanza *et al.*, 1991). There was a delay of only  $7 \pm 1$  min before the insulin concentration in the perfusate began to increase. Although this response is well within a time frame compatible with closed-loop insulin delivery (pharmacokinetic modeling of glucose homeostasis in humans suggests that the lag time of the increase in insulin delivery by an artificial pancreas must be <15 min to avoid the overexcursion of postprandial blood glucose) (Kraegen *et al.*, 1981), a reduction in the volume of the islet cell compartment would further improve the transmission of the glycemic signal from the blood to the islets, and of insulin from the islets to the recipient. Immunoisolated islets lack intimate vascular access, and must be supplied with oxygen and nutrients by diffusion from the nearest blood vessels over distances greater than those normally encountered. In wider-bore membrane chambers, the problem of cell death or dysfunction as a result of oxygen supply limitations, or accumulation of wastes or other cellular products, is likely to be more severe. Chambers with a 4.8-mm inner diameter retrieved from the peritoneal cavity of dogs several months after allotransplantation contained a central core of necrotic islets. Only a rim of islets remained viable within approximately 0.5–1 mm of the inner membrane wall. Similar results were obtained with canine islet implants into rats. These findings are in agreement with the theoretical model of Eq. (7). Clearly, careful attention must be paid to the diffusion distances and transport properties of the membranes. The relatively small volume (and short distances) associated with smaller spherical devices would maximize the transfer of oxygen and nutrients to the islets, and minimize the suppression of function by any islet hormonal or metabolic products that could accumulate in the islet compartment.

### HOST SENSITIZATION

Although encapsulation systems serve to block uptake of antibodies and complement, the possibility must be considered that antigens released from the cell compartment could stimulate a host

humoral response. Such antibodies could be induced by antigens shed from the cell surface, or by proteins secreted by live cells or liberated after cell death. This could lead to an allergic response and/or immune complex disease. Studies have been performed by Lanza *et al.* (1994a,b) in order to help rule out the possibility of serious immunologic sequelae in recipients. Although these studies were carried out using islets encapsulated inside tubular membrane chambers, the results may be reflective of other cell encapsulation systems as well, including microcapsules, hollow fibers, devices anastomosed to the vascular system as arterioventricular shunts, and other types of implantable diffusion chambers.

In these studies, chambers containing porcine or bovine islets were implanted intraperitoneally into streptozotocin-induced diabetic rats. Sera were collected at various intervals and tested against isolated canine and porcine islets for tissue specificity and interspecies cross-reactivity by fluorescence immunocytochemistry. No immunofluorescence (or only weak background staining) was obtained when islets were exposed to horse sera, or to sera obtained prior to implantation of devices containing xenogeneic islets. Within 2–6 weeks, however, the postimplantation sera showed strong immunoreactivity. The antibodies were found to be reactive to multiple tissues, and to possess little or no interspecies cross-reactivity.

The appearance of these xenoantibodies coincided with the appearance of circulating soluble immune complexes. However, none of the respiratory, cutaneous, or gastrointestinal manifestations that are characteristic of an anaphylactic reaction, or of the diseases of immediate-type hypersensitivity, were observed, even following the intraperitoneal injection of additional naked islet tissue. Renal glomeruli did not stain for IgG or C3 in islet recipients. These results suggest that islet cell antigens crossed the membrane and stimulated antibody formation in the host, although they did not appear to cause renal or immune complex disease during the course of this study.

## CAPSULE DEVELOPMENT

### ALGINATE/POLY(L-LYSINE) CAPSULES

Capsules fabricated from alginate and poly(L-lysine) (PLL) were originally described by Lim and Sun in 1980, and have been used to reverse diabetes in animals and more recently in a small-scale clinical trial (Soon-Shiong *et al.*, 1993, 1994; Sun *et al.*, 1996). However, the inability to adjust capsule parameters independently (e.g., immunoisolation versus mechanical strength versus permeability) has limited the success of this system. Implanted discordant islet xenografts produced blood glucose control for a shorter period of time. These studies performed in mice usually required adjunctive treatment with immunosuppressive agents (Calafiore *et al.*, 1987; Ricker *et al.*, 1987; Wang *et al.*, 1987). Weber *et al.* (1990) found that alginate/PLL microcapsules containing canine islets functioned for <2 weeks in diabetic NOD mice. With anti-CD4 monoclonal antibody treatment, however, long-term functional survival was observed in many of the recipients. Patrick Soon-Shiong *et al.* (1993) have also reported successful long-term implantation of a microencapsulated allograft in larger animals. They treated spontaneous diabetes in dogs administered low doses of cyclosporin. Using the same technology, Soon-Shiong *et al.* (1994) have also achieved insulin independence in a patient for approximately 1 month. However, this patient was on a regimen of immunosuppressive drugs, and subsequently required exogenous insulin therapy. Calafiore (1992) has also achieved insulin independence in one of three alloxan-induced diabetic dogs and, transiently, in one of two patients without any pharmacologic immunosuppression. However, these microcapsules were coated with PLL and were deposited in artificial prostheses directly anastomosed to blood vessels.

### BIODEGRADABLE CAPSULES

Prolongation of discordant xenograft survival in streptozotocin-induced diabetic mice has been achieved without immunosuppression using alginate microspheres without the synthetic poly(L-lysine) membrane (Lanza *et al.*, 1995). Uncoated alginate spheres containing porcine and bovine islets routinely reversed hyperglycemia after intraperitoneal injection into diabetic mice. All but one (13/14) of the grafts functioned for at least 1 month, and 11 animals lived for at least 10 weeks. In comparison, free islet transplants failed to function, or sustained euglycemia for <4 days.

The ability of uncoated microspheres to achieve marked prolongation of discordant xenograft

Fig. 36.4. Mean nonfasting plasma glucose levels in four streptozotocin-induced diabetic rats that received intraperitoneal implants of alginate-encapsulated bovine islets. All of the animals received low-dose cyclosporin A (10–20 mg/kg/day, subcutaneous). Immunohistochemical staining of the grafts (>100–150 days) revealed healthy viable islets (80–100%, comparable to the day 0 control specimens), with well-granulated alpha, beta, and delta cells. This method for transplanting discordant islets into rats is simple and inexpensive, and may also be a useful procedure for transplanting other cells and tissues. The spheres can be formed simply by extruding a mixture of cells and sodium alginate with a 16-gauge angiocatheter into a  $\text{CaCl}_2$  solution. From Lanza *et al.* (1995b), with permission.

survival is surprising, because the destruction of the grafts might have been expected to occur based on the presence of circulating preformed natural antibodies in the recipients in reaction to cells of the donor (Platt and Bach, 1991). The data suggest that the alginate matrix served as a physical barrier to prevent direct effector cell contact with the donor tissue. However, we cannot rule out the possibility that immunologic effector molecules were excluded from the negatively charged alginate gels based on properties other than simply molecular weight.

Although the results using uncoated alginate microspheres in mice are encouraging, preliminary experiments in diabetic rats suggest that uncoated alginate spheres containing porcine and bovine islets can reverse hyperglycemia for periods of up to more than 175 days (Fig. 36.4) (Lanza *et al.*, 1995). Experiments in spontaneously diabetic dogs have also been performed by Lanza *et al.* (1995c). Results indicate that long-term survival of canine islet allografts can be achieved by encapsulation inside uncoated alginate spheres (Fig. 36.5). However, these results have been inconsistent and usually have required adjunctive treatment with immunosuppressive agents.

To overcome this limitation, Lanza *et al.* have designed a hydrogel-based microcapsule based on the uncoated microsphere technology (Lanza *et al.*, 1999). These new composite capsules break

Fig. 36.5. Fasting blood glucose concentrations of a spontaneously diabetic dog that received an intraperitoneal implant of alginate-encapsulated canine islets. From Lanza *et al.* (1995d), with permission.

Fig. 36.6. Biodegradable microreactor. Encapsulated bovine islet retrieved from the peritoneal cavity of a dog 6 weeks after xenotransplantation. These new biodegradable microreactors are injectable and do not appear to require the use of immunosuppressive drugs to prevent rejection.

down at a rate that can be adjusted to correspond to the functional longevity of the encapsulated cells, and can be engineered to degrade over several weeks to months for short-term drug delivery, or to remain intact and immunoprotective for more extended periods of time. When the supply of cells needs to be replenished, no surgery will be required to localize and remove the old capsules. This system has been tested successfully in rats using discordant porcine and bovine islet tissue. The tissue remained in excellent condition indefinitely (>40 weeks.) The viability was comparable to preimplant control specimens without use of any immunosuppression. Large animal studies are underway (Fig. 36.6).

### PMCG CAPSULES

A new multicomponent capsule based on a theoretical model was developed by Wang *et al.* (1997). Over a thousand combinations of polyanions and polycations were studied in search of polymer candidates that would be suitable for entrapment capsules. A combination of sodium alginate (SA), cellulose sulfate (CS), poly(methylene-co-quinidine) (PMCG), calcium chloride ( $\text{CaCl}_2$ ), and sodium chloride (NaCl) (Lacik *et al.*, 1998; Wang *et al.*, 1997) was found to be most promising. The polyelectrolyte complexation has distinct advantages. It is very simple and inexpensive and can be processed under extremely mild physiologic conditions. A distinct advantage of this multicomponent system was the ability to adjust the capsule's mechanical properties, permeability (Brissova *et al.*, 1998), and surface properties (Xu *et al.*, 1998) independently, as well as the capsule size for retrieval if needed.

Encapsulated rat islets reversed chemically induced diabetes in mice (streptozotocin) for at least 4–6 months. Similar studies were performed with diabetic NOD female mice and diabetes was reversed for up to 180 days. Wang and Elliott of New Zealand have successfully reversed diabetes (14 weeks) in a NOD mice model with encapsulated porcine islets without the use of any immunosuppression (Fig. 36.7). The capsules were found freely floating in the peritoneal cavity, and showed no significant fibrosis histologically and no tissue reaction. The encapsulated islets continued to maintain long-term function as assessed by their ability to secrete insulin following glucose stimulation. The eventual failure of encapsulated islets transplanted into animals with chem-

Fig. 36.7. Transplantation of encapsulated porcine islets reverse diabetes. Encapsulated porcine islets were transplanted into the peritoneal cavity of female NOD mice that had developed spontaneous diabetes by the age of 20 weeks. Of the diabetic mice that received transplants, the number of nondiabetic animals at selected time points is shown. This experiment is part of the results of a collaborative effort between T. Wang and R. Elliott of New Zealand.

ically induced diabetes did not result from capsule rupture or from an immune attack. Capsules retrieved from such animals were freely floating and their surface was free of fibrosis. Thus, the failure likely results from gradual islet death within the capsule from either a nutrient deficiency or from islet toxicity because of soluble immune factors (cytokines). In contrast, the failure of encapsulated islets transplanted into NOD mice may have resulted from an immune or autoimmune attack. Capsules retrieved from such animals were clumped and demonstrated marked fibrosis around the capsule surface. Experiments to extend the longevity of the capsules by optimizing the permeability, wall thickness, and surface characteristics are in progress with very promising results. Large animal studies have also been initiated with encouraging preliminary results.

### OTHER APPROACHES

Many other ingenious approaches are being tested in other research labs. Macro-Agarose beads (The Rogosin Institute), poly(ethylene glycol) capsules (Neocrin), Stealth microcapsules (Encell), and Islets Sheet (Islets Sheet Medical) all offer interesting possibilities. Unfortunately, there are little or no published data available on these systems at the present time.

### DISCUSSION

Organ transplantation is one of the miracles of the twentieth century. However, along with success has come frustration. The supply of human organs is insufficient to satisfy demand. Within the United States alone, thousands of patients await transplants of heart, liver, kidney, and lung, and millions more struggle with diseases such as diabetes. Demand exceeds the supply by two orders of magnitude. So the pressure is mounting to devise ways such as immunoisolation to use animal tissues and cells as possible substitutions for human biologic material, but without the need for immunosuppression and its accompanying side effects. There is considerable excitement

among researchers and clinicians who hope to see the introduction of a hybrid pancreas to replace conventional insulin therapy.

Polymer membranes have been the choice to encapsulate living cells for immunoisolation. Data have shown exciting successes in animal models. A new physical picture and a better understanding of the mechanisms of immunoisolation have advanced the systematic studies in preparation for human clinical trials. The next few years should prove to be a great challenge and it is hoped with great excitement that the promise of islet transplantation comes to fruition. It appears likely that in the year 2000 clinical trials utilizing encapsulated islet xenografts to treat diabetic patients will be a reality. This will serve as an important starting point for developing living drug delivery systems for treating a wide range of additional disorders. For patients with diabetes as well as those with other diseases, such as cancer, hemophilia, liver failure, and Parkinson's disease, the coming years hold promise for greatly improved therapy.

#### ACKNOWLEDGMENTS

The Vanderbilt University studies were supported by grants from the Evans–Gilruth Foundation, Vanderbilt University School of Engineering, and the Vanderbilt Diabetes Research and Training Center (NIH DK20593). T. W. wishes to express gratitude for the valuable contribution provided by Igor Lacik, of the Polymer Institute, Slovak Academy of Sciences; A. V. Anilkumar; Paul LeMaster, of Vanderbilt University; and A. C. Powers, of Vanderbilt University Medical School/VA Hospitals. T. W. also acknowledges the excellent support provided by New Zealand colleagues, in particular, Prof. R. Elliott and Dr. Livia.

# PARATHYROID

C. Hasse, A. Zielke, T. Bohrer, U. Zimmermann, and M. Rothmund

## HISTORY OF PARATHYROID ALLOTRANSPLANTATION

Although autotransplantation of parathyroid tissue is a well-established clinical procedure (Wells and Christiansen, 1974), allotransplantation of the parathyroid gland still is at the level of experimental surgery. In 1884 the German physiologist Moritz Schiff was the first to demonstrate that tetany, occurring after total thyroidectomy, could be reversed by replantation of the thyroid (Welbourn, 1990). Six years later, Loeb, who investigated the cramps of isolated muscles submerged in a low-calcium saline solution *in vitro*, demonstrated that addition of calcium to the medium resolved the spasms, thus uncovering the relation between hypocalcemia and tetany (Loeb, 1899–1900). In 1909 MacCallum and Voegtlin discovered that hypocalcemia after thyroidectomy was caused by parathyroidectomy. Hanson in 1924 and Collip in 1925 were the first to try to reverse this effect by intramuscular injections of parathyroid extracts to patients with post-thyroidectomy tetany. For limited periods of time, they were able to restore normocalcemia in these patients.

In 1972, almost 90 years after Schiff's first report of thyroid replantation, Tochilin (1972a,b,c) performed the first allotransplantation of fetal thyroid and parathyroid glands in humans and documented long-term reversal of hypothyroidism, but only short-term reversal of hypoparathyroidism. Tochilin later combined this treatment with simultaneous transplantation of the pancreas, and achieved similar results (Kiprenskii *et al.*, 1990). The first allotransplantation of parathyroid glands with systemic immunosuppression was reported by Groth *et al.* in 1973, in a patient who had previously undergone successful renal transplantation. Because the patient became normocalcemic with no further need for calcium supplementation, the transplant apparently was functioning; however, neither the further course of the patient nor the period of time that normocalcemia was maintained is known. The potential long-term outcome of simultaneous renal and parathyroid allotransplants with systemic immunosuppression was outlined in a case report of 1979. In this particular case, the function of the parathyroid tissue was documented by determination of parathyroid hormone (transplant-bearing versus non-transplant-bearing forearm) as well as by histology from a biopsy of the allotransplanted tissue. Function continued until complete rejection of both organs 30 months postoperatively (Ross *et al.*, 1979). Also in 1979, two children with hypoparathyroidism due to DiGeorge syndrome (see later) received parathyroid allotransplants without immunosuppression. Because of a severe concomitant immune defect, both children died too soon to allow for an assessment of allograft function (Wells *et al.*, 1979).

Kunori *et al.* (1991) also completely ignored the ensuing immunologic reaction following transgenous transplantation. They reported the first successful long-term therapy of postoperative hypoparathyroidism by repetitive allotransplantation of fresh and cryoconserved parathyroid tissue particles in 1991. The patient received initial immunosuppressive medical therapy for the first 2 days postoperatively. For a period of 6 months, the patient reportedly had normal levels of serum calcium and improvement of symptoms with half of the substitutive therapy (Kunori *et al.*, 1991). One year later, Segerberg *et al.* (1992) performed the first successful syngenous transplantation of

**Table 37.1 Historic synopsis of significant achievements along the way to parathyroid allotransplantation**

Year	Investigator	Achievement
1884	Schiff	Reversal of postthyroidectomy tetany by thyroid replantation
1924/ 1925	Hanson Collip	Treatment of hypoparathyroidism with injections of parathyroid extract
1960	Swan <i>et al.</i>	First attempt of parathyroid tissue immunoisolation by coating the tissue with millipore membranes
1967	Fischer <i>et al.</i>	Increase of parathyroid graft function by choosing the anterior eye chamber as transplant site
1972	Tochilin	Homologous <i>en bloc</i> transplantation of the thyroid–parathyroid complex
1973	Groth <i>et al.</i>	First allotransplantation of the parathyroid with systemic immunosuppression in secondary hypoparathyroidism
1974	Raaf <i>et al.</i>	First attempt to reduce parathyroid tissue immunogenicity by tissue culture passage
1977	Starling <i>et al.</i>	First use of antidonor serum for allotransplantation of the parathyroids
1979	Ross <i>et al.</i>	Survival for 30 months of allotransplanted parathyroid allotransplant with systemic immunosuppressions
1979	Wells <i>et al.</i>	First allotransplantation of the parathyroid without systemic immunosuppression in primary hypoparathyroidism
1983	Sollinger <i>et al.</i>	Function for 15 months of a human parathyroid following ionizing irradiation and nud mouse <i>in vivo</i> passage of the parathyroid tissue
1989	Fu and Sun	First successful immunoisolation of parathyroid cells using microencapsulation: function <i>in vivo</i> for 12 weeks
1990	Kiprenski <i>et al.</i>	First homologous <i>en bloc</i> transplantation of parathyroid, thyroid gland, and pancreas
1991	Kunori <i>et al.</i>	First successful treatment of postoperative hypoparathyroidism by repeated allotransplantation of parathyroid tissue particles after initial immunosuppression
1992	Segeberg <i>et al.</i>	First successful syngeneous transplantation of human parathyroids without immunosuppression
1993	Yao <i>et al.</i>	Intracerebral parathyroid allotransplant survive for 12 weeks without systemic immunosuppression
1995	Anton <i>et al.</i>	First allotransplantation of single parathyroid cells after reduction of MHC I/II antigens: transplants function for 3 months with mild immunosuppression
1996	Tolloczko <i>et al.</i>	First allotransplantation of single parathyroid cells without immunosuppression: hormonally active for up to 1 year
1997	Hasse <i>et al.</i>	First successful clinical allotransplantation of cultured, microencapsulated parathyroid tissue without immunosuppression

parathyroid glands in identical twins, one of whom suffered from permanent postoperative hypoparathyroidism. A chronology of parathyroid allotransplantation is given in Table 37.1.

Many subsequent *in vitro* investigations and experimental animal studies have been performed to accomplish parathyroid allotransplantation without the need of postoperative immunosuppression. The earlier assumption, that parathyroid tissue would be less immunogenic than other tissue types, was proved wrong (Wells *et al.*, 1973a,b). In general, two basic lines of research have evolved. Some have tried to transplant parathyroid tissue to regions with apparently little or no immunologic competence. For instance, Fisher *et al.* (1967) used the anterior eye chamber, and a Chinese group reported transplantation to the lateral ventricle of the brain (Dib-Kuri *et al.*, 1975) and to the scrotum. However, all three attempts did not achieve long-term graft function (Fisher *et al.*, 1967; Dib-Kuri *et al.*, 1975; Yao *et al.*, 1993). Others have aimed to reduce the immunogenicity of the tissue to be transplanted. Ultraviolet and ionizing irradiation, various tis-

sue culture methods, coating of the graft with millipore membranes, nude mice *in vivo* passage, as well as treating the recipient with antidonor serum have been employed in an attempt to reduce the immunologic response. However, a reproducible increase of *in vivo* graft survival for more than just several weeks has not yet been accomplished (Swan *et al.*, 1960; Raaf *et al.*, 1974; Starling *et al.*, 1977; Gough and Fimmimore, 1980). Only Sollinger and co-workers (1983) were able to obtain functioning parathyroid transplants in two patients without postoperative immunosuppression for a period of 15 months, following pretreatment of parathyroid tissue with ionizing irradiation and subsequent nude mouse *in vivo* passage. The course of both patients and whether the patients further required substitutive therapy are, however, unclear. Although the authors concluded that their procedure was effective and very promising, there have been no further clinical reports on this combination of techniques (Sollinger *et al.*, 1983). Dyna-beads, i.e., magnetic microspheres loaded with specific antibodies, effectively reduce major histocompatibility complex (MHC I and MHC II) antigen concentrations of single parathyroid cells. Using this technique, the first successful transplantation of single parathyroid cells was reported. With the patients receiving "mild immunosuppression," transplants were functioning for periods of up to 12 weeks, allowing for a reduction of oral calcium and vitamin D substitution (Anton *et al.*, 1995). A combination of this technique with cell separation and *in vitro* culture passage yielded hormonally active allotransplants without immunosuppression for periods of 3 months and—in one case—for a period of 1 year (Tolloczko *et al.*, 1996). In 1989 Fu and Sun published the first short-term *in vivo* results (12 weeks) of functioning parathyroid allotransplantations without postoperative immunosuppression, by implanting parathyroid cells coated with an alginate, a natural substrate used for immunoisolation of cells. The technique of microencapsulation has since been continuously enhanced. Several long-term animal experiments have documented long-term survival of syn- and transgenous parathyroid transplants without any immunosuppressive therapy (Hasse *et al.*, 1994, 1996, 1997a,b,c, 1998a,b). The first two clinical cases in patients with postoperative hypoparathyroidism receiving successful parathyroid allotransplants without immunosuppression have been reported, utilizing the technique of microencapsulation (Hasse *et al.*, 1997d).

## HYPOPARATHYROIDISM

### DEFINITION

Hypoparathyroidism is defined as a reduction of the concentration of intact parathyroid hormone and (total) serum calcium to subnormal levels, caused by impaired or absent parathyroid function (Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Habener *et al.*, 1995). Persistent, symptomatic hypoparathyroidism is diagnosed when the parathyroid hormone deficiency syndrome persists for more than 6 months and/or is accompanied by complaints or sequelae commonly associated with hypoparathyroidism.

### ETIOLOGY AND CLASSIFICATION

Symptomatic hypoparathyroidism may occur in a primary and a secondary form (Potts, 1995). Cases in which the etiology is unknown or cannot be established with certainty are referred to as idiopathic hypoparathyroidism (Ziegler, 1976). In principle, all of the different forms of symptomatic hypoparathyroidism may be an indication for parathyroid allotransplantation. Therefore, all of the parathyroid hormone deficiency syndromes, including some rare ones, are included in the following discussions (Fig. 37.1).

### Primary hypoparathyroidism (congenital hypoparathyroidism)

Congenital forms of persistent hypoparathyroidism comprise three distinct entities: autoimmune hypoparathyroidism, DiGeorge syndrome, and Kenny–Linarelli syndrome. Only few reports of these exist in the world literature, not allowing for estimates of the prevalence of these entities. They are, however, quite rare compared to the acquired parathyroid hormone deficiency syndromes.

#### *Autoimmune hypoparathyroidism*

Autoimmune hypoparathyroidism most commonly occurs as a part of the polyglandular autoimmune syndrome, autoimmune polyendocrinopathy/candidiasis/ectodermal dystrophy (APECED). Two types of autoimmune polyendocrinopathy have to be differentiated. Autoim-

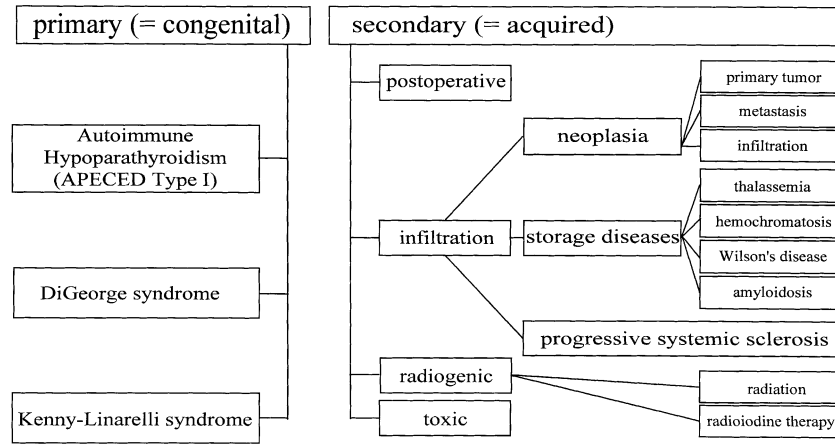

Fig. 37.1. Etiology and classification of diseases of persistent hypoparathyroidism.

Autoimmune hypoparathyroidism occurs only in association with type I, in which half of the cases are familial (autosomal recessive) and the other half are sporadic (Windeck and Reinwein, 1992). With variable frequency, type I is associated with pernicious anemia, Hashimoto thyroiditis, early-onset ovarian insufficiency, diabetes mellitus type I, and/or mucocutaneous candidiasis. Other ectodermal problems associated with type I autoimmune polyendocrinopathy include dental or nail dystrophy, alopecia areata, vitiligo, and keratinopathy (Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Windeck and Reinwein, 1992; Habener *et al.*, 1995). It is only in the familial cases that one may also encounter Addison's disease (Windeck, 1996). Persistent hypoparathyroidism is seen only in type I autoimmune polyendocrinopathy, with an incidence of 80%. Patients suffering from type II polyglandular autoimmune syndrome (Schmidt syndrome) have normal parathyroid function (Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Habener *et al.*, 1995).

### DiGeorge syndrome

Hypoparathyroidism in DiGeorge syndrome is due to agenesis of the parathyroid and the thymus gland caused by a failure of the development of the third and fourth branchial pouch. It may be associated with severe immunodeficiency, facial dysplasia, and anomalies of the heart (Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Windeck and Reinwein, 1992; Habener *et al.*, 1995; Windeck, 1996).

### Kenny–Linarelli syndrome

Kenny–Linarelli syndrome is an autosomal recessively inherited disease characterized by cretinism, delayed occlusion of the fontanel, myopia or hyperopia, cortical hyperostosis of cortical bones, and episodes of hypocalcemic tetanics due to hypoparathyroidism. Exogenous parathyroid hormone has been administered to patients affected by this syndrome, resulting in an increase of cAMP excretion in urine (Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Keck and Kuhlencordt, 1992; Habener *et al.*, 1995).

### Secondary hypoparathyroidism (acquired hypoparathyroidism)

Injury to the parathyroid glands during operative procedures in the neck is the main reason for acquired hypoparathyroidism. The parathyroids are either inadvertently removed or their blood supply is impaired by iatrogenic hypo- or devascularization, edema, or hematoma (Ziegler, 1976). The incidence of postoperative hypoparathyroidism is related to the type of surgery performed as well as to the event of prior surgery to the neck. Accordingly, the incidence may vary considerably, from 0 to 33% (Gann and Paone, 1979). Parathyroid hormone deficiency may also very occasionally be caused by neoplastic infiltration of the parathyroid glands. This has been reported for primary tumors of the parathyroid local tumors of various etiologies, and metastases (Ziegler, 1976, 1987; Keck and Kuhlencordt, 1992). Similar to the rare problems of the parathyroids secondary to progressive systemic sclerosis, storing of copper or iron, or amyloidosis, only very few cases have been reported or are anecdotally mentioned in textbooks (Fitzpatrick and Bilezikian,

branch of the facial nerve, may also be found in as many of 15% of healthy subjects. They are, however, considered characteristic of tetanic predisposition induced by hypocalcemia, if contractions in the area of distribution of the second and third branch of the facial nerve are elicited (Ziegler, 1976). Trousseau's sign is provoked by inflating a blood pressure cuff placed around the upper arm to pressures above the mean arterial pressure for several minutes. The test is regarded positive if carpopedal spasms are noted within 3 min. The test is positive in less than 1% of normocalcemic subjects (Ziegler, 1987; Keck and Kuhlencordt, 1992; Aurbach *et al.*, 1992; Habener *et al.*, 1995; Windeck, 1996). This sign may also be observed after 3 min of provocative hyperventilation (Ziegler, 1976; Fitzpatrick and Bilezikian, 1990). Both Chvostek's and Trousseau's signs were found in 55–62% of patients with postoperative hypoparathyroidism. Finally, the so-called Lust's sign is represented by reproducible extraplantar dorsiflexions of the foot, in response to tapping the fibular nerve at the height of the head of the fibula (Ziegler, 1976).

Laboratory tests will reveal low serum concentrations of total and ionized calcium, parathyroid hormone, and magnesium, as well as an increase of serum phosphate. Urinary excretion of calcium, phosphate, and cAMP is decreased. Normal serum levels of creatinine and urea, as well as normal levels of albumin, exclude renal insufficiency and syndromes of malassimilation as the cause of hypocalcemia, rendering the diagnosis of hypoparathyroidism very likely. Occasionally, electrocardiograms may show prolongation of the QT interval, caused by an increase in ST segments (Keck and Kuhlencordt, 1992; Windeck and Reinwein, 1992). Furthermore, T-wave inversion or peaking may be observed (Keck and Kuhlencordt, 1992).

Radiographic examinations in patients with congenital or long-standing persistent hypoparathyroidism may demonstrate scattered skeletal condensations combined with areas of demineralized bone as well as periarticular osteophytes (Windeck and Reinwein, 1992). Some 20% of patients will have evidence of calcifications of the basal ganglia or gray matter by plain radiograms or by computed tomograms of the skull (Keck and Kuhlencordt, 1992).

The diagnosis should be substantiated by functional tests. The diagnosis of hypoparathy-

<sup>b</sup>Mainly in children.

roidism is very likely if administration of intact parathyroid hormone (400 IU i.v.) yields a 5- to 10-fold increase of urinary phosphate excretion. This test is called the Ellsworth–Howard test (Ziegler, 1976; Keck and Kuhlencordt, 1992). If latent hypoparathyroidism is suspected, an ethylenediaminetetraacetate test (EDTA test) may be diagnostic. The EDTA chelate binds calcium potently. In healthy subjects, a decrease of ionized calcium following infusion of EDTA stimulates parathyroid (PTH) liberation, resulting in a fairly rapid restoration of normal serum calcium levels. In patients with latent hypoparathyroidism, this autoregulatory loop is deficient. During the test, serum calcium levels are repetitively determined before and after infusion of 50–70 mg sodium-EDTA per kilogram of body weight. In contrast to healthy individuals, a typical patient will not reach basal values of serum calcium within 12 hr after administration of the chelate (Ziegler, 1976). Another functional test can be used to differentiate pseudohypoparathyroidism from hypoparathyroidism. Healthy individuals as well as patients with primary hypoparathyroidism, administered infusions of synthetic human 1-34 PTH (30 µg within 5 min), will show a fourfold increase of 1,25-dihydroxy vitamin D within 24 hr, in contrast to those with pseudohypoparathyroidism, who will have no evidence of increasing levels of vitamin D. Electromyography (EMG) is a useful study to substantiate increased neuromuscular excitability. Doublets and triplets during hyperventilation evidence tetanic predisposition (Ziegler, 1976). If these signs and symptoms of hypoparathyroidism are accompanied by facial dysplasia in a child, the diagnosis of the rare DiGeorge syndrome is made. Persistent hypoparathyroidism combined with chronic mucocutaneous candidiasis leads to the diagnosis of APECED type I (Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Habener *et al.*, 1995). Table 37.3 depicts a complete investigative procedure in patients with suspected hypoparathyroidism.

## THERAPY OF HYPOPARATHYROIDISM

### Symptomatic therapy

Acutely symptomatic patients experiencing tetanic convulsions readily respond to slowly administered intravenous calcium (calcium gluconate, maximum of 2 ml/min) (Windeck, 1996). Care must be taken not to exceed a maximum dose of 15 mg calcium per kilogram of bodyweight (Ziegler, 1976). Chronic hypocalcemia due to persistent hypoparathyroidism is treated by continuous oral calcium. If relief of symptoms and serum calcium concentrations in the low normal range are not achieved with calcium alone, vitamin D (calcitriol) is given additionally (Windeck, 1996). Until the introduction of vitamin D in the 1930s, hypoparathyroidism was a life-threatening condition. Calcitriol raises serum calcium concentrations by osteolysis and by increasing intestinal absorption of calcium. Regular serum calcium and urinary calcium excretion tests are needed to evaluate the effectiveness of calcitriol therapy. The urinary calcium excretion must not exceed 250 mg/day (Windeck and Reinwein, 1992).

The overall course of persistent hypoparathyroidism mainly depends on how early therapy is initiated, its stringent implementation, and life-long control. Without adequate therapy and control, all of the symptoms and sequelae of the disease are imminent. Long-term therapy of patients in which the disease takes a rather moderate course with only minor symptoms is most challenging. A milder symptomatology is most commonly encountered in patients with postoperative hypoparathyroidism, representing by far the majority of patients with persistent hypoparathyroidism. Unspecific conditions such as bone pain, loss of energy, exhaustion, depressive mood, and latent convulsions are either ignored or unrecognized for many years until irreversible consequences arise (Ziegler, 1976, 1987). Permanent care of this large number of patients at risk is of particular importance.

However, even with rigorous, long-term therapy, sequelae of hypoparathyroidism may still occur. Chronic parathyroid hormone deficiency invariably results in a loss of activity of bone metabolism, resulting in osteoporosis and bone pain (Wagner, 1980). On the other hand, calcitriol lacks the full renal calcium-retaining ability of parathyroid hormone. Patients administered vitamin D inadvertently develop hypercalciuria, although their serum calcium levels may be normal or in the low normal range. Accordingly, these patients have an increased risk of nephrolithiasis, nephrocalcinosis, and subsequent impairment of renal function (Potts, 1995). Moreover, these patients have an increased risk of developing calcium depositions in the soft tissues, as well as accelerated arteriosclerosis.

Because the therapeutic range of calcium and vitamin D supplementation is small, patients are at risk of drug overdose at all times, manifesting as hypercalcemia syndrome of variable degree. Also, oral calcium and vitamin D supplements will level out the imbalances of calcium and phosphate metabolism at best. They are, however, unable to replace the many other metabolic actions of parathyroid hormone, which remain permanently untreated. It is therefore very important to provide definitive therapy for parathyroid hormone deficiency.

### Causative therapy

Treatment of the parathyroid hormone deficiency syndrome may involve administration of parathyroid hormone or transgenous transplantation of parathyroid tissue. In 1925 Collip described a hormone of the parathyroid glands to be the main factor in calcium homeostasis. However, it was not until 1978 that the hormone was sequenced in its entirety (Keutmann *et al.*, 1978). Meanwhile, genetically engineered human recombinant 1-34 PTH has become available. The first clinical trials indicate that, in principle, permanent hypoparathyroidism can be treated by recombinant 1-34 PTH (Winer *et al.*, 1996). For the time being, the short half-life and the *in vivo* instability of synthetic PTH do not allow for continuous, sufficient treatment. Moreover, resistance to the hormone after repetitive application has been described. Therefore, a major focus of continued research is to develop a tracer-bound hormone preparation, suitable for long-term replacement therapy.

Replacing the parathyroid organ is a much more promising approach if physiologic calcium homeostasis is to be achieved. Currently, parathyroid allotransplantation has been performed only with continuous systemic immunosuppression. This approach is not justified, because hypoparathyroidism is rarely ever a life-threatening condition and because systemic immunosuppression

causes significant side effects. The advantages of functional replacement of the organ are undisputed. Therefore, allo- and xenotransplantation of parathyroid glands without a need for systemic immunosuppression are a matter of intense research activity. Several different procedures have progressed from the stage of animal experimentation to that of first clinical trials. Encouraging results have been reported, particularly for those techniques that aim to either reduce the immunogenicity of the tissue to be transplanted or to immunoisolate it. At present, however, only first clinical observations have been published and none of the methods has yet been established as a clinical procedure (Anton *et al.*, 1995; Tolloczko *et al.*, 1996; Hasse *et al.*, 1997). Which of the methods, or combinations thereof, are best suited for long-term treatment of patients with symptomatic postoperative hypoparathyroidism awaits further clinical trials in larger series of patients.

## MICROENCAPSULATION

Microencapsulation refers to a process by which gas, fluids, or solid active ingredients are encapsulated by a shell substance, producing microspheres of a size ranging from 1  $\mu\text{m}$  to 7 mm, isolating the incorporated core substance from the surrounding environment (Franjione and Vasishta, 1996). In principle, the encapsulated substance may be released by three different ways. One is mechanical disruption of the capsule. For instance, microcapsules applied to the back of carbonless copy paper burst and release the incorporated dye when pressure is applied with a pen point. This application of the microencapsulation technology was first introduced by the American chemist Green in the 1930s (Fanger, 1974). Second, the capsule may slowly erode or biodegrade. This mechanism is utilized to encapsulate protein-reactive enzymes in powder detergents, which are released at defined conditions, e.g., a certain temperature. Finally, other applications make use of the fact that the contents of a microcapsule are released slowly over time by diffusion, maintaining the integrity of the capsule. This particular aspect, together with the ability of a microcapsule to isolate the core substance from its environment, have made this technology a major focus of interest in transplant medicine.

Ennis and James in 1950 devised the first apparatus by which they were able to obtain single droplets of a uniform size. They modified the principle of producing small amounts of aqueous and nonaqueous fluid spheres conceived in 1947 by Lane and Levvy and called it "droplet sizer" (Ennis and James, 1950). This apparatus was the progenitor of the microencapsulation technology from which many applications currently used in industry, basic research, and medicine have developed. The first application of this technology in the field of medicine was proposed by in 1964 Chang, who intended to develop artificial cellular systems to be used to replace blood. While investigating different carrier systems to encapsulate hemoglobin and several different enzymes simultaneously by thin nylonlike semipermeable membranes, he developed a method of microencapsulation based on interfacial polymerization. However, the reaction needs to be carried out under severe conditions, resulting in liberation of cytotoxic byproducts. Moreover, the membranes were found to be not entirely biocompatible, and the monomers are chemically active to the extent that necrosis of cells is induced. This prompted extensive efforts for alternative shell substances.

## ALGINATES

Alginates are extracted from brown algae (*Macrocystis pyrifera*), which are most commonly found on the shorelines of Scotland and Great Britain. In the seventeenth century it was known that the ashes of brown algae contained high amounts of soda, which was used in the production of soap and glass. In 1811, iodine was discovered in the ashes. After less expensive methods to produce soda had been established, the production of potash and iodine kept the local algae-based industry alive. Today, alginates are used for many different purposes in industry (e.g., food, concrete, fire-resistant synthetic materials) as well as in medicine (wound dressings, prosthetics, orofacial surgery). Commercially extracted alginates are a mixture of uronic acid polymers, composed mainly of mannuroic and guluronic acid. Calcium ions are used as a cross-linking agent. The polymer is a complex three-dimensional network of varying density, depending on the concentration of the two mayor compounds. Grant *et al.* (1973) have referred to the ultrastructure of the cross-linked polymer as an "egg-box model" because of a similar pattern of layering.

In 1977 Kierstan and Bucke were the first to use alginates as a shell substance in microencapsulation. For the first time, microencapsulation of viable cells was achieved. By dropwise addi-

tion of cells immersed in sodium alginate into a calcium chloride solution, stable hydrogel beads were formed (Kierstan and Bucke, 1977). A drawback of this technique is the instability of the capsule. Biodegradation occurs as a consequence of dilution of calcium ions reacting with phosphates of the recipient. Therefore, Lim and Sun (1980) proposed to coat the alginate capsules with a second membrane of poly(L-lysine) (PLL membrane). Zimmermann and co-workers (1992) succeeded in integrating more stable ions, e.g., barium, as cross-linking agents. Appropriate incubation conditions provide highly stable, fully biocompatible alginates.

## EXPERIMENTAL AND CLINICAL TRANSPLANTATION OF MICROENCAPSULATED PARATHYROID TISSUE

We adopted the well-described technique of microencapsulation with alginates already used in pancreatic islet cell transplantation and modified it extensively for transplantation of parathyroid tissue. Combining refined tissue culture techniques and microencapsulation, iso-, allo-, and xenotransplantation of microencapsulated parathyroid tissue were reproducibly achieved in an animal model of experimental hypoparathyroidism without a need for systemic immunosuppression (Hasse *et al.*, 1994, 1997a).

Prior to the first clinical use, continued analysis of the alginate for the purpose of biocompatibility testing revealed mitogenic properties. Using patented techniques, a purified, amitogenic alginate suitable for clinical use was isolated by the Institute of Biotechnology of Würzburg, Germany (Zimmermann *et al.*, 1992; Klöck *et al.*, 1994). The novel alginate displayed distinctly different biochemical and biophysical properties compared to the mitogenic alginate, which required several adjustments of the purification and the microencapsulation procedures. However, subsequent *in vivo* studies in syn- and allogenic animal models unequivocally showed that the same results as with the mitogenic alginate were also obtained when the novel amitogenic alginate was used (Hasse *et al.*, 1996, 1997b,c, 1998a,b). These results founded the rationale for a first clinical use of microencapsulated parathyroid allotransplants in patients suffering from symptomatic persistent postoperative hypoparathyroidism. We have published the data on the first two patients treated with this method. Twelve weeks following allotransplantation of cultured and microencapsulated hyperplastic parathyroid tissue, the two patients were normocalcemic and had normal levels of parathyroid hormone without immunosuppression. Both patients reported an impressive improvement of symptoms and sequelae of hypoparathyroidism (Hasse *et al.*, 1997d).

## ALTERNATIVE APPROACHES AND PERSPECTIVES

The feasibility of parathyroid allotransplantation to patients receiving systemic immunosuppression has already been outlined. This has repeatedly and successfully been performed during transplantation of the kidney, pancreas, heart, and liver, and, because these patients already require life-long immunosuppression, is an entirely justified approach (Groth *et al.*, 1973; Starling *et al.*, 1977; Wells *et al.*, 1979; Bloom *et al.*, 1987). For the time being, this approach is the only clinically established method that allows for a definitive therapy of persistent symptomatic hypoparathyroidism.

Reducing the immunogenicity of parathyroid tissue has been accomplished utilizing several different methods. However, except for the few already mentioned exceptions, these methods will not be of clinical relevance until long-term success is documented for clinical allografting without prolonged immunosuppression (Anton *et al.*, 1995). It would therefore appear that the only two alternatives to allotransplantation of cultured and microencapsulated parathyroid tissue that may be of relevance for the treatment of hypoparathyroid patients without posttransplant immunosuppression are substitution of parathyroid hormone and implantation of parathyroid cells pretreated by specific tissue culture methods aiming to reduce its antigenicity. All of these approaches are at the stage of first clinical trials.

Earlier attempts to use bovine PTH were hampered by an invariable development of antibodies, resulting in hormone resistance (Melick *et al.*, 1967). Although synthetic human PTH has become available, it appears that development of hormone resistance prevails. In 1990 Stögmänn *et al.* reported their initial experience with two patients treated with subcutaneous injections of synthetic human 1-34 PTH (400 E daily). One patient developed resistance after only 10 weeks and the other was able to maintain normal levels of serum calcium for a period of 7 months. The further history of these patients is unknown (Stögmänn *et al.*, 1990). These observations were con-

firmed in another report of a larger series of patients treated for a period of 10 weeks. During this short-term trial, therapy with 1-34 synthetic PTH was successful. However, the problem of overcoming resistance during long-term treatment remains to be solved (Winer *et al.*, 1996).

In 1991 Tolloczko *et al.* reported several cases in which allografting of cultured parathyroid cells by subfascial injection to the nondominant forearm had been performed. Their series, currently comprising 23 patients, of whom some showed evidence of allograft function for up to 14 months after the transplantation without immunosuppression, has been updated (Tolloczko *et al.*, 1991, 1994, 1996). Unfortunately, the details of how these results were achieved are not entirely clear. At first, hyperplastic parathyroid tissue from patients with renal hyperparathyroidism was assessed for infiltration with passenger lymphocytes and expression of HLA antigens using immunohistochemical methods. Without a detailed description of selection criteria, 10–15 particles of parathyroid tissue that seemed most appropriate were used for *in vitro* culture. Tissue culture was initiated by primary explant technique and maintained for 6 to 12 weeks, apparently without further attempts to select for parathyroid cells. Subsequently,  $2 \times 10^6$  to  $2-3 \times 10^7$  viable cells, assumed to be antigen-depleted parathyroid cells, were allotransplanted (Wozniewicz *et al.*, 1996). However, during the serial subculture an exponential decrease of PTH secretion was noted, which may be explained either by necrosis of parathyroid cells or by fibroblastic overgrowth. Cellular contamination and residual antigenicity were underscored by an increasing posttransplant donor-specific T cell reactivity, with gradual cessation of parathyroid allograft function observed in all recipients (Tolloczko *et al.*, 1994).

At present, there is no validated approach, without immunosuppression, to treat the considerable number of patients with persistent hypoparathyroidism. However, several developments have delivered promising early results. Evidently, a combination of different methods—including those that reduce the immunogenicity and immunoisolate the graft—is needed to achieve long-term *in vivo* graft function without posttransplant immunosuppression. To optimize these different approaches and investigate the clinical utility of their combination is a promising approach that should be further explored.

1990; Aurbach *et al.*, 1992; Keck and Kuhlencordt, 1992; Habener *et al.*, 1995; Windeck, 1996). This is also true for some isolated cases of hypoparathyroidism occurring after irradiation therapy, radioiodine treatment, and chemotherapy (Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Keck and Kuhlencordt, 1992; Habener *et al.*, 1995).

### PATHOGENESIS

The concentration of ionized extracellular calcium is regulated by parathyroid hormone and vitamin D (calcitriol) within tight margins of variance. Due to a reduction of parathyroid hormone-dependent osteoclastic bone resorption, chronic parathyroid hormone deficiency invariably results in hypocalcemia. The symptoms of parathyroid hormone deficiency are caused by hypocalcemia (Ziegler, 1976; Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Habener *et al.*, 1995). Serum calcium concentrations may drop to a minimum of 1.5 mmol/liter. Below this threshold range, the gradient between the calcium concentration of the bone and that of the unsaturated extracellular fluid is such that bone-derived calcium will effectively go into solution independent of parathyroid hormone (Ziegler, 1976). In this respect, the often observed hyperphosphatemia, resulting from an increase in tubulorenal reabsorption, is of minor importance.

### SYMPTOMS

The signs and symptoms of chronic hypoparathyroidism were first described in 1941 by Lachmann. One of the main features of symptomatic hypoparathyroidism is increased neuromuscular excitability resulting from hypocalcemia (Ziegler, 1976; Wagner, 1980; Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992). Hyperexcitability may cause severe muscular convulsions without loss of consciousness (Keck and Kuhlencordt, 1992; Habener *et al.*, 1995). They are either appreciable as tonic convulsions or isolated muscular spasms, which often occur as symmetric spasms of the extremities (Wagner, 1980; Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992). The characteristic clinical sign of carpopedal tetany induced by hypocalcemia is referred to as “obstetricians’ hand” and talipes in the case of tarsopedal tetany (Ziegler, 1976, 1987; Wagner, 1980; Fitzpatrick and Bilezikian, 1990; Keck and Kuhlencordt, 1992; Habener *et al.*, 1995). Spasms of the perioral muscles cause a typical facies commonly referred to as “fish mouth appearance” (Ziegler, 1987). The bronchi and the respiratory muscles may also be affected, causing laryngeal spasms and severe dyspnea (Aurbach *et al.*, 1992; Keck and Kuhlencordt, 1992). Occasionally, hypocalcemia may also be responsible for cramping abdominal pain, hence the term visceral tetany, and for stenocardic complaints in some patients (Ziegler, 1987; Fitzpatrick and Bilezikian, 1990; Aurbach *et al.*, 1992; Habener *et al.*, 1995; Windeck, 1996).

All of these spasms may occur without any appreciable precipitating cause, yet more often in situations of increased physical or psychic stress. They may last for only a few minutes as well as for up to several hours. Females are more often affected than males and a periodic increment in frequency as well as severity has been reported, suggesting a relation to the menstruation cycle. Also, these spasms apparently have a tendency to occur more often during spring and autumn (Ziegler, 1976).

The typical clinical appearance of a tetany is easily diagnosed; however, in only one-fourth of patients is it fully appreciable (Ziegler, 1987). This may explain why less obvious cases of “latent” hypoparathyroidism are often overlooked. Muscular hyperexcitability may be discrete and appreciated only as aching, tingling, and numbness of extremities [“tingling paraesthesia” (Ziegler, 1976; Wagner, 1980; Habener *et al.*, 1995)].

A comprehensive synopsis of all the symptoms associated with persistent hypoparathyroidism is given in Table 37.2.

### DIAGNOSIS

An in-depth patient history and physical examination are the keystones of making the diagnosis of hypoparathyroidism. Symptoms and sequelae of the disease as described previously are considered; they are either reported by the patient or are found as a result of a meticulous questioning and exam. A number of clinical tests can be employed. For instance, tapping the cheek of the patient just anterior to the ear, may cause reproducible contractions of the facial muscles, a sign commonly referred to as Chvostek’s sign (Ziegler, 1987; Keck and Kuhlencordt, 1992; Habener *et al.*, 1995; Windeck, 1996). Such contractions of the facial muscles, conducted by the third

## INTRODUCTION

Tissue engineering is an emerging multidisciplinary effort for therapeutic intervention beyond the current state-of-the-art treatments for a variety of clinical scenarios in which there is insufficient tissue. The rationale and historical background for the current state of tissue engineering neointestine for patients suffering from short bowel syndrome is addressed. Specific emphasis is placed on enterocyte isolation and morphogenesis of tissue-engineered neointestinal mucosa.

The maintenance of life by all organisms is dependent on the acquisition and utilization of food. Nutrients are broken down into simple compounds and provide the energy necessary for the maintenance of bodily functions as well as the materials for growth of the organism and repair of tissues that have been damaged.

Simple forms of life, such as bacteria, absorb their nutrients directly through their outer surface layer. As multicellular animals have evolved, specialized cavities have developed in which food is prepared for absorption by a process of digestion. The alimentary tract in humans is a highly specialized organ that is anatomically and functionally divided into the mouth and pharynx (mastication and swallowing), esophagus (transport), stomach and small intestine (digestion, absorption, endocrine, and immunologic), and colon (absorption of water and evacuation). In addition, the liver and pancreas, glandular organs connected by special ducts to the lumen of the intestine, produce juices that aid in the digestive and absorptive process (Hamilton and McMinn, 1976).

A widely varied pathology can affect the different regions of the alimentary tract, requiring different modes of treatment. The goal of any surgical intervention is to remove diseased or insufficient tissue and to reconstruct the remaining tissues in an anatomically and physiologically meaningful fashion. Surgical ablation can result in significant tissue loss of single or multiple anatomic subdivision(s). In most circumstances successful anatomic reconstruction can be achieved without substantial loss of function. The small intestine is a notable exception due to its unique characteristics for digestion and absorption.

Short bowel syndrome (SBS) refers to a condition of malabsorption and malnutrition following major resection of the small intestine, which may also include some or all of the large intestine. The clinical signs and symptoms of SBS are characterized primarily by intractable diarrhea, steatorrhea, weight loss, dehydration, malnutrition, vitamin and electrolyte deficiencies, as well as macrocytic anemia (Tilson, 1980).

The diseases leading to massive small bowel resection depend on the age group of the patient. In newborns, congenital short small bowel, multiple bowel atresias, extensive aganglionosis (Hirschsprung's disease), gastroschisis, meconium peritonitis, and acquired disease such as midgut volvulus and necrotizing enterocolitis all have the potential for producing insufficient intestinal length. In children and adults the common causes include abdominal trauma, Crohn's disease, radiation enteritis, and mesenteric ischemic vascular disease (Kern *et al.*, 1990). In adults, resection of 70% or more of the small intestine can significantly impair the ability of the patient to maintain normal nutrition and metabolism. These patients require special nutritional care on a long-term or permanent basis, especially with the loss of the terminal ileum and ileocecal valve (Du-

drick *et al.*, 1991). Infants with greater than 10–15 cm of jejunioileum with an intact ileocecal valve or 25–40 cm of small bowel without the ileocecal valve are usually given the benefit of long-term parenteral nutrition to allow their residual intestine sufficient time to adapt and permit survival without parenteral nutrition (Williamson, 1978a,b).

Intestinal adaptation occurs due to a variety of luminal, circulating, and cellular influences resulting in increased gut surface area for absorption through mucosal hyperplasia, villous lengthening, deepening of intestinal crypts, and increase in diameter of the remaining intestine (Chaves *et al.*, 1987; Lak and Baylin, 1983; Unger *et al.*, 1968; Weber *et al.*, 1991). These adaptive changes occur slowly and can take up to 2 years before adequate nutrition can be maintained through oral intake alone. Children have greater adaptive potential than adults do because the intestine grows as the child ages (Touloukian and Smith, 1983).

Survival of patients with SBS, particularly infants and children, has improved primarily because of the increased use of total parenteral nutrition (TPN) both during hospitalization and at home (Cooper *et al.*, 1984; Dorney *et al.*, 1985; Grosfeld *et al.*, 1986). However, this therapy is not without consequence. Catheter-related complications (systemic infection, venous thrombosis, mechanical breakage, and malfunction) are frequent and the vast majority of patients require rehospitalization (Caniano *et al.*, 1989; Thompson, 1990). Progressive bone demineralization is characteristic of patients on chronic TPN (Foldes *et al.*, 1990). Transient liver enzyme abnormalities, cholestasis, and cholelithiasis are common. Progressive cholestatic jaundice and cirrhosis associated with TPN account for more than 50% of deaths among infants and children maintained with chronic TPN and 5% of deaths among adults (Howard *et al.*, 1986). The cost of TPN at home currently exceeds \$150,000 per year.

Numerous innovative surgical techniques for increasing intestinal surface area and improving absorption have been developed. Several approaches have been investigated, including tapering (Weber *et al.*, 1982) and lengthening (Pokorny and Fowler, 1991) residual intestine, slowing intestinal transit by creating artificial ileocecal valves (Ricotta *et al.*, 1981) and utilizing reversed intestinal segments (Diego *et al.*, 1982), recirculating loops of bowel and growing intestinal neomucosa (Thompson *et al.*, 1984), and intestinal transplantation (Bueno *et al.*, 1999; Reyes *et al.*, 1998).

None of the currently available surgical alternatives for treatment of SBS is sufficiently safe and effective for routine and widespread use. Transplantation of small intestine seemingly offers the most reasonable alternative in patients with near fatal loss of intestine and therefore no hope for adaptation and in those with intolerance to TPN. Despite recent improvements in immunosuppression and preservation of harvested small intestine, the major clinical obstacle to intestinal transplantation continues to be allograft rejection, graft-versus-host disease, and cytomegalovirus infection (Reyes *et al.*, 1998; Schraut *et al.*, 1986). The development of lymphoproliferative complications is also a major concern. The adverse effects to growth and development of chronic corticosteroid use in children are a significant limitation. Thus, the mortality and morbidity remains high with intestinal transplantation. Furthermore, when these immunologic problems are resolved, this therapy will still be faced with donor scarcity, the other significant problem facing all of the field of whole-organ transplantation.

## TISSUE ENGINEERING

Transplanting selected cell populations is a method to create new tissue substitutes for the replacement and repair of lost or damaged tissue (Russell, 1985). The emerging field of tissue engineering involves a multidisciplinary effort, merging the fields of cell and molecular biology, materials science, and surgical reconstruction to engineer new tissue (Langer and Vacanti, 1993).

A variety of strategies have been adopted by numerous investigators to engineer virtually every mammalian tissue. Our laboratories have been utilizing highly porous synthetic polymeric devices to deliver the transplanted cells to a given anatomic location, and to serve as a template for the reorganization of the transplanted cells as they form new tissue (Vacanti *et al.*, 1988). The morphogenesis of the implanted cell–polymer construct involves the ingrowth of fibrovascular elements from the host implantation site into the graft, resorption of the bioerodable scaffold, and expression of a differentiated phenotype by the implanted cells in a permanently engrafted new tissue. Various surgical manipulations have been explored and incorporated into the tissue engineering

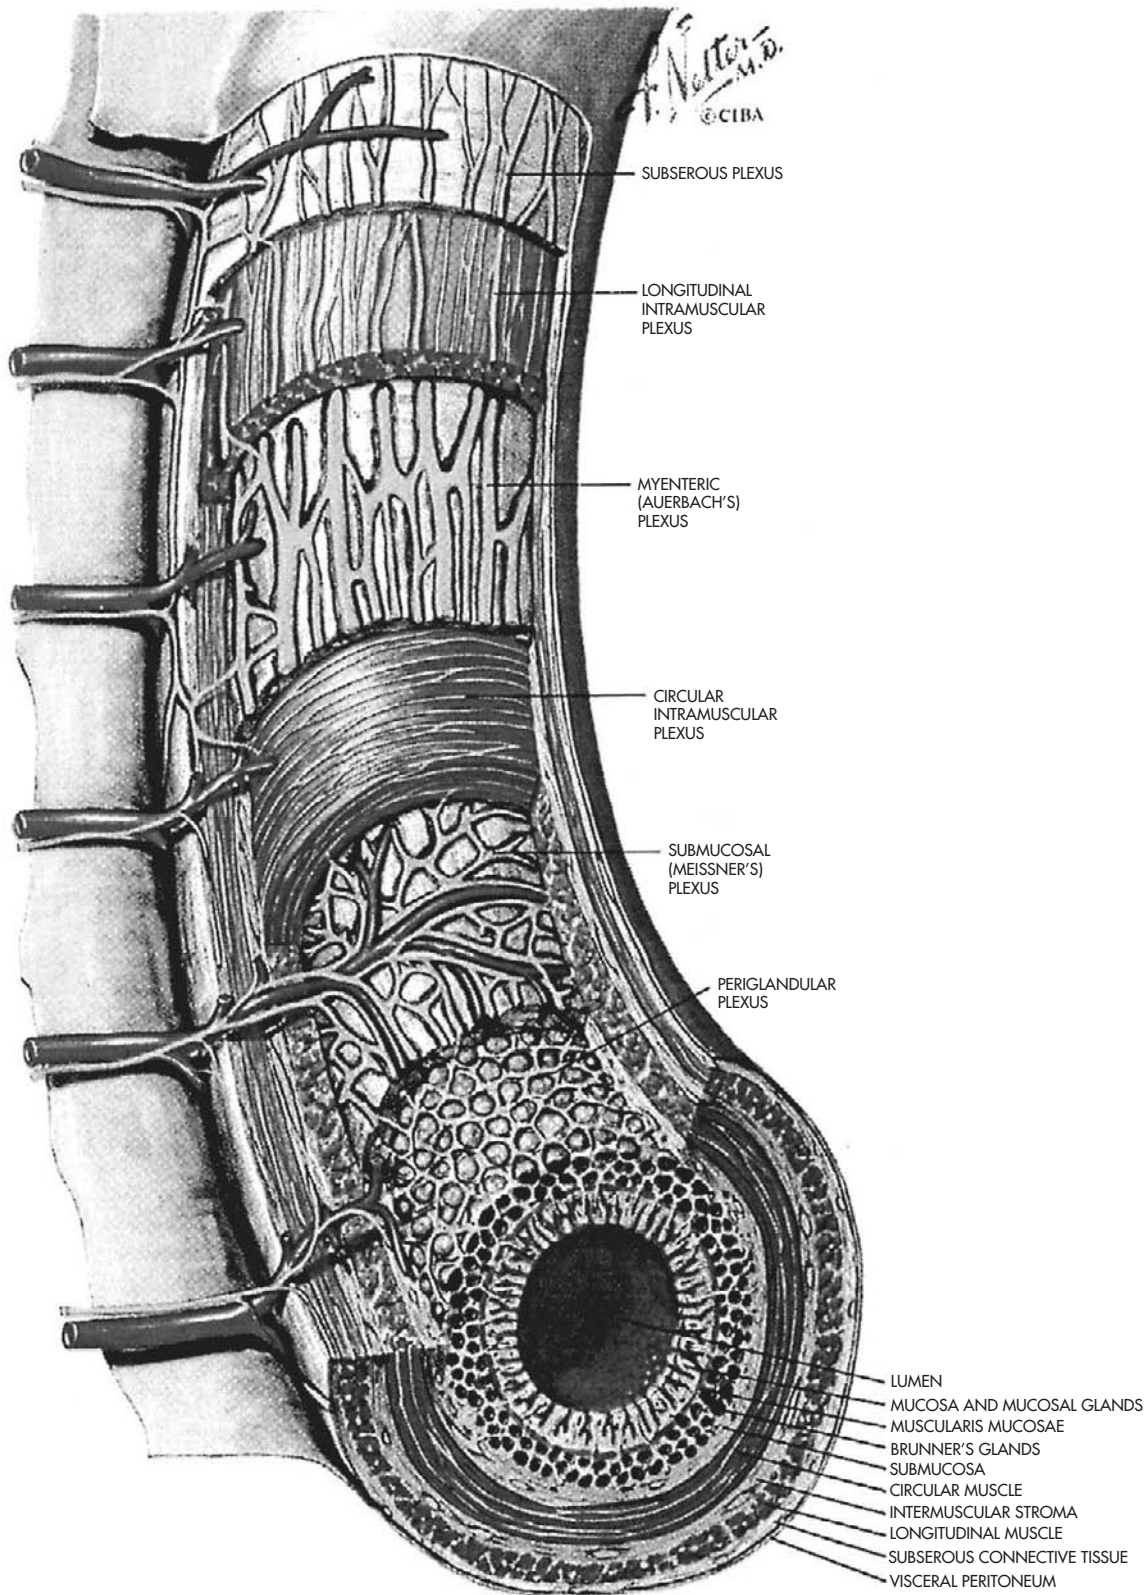

Fig. 38.1. The small intestine is a laminated, tubular organ composed of an inner mucosal layer for digestion and absorption and an outer neuromuscular layer for peristaltic propulsion of nutrients. Netter, M.D., All rights reserved.

strategy to take advantage of adaptive responses. A successfully engrafted and functioning new three-dimensional cell mass would be a true chimera of implanted parenchymal elements from the donor and mesenchymal elements (endothelial cells, fibroblasts, lymphatic and neural cells) from the recipient. The term “chimeric neomorphogenesis” has been coined to describe this approach (Vacanti, 1988).

The small intestine is a laminated, tubular organ composed of an inner mucosal layer for digestion and absorption and an outer neuromuscular layer for peristaltic propulsion of nutrients (Fig. 38.1). The goal of this project is to develop a small animal model for generating new intestinal mucosa, to increase intestinal epithelial surface area for digestion and absorption, as the essential first step to tissue engineer a composite tubular tissue with a neuromuscular coat. The fundamental elements in our approach to engineer new tissue equivalents consist of parenchymal cell isolation, cell–polymer construct formation, cell–polymer construct implantation, and histologic and functional assessment of the engrafted tissue. Perhaps the most critical step in this process is the isolation procedure. A guiding principle of tissue engineering any tissue equivalent is that the harvested parenchymal cells must be viable and maintain their ability to regenerate the tissue of interest *in vivo*.

## ENTEROCYTE ISOLATION

The epithelial cells of the small intestine, referred to as intestinal epithelial cells (IECs) or enterocytes, represent a rapidly renewing cell population characterized by continuous growth and differentiation *in vivo* (Carnie *et al.*, 1965a,b; Cheng and Leblond, 1974a,b). Cell replication is limited to the lower two-thirds of the crypts and is balanced by continuous loss of differentiated cells at the villus tip (Fig. 38.2). This pattern of programmed cell death has been termed apoptosis (Potten *et al.*, 1997). IECs have a rapid cell turnover, with a mean cell life-span of 2–3 days in most animals. Approximately 75% of IECs are differentiated, mature absorptive columnar-shaped villus cells and 25% consist of their precursors, the rapidly proliferating undifferentiated cuboidal-shaped crypt cells. Differentiation of these mitotically active crypt cells is accompanied by dramatic changes in enzyme and transport activities along with changes in morphology, including the appearance of a well-organized brush border at the luminal surface and a more columnar cell shape. The four main cell types of the intestinal epithelium—villus columnar, mucous goblet, enteroendocrine, and Paneth cells—originate from pluripotent stem cells located in the crypts of Lieberkuhn (Cheng and Leblond, 1974a,b).

In the first edition of “Principles of Tissue Engineering” we described our initial approach at tissue engineering neointestinal mucosa utilizing suspensions of individual or small clusters of IECs (Organ and Vacanti, 1997). Weiser’s chelating method for isolating IECs in a villus-to-crypt cell gradient was modified to harvest IECs on a large scale (Organ *et al.*, 1993a,b; Organ and Vacanti, 1995). A syngeneic Lewis rat model as developed for selective isolation of highly proliferative, crypt cell-enriched fractions of IECs. IECs were seeded onto  $10 \times 10 \text{ mm}^2$  sheets of non-woven fibers of poly(glycolic acid) (PGA) to form constructs. IEC–PGA constructs were rolled around a silastic stent and implanted into various vascular beds. Histologic analysis confirmed that the grafts (1) contained cells that have the cytologic characteristics of IECs and formed a stratified epithelium, (2) had positive cytokeratin immunohistochemical staining features of epithelial cells, (3) showed labeling of implanted IECs with fluorescent vital dyes, confirming the origin of the engrafted cells, and (4) maintained remarkable proliferative cell capacity up to 28 days after implantation. At any of the observed time points out to 60 days, there was not evidence of neomucosa that had remodeled with typical small intestinal villus/crypt morphology. The histologic appearance of the transplanted IECs was reminiscent of fetal intestinal development, arrested at the stratified epithelial stage.

Advances in the field of developmental biology have focused on the importance of the epithelial–mesenchymal interactions, particularly in intestinal organogenesis (Kedinger *et al.*, 1986, 1987). Evans and Potten described an improved method of isolating IECs utilizing neutral protease and collagenase (Evans *et al.*, 1992). This method yields intact crypts with their pericryptal fibroblast, thus maintaining the epithelial–mesenchymal interaction. The resulting crypt cell aggregates (IECs) have been shown to have significantly improved viability, greater *in vitro* proliferation, and expression of differentiated function.

## PROCEDURAL STEPS

### IECA ISOLATION

Neonatal (6–26 g) Lewis rats ( $n = 4–8$ ) serve as donors (Organ *et al.*, 1998a,b). Under Enflurane inhalation anesthesia the abdominal viscera are eviscerated through a midline laparotomy. The stomach is intubated, the distal ileum transected, and peroperative lavage performed with 30 ml of 0.9% normal saline at room temperature to remove fecal material and mucous debris. The intestine is lavaged with 10 ml of Dulbecco's Modified Eagle's Media (DMEM) at 0–4°C to institute a state of cellular hypometabolism. The intestine is ligated distal to the ligament of treitz and at the distal ileum. The mesenteric attachments are sharply divided and the bowel is measured and placed in a glass petri dish on ice with Hank's Balance Salt Solution (HBSS). After harvesting all the donor bowel, the small intestine is slit longitudinally and sharply diced into sections 2–3 mm<sup>2</sup>, transferred to a T25-ml flask, and washed eight times in 25-ml changes of HBSS at 0–4°C with vigorous shaking on an orbital shaking platform at 80 cycles/min. The contents are transferred to a sterile petri dish and sharply diced into pieces 1 mm<sup>3</sup> and transferred into a T25-ml flask for enzymatic digestion (see Fig. 38.3 for details of isolation).

Fig. 38.3. Evans and Potten collagenase/dispase method for IECA isolation. (a) 1 mm<sup>3</sup> diced segments of small intestine are placed into a T25 flask with 20 ml of ES on an orbital shaking platform (80 cycles/min  $\times$  25 min at 25°C). (b) Pipette suspension vigorously for 30 sec with a 10-ml pipette and transfer to a 60-ml conical tube (tube A). (c) Allow suspension to sediment under gravity for 60 sec. Carefully remove the supernatant and transfer to conical tube B at 0–4°C. (d) Resuspend sediment in tube A with 20 ml of ES and repeat step c twice. (e) Add 10 ml of DMEM-S to conical tube B, mix, and centrifuge at 8 g for 2 min at 0–4°C. Carefully aspirate supernatant and discard. (f) Resuspend pellet in tube B with 20 ml of DMEM-S and repeat step e centrifugation and supernatant aspiration cycles 4 times. (g) Resuspend pellet 100–200  $\mu$ l in DMEM 3–5 ml to form final suspension for construct formation and assays. Media: ES, 0.1 mg/ml dispase (neutral protease type I, Boehringer) and 300 U/ml collagenase (type XI, Sigma) in Hank's Balanced Salt Solution (Life Technologies), pH 7.4; DMEM-S, Dulbecco's Modified Eagle Medium (1  $\times$  high glucose with L-glutamine, Life Technologies) + 2.5% fetal calf serum (lot no. 1007757, Life Technologies) + 2% fungizone, 0.25  $\mu$ g/ml (Biowhittaker). From Evans *et al.* (1992).

## ASSAYS

The final suspension of isolated IECAs is counted in a standard hemocytometer. The dimensions of the IECAs, which are estimated to contain 600–800 cells in a single crypt aggregate, preclude performing hemocytometric counts in the standard fashion (i.e., applying the suspension to the trough of the hemocytometer and allowing the chamber to fill by capillary action). We have modified the procedure by applying 12  $\mu\text{l}$  of the final suspension onto the surface of the hemocytometer, placing the cover slip, and then counting four quadrants in the standard fashion. Hemocytometer counts are performed in triplicate. The final IECA suspension is assayed for cell protein, measured in triplicate, as a separate measure to quantitative cellular mass. Viability is determined by mitochondrial reduction of a tetrazolium salt, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), to formazan, measured spectrophotometrically (OD 570 nm) in triplicate (Plumb *et al.*, 1989).

To quantify seeding efficiency a cohort of IECA–PGA constructs ( $n = 2\text{--}4$ ) are seeded with 500  $\mu\text{l}$  of the final suspension in a separate 24-well plate and incubated for 60 min in a 5%  $\text{CO}_2$  incubator at 37°C. Constructs are removed from their original seeding well and placed into a secondary well. MTT activity is measured in the original seeding wells and grafting efficiency is determined by the percentage of MTT activity of the residual IECAs in the original seeding well divided by the MTT activity of the final suspension. IECA cell mass delivered is derived by multiplying the MTT-generated grafting efficiency by the number of IECAs seeded. Donor neonatal intestine yields  $779 \pm 224^*$  IECA/cm. Employing eight donors, the final suspension typically contains  $10,645 \pm 2979^*$  IECA/ml with a cell protein concentration of  $2.18 \pm 0.08^*$  mg/ml. Relative viability of IECA was  $25.5 \pm 1.5^*$  OD/mg cell protein. Seeding efficiency was  $83 \pm 1.1\%^*$ , resulting in delivery of  $4418 \pm 1236^*$  IECA/cm<sup>2</sup> (\*, SEM).

## IECA–PGA CONSTRUCT FORMATION

A volume of 500  $\mu\text{l}$  of the final IECA suspension is gently seeded onto 1-cm<sup>2</sup> patches ( $n = 4\text{--}8$ ) of nonwoven polymer fibers (diameter, 15  $\mu\text{m}$ ; pore size, 150–200  $\mu\text{m}$ ; 4-ply at 80–100  $\mu\text{m}$  thickness, Davis & Geck) of poly(glycolic acid) in a 24-well plate (Fig. 38.4). The seeding

Fig. 38.4. Scanning electron micrograph of freshly seeded IECA–PGA construct. The IECA is firmly adherent to the PGA fiber. Courtesy of D. J. Mooney, University of Michigan, Department of Chemical Engineering.

technique for optimal distribution and attachment efficiency is to apply the final IECA suspension a single drop at a time, in a smooth, circular motion starting at the center of the PGA and proceeding toward the edges. An additional 500  $\mu$ l of DMEM is gently added to each well. IECA-PGA constructs, grouped in cohorts of four constructs per 24 well plate, are placed in a 5% CO<sub>2</sub> incubator at 37°C for 1–2 hr prior to implantation.

### IMPLANTATION

Four constructs are implanted as a single cohort. On removal from the incubator, the IECA-PGA constructs are placed on ice. The constructs are gently rolled around a sterile silastic stent (outer diameter, 2.2 mm) and placed on the eviscerated omentum of a male Lewis rat (50–225 g). The omentum is atraumatically folded around the construct and secured with 7-0 Prolene sutures placed in a nonischemic fashion, parallel to the gastroepiploic arcade. The omentum is returned to the peritoneal cavity, 1–2 ml of sterile normal saline is added to the abdominal cavity for postoperative fluid resuscitation, and the incision is closed in two layers.

### HISTOLOGIC ASSESSMENT

IECA-PGA grafts are retrieved at serial time points out to 28 days and fixed in 10% buffered formalin. Stents are removed and the implants are cross-sectioned into thirds and embedded in paraffin. Three to four serial 5- $\mu$ m sections are mounted on glass slides and submitted for histologic evaluation after staining with hematoxylin and eosin. Selected sections were evaluated with periodic acid/Schiff, mucicarmine, and CEA stains.

Histologic evaluations at various time points up to 1 month after implantation demonstrate a distinct pattern of morphogenesis. IECA-PGA constructs stimulate a characteristic pattern of acute inflammation followed by a rich fibrovascular ingrowth from the omental implantation site from day 3 to day 7. During this time period, IECA form microcystic structures that are identified as early as day 3 and are prominent by day 7. The microcysts appear adherent to the PGA fibers and are surrounded by a fibrovascular stroma (Fig. 38.5). Cysts are found superficial to a layer of fibroblasts situated adjacent to the luminal stent. Evidence of cytologic differentiation is not appreciated during the first week. Depletion of goblet cells is characteristic of the late phase of intestinal epithelial injury and early regeneration (Lewin *et al.*, 1992b).

Day 10 implants are characterized by development of a simple cuboidal/columnar epithelium, with basally oriented nuclei, that appear to be emanating from cryptlike structures (Fig. 38.6a). This neointestinal epithelium develops on a bed of granulation, presumably from the omentum, adjacent to the luminal stent. The thin band of fibroblasts, visualized adjacent to the stent on day 7, seem to have been separated from the underlying granulation tissue by the advancing epithelium. Areas of transition from cuboidal to columnar cells bear a striking resemblance to regenerating intestinal epithelium recovering from a variety of pathologic insults (Lewin *et al.*, 1992a). By day 14 immature villi are present and mitotic figures are seen exclusively in the crypts (Fig. 38.6b). Goblet cells are abundant, and positive staining of the cytoplasmic droplets with mucicarmine and periodic acid/Schiff confirm this level of phenotypic differentiation. The lumen is filled with degenerated cells and debris, suggesting apoptosis is occurring. The PGA fibers are engulfed by a chronic foreign body response.

By day 28 the neointestinal mucosa displays mature villus-crypt axis formation (Fig. 38.7a). Ongoing proliferation is apparent by the presence of multiple mitotic figures isolated to the crypts (Fig. 38.7b). In addition to goblet cells, Paneth cells are identified by their characteristic large, supranuclear, eosinophilic granules in the base of the crypts (Lewin *et al.*, 1992a). Occasional argentaffin cells are also seen. Positive CEA staining was not a feature observed in plants at any of the time points. The grafting efficiency for this study was 54%.

### DISCUSSION

The goal of this effort is to tissue engineer a short segment of tissue equivalent to the small intestine as therapy for those afflicted with SBS. In essence, the small intestine is a laminated, tubular organ composed of an inner mucosal layer for digestion and absorption and an outer neuromuscular tube for peristalsis. We have focused on the intestinal epithelium as the fundamental step in this endeavor.

Our initial approach at tissue engineering neointestinal mucosa concentrated on implanting

Fig. 38.5. Day 7 IECA-PGA implant. (a) Low-power view demonstrating rich fibrovascular ingrowth from the omentum. The triangle is directed at the IECA forming the microcyst. L, Lumen after the stent is removed. Bar, 100  $\mu\text{m}$ . (b) Triangles identify the implanted IECA forming the adjacent microcystic structures, lined with simple cuboidal/columnar epithelium. Black arrow heads are PGA fibers in cross-section. Bar, 50  $\mu\text{m}$ .

constructs of individual small clusters of IECs from crypt cell-enriched fractions seeded onto matrices of PGA (Organ *et al.*, 1993b). Although the histologic appearance at 1 month resembled normal fetal intestinal development arrested at the stratified epithelial stage, it was not organotypic of mature intestinal mucosa. We adhere to the principle that structure and function are intimately intertwined. To tissue engineer successfully any *functional* organ or tissue, a derived organ or tissue must have a structural form close to, if not identical to, a normal organ or tissue, to be of therapeutic benefit.

Fig. 38.6. (a) Day 10 implant. Triangles: simple cuboidal/columnar epithelium, with basally oriented nuclei, emanating from cryptlike structures (C) overlying fibrovascular ingrowth from omentum (OM) Bar, 50  $\mu$ m. (b) Day 14 implant. Immature villi (V) arising from crypts (C) and abundant goblet cells (arrowheads), indicative of phenotypic differentiation. Arrows: mitotic figures. PGA fibers (P) are surrounded by granulomatous foreign body reaction. Bar, 50  $\mu$ m.

The field of developmental biology has illuminated the importance of epithelial–mesenchymal interaction(s) in the morphogenesis of a variety of epithelial organs. Armed with a new method of IEC isolation that maintains the interaction(s) between endodermal and mesenchymal-derived cell types of the intestinal epithelium, we hypothesized that changing this sole variable (i.e., IEC isolation) in our existing model would result in tissue-engineered neointestinal mucosa that is

Fig. 38.7. Day 28 implant. (a) Tissue-engineered neointestinal mucosa displays mature villus/crypt axis formation. V, Villi; C, crypts. Bar, 50  $\mu$ m. (b) Ongoing proliferation is evident from the presence of multiple mitotic figures (arrows). Advanced phenotypic differentiation is evident from the presence of Paneth cells (+). Bar, 50  $\mu$ m.

organotypic of mature small bowel (Organ *et al.*, 1998b). Prior to testing this hypothesis, 25 experimental IECA isolation procedures were conducted to evaluate, optimize, and demonstrate consistency with this multistep protocol. These results are the culmination of 9 isolation–implantation cohorts to generate satisfactory numbers for meaningful quantitative results and empiric histologic observations. Each cohort requires 4–6 hr of preparation, 8 hr to execute, and an additional 6 hr to conduct assays and tabulate results. We deliberately utilized serum-free media

and did not employ growth factors or extracellular matrix proteins with this model, thus allowing determination of base line patterns of vascularization and morphogenesis. In addition, growth factors from other species could be expected to harbor antigenic epitopes that may elicit an incremental inflammatory response.

It is generally accepted that the undifferentiated, pluripotent stem cells of the intestinal epithelium are located in the basal region of the crypts of Lieberkühn. In addition to giving rise to the four main cell types of the intestinal epithelium, these stem cells have a large capacity for epithelial regeneration after tissue injury. Morphometric data from the oncology literature indicate that a surviving stem cell fraction of 1 in 100,000 is capable of regenerating new intestinal epithelium after cytotoxic insults from irradiation or chemotherapy (Moore, 1985; Potten, 1990; Potten *et al.*, 1990). We have utilized these benchmark numbers, which are critical guidelines for determining toxicity in therapeutic oncology, to determine the minimal numbers of IECAs to deliver in this model system.

From detailed modeling of *in vivo* enterocyte kinetics, Potten and Loeffler (1990) have concluded that the small intestinal crypts contain 4–16 actual stem cells in steady state and 30–40 potential stem cells (clonogenic cells) that may take over stem cell properties following perturbations. In this study we delivered  $3\text{--}5 \times 10^4$  IECA/cm<sup>2</sup>, yielding  $12\text{--}80 \times 10^4$  actual stem cells and  $90\text{--}200 \times 10^4$  potential stem cells. With the notable exception of cartilage and bone cells, it has been the empiric observation of our laboratories that most transplanted cell types, employing this open-matrix approach to tissue engineering, demonstrate significant decrement in survival in the first 24–48 hr after implantation. This has been attributed to the trauma of the isolation procedure and the ability of the cells to survive on diffusion of oxygen and nutrients from the host implantation site until neovascularization has occurred. If 1 in  $10^5$  of the stem cell fraction of the implanted IECA survives, this should deliver 0.1–0.8 actual stem cells and 0.9–2.0 potential stem cells. Therefore, we determined that  $3\text{--}5 \times 10^4$  was the minimum number of IECA/cm<sup>2</sup> to transplant. Our grafting efficiency of 54% for this model suggests this is the minimum acceptable critical mass of IECAs to deliver in this model system.

Histologic evaluation of tissue-engineered neomucosa demonstrates a pattern of morphogenesis identical to intestinal epithelial regeneration from a variety of infectious, inflammatory, ischemic, or dysplastic causes (Lewin *et al.*, 1992b). The IECA–PGA construct elicits an acute inflammatory response evident in the first 3 days after implantation. Days 3–7 are characterized by a rich fibrovascular ingrowth from the omentum. IECAs are identified as microcystic structures with a cuboidal/columnar epithelial lining as early as day 3, and are numerous by day 7. These cryptlike structures begin epithelializing the fibrovascular ingrowth with a simple cuboidal/columnar epithelium by days 10–14. Mature villus/crypt formation with cytologic differentiation of the four cell types of normal intestinal epithelium is present by day 28.

In a complimentary body of work Choi and Vacanti and associates have reported on the successful engraftment and function of tissue-engineered neointestine using a similar model (Choi *et al.*, 1998). Intestinal epithelial organoid units (IEOUs) were isolated utilizing the Evans–Potten technique acquired from sediment of disaggregated smooth muscle, villi, and crypts (see Fig. 39.3, step d). A volume of  $30 \times 10^4$  to  $50 \times 10^4$  IEOUs was seeded onto a similar PGA mesh sprayed with 5% poly(lactic acid) to confer rigidity, obviating the need for a luminal stent, and coated with collagen. Serial evaluation out to 14 weeks demonstrated organotypic small intestinal histology in cystic structures with a grafting efficiency of 93%. Immunohistochemistry confirmed sucrase activity at the apical epithelial surface and deposition of laminin in the lamina propria. Positive actin staining demonstrated smooth muscle elements. Neomucosa was mounted in a Ussing chamber and exhibited transepithelial resistive measures comparable to adult rat ileum, thus providing evidence for the functional epithelial integrity of tissue-engineered neomucosa. Important morphometric data of tissue-engineered neomucosa have been documented for base line conditions and in response to 75% small bowel resection, 75% partial hepatectomy, and portacaval shunting at 10 weeks (Kim *et al.*, 1999). Omental implants have been anastomosed in a side-to-side fashion, 3 weeks after implantation, and retrieved at 10 weeks (Kaihara *et al.*, 1999). Patency of 90% or greater of the anastomosis was documented on upper gastrointestinal radiographic examination and direct visualization. Significantly greater villus number, height, and surface length were documented in the anastomosis group, documenting the trophic effects of succus entericus.

The development of tissue-engineered neointestinal mucosa has proceeded in a systematic,

step-wise fashion to its current state. Our laboratories have collaborated and employed some of the lessons and observations learned in tissue engineering other tissues. Critical empiric observation, progressively more quantitative assessment of the end point of our work, and application of advances made in the field of epithelial biology have dramatically moved this endeavor closer to clinical application.

The future of tissue engineering neointestinal mucosa must address some important obstacles. Developing methods of IECA isolation for more mature small intestinal epithelium is a rate-limiting obstacle for the whole field of epithelial biology. Because of the significant immunologic issues involved in transplanting intestine, creating methods for isolating IECAs from an SBS patient's own intestine takes on additional importance. Because the intestinal epithelium is the most rapidly proliferating tissue in the human body, this affords a unique opportunity in the field of tissue engineering. Assessing the role of growth factors and extracellular matrix molecules, particularly *in vitro*, will require development of more stringent quantitative measures for these large, multicellular aggregates. Demonstration of the absorptive function of tissue-engineered neomucosa will also play an important role moving this approach toward clinical applicability. Developing a neuromuscular coat for peristalsis will have a profound impact, and is required for a functional, tissue-engineered neointestine.

Although many challenges lie ahead for the entire field of tissue engineering, tremendous strides have been made over the past decade. The foundation for therapeutic implementation of tissue-engineered organs and tissues is being established today. The hope and expectation is that, someday, equipping patients with tissue-engineered organs and tissues may be as routine as coronary bypasses are today (Langer and Vacanti, 1999).

# LIVER

Hugo O. Jauregui

## INTRODUCTION

Historically, the development of liver support devices has progressed from passive to bioactive systems. Passive systems to remove blood toxins accumulated during liver failure have included hemodialysis, hemoperfusion, hemofiltration, and plasma exchange (Malchesky, 1994). Although some studies have reported transient improvement of some blood parameters or symptoms associated with liver failure (e.g., hepatic encephalopathy), passive methods did not improve patient survival. Simultaneously, in several medical centers, studies of bioreactors or cell-based liver support systems were implemented to replace key functions that prevent hepatic encephalopathy development or assist in its management and thereby improve the outcome of patients with hepatic failure. This chapter presents a critical overview of cell-based liver assist devices, including new prototypes as well as the one that has reached clinical testing. The succinct review of liver anatomy and function, as well as the pathophysiology of hepatic failure, facilitates understanding of this type of cellular therapy.

## ANATOMY AND FUNCTION OF THE LIVER

Specialized metabolic, synthetic, and secretory liver functions occur through complex interactions between blood and hepatocytes (parenchymal liver cells). The liver of a 70-kg adult weighs nearly 1.75 kg (~2.5% of total body weight), of which the hepatocyte mass represents approximately 1.2 kg (Arias *et al.*, 1988).

Hepatocytes, in their arrangement as plates of single-cell thickness, receive a dual blood supply derived from the portal vein and the hepatic artery. Combined, these vessels create an extensive vascular space, called the liver sinusoid (Figs. 39.1 and 39.2). Although these sinusoids are lined by endothelial cells, the endothelium is interrupted by pores or fenestrations that allow free passage of most solutes into a pericapillary space (the space of Disse). Hepatocytes project the microvilli of their sinusoidal domain (72% of total cell surface area) into this space, which is rich in basement membrane proteins and proteoglycans, such as collagen type IV, (the major type of collagen of this area), fibronectin, and heparin sulfate. Laminin is not present in this space in adult rodent livers, but is contributory to the embryogenesis of the liver (Martinez-Hernandez *et al.*, 1991). In addition to the sinusoidal domain, hepatocytes present a lateral surface (15% of cell surface) contiguous to other hepatocytes, but interrupted by a canalicular pole (13% of cell surface). Bile canaliculi from the two hemicanaliculi are sealed by tight junctions and present numerous microvilli (Fig. 39.3). This histology constitutes the beginning of the biliary duct system and contributes to the formation of canalicular bile, which is further modified at the bile duct level. This succinct histological description permits appreciation of the structural hepatic organization responsible for a functional organization that allows unidirectional perfusion of polarized hepatocytes arranged in plates. Perfusion studies have shown a hepatocyte distribution that forms a structure called the liver acinus (Rappaport *et al.*, 1954), a microvascular unit in which hepatocytes near the terminal portal venule and hepatic arteriole (periportal cells) are first perfused with blood and

Fig. 39.1. Three-dimensional display of a liver lobule, showing the vascular, biliary, and hepatocyte arrangement. Copyright Eli Lilly and Company. Used with permission.

those near the hepatocyte venule (terminal veins) are perfused secondarily with blood modified previously by upstream hepatocytes. In fact, Rappaport defined a hepatic acinus with three zones (Rappaport *et al.*, 1954): zone one (periportal) receives the highest concentrations of oxygen and

solutes, zone three (pericentral) meets with the lowest blood concentration of oxygen, and zone two lies between zones one and three.

The concept of zonal hepatocyte distribution may prove important in the design of artificial liver support systems. Liver assist devices (LADs) that incorporate specific zonal hepatocytes with characteristic functions in an arrangement similar to that found *in situ* could be manufactured, provided that (1) hepatocyte functions responsible for the often fatal central nervous system derangement, hepatic coma, could be defined, (2) technology could be developed to isolate zonal hepatocytes in quantities compatible with therapeutic applications, and (3) expression of these functions could be maintained.

Regarding zonal hepatic function, it should be mentioned that whenever toxins, infectious agents, or circulatory distress damage the liver, they typically do so in a zonal pattern of the acinus. Hepatocyte injury commonly generates two processes that also have a zonal distribution, namely, liver regeneration by the remaining hepatocytes and hepatocyte necrosis. It is well known that only three to four hepatocytes situated in proximity to the portal space of the liver acinus have the capacity for mitosis. Although *in vivo* these hepatocytes are responsible for a very slow renewal of liver cells (through the development of proper separation techniques), they may be the source of the cellular component of artificial liver support systems. On the other hand, pericentral hepatocytes are responsible for the detoxification activity of the liver, a process that requires expression of a complex group of enzymes known collectively as the cytochrome oxidase P450 system (Kaplowitz, 1992).

Zonal hepatocyte necrosis frequently stimulates the stromal component of the liver to produce wide areas of fibrous scarring, which ultimately progresses to a general impairment of liver functions. Because the liver receives a dual blood supply, special hemodynamic situations are created by this generalized scarring process (cirrhosis). In this condition, the blood from the portal vein and the hepatic artery is diverted directly into the large hepatic veins (without the usual passage through the sinusoidal circulation) and from there into the inferior vena cava. These shunts

conspire against proper blood detoxification because toxins, which should contact liver cells to be metabolized, remain in the systemic circulation and act on other organs, particularly the central nervous system.

Electron microscopic examination of the hepatocyte cytoplasm reveals abundant smooth and rough endoplasmic reticulum cisternae, numerous ribosomes, and mitochondria along with many lysosomal and endocytic vesicles. The major aspects of detoxification occur in the smooth endoplasmic reticulum cisternae.

Total replacement of liver functions by an artificial liver would entail regulation of plasma protein production, metabolism, and storage of vitamins; biotransformation and detoxification of drugs; synthesis of lipoproteins and cholesterol; maintenance of glycogenesis and glycogenolysis; and the conversion of heme to bilirubin and biliverdin (to name just some of the physiological activities of this organ). Although the design of a liver support system probably does not require the provision of all liver functions, the functions essential for liver support are not yet known.

### LIVER FAILURE: PATHOPHYSIOLOGICAL CLASSIFICATION

Excessive alcohol consumption is the major cause of morbidity and mortality of liver disease in the United States and most other Western countries. From the 56,773 cases of viral hepatitis reported in 1988 (Zeldis, 1992), 41% were due to hepatitis B, 50% to hepatitis A, and about 5% to hepatitis C. Each virus case presents a similar clinical syndrome, but only hepatitis B and C have the potential to produce chronic hepatitis.

Many drugs are also associated with the production of either chronic or acute liver failure. The metabolism of foreign compounds by the P450 system is invaluable to process xenobiotics, but on occasion this system gives rise to toxic products. It is customary to divide these toxic drug metabolites into electrophiles and drug free radicals. Electrophiles arise from electron sharing of covalent bonds with substances that can donate electrons. Examples of drugs that produce electrophile metabolites, which in turn produce hepatocyte necrosis, are acetaminophen (attacks thiol groups) and halothane (reacts with protein amino groups). Drug free radicals preferentially attack membrane phospholipids, leading to lipid peroxidation.

These various agents produce different types of hepatic failure that are treated either medically or surgically by liver transplantation. The most life-threatening aspect of hepatic failure is the syndrome characterized by a severe impairment of liver function that proceeds to the development of hepatic encephalopathy (HE) (hepatic coma) within 8 weeks of the first symptoms of illness. Bernuau has divided patients with acute liver failure into fulminant hepatic failure (FHF) (appearance of HE within 2 weeks from the onset of jaundice) and subfulminant hepatic failure (HE appearance between 2 weeks and 3 months postjaundice) (Bernuau *et al.*, 1986). The important points to differentiate FHF from chronic hepatic failure (CHF) are that, in FHF, there is no evidence of preexisting liver disease and the mortality rate is about 70–95%. In CHF, mortality is lower, evidence of chronic liver disease exists, and medical management may prove successful, at least in the first stages of HE. Despite widespread disagreement, but because both acute and chronic liver failure may be complicated by HE, there is a tendency to discuss this entity under unifying pathogenic mechanisms (Schenker, 1989).

Probably the most common denominator in FHF and CHF is the shunting of portal–venous

**Table 39.1. Clinical observations provide clues to pathogenesis<sup>a</sup>**

Neurotoxin origin	Precipitation of encephalopathy
Intestinal (mainly colonic)	Constipation, portal–systemic shunting
Nitrogenous compounds	Protein meal
Bacterial	Infection (nonabsorbable antibiotics improve encephalopathy)
Metabolization by the liver, first-pass extraction	Portal–systemic shunting, portacaval high anastomosis

<sup>a</sup>Based on four postulated mechanisms: ammonia levels, synergistic neurotoxins, false neurotransmitters, and GABA/endogenous benzodiazepines.

blood into the systemic circulation, bypassing the liver. This shunting was discussed above as it pertains to CHF cases resulting from cirrhosis. In FHF, the architecture of the liver is severely affected and the large portal blood flow joins the systemic circulation without the benefit of the detoxification activity of the few remaining hepatocytes. Despite the extensive hepatocyte necrosis, some cases of FHF are known to survive with complete histological recovery of the liver (Jones and Schafer, 1990). Which of the toxic products responsible for hepatic coma should be metabolized by a LAD? Where do they originate? The clinical signs and symptoms of patients with acute or chronic liver failure offer important clues to answer those questions. Table 39.1 lists relationships between encephalopathy and neurotoxin origin (Blei, 1992).

## MECHANISMS OF HE IN LIVER FAILURE

### AMMONIA

There is no correlation between the grade or stage of hepatic encephalopathy and arterial ammonia levels, but elevated cerebrospinal fluid ammonia does correlate with HE stages (Blei, 1992). In addition, HE may improve if the intestinal  $\text{NH}_3$  production common in CHF is reduced. Unfortunately, dialysis treatment of HE patients has failed to awaken these patients in spite of an evident decrease in their levels of blood  $\text{NH}_3$ . For example, feeding cirrhotic patients methionine (a mercaptain precursor) induced changes in mental state without concomitant changes in blood  $\text{NH}_3$  levels (Blei, 1992).

### FALSE NEUROTRANSMITTER HYPOTHESIS

Hepatic coma may occur when brain neurotransmitters (dopamine and noradrenaline) are replaced in cirrhotic patients by weak neurotransmitters (octopamine) generated in the intestine and shunted into the general circulation (Schafer and Jones, 1990). This hypothesis, however, was greatly discredited by studies showing that the administration of octopamine failed to change the mental state of experimental animals and by data showing lower levels of octopamine in the brains of cirrhotic patients than in normal brains (Blei, 1992).

### GABA–BENZODIAZEPINE HYPOTHESIS

The decarboxylation of glutamine in the nervous system produces  $\gamma$ -aminobutyric acid (GABA), which causes neuroinhibition through receptor binding. The GABA receptor (subtype A) also binds benzodiazepines and barbiturates. Benzodiazepine action results in the modulation of GABA-ergic neurotransmission. Studies suggest that endogenous benzodiazepines, which are not properly metabolized by the liver, may be associated with the HE that is present in FHF. The benzodiazepine role in HE pathogenesis is supported by the observation that the administration of a benzodiazepine receptor antagonist (flumazenil) improves the status of animals and humans with FHF (Bansky *et al.*, 1989).

An understanding of the possible pathogenic mechanisms of HE is useful to assess current and future development of the LAD in humans and/or experimental animals. Because the pathogenesis of HE is not known, investigators often validate the efficacy of liver-assist devices by testing drug metabolism or hepatic protein synthesis *in vitro*. Two well-established models of acute hepatic failure (AHF) (Blei, 1992) are end-to-side portacaval anastomosis in the rat and the galactosamine-intoxicated rabbit. However, due to the small size of these animals, devices intended for human use are commonly tested in toxin-induced or anhepatic large animal models of liver failure, which may not closely produce the clinical symptoms of HE (Terblanche and Hickman, 1991). In addition, there are no adequate animal models of CHF (Blei, 1992).

## MEDICAL NEED FOR LIVER-ASSIST DEVICES

Although several approaches have been used to address liver failure, whole-organ transplantation remains the procedure of choice. However, this approach has several limitations. First, the number of available organs does not meet the demand; second, the procedure carries risks, which increase in certain conditions complicated by AHF; and third, liver transplantation is expensive. Because of the success of liver transplantation, cell-based bioreactors constructed with cells capable of performing liver functions are a potential alternative to treat reversible acute liver failure or a bridge to liver transplantation.

It can be predicted that early use of LADs may result in an improvement of the clinical stages of AHF. Potentially, a total recovery by use of these devices will reduce the typical brain edema found in these critically ill patients. In these cases, LADs should work as a bridge-type therapy by providing the necessary clinical support until a liver becomes available for transplantation or until the native liver regenerates.

## BIOLOGICAL COMPONENT OF LIVER-ASSIST DEVICES

Hepatocyte transplantation studies in rats showed that  $1.0 \times 10^7$  microcarrier-attached hepatocytes (1–2% of liver mass) improved survival of rats with 90% hepatectomy when compared to nontransplanted controls (Demetriou *et al.*, 1988). It was also demonstrated that patients could survive after 90% partial hepatectomy (Monaco *et al.*, 1964). Therefore, an artificial liver should at least provide 1–10% of the liver mass (Demetriou *et al.*, 1988; Monaco *et al.*, 1964; Margulis *et al.*, 1989; Jauregui *et al.*, 1995). An artificial liver support designed for a 70-kg patient and including as much as 10% of the native liver functions would require approximately 120 g of liver tissue or  $25 \times 10^9$  cells. This figure is controversial, but it should be stated that the liver mass previously employed in artificial liver support systems has ranged from 1 (Margulis *et al.*, 1989) to 15% (Sussman *et al.*, 1994). Due to the limited availability of human livers, the source of the liver cells remains an issue. Alternatives currently being explored include the use of transformed cells, freshly isolated hepatocytes, and cultured hepatocytes.

## TOTALLY TRANSFORMED (MALIGNANT) HEPATOCYTES

The primary advantage of totally transformed hepatocytes is the nearly limitless capacity to maintain growth. Under culture conditions, these neoplastic hepatocytes may be subjected to ongoing assessment of purity, function, and pathogenicity. Wolf used a Reuber hepatoma cell line in a hollow-fiber device to treat Gunn rats and demonstrated bilirubin conjugation (Wolf *et al.*, 1979). C3A, a cell line derived from HepG<sub>2</sub> (a human hepatoblastoma cell line), has been established and grown in hollow-fiber cartridges (Kelly and Darlington, 1989). Concern arises regarding the potential of totally transformed hepatocytes to exhibit spontaneous changes in chromosome number and in gene expression after a period under culture conditions. Also of concern is the potential of an accidental infusion of tumorigenic cells into the patient's systemic circulation. In addition, the cost associated with cell production (culture supplies, quality control, bioburden monitoring, etc.) may be elevated. For instance, it takes approximately 1 month to grow sufficient C3A cell mass (200 g) for a device (Sussman *et al.*, 1992).

## FRESHLY ISOLATED HEPATOCYTES

A second approach is the use of primary hepatocytes, which can be cryopreserved after isolation and thus shipped and stored at the clinical site. Soyer and Eiseman were the first to use cell suspensions or slices to provide hepatic functions (Soyer *et al.*, 1973), but Matsumura, in 1987, was the first to treat successfully a patient in hepatic failure using a suspension of rabbit hepatocytes (Matsumura *et al.*, 1987). LADs containing porcine hepatocytes attached to collagen-coated dextran microcarriers, inoculated into the extracapillary space of cellulose acetate hollow fibers, have been tested in dogs with surgically induced liver ischemia (Rozga *et al.*, 1993a,b). A scaled-up version of this LAD is now in clinical trials. The choice of porcine cells appears justified from previous reports of extracorporeal pig liver perfusion to support patients with liver failure (Abouna *et al.*, 1973; Chari *et al.*, 1994). In addition, there are several attributes in favor of the pig over other animal donors. Pigs have large litters, are inexpensive, rapidly reach maturity (6 months), are relatively disease resistant, and can be raised in controlled herds (e.g., specific pathogen-free herds). Their organs have similarities to human organs with regard to size and physiology, and large numbers of cells (e.g., hepatocytes) can be harvested. Freezing of porcine hepatocytes facilitates their availability in quantities compatible with commercial use. The entire process of isolation and cataloging volumes of porcine hepatocytes demands well-established protocols and reliable methodology that spares any microbiological, virological, and toxicological contamination. A significant effort has been devoted to the cell supply issue through animal sourcing programs. Because the hepatocytes isolated from porcine livers cannot be subsequently sterilized, a comprehensive herd and animal bioburden screening program should be developed to provide adequately "clean" animals, particularly free of potential zoonotic viruses (Gil, 1995). There are certain practical and theoretical objections to the use of porcine hepatocytes. We should mention that there is great concern

about the presence of porcine endogenous retroviruses in all pig herds tested to date; the passage of porcine protein into the circulation of the patient and the need to control the source of hepatocytes on a regular basis are additional concerns.

### CULTURED HEPATOCYTES

The use of primary cultures of hepatocytes as the biological component of LADs offers some interesting alternatives to the use of freshly isolated hepatocytes, but at the same time presents some complications, particularly the logistics and cost of a massive tissue culture production. One possibility would be to use hollow-fiber devices as tissue culture bioreactors, which would subsequently become LADs by replacing the appropriate tissue culture media with the blood or plasma of the patients. This approach, similar to the one implemented in previous models with tumor cells, is at best not well suited to growing porcine hepatocytes in large quantities, although the system has proved worthwhile to grow rat hepatocytes.

Microcarrier technology to grow hepatocytes in commercial quantities is actively being explored in our laboratory. In this context, it should be stated that short-term monolayer culture of pig hepatocytes produces a cell that metabolizes diazepam, acetaminophen, and ammonia more efficiently compared with freshly isolated cells (Naik, *et al.*, 1996). An important area of improvement to maintain the phenotypic expression of hepatocytes in long-term culture is the identification of new tissue culture (TC) media with defined formulations that will avoid the supplementation with human or animal serum. Following this line, Jauregui *et al.* (1994) have modified a TC medium, Chee's Modified Eagle's Medium (CEM), to cultivate rat (Naik *et al.*, 1992), rabbit (Jauregui and Naik, 1991), and monkey hepatocytes and are actively pursuing the optimal medium for porcine cells.

A controversial subject in hepatocyte culture is the choice of TC substrate. Vitrogen, (Naik *et al.*, 1992), Biomatrix (Rojkind *et al.*, 1980), and Matrigel (Schuetz *et al.*, 1988) (primary laminin) as well as a newly developed polymer (Kobayashi *et al.*, 1986) that binds the so-called asialoglycoprotein receptor, have all been used to maintain long-term viability. Often these substrates are used but not compared with old and well-known substrates that failed to maintain phenotypic expression. Furthermore, there are few if any publications that address the subject in a comprehensive fashion (e.g., by measuring multiple parameters of hepatocyte function).

### PARTIALLY TRANSFORMED (IMMORTALIZED) HEPATOCYTES

Implementation of a LAD as a treatment for acute liver failure will be greatly advanced by the availability of porcine hepatocytes that grow indefinitely, with maintenance of functional activity but expressing no tumorigenicity. Likewise, patients with chronic liver failure could be maintained with prolonged treatment with devices harboring partially transformed human hepatocytes. The commercial production of these types of cells has been addressed by the transfer of specific viral oncogenes that can generate cell lines that divide, expressing an intermediate stage of differentiation, a process known as immortalization (Westerman, 1996). As reported by researchers in this field, only few human cells become truly "immortal" following the introduction of viral oncogenes such as the SV40 T antigen (Westerman, 1996). Indeed, although early stages of the immortalization process may expand the life-span of primary human cells in culture, sooner or later these cells senesce and will enter a phase called "crisis," from which only few immortalized cells will evolve as liver cells (Westerman, 1996). Studies with temperature-sensitive forms of oncogenes have shown that oncoprotein inactivation at a nonpermissive temperature allows cells to resume *in vivo* as well as *in vitro* normal differentiation (Renfranz *et al.*, 1991).

The SV40 virus transforms cells of many species. Depending on the genetic properties of the cell in question, the virus infection will be lytic and consequently these cells, called permissive cells, will support full expression of the viral genome and release progeny of viral particles (Chou, 1989). Monkey cells are permissive and are killed after the SV40 infection. On the other hand, mouse, rat, and rabbit cells, which are not permissive and consequently do not support viral replication, express some viral early genes and can become transformed by SV40. Human and porcine hepatocytes are semipermissive, supporting a limited infection with the release of a low number of virions, and thus also become transformed by SV40. To obtain SV40-transformed hepatocyte lines free of infectious virus, we and others use the transforming T antigen, a partial viral particle that is responsible for viral replication but is not related to the viral constituents that are responsible for the viral infectivity (Liu *et al.*, 1999). This viral regulatory protein directs an ordered sequence

of events that, starting in early phases of the SV40 infection (prior to the viral DNA replication), proceed into the late phase of infection (Westerman, 1996). This early phase allows the accumulation of T antigens in the cell nucleus, where they alter transcription patterns, stimulating quiescent cells such as hepatocytes in culture to synthesize cellular DNA. How does SV40 T transform cells? This question is still not completely answered but the principal effect is the inactivation of multiple growth suppressors, at least pRb, p53, and an immortalization gene on chromosome 6 (Kim *et al.*, 1998). The HepLiu immortalized porcine hepatocyte line was developed in our laboratory in 1995 and since then has undergone 60 passages and is not tumorigenic when grafted in severe combined immune-deficient (SCID) mice. The HepLiu cell line is the product of several subcloning steps that select for hepatocytes metabolizing diazepam as well as acetaminophen, but not producing albumin (Liu *et al.*, 1999). The latter facilitates the use of these cells in hollow-fiber devices with high-molecular-weight cutoff membranes.

## LIVER-ASSIST DEVICE CONFIGURATIONS

Device design focuses on providing an environment for maximum cell viability and function. Criteria for device performance include transport of nutrients and oxygen to maintain cell viability and function, and transport of toxins and metabolites for patient support. Several bioreactors or culture systems have been developed for the cultivation of cells in a three-dimensional architecture: static cultures, matrix cultures, roller bottles, stirred suspension, packed beds, fluidized beds, and hollow-fiber bioreactors (Jessup *et al.*, 1993). Each of these systems has advantages and disadvantages for use as an extracorporeal cell-based liver-assist device. Numerous design variations have been proposed for cell-based LADs (Margulis *et al.*, 1989; Sussman *et al.*, 1992, 1994; Kasai *et al.*, 1994; Dixit, 1994; Rozga *et al.*, 1994; Uchino *et al.*, 1988; Kawamura *et al.*, 1985; Kimura *et al.*, 1980; Yanagi *et al.*, 1989; Li *et al.*, 1993; Wolf and Munkelt, 1975; Gerlach *et al.*, 1994; Nyberg *et al.*, 1993a,b); however, only three main designs (hepatocyte suspension, packed-bed, and hollow-fiber bioreactors) have reached clinical evaluation (Table 39.2).

### HEPATOCYTE SUSPENSION

The bioartificial liver developed by Matsumura was based on the principle of hemodialysis against a suspension of hepatocytes (Matsumura *et al.*, 1987). A modified plate hemodialyzer fitted with a dialysis membrane permeable to middle-weight molecules, but impermeable to albumin, was used. A patient in hepatic failure, secondary to bile duct carcinoma, underwent two treatments of 5 and 4.5 hr each over a period of 3 days. The patient's blood was dialyzed against a flowing suspension of 100 g of previously cryopreserved rabbit hepatocytes. Reduction in serum bilirubin level and improvement in mental states were observed following each treatment, and the patient was discharged from the hospital after the second treatment. However, there has been no further report on the development of this device.

Margulis *et al.* (1989) reported the development of a 20-ml capsule containing a suspension of  $40 \times 10^6$  porcine hepatocytes and activated charcoal. Each device was used for only 1 hr and a treatment lasted 6 hr; six devices were used per treatment. Mortality in the treated group of 59 patients with acute liver failure was 37% compared to 59% in the control group consisting of 67 patients who received only intensive medical care. However, little information was provided on metabolic support during treatments.

### PACKED-BED BIOREACTOR

Li *et al.* (1993) inoculated hepatocytes in a column filled with glass beads. The packed-bed bioreactor maintained urea and albumin synthesis, and interconnecting three-dimensional structures resembling the cell plate anatomy of the native liver were maintained for up to 15 days in culture. A 10-year-old patient with fulminant hepatic failure was successfully treated with the system. There has been no further report on the development of this device.

### HOLLOW-FIBER BIOREACTOR

The first hollow-fiber LAD was developed by Wolf and Munkelt (1975). The device contained a rat hepatoma cell line cultured on the exterior surface of semipermeable hollow fibers enclosed within a plastic housing. Sussman *et al.* (1992, 1994) and Sussman and Kelly (1995) developed a similar extracorporeal liver-assist device (ELAD), except that a hepatoma cell line of

**Table 39.2. Artificial liver support clinical trials**

Investigator	Device configuration	Perfusion medium	Cell selection	Survival rate <sup>a</sup>	
				Treatment	Control
Matusmura <i>et al.</i> (1987)	Cell suspension (cellulose membrane 70-kDa cutoff)	Blood (100 g)	Rabbit hepatocytes	100 (1/1)	—
Margulis <i>et al.</i> (1989)	Cell suspension (40 × 10 <sup>6</sup> ) × 6	Blood	Pig hepatocytes	63 (37/59)	41 (27/67)
Li <i>et al.</i> <sup>20</sup> (1993)	Packed bed (glass beads)	Plasma	Pig hepatocytes	100 (1/1)	—
Sussman <i>et al.</i> (1994)	Hollow-fiber ELAD (cellulose acetate, 70-kDa cutoff)	Blood cell line (200 g)	Human hepatocytes	45 (5/11)	—
Rozga <i>et al.</i> (1994)	Hollow-fiber BAL (cellulose acetate, 0.2-μm pore size)	Plasma (5 × 10 <sup>9</sup> )	Pig hepatocytes	88 (8/9)	—

<sup>a</sup>Patient survival rates are expressed in percentages; actual numbers are given in parentheses.

human origin (C3A) was used. The ELAD consisted of a cellulose acetate hollow-fiber hemodialyzer (70,000-Da cutoff) containing 200 g of cells grown on the outer surface of the fibers (Sussman *et al.*, 1992, 1994). Blood was perfused through the cartridge. During perfusion, a small amount of plasma was ultrafiltered by the fibers and perfused the cells before returning to the blood path downstream from the ELAD. Of the eleven patients treated with the ELAD, the first two were treated under “Emergency use of unapproved medical devices” and the remaining nine patients were treated according to an investigational device exemption (IDE) (see the Food and Drug Administration web site, <http://www.fda.gov/cdrh/manual/idemanul.html>). One patient survived, six patients died, and four patients were bridged to orthotopic liver transplantation. No short-term safety problems were associated with the use of the ELAD; however, metabolic support provided by the device was difficult to assess.

In 1985, W.R. Grace & Co. initiated the development of a cell-based liver-assist device in collaboration with Jauregui and co-workers at Rhode Island Hospital. The bioreactor consisted of microporous (0.15-μm pore size) polysulfone hollow fibers assembled in a cylindrical housing. The bioreactor was inoculated with rabbit hepatocytes, placed in an extracorporeal circuit, and perfused with whole blood. The efficacy of the LAD was assessed in two different animal models (Jauregui *et al.*, 1995): (1) normal rabbits injected with diazepam or lidocaine and (2) a galactosamine (Gal)-intoxicated rabbit model of fulminant hepatic failure (FHF).

In the first animal model, the blood levels of both diazepam and lidocaine metabolites clearly increased during treatment, indicating the maintenance of cell activity (P450 function) in the LAD. In the Gal model, a 6-hr treatment significantly increased the survival time and delayed the onset of hepatic encephalopathy when compared to two untreated control groups. Histological evaluations of postmortem livers showed greater hepatocyte regenerative activity in animals treated with the LAD compared with control animals. These findings support the concept that a hollow-fiber LAD containing hepatocytes is able to sustain drug detoxification *in vivo* as well as to modify the course of FHF in a well-characterized animal model. The device was then scaled up for human use and tested for safety using porcine hepatocytes in a sheep model.

Contemporaneous to the research conducted by W.R. Grace & Co., Demetriou and co-workers developed a bioartificial liver (BAL) consisting of hollow fibers and hepatocytes, and was testing the BAL in patients under compassionate use of the device (Rozga *et al.*, 1993b). In 1993, W.R. Grace & Co., and Demetriou and collaborators at Cedars Sinai Medical center joined efforts to further develop the BAL and a liver-assist system (LAS) including the BAL. A comprehensive description of this system is incorporated in this volume.

The hollow-fiber LAD (see Table 39.2) uses membranes of different selectivities (Sussman *et al.*, 1992, 1994). Sussman *et al.* (1994) as well as Matsumura *et al.* (1987) used membranes with

low-molecular-weight cutoff (70,000) that reduced passage of serum albumin and excluded proteins of higher molecular weights. Rozga *et al.* (1994) selected microporous (0.2- $\mu\text{m}$  pore size) hollow fibers, which allowed passage of plasma proteins but excluded the passage of cells (i.e., blood cells and hepatocytes). Microporous membranes allow for free exchange of toxins (soluble or protein bound) and large-molecular-weight proteins (e.g., clotting factors) between the blood or plasma and the hepatocytes. On the other hand, the membranes used by Sussman *et al.* (1994) and Matsumura *et al.* (1987) excluded immunoglobulins and provided an immunoprotected environment for the liver cells. However, because BAL treatments (Rozga *et al.*, 1993b) as well as extracorporeal pig liver perfusions have been well tolerated (Chari *et al.*, 1994) and patients have been successfully transplanted posttreatment (Rozga *et al.*, 1993b; Chari *et al.*, 1994), the short-term use (days) of artificial livers that use microporous membranes appears feasible and safe. Consistent with this are the findings of Ye *et al.* (1995), who reported that in primates, allograft transplants following pig heart xenotransplantation as well as pig blood transfusion functioned normally with no histopathologic features of hyperacute humoral or accelerated cellular rejection. This study (Ye *et al.*, 1995) supports the theory that bridging with a concordant or discordant donor xenograft does not prohibit subsequent organ allografting.

Currently, several types of liver-assist systems have been authorized by the Food and Drug Administration to begin human clinical studies to evaluate their safety and biologic activity. Pending the successful outcome of these early studies, scale-up of the manufacturing processes can begin in order to meet the requirements for follow-up multicenter studies and pivotal clinical trials. If progress continues at its current pace, approved liver-assist systems for general distribution will soon be a reality.

# HEPATASSIST LIVER SUPPORT SYSTEM

Claudy Mullon and Barry A. Solomon

## INTRODUCTION

Acute liver failure (ALF) complicated by hepatic encephalopathy is associated with high mortality, approaching 90% (Lee, 1993; Plevris *et al.*, 1998). The most successful treatment of ALF has been orthotopic liver transplantation (OLT), but the overall survival rate for ALF patients continues to be only 50 to 60% due to the shortage of organ donors and the rapid progression of the disease (Plevris *et al.*, 1998; Samuel, 1998). The success of OLT has led to the development of bioartificial liver support systems incorporating hepatocytes (Plevris *et al.*, 1998; McLaughlin *et al.*, 1999; Watanabe *et al.*, 1997a,b; Jauregui *et al.*, 1996). The aim of these systems is to support patients temporarily until recovery occurs or to bridge them to liver transplantation. This chapter introduces a bioartificial liver support system (HepatAssist System) containing porcine hepatocytes for use in the treatment of patients with acute liver failure and presents a summary of the first clinical experience with it.

## HEPATASSIST SYSTEM

The HepatAssist System (Fig. 40.1) is an extracorporeal circuit consisting of a hollow-fiber membrane bioreactor containing  $7 \times 10^9$  viable cryopreserved porcine hepatocytes, two charcoal columns, a membrane oxygenator, and a perfusion pump. The bioreactor contains polysulfone hollow fibers with a nominal 0.15- $\mu\text{m}$  pore size. Prior to treatment, the hepatocytes are thawed and placed into the bioreactor along with collagen-coated dextran beads for cell attachment and spatial distribution. The HepatAssist System is used in combination with a commercially available plasmapheresis machine; plasma is perfused through the system at a flow rate of 400 ml/min. One hepatocyte bioreactor is used per treatment.

## CELL PREPARATION

Porcine hepatocytes were isolated from 20- to 45-pound pigs meeting acceptance criteria established in compliance with United States xenotransplantation draft guidelines (U.S. Public Health Service, 1996). The cells were isolated using a modified method based on that reported by Morsiani *et al.* (1995). Typical yields were  $145 \times 10^6$  hepatocytes per gram of liver with better than 88% cell viability. The cells were cryopreserved after isolation to allow for quality control evaluation and distribution to and storage at medical centers (Cain *et al.*, 1996, 1999). All cell processing steps, including organ procurement, hepatocyte isolation, and cryopreservation, took place under the current good manufacturing practice (CGMP) standards of the Food and Drug Administration (FDA).

**THE HEPATASSIST CIRCUIT**

Fig. 40.1. HepatAssist liver support system, with permission from Circe Biomedical, Inc.

Cell quality control (QC) testing was performed at all critical steps of the process (Table 40.1) and the cryopreserved hepatocytes were released for clinical use only when all in-process and final-release testing parameters met established criteria. A minimum of 45 days was required to complete all QC testing and analyses on the animal donor, the final cell product, and the in-process cell and media samples.

### CLINICAL STUDY

A phase I/II clinical study to assess the safety and tolerability of treatment with the HepatAssist System was conducted at three centers, two in the United States and one in France, under an Investigational New Drug (IND) protocol from the United States FDA and with approval of the French regulatory authorities. The protocol was an open-label, uncontrolled, multicenter study in patients with acute liver failure and stages III and IV hepatic encephalopathy (Watan-

**Table 40.1. Porcine hepatocyte processing quality control**

Process steps	Tests and analyses
1. Pigs assessment	Serologic screening Blood analysis Bacteriology Mycoplasma screening Virology Histopathology
2. Organ procurement, hepatocyte isolation, hepatocyte cryopreservation	Bioburden Sterility Endotoxin Cell viability Cell count
3. Final product (cryopreserved hepatocytes)	Sterility Endotoxin Mycoplasma screening Virology Cell viability Cell count Cell function

abe *et al.*, 1997b; Hewitt *et al.*, 1998; Chen *et al.*, 1997). Key patient selection criteria were as follows:

#### Key inclusion criteria

1. Primary diagnosis of acute liver failure
2. Stages III and IV come according to Trey classification
3. Patients over 12 years of age or 40 kg body weight

#### Key exclusion criteria

1. Contraindication for liver transplantation
2. Malignancy, hypoxemia, irreversible brain damage
3. Overt bleeding or hematocrit less than 24%
4. Known hypersensitivity or allergic reaction to pig products

#### Key treatment withdrawal criteria

1. Procurement of suitable liver for transplantation
2. Improvement of hepatic encephalopathy to stage II prior to treatment
3. Withdrawal of patient from transplant candidate list

Thirty-one patients were enrolled in the study, 17 at Cedars-Sinai Medical Center, Los Angeles, CA; 5 at the University of California in Los Angeles; and 9 at Paul Brousse Hospital, Villejuif, France. Etiologies included 28 patients with acute liver failure and 3 patients with primary non function (PNF) following liver transplantation. An additional 8 patients (7 ALF, 1 PNF) were treated prior to the IND protocol under local institutional review board approval (Watanabe *et al.*, 1997b). Each treatment with the HepatAssist System lasted 6 hr and was administered at the rate of approximately one treatment per day. A total of 80 treatments were administered, or on average 2.1 treatments (range 1 to 5) per patient.

## SAFETY

The system was found to be well tolerated (Watanabe *et al.*, 1997b; Hewitt *et al.*, 1998; Chen *et al.*, 1997). The main adverse events were episodes of hypotension in eight patients. In most cases, these events were of mild severity, were readily managed, and did not cause an interruption in the liver support treatment. There was no evidence that treatment with the liver support system resulted in unmanageable adverse events.

**Table 40.2 Survival rates of FHF/PNF patients treated with the HepatAssist System**

Patients	N <sup>a</sup>
Treated with HepatAssist System	39 (100%)
Died waiting for a liver graft	0 <sup>b</sup> (0%)
Survived without transplantation	6 (15%)
Transplanted	32 (82%)
Died 1 to 30 days post-transplantation	3 (8%)
Survived 30 days and beyond	35 (90%)

<sup>a</sup>Number of patients (percentage survival rate).

<sup>b</sup>One patient died after being taken off the transplant waiting list.

### PERFORMANCE

Survival rates for all 39 patients are summarized in Table 40.2. Six patients recovered post-treatment without the need for a graft; all patient candidates for orthotopic liver transplantation were transplanted and the overall patient survival rate at 1 month was 90%. This study did not include a control group; however, the survival of ALF patients, including OLT, is typically 50–60% (Plevris *et al.*, 1998; Samuel, 1998).

Samuel (1998), from Paul Brousse Hospital (one of the three centers in the HepatAssist System clinical study), reported a series of 177 ALF patient candidates for OLT (Table 40.3). Of these, 25 patients (14%) died while waiting for a liver and 2 patients (1%) survived without the need for a graft. Overall survival rate at 1 month was 67 and 58% at 1 year. The principal cause of death before and after liver transplantation was brain death; 95% of the patients were in coma at the time of transplantation and 56% had increased intracranial pressure requiring treatment. In a series of 17 patients treated at Cedars Sinai Medical Center with the HepatAssist System, the intracranial pressure decreased from 17.2 mmHg pretreatment to 9.7 mmHg ( $p < 0.01$ ) posttreatment, and several neurologic parameters improved (Hewitt *et al.*, 1998; Chen *et al.*, 1997). The Glasgow coma score increased from 6.9 to 7.5 ( $p = 0.05$ ), and the comprehensive level of consciousness score increased from 24.8 to 31.2 ( $p < 0.01$ ). In addition, blood ammonia, bilirubin, and liver enzymes improved posttreatment (Hewitt *et al.*, 1998; Chen *et al.*, 1997).

### PATIENT SCREENING FOR PORCINE ENDOGENOUS RETROVIRUS

Porcine endogenous retrovirus (PERV) genomic sequences are present in pig cells. Although PERV infectivity has been documented to date only *in vitro* in porcine and human cell line cocultures, the possibility that xenotransplantation with porcine tissue may induce porcine retroviral expression in the recipient is of concern (Bach and Fineberg, 1998; Vogel, 1998; Patience *et al.*, 1997, 1998; Heneine *et al.*, 1998; Chapman *et al.*, 1999). We conducted a retrospective study

**Table 40.3. Survival rates of FHF patients admitted at Paul Brousse Hospital<sup>a</sup>**

Patients	N
Patients admitted for transplantation	177 (100%)
Died waiting for a liver graft	25 (14%)
Survived without transplantation	2 (1%)
Transplanted	150 (85%)
Died 1 to 30 days posttransplantation	34 (19%)
Survived 30 days and beyond	118 (67%)

<sup>a</sup>Patients were candidates for liver transplantation (Samuel, 1998).

to assess PERV infectivity in 28 patients treated with the HepatAssist System. All patients tested negative for PERV using polymerase chain reaction DNA analysis of peripheral blood mononuclear cells collected 1 to 5 years posttreatment. Of the 28 patients, 25 were transplanted posttreatment and received immunotherapy for up to 5 years; the other 3 patients recovered without the need for a graft. In summary, our results did not support the presence of PERV infectivity in patients treated with this porcine hepatocyte-based bioartificial liver.

*In vitro* results also showed that our porcine hepatocytes did not produce infectious PERV in cocultures with human kidney cell line 293 (Patience *et al.*, 1997). In addition, *in vitro* experiments using cartridges seeded with the porcine cell line PK-15, which expresses PERV, showed that the membrane in the HepatAssist System decreased PERV transmission by a factor of  $10^5$  to  $10^6$ .

## CONCLUSION

Numerous extracorporeal therapies have been clinically evaluated for their ability to temporarily support patients with acute liver failure (Riordan and Williams, 1997). The success of orthotopic liver transplantation has demonstrated the importance of not only detoxification but also of synthetic and metabolic functions in supporting ALF patients. This led to the advent of cell-based systems or bioartificial livers. There are three potential areas in which a liver support system can benefit ALF patients: (1) increasing patient survival without the need for a graft, (2) bridging patients to transplantation, and (3) decreasing patient mortality posttransplantation.

Initial clinical evaluation of the HepatAssist System demonstrated its safety and tolerability in patients with acute liver failure (Watanabe *et al.*, 1997b; Hewitt *et al.*, 1998; Chen *et al.*, 1997). The study showed a 90% survival rate; a pivotal phase II/III, multicenter, randomized, controlled, parallel group study of the HepatAssist System compared to standard surgical-intensive care in patients with acute hepatic failure has been initiated to further establish system efficacy.

The protocol includes patients with stages III and IV hepatic encephalopathy due to fulminant hepatic failure or primary nonfunction following liver transplantation. The primary end point is 30-day patient survival. The study includes the enrollment of 150 patients with interim analyses. The clinical study was approved in July 1998, and 14 clinical centers in the United States and Europe are currently participating in the study.

The HepatAssist design is based on hollow-fiber membrane bioreactors. Plasma circulates through the lumen of the fibers and the cells are held in the extracapillary space. Although the membrane's porous structure is impermeable to the hepatocytes, it has been designed to maximize mass transfer so that circulating toxins and nutrients reach the cells and metabolites and synthetic products are returned to the patient. However, the membrane also plays a role in decreasing the potential risk of transmission of pathogens. The membrane used in the HepatAssist System decreased by a factor of at least 100,000 the transmission of PERV as measured *in vitro* by the infectivity of human cell line 293. In addition, the membrane is not permeable to porcine cells, therefore significantly reduces the risk of porcine cell infusion into the patient and cell microchimerism in patients treated with the HepatAssist System.

We are currently conducting the first controlled, randomized, multicenter trial in the development of a bioartificial liver. It is our hope that our study, as well as other future studies, will help explore more fully the critical elements of a liver support system (e.g., design, cell sources) and improve our understanding of the pathogenesis of acute liver failure. These systems might also help define an understanding and other potential therapeutic approaches regarding liver regeneration in patients with liver disease.

## ACKNOWLEDGMENT

The authors would like to acknowledge and thank Phyllis Ohanian for her help in the preparation and editing of this manuscript.

## INTRODUCTION

Tissue engineering offers a revolution in basic research and in clinical programs in cell and gene therapies, novel forms of plastic surgery, implantable devices, and bioartificial organs. Much of the foundation of this new field is a synthesis of the concepts and technologies in cell and molecular biology, cell and organ culture, extracellular matrix biology and chemistry, polymer sciences, and stem cell and lineage biology. Its greatest impact has been with respect to quiescent tissues, long the bane of investigators, who were forced to study quiescent tissues *in vivo* to achieve any realistic expectations of fully normal and differentiated cells or, if they used them in culture, were forced to offer feeble qualifiers to explain the aberrant behavior *ex vivo* of such differentiated cells.

Despite the extraordinary collective knowledge extant in the fields of cell and molecular biology, investigators have been stymied in trying to maintain tissues *ex vivo* and have struggled to identify conditions under which the cells would express their differentiated functions for more than a few days. In retrospect, past years of confusion are understandable, because the requirements for normalcy in the biology of cells and tissues are multifactorial and complex. Thus, the common approach of utilizing clonal cell populations, desirable for achieving rigorous controls, precluded the essentials of metazoan biology, that is, the biology of communities of cells with dynamic and complicated interactions. It is now appreciated that tissue-specific gene expression cannot be achieved by using a cloned cell population placed onto a foreign, nonbiological surface (glass, plastic) and in a soluble medium (basal medium) with serum that *in vivo* occurs only in a wound. Indeed, cultures on plastic and in serum-supplemented media are now recognized as models of scar tissue formation (cirrhosis, fibrosis) but not of normal physiologic processes.

Tissue engineering comprises a number of new approaches that include using porous, flexible biological substrata (extracellular matrix components) and media defined for specific nutritional and signaling needs; coculturing of multiple cell types with dynamic interactions, using conditions permitting the cells to achieve three-dimensionality; optimizing mass transfer; and recognizing that all tissues are organized as progenitors and maturational lineages. In this chapter we concentrate on these novel approaches, with a special focus on the following requirements:

1. The need for stem cells or progenitors as starting points for cell and gene therapies and for bioartificial organs
2. The importance of recognizing the maturational lineage with its implicit lineage-dependent growth properties and tissue-specific gene expression
3. The development of logical microenvironments using purified and defined components
4. The use of biodegradable scaffoldings to facilitate presentation of that microenvironment in configurations of three-dimensional space
5. An analysis of bioreactor designs to show the failings of most current bioreactors and some possible designs that might work for adherent cell populations

\*Authors contributed equally.

## 6. Novel approaches for analyses of bioartificial organs and including nuclear magnetic resonance spectroscopy (NMR) and magnetic resonance imaging (MRI)

To be able to focus on these diverse themes within a document of requisite brevity, we have elected to focus almost exclusively on liver as a model and will use representative literature to support the discussions, referring the reader to more exhaustive reviews for further details. For example, the history of the oval cell field, part of the background for current understandings of liver stem cell biology, has been given in the review in the first edition (Reid, 1997) and in several additional excellent reviews (Grisham and Thorgeirsson, 1997; Sell, 1998), and will not be presented here.

In intact organs and tissues, three interlocking factors—stem cell and maturational lineage mechanisms, soluble signals (hormones, growth factors, nutrients, gas exchange), and insoluble signals (extracellular matrices)—operating independently and interdependently, govern growth and differentiation of all cells. Dynamic and continuous interactions between these determinants are responsible for the complexity, the heterogeneity, and the subtleties of all aspects of tissue phenotype and regulatory processes. In the sections that follow, we will outline approaches we are taking to manage and/or manipulate each of these factors. The first section describes liver biology and the use of stem cells and early progenitors to generate entire tissues. The second section describes use of extracellular matrices with or without biocompatible and/or biodegradable supports that achieve the mass transfer requirements of the tissue, and presents engineering principles of tissue mimicry, optimization, and scale-up. In the third section, we describe the physical and biologic analyses of bioreactor designs that can be used for adherent cell populations such as the liver when trying to establish bioartificial organs. We also discuss methodologies that can be used to analyze cells in three dimensions, including novel NMR and MRI techniques.

## LIVER ORGANIZATION AND DEVELOPMENT

Tissue engineering of the liver requires honoring the architecture and cellular paradigms that govern its functions using principles of tissue mimicry. The primary structural and functional unit of the mature liver is the acinus (Fig. 41.1, see color plate), which in cross-section is organized like a wheel around two distinct vascular beds: three to seven sets of portal triads (each with a portal venule, hepatic arteriole, and a bile duct) for the periphery, and with the central vein at the hub. The liver cells are organized as cell plates lined on both sides by fenestrated endothelia, defining a series of sinusoids that are contiguous with the portal and central vasculature. A narrow space, the space of Disse, separates the endothelia from hepatocytes all along the sinusoid. As a result of this organization, hepatocytes have two basal domains, each of which faces a sinusoid, and an apical domain, which is defined by the region of contact between adjacent hepatocytes. The basal domains contact the blood and are involved in the absorption and secretion of plasma components, whereas the apical domain forms bile canaliculi, specialized in the secretion of bile salts, and is associated through an interconnecting network with bile ducts. Blood flows from the portal venules and hepatic arterioles through the sinusoids to the terminal hepatic venules and the central vein.

Based on this microcirculatory pattern, the acinus is divided into three zones: zone 1, the periportal region; zone 2, the midacinar region; and zone 3, the pericentral region (Table 41.1 and Fig. 41.2). Proliferative potential, morphologic criteria, ploidy, and most liver-specific genes are correlated with zonal location (Gebhardt, 1988; Traber *et al.*, 1988; Gumucio, 1989). Gradients in the concentration of blood components (including oxygen) across the acinus, and following the direction of blood flow from the portal triads to the central vein, are responsible for some of this zonation—for example, the reciprocal compartmentation of glycolysis and gluconeogenesis. However, the periportal zonation of the gap junction protein connexin 26 and the pericentral zonation of glutamine synthetase, to name only two, are insensitive to such gradients, are more representative of most tissue-specific genes, and appear to be determined by factors intrinsic to the cells or to variables other than blood flow in the microenvironment.

In addition to hepatocytes, bile duct epithelial cells (cholangiocytes), and endothelial cells, the region between the portal and central tracts contains other cell types, such as Ito cells and Kupffer cells. These play prominent roles in pathogenic conditions of the liver, especially in inflammation and fibrosis, but their direct contribution to the main homeostatic functions of the normal organ is apparently small. Although their biology is of importance, they will not be discussed further here.

**Table 41.1 Liver acinus zones**

Characteristic	Zone		
	1	2	3
Ploidy	Diploid	Tetraploid	Mix of tetraploid and octaploid
Average size	7–20 $\mu\text{m}$	20–30 $\mu\text{m}$	30–50 $\mu\text{m}$
Growth	Maximum	Limited (mostly hypertrophic)	Negligible
Extracellular matrix	A gradient in the matrix chemistry located in the space of Disse		
Gene expression	Early	Intermediate	Late

The liver develops as a result of the convergence of a diverticulum formed from the caudal foregut and the septum transversum, part of the splanchnic mesenchyme (reviewed in Zaret, 1998). The formation of the hepatic cells begins after the endodermal epithelium interacts with the cardiogenic mesoderm (Douarin, 1975), probably via fibroblast growth factors (Jung *et al.*, 1999). The specified hepatic cells then proliferate and penetrate into the mesenchyme of the septum transversum with a cordlike fashion, forming the liver anlage. The direct epithelial–mesenchymal interaction is critical in these early developmental stages of the liver and dictates which cells will become hepatocytes or cholangiocytes, and the fenestrated endothelia, respectively. Mutations in the mesenchyme-specific genes *blx* and *jumonji* block liver development, illustrating the importance of contributions from this tissue (Hentsch *et al.*, 1996; Motoyama *et al.*, 1997). Early in its development, the liver consists of clusters of primitive hepatocytes bounded by a continuous endothelium lacking a basement membrane, and abundant hematopoietic cells. As the endothelium is transformed to become a discontinuous, fenestrated endothelium, the vasculature, especially the portal vasculature, becomes more developed, with the production of basement membranes. The portal interstitium may provide the trigger for the development of bile ducts, and as it surrounds the portal venules, hepatic arterioles, and bile ducts, portal triads are formed. Immature hepatocytes rapidly proliferate and parenchymal plates are formed, probably in response to changes in the amount and distribution of tissue-organizing molecules such as cell–cell adhesion molecule 105 (CCAM 105), Agp110, E-cadherin, and connexins, coincident with the relocation of most, but not all, of the hematopoietic cells to the bone marrow (Stamatoglou and Hughes, 1994). Studies suggest that some hematopoietic progenitors persist in adult quiescent rodent livers (Sigal *et al.*, 1995a), and hematopoietic stem cells have been isolated from both adult human (Crosbie *et al.*, 1999) and murine liver (Taniguchi *et al.*, 1996, 1997). The mature physical organization is achieved within the first weeks after birth in rodents. Metabolic zonation is established according to somewhat different schedules for different enzymes, but becomes evident in the period following birth.

Fig. 41.2. Schematic of the liver acinus. Information relevant to the pattern of size, ploidy, growth, and gene expression are given in Table 41.1. PV, Portal vein; BD, bile duct; HA, hepatic artery; SE, sinusoidal endothelium over the space of Disse; CV, central vein. (Modified from Brill *et al.*, *Proc. Soc. Exp. Biol. Med.* (1993). **204**, 261–269, with permission.)

## IDENTIFICATION, ISOLATION, AND SOURCING OF CELLS FOR TISSUE ENGINEERING

### STEM CELLS AND COMMITTED PROGENITORS

Tissues are organized as maturational lineages fed, like a spring, by stem cells or early progenitor cell populations (Sigal *et al.*, 1992; Sell, 1993; Potten, 1997). The tissue is defined as going from young, to middle age, to old cells. The maturational process is accompanied by lineage-position-dependent changes in cell size, morphology, antigenic profiles, growth potential, and gene expression. Growth is maximal in the stem cells and early progenitors and wanes with progression through the lineage. Indeed, in many mammalian tissues, the majority of the cells in the adult tissue are polyploid, mostly tetraploid, or octaploid. Even in the liver, one of the most renowned regenerative tissues in the body, less than a third of the cells are diploid. Only the diploid cells have been found capable of undergoing repeated, complete cell division. Data support the concept that the bulk of the regenerative potential in a tissue derives from the diploid cell population and that the older cells contribute to regeneration by increasing cell mass via hypertrophic responses associated with polyploidy (Sigal *et al.*, 1999). Therefore, the best hopes for cell growth, whether in cell or gene therapies or in bioartificial organs, are with the diploid cell population of the tissue.

Defining stem cells is difficult (Loeffler *et al.*, 1997; Morrison *et al.*, 1997). In the older embryological literature, stem cells were defined as primitive cells that self-replicate, that are pluripotent, i.e., produce daughter cells with more than one fate, that grow very, very slowly (are largely in  $G_0$ ), and that are dependent on signals (undefined) derived from tissue-specific forms of mesenchymal cells. As discussed extensively in an interesting and provocative review (Morrison *et al.*, 1997), this definition does not apply in its entirety to all known stem cells. There are stem cells that cannot be considered the most primitive cells within a tissue, self-replication appears to apply rigorously only to germ cells, pluripotency can be variable depending on the circumstances, and the growth rate of the stem cells is tissue-specific. Despite the increasing complexity in the characterizations of stem cells, there are generic attributes that seem to hold. As Morrison *et al.* (1997) joked, "It is hard to define, but I know it when I see it," a phrase they quoted from United States Supreme Court Justice Byron White's comments with respect to pornography. The definitions and markers for stem cells are likely to emerge in the coming years with the enthusiastic interest now being bestowed on stem cells by many investigators. For now, the terminology and concepts of the stem cell field are as summarized briefly below.

### EMBRYONIC STEM CELLS AND OTHER TOTIPOTENT CELLS

Cells with the potential to participate in the development of all cell types, including germ cells, are referred to as "totipotent" and include the zygote and normal embryonic cells up to the 8-cell stage (the morula). Embryonic stem (ES) cells consist of permanent cell populations derived from totipotent normal cells (blastocysts) and were first reported in the early 1980s (Evans and Kaufman, 1981; Martin, 1981). ES cell lines can be cultured *in vitro* with maintenance of totipotency. ES cells are tumorigenic if introduced into immunocompromised hosts in any site other than *in utero*, forming teratocarcinomas. However, when they are injected back into normal blastocysts, they are able to resume embryonic development and participate in the formation of a normal, but chimeric, mouse. Although ES cell lines have been established from many species (mouse, rat, pig, etc.), only the mouse system has been used routinely to generate animals with novel phenotypes (knockouts, transgenics) by merging modified ES cells from culture to blastocysts and then implanting the blastocysts into pseudopregnant hosts. Embryonic germ (EG) cell lines, which show many of the characteristics of ES cells, can be isolated directly *in vitro* from the primordial germ cell population. As with ES cells, the EG cells form teratocarcinomas when injected into immunocompromised mice and contributed to chimeras, including the germ line, when injected into blastocysts (Labosky *et al.*, 1994).

Transformed totipotent cells include embryonal carcinomas and teratocarcinomas. Stevens (1964) identified and described teratocarcinomas in mice and showed that many cell types are present in these tumors. On the basis of cellular characteristics and multipotent developmental activity, the most primitive of teratocarcinoma cells have been designated embryonal carcinoma (EC) cells (Stevens and Pierce, 1975). Ralph Brinster and associates showed that following the transfer of EC cells into blastocysts, the EC cells were able to contribute to donor tissues such as hair (Brin-

ster, 1974). Subsequently, Mintz and Illmensee (1975) demonstrated in a beautiful series of publications that embryonal carcinoma cells, fused with blastocysts and implanted *in utero* in pseudo-pregnant hosts, are capable of yielding an animal with contributions by the embryonal carcinoma cells to all tissue types. Thus, the malignancy of the cells was thought initially to be due to multipotent cells being in the wrong microenvironment at a critical time (Mintz and Illmensee, 1975). However, even though malignant totipotent cells were able to participate normally in development, findings that support the importance of the microenvironment for normal differentiation, there has always been recognition that an aberrant gene(s) is also a factor, along with microenvironment, in giving rise to malignancies. Consequently, there was a drive toward using normal totipotent cells, efforts that came to fruition in the development of embryonic stem cell lines.

Highly publicized experiments have reported that human ES cell cultures have been established now from human embryos (Thomson *et al.*, 1998). The intent for these human ES cells is to inject them into tissues with the hope that they will be able to reconstitute damaged organs and tissues. Given the findings that ES and EG cells form tumors when injected into sites other than *in utero* (see above), the plan to inoculate human ES cells into patients is unrealistic and carries the grave possibility of creating tumors in the patients. To overcome this impasse, some groups are pursuing the plan of differentiating the ES cells under defined microenvironmental conditions to become determined stem cells that can then be inoculated into patients (Kirby *et al.*, 1996). For example, there is some measure of success in generating hematopoietic progenitors (Kennedy *et al.*, 1997). However, there still remains the concern that residual ES cells in the culture could pose the risk of tumorigenesis, if the cultures are inoculated into a patient. In summary, until research in developmental biology reveals the myriad controls dictating the fates of cells during embryogenesis, the ES cells will remain as an experimental tool with little hope for clinical programs in cell or gene therapies. The only realistic option for clinical programs in cell and gene therapies is to use determined stem cells that have restricted their genetic potential to that for a limited number of cell types. By contrast, the ES cells may hold great promise for bioartificial organs for those tissue types (e.g., hematopoietic cells) that are produced by ES cells under known conditions.

## TELOMERASE

Telomeres are nucleoprotein structures that serve a critical function in protecting the ends of linear chromosomes. Telomerase, a ribonucleoprotein reverse transcriptase, plays a key role in the maintenance of telomere length and function. Telomerase is composed of a protein catalytic subunit, telomerase reverse transcriptase (TERT), and an RNA component, telomerase RNA (TR). Only TERT and TR are required for core *in vitro* telomerase activity (Greider, 1998).

Whereas embryonic stem cells have high levels of telomerase and determined stem cells have detectable to moderate levels of telomerase, differentiated somatic cells possess low or undetectable telomerase activity, and telomeres shorten with each cell division *in vivo* and *in vitro*. Accelerated loss of telomeres is associated with cellular senescence. Tumor cells, increasingly recognized to be transformants of stem cells and early progenitors, have high telomerase levels. These observations support the proposition that telomere shortening in the absence of telomerase plays a critical role in cell entry into senescence. In fact, ectopic expression of TERT in primary culture was sufficient to induce telomerase activity and allow unlimited growth (Bodnar *et al.*, 1998). One can expect that stem cell or progenitor populations with high proliferative capacity should have high telomerase activity to maintain the telomere structures. Weissman and colleagues assayed telomerase activity in single hematopoietic cells at different developmental stages, and found that 70% of bone marrow hematopoietic stem cells exhibited detectable telomerase activity (Morrison *et al.*, 1996). However, only a minority of differentiating and transient multipotent progenitors had detectable telomerase activity. These results indicate that telomerase expression is associated with self-renewal potential, rather than proliferative potential or undifferentiated status of cells. Confirming this, germinal center B cells in the process of clonal expansion were enriched in telomerase-positive cells more than 10-fold relative to splenic B cells (Morrison *et al.*, 1996).

To explore the effect of telomere loss *in vivo*, telomerase-deficient mice (knockouts) were generated by deletion of the mouse TR gene (Blasco *et al.*, 1997). Telomerase deficiency leads to a depletion of male germ cells, diminished hematopoietic colony formation, and impaired mitogen-induced proliferation of primary splenocytes (Lee *et al.*, 1998). These findings indicate an essential role for telomerase in organ systems with high proliferative activity. The effects on splenic lym-

phocytes demonstrate that the association between self-renewal potential and telomerase expression is not specific to primitive progenitors. The TR knockout mice also show that short telomere length leads to chromosome instability, suggesting that placing normal cells that do not contain telomerase into a proliferative environment subjects them to increased risk of tumorigenic mutations. This is yet further evidence that determined stem cells, not well-differentiated somatic cells or embryonic stem cells, are reasonable candidates for *ex vivo* expansion for tissue engineering or for cell and gene therapies. Moreover, study of determined stem cells should help in defining approaches for directed differentiation of the totipotent cell lines.

### NUCLEAR TRANSFER TECHNIQUES FOR CLONING OF MAMMALS

Genetic engineering of mammals has long been possible with ES cells, but not with embryonic germ cells or with somatic cells, even determined stem cells. The ability to clone mammals has now been achieved by utilizing nuclear transfer from some but not all somatic cells into enucleated cells, suggesting that cytoplasmic factors are responsible for restricting the genetic potential of the nucleus (Wilmut *et al.*, 1997; Kato *et al.*, 1998; Wakayama *et al.*, 1998; Wells *et al.*, 1999). The groundwork for this realization was pioneered by Gurdon and associates, who developed the techniques of nuclear transplantation (Gurdon, 1962). They hypothesized that nuclei remain totipotent even in a differentiated somatic cell and tested the idea by transferring nuclei from the intestinal endoderm of *Xenopus* tadpoles into activated enucleated eggs. Of the eggs injected, 1.4% of them (10 individuals) developed to the feeding tadpole stage. Serial transplantation, in which the blastula formed as a result of the initial transfer was used as a donor of nuclei for a second transfer into activated eggs, yielded 7% to the feeding tadpole stage, and 7 individuals that metamorphosed into fertile adult frogs (Gurdon, 1962), showing that the original donor nuclei were totipotent. Two major criticisms, that either primordial germ cells, which can migrate through to the gut, were the actual nuclear donors, or that the intestinal epithelia of the feeding-stage tadpole are not truly differentiated, as witnessed by the presence of yolk platelets, were addressed in subsequent experiments. Cultured epithelial cells from adult frog foot webbing, which expressed keratin and were thus considered differentiated, were used as nuclear donors. Serial transplantation yielded numerous tadpoles (Gurdon *et al.*, 1975), demonstrating that the nuclei of some, but not all, somatic cells can be reactivated by transferring the nucleus into an embryonic cytoplasm to yield cells that can mature into neurons, blood cells, muscles, or bones of a swimming tadpole.

### MAMMALIAN CLONING

Wilmut and colleagues (1997) have found that viable lambs can be produced by transplanting nuclei from cellular subpopulations of adult mammary glands. By transplanting nuclei from cultured cells from the mammary gland of a 6-year-old ewe in the last trimester of pregnancy at passage numbers 3–6 to an enucleated metaphase II-arrested oocyte, they have created a viable lamb. The success is due largely to the fact that nuclei were taken from cells in the G<sub>0</sub> phase of the cell cycle. Quiescent, diploid donor cells were produced by reducing the concentration of serum in the medium from 10 to 0.5% for 5 days, causing the cells to exit the growth cycle and arrest in G<sub>0</sub> (Wilmut *et al.*, 1997). Moreover, they investigated the telomere length in the cloned sheep. The mean size telomere length decreases in control animals with increasing age, at a mean rate of 0.59 kilobase (kb) per year. The size in the cloned sheep was reduced significantly compared with the age-matched control animals (Shiels *et al.*, 1999). The smaller size is consistent with the age of the progenitor mammary tissue (6 years old) and with the time spent in culture before nuclear transfer. The most likely explanation for the shorter telomere size in the cloned sheep is a reflection of the transferred nucleus, although it is not known whether the actual physiologic age of animals derived by nuclear transfer is reflected accurately by the telomere length (Shiels *et al.*, 1999). It is unknown whether nuclei from any maturational stage of somatic cell can be totipotent, or whether totipotent nuclei are restricted to a discrete subpopulation of maturational stage(s) (e.g., progenitors). However, the important realization at present is that any somatic cell can have a totipotent nucleus.

The cloned sheep has undergone two normal pregnancies and has successfully delivered healthy lambs (Shiels *et al.*, 1999). Mammalian cloning using nuclear transfer techniques with donor nuclei from somatic cells has now been used also to generate mice and calves (Kato *et al.*,

1998; Wakayama *et al.*, 1998; Wells *et al.*, 1999). The results suggest that nuclei of some (all?) somatic cells can be converted to a pluripotent or totipotent state if put through nuclear transfer into an enucleated cell with embryonic cytoplasm. Although the cloning experiments will yield numerous studies on nonhuman species to generate cloned animals of some scientific or commercial significance, their implications for humans are far more limited. Mostly, they will be used to define the sources of controls for differentiation, now shown to occur in the cytoplasm, offering hope by which to dictate the fates of a totipotent cell such as the ES cells. Thus, for now there are no immediate ramifications of this technology for cell or gene therapies or for other tissue engineering goals such as bioartificial organs for humans.

### DETERMINED STEM CELLS

Determined stem cells derive from embryonic stem cells but have restricted genetic potential through molecular mechanisms of “cellular commitment” that are understood now to derive from poorly defined changes occurring in the cytoplasm, and occurring during embryogenesis following the 8-cell stage embryos. The one division between the 8-cell and 16-cell stages begins the specialization process toward tissues. One can hypothesize that there may be remnants of the stem cells from the germ layers of the early embryo or determined stem cells producing families of tissues. If germ layer-determined stem cells exist, there would be three types: ectodermal (epidermal and nervous tissues), mesodermal (blood, bones, cartilage, blood vessels), and endodermal (lung, thyroid, intestine, pancreas, liver, etc.). The hypothesis of adult tissues containing determined stem cells equivalent to the germ layer stem cells is untested at present.

Currently, the term “stem cell” persists in being defined as a population of cells that self-replicate, have extensive growth, and are pluripotent. All known determined stem cells have been shown to have extensive growth and to be pluripotent (Potten, 1997). However, there is debate whether any known determined stem cell is capable of self-replication. The debate has been fueled by the studies on telomerase in which determined hematopoietic stem cells from embryos versus adults have distinct telomerase levels. This issue is likely to be the basis of much research in the coming years and so cannot be addressed rigorously at this time.

Although it is implicit that there must be a cascade of stem cells with increasingly narrower phenotypic potential, our knowledge of determined stem cells derives entirely from those thought to be capable of producing the mature cells of a limited number of tissues or even of only one organ or tissue, and which are located in those tissues. Because studies of determined stem cells have focused only on their fates as the mature cells of the designated tissue (epidermal stem cells to yield skin; neuronal stem cells to yield nervous tissue; etc.), their real potential is unknown.

In the past few years, the first real evidence has emerged that identifies determined stem cells with a phenotypic potential intermediate between that of embryonic stem cell and a tissue-specific stem cell. One example will be used as representative: the hemangioblast. The hemangioblast is considered a parental stem cell to determined stem cells for endothelia and hematopoietic cells. The close temporal and spatial relationship of hematopoiesis and vascular development is consistent with the existence of a postulated progenitor. Blood and endothelial progenitors coexpress some molecular markers, such as CD34 and Flk-1 [a receptor for vascular endothelial cell growth factor (VEGF)]. Targeted disruption of Flk-1 results in combined vascular and hematopoietic defects (Shalaby *et al.*, 1995). Flk-1 null embryonic stem cells also fail to contribute to either endothelium or hematopoiesis in chimeric mice (Shalaby *et al.*, 1997). These results show that Flk-1 is essential for both lineages. Furthermore, single Flk-1-positive cells from avian embryos can develop into either hematopoietic or endothelial colonies (Eichmann *et al.*, 1997). These studies are all consistent with the existence of the Flk-1-positive hemangioblast. Such a progenitor may develop under the influence of the stem cell leukemia/T cell acute leukemia-1 (SCL/TAL-1) gene, which was first identified through its translocation in acute T cell leukemia. It encodes a basic helix–loop–helix (bHLH) transcription factor that is expressed specifically in hematopoietic cells, vascular endothelium, and the developing brain. SCL null mice lack embryonic hematopoiesis, and SCL null ES cells also fail to contribute to any hematopoietic lineage in the chimeric mice (Porcher *et al.*, 1996; Robb *et al.*, 1996). Although the role of SCL in endothelial development remains obscure in mice, it was shown that the ectopic expression of the zebrafish SCL homolog in early posterior mesoderm resulted in overproduction of common hematopoietic and endothelial precursors. This gain-of-function experiment in zebrafish indicates that SCL specifies formation

of hemangioblasts (Gering *et al.*, 1998). It is worth considering the possible role of bHLH proteins in the control of cell fate in other tissues. For instance, ectopic expression of the myogenic bHLH proteins MyoD, Myf-5, MRF4, or myogenin all induced muscle differentiation (Weintraub, 1993), and the crucial role of the *achaete-scute* complex, bHLH genes in *Drosophila*, in neural development is conserved over species (Guillemot *et al.*, 1993).

The bulk of the literature on determined stem cells is with respect to hematopoietic stem cells (Heimfeld and Weissman, 1991; Marshall and Lord, 1996). However, proof of the existence and the potential for stem cells in other tissues has emerged within the past decade (Potten, 1997). The most well studied of these, independently of the hematopoietic stem cells, are the neuronal stem cells (Snyder and Macklis, 1995; Calof *et al.*, 1998; Kempermann and Gage, 1999), mesenchymal stem cells (Caplan, 1994), skin stem cells (Reynolds and Jahoda, 1994; Cotsarelis *et al.*, 1999), intestinal stem cells (Potten, 1998), and liver stem cells (Sell, 1994; Reid, 1996; Grisham and Thorgeirsson, 1997). Disparate, diverse investigations suggest that stem cells are also in the pancreas (Gittes *et al.*, 1996), lungs (Mason *et al.*, 1997), prostate (De Marzo *et al.*, 1998), and other tissues (Potten, 1997).

### DETERMINED STEM CELLS IN THE LIVER

In reviews and articles, we and others have summarized the evidence for and against the hypothesis that the liver, even the adult liver, contains determined stem cells that can give rise to cholangiocytes and hepatocytes (Sigal *et al.*, 1992, 1994, 1995b; Brill *et al.*, 1995; Grisham and Thorgeirsson, 1997). The discussion below is much abbreviated, and readers should consult any of the published reviews on hepatic determined stem cells (and see Reid, 1997) to see discussion of the very extensive literature on this subject. In brief, there are currently three competing models with respect to liver biology and regeneration:

Model 1. There are no stem cells. All of the liver cells are coequal and fully capable of clonal growth both *in vitro* and *in vivo* (Farber, 1995; Kennedy *et al.*, 1995; Michalopoulos and DeFrances, 1997). These arguments maintain that the ploidy state of the liver cells is irrelevant, that the tetraploid and octaploid cells should proliferate just as well as diploid cells, and the only variables to consider for proliferative potential are microenvironmental factors.

Model 2. There are hepatic stem cells, but they constitute a small, residual population left over from embryogenesis within the adult liver and are silent except in disease states such as cancer (Sell, 1994; Grisham and Thorgeirsson, 1997; Kay and Fausto, 1997). All liver biology and liver regeneration in the adult occur from adult liver cells that are coequal and capable of clonal growth (largely similar to the opinions expressed in the first model).

Model 3. The stem cells constitute the "cellular spring," located near the portal triads and yielding a maturational lineage of daughter cells that undergo a slow, unidirectional, maturational process ending in terminal differentiation or apoptosis near the central vein (Sigal *et al.*, 1992, 1995a; Reid, 1997). This model is similar to lineage systems in skin, gut, and hematopoietic tissue, but is proposed to occur much more slowly in liver, accounting for the confusion with respect to the role of candidate progenitors in the liver. This model assumes that the diploid cell population have far greater growth potential than do the tetraploid cells, and that the octaploid cells have no or minimal growth potential. Morphology, cell size, growth potential, and the expression of many tissue-specific genes are assumed to be lineage-position dependent.

Wilson and Leduc first postulated the presence of liver stem cells in 1958. However, as in the hematopoietic field, the concept of a liver stem cell gained the most credibility from extensive studies of liver carcinogenesis. A number of experimental protocols have been established that combine a hepatotoxic insult resulting in loss of cells in zones 2 and/or 3 of liver acinus, causing proliferation of small (7–15  $\mu\text{m}$ ) cells with scant cytoplasm and ovoid nuclei, termed "oval cells." With chronic insults, these oval cells become altered and can give rise to malignantly transformed cells. Overwhelming experimental evidence has implicated oval cells as partially or completely transformed liver progenitors, and some studies suggest that they are derived from progenitors for liver, gut, and pancreas (reviewed in Grisham and Thorgeirsson, 1997). Although it is experimentally simple to induce the appearance of oval cells, it has proved difficult to identify unequiv-

ocally the cells from which they arise. The cells of origin in all likelihood reside in proximity to bile ductules, but whether they are terminal ductule cells or distinct periductular cells remains a matter for debate.

Studies on both normal hepatic progenitors and on their transformed counterparts, oval cells, have been facilitated by the use of monoclonal antibodies (mAbs) raised against antigens characteristic of oval cells (Sell *et al.*, 1987; Hixson *et al.*, 1990). Using mAbs, hepatic progenitors have been found in normal adult livers as well as in fetal and neonatal livers (Sigal *et al.*, 1994, 1995b). Both oval cells and their normal counterparts, hepatic progenitors, are heterogeneous with respect to the binding of the various anti-oval cell antigen mAbs, and can be divided into subpopulations on this basis. Antigenic profiles of hepatic progenitors suggests that three groups exist: bipotential cells capable of differentiation to biliary or hepatocytic cells, precursors committed toward a biliary lineage, and precursors committed toward a hepatocytic lineage (Sigal *et al.*, 1994, 1995a; Brill *et al.*, 1995, 1999; Zvibel *et al.*, 1998). Numerous studies have shown that cells exhibiting combinations of antigenic markers characteristic of hepatocytes and cholangiocytes can be cultured readily from fetal rodent livers (Grisham and Thorgeirsson, 1997). Bipotential cells are present in large numbers in rats through embryonic day 15, when the numbers of the committed biliary and hepatocytic progenitors begin to increase. Subpopulations of hepatic progenitors from rat liver purified by fluorescence-activated cell sorting (FACS) also differ in their fates after introduction into congenic hosts lacking the prevalent liver protein, dipeptidyl peptidase (Sigal *et al.*, 1995b). The data suggest that there exist discrete numbers of antigenically definable, determined hepatic stem cells in fetal, neonatal, and adult liver, despite the view held by some that the liver contains none.

The proposal that there is an active, if slow, lineage system in the liver has been controversial, but increasing evidence has resulted in increasing support for the concept (Sigal *et al.*, 1992, 1995a; Reid, 1996). Parenchymal cells show a gradient of increasing ploidy, granularity, and autofluorescence from the periportal (zone 1) to midacinar (zone 2) to pericentral (zone 3) zones of the liver acinus. These features have been used to define senescing or apoptotic processes in other tissues and are now hypothesized to define an ongoing terminal differentiation process in the liver (Sigal *et al.*, 1995a). Age-related shifts in the parenchymal component of the liver, that is, more cells showing the characteristics of fully mature cells and fewer cells bearing characteristics of young cells, is reminiscent of age-related changes in skin, gut, and blood. Consistent with these observations, zone 1 cells have been observed to progress to a zone 3 phenotype. Periportal hepatocytes transplanted into periportal locations in host livers and translocated to pericentral locations as part of the response to CCl<sub>4</sub>-induced liver injury begin to express zone 3-specific cytochrome P450 (Gupta *et al.*, 1999). This demonstrates the biologic potential of periportal hepatocytes to adopt the phenotype of hepatocytes of any zone. The potential of pericentral hepatocytes in this respect is unknown at present, and is predicted by the lineage model to be greatly restricted.

Another prediction of the lineage model is that there should be differences in growth potential correlating with maturational state. Liver repopulation studies have shown that small subpopulations of normal murine parenchymal cells have a proliferative capacity approximating that of hematopoietic stem cells (Overturf *et al.*, 1997). It is highly unlikely that polyploid, multinuclear hepatocytes, which make up a large percentage of the hepatocytes in adult liver, have this capability. In addition, periportal rat hepatocytes respond more strongly in culture to the mitogenic effect of HGF (Rajvanshi *et al.*, 1998), which is in agreement with the proposition that they represent cells of lesser maturity. Therefore, analogous to other lineage systems, it appears that a large reservoir of proliferative capacity resides in a small subpopulation of liver cells, certainly subpopulations within the diploid cells of the liver.

These observations indicate that periportal hepatocytes have properties that make them attractive as cellular feedstocks for artificial livers: they can attain the phenotype of all parenchymal cells in the mature acinus, and they have better proliferative potential than the hepatocyte population in general, which suggests that they may be seeded into devices at a lower density than is possible with more mature cells. The importance of the determined stem cell and lineage model of the liver is that it predicts that there is a population of cells, even in mature liver, whose potential utility is even greater. Hepatic progenitor cells meeting some of the criteria for determined stem cells have already been isolated from rodents, and work is proceeding on accomplishing this from human tissue. The ultimate impact of the harnessing of determined stem cells from liver is that it

will overcome difficulties with supply and storage and make it possible to construct and maintain bioartificial liver-assist devices using human cells.

### COMMITTED PROGENITORS

Committed progenitors are descendents of the stem cells and have undergone “commitment,” a restriction in their genetic potential to limit their fate to that for one cell type. For example, in the liver, there are committed biliary progenitors and hepatocytic progenitors that yield descendents that are bile duct epithelia or hepatocytes, respectively. The committed progenitors of the skin (“transit amplifying cells”), of the intestine, or of the liver are the most rapidly growing cells of the tissue (Reid, 1996; Potten, 1997).

### STRATEGIES FOR IDENTIFICATION AND MANIPULATION OF DETERMINED STEM CELLS

From the many studies on determined stem cells, there are some generic approaches that have emerged as well as recognition that markers once thought to be unique to a specific determined stem cell may be generic to stem cells. To find a determined stem cell, one must identify one or more tissue-specific characters to decide their identity and to be used as a guide during purification processes. The markers can be surface markers permitting immunoselection technologies (e.g., CD34) for purification of the cells or can be culture conditions that are selective for the stem cells (e.g., those used for mesenchymal stem cells) (Bruder *et al.*, 1994) or for neuronal stem cells. For example, the hemangioblast is identified by the master gene for the bHLH family of transcription factors, whereas hepatic lineages all have  $\alpha$ -fetoprotein and albumin (Zaret, 1998) (see Fig. 41.3). Ideal models for searching for surface markers are transformants of the determined stem cells and consisting of tissue-specific cell lines, whether frankly transformed or only partially transformed (Zvibel *et al.*, 1998). Telomerase activity can be used as an assay for the self-renewal potential of

Fig. 41.3. Cytospin of rodent hepatoblast purified by multiparametric flow cytometry (contrast the mature cells shown in Fig. 41.4). The cells are mostly nucleus with a thin rim of cytoplasm, express  $\alpha$ -fetoprotein, weakly express albumin, are diploid, are approximately 7–10  $\mu$ m in diameter, and are agranular.

the candidate stem cells. *Ex vivo* expansion or differentiation conditions should be focused to maintain the tissue-specific identity and the telomerase activity. Markers defining known stem cells include receptors for signaling pathways (e.g., c-kit, CD38), telomerase, developmentally regulated cell adhesion molecules (e.g. CD34), and transcription factors (e.g., bHLH family).

## SOURCING OF HUMAN CELLS FOR TISSUE ENGINEERING

A major problem for all basic, clinical, or industrial investigations on human tissue is being able to get it reliably, when needed, and in reasonably good condition. The supply of human tissue is erratic, such differentiated tissues are difficult to cryopreserve and therefore difficult to stockpile, and there is always the concern that a disease in the cells may be transmitted to a gravely ill and/or immunocompromised recipient. These difficulties have resulted in serious consideration of the use of established and well-characterized cell lines (at least for use in bioreactors) or even of the use of nonhuman tissues, such as from pigs (Sussman *et al.*, 1994; Baquerizo *et al.*, 1999).

Cell lines have long been a popular option, given the ease in handling, expansion, and storage. Concern about “metastasis” of tumor-derived cell lines or transmission of uncharacterized infectious agents from tumor cells or animal tissue in bioartificial organs to patients makes it unlikely that devices containing these readily available cells will attain widespread use. Even the use of “normal” cell lines has very limited potential, because their establishment in culture is via processes that inherently result in partially or completely transformed cells, with resulting truncation of the functions to those of their normal counterparts, the progenitors of the tissue from which the cell line derived (Potter, 1978, 1981; Sell, 1994; Zvibel *et al.*, 1998). The cells are blocked in the ability to mature through their lineage to yield cells capable of intermediate or late functions (Potter, 1981; Sell, 1994).

The use of porcine tissues for bioartificial organs and even for some types of cell therapies is another approach that has received very serious attention (Chari *et al.*, 1994; Baquerizo *et al.*, 1997, 1999). The advantages are, of course, that the animals can be maintained under strict, germ-free conditions and can provide a ready supply of healthy tissue. However, concern that transfer of zoonoses that are nonpathogenic in pigs but possibly pathogenic in humans has spawned much controversy and a flurry of intense debates within the Food and Drug Administration (FDA) and among scientists. Clearly, if human tissues were available, the motivation to pursue nonhuman tissues would be eliminated or reduced.

Long-term success after transplantation of whole organs leads one to believe that normal human cells, with appropriate safeguards, present much less risk than either cell lines or porcine cells. By this important criterion, normal human cells are the best choices for cell and gene therapies and for bioartificial organs. Although in the past, procurement of human tissue has proved difficult, the rise of well-established procurement organizations, such as the United Network for Organ Sharing or (UNOS), has made access to human tissue much easier. Some tissues, such as heart valves, corneas, and skin are retrieved postmortem, whereas other types of tissues or organs (kidney, liver, lungs, etc.) are presently thought to be usable only if from abortuses (fetal tissues) or from organ transplantation programs.

Investigators routinely use fetal tissues, because they are easy to get and to handle, are relatively inexpensive, and are readily established in culture; they account for much of the research on human tissues. Yet there is widespread resistance to using fetal tissue in clinical or industrial programs for fear of political, ethical, and/or legal repercussions.

Whole organs for transplantation are collected through organizations such as UNOS (see their web site at <http://www.unos.org>). In general, organs for transplantation can derive only from donors who are brain dead but who have not undergone cardiac arrest, accounting for approximately 2% of candidate donors. The organs collected for transplantation are evaluated after removal from the donors. Approximately 90% are transplanted into appropriate recipients, leaving 5–10% (this varies considerably from tissue to tissue) that are rejected for reasons such as abnormalities in the vascular anatomy, lesions in the tissue, or presence of a pathogen(s), such as a virus. It is these rejects that are made available for basic, clinical, or industrial investigations. Another variable is the considerable length of time that can pass from the time at which the organ is removed from the donor to the time at which it is received by investigators. On average, it is about 20 hr, a time frame that can result in severe ischemia and autolysis of the tissue. Although postmortem collection of organs has been found unacceptable for whole organ transplantation, it re-

mains an untested option for any organs to be dispersed into cell suspensions and remains as one of the major untapped resources for human cells and tissues.

For a liver-assist device to be effective, a cellular mass representing 10–20% of the liver cell mass of the patient is needed. Because harvesting mature liver cells from donated human livers is relatively inefficient, because the mature cells have limited growth, and because no really successful cryopreservation methods for them yet exist, a limited number of bioartificial livers can be established from each donor organ. Therefore, cellular growth potential will determine the number of bioartificial organs that can be produced and used. This reasserts the issue of defining the cells within the liver with the greatest proliferative potential. A major clue is the fact, discussed in brief above, that the majority of mature liver cells are polyploid (tetraploid or octaploid) (Styles, 1993; Mossin *et al.*, 1994; Seglen, 1997; R. A. Williams *et al.*, 1997; Yin *et al.*, 1998). The extent of polyploidy is developmentally dependent. Fetal and neonatal tissues are entirely diploid. In the liver, there is a gradual appearance of binucleated diploid cells that have undergone nuclear division but with absence of cytokinesis. Subsequently, some of these binucleated cells give rise to daughter cells, and the nuclear membranes of the two nuclei fuse, resulting in tetraploid cells. The majority of the rat and human liver cells are tetraploid (up to 80% in rat livers). A similar process occurs, resulting in binucleated cells with tetraploid nuclei that subsequently convert to octaploid cells. Although polyploidy has been well documented in the liver, it is beginning to be studied in the mature cells of other quiescent tissues (Hamada *et al.*, 1990; Maturri *et al.*, 1991). In general, the polyploid cells undergo limited complete cell division and preferential hypertrophic growth in response to regenerative stimuli. In addition, maturation is associated with increasing autofluorescence, due to changes in amounts of fluorescent cytoplasmic pigments such as lipofuscins, and with increasing cytoplasmic “complexity,” as perceived by flow cytometric analyses, due to maturation-dependent increases in mitochondria, ribosomes, and other cytoplasmic organelles. The studies of Gupta and associates have provided suggestive evidence that the periportal diploid cells are highly proliferative (Rajvanshi *et al.*, 1998). Therefore, even if the markers for purification of determined stem cells or early progenitors are not known, it would seem logical to select for diploid cells as candidates for maximal proliferation potential.

In addition to a quantitative benefit (owing to the utilization of feedstock cells with great expansion potential), the developmental potential of progenitor cells—or at the very least diploid cells—should translate into an improved opportunity for cell or gene therapies or for recreating acinar heterogeneity in the bioartificial liver. This in turn may mean that in a patient or in a bioreactor, all isoforms of such clinically important, zone-specific enzymes (e.g., the cytochromes P450) are expressed. The initial cell population should have the developmental capacity to take on the characteristics of any acinar zone, if the bioreactor and extracellular matrix conspire to provide the appropriate environment.

## MICROENVIRONMENT

### PRINCIPLES

The determinants of a cell's position within the lineage and its phenotype at that position have been shown to be due to a combination of at least three factors:

1. Autonomous intracellular mechanisms that are division number dependent or time dependent, such as chromatin rearrangements or methylation events, controls on nuclear division or cytokinesis, etc. (discussed above).
2. Signal transduction mechanisms activated by (a) gradients of soluble signals (autocrine, paracrine, or endocrine factors), of nutrients, and of gases ( $O_2/CO_2$  levels), in multiple combinations, and/or in synergistic effects with extracellular matrix components, and (b) gradients of extracellular matrix components—a complex, insoluble mixture of proteins and carbohydrate-rich molecules found on the lateral borders (lateral matrix) and on the basal borders (basal matrix) of all cells.
3. Mechanisms affecting mass transfer of nutrients, gases, or signals to the cells. *In vivo* and especially *in vitro*, the ability of signals to access the cells is a critical variable, dictating the gradients of the signals and the biologic responses of the cells. These factors are especially important

when cells are being established under three-dimensional conditions, such as in bioreactors, or even, in simple form, in spheroids.

The issues of mass transfer are more extensively addressed in the discussion on bioreactors (below). Therefore, here will be discussed the other microenvironmental variables regulating the growth and differentiation of cells.

The heterogeneity of gene expression and the growth potential in all tissues is now recognized to be lineage-position dependent. In effect, there are early, intermediate, and late genes activated in a lineage-position-dependent fashion. Identical microenvironmental cues induce distinct genes at different maturational stages. Thus, signals from cell–cell interactions maintain and regulate growth and govern gene expression of a restricted set of genes, those defined by the maturational stage of the cells.

### SOLUBLE SIGNALS

Signals from cell–cell interactions consist of a soluble set and an insoluble set. Soluble signals include autocrine factors, produced by a cell and active on the same cell; paracrine factors, produced by one cell and acting on a neighboring cell(s); and endocrine factors, produced by one cell and acting on a target cell at a distance from the source cell and delivered to the target cell(s) through blood or lymph. All of these soluble signals, including the autocrine ones, are highly regulated and under very strict controls. The wealth of knowledge on the myriad hormones and growth factors precludes the possibility of any detailed discussion of individual factors. However, many of them have been reviewed and detailed in various publications (Loughna and Pell, 1996; Ziegler *et al.*, 1997; Dickson and Salomon, 1998; McKay and Brown, 1998). Moreover, the efforts of many investigators have revealed most of the rules with respect to the identification of soluble signals or nutrients required for growth and/or differentiation of specific cell types (Reid, 1990; Reid and Luntz, 1997). Below will be presented simply a summary of the findings and of approaches to generate the microenvironment needed for cells in culture or in bioreactors.

Any cell type can be maintained *ex vivo* if it is provided with an appropriate substratum of extracellular matrix and with a serum-free, hormonally defined medium (HDM) containing purified hormones, growth factors, trace elements, and nutritional factors. The exact composition of any HDM is tissue specific, and very rarely is species specific. Thus, for example, an HDM developed for optimal growth of rat lung tissue will be virtually identical to that for growth of human lung tissue. For the few tissues for which cells at distinct maturational stages have been isolated in bulk (hematopoietic cells, liver), the exact composition of HDM contains subsets that are identical for all maturational stages and others that are distinct. Complementing this is the realization that the exact composition of an HDM is distinct for cells in an optimal growth versus optimal differentiation state.

Classic cell culture conditions, tissue culture plastic and serum-supplemented medium (SSM), produce cell cultures with minimal differentiated functions due to inhibition of transcription of tissue-specific mRNAs and destabilization, i.e., short half-lives, of those mRNAs. Common gene mRNAs (e.g., actin, tubulin) are stabilized by these conditions. Moreover, normal cells, especially epithelial cells, survive for only a few days when cells are plated on tissue culture plastic substrata and in a serum-supplemented medium. Tumor cells and stroma are better able than normal epithelial cells to survive the deleterious effects of serum, a factor in their preferential selection (e.g., stromal cell overgrowth) in classic cell cultures. Serum-free, hormonally defined media and tissue culture plastic result in cell cultures that have far more stable tissue-specific messenger RNAs, hence greatly enhanced differentiated function. However, the cells still cannot synthesize their tissue-specific mRNAs at normal rates. Thus, the cells maintained on tissue culture plastic and in HDM regulate entirely or almost entirely under posttranscriptional regulatory mechanisms. Survival of both normal and tumor cells maintained as primary cultures on tissue culture plastic persists for only a few days, a week at most.

### EXTRACELLULAR MATRIX

Insoluble signals include components of the extracellular matrix, an insoluble material produced by all cells and found on the lateral borders between homotypic cells (the lateral matrix

chemistry) and on the basal surfaces of cells, separating them from heterotypic cell types. The soluble and insoluble signals are interregulated and also have multiple synergistic effects. That is, soluble signals can induce synthesis of specific matrix components; matrix substrata can dictate output of specific soluble signals or regulate receptors and can also be “hardwired” for soluble signals; and distinct sets of matrix components and soluble signals cooperate in the regulation of specific physiologic processes. Extracellular matrix components turn over slowly, on the order of days to weeks, and serve to stabilize cells in specific configurations of adhesion sites, antigens, hormone receptors, ion channels, etc. Because the extracellular matrix is connected directly to the cytoskeleton via transmembrane molecules, changes in the conformation of one or more matrix components can directly influence cell shape. The soluble signals that have a more rapid turnover, on the order of seconds to minutes, activate signal transduction processes that induce a specific physiologic process such as growth or expression of tissue-specific genes. The effect of a soluble factor is entirely dependent, both qualitatively and quantitatively, on the matrix chemistry associated with the cell.

The purified matrix components, many of them commercially available, produce highly reproducible biological responses in cells, particularly when they are used in combination with HDM (Maher and Bissell, 1993; Knop *et al.*, 1995; Bader *et al.*, 1996; Nishikawa *et al.*, 1996; Gomez-Lechon *et al.*, 1998; Schuppan *et al.*, 1998). The availability of some classes of matrix components, e.g., proteoglycans, in rigorously prepared forms, remains quite limited. No individual, purified matrix component will enable cells to survive and function for more than a week or two. Rather, long-term stability of survival and physiologic responses has been afforded only by extracts enriched in extracellular matrix and, to less extent, mixtures of matrix components. Tissue extracts enriched in extracellular matrices have proved of great importance in popularizing the importance of matrix substrata for normal or near-normal biologic functions in cells. One of the most popular has been Matrigel, a urea-derived extract from murine embryonal carcinoma tumors [Engelbreth–Holm–Swarm (EHS) tumors]. Matrigel contains primarily laminin, type IV collagen, heparan sulfate proteoglycan, and entactin, resembling the composition of basement membranes as found in tumors. Liver cells cultured on Matrigel attach loosely via laminin bridges to the gel and use their lateral matrix chemistry to form spheroidal aggregates that show greatly increased maintenance of differentiated function (Bissell *et al.*, 1987; Moghe *et al.*, 1996; Coger *et al.*, 1997). Other tissue extracts that have also been used extensively have been biomatrices (e.g., Rojkind *et al.*, 1980; Doerr *et al.*, 1989) derived from any tissue, normal or diseased, and amnionitic membrane extracts (Liotta *et al.*, 1980), used often for cultures of endothelia.

A major function of the matrix is to induce three-dimensional states in cells, essential for achieving full normalcy in cellular phenotype and for normal transcription rates of tissue-specific genes (Ingber *et al.*, 1995; Ingber, 1998). The future, therefore, will be in identifying precise mixtures of purified matrix components that confer stable survival and physiologic responses.

#### CHANGES IN MATRIX CHEMISTRY WITH RESPECT TO LINEAGE POSITION

The lateral matrix chemistry, found between homotypic cells, consists of cell adhesion molecules (CAMs) and proteoglycans, but no collagens, fibronectins, or laminins. The basal matrix chemistry, found between closely associated heterotypic cell types (e.g., epithelia and mesenchymal cells), consists primarily of CAMs, proteoglycans, basal adhesion molecules (fibronectins or laminins), collagens, and other components that can be tissue specific in their distribution either qualitatively or quantitatively (e.g., entactin, tenascin). Collagen scaffoldings in the basal matrix chemistry of two adjacent cell types are cross-linked by an enzyme, lysyl hydroxylase, thereby physically connecting the two cell layers.

The chemistry of the basal and lateral matrices changes in predictable ways within a maturational lineage. All known determined stem cells are associated with fetal lateral and basal matrix chemistries consisting of isoforms of CAMs [e.g., CD34, intercellular adhesion molecules (ICAMs)] and proteoglycans (e.g., certain syndecans) and fetal isoforms of laminin, type IV collagen, and often high levels of hyaluronates (Jones and Watt, 1993; Martinez-Hernandez and Amenta, 1993; Watt, 1998). Commitment and subsequent maturation of the cells are associated with a shift, in gradient fashion, in the lateral and basal matrix chemistries. The shift includes a decline or even loss of expression of the basal matrix components, a decline or loss in the expres-

sion of hyaluronates, a conversion to fibrillar collagens, and a shift to adult isoforms of basal adhesion proteins, of CAMs (e.g., CCAM 105), and of proteoglycans (e.g., heparin proteoglycans).

Although all tissues studied have similar basal and lateral matrix chemistries within the stem cell compartment, there are three major variations known in basal and/or lateral matrix chemistries occurring with maturation, as discussed below.

### **Preservation of expression of all major classes of matrix components but with gradients in isoforms within those classes**

Some lineages, exemplified in gut and liver, are associated with a preservation in the expression of all classes of matrix components but a shift in which isoforms are expressed. The liver progenitor cells and intestinal stem cells are associated with a classic embryonic basal lamina consisting of laminin, type IV collagen, fetal CAMs, and specific forms of syndecan, a heparan sulfate proteoglycan. Maturation is associated with gradual shift to increasingly more stable forms of fibrillar collagens, fibronectin, and a heparin-like heparan sulfate proteoglycan, located at highest concentrations in association with the most mature cells (for example, around the parenchyma near the central vein in the liver). In the past, the liver was considered an “epithelioid organ” and not a true epithelium, because most of the mature liver cells were associated with a form of extracellular matrix in the space of Disse that is distinct morphologically from basement membranes. Now it is realized that the liver, as well as the gut, are both true epithelia with gradients of matrix chemistry paralleling and coordinate with maturing lineages of cells.

### **Loss in expression of basal matrix components**

The skin and nervous system undergo maturational processes in which there is a loss in the expression of basal matrix components but retention in expression of lateral matrix components. The lateral matrix components undergo the maturational shifts in chemistry known for all lineages.

### **Loss in expression of collagens and shift to regulated expression of adhesion proteins with cell-binding domains**

Hematopoiesis is associated with loss of collagen expression and with loss of expression of exons encoding the cell-binding domains of adhesion proteins in those cells that become free floating. Expression of the isoforms of the adhesion proteins still containing those cell-binding domains is retained by immunocytes but utilized in a highly regulated way for the many complex cellular interactions involved in immunologic responses. Other hematopoietic cell types, especially the monocytic–macrophage lineage, retain the capacity to produce collagens; their matrix maturational patterns are too poorly characterized to permit generalizations.

### **FEEDER CELLS**

Although many of the soluble and matrix signals driving growth and differentiation of cells have been identified and well characterized, new factors are being recognized from the use of cocultures, the mixture of two or more cell types, and assessment of biologic function. The most common cocultures are those in which feeders of stromal cells are used to support various type of epithelia (Kawase *et al.*, 1994; Talbot *et al.*, 1994; Moore *et al.*, 1997). Stromal cell-derived growth factors active on epithelia include the interleukin-6 (IL-6) family and hepatocyte growth factor (HGF) (Rathjen *et al.*, 1990; Montesano *et al.*, 1991a,b). In addition, many of these signals are presented as complexes with glycosaminoglycans or proteoglycans, having carbohydrate chemistry that modulates the biologic responses of the cells to the protein ligands (Zvibel *et al.*, 1991, 1995; Lyon *et al.*, 1994).

Two descriptive studies have provided suggestions of yet other factors that may be relevant to full function of liver cells and involved cocultures of mixtures of endothelial cells, Ito cells, hepatocytes, bile duct cells, and Kupffer cells (Michalopoulos *et al.*, 1999; Mitaka *et al.*, 1999).

### **EXPANSION VERSUS DIFFERENTIATION OF CELLS**

Liver tissue engineering comprises two steps: a growth phase, in which the seeded progenitor cells expand *in vivo* within the tissue of the host or *ex vivo* in culture or a bioreactor, and a differ-

**Table 41.2. Summary of common requirements for all lineage stages<sup>a</sup>**

Variable	Growth	Differentiation
Substratum	Flexible, porous substratum coated with type IV collagen and laminin	Flexible, porous substratum coated with fibrillar collagens and fibronectins
Calcium	Less than 0.5 mM	Above 0.5 mM
Glycosaminoglycans/ proteoglycans	Ideally, tissue-specific forms of heparan sulfate-PGs or heparan sulfate saccharides	Ideally, tissue-specific forms of heparin-PGs or specific heparin saccharides
Basal medium	Nutrient-rich medium supplemented with nicotinamide and trace elements (tissue specific) that include selenium	

<sup>a</sup>Requirements given are with respect to liver, but are also applicable in most regards to most differentiated epithelia.

entiation phase, in which the cells cease proliferation and assume their fully mature states. These phases occur naturally when cells are inoculated *in vivo*. By contrast, the conditions appropriate for controlling these phases must be carefully designed for *ex vivo* maintenance of liver cells. Detailed descriptions of the conditions for growth versus differentiation have been published (Brill *et al.*, 1994; Reid and Luntz, 1997; Reid, 1997) and are summarized in Tables 41.2 and 41.3. In brief, the particular conditions required to permit the survival and growth of progenitors are (1) serum-free basal medium, (2) attachment to a porous, flexible surface coated with extracellular matrix of a chemistry identical to that in the stem cell compartment *in vivo*, (3) provision of relevant

**Table 41.3. Summary of known requirements that are maturational lineage-position dependent**

Variable	Stem cells	Committed progenitors	Mature cells
Nutrients	Complex mixture lipids including HDL, phospholipids, and free fatty acids essential for survival		Lineoleic acid suffices (although preferably the complex mixture)
Attachment	Some determined stem cells prefer suspension; anchorage results in differentiation; those that adhere have the requirements as specified in Table 41.2		Adherence to a substratum required for survival
Feeder layers	Embryonic feeders required (can be tissue-specific)	Feeders required but tolerant of feeders from diverse sources	Feeders not required
Strict mitogens	Unidentified signals from feeders (local signaling dominant)		Systemic signaling dominant (for liver: insulin, EGF)
Other mitogens		IGF II, EGF, and transferrin/Fe are common	Insulin, EGF, thyroid hormones, growth hormone, prolactin
Differentiation signals	The repertoire of genes available for regulation is lineage-position dependent; each gene is regulated coordinately by several soluble signals (usually 3–4) in the context of a specific matrix chemistry		
Serum	Usually inhibitory for survival or growth		Inhibitory for tissue-specific gene expression
Gas exchange	Anaerobic conditions tolerated		Critically dependent on aerobic metabolism

Fig. 41.4. Cultures of mature rat liver in serum-free, hormonally defined media tailored for optimal growth, on purified type I collagen.

nutrients not typically in basal media (e.g., lipids, trace elements), (4) provision of critical soluble signals (hormones, growth factors), and (5) coculture with feeder cells that supply soluble signals that have yet to be identified (e.g., embryonic stromal cells). Experience with rodent cells suggests that differentiation can be achieved by removal of the feeders, or by administering one of several known growth factors [e.g., HGF, FGF, and insulin-like growth factor II (IGF-II)] (Brill *et al.*, 1995; 1999) (see Fig. 41.4).

Maintenance of highly differentiated liver cells, at least short-term, has been achieved with a variety of culture media that often differ in seemingly insignificant ways except that the omission of serum is now recognized as essential (Jefferson *et al.*, 1984). Another stringent factor in culturing is the provision of cell–matrix substrata [discussed above and extensively in reviews by Brill *et al.* (1994), Reid (1997), and Reid and Luntz (1997)]. In addition to the exact chemistry of the matrix substrata, the achievement of three-dimensionality is essential (Wang and Ingber, 1994). This requirement has been shown both by elegant engineering analyses (Ingber *et al.*, 1995; Huang *et al.*, 1998; Ingber, 1998) and by simple culture conditions that elicit three-dimensionality such

as spheroid cell cultures (Koide *et al.*, 1989; Tong *et al.*, 1992) and matrix–cell–matrix sandwiches with collagen I gels and Matrigel (LeCluyse *et al.*, 1994; Moghe *et al.*, 1996). Cells grown in such configurations are more cuboidal than those grown on plastic or on matrix proteins coated on plastic, and may have the capability of forming more extensive cell–cell contacts with their neighbors than flattened cells can. The extensive cell–cell contacts achieved by hepatocyte spheroids may similarly account for the high degree of differentiated cell function in this culture system (Hamamoto *et al.*, 1998).

In a bioartificial liver, it is perhaps more important to consider how the medium is brought to all parts of the culture, involving essential issues of mass transfer and thus crucial for achieving high-density cultures. If the developing bioartificial liver is to begin with a small inoculum of cells that proliferate to fill the chamber and proceed to a highly differentiated state in which cell–cell contact is maximized, a combination of biodegradable polymers coated with matrix proteins and sparsely seeded hepatic progenitors should provide conditions that encourage expansion of the cells. As the cells multiply, the biodegradable polymers should disappear to be replaced by a natural extracellular matrix produced by the cells and governed by the cell density and the microenvironment of the bioreactor chamber.

### COMPARISON OF NORMAL AND TUMOR CELLS

Tumor cells have *ex vivo* maintenance requirements that overlap extensively with the requirements of normal progenitor cells, their normal counterparts (Zvibel *et al.*, 1998). The fallacy in many of the prior assumptions about tumors has been in the comparison of them with normal, mature cells. For example, the requirements for *ex vivo* maintenance of hepatoblastomas are almost identical to those of hepatoblasts but are quite distinct from those of mature hepatocytes. Similarly, well-differentiated hepatomas or cholangiomas have requirements close to that of committed hepatic or biliary progenitors, respectively (Zvibel *et al.*, 1998). The phenotypic expression of tumors and cultures of them also parallels that in their normal counterparts. Thus, as Potter and Pierce have long argued, tumors are maturationally arrested progenitors, and the expression of fetal genes is simply part of the normal phenotype of the progenitor cells (Potter, 1981; Sell and Pierce, 1994). Proof of the hypothesis of Potter and Pierce has been supported by more additional studies comparing normal hepatic progenitor cells and hepatic tumor cells (Zvibel *et al.*, 1998). For example, matrix/hormonal synergies have been found to regulate fetal (early) genes such as IGF II and TGF, both transcriptionally and posttranscriptionally in tumors (Zvibel *et al.*, 1991) and in their normal counterparts, hepatic progenitors (Zvibel *et al.*, 1998). Identical hormone/matrix synergies regulate adult-onset genes in mature parenchymal cells (Brill *et al.*, 1995). If the tumor cells express any adult-onset genes, they are regulated, invariably, by posttranscriptional mechanisms entirely or with muted transcriptional regulatory mechanisms in combination with the posttranscriptional mechanisms.

### BIODEGRADABLE POLYMERS

#### CRITERIA FOR DESIGN OF BIODEGRADABLE POLYMERS IN TISSUE ENGINEERING OF LIVER

The final realization of tissue engineering of liver depends on the success of research endeavors in (1) liver biology, especially in understanding the extracellular matrix (ECM) biology and chemistry, and liver as a maturational lineage system (Reid, 1997), (2) design and engineering of novel bioreactor systems (Macdonald *et al.*, 1999), and (3) development of degradable extracellular substrata. Biodegradable polymer support in tissue engineering of liver is to provide (1) a surface coated with growth-permissive ECM for attachment/adhesion of anchorage-dependent hepatocytes, (2) a three-dimensional scaffold for localization of cells, which is critical for cell interaction and tissue-specific gene expression (Reid, 1997), (3) a porous structure allowing sufficient nutrient delivery, waste removal and gas exchange, and ingrowth of host tissue, and (4) a vehicle for local delivery of bioactive factors to encourage vascularization and angiogenesis, and thus guiding the growth of hepatic tissue. Polymer supports should have a controllable degradation, thus allowing the role of polymer support to be taken over eventually as a result of tissue growth

and ECM formation (Vacanti *et al.*, 1994; Davis and Vacanti, 1996; Kim and Mooney, 1998; Marler *et al.*, 1998). In addition, suitable polymer supports should have sufficient mechanical tensile strength and compressive resistance for transplantation, and desirable physical and chemical characteristics for fabrication into desirable physical formats. Synthetic or modified natural polymers should be biocompatible to minimize or eliminate host inflammatory response. Polymers should be stable both chemically and physically for sterilization.

### NATURALLY DERIVED POLYMERS FOR TISSUE ENGINEERING OF LIVER

Naturally derived matrix polymers (e.g., collagens, elastin) may be divided into two classes based on their biological function: fibrous structural proteins, providing important mechanical and organizational support to the tissue, and glycosaminoglycans and derivatives capable of forming hydrated gels through which the fibrous and polysaccharide components of the matrix provide tensile strength and compression resistive support, respectively. Natural ECM components, e.g., collagen and laminin, have been used as cell attachment support by coating on various surfaces such as polystyrene, polyurethane, urethane epoxy on glass, plastic, and cross-linked dextran (Demetriou *et al.*, 1988; Cima *et al.*, 1991; Mooney *et al.*, 1992; Bhatia *et al.*, 1994; Powers and Griffith-Cima, 1996). The advantage of naturally derived polymers is their close compatibility with the ECM environment, thus providing better substrata for *ex vivo* culture of cells. However, they typically lack the necessary mechanical integrity for fabrication into scaffolds or other shaped polymer structures, and suffer from the limitation of sufficient supply and source variation, which limits their use for tissue engineering.

Collagen, a major component of the ECM for both structure and functional support of liver cells, is the most widely used natural polymer for liver cell attachment in *ex vivo* culture. Native and partially digested collagens have been used in various forms, including coating on plastic surfaces to provide attachment support for liver cells (Shimbara *et al.*, 1996); entrapment of hepatocytes and nonparenchymal cells, overlaying to form sandwich systems (Berthiaume *et al.*, 1996; Koike *et al.*, 1996; Kono *et al.*, 1997; Moghe *et al.*, 1997); encapsulation of liver cells to form spheroids (Lazar *et al.*, 1995; Wu *et al.*, 1996; Hu *et al.*, 1997); and entrapment of liver cells onto the surfaces of porous synthetic polymer sponges (Kaufmann *et al.*, 1997; Takeshita *et al.*, 1998). Entrapment and encapsulation of liver cells creates a culture environment allowing direct contact among hepatocytes, which is important to the maintenance of differentiated hepatocyte functions. Encapsulation also function as microfiltration barriers for host immunoglobulins and entrapped hepatocytes while allowing free exchange of metabolites, which is critical for use of allogeneic or exogeneic hepatocytes in extracorporeal liver-support devices (Hu *et al.*, 1997). Despite the importance of collagen for hepatocyte attachment, because of the lack of suitable physical and chemical properties, it is difficult to fabricate collagen into three-dimensional scaffolds to support *ex vivo* culture or transplantation of hepatocytes.

Derived from seaweed, anionic alginate forms gel on cross-linking by  $\text{Ca}^{2+}$ . It can be readily prepared as microcapsules, threads, or layers of gel. It offers better physical characteristics for entrapment of cells compared to collagen. Alginate encapsulation of liver cells allows the formation of spheroids within the capsules, which is important to hepatocyte differentiated functions such as secretion of albumin and maintenance of P450 activity (Ito and Chang, 1992; Selden *et al.*, 1998). Alginate-encapsulated hepatocytes cultured in bioreactors are used as an extracorporeal liver-assist device (Fremond *et al.*, 1993), and for direct transplantation into rats (Dixit *et al.*, 1990; Gupta *et al.*, 1993; Hirai *et al.*, 1993). Attachment of hepatocytes to alginate also improves the viability and differentiated function of cryopreserved hepatocytes (Guyomard *et al.*, 1996).

Among the naturally derived polymers used in culture of hepatocytes is chitosan, a derivative from partial N-deacetylation of chitin; chitosan contains a binary heteropolysaccharide of [1 → 4]-linked 2-acetamide-2-deoxy-D-glucopyranose and 2-amino-2-deoxy-D-glucopyranose monosaccharide (Draget *et al.*, 1992). It has characteristics similar to glycosaminoglycans, a component of liver ECM, and is biodegradable and nontoxic (Muzzarelli *et al.*, 1988). To improve its biocompatibility and encourage hepatocyte attachment to chitosan-coated surfaces, collagen, albumin, and gelatin have been blended with the polymer (Elcin *et al.*, 1998). Fructose-modified chitosan was found to be better than collagen alone in encouraging hepatocyte attachment and maintenance of differentiated function (Yagi *et al.*, 1997). Chitosan cross-linked by glutaraldehyde was

found to improve the mechanical strength of polymers, while maintaining hepatocyte biocompatibility, as demonstrated by cell attachment and maintenance of differentiated function (Kawase *et al.*, 1997).

### SYNTHETIC BIODEGRADABLE POLYMERS FOR TISSUE ENGINEERING OF LIVER

Synthetic biocompatible and biodegradable polymer is widely used in surgical sutures and constructs for *ex vivo* cell culture, expansion, and cell transplantation. There is a variety of synthetic biodegradable polymers, including polyesters, polypeptides, hydrogels of large variations in backbone and side chain structures, and copolymer combinations. General discussions of synthetic polymers can be found in Hubbell (1995), Peters and Mooney (1997), and Marler *et al.* (1998). The most widely used synthetic biodegradable polymers, however, are the poly( $\alpha$ -hydroxy acid) family of polymers, including poly(glycolic acid) (PGA), poly(lactic acid) (PLA), poly(D,L-lactide-co-glycolide) (PLGA) copolymer, and their modified derivatives. Because of their wide range of desirable physical properties, synthetic polymers can be precisely constructed in various formats of defined size, shape, and surface and internal morphology (e.g., Peters and Mooney, 1997; Marler *et al.*, 1998) that facilitate cell attachment and localization, mass transfer, gas exchange, and growth of cells. They can be designed and constructed to degrade under *in vitro* and *in vivo* conditions over time by varying the molecular weight, monomer mass distribution in copolymers, chain structure, and surface and internal porous structures (Gilding, 1981). The role of eventually degraded polymer supports may be taken over by the formation of natural ECM and tissue structure with a minimal degree of chronic foreign body responses from the host, which is often caused by nonbiodegradable polymers. However, despite the eventual degradation of biodegradable polymers, their interactions with cells in culture and the initial host response to introduced tissue engineering devices resulted from the immune reaction between synthetic polymers and cellular components present a critical challenge in the design of synthetic polymers (Ignatius and Claes, 1996; Anderson, 1998; Babensee *et al.*, 1998).

Hybrid polymers typically possess both the physical properties of synthetic polymers and the biocompatibility of natural polymers (Hubbell, 1995; Peters and Mooney, 1997; Kim and Mooney, 1998). At present most of the hybrid polymers are based on coupling of cell adhesion peptide sequences or sugar moieties onto synthetic polymers such as poly(ethylene oxide) (PEO), polyurethane, and poly(ethylene glycol) (PEG) (Dai *et al.*, 1994; Griffith and Lopina, 1998). Incorporation of cell-recognizing sequences, e.g., arginine-glycine-aspartic acid (RGD) for the integrin super family of cell adhesion proteins, encourages the attachment of hepatocytes (Hynes, 1992; Dai *et al.*, 1994; Hubbell, 1995; Kim and Mooney, 1998). Carbohydrate-based cell recognition has also been applied to the design of hybrid polymers with improved characteristics of hepatocyte attachment (Weigel *et al.*, 1978; Oka and Weigel, 1986; A. Kobayashi *et al.*, 1992; Cima, 1994; Gutsche *et al.*, 1994; K. Kobayashi *et al.*, 1994; Lopina *et al.*, 1996; Park *et al.*, 1998). The favorable interaction of hepatocytes with galactose-modified surfaces is thought to be attributed to the specific interaction between the polymer ligand (galactose moiety) and a hepatocyte surface receptor, presumably the ASGP-R (Lopina *et al.*, 1996; Griffith and Lopina, 1998). Similarly, lactose and heparin hybrid porous polystyrene foams were found to promote hepatocyte attachment and maintenance of a rounded cellular morphology (Gutsche *et al.*, 1996).

### BIOCOMPATIBILITY AND TOXICITY OF SYNTHETIC POLYMERS

To limit chronic foreign body response by host tissue, it is necessary for polymers implanted into host tissue as hepatocyte-polymer conduits and their degraded products to cause low or minimal local and systematic host inflammation. The intensity and duration of the host response determine the biocompatibility of a polymer implant, which is characterized by fibrosis and vascularization of the tissue surrounding the implant device (Anderson, 1998; Babensee *et al.*, 1998). As a result of host response to an implanted device, local reorganization and generation of tissue, as part of the healing response to tissue injury from implantation, lead to formation of fibrovascular tissue and fibrous encapsulation of implant, a key outcome of host response. For hepatocyte transplantation, host tissue ingrowth into the polymer scaffold, vascularization, angiogenesis, and population of cells in the polymer support are important to the survival, growth, and function of transplanted cells. Slow degradation of biodegradable polymer implants allows the formation of

tissue vasculature to take over the role of polymer implants, thus alleviating the chronic inflammatory response caused by nondegradable materials.

Natural polymers, e.g., collagens or Matrigel, because of their biologic origin, possess the best biocompatibility. Most synthetic polymer scaffolds for hepatocyte seeding and tissue engineering have largely derived from the poly( $\alpha$ -hydroxy acid) family of biodegradable polymers, including PGA, PLA, and copolymer PLGA. They are, at present, among the safest synthetic polymers commercially available. The degraded products of the poly( $\alpha$ -hydroxy acid) family of biodegradable polymers are lactic and glycolic acids, both metabolites of the Krebs cycle, and thus cleared by respiratory reactions (Gilding, 1981). In principle, they should not induce chronic toxic response by host tissue. There is a concern about the local acidification by lactic and glycolic acids. However, the slow release of lactic and glycolic acids may not be significantly detrimental to the local surrounding tissue, as shown by the grossly normal engineered tissue (Mooney *et al.*, 1997). Metabolic study of the mitochondrial function of a mouse fibroblast cell line also shows no significant cytotoxicity in the presence of low levels of degraded products of PLA and PLGA, a finding supportive to their use as biocompatible materials (Ignatius and Claes, 1996). Although the biocompatibility of the poly( $\alpha$ -hydroxy acid) family of biodegradable polymers as a core material has been investigated, with the rapid advance in the research on synthetic hybrid polymers, the biocompatibility and cytotoxicity of the new biodegradable polymers should be thoroughly evaluated to determine the short- and long-term effects on host tissue and transplanted cells or tissue.

### BIODEGRADABLE POLYMER SUPPORTS OF VARIOUS PHYSICAL FORMATS

For culture of metabolically highly active hepatocytes, biodegradable scaffolds ideally should meet the criteria discussed above. Biodegradable fiber meshes or sponges of highly porous surface and internal structure have been developed to meet some of those design criteria (Vacanti *et al.*, 1994; Davis and Vacanti, 1996; Peters and Mooney, 1997; Eiselt *et al.*, 1998; Kim and Mooney, 1998). Encapsulation of hepatocytes in collagen, alginate, or synthetic polymers has also been used to provide an attachment surface and a filtration barrier (Wong and Chang, 1986; Chang, 1992; Nyberg *et al.*, 1993). Porous microspheres may also be used to provide a large surface for hepatocyte attachment. The advantages and shortfalls of the various formats for tissue engineering of liver are discussed below. The techniques for fabrication of biodegradable polymers into various formats have been discussed in Chapter 21 of this volume.

#### Scaffolds of sponge and fiber mesh

Among various types of biodegradable scaffolds, scaffolds of porous sponge have been most extensively investigated for *ex vivo* culture and transplant of hepatocytes. They can be fabricated into foamlike porous structures (Mikos *et al.*, 1993c, 1994), or templates of complex internal interconnecting networks with spatial resolutions as small as several hundred micrometers. The polymer template can be fabricated to achieve the size and distribution of the channels precisely based on the requirement of the cell seeding distribution, nutrient delivery, and gas exchange of hepatocytes and other cells, and resistance to compressive load (Giordano *et al.*, 1996; Griffith *et al.*, 1997; Kim *et al.*, 1998). Galactose tethered on the surface of the polymer template can encourage hepatocyte attachment (Park *et al.*, 1998). Biodegradable sponges and bonded fiber structure of highly porous surface and internal structure (>83% porosity) have been used to support the growth of hepatocytes *in vitro* and *in vivo* (Mikos *et al.*, 1993a,b,c; Wald *et al.*, 1993; Mooney *et al.*, 1994). To improve seeding of hepatocytes and flow distribution of nutrients throughout the porous sponge, coating PLA or PLGA sponges with surfactant polyvinyl alcohol (PVA) increases the surface hydrophilicity, leading to a greater infiltration of hepatocytes and media flow into the porous sponge structure (Mooney *et al.*, 1995). However, a significant shortfall of porous sponges typically is the insufficient nutrient delivery into the core of the polymer sponge, which can result in necrosis of seeded hepatocytes (Mooney *et al.*, 1997). A number of approaches have been investigated to improve the survival, growth, and maintenance of differentiated function of transplanted hepatocytes. These include increasing hepatic stimulation for vascularization by increasing delivery of portal blood to transplanted cells, prevascularization of polymer sponges, and localized release of epidermal growth factors (Mikos *et al.*, 1993c; Mooney *et al.*, 1996, 1997; Kaufmann *et al.*, 1997). With a highly porous (>90%) structure and a large surface-to-volume ratio

(as high as  $0.05 \mu^{-1}$ ) (Mikos *et al.*, 1993a), biodegradable fiber mesh-based scaffolds represent another class of polymer support for cell culture and transplantation (Gilbert *et al.*, 1993; Vacanti *et al.*, 1994; Takeda *et al.*, 1995). Nonwoven porous polymer tubes fabricated from nonwoven meshes of PGA fiber have been used for seeding with rat hepatocytes and implantation of cells in the small intestinal submucosa (SIS) conduit (Kim and Mooney, 1998).

### Hepatocyte encapsulation in polymer supports

The concept of microencapsulation of hepatocytes arose from the need to prevent antibody and antigen interaction in allogeneic or xenogeneic transplantation of hepatocytes. Collagen and alginate form a thin layer, encapsulating the cells in the core region (Wong and Chang, 1986; Chang, 1992; Fremont *et al.*, 1993; Nyberg *et al.*, 1993; Fremont *et al.*, 1996; Hu *et al.*, 1997). Proteins and other macromolecules cannot permeate through the encapsulating membranes, but small metabolites are freely permeable to the barriers and are in free exchange between media and the encapsulated volume. The advantage of microencapsulation over other forms of polymer support is the microfiltration effect of host antibodies, which prevent host rejection of transplanted xenographs. Similar to microcarriers as an attachment support for hepatocytes, encapsulation and entrapment also provide a large area for hepatocyte anchorage in addition to microfiltration of immunoglobulins and other cytotoxic macromolecules. However, the drawback of the microfiltration barrier is the hindrance of mass transfer between the cells and media or blood in perfusion. In addition, encapsulation and entrapment are often highly heterogeneous in the number of cells entrapped. Thus, insufficient nutrient delivery and gas exchange may occur for cells residing in the core region (Peters and Mooney, 1997). However, this may be overcome by decreasing the size of microcapsules or entrapment, or by localizing microentrapment in a narrow nutrient-permeable hollow fiber (Nyberg *et al.*, 1993; Hu *et al.*, 1997; Peters and Mooney, 1997).

### Microcarrier polymer support

ECM-coated microcarriers represent another alternative attachment support for hepatocytes. ECM-coated microcarriers offer a large surface for hepatocyte anchorage as a result of their large surface-to-volume ratio. Hepatocytes attached to the microcarriers may be transplanted to recipients by injection or may be cultured *ex vivo* in bioreactors of various physical designs. In addition, protein and other bioactive factors may be incorporated into the polymer or presented on the surface to enhance localized delivery of extracellular signals. However, microcarriers lack the ability to form defined three-dimensional environments in comparison with sponges or fiber-mesh-based scaffolds. Type I collagen-coated cross-linked dextran microspheres have been used for attachment of rat and human hepatocytes for transplantation (Demetriou *et al.*, 1988, 1991; Moscioni *et al.*, 1989) and *ex vivo* culture of hepatocytes in an extracorporeal liver-assist device with limited success in maintaining the hepatocyte differentiated function and encouraging host vascularization (Rozga *et al.*, 1994; Riordan and Williams, 1997; Watanabe *et al.*, 1997). Alternatively, biologically modified poly(2-hydroxyethyl methacrylate) (pHEMA) microcarriers are used to achieve better hepatocyte attachment for culture in a bioreactor (>75%) (Dixit *et al.*, 1990; Dixit, 1994, 1995). Although the exact role of microcarriers in maintaining the survival and function of attached hepatocytes is unclear, it may be attributed to the dependence of hepatocytes on attachment to a collagen matrix for expression and maintenance of differentiated function, and/or the promotion of early vascularization by extracellular matrix-coated microcarriers (Moscioni *et al.*, 1989; Watanabe *et al.*, 1997).

Commercially available nonbiodegradable microcarriers, e.g., heavily cross-linked dextran coated with type I collagen (e.g., Cytodex-3 beads), are used as ECM-coated microcarriers for hepatocyte culture, transplantation, and *ex vivo* culture. However, non-growth-permissive type I collagen-coated nondegradable beads have not been used successfully for long-term *ex vivo* culture or transplantation of hepatocytes. The lack of hepatocyte attachment to a type I collagen-coated microcarrier surface contributes to the difficulty of *ex vivo* culture of rat hepatocytes in hollow-fiber bioreactors with integral oxygen and media supply (A. S. L. Xu, J. M. MacDonald, and L. M. Reid, unpublished data). To provide a nonrigid, growth-permissive ECM-coated biodegradable support for *ex vivo* culture of hepatocytes or hepatic progenitors, porous PLGA beads have been prepared by a polymer emulsion-rapid solvent evaporation method, and a low-temperature-casting/salt-leaching procedure, respectively. Figure 41.5 shows the surface and internal porous structure of

Fig. 41.5. Scanning electron micrograph showing the porous surface morphology of PLGA beads (50/50%) prepared by a polymer emulsion–rapid solvent evaporation method (A and B). (C) The porous internal structure of PLGA beads prepared by a low-temperature casting/salt-leaching procedure. Magnification (A, B, and C, respectively):  $\times 17$ ,  $\times 172$ , and  $\times 168$ .

PLGA beads prepared by the two methods. Rat primary hepatocytes were found attached to the type IV collagen-coated surface (Fig. 41.6). Preliminary study of rat primary hepatocytes cultured on PLGA beads in a commercial hollow-fiber bioreactor shows a small but significant increase in survival (A. S. L. Xu, J. M. Macdonald, and L. M. Reid, unpublished data). Thus, biocompatible, biodegradable porous microcarriers coated with growth-permissive ECM may be suitable for *ex vivo* culture and expansion of hepatocytes.

### Localized delivery of bioactive factors by polymer support

For both *ex vivo* engineering of functional liver tissue and reconstitution of liver by long-term cell therapy (i.e., hepatocyte transplantation), the diverse function of liver would have to be maintained not only by parenchymal cells, but also nonparenchymal cells, such as sinusoidal endothelial cell, Ito cells, and Kupffer cells (Arias *et al.*, 1994), through their unique *in vivo* tissue structure and cell interaction. A well-developed vasculature for transplanted hepatocytes and nonparenchymal cells, or hepatocytes *ex vivo* cultured in a three-dimensional environment, is needed to achieve sufficient delivery of nutrient, hormones, factors, and oxygen, and thus is critical to cell survival, differentiated function, and growth. Without a developed vasculature, the therapeutic benefit from transplanted hepatocytes and the hepatocytes in bioartificial liver-assist devices may only be short term with limited functional support, because of the critical dependence of hepatocyte growth and expression of differentiated function on formation of tissue vasculature. One of the effective approaches in the design and fabrication of biocompatible and biodegradable polymers is to use polymer support as a vehicle for controlled localized delivery of bioactive factors, to encourage vascularization and angiogenesis. A number of tissue-specific angiogenic factors, such as vascular endothelial growth factor, epidermal growth factor (EGF), and fibroblast growth factor, have been identified as important to angiogenesis and vascularization (Folkman and Klagsburn, 1987; Thomas, 1996; Norrby, 1997; Ajioka *et al.*, 1999; Gerber *et al.*, 1999). However, the cellular origin, molecular mechanism of control, and regulation of angiogenic growth factors under physiologic and pathologic conditions (e.g., increased level in tumor cells) remain to be fully understood. Angiogenic growth factors such as VEGF are present under physiologic conditions at nanomolar to micromolar levels during both initial stages of embryonic development and organ growth in

Fig. 41.6. Rat hepatocytes attached to PLGA microcarriers coated with type IV collagen serum-free media containing EGF and insulin (upper panels); hepatocytes incubated with PLGA microcarriers without a coating of ECM in the same serum-free media (lower panel).

lung alveolar cells, kidney glomerular and proximal tubules, hepatic tissue, and brain (Thomas, 1996). Hepatocyte growth factor is another widely recognized multifunctional cytokine that has target receptors among hepatocytes, keratinocytes, kidney tubular epithelia cells, and breast epithelial cells (Michalopoulos, 1995; Zarnegar and Michalopoulos, 1995). In liver, it stimulates hepatocyte DNA synthesis and thus normal hepatic tissue regeneration. Other growth factors, e.g., platelet-derived growth factor, and roles in wound healing, tissue remodeling, and significance to tissue engineering have been discussed in Chapter 12 of this book. Growth factors are tissue specific with a short half-life in the plasma circulation (Davidson *et al.*, 1985; Folkman and Klagsburn, 1987; Thomas, 1996; Norrby, 1997; Baldwin and Saltzman, 1998; Ajioka *et al.*, 1999; Gerber *et al.*, 1999). Under *ex vivo* tissue culture conditions, supplementing media with growth factors is often problematic as a result of factor short half-life and diffusive distribution in plasma and media supply. Under *in vivo* conditions, however, delivery of growth factors to transplanted hepatocytes by microcapillary blood circulation is a formidable task before sufficient tissue vasculature is established among transplanted cells (Assy *et al.*, 1999). This difficulty is compounded further by the very low or inactive state of vascularization under most physiologic conditions (Thomas, 1996; Norrby, 1997). Expression of VEGF in VEGF-transfected hepatocytes was found to induce significant proliferation of endothelial cells, which in turn, led to the increased formation of vascular network in established functional hepatic tissue (Ajioka *et al.*, 1999).

The role of biocompatible and biodegradable polymers in tissue engineering and cell transplantation is not limited to providing a mechanical support for cells. Rather, their usefulness may be attributed to their application to encapsulate or incorporate bioactive factors for controllable localized delivery of factors at the interface between matrix-coated polymer constructs and seeded cells (Hubbell, 1995; Peters and Mooney, 1997). The localized release of factors may promote more effective and locally selective vascularization and angiogenesis, which in turn leads to increased tissue vasculature formation. Delivery of epidermal growth factor by encapsulation with PLGA microspheres was shown to enhance the engraftment of transplanted hepatocytes (Mooney *et al.*, 1996). To increase the survival and transplant engraftment of fetal porcine hepatocytes xenotransplanted into rats, chitosan is used as a scaffold for the hepatocyte attachment, VEGF load-

ing, and delivery (Elcin *et al.*, 1999). Localized delivery of bioactive factors by their physical incorporation or encapsulation in biodegradable polymer constructs depends on the degradation rate of the polymer, a process that is a function of polymer degradation chemistry and the microenvironment in which the polymer resides. Precise delivery of bioactive factors by these approaches may be difficult to control because of an initial burst (or rapid release) of growth factor when encapsulation is used (Ogawa, 1997; Baldwin and Saltzman, 1998), and because of diffusive spread, endocytosis of growth factor, and cell surface receptor complexes. An alternative approach is covalently tethering of a growth factor such as EGF onto the culture polymer surface by coupling EGF with a PEO linker arm, thus providing prolonged and stable cytokine signaling (Kuhl and Griffith-Cima, 1996).

## DESIGNING BIOREACTORS FOR TISSUE ENGINEERING

### INTRODUCTION

In all tissues, blood flows from the periphery to the central circulation through a capillary bed, and physical, chemical, and biologic gradients exist across the tissue. Figure 41.7A is a two-dimensional schematic representation of blood flow and corresponding gradients in generic tissue. Soluble components such as gases (e.g., oxygen), small molecules (e.g., sugars, amino acids, and fats), and macromolecules (e.g., proteins) have characteristic concentration profiles across the tissue that are described by the appropriate mass transfer equation. Mass transfer depends on the diffusivity, volumetric consumption/production rate, and initial concentration of the soluble component (see Chapter 17, this volume) (Macdonald *et al.*, 1999). Oxygen is typically the biolimiting nutrient in tissues and is especially so in bioreactors, where its relatively high consumption rate and low initial concentration ( $\sim 0.2$  mM at  $37^\circ\text{C}$ , 1 atm) combine to make it difficult to provide adequate levels.

### A Generalized Flow Dynamics in Tissue

### B Tissue Mimicry

### C Scale-up

Fig. 41.7. Generalized blood flow in tissue (A), and demonstration of the tissue engineering principles of tissue mimicry (B) and scale-up (C) using coaxial fibers.

Due to the potential for clot formation and the added expense of including hemoglobin additives with perfusion media, bioreactors lack the oxygen-carrying capacity of blood, and in general, oxygen in a bioreactor becomes limiting to cells beyond 200  $\mu\text{m}$ , when mass transfer is dominated by diffusion. This limitation cannot be addressed by significantly increasing the amount of dissolved oxygen, because at high concentrations oxygen is toxic (Macdonald *et al.*, 1999). The presence of an extensive vascular network in natural tissues means that cells are only one or two cell distances from the flowing blood, or nutrient source. This increases the diffusivity term in the mass transfer equation about four orders of magnitude over incoherent diffusion ( $2 \times 10^{-6} \text{ cm}^2/\text{sec}$ ) due to the coherent convective flow of nutrients, which is on the order of 0.01 cm/sec in the sinusoids [red blood cell velocity ranges from 0.25 to  $3 \times 10^{-2} \text{ cm/sec}$  (McCuskey, 1994)]. The blood velocity increases from normal to cirrhotic tissues and is driven by a pressure drop from 10 to 25 mm Hg in the periportal sinusoid to just a few mm Hg in the pericentral sinusoid (McCuskey, 1994). Because primary cells are adapted to conditions that provide for the optimum mass transfer of nutrients, their use in artificial devices suggests that tissue mimicry should become a primary tissue engineering principle. Tissue mimicry can be divided into two parts: (1) reproducing the smallest organizational unit and (2) scaling up the smallest organizational unit.

### TISSUE MIMICRY

Figure 41.7B illustrates the concept of tissue mimicry in tissue engineering of liver (described in detail in Chapter 2 and Part IV). On the left is a depiction of the blood flow in the liver acinus, the smallest physiologic unit of the liver. Peripheral blood from the intestine, spleen, and lungs is passed into the liver acinus by way of portal triads, then through the liver cell mass by way of sinusoids, and back to the central circulation through the central vein. The sinusoids consist of endothelial cells that sandwich a double layer of parenchymal cells, the hepatic plates; endothelia and parenchymal cells are separated by the space of Disse in which the liver's extracellular matrix (i.e., insoluble components) is found. Therefore, endothelial cells experience some level of shear force due to the convective flow of blood perpendicular to its cell surface. By contrast, the parenchymal cells experience very little shear force, and nutrients are delivered primarily by diffusion of interstitial fluid through fenestrated pores (1–2  $\mu\text{m}$ ) in the endothelial wall and through the extracellular matrix in the space of Disse. On the right side of Fig. 41.7B is an illustration of the primary functioning unit of a coaxial hollow-fiber bioreactor (Macdonald *et al.*, 1998) that mimics the liver acinus. The arrows depict the flow of media through the bioreactor. If plasma from a patient was being passed through the bioreactor, its flow would be similar to that of the media. As noted, oxygen becomes limiting by 200  $\mu\text{m}$ . However, the radius of the liver acinus is 500  $\mu\text{m}$  and the hepatic plates are less than 200  $\mu\text{m}$  thick (Fig. 41.7B, left side). If radial flow can mimic liver acinar blood flow as depicted in Fig. 41.7B (right side), then the coaxial fibers could be separated by a distance similar to that of the liver acinus radius (i.e., 500  $\mu\text{m}$ ). Otherwise, an annular distance similar to that whereby oxygen becomes limiting by diffusion alone ( $\sim 200 \mu\text{m}$ ) must be used, and thus effectively mimicking liver tissue at the lower tissue level, that of the hepatic plates. Therefore, the *in situ* flow dynamics must be characterized before the optimum coaxial bioreactor dimensions can be determined. The use of noninvasive *in situ* techniques to determine physical parameters in bioartificial organs is discussed below.

### SCALE-UP

Typically, one empirically determines or models the optimum mass transfer parameters for the smallest repeatable unit and then scales these units up to a sufficiently sized bioreactor. Some practical problems of scale-up are mass transfer, head pressures, and shear forces. For example, practical aspects of conventional hollow-fiber bioreactor construction can confound the theoretically calculated mass transfer parameters, such as inhomogeneous fiber spacing (Chresand *et al.*, 1988), and large voids within the fiber bundle, and between the fiber bundle and housing. In addition, the large flow rate necessary to alleviate axial oxygen gradients creates large head pressures and shear forces. Cells rest between two fibers in the coaxial bioreactor described in Fig. 41.7B (right side), which prevents hypoxic patches from forming within the fiber bundle and between the housing and fiber bundle.

Figure 41.7C illustrates the principle of scale-up in tissue engineering of liver, and the ease with which the coaxial design can be scaled-up to generate an entire liver necessary for clinical liv-

er support. With present biocompatible materials, this would be an extracorporeal device and a "bioartificial liver" because the bioreactor is composed of an artificial component. Because bioartificial livers are described elsewhere in this book, this will be discussed briefly as they relate to tissue mimicry and scale-up. Biodegradable scaffolds leading to implantable liver tissue were previously discussed in detail.

### BIOARTIFICIAL LIVER

Most bioartificial liver (BAL) designs incorporate the principles of tissue mimicry and scale-up and have been extensively reviewed (Nyberg *et al.*, 1992; Kasai *et al.*, 1994; Bader *et al.*, 1995; Demetriou *et al.*, 1995; Anand, 1996; Dixit and Gitnick, 1996; Fremond *et al.*, 1996; Gerlach *et al.*, 1996; Hughes and Williams, 1996a; Sussman and Kelly, 1996; Jaregui *et al.*, 1997; Reid, 1997a; Macdonald *et al.*, 1999). Many other bioartificial liver designs rely on tissue mimicry of the hepatic plates, such as multiplate bioreactors (Yarmush *et al.*, 1992; Bader *et al.*, 1995; Smith *et al.*, 1997), biodegradable scaffolds of a complex interconnecting network (Griffith *et al.*, 1997), spirally wound bioreactors (Flendrig *et al.*, 1997), and hollow-fiber bioreactors (Nyberg *et al.*, 1992). Lower levels of organization, such as spheroids, have been encapsulated (Fremond *et al.*, 1996) and perfused in various bioreactor types, especially for transplantation (Macdonald *et al.*, 1999).

In tissues, hemoglobin acts as an oxygen and carbon dioxide carrier. Confounding the oxygen mass transfer problem in a BAL is the high oxygen requirement of parenchymal cells. A common feature in the most recently developed BALs is integral oxygenation, or oxygenation within the bioreactor proper (Macdonald *et al.*, 1999). Novel multiplate (Smith *et al.*, 1997), spirally wound (Flendrig *et al.*, 1997), and hollow-fiber (Gerlach, 1994; Goffe, 1997) bioreactors all have a compartment for oxygenation within the bioreactor. The more compartments in a BAL design, the more physiologic functions can be performed. The mimicry of arterial-venous flow (Knazek *et al.*, 1980) has introduced convective flow created by the peripheral-to-central circulation (Fig. 41.7A). In conventional two-compartment hollow-fiber bioreactors a convective flow can be created using Starling flow in conjunction with various flow configurations (Macdonald *et al.*, 1999). Starling flow is the convective component of diffusivity responsible for flow of nutrients from blood vessels to capillary beds. However, membranes foul when the bioreactor is completely filled with cells, and convective flow is difficult to maintain, often resulting in burst fibers (Callies *et al.*, 1994). Even in bioreactors with more than two compartments (Gerlach, 1994; Dixit, 1995), membrane fouling occurs, but across the cellular compartment convection can be more easily controlled by creating a pressure drop between two compartments sandwiching the cell compartment. Four functional bioreactor compartments are necessary to have integral oxygenation and regulated peripheral-to-central circulation. The multicompartment hollow-fiber bioreactors such as that described by Gerlach (1994) and others consists of at least four functional compartments (MacDonald *et al.*, 1999).

## TECHNICAL ASPECTS OF TISSUE ENGINEERING

### CRYOPRESERVATION

Tissue engineering of human tissues and human cell therapies or *ex vivo* gene therapies will be severely constrained until successful cryopreservation methods for stock cells are developed. There is considerable interest in developing these technologies at present. Although bone marrow samples are routinely cryopreserved for clinical programs, the ability to cryopreserve liver cells with retention of function is still at an impasse (Kravchenko *et al.*, 1989; Koebe *et al.*, 1990, 1996; Bischof and Rubinsky, 1993; Ek *et al.*, 1993a,b; Rozga *et al.*, 1993; Bischof *et al.*, 1997; Pazhayanur and Bischof, 1997). Common features to the most successful efforts to date are the use of dimethyl sulfoxide, the addition of Viaspan (University of Wisconsin solution) or the embedding of the cells in collagen gels, careful equilibration of the cells in cryopreservation buffers, and the use of computer-controlled cryopreservation equipment. Although these improvements have resulted in high viabilities (above 75%) of the cells when assessed immediately after thawing and some success with attachment efficiencies onto matrix-coated plates, the cells still do not survive for longer than 24–36 hr after thawing, do not grow, and do not have full functions. Clearly, this is an area in critical need of extensive research efforts.

### ANALYSIS OF BIOREACTOR PERFORMANCE

Conventional analyses of physical, chemical, and biologic aspects of bioreactor performance have been somewhat invasive or indirect, or require modification of the bioreactor to accommodate analysis. Recent methods of analysis, such as nuclear magnetic resonance spectroscopy and magnetic resonance imaging permit direct determination of flow dynamics and intracellular metabolites (Fernandez, 1996). The analysis of bioreactors is divided into three areas: determination of physical and biologic factors, and quality assurance.

### PHYSICOCHEMICAL MEASURES: FLOW DYNAMICS AND CELL DISTRIBUTION

Flow distribution in hollow-fiber bioreactors has been determined by the use of tracers (Noda et al., 1979; Park and Chang, 1986) and radioopaque dyes in conjunction with X-ray computed tomography (Takesawa et al., 1988), but this is difficult to perform with *in situ* cultures, and to the best of our knowledge, there is no report using these techniques with *in situ* cultures. Diffusion-weighted (Moseley et al., 1990a,b) and velocity-encoded MRI (Lee et al., 1995) have been applied to determine cell distribution (Neeman et al., 1991; Van Zijl et al., 1991; Callies et al., 1994) and flow dynamics (Hammer et al., 1990; Donoghue et al., 1992; Zhang et al., 1995) in hollow-fiber bioreactors. Ideally, empirical measurement of flow dynamics by MRI could be integrated with mass transfer models in hollow-fiber bioreactors (Cima et al., 1990) to accurately describe flow dynamics and mass transfer in bioreactors. In fact, oxygen mass transfer predictions can be evaluated in bioreactors using  $^{19}\text{F}$  NMR in conjunction with fluorinated oxygen indicators to obtain oxygen distribution profiles (S. N. O. Williams et al., 1997).

Phase-contrast MRI is a robust, commonly used technique for quantifying flow dynamics (Caprihan et al., 1990). The basic underlying principle of phase-contrast MRI is summarized below. Because the rate of nuclear spin precession is proportional to the magnitude of the local magnetic field, the accumulated phase  $\phi$  of nuclear spins located at location  $\mathbf{r}$  (with respect to that of spins located at the spatial origin) in the presence of a linear magnetic field gradient  $\mathbf{G}$  is given by

$$\phi = \gamma \int \mathbf{G} \cdot \mathbf{r} dt, \quad (1)$$

where  $\gamma$  is the gyromagnetic ratio of the spins. Following a Taylor series expansion of the function  $\mathbf{r}$  and assuming zero acceleration and higher orders of motion, the phase term becomes

$$\phi = \gamma \int \approx \cdot (\mathbf{r}_0 + \mathbf{v}t + \frac{1}{2} \mathbf{a}t^2 + \dots) dt \cong \gamma \int \mathbf{G} \cdot \mathbf{r}_0 dt + \gamma \int (\mathbf{G} \cdot \mathbf{v}) t dt. \quad (2)$$

The first term of the right-hand side is the familiar phase shift used for spatial encoding, and the added phase shift is proportional to the magnitude of flow and the first moment of the gradient pulses. Therefore, by encoding velocity in at least two different magnitudes of the gradient pulses, flow velocity can be estimated from the slope of the phase-first moment plot. The encoding gradient pulses are typically implemented as a pair of identical gradient pulses located at either side of the inversion pulse of a spin-echo pulse sequence, and the vector direction of the gradient pulses defines the direction of flow sensitization. Due to the cyclic nature of the phase function, a potential pitfall of the phase-contrast approach is that flow rates higher than the set measurement dynamic range will be “wrapped around” and thus can be erroneously interpreted. Care must be taken to avoid or correct for this complication.

Figure 41.8 shows magnetic resonance images from two coaxial bioreactors using two imaging pulse sequences,  $T_2$  weighted (A) and velocity encoded (B) (see color plate). The  $T_2$ -weighted image defines both flow and cell distribution, whereas the velocity-encoded image defines the axial flow dynamics (note the characteristic parabolic laminar flow in the intracellular and extracellular compartments, respectively). Diffusion-weighted imaging can define the cell distribution in bioreactors (Neeman et al., 1991; Van Zijl et al., 1991; Callies et al., 1994) and if this sequence were applied to the coaxial bioreactor depicted in Fig. 41.8 the cell mass would be the most intense portion of the image.

### BIOLOGIC MEASURES: GROWTH AND FUNCTIONS

Determination of growth and function in bioreactors using conventional methods has been by analysis of components in media streams. Typically, glucose uptake rate (GUR) [Eq. (3)] and

lactate production rate (LPR) [Eq. (4)] in batch mode cultures are determined by the difference in their concentrations between media changes using the following equations:

$$\text{GUR} = F(G_f - G) + V(G_1 - G), \quad G = (G_1 - G_2)/2, \quad (3)$$

$$\text{LPR} = [F(L - L_p) + V(L - L_1)]0.09, \quad L = (L_1 - L_2)/2, \quad (4)$$

where  $G_p$ ,  $G_1$ , and  $G_2$  are the concentrations of glucose in the media initially, at the end of the prior day, and in the current sample, respectively;  $F$  is the feed rate;  $V$  is the volume of the reservoir; and  $L_p$ ,  $L_1$ , and  $L_2$  are the concentrations of lactate in the media initially, at the end of the prior day, and in the current sample, respectively. Some measure of oxidative metabolism can be determined by the GUR:LPR ratio plotted daily. GUR is not a reliable measure of growth in functional liver cultures because parenchymal cells are glucogenic and one could derive a negative GUR even though there is growth. Synthetic and biotransformatory functions of engineered liver are typically determined by quantification of protein production rates and phase I and II metabolism, respectively (Macdonald *et al.*, 1999). Clinical liver function assays are often used, but their meaning and significance to bioreactor performance are fuzzy. More robust liver function assays are needed (Hughes and Williams, 1996b). Growth and biotransformatory functions can be robustly measured noninvasively by multinuclear NMR spectroscopy (Fernandez, 1996).

Growth and function are generally determined by measuring nutrients, xenobiotics, or proteins in media streams, but NMR spectroscopy can noninvasively measure growth and functions in real-time within bioreactor cultures (Mancuso *et al.*, 1990; Gillies *et al.*, 1991; Macdonald *et al.*, 1998) or by in-line media streams analysis (O'Leary *et al.*, 1987). The design of protocols to test liver functions will be difficult (Hughes and Williams, 1996a), and the optimum and minimum number of tests for liver function and quality control are still being debated. Recently,  $^{31}\text{P}$ / $^{23}\text{Na}$ ,  $^{13}\text{C}$ , and  $^{19}\text{F}$  nuclear magnetic resonance (NMR) spectroscopies have been applied to measure growth (Mancuso *et al.*, 1990; Gillies *et al.*, 1991), metabolic rates (Mancuso *et al.*, 1998), and metabolic profiles (R. A. Williams *et al.*, 1997), respectively, in hollow-fiber bioreactors.

Multinuclear NMR spectroscopy utilizes stable isotopes and strong magnet fields to noninvasively measure levels of nutrients or wastes inside cells (Fernandez, 1996) or media streams (O'Leary *et al.*, 1987). Growth is typically measured by  $^{31}\text{P}$  NMR (Hrovat *et al.*, 1985; Gillies *et al.*, 1991) or  $^{23}\text{Na}$  NMR (Mancuso *et al.*, 1990) by monitoring changes in ATP and  $^{23}\text{Na}$  levels over the culturing period.  $^{19}\text{F}$  NMR can be used in conjunction with fluorinated indicators to measure oxygen profiles (S. N. O. Williams *et al.*, 1997) and intracellular ions (Murphy *et al.*, 1990; London, 1991, 1994), or by direct measure of fluorinated substrates of phase I and II enzymes (Scarfe *et al.*, 1999).  $^{13}\text{C}$  NMR in conjunction with isotopomeric analysis can be used to measure primary metabolism in bioreactors (Mancuso *et al.*, 1998), and has been used clinically to determine liver gluconeogenesis and tricarboxylic acid flux (Jones *et al.*, 1998a,b). The reader is directed to several reviews on the use of isotopomeric analysis to determine metabolic fluxes (London, 1988; Malloy *et al.*, 1988) and as input into metabolic control analysis models (Brindle *et al.*, 1997). Indirect detection of  $^{15}\text{N}$  NMR has been used to measure ammonia metabolism in rat brain (Kanamori *et al.* 1995), and could be used in a similar fashion for engineered liver.

## QUALITY ASSURANCE

Quality assurance is necessary to define the limitations of bioreactor operation. For example, the determination of bubble point and hydraulic permeability in hollow-fiber bioreactors is necessary to assure bioreactor integrity and the maintenance of modeled hydrodynamics. MRI is a powerful tool to determine bioreactor integrity (Callies *et al.*, 1994). A quality assurance protocol should also be developed for step-by-step construction of bioreactors.

## FUTURE CONSIDERATIONS

The excitement with respect to tissue engineering has invaded most biologic and clinical fields. The ability to study tissues *ex vivo* with rigorous controls and with maintenance of their normal functions will revolutionize diverse fields. The ramifications are extensive, and the following list includes only some representative future applications:

1. There will likely be much interest in defining and characterizing maturational lineages in many quiescent tissue types.

2. The delineation of expansion conditions for stem cells should greatly facilitate facets of cell and gene therapies.
3. The markers used to define hematopoietic stem cells (e.g., CD34) are proving generic for many types of early progenitors. The implications are that growth regulation and function in early progenitors have common features that cross tissue boundaries.
4. Clinical programs to address degenerative diseases and tissue failure will be revolutionized by forms of cell therapies paralleling bone marrow transplant and dependent on progenitors with high proliferative potential.
5. Gene therapies, about which there has been so much excitement, have not lived up to expectations yet, given the many difficulties in trying to apply them using targeted injectable vectors. It is likely that *ex vivo* gene therapy using modified progenitors will be far more successful.

Bioartificial organs of many tissues will be developed using the combination of new bioreactor designs, highly proliferative progenitor cell populations, and defined hormone and matrix conditions in conjunction with biodegradable polymers. Such bioartificial organs will be useful for scientific and clinical programs in toxicology, drug therapy, vaccine production, and protein production, as well as general cell and molecular biology. In addition, they will be used clinically as assist devices for patients with organ failure and/or who need drastic treatments for diseases such as cancer.

## SUMMARY

Tissue engineering requires a merging of biologic and engineering techniques and principles in order to achieve its goal of tissue replacement. We have shown how extensive cell culture data on the effects of numerous soluble and insoluble factors, accumulated by generations of scientists, all attempting to reproduce the natural function of liver cells *ex vivo*, provide a wealth of information to use as a guide in designing three-dimensional culture systems. In addition, knowledge of the development and mature organization of the liver furnishes biologic principles that artificial systems can be made to mimic. Using new concepts in bioreactor design, taking advantage of new biodegradable materials and new methods of fabricating these materials, it is possible to come ever closer to the goal of reproducing natural liver function. Finally, it is clear that, from a practical standpoint, the near-term use of bioartificial livers will require the harvesting and culturing of human hepatic progenitors.

## ACKNOWLEDGMENTS

Support for the research programs summarized in the review has been provided by grants to L. M. R. from NIH (DK52851), from the North Carolina Biotechnology Center (#1897), by Vertex Pharmaceuticals, and by Renaissance Cell Technologies. Support was also derived from an NIH grant to the Center for Gastrointestinal and Biliary Disease Biology (DK34987, R. Sandler, P. I.) and by grants to J. M. and L. M. R. derived from the Johns Hopkins Center for Alternatives to Animal Testing and an NRSA award (1F32DK09713).

We wish to thank Ms. Cynthia Lodestro for administrative and technical support, Dr. Yi Wei Rong for technical support in liver perfusions, and Mr. Alan Fisher for technical support in flow cytometry. We also thank the Duke University *In Vivo* Magnetic Resonance Microscopy Facility.

## NOTES ADDED IN PROOF

Several recent articles are of special note. An extensive electron micrographic analysis of the Canals of Hering, thought to be the reservoir of hepatic progenitors in the liver, have revealed that they extend in a bottle-brush pattern throughout zone 1 of the liver (Thiese *et al.*, 1999). The ramifications of their findings are to alter potentially the whole issue of "streaming of liver cells" in liver turnover and regenerative processes.

Several investigators have been evaluating heterogeneity in growth potential of subpopulations of adult liver cells. Grompe and his associates have shown that there is variable growth potential of fractionated adult liver cells, although extensive growth potential has been observed with adult hepatocytes with average diameter of about 25  $\mu$  (Overturf *et al.*, 1999). In addition, Yoshizato and associates (Tateno *et al.*, 2000) have shown that the only adult cells capable of clonal growth *in vitro* are in the size range of so-called "small" hepatocytes and with an average diameter of about 17  $\mu$ .

# RED BLOOD CELL SUBSTITUTES

Thomas Ming Swi Chang

## INTRODUCTION

**H**emoglobin molecules extracted from red blood cells are modified by microencapsulation or cross-linkage to produce red blood cell substitutes. The encapsulation and linkage processes stabilize the hemoglobin molecules and also allow sterilization of the products to remove human immunodeficiency virus (HIV) and other microorganisms. Rapid progress has been made in the past decade toward clinical use of red blood cell substitutes. A number of groups are already well into phase III clinical trials in humans to study safety and efficacy in patients.

In 1956, the first research was initiated on artificial cells, including studies on modified hemoglobin (Chang, 1957, 1964, 1965). Artificial cells (Fig. 42.1) contain biologically active materials such as hemoglobin, enzymes, cells, adsorbent components, and other material (Chang, 1972, 1977a; Chang and Prakash, 1998). The membranes of artificial cells allow permeant molecules such as oxygen and substrates to enter and allow metabolic products, peptides, and other material to leave. In this way the enclosed materials are protected from immunological rejection and from other materials in the external environment.

Until about 1989, most research on artificial cells focused on those containing enzymes, cells, microorganisms, adsorbent components, peptides, and other materials (Chang, 1964, 1965, 1972). Concentrated research and development on modified hemoglobin started after 1987 because of public concerns about HIV-induced autoimmune deficiency syndrome (AIDS) in donor blood recipients. After extraction from red blood cells and before modification, hemoglobin can be sterilized by pasteurization, ultrafiltration, and chemical means. These procedures can remove microorganisms, including those responsible for AIDS, hepatitis, and other blood-borne diseases. There are many situations wherein modified hemoglobin has the potential to substitute for red blood cells (Bowersox and Hess, 1994; Chang, 1997a; Klein, 1994; Winslow, 1994, 1996), including cardiopulmonary bypass surgery, cancer surgery, elective surgery, organ preservation cardioplegia, and in emergency treatment for severe traumatic injuries resulting from traffic accidents and other accidents that cause severe bleeding and hemorrhagic shock. The number of traumatic injuries requiring blood substitutes in civilian use is small when compared to the requirements in major disasters or wars (Bowersox and Hess, 1994). Modified hemoglobin is especially useful in emergency situations such as these. Because modified hemoglobin does not contain red blood cell membrane and therefore no blood group antigens, it can be used without the need for cross-matching or typing. This would save much time and resources and would permit on-the-spot transfusion as required, similar to giving intravenous salt solution. This is further facilitated by the fact that modified hemoglobin can be lyophilized and stored as a stable dried powder that can be reconstituted with the appropriate salt solution just before use. Another application is in treating patients whose religious beliefs do not allow them to use donor blood for transfusion.

## WHY DO WE HAVE TO MODIFY HEMOGLOBIN?

Hemoglobin in the red blood cell is responsible for carrying oxygen from the lung and delivering oxygen to tissues. Hemoglobin is a tetramer of four subunits: two  $\alpha$  subunits and two  $\beta$  sub-

Fig. 42.1. Artificial cells can be prepared as microcapsules, nanocapsules, or cross-linked proteins. The artificial cell retains biologically active materials, thus protecting the contents from the external immunological system and other destructive elements. At the same time, permeant molecules can enter or leave rapidly, allowing molecules such as oxygen, substrates, metabolites, toxins, and other materials to enter and be acted on by the enclosed materials. Any products derived from the enclosed materials, such as peptides, hormones, metabolites, and oxygen, can readily diffuse out. Reprinted from Chang (1993) by courtesy of Marcel Dekker Inc.

units (Perutz, 1980) (Fig. 42.2). Hemoglobin is in the oxy, related state (R state) when it is carrying oxygen. To release oxygen, the hemoglobin molecule undergoes conformational change with a  $15^\circ$  rotation. The molecule is then in the deoxy, tense state (T state). Red blood cells contain a cofactor 2,3-diphosphoglycerate (2,3-DPG), that facilitates this conformational change. Thus hemoglobin inside red blood cells has a high  $P_{50}$ , which allows it to release oxygen readily to tissue at physiological oxygen tensions.

Hemoglobin can be extracted from red blood cells and infused into animals experimentally (Amberson, 1937), but this causes renal toxicity. Removal of the cell membranes to form a stroma-free hemoglobin blood substitute still causes renal toxicity, because of a number of reasons. When infused into the circulation, each four-subunit hemoglobin molecule (tetramer) is rapidly broken down into two subunits (dimers) (Fig. 42.3). The smaller dimers are rapidly excreted by the kidneys, and this also has renal toxicity (Savitsky *et al.*, 1978). Furthermore, without the required 2,3-DPG present inside the red blood cells, hemoglobin cannot readily release oxygen (low  $P_{50}$ ) until the tissue oxygen tension has reached a lower value.

Fig. 42.2. Inside the red blood cells, each hemoglobin molecule exists as a tetramer of four subunits: two  $\alpha$  subunits and two  $\beta$  subunits. Cofactor 2,3-DPG is regained in the red blood cell to facilitate the release of oxygen by hemoglobin, as required by the tissues. Reprinted from Chang (1992) by courtesy of Marcel Dekker Inc.

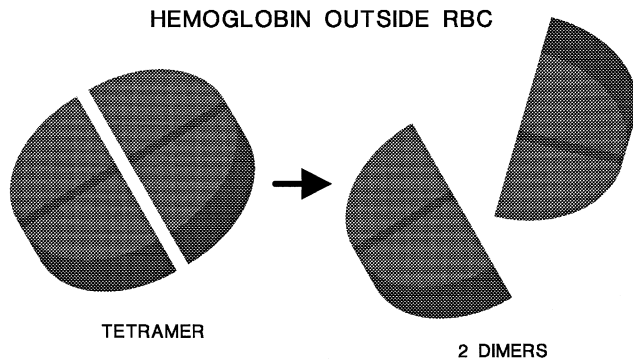

Fig. 42.3. When hemoglobin is outside the red blood cell, the first problem is that 2,3-DPG is no longer available to facilitate the release of oxygen; second, the hemoglobin tetramer breaks down into two dimers, which are rapidly excreted by the kidney. Reprinted from Chang (1992) by courtesy of Marcel Dekker Inc.

### MODIFIED HEMOGLOBIN

Biotechnological approaches can be used to either cross-link or encapsulate hemoglobin molecules to prevent the hemoglobin from dissociating into dimers and also to allow hemoglobin to maintain an acceptable  $P_{50}$ . Many research groups have contributed to major progress in modifying hemoglobin, especially in the past decade. A number of groups are in phase III clinical trials in humans. The following discussions provide details on the two major subclasses of modified hemoglobin: encapsulated hemoglobin and cross-linked hemoglobin.

### ENCAPSULATED HEMOGLOBIN: ARTIFICIAL RED BLOOD CELLS

The first artificially created red blood cells have a  $P_{50}$  and an oxygen dissociation curve similar to normal red blood cells, because 2,3-DPG is retained inside (Chang, 1957) (Fig. 42.4). Hemoglobin is also retained inside as tetramers. These artificial red blood cells do not have blood group antigens on the membrane and therefore do not aggregate in the presence of blood group antibodies (Chang, 1972). However, the single major problem is the rapid removal of these artificial cells from the circulation. Much of the research since the creation of these cells has been focused on improving their survival in the circulation by decreasing their uptake by the reticuloendothelial system. Because removal of sialic acid from biological red blood cells results in their rapid removal from the circulation (Chang, 1965, 1972), we modified the surface properties of artificial red blood cells using synthetic polymers, cross-linked protein, lipid-protein, lipid-polymer, and other surface modifications (Chang, 1964, 1965, 1972). However, the available technology at the time we conducted these studies allowed production of artificial red blood cells of down to only about 1  $\mu\text{m}$  in diameter.

Fig. 42.4. Modification of hemoglobin by microencapsulation inside artificial cells provides an intracellular environment similar to that of biologic red blood cells (Fig. 42.2). Reprinted from Chang (1992) by courtesy of Marcel Dekker Inc.

Later, new technology allowed the preparation of smaller submicron lipid membrane artificial red blood cells with further improvements in circulation time (Djordjevich and Miller, 1980). Circulation time improved by additional surface modifications. Microencapsulated hemoglobin and artificial red blood cells are now being extensively explored by many researchers (Chang, 1997a; Rudolph *et al.*, 1997; Tsuchida, 1995). Developmental advances have increased the average circulation half-time to 20 hr, and modifications using poly(ethylene glycol) have increased the circulation half-time to around 40 hr (Rudolph *et al.*, 1997). It is possible to replace 90% of the red blood cells in rats with artificial red blood cells, and animals with this percentage of exchange transfusion still remain viable. Studies have also reported success in treating hemorrhagic shock. Preliminary studies by a number of groups show that the artificial cells are not toxic; there are no changes in the histology of brain, heart, kidneys, and lungs in rats. Larger scale production is now feasible by using extrusion methods with a microfluidizer. The uptake is mainly by the reticuloendothelial system. To further improve stability and biodegradability, we are now using biodegradable polymer membranes to nanoencapsulate hemoglobin. This results in artificial red blood cells of about 168 nm (0.168  $\mu\text{m}$ ) in diameter (Chang and Yu, 1997, 1998; Yu and Chang, 1996).

Microencapsulation of hemoglobin to prepare artificial red blood cells is a rather ambitious approach. Although this attempt to mimic red blood cells has resulted in a complete red blood cell substitute, it is rather complicated. Further research is needed and this approach is now considered to yield a second-generation modified hemoglobin. A simpler cross-linked modified hemoglobin has been developed as a first-generation modified hemoglobin for more immediate clinical applications (Chang, 1997a; Rudolph *et al.*, 1997; Tsuchida, 1995; Winslow, 1994, 1996).

#### CROSS-LINKED POLYHEMOGLOBIN

Extensive studies of cross-linked hemoglobin have been carried out by many groups, especially in the past decade. Hemoglobin contains many amino groups, most of which are on the surface of the hemoglobin molecule. The use of a bifunctional agent (diacid) to cross-link hemoglobin was first reported by Chang (1964, 1965, 1972) (Fig. 42.5). Diacid was initially used to form cross-linked hemoglobin membranes for artificial red blood cells, but it was found that with decreasing size of artificial cells, all the hemoglobin molecules are cross-linked into polyhemoglobin (Chang, 1964, 1965, 1972). The reaction is as follows:

Diacid

Hemoglobin

Cross-linked polyhemoglobin

#### INTERMOLECULAR(+INTRA) XLINKING POLYHEMOGLOBIN

FIRST CROSSLINKERS USED:  
SEBACYL CHLORIDE (CHANG, 1964)  
GLUTARALDEHYDE (CHANG, 1971)

Fig. 42.5. Cross-linking of hemoglobin using bifunctional agents prevents the breakdown of tetramers into dimers. The addition of pyridoxal phosphates or other 2,3-DPG analogs facilitates oxyhemoglobin in releasing oxygen. Reprinted from Chang (1992) by courtesy of Marcel Dekker Inc.

Another cross-linking reaction, using glutaraldehyde as the bifunctional agent to form another type of polyhemoglobin, was studied (Chang, 1971):

dialdehydes                      hemoglobin                      Cross-linked polyhemoglobin

Cross-linking prevents the breakdown of hemoglobin tetramers into dimers. The addition of a 2,3-DPG analog, pyridoxal phosphate, to cross-linked polyhemoglobin improves the  $P_{50}$  (Benesch *et al.*, 1975). This approach has been developed (Dudziak and Bonhard, 1980; Sehgal *et al.*, 1980; DeVenuto and Zegna, 1982). The resulting pyridoxalated glutaraldehyde polyhemoglobin is in phase III clinical trial, and Gould *et al.* have successfully infused 10,000 ml into patients (Gould *et al.*, 1998). Another glutaraldehyde cross-linked polyhemoglobin using bovine hemoglobin is also in phase III clinical trial in humans and is already approved by the Food and Drug Administration (FDA) for use in canines (Pearce and Gawryl, 1998). Other cross-linkers are also being developed. Some of these are based on bifunctional dialdehydes derived from oxidizing the ring structures of sugars or nucleotides. These are designed to have the dual function of a bifunctional cross-linker, which also acts as a 2,3-DPG analog. One approach being developed for clinical trial involves the use of a dialdehyde prepared from oxidizing a sugar molecule to form ring-opened raffinose, *o*-raffinose (Hsia, 1991). The *o*-raffinose polymerized hemoglobin has a good  $P_{50}$  without the need for an additional 2,3-DPG analog. It is now in phase III clinical trial (Adamson and Moore, 1998).

### CROSS-LINKED TETRAMERIC HEMOGLOBIN

The cross-linkers described above can be used for both intermolecular and intramolecular cross-linkage. Studies have been carried out to specifically cross-link hemoglobin molecules intramolecularly to prevent dimer formation after infusion (Bunn and Jandl, 1968). Another example is a bifunctional agent, 2-nor-2-formylpyridoxal 5-phosphate, which is also a 2,3-DPG analog that can intramolecularly cross-link the two  $\beta$  subunits of the hemoglobin molecules (Benesch *et al.*, 1975). Another 2,3-DPG pocket modifier, bis(3,5-dibromosalicyl) fumarate (DBBF), intramolecularly cross-links the two  $\alpha$  subunits of the hemoglobin molecule (Walder *et al.*, 1979). This prevents dimer formation and also improves the  $P_{50}$ . This product, the so-called  $\alpha$ - $\alpha$ -hemoglobin, has been tested up to phase III clinical trial (Estep *et al.*, 1992; Nelson, 1998). Analysis of results has led to cancellation of the clinical trial of this cross-linked tetrameric hemoglobin.

### CONJUGATED HEMOGLOBIN

Conjugated hemoglobin is the result of cross-linking hemoglobin to polymers. Initially, hemoglobin was cross-linked to polyamides (Chang, 1964, 1965, 1972). The use of soluble polymers resulted in soluble conjugated hemoglobin with good circulation time (Iwashita *et al.*, 1988; Iwashita, 1992; Nho *et al.*, 1992; Shorr *et al.*, 1996; Wong, 1988). These are being tested in humans in phase II clinical trial.

### SOURCES OF HEMOGLOBIN

Where do we obtain all the hemoglobin needed for preparing modified hemoglobin? In addition to hemoglobin from human sources, bovine hemoglobin is being actively investigated for use in glutaraldehyde cross-linked bovine polyhemoglobin (Pearce and Gawryl, 1998) and as conjugated hemoglobin (Nho *et al.*, 1992; Shorr *et al.*, 1996). Unlike human hemoglobin, bovine hemoglobin outside of red blood cells has a high  $P_{50}$  without requiring 2,3-DPG or its analogs. Bovine hemoglobin has been cross-linked into polyhemoglobin and is being used in phase III clinical trial (Pearce and Gawryl, 1998). Human hemoglobins produced by recombinant technology in microorganisms (Hoffman *et al.*, 1990) and from transgenic animals (O'Donnell *et al.*, 1992) are other exciting potential sources. The recombinant approach using *Escherichia coli* allows the modification of hemoglobin to prevent dimer formation and also affords a good  $P_{50}$ . This has been tested up to phase II clinical trial (Freytag and Templeton, 1997), but has been discontinued in order to develop a recombinant hemoglobin that has less affinity for nitric oxide and therefore does not cause vasoconstriction (Doherty *et al.*, 1998). Another potential approach is synthetic heme (Tsuchida, 1995).

## CIRCULATING TIME OF MODIFIED HEMOGLOBIN

Removal of polyhemoglobin and conjugated hemoglobin after infusion is mainly accomplished by the reticuloendothelial system. The half-time of polyhemoglobin in the circulation is about 25 to 30 hr. Conjugated hemoglobin stays in circulation slightly longer. Intramolecularly cross-linked tetrameric hemoglobin escapes more rapidly from the circulation and therefore has a shorter circulation time. Survival time of modified hemoglobin in the circulation depends on the dose and the animal species, and is much shorter than that of red blood cells. However, the survival time is adequate for most of the shorter term uses described earlier. For example, all three types of cross-linked hemoglobin are effective in animal studies of hemorrhagic shock and isovolemic exchange transfusions.

## SAFETY OF MODIFIED HEMOGLOBIN BLOOD SUBSTITUTE

How safe is modified hemoglobin when injected into animals and humans? To evaluate this, proper selection of a toxicity animal model is important. This has been described in detail in the FDA publication, "Points to consider in the safety evaluation of hemoglobin-based oxygen carriers" (Frantantoni, 1991). Animal studies using properly prepared cross-linked hemoglobin have not shown any adverse effects on coagulation factors, leukocytes, platelets, or complement activation. Very sensitive immunological studies have been carried out for polyhemoglobin, conjugated hemoglobin, and microencapsulated hemoglobin (Chang *et al.*, 1992; Estep *et al.*, 1992). Results show that modified homologous polyhemoglobins (e.g., rat polyhemoglobin injected into rats) are not immunogenic even with repeated injection. Heterologous polyhemoglobin (e.g., nonrat hemoglobin injected into rats) is not immunogenic initially but is immunogenic after repeated injections with Freund's adjuvant. Conjugation and microencapsulation markedly decreased the antigenicity of heterologous polyhemoglobin. Other studies show that without the use of Freund's adjuvant, repeated subcutaneous and intravenous injections of heterologous cross-linked hemoglobin are much less immunogenic. Because hemoglobin has a high affinity for nitric oxide, extensive studies have been carried out to see the effects of vasoactivity. Tetrameric hemoglobin in the intramolecularly cross-linked form or in the recombinant form causes more vasoactivity than does polyhemoglobin (Chang, 1997c). Those polyhemoglobins with less than 1% tetrameric hemoglobin (Gould *et al.*, 1998) did not show vasoactivity. It is likely that hemoglobin, being less

Fig. 42.6. Tetrameric hemoglobin (HB), being small, can move across the intercellular junction of endothelial cells. This hemoglobin binds nitric oxide (NO) in the interstitial space and lowers the NO concentration, resulting in vasoconstriction. Other types of modified hemoglobin contain a varying amount of tetrameric hemoglobin that can also act similarly. Removal of these smaller tetrameric hemoglobins from polyhemoglobin, conjugated hemoglobin, and microencapsulated hemoglobin would prevent this. Reprinted from Chang (1997c) by courtesy of Marcel Dekker Inc.

negatively charged than albumin, can cross the intercellular junction of the endothelial cells of the vasculature (Fig. 42.6). Once there, hemoglobin, with its high affinity for nitric oxide, would remove nitric oxide that is needed for vasodilatation. There has been success in preparing recombinant tetrameric hemoglobins with low affinity for nitric oxide resulting in little or no vasoconstrictor effects (Doherty *et al.*, 1998). Another important area of safety study is the distribution of modified hemoglobin after infusion and also its effect on the reticuloendothelial system.

Cross-linked hemoglobin appears to be safe in animal testing as described above; however, in 1991, the FDA reported unexplained clinical reactions in phase I clinical trials in humans and emphasized the need for further careful safety evaluation (Frantantoni, 1991). One of the problems with safety studies is that a response in animals is not necessarily the same as in humans, especially in the case of immunologic and hypersensitivity types of reactions. We have worked out a simple *in vitro* screening test (Chang and Lister, 1990, 1993a,b, 1994) that consists of adding 0.1 ml of modified hemoglobin to a test tube containing 0.4 ml of human plasma or blood, followed by analysis for complement activation after incubating for 1 hr. This *in vitro* test can be used in research or in industrial scale-up production. It can detect trace contamination of blood group antigens, antibody-antigen complexes, endotoxin, trace fragments of microorganisms, impurities in polymers, and some emulsifiers, for example. This figure has been used to rule out potential problems in industrial scale-up.

## EFFICACY OF MODIFIED HEMOGLOBIN BLOOD SUBSTITUTE

Animal studies show that cross-linked hemoglobin is effective in short-term applications, including hemorrhagic shock, hemodilution in surgery, and angioplasty. Animal studies indicate that polyhemoglobin, intramolecularly cross-linked hemoglobin, conjugated hemoglobin, and microencapsulated hemoglobin are all effective in the resuscitation of lethal hemorrhagic shock and in isovolemic exchange transfusion. For obvious reasons this type of severe test of efficacy using lethal animal models cannot be used in human clinical trials. As a result, discussions still continue regarding the types of end points one needs to use for clinical trials of efficacy in humans. The FDA has published a summary on "points to consider" for efficacy designs in efficacy clinical trials in humans (Frantantoni, 1994).

## PRESENT STATUS AND FUTURE RESEARCH AND DEVELOPMENT

The different polyhemoglobins now in phase III clinical trials are likely to be the first modified hemoglobins ready for routine clinical use. With these first-generation modified hemoglobin

1. ATP → ADP → AMP → ADENOSINE → INOSINE → HYPOXANTHINE
2. XANTHINE DEHYDROGENASE → XANTHINE OXIDASE

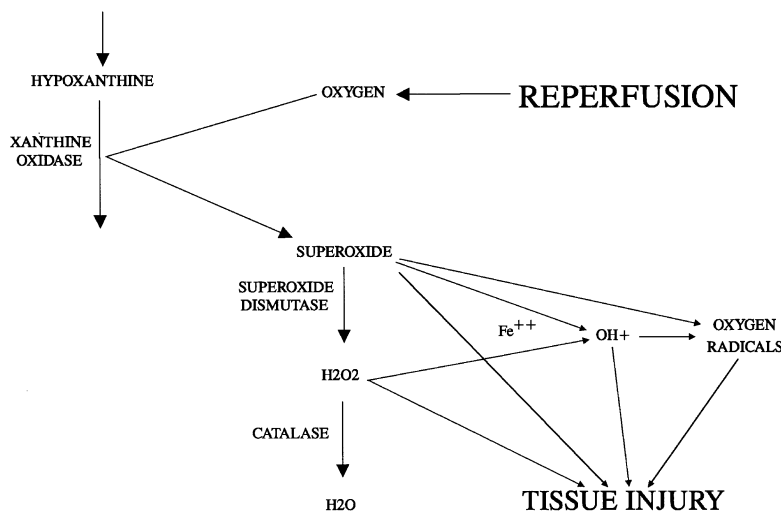

Fig. 42.7. Ischemic reperfusion injuries. Ischemia leads to accumulation of hypoxanthine and activation of xanthine oxidase. Reperfusion brings in oxygen, resulting in superoxide formation. This and other resulting oxidants and oxygen radicals can cause tissue injury. First-generation modified hemoglobin is prepared from ultrapure hemoglobin and therefore does not contain the required deoxidant enzymes. It has been shown that cross-linking polyhemoglobin with superoxide dismutase and catalase can significantly decrease the formation of oxygen radicals (D'Agnillo and Chang, 1998a). Reprinted from Chang (1997c) by courtesy of Marcel Dekker Inc.

Fig. 42.8. Third-generation modified hemoglobin blood substitute consisting of biodegradable polymeric membrane nanoencapsulated hemoglobin and enzyme systems (Chang, 1997c; Yu and Chang, 1996). Reprinted from Chang (1997c) by courtesy of Marcel Dekker Inc.

blood substitutes being tested in humans, studies have already started on further refinements of cross-linked hemoglobin. One example is the incorporation of superoxide dismutase and catalase into cross-linked hemoglobin to prevent reperfusion injury due to oxygen radicals (Fig. 42.7) (D'Agnillo and Chang, 1997, 1998a,b; Chang *et al.*, 1998). Artificial red blood cells based on microencapsulation afford a more complete red blood cell substitute and are also being extensively developed. These are more similar to biologic red blood cells because hemoglobin is not exposed to the outside environment. Furthermore, multienzyme systems can also be enclosed. This includes the entrapment of catalase and superoxide dismutase with hemoglobin (Fig. 42.8) (Chang and Yu, 1997). The approach of microencapsulation of multienzyme systems with cofactor recycling is also being used to prevent methemoglobin formation. This brief overview cannot include the numerous ongoing studies and research in this area. Details are available in many published books, journals, and symposia, and on the web site at <http://www.artcell.mcgill.ca> (Chang, 1997b, 1998; Rudolph *et al.*, 1997; Tsuchida, 1995; Winslow, 1996). There is also a chemical approach to red blood cell substitutes based on perfluorochemicals (Keipert, 1998; Reiss, 1998). However, this is not within the scope of this chapter, which describes only the biotechnological approaches. Details on the topic of perfluorochemicals are available in Keipert (1998) and Reiss (1998).

# LYMPHOID CELLS

Una Chen

## INTRODUCTION

For researchers who are interested in cell-based therapy, it is a great challenge to learn how to expand normal lymphoid cells and their precursor cells *ex vivo* under defined conditions. Lymphocytes are defined by cell surface receptors—immunoglobulin (Ig) for B cells, and the T cell receptor (TCR) for T cells. Precursor B cells bear a pre-B receptor, which contains  $\lambda 5$  in mice ( $\Psi$  in humans), and precursor T cells bear a pre-TCR- $\alpha$ . No biochemically and genetically defined surface receptors for the progenitors of lymphoid precursors have been reported. It is not entirely clear how committed stem cells differentiate into lymphoid cells, which then mature into effector cells. Many theories have been postulated. Differentiation and maturation involve both antigen-independent and antigen-dependent processes. For the first process, I will explore the sequential commitment model proposed by Brown *et al.* (1985, 1988). For my treatment of the second process, I am indebted to many colleagues who helped me to summarize current views.

Ligand–receptor interactions must play an important role in activating lymphoid cells to proliferate and to differentiate. The term “ligand” means all external signals, including those provided by stroma cells and cytokines during the antigen-independent stage and those provided by antigens and accessory cells during the antigen-dependent stage. The process of turning on and turning off of transcription factors at each stage of differentiation as a consequence of ligand–receptor interaction is the key element controlling both phenotype and function of cells. Thus, hoping that the growth of lymphoid (precursor) cells can be manipulated at will in the future by using genetic tools, I will discuss transcription factors known to be important at various stages of lymphopoiesis. So far, there are only a few successful examples of expansion of normal lymphoid (precursor) cells in culture. All are based on the support of stroma cell lines and cytokines. On removal of these elements, cells either differentiate toward terminal effector cells or die.

I have arbitrarily defined seven stages of lymphopoiesis to discuss in detail. For each one I will discuss the available cellular and molecular markers, our current understanding of cellular phenotype, the potential of these cells to expand *ex vivo*, and what could be done in the future. In general, both somatic and genetic manipulations are possible in animal models. By combining modern cellular technology and available mutant mice, one should be able to grow normal lymphoid (precursor) cells at every stage of lymphopoiesis. Due to ethical and safety considerations, only somatic manipulation is considered for use with human beings.

Despite the efforts in many labs in the past few years, human stroma cell lines that can reproducibly support the growth of different stages of lymphoid (precursor) cells are still not available. To apply inducible regulation of stage-specific and lymphoid-specific transcription factors in controlling the growth of normal lymphoid cells seems to be the key element—a great task for the year 2000 for researchers in this field.

The aim of this chapter is to understand lymphocytes and their precursors. The purpose is to learn how these cells might be manipulated to make them useful in cell-based, somatic gene therapy. I will attempt to address the possibility of growing normal lymphoid cells and their stem cells

of mouse and human origin in a controllable manner. That is, cells should proliferate *ex vivo* without becoming malignantly transformed and with little or no differentiation.

We distinguish two main sorts of stem cells: totipotent and multipotent. Totipotent stem cells usually divide symmetrically to give rise to two totipotent daughter stem cells, which are identical in phenotype to their parent. Under appropriate conditions, totipotent stem cells can differentiate into any other form of stem cell. The only known stem cell lines that seem to be close to totipotent are mouse embryonic stem cells (ESCs), and, more recently, human ESCs. Multipotent stem cells, which exist for the lifetime of an organism, undergo primarily asymmetric divisions. One daughter cell is another stem cell like its parent, whereas the other daughter cell is a more highly differentiated cell that performs a tissue-specific function. Due to this unique property, multipotent stem cells are ideal vehicles for cell-based, somatic gene therapy. They will carry the transgene for the lifetime of the organism and they will maintain expression of the transgene in the differentiated cells that they spawn.

Both lymphoid and lymphoid precursor cells are the progenies of hematopoietic stem cells. One of our main tasks here is to review whether lymphoid cells and their progenitors possess stem cell-like properties. Are they self-renewing, and with available culture conditions and technology, can they expand *ex vivo* under controllable growth conditions? Unlimited growth of lymphoid cells and their progenitors is well documented. Lymphoid leukemia cells develop either spontaneously or after infection with viruses. These cell lines are useful for studying lymphoid cells, but not for cell-based therapy because they develop tumors when reintroduced into the organism. Thus, this chapter is devoted to exploring the possibility of growing “normal” lymphoid cells that can be engineered in culture and reimplanted into syngeneic or autologous hosts for therapeutic purposes.

### PROPERTIES OF LYMPHOCYTES

Lymphoid precursor cells are bipotent progenitors of pre-T and pre-B cells. The development of lymphoid precursor cells is independent of the presence of antigen (Ag). It is controversial whether lymphoid precursor cells divide asymmetrically with self-renewal. Lymphocyte types are defined by cell surface receptors—immunoglobulin (Ig) for B cells, and the T cell receptor for T cells. Precursor B cells bear a pre-B receptor, which contains  $\lambda 5$  in mice, and  $\Psi$  in humans, and precursor T cells bear a pre-TCR- $\alpha$ . So far, no biochemically and genetically defined surface receptors for the progenitors of lymphoid precursors have been reported. Lymphocytes and their precursors are similar to cells of other lineages in that they proliferate, differentiate, communicate with other cells, age, and die. However, lymphocytes also possess unique properties that distinguish them from other cells: (1) formation of receptor genes by VDJ recombination, (2) requirement for a thymuslike environment to generate mature CD4<sup>+</sup>8<sup>+</sup> T cells, (3) requirement for somatic education and selection by antigen, (4) somatic hypermutation to generate more diversity in B cells, (5) immunologic memory, (6) Ig heavy chain class switch recombination in B cells, and (7)  $\kappa$  light chain editing somatically to generate new specificities of B cell receptor (Hertz and Nemazee, 1998). Development of techniques to expand *ex vivo*, genetically manipulate, and reimplant into host animals lymphocytes and their precursors requires lymphocyte engineers.

### LYMPHOCYTE ENGINEERING: REALITY AND POTENTIAL

Two models describe the sequence of cell commitment during lymphopoiesis: stochastic and inductive. In this section, I will use an inductive model in an attempt to explain lymphocyte commitment during development of the organism and in the adult.

#### INDUCTIVE MODEL OF SEQUENTIAL CELL COMMITMENT OF HEMATOPOIESIS

This model is divided into two parts. The first part deals with the antigen-independent stage, starting with the differentiation from the null cells (fertilized egg to embryonic stem cells) to mesoderm and then to lymphoid precursor cells. A significant portion of the first part of this model was expanded from Bailey's hypothesis of developmental progress (1986) and modified according to Brown *et al.* (1985, 1988).

#### Antigen-independent stage of lymphopoiesis—Part 1

As multipotent stem cells are committed to differentiate, it is hypothesized that the differentiation sequence is genetically determined. Cells within the sequence are precommitted in their

ability to respond to various inducers of differentiation, and on encountering appropriate factors or a suitable microenvironment, they proliferate and mature along a particular pathway. Brown *et al.* (1985, 1988) suggested that multipotential stem cells that do not receive a signal for differentiation toward mature end cells progress to the next stage in the sequence of development. Alternatively, cells that do not receive a signal die. Only cells that receive proper signals will differentiate further toward the mature end cells. Because commitment is gradual, there is a continuous spectrum of multipotential stem cells. Thus, some of them may be able to respond to inducers of one or another sort. In terms of self-renewal, multipotential stem cell populations continuously occupy each potential for proliferation at any given time and therefore respond to the requirement for each cell type. Some daughter cells will differentiate into the next stage. The continuous development of stem cells may not be diverted entirely toward one cell type, even in the presence of differentiation factors for that type. Because stem cells divide as they respond, some cells are still able to progress to the next stage of commitment.

### Antigen-dependent stage of lymphopoiesis—Part 2

The second part of this model deals with the antigen (Ag)-dependent stage, after receptors are expressed on the surface of lymphocytes. There are two main lineages of lymphocytes: T and B cells. T cells can mature into CD8<sup>+</sup> cytotoxic T cells and CD4<sup>+</sup> helper T cells. Based on their function and the spectrum of cytokines produced, helper T cells can be divided into Th1 and Th2 subpopulations. The main functions of CD4<sup>+</sup> T cells are to recognize cell-bound antigen and to communicate with and help cytotoxic T cells and B cells to perform their duties as effector cells. Both lineages generate memory cells. How and when lymphoid cells are committed to differentiate into effector cells or into memory cells remain a mystery.

### DIAGRAMS TO EXPLAIN THIS MODEL

Figure 43.1 is a simple diagram to explain this model. Hematopoietic stem cells (HSCs) are multipotential stem cells derived from the mesoderm. Originally they are descended from common stem cells (null, or 0, cells) such as fertilized eggs and from mouse embryonic stem cell lines. The cells diagonally to the right (Fig. 43.1) represent cells committed to hematopoietic lineages, which gradually lose their multipotentiality during embryogenesis. This concept is expressed with numbers (5, 4, 3, and 2), inside the progenitor cells on the diagonal. For example, HSCs (noncycling) enter the proliferating stage to become the hematopoietic progenitor cells (HPCs; cycling). The number 5 cell, for instance, means that the HPCs at this stage have the potential to differentiate into five different types of precursor cells.

The committed, monopotential precursor cells then differentiate toward mature end cells such as megakaryocytes (Me), erythrocytes (E), neutrophils/granulocytes (G), monocytes (M), and lymphocytes (L). Lymphoid precursor cells then differentiate into monopotential precursors for B and T cells. After expression of Ag receptors on the cell surface and on encountering Ag, B cells differentiate into plaque-forming cells (PFCs; i.e., plasma cells) or memory B cells. T cells become CD8<sup>+</sup> or CD4<sup>+</sup> after thymic education, maturation, and negative and positive selection. Memory T cells are generated later during differentiation. Figures 43.2–43.4 show the markers and events that occur during the development of pre-T cells—the process of maturation, education, and apoptosis of mature CD4<sup>+</sup> or CD8<sup>+</sup> T cells from CD4<sup>+</sup>8<sup>+</sup> T cells (Kisielow and von Boehmer, 1995; Rodewald and Fehling, 1998). Genes encoding transcription factors and other important genes known to be specifically expressed in lymphopoiesis and which affect function when knocked out include *Brachyury*; *scl*; *c-myb*; *GATA-1*, *-2*, and *-3*; *rbtn2*; *pu.1/spi-1*; *Ikaros*; *Tcf-1*; *E2A*, *pax 5*; *Oct-2*, *Blimp-1*; *pTα*; *bcl-x*; and *p53*.

### SOME COMMENTS ON THIS MODEL

Practically nothing is known about how totipotent stem cells differentiate into ectoderm, mesoderm, and endoderm, nor how mesoderm differentiates into hematopoietic lineages. These are the central issues of embryogenesis, and this part of the model is intentionally very sketchy. Why and when multipotential, lineage-specific stem cells divide asymmetrically or progress to the next stage of commitment are unknown. The underlying rules may be stochastic (Ogawa, 1993) or inductive as suggested by Brown *et al.* But I think the progression of the stage of commitment might more likely be due to the turning on and off of genes encoding transcription factors.

Brown and co-workers originally formulated their model based on the data from the differ-

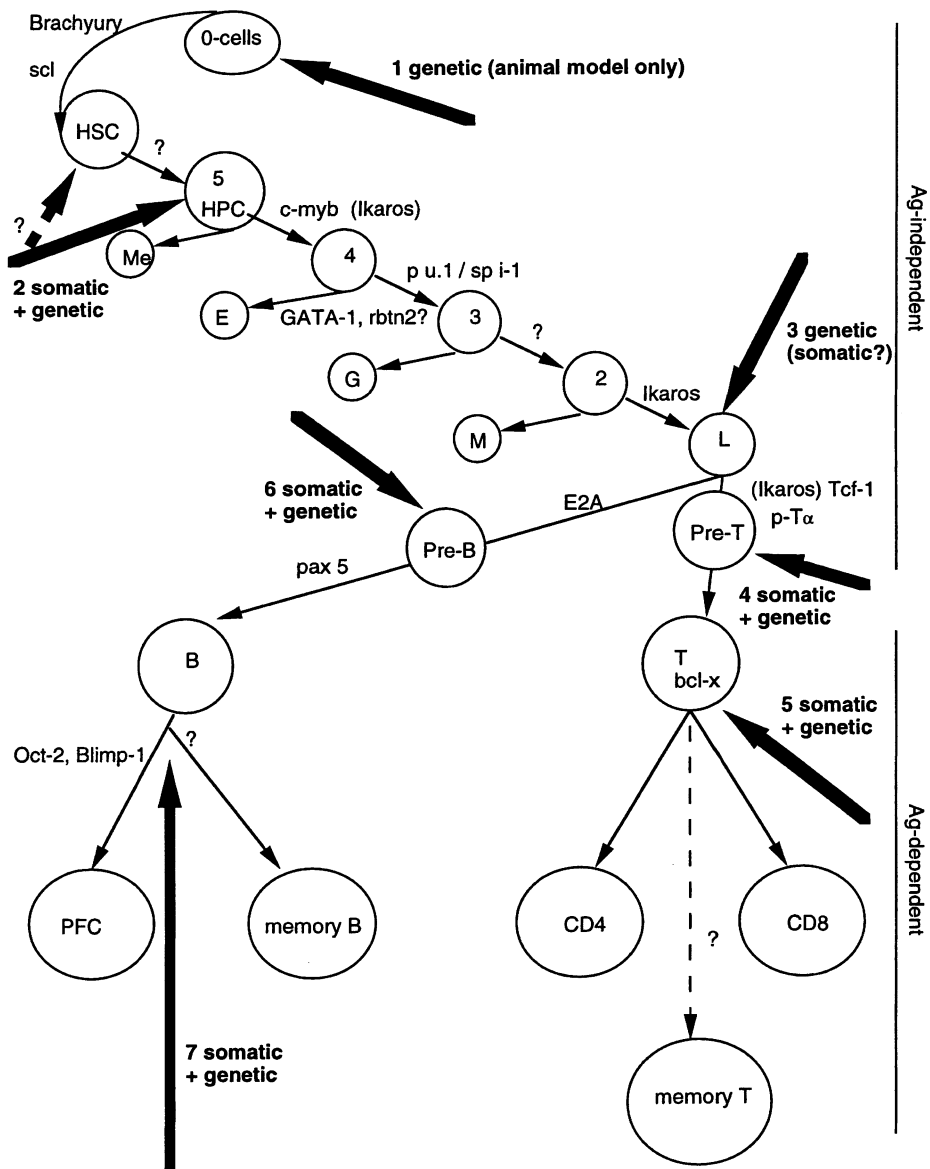

Fig. 43.1. Proposed sequence of cell commitment during lymphopoiesis and stages of hematopoiesis and lymphopoiesis at which somatic and/or genetic engineering of lymphocytes and their precursor cells might be feasible. Solid block arrows point to the cell stages that might be targeted. The first part of the theory is the sequential commitment model of hematopoiesis of Brown et al., (1985, 1988), modified to include the pattern of expression of transcription factors (H. Singh, M. Koshland, and A. Schimpl, personal communications). The cells depicted diagonally to the right represent hematopoietic stem cells (HSC) committed to multipotential precursor cells or hematopoietic progenitor cells (HPC), which gradually lose pluripotency, as expressed by the numbers 5, 4, 3, and 2, inside the stem cells. Number 5, for example, means that the HPCs at this stage have the potential to differentiate into five different types of precursor cells. The committed monopotential precursor cells can then differentiate toward mature end cells such as megakaryocytes (Me), erythrocytes (E), neutrophils/granulocytes (G), monocytes (M), and finally lymphocytes (L). HSCs are derived from very primitive stem cells (null cells, or 0 cells) such as fertilized eggs, and/or mouse embryonic stem cells (ESC). In the second part of the theory, lymphoid precursor cells differentiate into monopotential precursor B cells (B) and monopotential precursor T cells (T). After the expression of cell surface receptors, and on encountering antigen (Ag), B cells can differentiate to plaque-forming cells (PFC) or memory B cells. T cells can become CD8<sup>+</sup> or CD4<sup>+</sup> cells after education and maturation in the thymus. Memory T cells can be generated at a certain stage of differentiation. The transcription factors are expressed and are known to affect differentiation. The data come mostly from phenotypic defects in knockout mice: Brachyury (Wilson et al., 1993; Kispert and Hermann, 1993, 1994), scl (Robb et al., 1995; Shivdasani et al., 1995), c-myb (Mucenski et al., 1991), GATA-1 (Penvy et al., 1991), rbtn2 (Boehm et al., 1991), pu.1/spi-1 (Scott et al., 1994), Ikaros (Georgopoulos et al., 1994), Tcf-1 (Verbeek et al., 1995), E2A (Bain et al., 1994; Zhuang et al., 1994), pax 5 (Urbanek et al., 1994), Oct-2 (Corcoran et al., 1993; Corcoran and Karvelas, 1994; Chen et al., 1991), and Blimp-1 (Turner et al., 1994) (no knockout mice generated yet). Other examples of gene products that might be critical for engineering are pTα (Fehling et al., 1995), bcl-x (Boise et al., 1993; Ma et al., 1995), and p53 (Bogue et al., 1996; see also Chen, 1996).

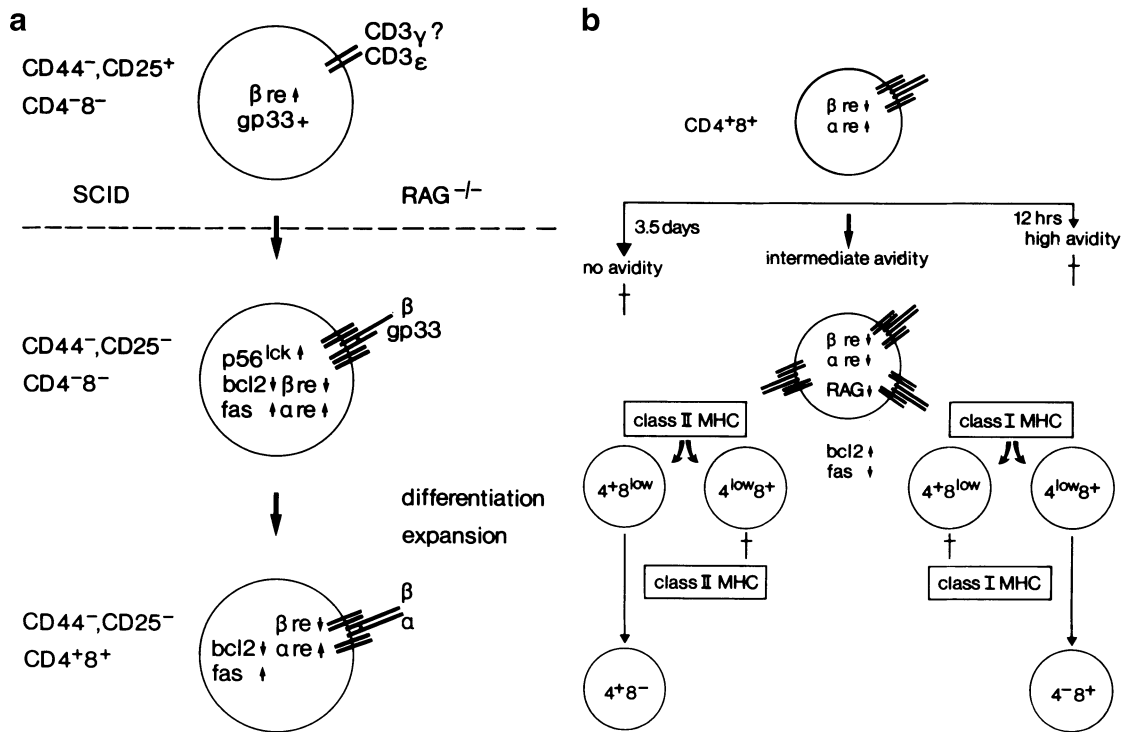

Fig. 43.2. (a) Developmental control by the pre-T cell receptor. CD4<sup>-</sup>, CD8<sup>-</sup>, CD44<sup>-</sup>, CD25<sup>-</sup>, thymocytes rearrange the TCR-B locus while expressing the gp33 gene encoding the invariant chain of the pre-T cell receptor. The pre-TCR complex associated with CD3 signal-transducing molecules is inserted in the membrane. Signaling by the pre-TCR, which may or may not involve binding to an intrathymic ligand, results in massive cellular expansion as well as differentiation. Differentiation events may include CD4<sup>+</sup>8<sup>+</sup> expression, suppression of TCR-β and enhancement of TCR-α rearrangement, down-regulation of the Bcl-2 protein, and up-regulation of the Fas protein. (b) Developmental control by the αβ T cell receptor. CD4<sup>+</sup>8<sup>+</sup> cells with αβ TCRs have a lifespan of 3 or 4 days, during which TCR-α rearrangement continues and cells produce new receptors. During this time, if the αβ TCRs do not bind to intrathymic ligands, the cell will die a programmed death (left). If the receptor binds to the specific peptide (left), cell death will be precipitated and the cell will be eliminated by apoptosis within hours (right). If the receptor binds to a positively selecting ligand different from the MHC-specific peptide, the cell will be rescued from programmed cell death and begin to down-regulate either CD4 or CD8 coreceptors (center). This may be an entirely or partly stochastic event. As a rule, only cells with "fitting" αβ TCR-CD4, CD8 coreceptor combinations, able to bind to the same class I or class II MHC molecule, will fully mature. Cells with a mismatched combination will die. Positive selection will terminate ongoing TCR-α rearrangement and induce higher expression of Bcl-2 protein while down-regulating Fas protein levels. From Kisielow and von Boehmer (1995).

entiation pattern of several myeloid cell lines. The scheme of the development of lymphoid lineages was purely hypothetical in the original model, and the development of mature lymphoid cells (in Part 2) was not included. It was proposed that precursor B cells become committed before precursor T cells. I have modified this step to the precommitment to lymphoid precursor cells. Also, I have changed the commitment of lymphoid precursor cells to occurring after the myeloid precursor cells. However, the committed lymphoid precursor cells should still be viewed as hypothetical, because there are many examples supporting the common lineage development of B cells and myeloid cells, and not precursor T cells. Committed lymphoid precursor cells have never been clearly identified and isolated.

There is ambiguity in the original model. For example, the issue of the timing of each point of decision was not addressed. The original hypothesis implied that stem cells that do not receive the appropriate signals will proceed "spontaneously" to the next stage in the differentiation sequence. Based on much published data and on observations on the abortive development of lym-

Fig. 43.3. Schematic illustration of early T cell development. Dashed lines with arrows at both ends indicate the four, developmentally successive triple negative (TN) subsets defined by the differential expression of CD25, CD44, and c-kit surface markers. Percentages give the approximate proportion of each respective subset within the TN population. The three prethymic stages of T cell development are defined only functionally, i.e., by their developmental potential. Thin arrows indicate minor pathways within the thymus that give rise to non-T lineage cells. It is not yet clear whether B, NK, and thymic dendritic cells are generated from extra-, and/or intrathymic pathways. The dark bars symbolize points of complete developmental arrest due to null mutations in specific genes mentioned on top of the respective bar. In GATA-3-deficient and c-kit  $\times$   $\gamma_c$  double-deficient mice, T cell development may actually be arrested before precursor entry into the thymus. This may also be true for some Ikaros-deficient mice, as indicated by dashed bars. The developmental block in p56<sup>lck</sup>-deficient mice is partial (stippled bar). It has not been investigated to what relative extent the pre-TCR-dependent and the two minor pathways are inhibited by the absence of p56<sup>lck</sup>. Other mutations that result in a partial block of thymopoiesis are not included in the scheme nor are mutations that cause a complete block only during fetal, but not adult, thymopoiesis.  $\gamma_c$  denotes the common cytokine receptor  $\gamma$  chain. The indicated block in thymopoiesis in pT $\alpha$   $\times$   $\gamma_c$  double-deficient mice has not yet been published (J. DiSanto, personal communication). From Rodewald and Fehling (1998).

phoid cells from blood islands derived from embryonic stem (ES) embryoid bodies (Chen *et al.*, 1997), and on the essential requirement of cytokines to maintain and to propagate stem cells derived from transgenic fetal liver, I tend not to be in favor of spontaneous progression; appropriate inductive signals for the transcriptional activation of lineage-committed genes are stringently required. Moreover, because programmed cell death plays an important role in the fate of cells during embryogenesis, I have included apoptosis as another important factor. This model has gained great support from the phenotypes of mice in which genes encoding transcription factors have been knocked out. Transcription factors controlling the sequential commitment of HSCs have been summarized (Chen, 1996).

### CRITERIA FOR ENGINEERING DEVELOPMENTAL STAGES OF LYMPHOPOIESIS

I will attempt to explore the feasibility of engineering lymphoid cells and their stem cells at several defined stages of differentiation. My criteria for deciding on feasibility are (1) intrinsic self-

Fig. 43.4. Thymic cellularity as a function of age in wild-type and mutant mice. Total thymic cellularity is shown during both fetal and adult life. Cell numbers are given only as approximations based on data from the following mutant mice: *Ikaros*  $N^{-/-}$  mice lack N-terminal sequences of *Ikaros*. This mutation appears to act in a dominant negative fashion (Georgopoulos et al., 1994). *Ikaros*  $C^{-/-}$  mice, considered as *Ikaros* null mutants, carry a deletion of the C terminus of *Ikaros* (J.-H. Wang et al., 1996). For mutations with an early embryonic lethal phenotype, chimeric mice were generated by RAG complementation. In such chimeric mice, the effects of lack of GATA-3 (Ting et al., 1996) or  $\alpha 4$  integrin (Arroyo et al., 1996) on T cell development were determined. Mice lacking *c-kit* and  $\gamma_c$  (Rodewald et al., 1997) live until  $\sim 10$  days after birth, precluding analysis of adult thymocyte development. Disruption of *TCF-1* in mice (Verbeek et al., 1995) causes a block at the earliest stages in thymopoiesis in late adult, but not fetal or early postnatal, life. From Rodewald and Fehling (1998).

renewal of HSCs, HPCs, and more differentiated cells, (2) the availability of cell surface markers for identification and purification, (3) the supply of recombinant growth factors and appropriate stroma cells, (4) the existence of favorable cell culture conditions that promote growth instead of differentiation, (5) the possibility of educating lymphocytes to become antigen-specific memory cells, and (6) the possibility of introducing, either genetically or somatically, genes of interest along with inducible promoter and regulatory sequences. Technical advances make the engineering of HSCs, HPCs, and lymphoid cells attractive for further manipulation, such as introducing new genes or reprogramming cells.

### STAGES OF LYMPHOPOIESIS FOR ENGINEERING

Figure 43.1 shows a schematic diagram of the stages at which lymphoid cells and lymphoid precursor cells might be engineered. The stages will be discussed individually.

#### Stage 1: 0 cells

Null (0) cells are fertilized eggs or embryonic stem cell lines. Mouse ES cell lines of different strain origin have been available for a long time. Establishment of human ES-like cell lines has been reported in the United States, using expired-date frozen, fertilized eggs. Several lineage-committed cells, such as from bone and cartilage, have been shown to be obtainable through differentiation *in vitro*. However, strictly speaking, the only way to prove that an ES cell line is truly totipotent is to demonstrate germ-line transmission in human beings—a task that should not even be considered. Similarly, I think that both genetic and cellular engineering at this level should be limited to mouse studies. ES cells are stem cell lines that divide symmetrically. Unlike the lineage-committed stem cells, which are rare, ES cells are almost an exception, being readily available. They can proliferate without differentiation if feeder cells and/or cytokines are provided. They can be induced to differentiate by removing the feeder cells and cytokines. Only a few surface molecules are available for characterizing ES cells. Antibodies against stage-specific embryonic antigen-1 (SSEA-1) enable one to distinguish undifferentiated from differentiated ES cells. In recent years, many genes encoding lymphoid-specific functions have been knocked out, and more studies are in progress to develop specific deletions or replacement of genes by various techniques using homologous recombination (Figs. 43.1, 43.3, and 43.4). Vectors with inducible promoters are being

used to introduce genes in a controllable, tissue-specific manner. This may be another powerful tool to study the commitment of cells from one lineage to another.

### Growth requirement for differentiation of ES cells to lymphoid cells

Under appropriate conditions, ES cells can differentiate *in vitro*. Many different culture systems are available for studying the development of lineage commitment. Because ES cells are totipotent, optimal culture conditions would enable the formation of mature cells and tissues and even organs in well-organized three-dimensional structures *in vitro*. That is, one should be able to generate an artificial fetus in culture without any external cells or other factors. In fact, of course, organogenesis from ES cell culture is but a dream. Nevertheless, with the culture conditions and system that we have developed, mature and embryonic cells in some form of tissuelike organization, though never organs, of certain orderly structures (gutlike, epidermal-like, and thymuslike structures), can be observed. In recent years, many researchers have attempted but failed to study the differentiation of lymphopoietic precursor cells obtained from ES cells. Many observe the development of yolk sac blood islands in culture; these presumably contain HSCs, but only myeloid cells could be produced in the culture systems reported. Only a few systems allow the generation of lymphoid precursor cells, mostly B cells, but also T and B cells, in a quantity sufficient for further manipulation (Chen *et al.*, 1997; Potocnik *et al.*, 1994, 1997a,b).

Reasons for these variations are unclear. It is partially due to the origin and totipotentiality, hence the fragility and variability, of ES cells, but partially due to experimental manipulations. Even in the hands of a single researcher, the potential of lymphopoiesis from the same ES cell lines varies greatly among different experiments, and why this is so remains a mystery. The culture conditions vary, depending on which lineages are chosen for study. For example, methylcellulose culture is preferred for myeloid lineages but is inferior for lymphoid lineages. Several culture conditions that favor the differentiation of ES cells to lymphoid lineages are available.

Through the work of at least five groups, it has become clear that lymphoid precursor cells can be obtained from ESCs in culture. However, the development of mature B plasma cells and mature T cells requires a two-step procedure—a two-step culture procedure for plasma cells, and culture and animal implantation for mature B and T cells. When chimeric bone marrow cells from embryoid body-implanted mice, which contain cells of ESC origin, were injected into the host mice, the bone marrow cells were shown to repopulate the primary and secondary lymphoid organs, i.e., bone marrow, spleen, and lymph nodes. The data indicate that HSCs and HPCs of ESC origin can be transferred. However, further transfer experiments similar to those performed by Harrison *et al.* (1988, 1993) were not done.

Our culture system can also be used to study thymic stroma as well as well-organized, highly differentiated cells of many other lineages, including gut epithelia, skin with hair follicles, bone, muscle, neurons, and glia. The development of endogenic thymic epithelial cells as well as stroma cells inside the ES-embryonic bodies also explains partially the findings of an efficient development of T cells in the absence of exogenous stroma cells. Stroma cell line RP.0.10 is able to support both T and B lymphoid precursor cells derived from ESCs in some labs, but this is not reproducible elsewhere. Stroma cell lines OP9 and S17 support B precursor cells and myeloid but not T precursor cells derived from ESCs. Many other stroma cell lines do not support the differentiation of ESCs to lymphoid precursor cells. Müller-Sieburg and co-workers have systematically compared the S17 stroma cell line, which is widely used in many labs, to many stroma cell lines for the production of cytokines and stroma function, i.e., the stem cell support function (Wine-man *et al.*, 1993, 1996) (see also below, Stage 2); there were no correlations in the assays. They postulated that a yet to-be-identified extracellular matrix molecule of S17 cell lineage may play a role in supporting the function of HPCs.

Bauer *et al.* (1998) reported that a novel protein molecule, dlk, an epidermal growth factor-like molecule of 66 kDa, in stroma cell lines influences the requirement for interleukin-7 (IL-7) in supporting mouse pre-B lymphopoiesis. They suggest that dlk may play an important role in the bone marrow HPC microenvironment. Cortex *et al.* (1999) reported the novel high-molecular-weight CD166 (HCA/ALCAM) glycoprotein expressed in human HPCs as well as stroma cells. The data suggest that this molecule is being involved in adhesive interaction between HPCs and stroma cells in the most primary blood-forming organs. Rethinking the seemingly conflicting results and the inconsistent report of differentiation of ES cells to lymphocytes, I wonder if cul-

turing ES-derived lymphoid progenitor cells on stroma cell lines derived from the most primitive stroma environment from the fetus (such as paraaortic cells) may be a better choice to obtain consistent results, rather than using the existing stroma cell lines?

## Stage 2: HSCs and HPCs

The terms “hematopoietic” stem cells, “progenitor” cells, and “precursor” cells are loosely used in the literature. Here, I define hematopoietic stem cells and hematopoietic progenitor cells as two populations of stem cells sharing similar surface markers. HSCs are rather quiescent, noncycling stem cells, whereas HPCs are cycling cells. In mice,  $c\text{-kit}^+$ ,  $\text{thy-1}^{\text{low}}$ ,  $\text{lin}^-$ ,  $\text{sca1}^+$  bone marrow cells are accepted as HSCs or HPCs. Many groups have shown that HSCs and HPCs in bone marrow are heterogeneous in size and in self-renewal capacity. Moreover, they have finite life-spans. In human bone marrow,  $\text{CD34}^+$ ,  $\text{HLA}^-$ ,  $\text{lin}^-$ ,  $\text{thy-1}^{\text{low}}$ ,  $\text{rhodamine 123}^{\text{low}}$  stem cells are generally defined as HSCs and HPCs. However, CD34 is also expressed in other lineages, such as vascular endothelial cells. It is well established that mouse HSCs and HPCs can be isolated, cultured, transduced by retroviruses, and used to repopulate animal hosts. In addition to bone marrow, they can be isolated from fetal liver, cord blood, fetal blood, yolk sac, and paraaortic splanchnopleura.

### *Do HSCs and HPCs self-renew?*

The self-renewal of HSCs and HPCs was carefully examined by Harrison and co-workers (1988, 1993). By transferring bone marrow stem cells from one host to the other, they found that the pool of donor bone marrow stem cells was smaller on transfer, and concluded that self-renewal is limited for somatic bone marrow stem cells. However, their results could be due to a dilution effect of the donor stem cells, if a certain absolute number of stem cells were required for the successful implantation of donor stem cells in the bone marrow. Using fluorescence *in situ* hybridization (FISH) and telomerase assays (Allsopp *et al.*, 1992), it was shown that telomere DNA length predicts the age and replication capacity of human fibroblasts. Similarly, Lansdorp and co-workers (Vaziri *et al.*, 1994; Lansdorp, 1995a,b) have correlated telomere length with the replication potential of HSCs and HPCs. In human  $\text{CD34}^+$ ,  $\text{CD71}^{\text{low}}$ ,  $\text{CD45RA}^{\text{low}}$  bone marrow stem cells, the length of telomeric DNA in HSCs and HPCs is correlated with the age of the donor. The stem cells in adults have shorter telomerases than are found in fetal cells, but both have the same telomerase activity. When the HPCs were expanded with cytokines without the support of stroma cells, there was a loss of telomeric DNA in culture. The loss of telomeric DNA in HSCs and HPCs from older people and cultured stem cells was interpreted to mean that their replication potential is finite. An alternative interpretation would be that the culture conditions that allow stem cells to grow in the presence of cytokines may not favor the maintenance of telomerase activity and hence not the self-renewal of HSCs and HPCs.

Many culture systems for studying the biology of mouse HSCs and HPCs are available. Many mouse stroma cell lines support the growth of HPCs. Studies on human stem cells use mouse stroma cell lines such as S17 (Collins and Dorshkind, 1987) and others (Wineman *et al.*, 1993), or mixed primary stroma populations isolated from human bone marrow or other sources (Dittel and LeBien, 1995), to support purified HSCs and HPCs or unseparated bone marrow cells. There was a report of the establishment of heterogeneous human stromal cell lines with the help of a plasmid containing SV40 T antigen under the control of an inducible metallothionein promoter (Cicutini *et al.*, 1992), but their ability to support lymphopoiesis could not be demonstrated. Simmons *et al.* (1992) have obtained mixed human stroma cells and cell lines that support human long-term culture initiating cells. However, these human stroma cell lines could not be shown to support the development of human lymphocytes from bone marrow stem cells.

Major problems in this field are the variability of culture conditions, the efficiency of differentiation of the cultured cells to lymphoid lineages, and the poor reproducibility in the hands of different investigators. Also contributing to problems is failure to report specific reagents and ingredients used as well as undescribed procedures, stroma cell conditions, batches of serum, and growth factors required in each system. Of course, the intrinsic multipotentiality of HSCs and HPCs also contributes significantly to the elements of variability. Many have claimed that a cocktail of cytokines alone could promote the differentiation of myeloid lineages from HSCs and HPCs in mouse (Timothy *et al.*, 1995) and human (Henschler *et al.*, 1994) systems. A few have claimed the development of B cells at various stages of maturation, but no mature T cells could be found

in such culture conditions. The maintenance of long-term cultures of self-renewing stem cells with potency for lymphopoiesis, especially T lymphopoiesis, requires stroma cells, additional cytokines, and other culture conditions yet to be defined. Several existing culture systems seem to be promising for expansion *ex vivo* and potential differentiation of human (Koller *et al.*, 1993; Dittel and LeBien, 1995) and mouse HSCs. Because large quantities of cultured cells are needed for manipulation and reimplantation, the development of bioreactors and the development of reliable human stromal cell lines for lymphopoiesis are of high priority.

### *Selected examples of clinical applications of human HSCs and HPCs*

Using human HSCs and HPCs as the cell base for gene therapy is a complicated issue. In most clinical protocols, HPCs are transduced *ex vivo* with retroviral vectors and reimplanted into patients. One example currently undergoing phase I clinical trial is the treatment of adenosine deaminase (ADA) deficiency. ADA deficiency exists in all cells examined. However, T cells of these patients are selectively missing, causing a severe combined immunodeficiency symptom. Despite more than three decades of study, the mechanism by which the ADA defect causes specific deficiency of T cells remains unknown. Four possible mechanisms have been postulated and reviewed by Resta and Thompson (1997). The apoptotic pathway of CD95 (Fas/apo-1)-induced cell death might be the most likely mechanism. Patients suffering from ADA deficiency have been treated using ADA gene transfer therapy (Bordignon, 1993; Blaese *et al.*, 1993). Stem cells were expanded *in vitro* and transduced with retroviral vectors containing ADA genes. Several ADA-deficient children were subsequently followed up using the polymerase chain reaction (PCR) assay to assess the expression of circulating T cells bearing the transduced ADA gene. Peripheral blood carrying the transduced ADA gene was shown to persist for 7 months before disappearing. Bone marrow cells appeared later and became the major source of T cells expressing the transduced ADA gene in the peripheral blood.

Although initial reports of these studies claimed to be successful, careful evaluation of ADA gene therapy protocols shows that there is a major problem with the protocols. During *ex vivo* expansion and manipulation for gene transfer, HPCs lose their capacity to proliferate in favor of differentiation and maturation. Thus there is a great need for repeated treatments of the same patient with retrovirus transduction, and continuous infusion of poly(ethylene glycol)-conjugated ADA enzyme. There is another trial using autologous cord blood CD34<sup>+</sup> cells in ADA-deficient babies, and the combined gene and enzyme therapies seem to generate better immune function (Kohn *et al.*, 1998). The different results are due to the fact that very few mature, functional T cells make enough enzyme to detoxify the serum in ADA patients. If stem cells are rare, small differences in technique and uncontrolled variables could make the difference between success and failure. Another, not mutually exclusive, interpretation of the lack of long-term reconstituting stem cells is that the cycling HPCs transduced are not the true stem cells. Human immunodeficiency virus (HIV)-based lentiviral vector has been shown to efficiently transfer foreign genes into post-mitotic and noncycling cells, including HSCs. Nevertheless, this vector is still under development, and no package cell line is yet available for lentiviral vectors. Improved culture conditions for growth and maintenance of human stem cells in large quantities are urgently required. The establishment and use of reliable human stroma cell lines that could support the growth of lymphopoietic HPCs *in vitro* might prove to be a breakthrough in this field.

### **Stage 3: Lymphoid precursor cells**

Until recently, no published work described the characterization of lymphoid lineage-committed precursor cells defined in terms of cell surface markers and functional assays of precursors and progenies. One cell type that is described closest to the definition of lymphoid precursor cells is the CD4<sup>low</sup> precursor population isolated from adult thymus by Shortman and co-workers (Shortman and Wu, 1996). Because this population of cells is restricted in its potential to differentiate into myeloid cells, it is preferentially committed to differentiate into T and B cells. Amazingly, these cells can also differentiate into thymic dendritic cells. The molecular markers of this population have not been well characterized. It would be interesting to see whether this population of cells can differentiate into myogenic cells, because J. Morgan and T. Partridge (personal communication) did obtain differentiated myogenic cells from adult thymus. Thymus contains lymphoid and presumably mesenchymal precursor cells that can develop into other lineages, such as bone, cartilage, and lung (Pereira *et al.*, 1995).

Nothing is known about the culture conditions for growing this population of cells. It is possible that stroma cell lines such as S17 could be used to expand the CD4<sup>lo2</sup> population of cells in culture, because Godin *et al.* (1995) was able to use S17 and cytokines to maintain paraaortic spanchnopleura-derived precursor cells possessing the T cell lineage potency in culture for some time. Originally, Ikaros, a lymphoid lineage-specific transcriptional factor (Georgopoulos *et al.*, 1994), was thought to be an important molecular marker of lymphoid precursor cells at this specific stage of development. Ikaros was subsequently shown to have multiple effects on HSCs, lymphoid cells, T precursor cells, and others (Nichogiannopoulou *et al.*, 1998) (see Fig. 43.4).

The human counterpart of the CD4<sup>low</sup> population is unknown. Dittel and LeBien (1995) reported the expansion of CD34<sup>+</sup>, CD31<sup>+</sup> human bone marrow B progenitor cells and partial differentiation to B precursors in serum-free culture medium in the presence of mixed primary human stroma cells and IL-7 for a duration of 16 days. A few CD34<sup>+</sup> precursor cells maintained under their culture condition could differentiate into natural killer (NK) cells and T precursors when subjected to a secondary culture conditions, presumably providing the precursor population with the thymic environment. It is not clear whether T precursor cells are derived from HPCs or are the precommitted precursor cells migrating to bone marrow.

#### Stage 4: Precursor T cells

Precursor T cells are thy-1<sup>+</sup>, CD117<sup>low</sup>, DC3<sup>-</sup>, pT $\alpha$ <sup>+</sup> (Fehling *et al.*, 1995; Kisielow and von Boehmer, 1995; Fehling and von Boehmer, 1997). They can be derived from fetal and adult blood. Using new markers such as the SCA-2 and CD44 variants, they can be classified into subpopulations (Rodewald and Fehling, 1998) (see Figs. 43.3 and 43.4). Both somatic and genetic manipulations seem to be possible. However, this population of cells is not self-renewing. Large-scale expansion of this population is questionable, because apoptosis occurs easily, and only some cells of this compartment differentiate into double-positive mature T cells. Fetal thymus organ culture systems and suspension cultures with dissociated thymic epithelial cells for studying the differentiation and education of T cells are available (Jenkinson *et al.*, 1982; Jenkinson and Anderson, 1994). However, how to expand precursor T cells *ex vivo* without differentiation and apoptosis will be a challenge to the workers in this field. Changing the O<sub>2</sub> concentration in the fetal organ culture system was shown to help the survival of T cells and precursor T cells (Mackinnon and Ceredig, 1986; McLaughlin *et al.*, 1996). Perhaps O<sub>2</sub> and other radicals stimulate intracellular molecules that lead to the apoptotic pathway. Reducing the O<sub>2</sub> concentration with N<sub>2</sub> or a high density of stroma cells favors the survival of (precursor) T cells. Although Godin *et al.* (1995) can transiently expand paraaortic spanchnopleural precursor T cells in their culture conditions, that population of precursor T cells perished after a few generations in culture. Whether the additional cytokines and reducing the O<sub>2</sub> concentration could help to keep these cells proliferating longer remain to be tested.

#### Stage 5: Memory T cells

Using cultures of mature T cells in the presence of antigen-presenting cells and recombinant cytokines, one can study the growth and differentiation of T cells from a variety of sources. Long-term mouse and human T cell clones are also available. For unknown reasons, T cells can be maintained as clones in culture far longer than B cells. However, long-term human T cell clones, even from healthy donors, have not been reimplanted into patients. Human T cells (mainly natural killer cells) grown in the presence of cytokines in a short-term culture have been reimplanted into autologous cancer patients. No study was reported to evaluate their long-term repopulating potentiality in the human severe combined immunodeficient (SCID) model or the self-renewal property of long-term mouse T cell clones *in vivo*. Most CD8<sup>+</sup> and CD4<sup>+</sup> T cells have a short life-span. Memory T cells have been well studied, but, in reality, they do not exist in abundance and can be demonstrated *in vivo* only by repeated priming with antigen. They are very difficult to define at cellular and molecular levels. There is no isotype 3'-end downstream of the TCR constant region for class switching to occur. Somatic hypermutation of the TCR- $\beta$  gene has never been claimed, and it is controversial whether the TCR- $\alpha$  gene is hypermutable. Memory T cells are thus defined using criteria such as accelerated cellular responses, distinct pathways of lymphocyte recirculation *in vivo*, distinct DNA motifs of TCR genes, cytokine-producing pattern and diminishing expression of surface markers (Bradley *et al.*, 1993; Dutton *et al.*, 1998), and functional and antigen requirements (Gray and Matzinger, 1991). In mice, memory CD4<sup>+</sup> T cells are CD45RO, L-selectin

(MEL-14)<sup>lo2</sup>. There is the equivalent of human CD45Ro, keeping in mind that the CD45R family (A, B, C, and O) may not be the best marker to define naive versus memory T cells. Because foreign antigens do not always quickly elicit unprimed T cells, memory T cells must exist, but the commitment, the mechanism of development, and the maintenance of these cells are unknown. Memory T cells are thought to be generated either when T cells acquire specificity to kill or to help during thymic education, or are generated during the mature stage.

### **Memory DC8<sup>+</sup> T cells**

Because cell-bound antigen on antigen-processing cells and more than one signal are required for educating T cells to perform effector functions instead of becoming tolerized, work on the generation of CD8<sup>+</sup> memory T cells has been mainly *in vivo*, using viruses. Although the short-term expansion of memory T cells can be demonstrated in culture, it is not clear how long these cells can be maintained in culture. Interesting questions remain to be addressed: Is it possible to prevent cytotoxic T cells from performing their function by releasing granzymes, and, if so, what happens to committed CD8<sup>+</sup> T cells? Do they die, or become anergic, or become memory cells? A study addressing the avoidance of granzyme B-induced apoptosis in target cells is interesting in this regard (Greenberg and Litchfield, 1995; Wang *et al.*, 1996). Dephosphorylation of cdc2 was shown to be a critical step in granzyme B-induced apoptosis in the targets of cytotoxic T cells. A nuclear kinase encoded by the *wee1* gene was transiently expressed and shown to induce phosphorylation of the tyrosine residues of cdc2 kinase, and that in turn provoked mitosis and the rescue of target cells. Because cytotoxic T cells are subject to being killed by their colleagues, the apoptosis pathway in these cytotoxic T cells could be similar to that of the target cells. It remains to be demonstrated whether expression of *wee1* or equivalents could be induced to rescue cytotoxic T cells to become memory T cells.

### **Memory CD4<sup>+</sup> T cells**

Like memory CD8<sup>+</sup> T cells, the generation of memory CD4<sup>+</sup> T cells is studied *in vivo*. This population of cells has been well characterized in mice. By using the soluble protein antigen keyhole limpet hemocyanin (KLH), Bradley *et al.* (1993) found effector memory CD4<sup>+</sup> cells in mouse spleen to be CD45RO, L-selectin<sup>-</sup>, CD44<sup>+</sup> and to produce elevated levels of IL-4. McHeyzer-Williams and Davis (1995) used a different soluble antigen-priming system to study memory CD4<sup>+</sup> T cells. Whether this population of cells can be expanded *ex vivo* has not been reported. Because T cells of IL-2 knockout mice survive much longer than those of conventional mice, they may be useful for studying the development of memory T cells. Moreover, molecules such as Fas and Fas ligands of the apoptotic pathways play critical roles in determining the fate of cells after activation. The Bcl-2/bcl-x family seems to function by helping the survival of cells via action on the intermediate steps of apoptosis (Nagata and Golstein, 1995; Krammer *et al.*, 1994; Korsmeyer, 1995). Genes controlling the cell death pathway may play critical roles in the development of, and the subsequent genetic manipulation of, memory T cells in the future. It is important to improve the conditions for growing CD8<sup>+</sup> T cells *in vitro*, because for tumor therapy, the generation of tumor-specific CD8<sup>+</sup> T cells is a very critical step.

Although surface markers and life-span of a population of T cells equivalent to those of the mouse system have been documented (Michie *et al.*, 1992), ethical and safety considerations have prevented a systematic study of human memory T cells *in vivo*. Thompson *et al.* (Boise *et al.*, 1995; Noel *et al.*, 1996; Levine *et al.*, 1997) have reported the possibility of producing human CD4<sup>+</sup> T cells on a large scale. By stimulating peripheral, resting T cells with cytokines such as IL-2, anti-CD28, and solid-phase anti-CD3, they reported that survival and proliferation of CD4<sup>+</sup>, but not CD8<sup>+</sup>, T cells could be greatly promoted. What remains to be shown are the specificity and function of these cells and how they are related to the regulation of the Bcl-2/bcl-x family (Boise *et al.*, 1993; Ma *et al.*, 1995) and CD95 (Fas/apo-1) ligand, and whether they are candidate memory CD4<sup>+</sup> T cells or abortive T cells.

## **Stage 6: Precursor B cells**

Mouse and human precursor B cells have been characterized extensively by several groups. Surface markers and molecular events of precursor B cells at intermediate stages of development have been defined (Table 43.1).

**Table 43.1. Expression of cellular and molecular markers during stages of B cell development**

<sup>a</sup>Key references: Dittel and LeBien (1995); Erlich *et al.* (1994); Lassoued *et al.* (1993); Li *et al.* (1993) Loeffert *et al.* (1994); Rolink *et al.* (1994); Melchers *et al.* (1995); Ghia *et al.* (1998).

### Mouse pre-B cell lines

In the mouse system, with the help of several stroma cell lines and recombinant growth factors such as IL-7 (Rolink *et al.*, 1991; see Melchers *et al.*, 1995), it becomes feasible to expand mouse pre-B cells without gross differentiation. On release from the stroma cells and IL-7, and in the presence of the bacterial mitogen lipopolysaccharide (LPS), some pre-B cell lines differentiate into plasma cells. Pre-B cell clones have been established from various lymphoid organs of wild-type mice, transgenic mice, and some knockout mice. Thus, both somatic and genetic manipulation of these cell lines becomes possible. Some pre-B cell lines have been used to repopulate SCID mice and RAG-2 knockout mice. Injected cells migrate to bone marrow, lymph nodes, peritoneal cavity, and spleen. Plasma cells, mature B cells, and pre-B cells were detected in the host. The percentage of cells mature into various B compartments seems to vary from experiment to experiment.

However, several questions remain to be answered. Do these pre-B cell lines retain the capacity to expand? Are these cells self-renewing *in vivo*, as stem cells must be? The critical experiment of repeatedly transferring donor pre-B cells, from one host to another, to show that the implanted cells are still precursor B cells, has not yet been done. It is interesting that pre-B cells established from pax 5<sup>-/-</sup> mice (Urbanek *et al.*, 1994) differentiated into T cells, myeloid cells, dendritic cells, and osteoclasts, but not mature B cells, in SCID mice. The data indicate that the microenvironment which plays a role in keeping pre-B cells committed to B cell lineage, may be missing in the pax 5<sup>-/-</sup> mice (A. Rolink, personal communication).

### *Curiosities of growing human precursor B cells*

The question of whether human precursor B cells can expand *ex vivo* is still open. Several reports claim it possible by using either primary mixed human stroma cells (Dittel and LeBien, 1995) or mouse stroma cells (Rawlings *et al.*, 1995). When subjected to mixed stroma cells and cytokines such as IL-7, most human bone marrow cells expand for a limited period, then either perish or differentiate (see Ghia *et al.*, 1998). In other words, the culture conditions established so far are only for short-term expansion of pre-B cells. However, no normal human pre-B cell lines have been established. This distinguishes mouse and human precursor B cells. The study of human pre-B cells cannot be separated completely from the study of human HSCs and HPCs, given the complexity of the cell types involved and the difficulty in establishing human stroma cell lines. The establishment of human stroma cell lines supporting the growth of human pre-B cells is critical. The failure lies in the inability of adherent cells derived from human bone marrow (stroma cells) to proliferate well under normal culture conditions with conventional sera. Methods for immortalizing human cells include transfecting plasmids or retroviruses containing oncogenes such as SV40 T antigen. Cell proliferation is a prerequisite for the stable integration of transgenes into chromosomes and for immortalization. A breakthrough for human HSCs and pre-B cells would be to establish stroma cell lines for B lymphopoiesis, and to optimize the conditions for the growth of stroma cells, as has been done for human mesenchymal stem cells (Yoo *et al.*, 1998).

### **Stage 7: Memory B cells**

B cells with surface Ig isotypes such as IgG, IgA, and IgE, which possess higher affinities for Ag, are generally defined to be memory B cells. In human beings, CD38<sup>+</sup>, CD20<sup>+</sup> germinal center B cells can be distinguished from memory CD38<sup>-</sup>, CD20<sup>+</sup> B cells and CD38<sup>+</sup>, CD20<sup>-</sup> plasma cells. In mice, there are no reliable surface markers to distinguish memory B cells from plasma cells and mature primary B cells. The mechanisms of memory B cell generation are unknown, and the subject of debate for decades. Memory B cells are mature B cells that have encountered antigen, have been activated but not tolerized, and have switched to higher affinity isotypes. IgM-secreting plasma cells are terminal cells, destined to die. It is unknown how memory B cells develop *in vivo*. *In vitro*, at least two systems may generate memory B cells: the germinal center-like culture system and the suspension culture system, wherein resting B cells are activated by LPS plus anti- $\mu$ . These B cells are activated, alive, proliferating, and nonabortive, but they are not plasma cells.

### *A system stimulating germinal centers in vitro to culture B cells*

In a culture environment that mimics the germinal center in lymphoid organs, B cells survive better and live longer. A germinal centerlike environment is a culture system that provides cytokines and supporting cells from either purified follicular dendritic cells (FDCs) from mouse spleen (Kosco *et al.*, 1992), or stroma cells (L cells transfected with CD40 ligand, or fibroblasts) (Flueckiger *et al.*, 1993; Arpin *et al.*, 1995; Wohlleben *et al.*, 1996). Both human and mouse B cells survive for 2 weeks instead of 3–4 days, and absolute cell numbers increase two- to threefold.

The *in vitro* germinal center culture system developed by Kosco and co-workers was designed to study the differentiation of mouse B cells into plasma cells rather than to maintain long-term B cells *in vitro*. Mouse FDCs are nonproliferating, terminally differentiated cells of unknown origin. However, other studies reported that the primary mouse FDCs can be partially replaced by fibroblast cell lines expressing CD40 ligand. The cytokines required to maintain mature B cells in growth phase and differentiation are controversial. For mouse B cells, combined IL-2, IL-4, and IL-5 induce differentiation into mature cells, and for further differentiation into plasma cells, IL-

6 seems to be essential. For human B cells, IL-2 plus IL-10 and combined IL-3, IL-6, and IL-7 have been reported to work. Also, if the CD40 ligand is removed in the secondary culture, human B cells differentiate into plasma cells. These memory-like cells are neither cell lines nor cell clones, rather they are a mixed B cell type with limited life-span (up to a few weeks), and they preferentially switch to certain Ig isotypes, such as IgG and IgA. The data suggest that down-regulation of the J chain may not be essential during the development of memory B cells.

### *A suspension culture system for stimulating B cells with LPS plus anti- $\mu$*

Systems for the short-term culture of primary splenic lymphocytes have long existed (Mishell and Dutton, 1966, 1967; Marbrook, 1967). These systems are invaluable for studying the proliferation and differentiation of B cells, T and B cell interaction, the priming of B cells by antigen, and the mechanism of memory B cell generation.

If B cells could be kept alive and untolerized, but could be prevented from becoming IgM secretory plasma cells, they might become memory B cells. An example is the finding that when stimulated with a bacterial mitogen, lipopolysaccharide, some B cells die and some proliferate and become plasma cells (Andersson *et al.*, 1974). When stimulated with anti- $\mu$ , most B cells die right away, some proliferate and exhibit growth arrest at G<sub>1</sub> phase, then die 2 days later, and none become plasma cells. When stimulated with LPS plus anti- $\mu$ , most B cells proliferate and none become plasma cells. This nonplasma cell phenomenon has been known as an antidifferentiation effect, and it was postulated to be a way to generate memory B cells (Chen-Bettecken *et al.*, 1985). Through efforts of many, the molecular mechanism of this antidifferentiation phenomenon became clear (Chen-Bettecken *et al.*, 1985; Chen, 1988; Leandersson and Hsu, 1985; Phillips *et al.*, 1996). In the presence of the two stimuli, B cells proliferate maximally, over 90% being in the cell cycle (Seyschab *et al.*, 1989), but IgM secretion is turned off. The block has been shown to be primarily at the level of nuclear RNA processing of the  $\mu$ m-to- $\mu$ s switch. Inducible nuclear factors binding to the pre-mRNA secretory polyA site have been reported, though the nature of these factors remains unclear because they have not been cloned.

### *Transcription factors active in the development of plasma cells*

On activation of B cells, many transcription factors become engaged in the production and secretion of Ig genes. B cell-specific transcription factors include Oct-2 (Chen *et al.*, 1991; Corcoran *et al.*, 1993, 1994) and Blimp-1 (Turner *et al.*, 1994; Schliephake and Schimpl, 1996; Lin *et al.*, 1997; Messika *et al.*, 1998). Both transcription factors play a role in the decision to switch from  $\mu$ m to  $\mu$ s. Blimp-1 is described as a cofactor of transcription factor pu.1 and was shown to bind to multiple Ig-enhancer motifs and the J chain regulatory element. It is crucial for the transcription of  $\mu$ ,  $\kappa$ , and J chains. Blimp-1 is active in many cell lines and drives the maturation of B cells into Ig-secreting cells in many cell lines. Blimp-1 has been shown to down-regulate *c-myc* in B cell lines.

Transcription factor Oct-2 binds to the  $\mu$  intron enhancer motif and is essential in transcriptional activation of the  $\mu$  chain. It was shown that Oct-2 and the J chain are highly expressed in LPS-stimulated B cells and are diminished in LPS + anti- $\mu$ -stimulated B cells. It has been shown that Blimp-1 is highly expressed in LPS-stimulated B cells and is diminished in LPS + anti- $\mu$ -stimulated B cells. On the other hand, sterile  $\gamma$  chain is highly expressed in the latter system. Transfection of *Blimp-1* into LPS + anti- $\mu$ -activated B cells provoked them to become IgM-secreting plasma cells. The data indicated that transcription factors such as Oct-2 and Blimp-1 are tightly regulated in plasma cell development. If one postulates that LPS + anti- $\mu$ -stimulated B cells represent some stage in memory B cell development, the down-regulation of Oct-2 and Blimp-1 reflects the specific transcriptional regulation when B cells make the commitment to the memory cell pathway instead of the plasma cell pathway. The identification of such candidate transcription factors that control memory B cell commitment would provide a powerful genetic tool to further manipulate the turning on and off of these lineages at will *in vivo*.

## CONCLUDING REMARKS AND PROSPECTS FOR LYMPHOCYTE ENGINEERING

I discussed and summarized the current understanding of the expansion of lymphoid cells and their precursors *ex vivo* at certain stages of lymphopoiesis. I have tried to address the feasibility of

expanding lymphoid cells under controlled growth conditions; that is, we need to expand untransformed, nonmalignant cells. In general, in order to maintain the status of cell survival and growth without apoptosis and differentiation, cytokines and cell contact with feeder cells are required. Fundamental questions regarding the engineering of lymphoid cells and their precursors for therapeutic purposes remain, and can be traced to our current understanding of the immune system. Do we ask too much for the survival in culture of cells that are programmed to die? From extensive studies in gene-manipulated mice, it is possible to generate antigen-specific memory T cells; it is still puzzling that there is no good systematic study of human memory cells in culture, although the surface markers are defined.

If there is massive programmed cell death during the development from HSCs to lymphoid precursors and from pre-T to T cell maturation, I wonder whether it is realistic to try to produce enough HSCs, HPCs, and precursor lymphoid cells for therapeutic purposes? In current clinical protocol, expansion of cells *ex vivo* for the purpose of reinfusion into patients is limited to as few passages as possible in order to avoid mutation and contamination *in vitro*. Bioreactors for large-scale production of cells in liquid suspension using cytokines are available. However, they are not designed for coculturing of stem cells with stroma cells. With advances in culture technology and bioreactors, and with increased supply of recombinant cytokines, it becomes possible to obtain a quantity sufficient for reimplantation from 10 ml of bone marrow cells. However, under these condition, very few cells engage in lymphopoiesis. Thus, to grow the HSCs and HPCs consistently and to favor lymphopoiesis, there is a great need for a better way to grow human stem cells using human stroma cell lines.

In view of the massive apoptosis at several stages of lymphopoiesis, I am amazed that mouse precursor B cells can grow normally, become lines and clones, and retain the potential to differentiate *in vitro* and *in vivo*. To grow cells from other stages of lymphopoiesis, it might be advantageous to use cells from the many available mutated mice (such as the  $p53^{-/-}$ ,  $Rb^{-/-}$ ,  $IL-2^{-/-}$ ,  $perforin^{-/-}$ , and BCL-2 transgenics). I am still optimistically thinking that the future of cell-based immune system therapy lies in the *ex vivo* expansion of cells. Because the techniques to establish ligand-regulatable vectors are available, the derived cell lines will become available soon and will become valuable resources for many purposes. Other areas remain to be improved, including the search for novel markers of true HSCs and precursor lymphocytes, better sources of HSCs and HPCs such as cord blood and fetal tissues, improved retroviral vectors, and large-scale culture systems for expansion of HSCs and HPCs and precursor lymphoid cells.

With advances in genetic tools and mutated mice technology, it is possible to turn on or off the transcription factors that control the differentiation of cells. Thus, immunology will continue to be a very exciting field in the next decade. One good example is the transcription factor Blimp-1, which is thought to serve as the checkpoint to control the switch from  $\mu_m$  to  $\mu_s$ , and J chain transcription, a critical juncture for plasma cell versus memory B cell development. The prediction would be that the specific turning on and off of this gene under the control of inducible promoter and regulatory sequences would allow one to switch at will from plasma cell to memory B cell and vice versa.

#### ACKNOWLEDGMENTS

The author wishes to thank Charley Steinberg, Anneliese Schimpl, and Iris Motta for fruitful discussions as well as critical reading and editing of this chapter. The author's research is supported by grants from the German DFG (No. BE793/8-1) and the European Community (EC-Biotech BIO4-CT95-0284).

# HEMATOPOIETIC STEM CELLS

Anne Kessinger and Graham Sharp

## INTRODUCTION

All of the mature functional cells of the hematopoietic and immune systems originate from a very small number of undifferentiated cells called hematopoietic stem cells (HSCs), the most primitive of which constitute about 1 in  $10^5$  of nucleated hematopoietic cells in bone marrow. HSCs also circulate in blood at a frequency of approximately 1 log less than their counterparts in the marrow. These cells, by a process of sequential clonal amplification and differentiation of their progeny, populate the hematopoietic and immune systems. Manipulation of the total mass of hematopoietic and immune (lymphoid) tissues presents special challenges because these interrelated cellular systems are arranged both as discrete masses of tissue as well as diffuse distributions throughout most other organs of the body. Migration is an essential component of their function (Sharp, 1993).

Hematopoietic precursor cells in blood can establish endothelial cells in culture. In the adult, whether HSC and endothelial precursors are separate and distinct populations or whether they are closely related, perhaps even daughter cells of the same rare primitive stem cell, is not clear. In the embryo, HSCs and vascular stem cells probably are closely related and share a common precursor (Kluppel *et al.*, 1997; Shalaby *et al.*, 1997). Whether distinct precursors to these two cell types are established and their common stem cell is lost or whether a rare common stem cell persists but is dwarfed in frequency by slightly more differentiated lineage-restricted progeny of hematopoietic versus endothelial cells in the adult is as yet unknown. A similar puzzle exists in adult bone marrow that clearly contains HSCs, mesenchymal stem cells (Vogel, 1999), and cells that appear to be able to give rise to muscle (Ferrari *et al.*, 1998). Are these stem cell populations entirely distinct or are they related? If they are related, when during development do they diverge? Is the divergence complete or do rare stem cells persist that are a common precursor? In other words, exactly how much plasticity exists in the most primitive HSC of adults? Neural stem cells can give rise to blood cells (Bjornson *et al.*, 1999). Is the converse true? Some reviews of this topic imply this might be so (Bjorklund and Svendsen, 1999), but for now these important questions remain unanswered. The answers will have profound implications for tissue engineering of the HSC, because HSC collection is not controversial and considerable experience in transplanting them exists. Might HSCs be a noncontroversial alternative source to embryonic stem cells (O'Shea, 1999; Solter and Gearhart, 1999; Vogel, 1999) for a variety of tissues?

In the embryo, hematopoietic stem cells originate in a region associated with the dorsal aorta, the lateral plate mesenchyme, and the yolk sac. These initial HSCs migrate via the embryonic circulation to the liver (which then becomes the primary hematopoietic organ of the fetus), to the spleen, and, before birth, to the developing bone marrow spaces to establish the primary hematopoietic organ of postnatal life (Lansdorp, 1995). The process of HSC migration to the bone marrow involves the expression of the chemokine receptor CXCR4 and interactions with its ligand, stromal-derived factor 1 (SDF1). CXCR4 knockout mice exhibit a defect of bone marrow hematopoiesis (Aiuti *et al.*, 1997; Ma *et al.*, 1998; Nagasawa *et al.*, 1996); SDF1 is also implicated in the successful engraftment of human HSCs in immunodeficient NOD/SCID mice (Peled

*et al.*, 1999). The possibility that a small reserve of HSCs remains in the circulation has been postulated but remains unproved. In the adult, the active red marrow retracts largely to the axial skeleton, leaving the long bones populated with yellow (fatty) marrow (Tavassoli, 1989). The progeny of HSCs differentiate, migrate to establish the lympho-hematopoietic component of other organs (thymus, spleen, lymph node, Peyer's patches), and circulate throughout the tissues of the body. They express essential properties of hematopoietic and immune cell effector functions, cytokine secretion, and provision of key enzymes required by tissues for detoxification of harmful materials. Consequently, congenital abnormalities of HSCs can lead to hematopoietic, immune, and systemic diseases. Tissue engineering by way of replacement (transplantation) or manipulation of hematopoietic stem cells offers an approach to the therapy of these diseases.

Because bone marrow and all of the lymphoid components of the body cannot be removed surgically, systemic therapies are required for manipulations of these tissues. These therapies may be either cytotoxic (radiation, chemotherapy, immunotherapy) or regulatory (recombinantly engineered cytokines), and have potential effects and toxicities for uninvolved tissues. Conversely, therapies targeted at nonhematopoietic or nonimmune tissues can damage the hematopoietic and immune systems. Such iatrogenic events can require cellular or tissue engineering to restore hematopoietic and immune function.

The diffuse nature of hematopoietic and immune tissues presents challenges, as well as opportunities. The most primitive HSCs and other bone marrow or lymphoid cells can be harvested from the body, manipulated, and reinfused. The reinfused cells home to appropriate microenvironments and resume their original *in vivo* functions or, if altered in function, begin their new activity. These properties can be exploited to introduce genes into the body to correct congenitally deficient genes, to add entirely new genes, or to alter genes expressed by the infused cells. Although genetic engineering of HSCs has succeeded in principle (Brenner and Rill, 1994), many practical issues remain to be solved before this approach will become an effective therapy. For example, the proportion of primitive HSCs in the cell cycle is a few percent at best (Goodell *et al.*, 1996). Consequently, HSCs are difficult to transduce with vectors that require a proliferating target (Agrawal *et al.*, 1996; Kohn, 1996). The use of cytokines to stimulate proliferation can promote terminal differentiation and cytokine-exposed cells may not engraft well (Kittler *et al.*, 1997). Even if transduction is successful, clonal succession of primitive HSCs can complicate the *in vivo* pattern of gene expression (Lansdorp, 1995). Systemic cytoreductive therapy may or may not be needed to "create space" for the infused manipulated cells. Quesenberry and colleagues have followed up on original observations by Brecher *et al.* (1982) that HSCs (bone marrow) infused into unmanipulated recipient mice competitively establish a significant degree of chimerism (Quesenberry *et al.*, 1994). The key to this process appears to involve daily infusion of donor cells over a few days, rather than a single infusion. If purified primitive HSCs are infused, their competitive repopulating capacity is substantial. Additionally, such cells do divide following transplantation, which might lead to integration of genetic vectors present in the cells (Bradford *et al.*, 1997).

Clearly, the field of tissue engineering using genetically altered HSCs presents many interesting and exciting challenges to overcome before achieving the status of a routine clinical procedure. In this review, an overview of hematopoiesis and its regulation together with the practical aspects of harvesting and processing of HSCs is presented as a basis for the discussion of the tissue engineering of HSCs.

## OVERVIEW OF HEMATOPOIESIS: PROPERTIES AND REGULATION OF HEMATOPOIETIC STEM CELLS RELEVANT TO TISSUE ENGINEERING

The hematopoietic stem cells compartment comprises a differentiation hierarchy in which relatively rare and uncommitted peripotent "primitive" stem cells give rise to multiple lineages of mature cells by a linear branching differentiation process (Sharp, 1993). Within each lineage, the cells are increasingly committed stochastically to the type of mature cells they produce (Ogawa, 1994). The existence of several "levels" of differentiation within this compartment potentially leads to confusion over the use of the terms "stem" cell, "progenitor" cell, "precursor" cell, etc. As a simplification, here all of these cell types are considered stem cells.

Hematopoiesis occurs in specific stromal microenvironments (Tavassoli and Takahashi, 1982), which vary in location during development and aging, and in pathologic situations. Stro-

mal cells in these microenvironments have multiple interactions with developing hematopoietic cells (Dexter, 1982; Lambertsen, 1984). These include the provision of extracellular matrix molecules (Anklesaria *et al.*, 1991; Siczkowski *et al.*, 1992; Yoder and Williams, 1995; Zipori *et al.*, 1985), soluble and membrane-bound growth and cell survival factors (Du and Williams, 1994; Whetton and Spooncer, 1998), and adhesion molecules (Conget and Minguell, 1995; Verfaillie *et al.*, 1994), as well as the regulation of the release of cells to the circulation at an appropriate stage of differentiation (Weiss and Geduldig, 1991). The potentials of marrow stromal cells have been reviewed (Owen, 1988). Stromal cell lines have been developed that duplicate many of these functions (Zipori, 1989a). A mesenchymal stem cell from bone marrow has been identified (Pittenger *et al.*, 1999). The use of such cells combined with HSCs might be necessary to solve some of the tissue engineering challenges presented by HSCs. Some of the progeny of primitive stem cells must pass through, or otherwise be influenced by, additional microenvironments, for example, the thymus, for key differentiation events to occur. Collectively, these processes produce the multiple mature cell types needed to sustain the hematologic and immunologic needs of the organism. Attempts to engineer these tissues, therefore, require a duplication of their key components, for example, provision of an appropriate population of stromal cells. The functional status of these stromal cells, i.e., whether they are promoting quiescence versus active replication of their associated HSC, also may be important. Maybe more than one stromal cell type will be necessary to provide a microenvironment “compleat” (Walton, 1653) for HSCs?

## ORGANIZATION OF THE STEM CELL COMPARTMENT

Do the most primitive hematopoietic stem cells comprise a “cell renewal” system to provide replacement of any cells lost from this compartment by cell division, or are a fixed number of stem cells available in an organism large enough to provide vast numbers of progeny without becoming significantly depleted in a lifetime (Harrison *et al.*, 1987; Lansdorp, 1995; Micklem *et al.*, 1983)? These two hypotheses of stem cell compartment organization are not necessarily mutually exclusive. Both receive some experimental support, and experiments that test unequivocally which of these alternatives, if either, is correct have been difficult to devise (Van Zant *et al.*, 1997). The answer underlies the likely success or failure of attempts to expand or genetically manipulate most primitive stem cells *ex vivo* for the purposes of tissue engineering (Lansdorp, 1995). The consequences of telomere shortening in this circumstance are a concern (Engelhardt *et al.*, 1997; Lansdorp *et al.*, 1997).

The best available evidence suggests that, in humans, HSCs, as identified by the CD34 antigen, self-renew in fetal liver to establish the physiologically necessary stem cell compartment. In the adult, few, if any, CD34-positive cells self-renew under normal circumstances (Lansdorp *et al.*, 1993). Fetal hematopoietic stem cells may differ significantly in their properties and perhaps in their regulation from stem cells in the adult. Although controversial for clinical use, fetal tissue might offer some advantages in engineering new or replacement tissues (Harrison *et al.*, 1997). Cord blood is an additional and potentially very useful source of stem cells for tissue engineering (Wagner *et al.*, 1995). In the mouse, the most primitive HSCs are CD34-negative cells, and CD34-positive cells are their progeny (Osawa *et al.*, 1996). CD34-negative stem cells likely exist in humans, but their proportion and place in the stem cell hierarchy remain to be defined (Goodell *et al.*, 1997).

## STROMAL MICROENVIRONMENTS

Just as hematopoiesis *in vivo* is limited to specific sites during development, hematopoietic cells demand stringent conditions for their maintenance in culture. For many years, the data suggested that mixed stromal cell populations, including large “blanket” cells, were necessary to maintain hematopoietic stem cells in culture (Dexter, 1982; Tavassoli and Takahashi, 1982). Stromal cell lines that support hematopoiesis have now been developed (Itoh *et al.*, 1989; Zipori, 1989a). Although an intimate association of stem cells with stromal cells is probably essential, contact may not be needed for their survival and differentiation (Verfaillie, 1992). Currently, all of the interactive properties of stromal cells with stem cells cannot be completely duplicated with known recombinant survival, growth, and differentiation factors. Consequently, the mechanisms by which cloned stromal cells support hematopoietic stem cells from several species (mouse, swine, and humans) in culture are incompletely defined. Potentially, these stromal cells either produce soluble

growth factor(s) or present a membrane-bound growth factor(s), or both, which regulate stem cell survival and production or inhibition of apoptosis and self-renewal versus differentiation (Whetton and Spooncer, 1998; Williams, 1994). Stromal cells or other cell types may also be a source of inhibitors of stem cell differentiation (Waegell *et al.*, 1994; Zipori, 1989b), and the presence and possible adherence of more differentiated hematopoietic cells (Verfaillie *et al.*, 1994) to stromal cells may be a feedback signal necessary to maintain inhibitor levels. If these differentiated cells or the inhibitors are removed, the inhibition of stem cell differentiation ceases and the stem cells may differentiate out of existence. Primitive HSCs likely have several signal transduction pathways that can be triggered by different signals (or combinations of signals). Stromal cells might be involved in regulating asymmetric versus symmetric division, which potentially involves a role for the *notch* gene and its ligands (Morrison *et al.*, 1997; Whetton and Spooncer, 1998). Different signaling pathways may be used for stem cell survival (vs. apoptosis), self-renewal, proliferation, and lineage-specific differentiation. Indeed, regulation of cell production by modification of the rate of apoptosis of hematopoietic cells might be a critical component of the process. Methods to alter (suppress) apoptosis have received little attention in tissue engineering, although this may be one of the mechanisms by which microenvironmental stromal cells act. In myelodysplastic syndromes, increased apoptosis appears to be a critical problem (Mundle *et al.*, 1994).

Other than in very early embryogenesis, the majority of stromal cell precursors are likely distinct from primitive hematopoietic stem cells (Dexter and Allen, 1992; Huang and Terstappen, 1992, 1994). Consequently, in any engineered system, using adult cells might require both hematopoietic stem cells and stromal cells, but in a temporal order, i.e., stromal cells first followed by HSCs might be necessary to establish appropriate stromal niches (Allen, 1981).

### ASSAYS OF STEM CELLS

Assays to enumerate stem cells at specific stages of differentiation, especially assays that require the production of mature progeny, must be designed to meet the physiologic demands of the cell types assayed. For example, the most primitive stem cells demand either an *in vivo* environment or a culture system that permits an intimate association with stromal cells. Assays that meet this criterion include the long-term repopulating ability (LTRA) assay using marked cells, e.g., the Y chromosome of male cells transplanted into female recipients (Watt and Visser, 1992), or, secondarily, the assay of long-term culture initiating cells (LTC-ICs) (Sutherland *et al.*, 1989). If the stem cells are grown on stromal lines and not harvested for assay of secondary colonies, but instead are assessed by hematopoietic cobblestone areas in the primary cultures, the assayed cells are designated as long-term culture cobblestone-area-forming cells (LTC-CAFCs) (Ploemacher *et al.*, 1991; Neben *et al.*, 1993). The frequency of CD34<sup>+</sup> cells in human bone marrow is at least 100 times greater than the frequency of LTC-ICs (Watt and Visser, 1992). Because the frequency of LTC-ICs correlates most closely with the LTRA in the mouse (the only species in which LTRA frequency has been accurately determined), this implies that in humans only a small fraction of CD34<sup>+</sup> cells actually belongs to the most primitive category of stem cells. The frequency of LTC-ICs in the blood of normal individuals is very low, 3/ml or  $1/2 \times 10^6$  nucleated cells, or approximately 100 times lower than in bone marrow (Udomsakdi *et al.*, 1992).

More differentiated stem cells will grow in a semisolid medium, e.g., agar or methylcellulose, provided their physiologic regulator(s) of differentiation, i.e., colony-stimulating factors (CSFs) and interleukins (ILs), are provided (Watt and Visser, 1992). Sudden removal of CSFs or ILs can trigger apoptosis of the target cells, indicating the critical importance of these regulators (Williams *et al.*, 1990). Because the differentiation hierarchy from primitive stem cell to the most differentiated progenitor cell is a linear branching system, the mature functional progenies of the more differentiated members of this hierarchy become evident much faster in colony-forming cell (CFC) assays, e.g., mature cells from committed granulocyte-monocyte CFCs (GM-CFC) at 7 days. The mature progenies of intermediately differentiated, high-proliferative potential colony-forming cells (HPP-CFCs) are evident after 14–28 days of culture compared to LTC-ICs, which require 4–8 weeks for assay (Ploemacher *et al.*, 1991). The more differentiated committed progenitors, GM-CFCs, require a single cytokine, GM-CSF, whereas HPP-CFCs need multiple CSFs or ILs and LTC-ICs must be grown on irradiated bone marrow stromal cells or carefully screened cloned stromal cell lines (Watt and Visser, 1992; Sutherland *et al.*, 1989; Ploemacher *et al.*, 1991).

## HUMAN HSC HARVESTING AND PROCESSING

The posterior crests of the pelvic bone provide the only readily accessible site from which marrow HSCs in amounts sufficient to provide a successful hematopoietic graft can be extracted. Marrow cells are collected by aspiration through specially designed needles. Approximately  $2 \times 10^8$  nucleated cells/kg recipient weight (approximately 11 ml/kg) are sufficient. The aspiration is usually performed while the donor is under the influence of general anesthesia.

Collection of HSCs from the circulation currently requires apheresis, because the numbers of HSCs per milliliter of blood are quite small. The HSC donor can be treated with cytokines or, in the case of autologous donors, with myelosuppressive chemotherapy plus cytokines to increase the number of circulating CD34<sup>+</sup> cells (Brugger *et al.*, 1992). When sufficient numbers of these cells are mobilized into the circulation, an adequate graft product can sometimes be generated with a single apheresis procedure (Pettengell *et al.*, 1993). However, autologous collections from patients who have already received substantial amounts of antitumor cytotoxic therapy often require several apheresis procedures to collect a useful graft product. Not all normal donors mobilize successfully. About 10–20% of normal donors are poor mobilizers, which suggests that factors other than prior cytotoxic therapy are implicated in poor mobilization. An undefined circulating inhibitor has been implicated (Kessinger and Sharp, 1998).

Harvested marrow cells or peripheral HSCs are cryopreserved and stored in either a liquid nitrogen freezer or in temperatures at or below  $-80^{\circ}\text{C}$ , unless they are to be infused within 24–48 hr. If *ex vivo* manipulations of these cells are performed, such procedures generally occur prior to cryopreservation.

At the time of infusion, the cells are thawed by placing their plastic storage bags in a warm water bath. The thawed cells are immediately infused into the circulation of an individual whose marrow function has been ablated with cytotoxic therapy. From there, the cells make their way to the appropriate niches in the marrow stroma to grow and restore hematopoietic function. Approximately 7 days are required after infusion before mature functional cells begin to appear in the circulation. In the meanwhile, patients are supported with red cell and platelet transfusions. Therefore, the first evidence that marrow function is returning after transplantation is the reappearance of circulating white blood cells.

## Replacement of congenitally defective HSC

Patients with congenitally defective stem cells present with a myriad of clinical manifestations, depending on the specific defect. The resultant diseases include severe combined immune deficiency (SCID), a disorder of the lymphoid stem cell (Wiscott–Aldrich syndrome), a disorder of the lymphoid and hematopoietic stem cells (thalassemia, or erythroid disorder), Fanconi anemia, and osteopetrosis (a disorder of osteoclasts), among others. Destruction of the defective marrow and replacement with normal marrow from a compatible donor will reverse these otherwise fatal diseases. For patients who lack donors, genetically engineered stem cell grafts are an alternative (Kohn, 1996; Liu *et al.*, 1997). In addition, patients with generalized congenital enzyme deficiencies such as osteopetrosis and Gaucher's disease can benefit from allogeneic hematopoietic stem cell transplant because the transplanted normal marrow cells provide progenies with sufficient amounts of enzyme to control the symptomatology of these disorders. Alternatively, they require engineered autologous grafts (Xu *et al.*, 1994; Dunbar and Kohn, 1996).

Patients with acquired stem cell defects can also be treated with allogeneic stem cell transplants. Disorders such as aplastic anemia, leukemia, myeloma, and dysmyelopoietic syndromes have been cured when the diseased marrow was destroyed and replaced with normal cells. Certain diseases (e.g., aplastic anemia subsequent to radiation or administration of chemotherapeutic agents) might arise from a microenvironmental defect (Testa *et al.*, 1985; Mauch *et al.*, 1995). Such disorders may not be amenable to cure by infusion of stem cells alone but could also require replacement of the microenvironment. Potentially, such defects would be primary targets for therapy with engineered bone marrow (Naughton *et al.*, 1994).

Unfortunately, observations in patients undergoing genetically engineered autologous transplants confirm data from primates and to some extent mice that, using current techniques, the transfection frequency of HSCs with retroviral vectors is low. The quiescent status of the majority of primitive hematopoietic stem cells is believed to be the cause of this problem. Forced cycling

of the HSCs by cytokines increases the transfection frequency (Luskey *et al.*, 1992). A concern with this approach, especially in adults, is that if the HSCs that are forced to cycle also differentiate, they may lose some of their "stemness" (Peters *et al.*, 1995). The survival time of such transfected cells on transplantation will be reduced and the loss of transfected gene expression or perhaps even complete loss of the grafted cells might occur. Potentially, the application of an engineered system that more closely duplicates *in vivo* hematopoiesis and in particular provides stromal cells will lead to improved gene transduction successes (Xu *et al.*, 1995; Naughton *et al.*, 1992). This is the attraction of some of the newly developed perfusion systems.

## Artificial bone marrow and perfused hematopoietic culture systems

### Historical

The evidence suggesting the need for a supporting matrix to maintain hematopoiesis has been reviewed by Flidner and Calvo (1978). Knospe and colleagues, following the lead of Seki (1973), employed cellulose ester membranes that were coated with various cell types then implanted *in vivo* (Knospe, 1989).

Long-term bone marrow cultures (LTBMCs) (Dexter *et al.*, 1977) have been acknowledged to represent the most physiological *ex vivo* model of hematopoiesis. Hematopoietic colony-forming cells can be detected in human LTBMCs for about 6 months and much longer in cultures from subhuman primates and mice (Dexter *et al.*, 1984). The demonstration that hematopoietic stem cells could be maintained in culture paved the way to the engineering of artificial bone marrow and perfused systems to support and grow stem cells. The application in modern times of tissue engineering to hematopoietic stem cells in bone marrow can be traced to pioneering work with artificial capillary cultures described by Knazek *et al.* (1972; Gullino and Knazek, 1979), who grew mouse fibroblasts and human choriocarcinoma cells, and to studies by Chick *et al.* (1975), who attempted to create an artificial pancreas. Based on this work, starting in the mid-1970s attempts to grow normal hematopoietic cells in artificial capillary cultures were made. The original intent was to grow bone marrow stroma or stromal cell lines in the extracapillary space and circulate hematopoietic cells suspended in medium through the stromal cell-surrounded capillaries. The technical challenges of this approach became quickly apparent. There was a very high cell death rate of the circulating hematopoietic cells. At that time damage by shear forces was thought to be primarily responsible. In retrospect, normal cell death due to physiological apoptosis was also a likely significant contributor. As an alternative, an attempt was made to grow an "artificial marrow" in the extracapillary spaces, which were perfused with medium flowing through the capillaries. Although this was somewhat more successful, the system was far from ideal because the extracapillary volume was relatively large compared to the volume of cells, perhaps because an inadequate matrix was available for normal cell growth. Additionally, the long-term (weeks to months) maintenance of sterility was difficult (Anderson and Sharp, 1981), emphasizing the need for relatively sophisticated engineering solutions to these problems. Consequently, partnerships with companies have become an essential element of tissue engineering of hematopoietic stem cells. In the remainder of this review reference is made to several company products; however, the references are not exhaustive and no endorsement of company products is implied. In order to obtain a better overview of available resources, a search of the Worldwide Web is recommended. The company names mentioned can serve as a measure of the effectiveness of the search engine employed.

Naughton and colleagues have employed nylon mesh templates as a matrix on which to grow rodent hematopoietic cells. Mature cells and late-stage precursors were observed for 39 weeks (Naughton *et al.*, 1987). Subsequently, they described the role of stromal cells in this system using rat, nonhuman primate, and human cells (Naughton and Naughton, 1989). The three-dimensional nylon mesh system supports human bone marrow stem cell differentiation into multiple lineages (Naughton *et al.*, 1990) and can be used to evaluate the effects of drugs on hematopoiesis (Naughton *et al.*, 1991) and for gene transfer studies (Naughton *et al.*, 1992). Naughton *et al.* (1994) evaluated the effects of surgical implantation of bioengineered bone marrow tissue in rats. Active hematopoiesis was observed at sites of implantation for up to 110 days without the addition of exogenous growth factors. A company, Cytomatrix, has also evaluated a porous biocompatible matrix to support hematopoiesis (Rosenzweig, 1999). The problem of shear stress has been

addressed by investigators at the National Aeronautics and Space Administration (NASA), who have devised microgravity bioreactors that are distributed by Synthecon (Goodwin *et al.*, 1993). Although this latter approach appears successful, it is unlikely to become a routine laboratory procedure.

### ***Bone marrow organoids***

In an attempt to circumvent the high loss of normal cells, established long-term bone marrow culture-derived cells were employed as starting material to establish bone marrow organoids. The majority of differentiated normal hematopoietic cells are lost from long-term cultures during the first few weeks of culture, which permits harvesting of hematopoietic stem cells associated with the adherent layer. The supernatant is discarded from the culture and the remaining cells are scraped from the flask. The cells can be concentrated to a slurry by gently pelleting in a conical centrifuge tube. When cultured for a subsequent period, these cells form bone marrow organoids. A micropipette is used to deposit a volume of this cell slurry onto a polycarbonate filter floating on a "raft" in medium. The hematopoietic reconstituting potential of these organoids can be demonstrated by transplanting them to lethally irradiated syngeneic recipients (Sharp *et al.*, 1985). If these organoids were transplanted under the kidney capsule of intact adult mice, then a fat organ resembling yellow bone marrow was formed. In contrast, in irradiated recipients not only did the organoid show hematopoietic differentiation, but spleen colonies were formed presumably by hematopoietic stem cells that migrated from the organoid (Sharp *et al.*, 1985). Such organoids are also a potential long-term source of hematopoietic regulatory factors (Brockbank and van Peer, 1983). The full scope of the potential of these hematopoietic organoids has yet to be explored. Because there are reports that graft-versus-host disease (GVHD) does not occur with long-term cultured cells (Spooncer and Dexter, 1983), whether organoids or artificial bone marrow alter the chimeric status and extent of GVHD in allogeneic recipients should be examined. Much more information has been gathered following infusion of bone marrow or blood as a cell suspension, which produces regeneration in the context of recipient stroma rather than the organoids, which possess donor stroma.

### ***Perfused systems***

Engineering solutions to the problems of shear stress, nutrition, oxygenation, etc. have been applied and this has led to the development of successful perfusion systems in which hematopoietic stem cell numbers can be amplified. Schwartz *et al.* (1991) demonstrated that increased long-term bone marrow perfusion was superior to the traditional approach. Establishment of more optimal perfusion conditions supported the continuous stable generation of human progenitor cells for over 5 months in culture (Schwartz *et al.*, 1991). This information was employed to design and construct a perfusion culture system employing bioreactors, which provides at least 1 log expansion over 14 days of total cells and of various progenitor cell types and almost 1 log expansion of the more primitive LTC-ICs (Koller *et al.*, 1993). The original system required establishment of a stromal layer and represents an automated media exchange system rather than a fully perfused culture system. Even so, an automated version of this system marketed by Aastrom permits from 10- to 15-fold marrow cell expansion under good manufacturing practice (GMP) conditions with minimal operator intervention (Bachier *et al.*, 1999). Stem and progenitor cells expanded using this system are now being evaluated in clinical trials (Koller *et al.*, 1993; Palsson, 1994). Bioreactors for stem cell expansion have also been described by Wang and Wu (1992), providing a severalfold increase in cell output over an 8-week period (Wang *et al.*, 1995). Several other groups are working on perfusion systems (Kompala and Highfill, 1994; Papoutsakis *et al.*, 1994). *Ex vivo* expanded progenitor cells have been shown to contribute to reconstitution of transplanted patients (Brugger *et al.*, 1995).

Newer technologies are approaching the goal of fully perfused culture systems. This approach is being pursued by Cytometrix. Acordis Research has also developed a fully perfused, oxygenated, waste-exchanging, culture perfusion unit (Glockner *et al.*, 1999), which should permit duplication of the environment experienced by blood stem cells. This system also accommodates the establishment of a stromal matrix that might more closely duplicate bone marrow microenvironment. Such systems may provide the environment for controlled proliferation of primitive stem cells without their terminal differentiation, thus duplicating events during the first 2 weeks post-

transplantation *in vivo*. Controlled proliferation of primitive stem cells might significantly increase the frequency of gene transduction, which should greatly amplify the potential applications of tissue-engineered hematopoietic stem cells. In addition to the application of gene-marked stem cells (Brenner and Rill, 1994), HSCs engineered for therapy have been employed in the treatment of adenosine deaminase SCID (ADA-SCID) (Kohn, 1996), Gaucher's disease (Dunbar and Kohn, 1996), and Fanconi anemia (Liu *et al.*, 1997), and HSCs engineered to be resistant to the human immunodeficiency virus (HIV) by Systemix are currently in a phase I/II trial (Dutton, 1999). Additionally, work has begun on the development of an artificial thymus (Chen, 1994). After about 25 years in development, tissue-engineered hematopoietic stem cells have finally been administered to humans. The outcome of transplantation of even more primitive stem cells grown and manipulated *ex vivo* is currently awaited (Kessinger, 1995), and the full potential of engineered stem cells has become an exciting topic of both research and contemplation.

#### ACKNOWLEDGMENTS

The authors wish to thank Shirene Seina, who typed this manuscript; Sally Mann, for technical assistance; and the National Institutes of Health, the National Cancer Institute, and the Nebraska Department of Health, for partial support of some of the research described. This overview was updated April 15, 1999.

# RENAL REPLACEMENT DEVICES

H. David Humes

## INTRODUCTION

The kidney was the first solid organ whose function was approximated by a machine and a synthetic device. In fact, renal substitution therapy with hemodialysis or chronic ambulatory peritoneal dialysis (CAPD) has been the only successful long-term *ex vivo* organ substitution therapy to date (Iglehart, 1993). The kidney was also the first organ to be successfully transplanted from a donor individual to an autologous recipient patient. However, the lack of widespread availability of suitable transplantable organs has kept kidney transplantation from becoming a practical solution to most cases of chronic renal failure.

Although long-term chronic renal replacement therapy with either hemodialysis or CAPD has dramatically changed the prognosis of renal failure, it is not complete replacement therapy, because it provides only filtration function (usually on an intermittent basis) and does not replace the homeostatic, regulatory, metabolic, and endocrine functions of the kidney. Because of the non-physiologic manner in which dialysis performs or does not perform the most critical renal functions, patients with end-stage renal disease (ESRD) on dialysis continue to have major medical, social, and economic problems (U.S. Renal Data System, 1998). Accordingly, dialysis should be considered as renal substitution rather than renal replacement therapy.

Tissue engineering of an implantable artificial kidney composed of both biologic and synthetic components will most likely have substantial benefits for the patient by increasing life expectancy, mobility, and quality of life, with less risk of infection and with reduced costs. This approach could also be considered a cure rather than a treatment for patients. A successful tissue engineering approach to the kidney is dependent on a thorough knowledge of the physiologic basis of kidney function.

## BASICS OF KIDNEY FUNCTION

Excretory function of the kidney is initiated by filtration of blood at the glomerulus, which is an enlargement of the proximal end of the tubule incorporating a vascular tuft. The structure of the glomerulus is designed to provide efficient ultrafiltration of blood to remove toxic waste from the circulation, yet retain important circulating components, such as albumin. The regulatory function of the kidney, especially with regard to fluid and electrolyte homeostasis, is provided by the tubular segments attached to the glomerulus. The functional unit of the kidney is therefore composed of the filtering unit (the glomerulus) and the regulatory unit (the tubule). Together they form the basic component of the kidney, the nephron. In addition to these excretory and regulatory functions, the kidney is an important metabolic and endocrine organ. Erythropoietin, active forms of vitamin D, renin, angiotensin, prostaglandins, leukotrienes, kallikrein-kinins, various cytokines, and complement components are some of the endocrinologic compounds produced by the kidney.

Because of the efficiency inherent in the kidney as an excretory organ, life can be sustained with only 5–10% of normal renal excretory function. Accordingly, the approach to a tissue engineering construct becomes easier to entertain, especially because only a fraction of normal renal excretory function is required to maintain life (Humes *et al.*, 1997a).

The process of urine formation begins within the capillary bed of the glomerulus (Brenner and Humes, 1977). The glomerular capillary wall has evolved into a structure with the property to separate as much as one-third of the plasma entering the glomerulus into a solution of a nearly ideal ultrafiltrate. This high rate of ultrafiltration across the glomerular capillary is a result of hydraulic pressure generated by the heart and vascular tone of the preglomerular and postglomerular vessels, as well as the high hydraulic permeability of the glomerular capillary wall. This hydraulic pressure and permeability of the glomerular capillary bed is at least two times and two orders of magnitude higher, respectively, than most other capillary networks within the body (Landis and Pappenheimer, 1965). Despite this high rate of water and solute flux across the glomerular capillary wall, this same structure retards the filtration of important circulating macromolecules, especially albumin, so that all but the lower molecular-weight plasma proteins are restricted in the passage across this filtration barrier (Anderson and Quinn, 1974; Chang *et al.*, 1975; Brenner *et al.*, 1978).

This ultrafiltration process of glomeruli in normal human kidneys forms approximately 100 ml of filtrate every minute. Because daily urinary volume is roughly 2 liters, more than 98% of the glomerular ultrafiltrate must be absorbed by the renal tubule. The bulk of reabsorption, 50–65%, occurs along the proximal tubule. Similar to glomerular filtration, fluid movement across the renal proximal tubule cell is governed by physical forces. Unlike the fluid transfer across the glomerular capillary wall, however, tubular fluid flux is principally driven by osmotic and oncotic pressures rather than hydraulic pressure. Renal proximal tubule fluid absorption is based on active  $\text{Na}^+$  transport, requiring the energy-dependent  $\text{Na}^+, \text{K}^+$ -ATPase located along the basolateral membrane of the renal tubule cell to promote a small degree of luminal hypotonicity (Andreoli and Schafer, 1978). This small degree of osmotic difference (2–3 mOsm/kg  $\text{H}_2\text{O}$ ) across the renal tubule is sufficient to drive isotonic fluid reabsorption due to the very high diffusive water permeability of the renal tubule cell membrane. Once across the renal proximal tubule cell, the transported fluid is taken up by the peritubular capillary bed due to the favorable oncotic pressure gradient. This high oncotic pressure within the peritubular capillary is the result of the high rate of protein-free filtrate formed in the proximate glomerular capillary bed (Knox *et al.*, 1983). As can be appreciated, an elegant system has evolved in the nephron to filter and reabsorb large amounts of fluid in bulk to attain high rates of metabolic product excretion while maintaining regulatory salt and water balance.

## TISSUE ENGINEERING APPROACH TO RENAL FUNCTION REPLACEMENT

In designing an implantable bioartificial kidney for renal function replacement, essential features of kidney tissue must be utilized to direct the design of the tissue engineering project. The critical elements of renal function must be replaced, including the excretory, regulatory transport, and endocrinologic functions. The functioning excretory unit of the kidney, as detailed previously, is composed of the filtering unit, the glomerulus, and the regulatory or transport unit, the tubule. Therefore, a bioartificial kidney requires two main units, the glomerulus and the tubule, to replace excretory function.

### BIOARTIFICIAL HEMOFILTER

The potential for a bioartificial glomerulus has been achieved with the use of polysulfone fibers *ex vivo* with maintenance of ultrafiltration in humans for several weeks with a single device (Golper, 1986; Kramer *et al.*, 1977). The availability of hollow fibers with high hydraulic permeability has been an important advancement in biomaterials for replacement function of glomerular ultrafiltration. Conventional hemodialysis for end-stage renal disease has used membranes in which solute removal is driven by a concentration gradient of the solute across the membranes, and is, therefore, predominantly a diffusive process. Another type of solute transfer also occurs across the dialysis membrane via a process of ultrafiltration of water and solutes across the membrane. This convective transport is independent of the concentration gradient and depends predominantly on the hydraulic pressure gradient across the membrane. Both diffusive and convective processes occur during traditional hemodialysis, but diffusion is the main route of solute movement.

The development of synthetic membranes with high hydraulic permeability and solute re-

Fig. 45.1. Schematic of a tissue-engineered hemofilter composed of a microporous synthetic bio-compatible hollow fiber, a preadhered extracellular matrix, and a confluent monolayer of autologous endothelial cells lining the luminal surface of the fiber. Arrows refer to vectorial ultrafiltrate formation.

tion properties in convenient hollow fiber form has promoted ESRD therapy based on convective hemofiltration rather than diffusive hemodialysis (Colton *et al.*, 1975; Henderson *et al.*, 1975). Removal of uremic toxins, predominantly by the convective process, has several distinct advantages, because it imitates the glomerular process of toxin removal with increased clearance of higher molecular-weight solutes and removal of all solutes (up to a molecular-weight cutoff) at the same rate. Distinct differences are apparent between diffusive and convective transport across a semipermeable membrane. The clearance of a molecule by diffusion is negatively correlated with the size of the molecule. In contrast, clearance of a substance by convection is dependent on size up to a certain molecular weight. The bulk movement of water carries passable solutes along with it in approximately the same concentration as in the fluid.

Development of an implantable device that mimics glomerular filtration will thus depend on convective transport. This physiologic function has been achieved clinically with the use of polymeric hollow fibers *ex vivo*. Major limitations to the currently available technology for long-term replacement of filtration function include bleeding associated with required anticoagulation, diminution of filtration rate due either to protein deposition in the membrane over time or to thrombotic occlusion, and large amounts of fluid replacement required to replace the ultrafiltrate formed from the filtering unit. The use of autologous endothelial cell-seeded conduits along filtration surfaces may provide improved long-term hemocompatibility and hemofiltration *in vivo* (Kadletz *et al.*, 1992; Schneider *et al.*, 1988; Shepard *et al.*, 1986). A report detailing the capability of isolating angioblasts from peripheral blood makes this approach more readily achievable (Asahara *et al.*, 1997). The initial step to develop a tissue-engineered hemofilter with adequate ultrafiltration rates through an endothelial-lined synthetic hemofiltration membrane has been achieved (Humes *et al.*, 1997b) and is depicted in Fig. 45.1.

A potential rate-limiting step in endothelial cell-lined hollow fibers of small caliber is thrombotic occlusion, which limits the functional patency of this filtration unit. In this regard, gene transfer into seeded endothelial cells for constitutive expression of anticoagulant factors can be envisioned to minimize clot formation in these small-caliber hollow fibers. Because gene transfer for *in vivo* protein production has been clearly achieved with endothelial cells (Zweibel *et al.*, 1989; Wilson *et al.*, 1989), gene transfer into endothelial cells for the production of an anticoagulant protein is clearly conceivable. This strategy has been used with hirudin, a protein from the blood-sucking leech, which is a potent specific inhibitor of thrombin. A replication-defective, amphotropic, recombinant retrovirus containing the hirudin gene has been used to infect endothe-

lial cells, which were then seeded onto a polysulfone membrane (Humes *et al.*, 1997a; Rade *et al.*, 1996). Culture supernatants of the transfected cells had high thrombin inhibitory activity, as determined by enzyme-linked immunosorbent assay.

For differentiated endothelial cell morphology and function, an important role for various components of the extracellular matrix (ECM) has been demonstrated (Carey, 1991; Carley *et al.*, 1988). The ECM has been clearly shown to dictate phenotype and gene expression of endothelial cells, thereby modulating morphogenesis and growth. Various components of the ECM, including collagen type I, collagen type IV, laminin, and fibronectin, have been shown to affect endothelial cell adherence, growth, and differentiation. Of importance, ECM produced by Madin–Darby canine kidney (MDCK) cells, a permanent renal epithelial cell line, promotes endothelial cells to develop fenestrations. Fenestrations are large openings that act as channels or pores for convective transport through the endothelial monolayer and are important in the high hydraulic permeability and sieving characteristics of glomerular capillaries (Carley *et al.*, 1988; Milici *et al.*, 1985). Thus, the ECM component on which the endothelial cells attach and grow may be critical in the functional characteristics of the lining monolayer.

### BIOARTIFICIAL TUBULE

As detailed above, the efficiency of reabsorption, even though dependent on natural physical forces governing fluid movement across biologic as well as synthetic membranes, requires specialized epithelial cells to perform vectorial solute transport. Fortunately, a population of cells residing in the adult mammalian kidney have retained the capacity to proliferate and morphogenically differentiate into tubule structures *in vitro* (Humes and Cieslinski, 1992; Humes *et al.*, 1996), and can be used as the key cellular element of a tissue-engineered renal tubule device.

The bioartificial renal tubule can be readily conceived as a combination of living cells supported by polymeric substrata, using epithelial progenitor cells cultured on water- and solute-permeable membranes seeded with various biomatrix materials so that expression of differentiated vectorial transport and metabolic and endocrine function is attained (Fig. 45.2). With appropriate membranes and biomatrices, immunoprotection of cultured progenitor cells has been achieved concurrent with long-term functional performance as long as conditions support tubule cell viability. This bioartificial tubule has been shown to transport salt and water effectively along osmotic and oncotic gradients (MacKay *et al.*, 1998).

A bioartificial proximal tubule satisfies a major requirement of reabsorbing a large volume of filtrate to maintain salt and water balance within the body. The need for additional tubule segments to replace other nephronal functions, such as the loop of Henle, to perform more refined homeostatic elements of the kidney, including urine concentration or dilution, may not be necessary. Patients with moderate renal insufficiency lose the ability to regulate salt and water homeostasis finely because they are unable to concentrate or dilute, yet are able to maintain reasonable fluid and electrolyte homeostasis due to redundant physiologic compensation via other mechanisms. Thus, a bioartificial proximal tubule, which reabsorbs isoosmotically the majority of the filtrate, may be sufficient to replace required tubular function to sustain fluid electrolyte balance in a patient with end-stage renal disease.

Fig. 45.2. Schematic of a tissue-engineered renal tubule. Renal epithelial cells form a confluent monolayer along the inner surface of a polysulfone hollow fiber with preadhered matrix molecules.

## IMPLANTABLE TISSUE-ENGINEERED KIDNEY

The development of a bioartificial filtration device and a bioartificial tubule processing unit would lead to the possibility of an implantable bioartificial kidney, consisting of a filtration device followed in series by the tubule unit. The filtrate formed by this device will flow directly into the tubule unit. This tubule unit should maintain viability, because metabolic substrates and low-molecular-weight growth factors are delivered to the tubule cells from the ultrafiltration unit (Nikolovski *et al.*, 1999). Furthermore, immunoprotection of the cells grown within the hollow fiber is achievable due to the impenetrance of immunologically competent cells through the hollow fiber (O'Neil *et al.*, 1997). Rejection of transplanted cells will, therefore, not occur. This arrangement thereby allows the filtrate to enter the hollow-fiber network internal compartments, which are lined with confluent monolayers of renal tubule cells for regulated transport function.

This device could be used either extracorporeally or implanted within a patient. In this regard, the specific implant site for a bioartificial kidney will depend on the final configuration of both bioartificial filtration and tubule device. As presently conceived, the endothelial-lined bioartificial filtration hollow fibers can be placed into an arteriovenous circuit using the common iliac artery and vein, similar to the surgical connection for a renal transplant. The filtrate is connected in series to a bioartificial proximal tubule, with the reabsorbate transported back into the systematic circulation. The processed filtrate exiting the tubule unit is then connected via tubing to the proximate ureter for drainage and urine excretion via the recipient's own urinary collecting system.

Although the ultimate goal of this approach is to construct a fully implantable bioartificial kidney with a hemofilter and tubular system, the pathway to achieve this goal will most likely occur along a staged developmental strategy, with each intermediate device providing both clinical therapeutic benefit and substantial experience in the use of more elementary tissue-engineered devices (Humes *et al.*, 1997b). In this regard, the initial component of the bioartificial kidney to be developed for clinical evaluation will be an extracorporeal renal tubule-assist device (RAD), to optimize current hemofiltration approaches to treat the clinical disorder of acute renal failure.

## DEVELOPMENT OF A RENAL TUBULE-ASSIST DEVICE

Replacement of the multivariate tubular functions of the kidney cannot be achieved with inanimate membrane devices, as has been accomplished with the renal ultrafiltration process, but requires the use of the naturally evolved biologic membranes of the renal tubular epithelium. In this regard, the tissue engineering of a bioartificial renal tubule as a cell therapy device to replace this missing component can be conceived as a combination of living cells supported on synthetic scaffolds (MacKay *et al.*, 1998; Nikolovski *et al.*, 1999). A bioartificial tubule can be constructed utilizing renal tubule progenitor cells (Humes and Cieslinski, 1992; Humes *et al.*, 1996), cultured on semipermeable hollow-fiber membranes on which extracellular matrix has been layered to enhance the attachment and growth of the epithelial cells (Timpl *et al.*, 1979). These hollow-fiber synthetic membranes not only provide the architectural scaffold for these cells but also provide immunoprotection, as has been observed in the long-term implantation of the bioartificial pancreas in a xenogeneic host (O'Neil *et al.*, 1997). The successful tissue engineering of a bioartificial tubule as a confluent monolayer has been achieved in a single hollow-fiber bioreactor system (Fig. 45.3) (MacKay *et al.*, 1998). The successful scale-up from a single-fiber system to a multifiber bioreactor and porcine renal proximal tubule cells has also been successfully engineered (Humes *et al.*, 1999b). Porcine cells were used because the pig is currently considered the best source of organs for both human xenotransplantation and immunoisolation cell therapy due to its anatomic and physiologic similarities to human tissue and the relative ease of breeding pigs in large numbers (Cozzi and White, 1995).

The scale-up from a single hollow fiber to a multifiber bioartificial renal tubule-assist device has proceeded with porcine renal proximal tubule cells grown as confluent monolayers along the inner surface of polysulfone immunoisolating hollow fibers (Humes *et al.*, 1999b). These hollow-fiber cartridges are packaged in bioreactor cartridges with membrane surface areas as large as 0.7 m<sup>2</sup>, resulting in a device containing up to  $2.5 \times 10^9$  cells. *In vitro* studies of these RADs have demonstrated their retention of differentiated active vectorial transport of sodium, bicarbonate, glucose, and organic anions (Humes *et al.*, 1999b). These transport properties were suppressed with specific transport inhibitors. Ammoniogenesis and glutathione metabolism, which are important differentiated metabolic processes of the kidney, were also demonstrated in these devices.

Fig. 45.3. Electron micrograph of a tissue-engineered bioartificial renal tubule. The nucleus (N) is indicated; arrows delineate apical microvilli (a differentiated morphologic characteristic of proximal tubule cells) and the arrowhead identifies the tight junctional complex of a transporting epithelium.

Cells

Matrix

Hollow  
Fiber

Synthesis of 1,25-dihydroxyvitamin D<sub>3</sub> as a key endocrinologic metabolite was also documented. These metabolic processes were also shown to be regulated by important physiologic parameters and achieved rates comparable to those of a whole kidney.

The critical next step for clinical application of a renal tubule cell therapy device was to ascertain whether the RAD maintained differentiated renal functional performance, similar to that observed *in vitro*, and viability in an extracorporeal hemoperfusion circuit in an acutely uremic dog. The RAD was accordingly placed in a series into a standard hollow-fiber hemofiltration cartridge; the cartridge had ultrafiltrate and postfiltered blood connections, to duplicate the structural anatomy of the nephron and to mimic the functional relationship between the renal glomerulus and tubule (see Fig. 45.4). The successful completion of this step has been reported (Humes *et al.*, 1999a). Data show that fluid and electrolyte balances in the animals, as reflected by plasma parameters, were adequately controlled with the bioartificial kidney. In fact, plasma potassium and blood urea nitrogen levels were more easily controlled during RAD treatment compared with sham control conditions. The step-up of oncotic pressure in the postfiltrate blood, which was delivered to the antiluminal space of the bioartificial proximal tubules, allowed the fractional reabsorption of sodium and water to achieve 40–50% of the ultrafiltrate volume, an amount similar to that seen in the nephron *in vivo*. Active transport of potassium, bicarbonate, and glucose by the RAD was demonstrated. To further evaluate the capacity of the RAD to optimize renal function replacement of the bioartificial kidney, three metabolic parameters were evaluated: ammonia excretion, glutathione reclamation, and 1,25-(OH)<sub>2</sub>D<sub>3</sub> production. With increasing time of use in the uremic animal, the RAD displayed incremental ability to excrete ammonia to a level as high as 100/μmol/hr. The RAD demonstrated effective reclamation of filtered glutathione and an improvement in plasma glutathione levels in the uremic animal. Finally, these studies also demonstrated the ability of the RAD to produce 1,25-(OH)<sub>2</sub>D<sub>3</sub>, the most active vitamin D metabolite (Rade *et al.*, 1996). This production rate was high enough to return plasma values of this hormone to normal levels from the significantly depressed levels observed in the acutely uremic condition.

It is, in fact, because of the ability of the RAD to replace the numerous metabolic processes

Fig. 45.4. The extracorporeal hemoperfusion circuit of a tissue-engineered kidney for the treatment of a patient with acute renal failure. The synthetic hemofilter is connected in series to the bioartificial renal tubule-assist device (RAD). Heat exchangers, flow and pressure monitors, and multiple pumps are required for optimal functioning of this extracorporeal device.

lost in renal failure that this form of cell therapy may optimize current renal substitution therapy of hemodialysis and hemofiltration. Patients who develop ischemic or nephrotoxic acute renal failure still have mortality rates exceeding 50%, despite hemodialysis or hemofiltration therapy. These patients suffer from high catabolic rates, immunologic dysregulation, and predilection to septic shock, all of which contribute to the high mortality rate (Humes, 1995; Humes *et al.*, 1997a). The ability of tubule cells to metabolize and synthesize critical compounds, such as various cytokines, glutathione, free-radical scavenging enzymes, and  $1,25\text{-(OH)}_2\text{D}_3$ , which play important roles in immunologic reactivity, may have the substantial added benefit of altering the natural history of this disease process. Because the pathophysiology of this disorder is due predominantly to proximal tubule cell injury and necrosis, the replacement of proximal tubule cell function with a cell therapy device would appear a logical therapeutic intervention for this condition. The results of this study indicate the technologic feasibility of this form of cell therapy in the acutely uremic state and set the stage to initiate clinical trials with this exciting new therapy in the very near future.

A second intermediate tissue-engineered device that may prove to have clinical utility is an implantable hemofilter with a capacity to produce 2–4 ml/min of ultrafiltrate. Although this rate of filtration is considerably less than the 10–15 ml/min rate required to correct the uremic state in ESRD patients, it is sufficient enough to improve solute clearance to lessen dialysis time and optimize clearance rates of urea and other uremic toxins. In addition, this rate of ultrafiltration from a stand-alone implanted hemofilter is small enough so that, with a urinary bladder capacity of 500–750 ml, a patient can tolerate the frequency of urination required from the filtrate draining directly into the urinary tract system. Both of these intermediate devices will provide substantial experience to improve the durability, efficacy, and efficiency of an implantable hemofilter and a tubule-assist device to achieve the required hemofiltration rate of 15–20 ml/min and selective

reabsorption for adequate clearance while avoiding volume depletion and intolerable urinary frequency.

## SUMMARY

Similar to gene therapy, cell therapy is an exciting new approach to the treatment of acute and chronic diseases (Gage, 1998). Cell therapy centers on techniques directed toward the expansion of specific cells to perform differentiated tasks and the introduction of these cells or cell products into a patient either within extracorporeal circuits or as implants. This approach leverages the natural abilities of cells to replace critical physiologic functions deranged or lost in clinical disorders. Tissue engineering is a further extension of cell therapy to combine the biologic and engineering disciplines to construct devices to replace tissue or organ functions lost to disease (Langer and Vacanti, 1993). Current approaches have focused on placing cells into hollow-fiber bioreactors or encapsulating membranes. Extracorporeal liver-assist devices and encapsulated islets of Langerhans to treat liver failure and diabetes mellitus are most promising examples (Watanabe *et al.*, 1997; Maki *et al.*, 1996). The progress in this area suggests that the application of these technologies may be successfully applied to renal replacement therapy.

The kidney was the first organ whose function was substituted by an artificial device. The kidney was also the first organ to be transplanted successfully. The ability to replace renal function with these revolutionary technologies in the past was due to the fact that renal excretory function is based on natural physical forces that govern solute and fluid movement from the body compartment to the external environment. The need for coordinated mechanical or electrical activities for renal substitution was not required. Accordingly, the kidney may well be the first organ to be available as a tissue-engineered implantable device that is a fully functional replacement part for the human body.

# GENITOURINARY SYSTEM

Byung-Soo Kim, David J. Mooney, and Anthony Atala

## INTRODUCTION

Large numbers of patients suffer from a variety of diseases in the genitourinary system, which is composed of kidneys, ureters, bladder, urethra, and genital organs. Genitourinary diseases include congenital abnormalities, iatrogenic injuries, and disorders such as cancer, trauma, infection, and inflammation. These diseases often involve or result in the loss of tissue structure or function.

Lost or malfunctioning genitourinary tissues have traditionally been reconstructed with native nonurologic tissues or synthetic prostheses. The nonurologic tissues include gastrointestinal segments (Atala and Hendren, 1994; Hendren and Atala, 1994; Leong and Ong, 1972), skin (Draper and Stark, 1956), peritoneum (Hutschenreiter *et al.*, 1978), fascia (Neuhof, 1917), omentum (Goldstein *et al.*, 1967), pericardium (Kambic *et al.*, 1992), and dura (Kelâmi, 1971). Synthetic prostheses have been fabricated from polymers, including silicone (Bogash *et al.*, 1960; Henly *et al.*, 1995), polyvinyl (Kudish, 1957; Ulm and Lo, 1959), and Teflon (Kocvara and Zak, 1962; O'Donnell and Puri, 1984; Politano *et al.*, 1974). Reconstruction with nonurologic native tissues rarely replaces the entire function of the original organ, and typically leads to complications, including metabolic abnormalities, infection, perforation, and malignancy (Atala, 1997; Khoury *et al.*, 1992; Leong and Ong, 1972; McDougal, 1992). Furthermore, the limited amount of autologous donor tissue confines these types of reconstructions. Attempts to use synthetic prostheses have usually failed due to the wide array of complications (e.g., device malfunction, infection, and stone formation) associated with mechanical or biocompatibility problems (Bona and De Gresti, 1966; Henly *et al.*, 1995; Kudish, 1957). Tissue engineering may provide an alternative to current therapies for the genitourinary system. Cell transplantation using three-dimensional, biocompatible scaffolds offers the possibility of creating new functional genitourinary tissues (Atala, 1997, 1999).

## TISSUE ENGINEERING STRATEGIES IN THE GENITOURINARY SYSTEM

Tissue engineering integrates cells, scaffolds, and specific signals to create new functional tissues (Kim and Mooney, 1998a). In this approach, cells isolated from a small biopsy and expanded *in vitro* can be seeded onto a suitable scaffold. They are either allowed to develop into new tissue *in vitro* or transplanted into patients to create new functional tissue that is structurally integrated with the body. Various types of cells can be isolated from tissues and greatly expanded *in vitro*, potentially providing an unlimited supply of therapeutic cells. The scaffolds provide an appropriate three-dimensional environment, and guide the development of the desired structure from the cells by providing mechanical support until the newly formed tissues are structurally stabilized. Application of specific signals (e.g., growth factors, cell adhesion molecules, and mechanical strain) during the process of tissue development may induce the appropriate pattern of gene expression in the cells, and may allow the engineered tissues to maintain proper specific functions.

One of the challenges in genitourinary tissue engineering is to expand a small number of genitourinary-associated cells to a clinically useful cell mass. Although cell transplantation has been

proposed for the replacement of a variety of tissues, including skin (Bell *et al.*, 1981; Yannas *et al.*, 1982), pancreas (Lim and Sun, 1980), and cartilage (Freed *et al.*, 1994), the concept of transplanting urothelial cells, which line most of the urinary tract, had not been approached in the laboratory setting until the early 1990s, because of the inherent difficulties encountered in expanding urothelial cells in large quantities. Our laboratory has been successful in greatly expanding urothelial cells from small biopsy specimens (Cilento *et al.*, 1994). The specifics of cell culture must be optimized for every cell type. Smooth muscle cells of ureter, bladder, urethra, and corporal cavernosum have also been successfully harvested and expanded in our laboratory (Atala *et al.*, 1993a; Cilento *et al.*, 1995; Kershen *et al.*, 1998; Oberpenning *et al.*, 1999; Park *et al.*, 1999; Yoo *et al.*, 1995, 1998b).

Scaffolds for engineering genitourinary tissues have been fabricated from three classes of biomaterials: naturally derived materials (e.g., collagen and alginate), synthetic polymers [e.g., poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and poly(lactic-co-glycolic acid) (PLGA)], and acellular tissue matrices (e.g., bladder submucosa and small intestinal submucosa). Collagen exhibits excellent biocompatibility and specific cellular interactions, and is amenable to cellular remodeling during the process of tissue formation (Cavallaro *et al.*, 1994). Alginate, a polysaccharide isolated from seaweed, has a great advantage for injectable cell-delivery vehicle applications owing to its hydrogel formation in the presence of calcium ions (Smidsrød and Skjåk-Bræk, 1990). Synthetic polymers can be produced reproducibly on a large scale and can be also processed into a scaffold in which the macrostructure, mechanical properties, and degradation time can be readily controlled and manipulated. Scaffolds fabricated from biodegradable polymers (e.g., PGA, PLA, and PLGA) will eventually erode in the body, avoiding a chronic foreign-body response. Acellular tissue matrices are collagen-rich xenogeneic matrices that are prepared by removing the cellular components of various tissues, such as intestine or bladder. Acellular tissue matrices have been utilized for the regeneration of many types of tissues [e.g., blood vessels (Badylak *et al.*, 1989; Lantz *et al.*, 1990, 1992), urethra (Atala *et al.*, 1999; Chen *et al.*, 1999), and bladder (Piechota *et al.*, 1998; Probst *et al.*, 1997; Yoo *et al.*, 1998b)], with no evidence of immunogenic rejection.

An important role of the scaffold in tissue engineering is to promote the development of new tissues with a predefined configuration and dimension. In these applications it is critical that the scaffold withstands *in vivo* forces exerted by the surrounding tissue and maintains its structure until the engineered tissue has sufficient mechanical integrity to support itself. This can be achieved by an appropriate choice of mechanical and degradative properties of the scaffolds (Kim and Mooney, 1998b). Urinary tissues with tubular structures (e.g., ureters and urethras) may be engineered with tubular scaffolds with central lumens (Atala *et al.*, 1993a). The ability of the tubular scaffolds to resist *in vivo* compressive forces and maintain the predefined structure can be controlled by the polymer type and physical structure (Mooney *et al.*, 1994, 1995, 1996a).

The tissue-specific function of an engineered tissue can be maintained by providing an appropriate combination of specific signals (e.g., growth factors) during the process of tissue development. The expression of genes by cells in engineered tissues may be regulated by interactions with the microenvironment, including interactions with the adhesion surface (Hynes, 1992), with other cells (Parsons-Wingerter and Saltzman, 1993), and with growth factors (Deuel, 1997), and by the mechanical stimuli imposed on the cells (Banes, 1993). These interactions can be controlled by incorporating or integrating a variety of signals, such as cell adhesion peptides (Bouhadir *et al.*, 1999; Hubbell, 1995; Rowley *et al.*, 1999) and growth factors (Mooney *et al.*, 1996b), into the scaffold or subjecting it to mechanical strain (Niklason *et al.*, 1999).

## ENGINEERING GENITOURINARY TISSUES

### KIDNEYS

The kidneys remove metabolic wastes from the blood, control fluid balance by maintaining homeostasis, and provide important regulatory activities by secreting hormones. End-stage renal failure is a devastating condition that involves multiple organs in affected individuals. Numerous pathologies, such as diabetes, hypertension, glomerulonephritis, and obstructive uropathy, result in end-stage renal disease. Current available therapies include hemodialysis, peritoneal dialysis, and renal transplantation (Amiel and Atala, 1999). Although dialysis can prolong survival for many patients with end-stage renal disease, only renal transplantation can currently restore renal func-

tion. However, the morbidity associated with renal transplantation, such as allograft failure, immunosuppression, or operative complications, is not trivial. Furthermore, renal transplantation is severely limited by a donor shortage.

There has been an effort directed toward the development of extracorporeal bioartificial renal units (Cieslinski and Humes, 1994; MacKay *et al.*, 1998). In this approach, the bioartificial kidney consists of two main units, glomeruli and tubules, which replace two critical renal functions, excretion and reabsorption. In the bioartificial glomerulus unit, hollow fibers with high hydraulic permeability facilitate filtration of blood delivered to the lumen of the fibers. The filtrate is then delivered to the lumen of hollow fibers in the bioartificial tubular unit, and epithelial cells on the lumen reabsorb the isoosmotic ultrafiltrate. It has been demonstrated that the combination of a synthetic filtration device and a renal tubule cell therapy device in an extracorporeal perfusion circuit replaces filtration, transport, metabolic, and endocrinologic functions of the kidney in a dog model (Humes *et al.*, 1999). However, the application of these extracorporeal devices may be best reserved for temporary situations rather than a permanent solution.

Augmentation of either isolated or total renal function with kidney cell expansion *in vitro* and subsequent autologous transplantation may be a feasible solution for complete replacement therapy. Our laboratory demonstrated the reconstruction of functional renal units by implanting isolated and cultured renal cells on three-dimensional polymer scaffolds (Atala *et al.*, 1995; Yoo *et al.*, 1996). Renal cells were successfully harvested, expanded *in vitro*, seeded onto polymer scaffolds, and implanted into host animals in which the cells can proliferate and organize into glomeruli and highly organized tubulelike structures (Fig. 46.1). These structures allowed for solute transport by the tubular cells across the membrane, resulting in the excretion of high levels of uric acid and creatinine through a urinelike fluid. Recent successes in harvesting and expanding renal cells *in vitro* and the development of biologically active scaffolds may allow the creation of three-dimensional functioning renal units that can be applied for partial or, eventually, full replacement of kidney function.

Fig. 46.1. Glomerulus formed *in vivo* by seeding renal cells onto a PGA scaffold and subsequent implantation (hematoxylin and eosin;  $\times 400$ ).

## URETERS AND URETHRA

The ureters are tubular conduits that convey urine from the renal pelvis to the bladder by peristaltic contraction. The urethra is a membranous canal conveying urine from the bladder to the exterior of the body. The primary indications for ureteral reconstruction are congenital or acquired obstructions that produce deterioration of renal function, carcinoma, and traumatic injury. Urethral reconstruction is performed often to repair hypospadias, epispadias (congenital defects in which the urethra terminates abnormally in the penis), urethral injuries with stricture formation, and malignant tumors of the urethra.

Various materials have served as a ureteral or urethral substitute. The use of nondegradable, synthetic materials [e.g., vitallium (Lord and Eckel, 1942), tantalum (Lubash, 1947), polyethylene (Tulloch, 1952), polyvinylchloride (Ulm and Lo, 1959), silicone (Blum *et al.*, 1963), Teflon (Kelâmi *et al.*, 1971; Kocvara and Zak, 1962), Dacron (Kocvara and Zak, 1962), and polyethylene vinyl acetate (Ramsay *et al.*, 1986)] has usually failed due to bioincompatibility and infection. Preputial skin is the most commonly used graft for urethral repair, but patients with more severe proximal urethral defects or failed urethral reconstruction may not have sufficient preputial skin for repair. In these instances, several alternatives have been used, including nonpenile skin (Devine and Horton, 1977), bladder mucosa (Koyle and Ehrlich, 1987), buccal mucosa (Dessanti *et al.*, 1992), and composite grafts (Bazeed *et al.*, 1983; Olsen *et al.*, 1992). However, some of these grafts are associated with several complications (e.g., hair growth, sebaceous secretions, stenosis, and salt deposits) and additional procedures for graft retrieval.

Our laboratory demonstrated that xenogeneic acellular collagen matrices (Chen *et al.*, 1999) and PGA mesh (Cilento *et al.*, 1995) are suitable grafts for repairing narrow urethral defects. The acellular collagen matrix was obtained from porcine bladder. Neourethras were reconstructed without any signs of strictures or complications. The animals were able to void through the neourethras. These results were confirmed clinically in a series of patients with severe urethral defects (Fig. 46.2) (Atala *et al.*, 1999). One of the advantages over previous tissue grafts is that the material is “off the shelf.” This eliminates the necessity of additional surgical procedures for graft harvesting, which may decrease the operative time, as well as the potential morbidity due to the harvest procedure.

Cultured sheets of urethral epithelium have been used for hypospadias repair in humans (Romagnoli *et al.*, 1990). In this approach, autologous epithelium was cultured *in vitro* from 1- to 2-mm urethral mucosa biopsies and subsequently transplanted. The transplanted cells formed the new urethra with a well-organized epithelium.

Fig. 46.2. Endoscopic view of urethra reconstructed with a collagen matrix. The urethra maintains patency.

Another approach for urethral and ureteral tissue reconstruction is to transplant urothelial cells using biodegradable polymer scaffolds as delivery vehicles. Our laboratory has succeeded in engineering tubular structures in animal models from cultured urothelial cells and PGA scaffolds (Atala *et al.*, 1992). In one study, urothelial cells isolated from human bladder and expanded *in vitro* were seeded onto PGA scaffolds with tubular configurations and implanted *in vitro*. Tubular structures developed from these implants, and the degradation of the polymer scaffolds resulted in the eventual formation of a new urothelial tissue. Similarly, human urothelial cells and smooth muscle cells were seeded onto PGA tubular scaffolds in another study (Atala *et al.*, 1993a). Following implantation, the urothelial cells proliferated to form a multilayered luminal lining, while smooth muscle cells organized into multilayered structures surrounding the urothelial cells. This study suggested that it was possible to engineer urologic tissues containing multiple cell types. This approach has been expanded to engineer new ureters (Yoo *et al.*, 1995) and urethras (Cilento *et al.*, 1995) by transplanting smooth muscle cells and urothelial cells on tubular polymer scaffolds *in vivo*.

## BLADDER

The function of the bladder is to store large amounts of urine at low pressures and to empty efficiently on demand. However, fibrosis, abnormal contraction, and nerve malfunction may result in poor compliance, decreased bladder capacity, and high urinary storage pressure. The causes of bladder malfunction are congenital (posterior urethral valves, bladder extrophy, or epispadias), traumatic (injury, multiple bladder procedures), inflammatory (chronic cystitis, interstitial cystitis, or tuberculosis), radiation induced (cancer of the cervix, rectum, prostate, and bladder), or functional contraction (neurogenic bladder dysfunction or idiopathic bladder instability) (Goldwasser and Webster, 1986). In turn, these problems may lead to recurrent urinary tract infections, incontinence, renal parenchymal damage, and renal impairment and failure (Atala, 1997).

To date, bladder reconstruction has been attempted with both natural materials [gastrointestinal segments (Leong and Ong, 1972), skin (Draper and Stark, 1956), peritoneum (Hutschenreiter *et al.*, 1978), fascia (Neuhof, 1917), dura (Kelâmi, 1971), omentum (Goldstein *et al.*, 1967), and gelatin sponges (Kropp *et al.*, 1996)] and synthetic polymers [silicone (Bogash *et al.*, 1960), polyvinyl (Kudish, 1957; Ulm and Lo, 1959), and Teflon (Bona and De Gresti, 1966)]. However, these attempts have usually failed due to mechanical, structural, or biocompatibility problems. Permanent synthetic materials usually succumbed to mechanical failure and urinary stone formation. The use of natural materials resulted in a reduced bladder capacity or various complications such as excessive mucus production, infection, perforation, stone formation, and tumor development (Atala, 1997; Khoury and Zak, 1962; McDougal, 1992; Leong and Ong, 1972).

A series of studies have shown that small intestinal submucosa (SIS) (Pope *et al.*, 1997; Tsuji *et al.*, 1967) and acellular bladder matrix (Piechota *et al.*, 1998; Probst *et al.*, 1997; Yoo *et al.*, 1998b) can promote morphological and functional regeneration of bladder tissues. SIS is a relatively acellular, collagen-rich biomaterial prepared from small intestine by removing the mucosa from the inner surface and serosa and the tunica muscularis from the outer surface of the intestine. The acellular bladder matrix is prepared by mechanically and chemically removing all cellular components from the tissue. In rat or dog models, partial cystectomy (35–70%) was performed, followed by bladder augmentation with SIS or acellular bladder matrix. All three layers of the bladder (mucosa, smooth muscle, and serosa) were regenerated (Piechota *et al.*, 1998; Pope *et al.*, 1997; Probst *et al.*, 1997; Tsuji *et al.*, 1967; Yoo *et al.*, 1998b). The regenerated bladders exhibited compliance similar to that of normal bladders (Yoo *et al.*, 1998b). Although the acellular matrices without seeded cells may be appropriate grafts for narrow defects, there could be limitations for tissue regeneration, especially if the size of the tissue to be regenerated is large. In most of the studies to date, the biomaterials were utilized without cell seeding. In these cases, bladder tissues were regenerated by cell ingrowth from the surrounding tissues. Our laboratory reported that bladder capacity increased significantly (100% increase) when augmented with scaffolds seeded with cells compared to scaffolds without cells (30% increase) (Yoo *et al.*, 1998b). It is hypothesized that this is due to a faster rate of scaffold resorption than that of cell ingrowth and subsequent shrinkage of the scaffold when implanted without cell seeding.

Our laboratory reported on the development of a viable bladder substitute using smooth mus-

Fig. 46.3. Radiographic cystograms 11 months after subtotal bladder removal. (a) Subtotal bladder removal without a reconstructive procedure; (b) reconstruction with a cell-free bladder-shaped polymer scaffold; (c) reconstruction with a tissue-engineered neobladder. The tissue-engineered neobladder appears normal in size and configuration, but the unaugmented trigone and the polymer-only implant show smaller sized reservoirs. From Oberpenning *et al.* (1999), with permission.

cle cells and urothelial cells isolated from autologous bladders and cultured on biodegradable polymer scaffolds (Oberpenning *et al.*, 1999). Most of the previous approaches have reconstructed the bladder either by surgical enlargement or by replacement of partial, defective walls using various biomaterials (Piechota *et al.*, 1998; Probst *et al.*, 1997; Pope *et al.*, 1997; Tsuji *et al.*, 1967). In this study, transplantable whole bladders were created using cultured bladder cells and polymer scaffolds. In this approach, urothelial and smooth muscle cells were isolated from 1-cm<sup>2</sup> bladder biopsies, expanded *in vitro*, and seeded on preformed bladder-shaped polymer scaffolds. These neobladders were implanted in dogs that had the majority of their native bladders excised. In functional evaluations for up to 11 months, the bladder neorgans demonstrated a normal capacity to retain urine, normal compliance, ingrowth of neural structures, and a normal histologic architecture (Figs. 46.3 and 46.4).

### GENITAL TISSUES

The management of inadequate genital function (e.g., impotence) and ambiguous genitalia, caused by a rudimentary penis, severe hypospadias, traumatic injury, cancer, infection, or chronic disease (e.g., diabetes and vascular insufficiency), may involve phallic reconstruction (Goodwin and Scott, 1952; Horton and Dean, 1990). Earlier attempts at penile reconstruction involved multiple stages of surgery using autologous rib cartilage as a stiffener. However, the unsatisfactory functional and cosmetic results due to its curvature discouraged its use. Silicone rigid prostheses were popularized in the 1970s. Although silicone penile prostheses are an acceptable treatment in adults, complications, such as erosion and inflammation, remain a problem (Nukui *et al.*, 1997).

Natural penile prostheses created from the patient's own cells may be preferable and may decrease the biocompatibility risks associated with the artificial prostheses. Our laboratory has demonstrated that cartilage rods can be created using chondrocytes seeded on preformed polymer

Fig. 46.4. Histologic analysis of the tissue-engineered neobladder 6 months after reconstructive surgery (hematoxylin and eosin;  $\times 140$ ). The neobladder tissue consists of a morphologically normal uroepithelial lining over a sheath of submucosa, followed by a layer of multi-form smooth muscle bundles.

scaffolds (Yoo *et al.*, 1998a). Biomechanical studies showed that the cartilage rods were readily elastic and could withstand high degrees of pressure. Additional studies demonstrated that autologous chondrocytes seeded on polymer scaffolds are able to form penile prostheses in an animal model (Yoo *et al.*, 1999).

The availability of transplantable autologous corpus cavernosum tissue for use in reconstructive procedures would be beneficial to many patients with congenital and acquired abnormalities of the genital system (Fig. 46.5). It would facilitate enhanced cosmetic results and provide the possibility of reconstructing *de novo* functional erectile tissue. Our laboratory has shown that cultured cavernosum cells seeded on biodegradable polymers formed corporal smooth muscle when implanted *in vivo* (Kershen *et al.*, 1998). Additional studies were performed in order to investigate the possibility of developing corporal tissue *in vivo* by transplanting smooth muscle cells in conjunction with endothelial cells on polymer scaffolds (Park *et al.*, 1999). The cell-polymer constructs formed neocorporal tissues, consisting of corporal smooth muscle and neovasculature formed by both the host and implanted endothelial cells. Similar studies have been performed with clitoral and vaginal tissues (Atala, 1999).

### FETAL TISSUE ENGINEERING

Engineering of fetal genitourinary tissues would benefit the newborn with prenatally diagnosed birth defects. Treatment of many congenital anomalies at birth is often impeded by lack of normal tissues or organs, either autologous or allogous. The severe donor shortage for tissue or organ transplantation is even more critical during the neonatal period. Autologous grafting is frequently not an option in newborns because of donor site size limitations. Having a ready supply of genitourinary-associated tissue for surgical reconstruction at birth may be advantageous. Fetal tissue can be engineered by a minimally invasive harvest of tissue prenatally. The tissue may be engineered *in vitro* while the pregnancy is allowed to continue so that a one-stage reconstruction can be performed at the time of birth.

Our laboratory utilized this concept to repair bladder defects in a fetal lamb model (Fauza *et al.*, 1998a). Bladder exstrophy (a developmental anomaly marked by absence of a portion of the lower abdominal wall and the anterior urinary bladder wall) was created in 90- to 95-day gestation fetal lambs. A small fetal bladder specimen was harvested via fetoscopy to obtain cells for en-

Fig. 46.5. Scanning electron micrograph of penile corporal smooth muscle cells seeded onto an acellular matrix (bar = 100  $\mu$ m).

gineering fetal bladder tissue (Fig. 46.6). At 7 to 10 days prior to delivery, the expanded cells were seeded onto polymer scaffolds and maintained *in vitro*. After delivery, the lambs had surgical closure of their bladder using the tissue-engineered bladder tissues. At 2 months after the reconstructive surgery, histologic analysis of the engineered tissues showed a normal histologic pattern, indistinguishable from native bladder. In addition, the engineered bladders were more compliant and had a higher capacity than did bladders closed using only the native bladders. This technology was also expanded to engineer other types of fetal tissues (e.g., skin) in an animal model (Fauza *et al.*, 1998b). Replication of this technology in humans may be possible in the future.

Fig. 46.6. Schematic diagram showing the arrangement for videofetoscopic harvest of fetal tissue.

## INJECTABLE THERAPIES

Endoscopic therapies using injectable bulking agents are attractive procedures to treat urinary incontinence and vesicoureteral reflux. Urinary incontinence results from a deficient or weak musculature in the bladder neck and urethral area. Primary vesicoureteral reflux results from a congenitally deficient longitudinal submucosal muscle of the distal ureter, which leads to an abnormal flow of urine from the bladder to the upper tract. For many years, open surgery [e.g., ureteral reimplantation, pubovaginal sling (McGuire and Lytton, 1978), and the artificial urinary sphincter (Webster *et al.*, 1992)] was the standard of care for the treatment of these diseases owing to intrinsic sphincteric dysfunction. In recent years, minimally invasive techniques for the endoscopic correction of these maladies have been developed and refined, obtaining reasonable success rates with significantly decreased patient morbidity. The endoscopic technique for the correction of both urinary incontinence and vesicoureteral reflux relies on increasing muscle resistance with the injection of bulking agents into the suburethral or subureteral tissues. In general, endoscopic procedures are less time consuming, more cost effective, and more easily performed, often in an outpatient setting.

Searching for an ideal material for injection has been a challenging task for many decades. The materials used for injection therapies include Teflon [poly(tetrafluoroethylene)] microparticles (O'Donnell and Puri, 1984; Politano *et al.*, 1974), poly(vinyl alcohol) (Merguerian *et al.*, 1990), autologous fat (Palma *et al.*, 1997), silicone microparticles (Henly *et al.*, 1995), and collagen (Appell, 1994; Leonard *et al.*, 1990). However, none of these materials is ideal due to migration, granuloma formation, and volume loss (Atala, 1994a,b; Claes *et al.*, 1989; Malizia *et al.*, 1984).

The ideal material for the endoscopic treatment of vesicoureteral reflux and incontinence should be injectable, nonantigenic, nonmigratory, volume stable, and safe for human use (Kershen and Atala, 1999). Our laboratory has investigated the use of chondrocyte–alginate gel suspensions as a possible injectable material for the treatment of vesicoureteral reflux and incontinence (Atala *et al.*, 1993b). Initially, chondrocytes mixed with alginate gel were injected into animals. The injected suspension formed cartilaginous tissues *in vivo* and showed no evidence of cartilage or alginate migration, granuloma formation, or volume loss. Additional studies demonstrated that vesicoureteral reflux could be treated with an autologous chondrocyte–alginate suspension without any evidence of obstruction in an animal model (Fig. 46.7) (Atala *et al.*, 1994). To use this approach in humans, a biopsy could be taken from the symphysis pubis or the cartilaginous part of

Fig. 46.7. Radiocystograms of pre- and postendoscopic treatment of reflux in a patient. A chondrocyte–alginate suspension was injected endoscopically in the subureteral region. Preoperative fluoroscopic cystogram (left) shows bilateral reflux. Postoperative radionuclide cystogram (right) shows resolution of reflux.

the ear under a local anesthetic. A few weeks later the patient would be treated with an endoscopic injection of the autologous chondrocyte–alginate suspension. The first human application of tissue engineering for the genitourinary system was accomplished with the injection of chondrocytes for the correction of vesicoureteral reflux (Kershen and Atala, 1999). Similar clinical trials with this technology have been initiated for the treatment of urinary incontinence. In addition to its use for the endoscopic treatment of reflux and incontinence, the system of injectable autologous cells may also be applicable for the treatment of other medical conditions, such as rectal incontinence, dysphonia, plastic reconstruction, and wherever an injectable biocompatible material is needed.

## FUTURE DIRECTIONS

Studies to identify factors that control proliferation, differentiation, cellular gene expression, and tissue organization may be required to engineer functional genitourinary tissues. This technology may allow for expansion of isolated cells in large quantities with the correct phenotype *in vitro*, while maintaining appropriate cellular gene expression during the process of tissue development. Although studies were performed to identify culture conditions of several types of cells in the genitourinary system, the mechanisms that control gene expression are not well understood. Appropriate bioreactor systems that would facilitate cell seeding onto scaffolds and subsequent culture *in vitro* must also be developed (Kim *et al.*, 1998).

A tremendous effort is being expanded to develop scaffolds that induce functional tissue development. Scaffolds with controlled mechanical and degradative properties (Bouhadir *et al.*, 1999; Kim and Mooney, 1998a) would promote tissue development with predefined configurations. The development of scaffolds with specific cell-recognition sites may induce tissue-specific gene expression of the seeded cells (Rowley *et al.*, 1999) and promote the spatial control of specific cell types in genitourinary tissues with multiple cell types (Hubbell *et al.*, 1991).

Vascularization and innervation of the engineered genitourinary tissues are essential for the successful integration of the construct with the host body. The vascularization of the engineered tissues could be achieved by growth factor-stimulated ingrowth of vascular cells from the surrounding tissue (Folkman and Klagsbrun, 1987) or transplantation of vascular cells (Holder *et al.*, 1997). Innervation may be promoted with graft, guidance channels, and various nerve growth factors (Bellamkonda and Aebischer, 1994).

Genitourinary tissue with genetic defects may be repaired with gene therapy. Genetically modified cells can be transplanted using the scaffold as a gene delivery vehicle. In one study, urothelial cell–polymer constructs were introduced with the DNA plasmid and transplanted (Yoo and Atala, 1997). The transplanted cells formed an organlike structure with functional expression of the transfected genes *in vivo*. This technology may be applied to any type of urological-associated pathology.

Several technologies developed in our laboratory are currently in clinical trials. Vesicoureteral reflux and urinary incontinence are being treated endoscopically with engineered chondrocytes. Urethral tissue replacement surgeries using engineered matrices are being performed in patients with severe disease. Engineered bladder tissue will soon be used in patients who require bladder augmentation. Even though a careful and long-term follow-up will be necessary in order to assess the currently available technologies, it is obvious that tissue engineering may play a vital role in the treatment of several genitourinary conditions.

# STRUCTURAL TISSUE ENGINEERING

Charles A. Vacanti, Lawrence J. Bonassar, and Joseph P. Vacanti

## INTRODUCTION

This chapter provides a review of important developments related to the tissue engineering of structural tissues, including bone, cartilage, ligament, and tendon, over the past 10 years, with an emphasis on recent developments. Basic principles of tissue engineering, focusing on cell biology and materials science as used currently in the field, are presented. Early efforts to combine cells with biocompatible materials are described along with more recent endeavors. Applications of the technology are presented with a particular focus on uses in orthopedics, plastic and reconstructive surgery, and maxillofacial surgery. Finally, future challenges are outlined from the perspective of integrating technologies from medicine, biology, and engineering in hopes of translating tissue engineering to clinical applications.

According to legend, the first homotransplantation of an entire limb was performed by two saints, Damian and Cosmas, as depicted by the artist, Fra Angelico. Indeed, the concept was described even earlier: “The Lord God, cast a deep sleep on the man, and while he was asleep, he took out one of his ribs and closed up its place with flesh. The Lord God then built up into a woman the rib that he had taken from the man” (New Jerusalem Bible, 1990).

Although the number of research centers undertaking tissue engineering has greatly increased during the past decade and potential applications have become more widespread, the basic concept that the repair and regeneration of biological tissues can be guided through application and control of cells, materials, and chemoactive proteins remains central. As such, tissue engineering is, at its core, an interdisciplinary field, requiring the interactions of physicians, scientists, and engineers.

Our goal is to utilize cells from either a relatively small specimen of tissue or a universal donor source, expand them *in vitro*, and deliver them associated with a template, in a configuration that will generate a new functional tissue. The ability to achieve this goal requires a keen understanding of the extracellular matrix, the structural framework, and the regulation of cell behavior.

As early as 1908, Lexer described early attempts at tissue engineering of structural tissue in his report of the use of freshly amputated or cadaver allografts for joint reconstruction. Several decades later, work by Huggins resulted in the search for the elusive bone morphogenic proteins. In 1965, Urist demonstrated the generation of one structural tissue, that is, bone, by means of autoinduction. He described “wandering histiocytes, foreign body giant cells, and inflammatory connective cells” being “stimulated by degradation products of dead matrix to grow in and repopulate the area of an implant of decalcified bone.” The process, as described by Urist, is followed immediately by autoinduction, in which both the inductor cells and the induced cells are derived from ingrowing cells of the host bed. Differentiation of the osteoprogenitor cell was felt to be elicited by local alterations in cell metabolic cycles.

In more recent times (1970s), Green (1977) described a series of experiments devoted to the generation of new cartilage. In one study, chondrocytes, seeded onto sterile bone spicules, were implanted into nude mice. Although the experiments were not entirely successful, Green correct-

ly postulated that the advent of new biocompatible materials might enable cells to be seeded onto a synthetic scaffolding and implanted into animals to generate new functional tissue.

The past two decades have given rise to a multitude of descriptions involving the replacement of bone and cartilage lost to injury and disease. Living cells have been delivered on alloplastic implants (Ohgushi *et al.*, 1989) to produce bone. Cartilage growth, whether achieved by use of cell suspensions alone (Bentley and Greer, 1971; Chesterman *et al.*, 1968; Grande *et al.*, 1989; Lipman *et al.*, 1983), cell attachment to naturally occurring matrices (Itay *et al.*, 1987; Wakitani *et al.*, 1989) from perichondrium (Upton *et al.*, 1981), or peptide stimulation (Wozney *et al.*, 1988), had been described only in minute quantities until the early 1990s. Until then, cartilage was generated only in association with, and confined to a defect in, underlying bone or cartilage, and was devoid of specific shapes. As such, the purpose of the efforts was to augment the quantity of native tissue to add or restore some function. New hyaline cartilage growth in significant amounts, not associated with endogenous bone or cartilage (Vacanti *et al.*, 1991), has now been achieved using a technology termed "tissue engineering" to generate parenchymal tissue (Vacanti, 1988; Vacanti *et al.*, 1988). During the past decade, the principles of tissue engineering have been applied to virtually every organ system in the body (Fig. 47.1), with a great deal of attention being focused on orthopedic and maxillofacial applications, including engineering of bone, cartilage, tendon, and ligament.

## MATERIALS DEVELOPMENT

The development of matrices to serve as templates for cell attachment/suspension and delivery has progressed at a tremendous rate during the past 5–10 years. Initial efforts have focused on the use of collagen as a natural matrix for cell delivery. A large degree of success was reported in the development of skin equivalents, primarily the dermal component. More recent studies have focused on using natural extracellular matrix (ECM) proteins such as collagen as the structural support for cell transplantation. Yannas (1988) first designed an artificial dermis from collagens and glycosaminoglycans. Others quickly followed in attempts at creating new blood vessels (Weinberg and Bell, 1986) and cartilage (Grande *et al.*, 1989; Wakitani *et al.*, 1989). Poor mechanical properties and variable physical properties with different sources of the protein matrices have hampered progress with these approaches. Concerns have arisen regarding immunogenic problems associated with the introduction of foreign collagen. Also, there are inherent biophysical constraints in collagen used as scaffolding. For example, cartilage grown from cells seeded on collagen must be confined in a rigid "well" such as underlying bone or cartilage, because of collagen's nonmoldability.

Following the developmental efforts using naturally occurring polymers as scaffolds, attention turned in the middle 1980s to the use of synthetic naturally occurring polymers as matrices for cell transplantation. It was believed that synthetic scaffoldings had the advantages of being biocompatible as well as biodegradable. It was postulated that the synthetic polymer scaffolds might act as cell anchorage sites and give the transplanted complex intrinsic structure. Employment of synthetic rather than naturally occurring polymers would allow exact engineering of matrix configuration so that the biophysical limitations of mass transfer would be satisfied. Synthetic matrices would also give one the flexibility to alter physical properties and potentially facilitate reproducibility and scale-up. The configuration of the synthetic matrix could also be manipulated to vary the surface area available for cell attachment as well as to optimize the exposure of the attached cells to nutrients. The chemical environment surrounding a synthetic polymer can be affected in a controlled fashion as the polymer is hydrolyzed. The potential exists to deliver continuously nutrients and hormones that can be incorporated into the polymer structure (Folkman and Hochberg, 1973). Much became known about the chemical environment surrounding these compounds as they degraded. The ratio of the surface area to mass can be altered or the porosity of differing configurations can be changed. The size of the pores of polymers of the same porosity can be altered to increase or decrease the intrinsic strength and elasticity of the polymer matrix, as well as compressibility or creep recovery. We can also change the rate of degradation of the polymer matrices and the environment into which the cells are implanted by systematically altering the surface chemistry of the polymers, creating an acidic or basic environment as they degrade. For instance, polyaminocarbonates cause a local basic environment, whereas poly(glycolic acid) and polyanhydrides cause a local acidic environment. Polyanhydrides and poly(ortho esters) show sur-

*Fig. 47.1. Scanning electron micrograph demonstrating the uniform distribution of cells suspended in the naturally occurring hydrogel calcium alginate.*

face erosion; other polymers show bulk erosion. By manipulating design configurations one can increase and decrease the surface area of the polymers. Also, synthetic polymers offer the advantage of consistent reproduction, and thus varying quality is not a problem as it sometimes is with naturally occurring polymers. With synthetic polymers, one has the potential of adding side chains to the polymer structure. Thus one might potentially deliver nutrients and hormones to the cells as the polymer breaks down.

Scaffold materials play a critical role in providing mechanical stability to constructs prior to synthesis of new extracellular matrix by the cells. It is then desirable to match the mechanical properties of the material with that of the tissue. Consequently, scaffolds for bone often contain ceramic hydroxyapatite, which has high stiffness like bone, and scaffolds for cartilage and tendon tend to be made from more compliant polymers. In addition to mechanical stability, scaffold materials often serve to reduce immune response to allogeneic cells. The most notable example of this is encapsulation of pancreatic islet cells for diabetes treatment.

During the past decade, many groups have turned to the use of synthetic biodegradable polymers as templates to which cells adhere and are transplanted. The polymers act as a scaffolding that can be engineered to allow for implantation of transplanted cells within only a few cell layers from the capillaries, and thus allow for nutrition and gas exchange by diffusion until successful engraftment is achieved. In this manner, it is hoped to generate permanent functional new tissues composed of donor cells and recipient interstitium and blood vessels.

A variety of biodegradable materials have been used for tissue scaffolds, including ceramics and polymers. The primary use of ceramics has been in tissue engineering of bone, where porous formulations of hydroxyapatite have been used to carry osteoprogenitor cells derived from perios-

teum or bone marrow. Typically, ceramic materials have long degradation times *in vivo*, often on the order of years. Synthetic polymers have seen widespread use as scaffold materials, due to their good processing characteristics. These materials have a range of degradation times from very short (days) to long (several months). Typically, polymer scaffolds are in the form of fibrous meshes, porous sponges or foams, or hydrogels. The more common polymers used in fibrous meshes and foams include the linear polyesters, e.g., poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and polycaprolactone (PCL); poly(ethylene glycol) (PEG); and natural polymers such as collagen and hyaluronic acid (HA). Polymeric hydrogels have the distinct advantage of being injectable, which allows the delivery of the construct to be less invasive and thereby reduces surgical risks. Employment of these types of polymers also ensures delivery of an even distribution of a precise number of cells. They can be configured to provide mechanical support to the cells to maintain their specific phenotype, without inhibiting migration. Common hydrogel substrates include the copolymers of poly(ethylene oxide) and poly(propylene oxide), known as Pluronics, and natural polymers, including alginate and agarose. The delivery of a known concentration of cells is simplified when using a hydrogel, whereby 100% of the cells are encapsulated within the delivery system, as compared to the fibers, for which cell delivery is dependent on cell attachment. The hydrogels also allow the suspended cells to be uniformly distributed throughout the volume of polymer delivered (Fig. 48.1). In contrast, the distribution of cells in the polymer fiber system is not uniform and is difficult to predict.

As the demand for new and more sophisticated scaffolds develops, materials are being designed that have a more active role in guiding tissue development. Instead of merely holding cells in place, these bioactive matrices are designed to encourage cell attachment to the polymer through cell surface adhesion proteins. Toward this end, polymers that have been synthesized have an integrin polypeptide sequence (RGD) in the backbone (Shakesheff *et al.*, 1998; Hern and Hubbel, 1998) or branches (Harrison *et al.*, 1997), or are constructed entirely of polypeptide sequences (Petka *et al.*, 1998). This allows the scaffold effectively to mimic the extracellular matrix and induce attachment of cells directly to the material. This may be particularly important in tissues that bear mechanical loads, because it would allow physical stimuli to be sensed by the cells in the developing tissue in a more physiologic manner.

## STRUCTURAL TISSUES

### BONE

In initial studies of bone tissue engineering, series of studies were performed to identify substrate features that would allow cells to be anchored and were thus important for maintaining cell function. Identification of these properties allowed us to incorporate them into appropriate polymer scaffolds to be used for transplantation. For example, when some cell types are cultured under conventional conditions, such as on plastic or collagen-coated dishes, gene transcription is depressed and cell-specific mRNA declines, whereas the mRNA of structure-related genes increases many fold. By contrast, when cultured on extracellular matrix, rich in laminin and type IV collagen, some cell types exhibit increased longevity and maintenance of several cell-specific functions. The capability of gene transcription persists (Bucher *et al.*, 1989) when cells are cultured on extracellular gel matrix. We learned that cell shape and function could be controlled by varying the coating density of any of a variety of different naturally occurring ECM substrates on bacteriologic plates (Mooney *et al.*, 1990a). Some cell types exhibit a rounded morphology when cultured on low-density ECM, and an increase in ECM coating density results in more spreading of the cells and epithelial-like morphology. ECM coating density also seems to affect the ability of the cells to enter the synthetic phase (S) and continue through the cell cycle, not exhibiting the S phase in low-density ECM studies but entering the S phase in a high percentage of the high-density ECM studies (Mooney *et al.*, 1990b). Some cell types are able to be switched between programs of growth and differentiation simply by modulating the ECM coating density, thereby altering the substratum's ability to resist cell-generated mechanical load. These and other studies also suggest that cell shape, which might be altered by manipulation of the physicochemical properties of the polymer, may be important in determining cell function. These principles, in combination with our studies, led us to conclude that the matrix to which specific cell types are attached *in vitro* is one of the most important variables in the engineering of new functional tissue.

New tissue-engineered bone is composed of donor cells embedded within recipient interstitium and blood vessels. We elected to work with biodegradable systems for reasons mentioned above. Our experience is based primarily on experience with cells derived from periosteum. We have employed several synthetic scaffolds as matrices. The first was a fiber-based scaffold composed of nonwoven mesh of fibers of poly(glycolic acid), 15  $\mu\text{m}$  in diameter, with average interfiber interspaces of 150–200  $\mu\text{m}$ . This was a polymer construct that had worked very well for the generation of tissue-engineered cartilage. Two other scaffolds for which we have accumulated a large body of data are injectable hydrogel systems, one being calcium alginate and the other being a reverse thermosensitive copolymer, referred to as Pluronic, composed of poly(ethylene oxide) (PEO) and poly(propylene oxide).

We initially chose periosteum as our source of cells to generate tissue-engineered bone. To demonstrate that these cells exhibited an osteoblast-like phenotype, they were nourished in media consisting of Tissue Culture Media 199 (Life Technologies; Baltimore, MD) with 10% fetal calf serum and 50  $\mu\text{g}/\text{ml}$  ascorbic acid with L-glutamine (292  $\mu\text{g}/\text{ml}$ ), penicillin (100 U/ml), and streptomycin (100  $\mu\text{g}/\text{ml}$ ) and were allowed to incubate *in vitro* at 37°C in the presence of 5%  $\text{CO}_2$ . Supernatant taken from the culture media was then analyzed for the presence of osteocalcin using a radioimmunoassay kit (Biomedical Tech. Inc.; Stoughton, MA). Our studies revealed that periosteal cells cultured in vitamin D-deficient medium secreted osteocalcin, ( $1 \pm 0.1$  fg/cell/day), whereas periosteal cells cultured in medium containing 1,25-dihydroxy vitamin  $\text{D}_3$  synthesized and secreted osteocalcin at a higher rate ( $3 \pm 1$  fg/cell/day), indicating that these cells indeed exhibited an osteoblast-like phenotype. Based on our experience with chondrocytes, we elected to seed various polymer constructs at a cellular density of 50–100 million cells/ml, at which time the cell–polymer complexes were then either injected/implanted immediately, or maintained *in vitro* for an additional 7–10 days (Vacanti *et al.*, 1993). When PGA fibers were employed, most of the fibers were coated with multiple layers of cells after a week to 10 days, at which time they were implanted subcutaneously. The cell–polymer constructs were excised and evaluated both grossly and histologically after being implanted for increasing periods of time.

As a result of several studies, we learned that cells shed from periosteum multiplied well *in vitro*. Implants seeded with periosteal cells resulted in the generation of what initially appeared to be cartilage, both grossly and histologically, within the first few weeks after implantation. In time, however, all specimens matured to form new bone containing the cellular elements of bone marrow. The rate of the morphogenesis from cartilage to bone correlated with the site into which the cell–polymer construct had been implanted, and seemed to be related to the vascularity of the site. This is in contrast to our experience with polymers seeded *in vitro* with chondrocytes rather than osteocytes. Chondrocyte-seeded implants generated cartilage that did not undergo a morphogenesis to bone, regardless of the site and the duration of time they had been implanted. To support this observation, bone defects surgically created in both weight-bearing and non-weight-bearing bones of male nude (athymic) rats were filled with polymer seeded with chondrocytes, periosteal cells, polymer alone, or nothing at all. Non-weight-bearing defects, 3–4  $\text{cm}^2$ , were created in the temporal and parietal bones using a dremel drill. Defects were made through the entire thickness of the bone down to the underlying dura, which was left intact. Weight-bearing defects were approximately 3 cm long and consisted of excision of the middle third of the femoral shaft, which was then bridge plated and filled as described above. Eight weeks after each weight-bearing defect had been created and “repaired,” the bone shaft was exposed, the bridge plate removed, and the area in which the defect had been created was examined. Wounds in animals having defects repaired 8 weeks earlier with polymer seeded with either periosteal cells or chondrocytes were then closed and the animals were allowed to recover from anesthesia and ambulate ad lib. We again observed that implants seeded with periosteal cells resulted first in the generation of “cartilage,” which ultimately underwent a morphogenesis to become bone. In contrast, polymers that had been seeded *in vitro* with chondrocytes remained hyaline cartilage regardless of the site of implantation, and remained cartilage even when it had been generated within a weight-bearing bone and allowed to ambulate on the tissue-engineered cartilage after the bridge plate had been removed.

These studies have led us to question the currently accepted concepts of endochondral ossification. It is interesting that the wave of advancing ossification in specimens of “cartilage” generated from polymers seeded with periosteal cells and undergoing a metamorphosis to become bone appears histologically to very closely resemble the growth plate, or epiphysis, of growing long bone

Fig. 47.2. Synthetic polymer mold of a rat distal femur seeded with periosteal cells.

in immature animals. In this system, it appears that implanted progenitor cells first develop into chondrocytes, followed by maturation into osteocytes. This provides support for the so-called “transdifferentiation” hypothesis, which was posed as an explanation for the mechanisms for long bone growth (Thesingh *et al.*, 1991).

When using periosteal cells, however, the generation of bone is optimized by the use of calcium alginate. The engineered tissue appears to extract the calcium from the hydrogel as it undergoes morphogenesis to bone. By using calcium alginate as a vehicle for delivery of periosteal cells, we have been able to make molds in specific shapes, such as the distal femur of a rat, which results in the generation of tissue-engineered bone of the same shape (Figs. 47.2 and 47.3). A vascularized pedicle of tissue-engineered bone has been successfully generated by molding a synthetic scaffolding, seeded with periosteal cells, around a vascular bundle. This vascularized pedicle of bone can then be transplanted into a large bone defect. Current efforts in the field are examining the efficacy of this approach in generating bone in large animals using autologous cells, as well as the ability to generate composite structures of bone and cartilage.

### CARTILAGE

The focus of cartilage tissue engineering to date has been in two main areas: orthopedic surgery and plastic and reconstructive surgery. In the field of orthopedic surgery, significant interest has been generated in the area of articular cartilage repair, sparked by a report of autologous chondrocyte transplantation in humans (Brittberg *et al.*, 1994). These studies involved harvest of cartilage from those locations of the articular surface that are deemed “low weight bearing,” isolation and culture of these cells, and injection of these cells in saline under a periosteal flap sewn over a focal defect. Results of these studies have been encouraging; however, interpretation of the data has been clouded by the inability to assess the possible contributions of cells from the periosteum, which have been used in separate studies to stimulate articular cartilage repair (O’Driscoll *et al.*, 1994).

Numerous other studies have investigated seeding of articular chondrocytes onto various synthetic and natural polymer substrates, including PGA (Freed *et al.*, 1993), PEO (Elisseeff *et al.*, 1999), fibrin glue (Silverman *et al.*, 1999), and collagen gels (Nehrer *et al.*, 1998). In addition, studies have addressed the issue of chondrocyte attachment to native cartilage matrix (Peretti *et al.*, 1998) and the ability of pieces of cartilage to generate mechanically functional repair tissue (Peretti *et al.*, 1999; Reindel *et al.*, 1995). To complement these efforts, enhancement of the car-

Fig. 47.3. (A) The tissue-engineered femur generated from the seeded mold shown in Fig. 47.2. Note that it has the same dimensions. (B) Histologic appearance, using hematoxylin and eosin stains, of the excised specimen. Note the lamellar structure of the new bone as visualized under polarized light. (C) Note the formation of what appears to be a haversian system in the specimen.

tilage repair process has been attempted using a variety of growth factors, including transforming growth factor  $\beta$  (TGF- $\beta$ ) (Glansbeek *et al.*, 1998) and bone morphogenetic protein 2 (BMP 2) (Sellers *et al.*, 1997).

Attempts at tissue engineering cartilage for orthopedic applications have not been restricted only to articular cartilage. Studies documenting tissue engineering of the meniscus (Ibarra *et al.*, 1997) and intervertebral disc (Kusior *et al.*, 1998) demonstrate the potential for regeneration or replacement of other cartilaginous tissues in the musculoskeletal system in addition to articular cartilage.

Efforts in cartilage tissue engineering for plastic and reconstructive surgery have had a slightly different focus than those in orthopedic surgery. Due to the types of tissues being replaced, the mechanical constraints and requirements for cartilage used in non-weight-bearing structures are much less. However, in these applications, new challenges arise around creating constructs in complex geometries that retain their form as they develop into cartilage. Several techniques have evolved specifically for the purpose of creating these forms, including the use of PLA-reinforced PGA scaffolds (Kim *et al.*, 1994) and injection molding of seeded hydrogels (Rowley *et al.*, 1998). Using these approaches, cartilage has been engineered for the replacement or reconstruction of the ear (Cao *et al.*, 1997), temporomandibular disc (Puelacher *et al.*, 1994a), nasal septum (Puelacher *et al.*, 1994b), orbital floor (Kim *et al.*, 1994), and nipple (Cao *et al.*, 1998).

An additional complication for the use of tissue-engineered cartilage for these applications lies in the subcutaneous environment in which implants are placed. Compared to the articular environment, the immune response evoked by implants is much greater in subcutaneous or intramuscular sites. This immune response may result from foreign body reaction to the material scaffold, or may be part of the general wound healing process resulting from implantation surgery. In both of these cases, the cells and the materials of a tissue-engineered construct are exposed to histiocytes and macrophages, as well as a variety of chemical and biochemical factors that may adversely affect the implant. Specifically, these environments are often at lower pH, which will accelerate the degradation of polyesters such as PGA and PLA. Further, inflammatory factors such as tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) and interleukins (IL-1 $\alpha$  and  $\beta$ ) are known to degrade cartilage and compromise the mechanical integrity of the tissue (Bonassar *et al.*, 1997).

For any potential therapeutic application involving tissue engineering of cartilage, expansion of the cell population *in vitro* is an important step in the process of building a construct. In the process, it is important to ensure that the expanded cell population retains its phenotypic function. This is of great concern for chondrocytes, which will dedifferentiate on repeated passaging (Benya and Shaffer, 1982).

The quality of newly engineered tissue is not only a function of optimal matching of the cell type to polymer matrix employed, but also of the animal species studied. In nude recipients for example, the fiber system is an excellent scaffolding for the generation of cartilage, whereas injectable hydrogels seem to be superior when engineering the same type of cartilage in immunocompetent animals using autologous cells. Excellent results are produced when delivering chondrocytes in the Pluronic system. This is in contrast to the use of calcium alginate, whereby the chondrocytes are encapsulated in a vehicle that seems to impair cell replication, and takes a long period of time to degrade. When chondrocytes are delivered in Pluronic, the polymer degrades much more rapidly, allows for cell replication with minimal inflammatory response, and generates excellent cartilage in higher species using autologous cells.

## TENDON AND LIGAMENT

Initial efforts in tissue engineering of tendon and ligament began with the use of denatured collagen as a scaffolding for generation of an anterior cruciate ligament repair. This material is implanted, not seeded, with cells, but ultimately is seeded by the host. Synthetic devices to replace or reinforce biologic materials have been used as grafts, with the belief that these materials would act as scaffolds on which fibrous tissue could be induced to proliferate and form ligamentous and tendinous tissues. It has been proposed that, in the presence of a tensile force, immature fibrous tissue so formed will gradually mature, with its fibers oriented functionally (Fujikawa, 1989; Jenkins *et al.*, 1976). However, this is disputed by reports (Andrish and Woods, 1984; Aronczyk *et al.*, 1986; McPherson *et al.*, 1985) that the induced tissue is characterized by a chronic foreign body reaction and by disorderly collagen fibers. The use of carbon fiber-derived scaffolds that are even-

tually replaced by fibrous tissue to ultimately replace the lost function of a tendon or ligament was extensively studied in the 1970s and 1980s (Forster *et al.*, 1978; Jenkins, 1978; Jenkins *et al.*, 1980; Tayton *et al.*, 1982; Rushton *et al.*, 1983). Nevertheless, the fact that carbon particles did not disappear completely, and were eventually found in regional lymph nodes even several years later, discouraged use of such scaffolds (Jenkins *et al.*, 1980). Later, carbon fibers were shown to somehow inhibit tendon fibroblast growth (Ricci *et al.*, 1991). Mendes *et al.* then concluded that collagen fibers did not significantly contribute to the tensile strength of carbon fiber composite ligaments and tendons (Irie *et al.*, 1992). Although some authors continue to report good results with their use (Demmer *et al.*, 1991), no significant differences have been shown in the outcome of patients in whom such devices have been used to reinforce or augment biologic grafts (Strum and Larson, 1985). Other synthetic materials such as Dacron have been used to replace or augment tendinous grafts in the treatment of injuries to the ligaments in the knee. However, histologic and biochemical studies have demonstrated that Dacron-induced fibrous tissue more closely resembles scar or granulomatous tissue than it does neoligament, and it has been shown to elicit a foreign body inflammatory reaction (Irie *et al.*, 1992).

Concerning the use of collagen tendon prostheses (Goldstein *et al.*, 1989; Kato *et al.*, 1991), such prostheses have been shown to have structures and mechanical properties similar to those of autogenous tendon grafts (Kato *et al.*, 1991). These implants are invaded by the host's fibroblasts and are eventually reabsorbed, giving way to the formation of a neotendon, following a biologic pathway similar to those of autografts and allografts. The use of xenografts (Milthorpe, 1994) or animal-derived collagen devices (Tauro *et al.*, 1991) has also been studied. Although they have advantages related to availability, decreased risk of transmission of infectious diseases, and avoiding damage to the patient's healthy tissues, the preparation of the grafts apparently affects significantly their biomechanical properties, and the possibility of rejection can still limit their use. Tendon autografts and allografts are currently the most commonly used substitutes to reconstruct injured ligaments or tendons. Allografts, however, still face the risk of potential transmission of infectious diseases (Conrad *et al.*, 1995; Asselmeier *et al.*, 1993), and some of the techniques used to sterilize them present the possible risk of affecting the biomechanical characteristics of the grafts (Rasmussen *et al.*, 1994). Tendon autografts are perhaps the most commonly transplanted tissue structures. Their biologic and biomechanical characteristics serve their purpose relatively well, considering that usually they rely on creeping substitution by the host's cells of a frequently inert organic scaffold from which most cells have usually disappeared (Aronczyk *et al.*, 1982; Rougraff *et al.*, 1993; Bosch and Kasperczyk, 1993; Abe *et al.*, 1993; Lane *et al.*, 1993; Kasperczyk *et al.*, 1993). Autografts, however, present the disadvantage of creating a secondary morbid site during harvesting, and the fact that a functioning structure has to be removed from its original site for use in a nearby or remote site.

## BIOMECHANICS

An understanding of the structure of engineered constructs needs to be closely associated with an assessment of tissue function. Indeed, the entire motivation for the field of tissue engineering is to restore function of tissue lost to disease, accident, or malformations. Therefore, it is critical to determine the extent to which the functional properties of generated tissues are similar to those of native tissue. The focus of many tissue engineering applications is on structural tissues, such as bone, cartilage, tendon, skin, and muscle, necessitating the analysis of the biomechanical properties of generated tissues. As with a discussion of tissue biochemistry or molecular biology, an understanding of the biomechanical properties of engineered tissue must start with an understanding of the mechanical properties of the native tissue. And as with the previous discussion, this requires an assessment of the level of sophistication that adequately describes the system. Tissues with nonlinear or time-dependent mechanical responses may not be adequately described by a modulus determined at equilibrium or at a single strain rate. Indeed, soft tissues such as skin, tendon, muscle, and cartilage require viscoelastic or poroelastic parameters in addition to the modulus to describe their mechanical behavior.

Further, it is critical to understand the relationship between the structure of native or engineered tissues and their mechanical properties. Tissues such as tendon and ligament can endure high tensile elongations due to the high content of collagen and elastin in the extracellular matrix. In a similar way, cartilage is composed of a highly charged proteoglycan network and a cross-linked

collagen that strengthen the tissue in compression and shear, respectively. The composition of bone includes a variety of extracellular matrix proteins, including collagen, as well as a mineralized component of predominantly hydroxyapatite. This mineral component gives bone not only its extraordinary compressive strength, but also its brittleness in tension or shear.

Adequate understanding of the mechanical properties of structural tissues is not only an important yardstick for evaluating tissue-engineered constructs, but also provides an important set of design criteria for material scaffolds. Even at the initial stages of development, engineered constructs implanted into a defect site must in some way endure the stress, strains, and flows to which the surrounding tissues are exposed. This is, in fact, reflected in the types of materials used in existing efforts to engineer structural tissues: ceramics for bone, polymer fibers and cross-linked proteins for tendons and ligaments, and hydrogels and polymer meshes for cartilage.

## CONCLUSION

From these studies we learned that if cell anchorage sites and reasonable structural cues are provided in an appropriate environment, the intrinsic ability of cells to reorganize and generate new tissue is enhanced. The efforts described enable the natural ability of the cells to reconstitute as functional tissue, and intercellular signaling mechanisms and a predetermined expression of genes may be the ultimate driving mechanisms behind the principles of tissue engineering that we have discussed. It is our hope to develop this system to maximize the potential of cells to generate functional replacement tissue as an alternative to conventional organ transplantation and tissue reconstruction. Advances in polymer design are allowing us to utilize this ability fully. We anticipate the onset of human trials with these structural cells within the next few years.

# BONE REGENERATION THROUGH CELLULAR ENGINEERING

Scott P. Bruder and Arnold I. Caplan

## INTRODUCTION

A teenager is found to have a tumor in the midshaft of the femur. To save this young individual's life, a large segment of the bone is excised. Why is it that the patient cannot simply regenerate bone to fill the huge gap? A baby is diagnosed as having osteogenesis imperfecta (OI) (brittle bone disease) caused by a single point mutation in the gene for type I collagen (Byers and Bonadio, 1985). If it is a "mild" penetrance, the parents will see their child grow to be a dwarf with multiple fractures of many of its bones. How can we cure this malady, given that we now know its cause? An elderly woman falls, fractures her hip, and never regains mobility. Osteoporosis has reduced both her total bone mass and her ability to produce enough new bone to heal the fracture. How can we replenish the supply of bone-forming cells in this condition? These three medical problems appear to be quite dissimilar, but potentially, through cell-based therapies, the skeletal tissues of these patients can be engineered to cure themselves by accomplishing what they cannot do normally. The key to any medical intervention is to mobilize and induce the body to accomplish feats that it does not normally have the capacity to do. In the first case, the solution is to grow osteoprogenitor cells in large enough numbers (Bruder and Jaiswal, 1996) to fill the excision gap. For this scenario, it is now possible to grow mesenchymal progenitor cells outside the body and then put them back in such a way that bone will be regenerated in a mass not normally possible. In the second case, the normal type I collagen gene will be molecularly inserted into osteoprogenitor cells, which continually renew themselves, so that when their eventual progeny naturally replace osteoblasts, the bone-forming cells of the body, bone will be fabricated with a normal type I collagen matrix. Alternatively, patients with OI can be exposed to chemotherapeutic drugs to destroy their bone marrow and normal, immunomatched allogeneic marrow containing normal osteoprogenitor cells can be grafted into the OI patient (Horwitz *et al.*, 1999). In this case, these normal osteoprogenitor cells will produce normal progeny that will replace the genetically defective osteoblasts that routinely expire. And in the third case, age-related bone loss and diminished repair potential may be prevented by periodic administration of autologous osteoprogenitor cells.

The key issues that control the successful medical interventions depicted above involve defining the parameters that govern natural regeneration and turnover of bone and engineering new technologies to make use of such insight. The primary assumption is that the principles that govern regeneration and natural turnover are, to some extent, recapitulations of embryonic-formative events and that reparative strategies must be structured to follow these recapitulation parameters.

## MARROW: THE SOURCE OF MESENCHYMAL PROGENITOR CELLS

The challenge of mesenchymal tissue regeneration is to bring large numbers of multipotent progenitors to the regeneration site as quickly as possible; the rapid formation of a mesenchymal

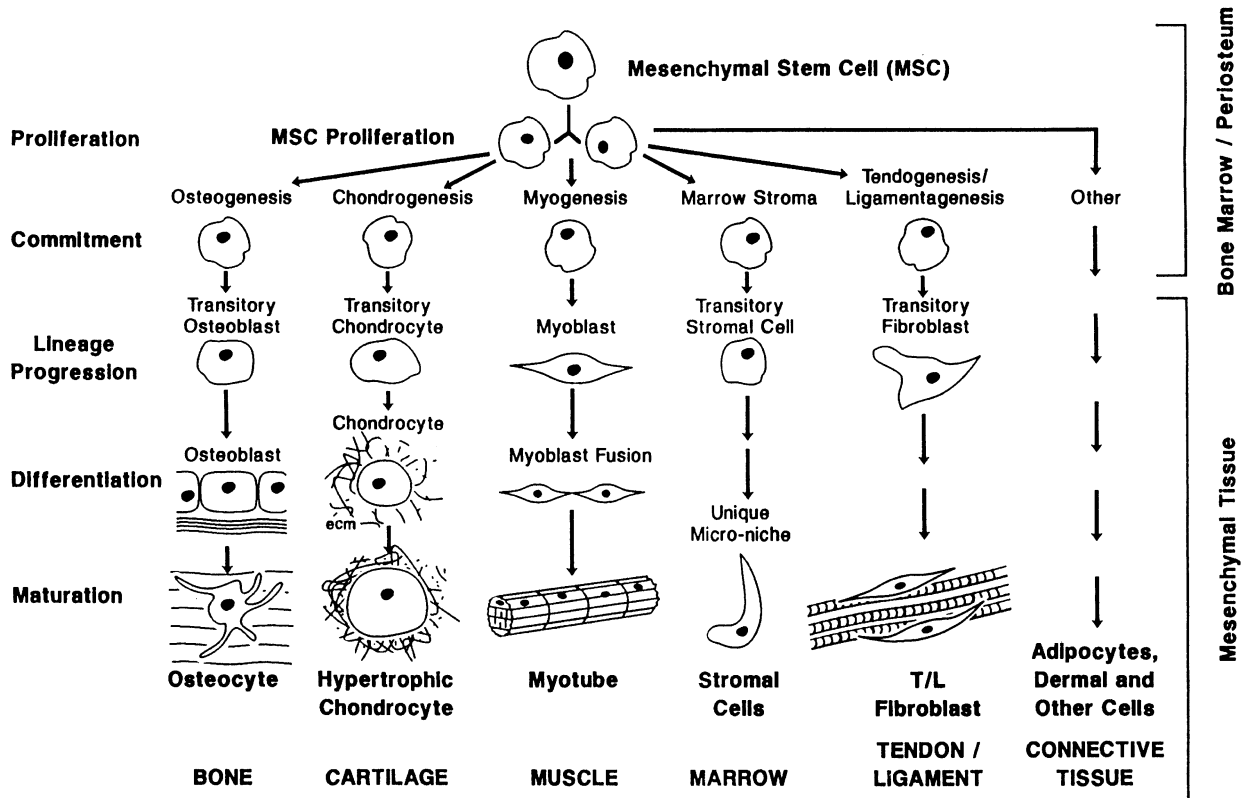

Fig. 48.1. The mesenchymal process. MSCs have the potential to differentiate into a variety of mesenchymal tissues, such as bone, cartilage, tendon, muscle, marrow, dermis and fat. Proliferating MSCs enter a lineage, following their commitment to that particular pathway. The commitment event involves the action of specific growth factors and/or cytokines, as does the next phase, in which the lineage-committed cells progress through a number of transitory stages in the lineage progression process. Terminal differentiation involves the cessation of proliferation and the massive biosynthesis of tissue-specific products. Last, these differentiated cells go through a maturation stage in which they acquire an ability to function in aspects of tissue homeostasis as opposed to high levels of synthetic activity. All of these end-stage-differentiated cells have fixed half-lives and can be expected to expire; these cells are replaced by newly differentiated cells arising from the continuous transition down the lineage pathway. The lineages are arranged from left to right based on the relative information known about definitive lineage stages.

blastema of critical size is the key step, because the waves of wound site instructional cues are ever changing and must coordinate with the mesenchymal differentiation sequence. There are several repositories of such mesenchymal progenitors in adults, with bone marrow and periosteum being the most accessible (Haynesworth *et al.*, 1992b; Nakahara *et al.*, 1990, 1992). Orthopedic surgeons have long understood that vascular continuity, excess marrow, and intact periosteum function to accelerate bone repair/regeneration (Hamm, 1930; Kojimoto *et al.*, 1988; Brighton, 1984). Notably, bone marrow has been studied in both human and animal models and has been shown to house isolatable osteochondral progenitor cells that we operationally refer to as mesenchymal stem cells (MSCs) (Haynesworth *et al.*, 1992a,b; Friedenstein, 1976; Owen, 1985; Beresford, 1989; Bruder *et al.*, 1990; Owen and Friedenstein, 1988; Caplan, 1991, 1994; Dennis and Caplan, 1993; Caplan *et al.*, 1993). In principle, these MSCs can differentiate into a number of mesenchymal phenotypes by entering discrete lineage pathways, as shown in Fig. 48.1. We have developed the technology to isolate these cells from bone marrow (Fig. 48.2) of patients ranging from newborns to individuals in their eighth and ninth decade of life (Haynesworth *et al.*, 1992a,b, 1994; Beresford, 1989). Importantly, there appears to be a decrease in the number of MSCs per total nucleated cells in marrow as a function of age (Oreffo *et al.*, 1998; Muschler *et al.*, 1997; Kahn *et al.*, 1995; Egrise *et al.*, 1992). This age-related deficit may be the cause of the reduced potential and/or kinetics of skeletal repair in older patients.

Fig. 48.2. MSC purification. A marrow aspirate of 10–20 ml is obtained with standard clinical biopsy procedures. Large particles of bone chips are removed and the cells applied to Percoll density gradient centrifugation, following the procedures of Haynesworth et al. (1992b). The MSCs are localized in the low-density fraction. The MSCs are recovered at a pooled density of 1.03 g/ml, centrifuged, resuspended in Dulbecco's modified Eagle's medium plus 10% fetal bovine serum from selected lots (Lennon et al., 1996), and seeded into cell culture dishes. The MSCs selectively adhere while most hematopoietic cells remain in suspension. Approximately 1000 to 3000 MSCs are recovered in these primary cultures and they grow as colonies.

Because it is now possible to isolate MSCs from bone marrow, and expand them in culture away from all hematopoietic and vascular cells, one can establish therapeutic paradigms for the treatment of mesenchymal tissue defects. These cells can flourish in culture, and when reintroduced into *in vivo* test sites, MSCs can differentiate into a variety of site-specified phenotypes, including bone-forming cells. That marrow contains uniquely potent mesenchymal progenitors has been clearly documented by isolating clones of such progenitors and documenting that the progenies of these single cells are capable of differentiating into a variety of mesenchymal phenotypes (Dennis and Caplan, 1996; Dennis et al., 1999; Pittenger et al., 1999).

This basic information is the foundation for our vision of regenerative tissue therapy, which capitalizes on the replicative potential of MSCs, their bioactivity following cryopreservation, and their ability to form appropriate tissue types after implantation in a site in need of tissue regeneration (Fig. 48.3). We have previously shown that MSCs, from a small marrow biopsy of an adult, can be passaged for over 30 population doublings *in vitro* and expanded in number by over 1 billion-fold without loss of testable osteogenic potential (Bruder et al., 1997b). Based on experiments indicating that MSCs are present in young adults at a level of 200 per milliliter of whole marrow, this billion-fold expansion is equivalent in MSC number to many thousands of liters of harvested

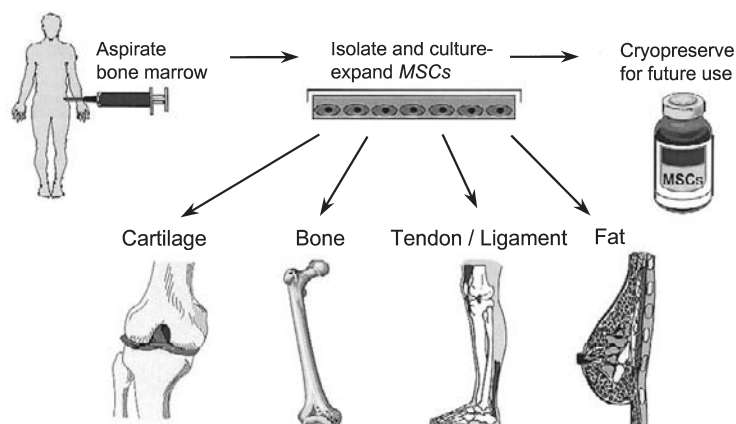

Fig. 48.3. Regenerative tissue therapy. Marrow is harvested and MSCs purified and seeded into cell culture, where they proliferate. These cells can be cryopreserved or used for cartilage resurfacing, bone repair, tendon/ligament repair, or adipocytic implantation. Suspensions of cells may also be injected for the treatment of osteoporosis or as an adjuvant therapy to bone marrow transplantation to improve the quality of marrow stroma.

Miscellaneous antigens Transferrin receptor, CD9, Thy-1, SH-3, SH-4, SB-20, SB-21	CD4,CD14, CD34, CD45, von Willebrand factor

<sup>a</sup>Adapted from Bruder *et al.* (1998a) and Pittenger *et al.* (1999). Abbreviations: bFGFR, basic fibroblast growth factor receptor; PDGFR, platelet-derived growth factor receptor; IL-R, interleukin receptor; IFN-γR, interferon-γ receptor; TNFIR, tumor necrosis factor I receptor; TNFIIR, tumor necrosis factor II receptor; TGF-βIR, transforming growth factor-β I receptor; TGF-βIIR, transforming growth factor-β II receptor; EGFR-3, epidermal growth factor receptor 3; ICAM, intercellular adhesion molecule; VCAM, vascular cell adhesion molecule; LFA-3, lymphocyte function-related antigen-3, ALCAM, leukocyte cell adhesion molecule, PECAM, platelet endothelial cell adhesion molecule; CD, cluster designation.

whole marrow. The entire adult human body contains less than 6 liters of whole blood and obviously much less marrow. Thus, after only two to three subcultivations, enough MSCs could be generated to provide a sufficient number of osteoprogenitor cells ( $3-5 \times 10^8$ ) to fill a massive bony defect in adults; this number of MSCs is more than those present in the entire adult human body. We have extended these observations to provide a detailed analysis of the surface molecules that characterize culture-expanded human MSCs (Table 48.1) (Pittenger *et al.*, 1999; Bruder *et al.*, 1998a). This work stems from our continued effort to document the changes that occur in cell surface architecture as a function of lineage progression (Bruder *et al.*, 1997a, 1998d). The profile of cell adhesion molecules, growth factor and cytokine receptors, and miscellaneous antigens serves to establish the unique phenotype of these cells, and provides a basis for exploring the function of selected molecules during osteogenic and other lineage progression.

In view of the fact that MSCs are believed to be the source of osteoblastic cells during the processes of normal bone growth, remodeling, and fracture repair in humans (Owen, 1985; Bruder *et al.*, 1994; Hollinger *et al.*, 1998), we have used them as a model to study aspects of osteogenic differentiation. When cultivated in the presence of osteogenic supplements (OSs) (dexamethasone, ascorbic acid, and β-glycerophosphate), purified MSCs undergo a developmental cascade defined by the acquisition of cuboidal osteoblastic morphology, transient induction of alkaline phosphatase (APase) activity, and deposition of a hydroxyapatite-mineralized extracellular matrix (Jaiswal *et al.*, 1997) (Fig. 48.4A–C). Gene expression studies illustrate that APase is transiently increased, type I collagen is down-regulated during the late phase of osteogenesis, and osteopontin is up-regulated at the late phase (Bruder *et al.*, 1998a) (Fig. 48.4D). Similarly, bone sialoprotein and osteocalcin (Jaiswal *et al.*, 1997) are up-regulated late in the differentiation cascade, and osteonectin is constitutively expressed. Additional studies detail the growth kinetics and high replicative capacity of these cells, which do not lose their osteogenic potential following a 1 billion-fold expansion or cryopreservation (Bruder *et al.*, 1997b). We have documented that OS-treated MSCs secrete a small-molecular-weight osteoinductive factor into their conditioned medium, which is capable of stimulating osteogenesis in naive cultures (Jaiswal and Bruder, 1997), similar to that reported for rat marrow stromal cells directed into the osteogenic lineage (Hughes and McCulloch, 1991). We have completed a comprehensive series of pulse–chase and transient exposure experiments using dexamethasone to determine which steps of the lineage pathway are dependent on exogenous factors, and which are supported by either (1) paracrine/autocrine fac-

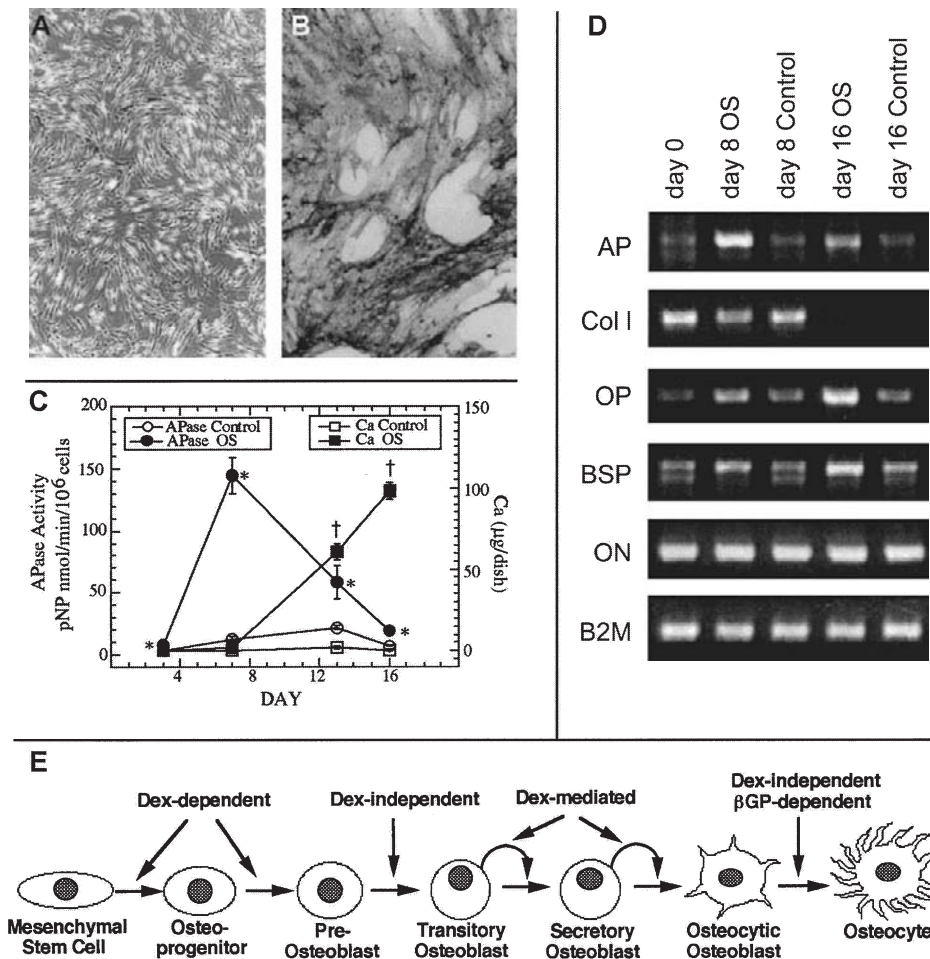

Fig. 48.4. Osteogenic differentiation of human MSCs *in vitro*. Phase-contrast photomicrographs of (A) human MSC cultures under growth conditions display characteristic spindle-shaped morphology and uniform distribution (unstained;  $\times 18$ ), and (B) human MSC cultures grown in the presence of osteoinductive supplements for 16 days and stained for APase and mineralized matrix. APase staining appears gray in these micrographs (originally red) and mineralized matrix appears dark (APase and von Kossa histochemistry;  $\times 45$ ). (C) Mean APase activity and calcium deposition of MSC cultures grown in control or OS medium and harvested on days 3, 7, 13, and 16 ( $n = 3$ ). The vertical bars indicate standard deviations; \* $P < 0.05$ ; † $P < 0.005$  (compared to control). (D) Expression of characteristic osteoblast mRNAs during *in vitro* osteogenesis. Reverse transcriptase–polymerase chain reactions using oligonucleotide primers specific for selected bone-related proteins were performed with RNA isolated at the indicated times. tors in culture or (2) sustained lineage progression events following brief exposure to dexamethasone (Bruder and Jaiswal, 1995; Jaiswal and Bruder, 1996). A diagrammatic representation of these results is presented in Fig. 48.4E).

## DELIVERY OF OSTEOPROGENITOR CELLS

It is clear that there is a coordinate relationship between bone formation and vasculature (Drushel *et al.*, 1985; Caplan and Pechak, 1987; Collin-Osdoby, 1994). It appears that vasculature provides the orientation for the secretory activity of osteoblasts and, hence, in engineering the delivery of osteoprogenitor cells to a reparative site, adequate space must be provided for the close juxtapositioning of capillaries to sheets of osteoprogenitor cells. Of importance to note here is the observation that if MSCs, at an *in vivo* site, aggregate into a dense mass in the absence of intervening capillaries, they differentiate into cartilage (Dennis and Caplan, 1993). Indeed, no one, to

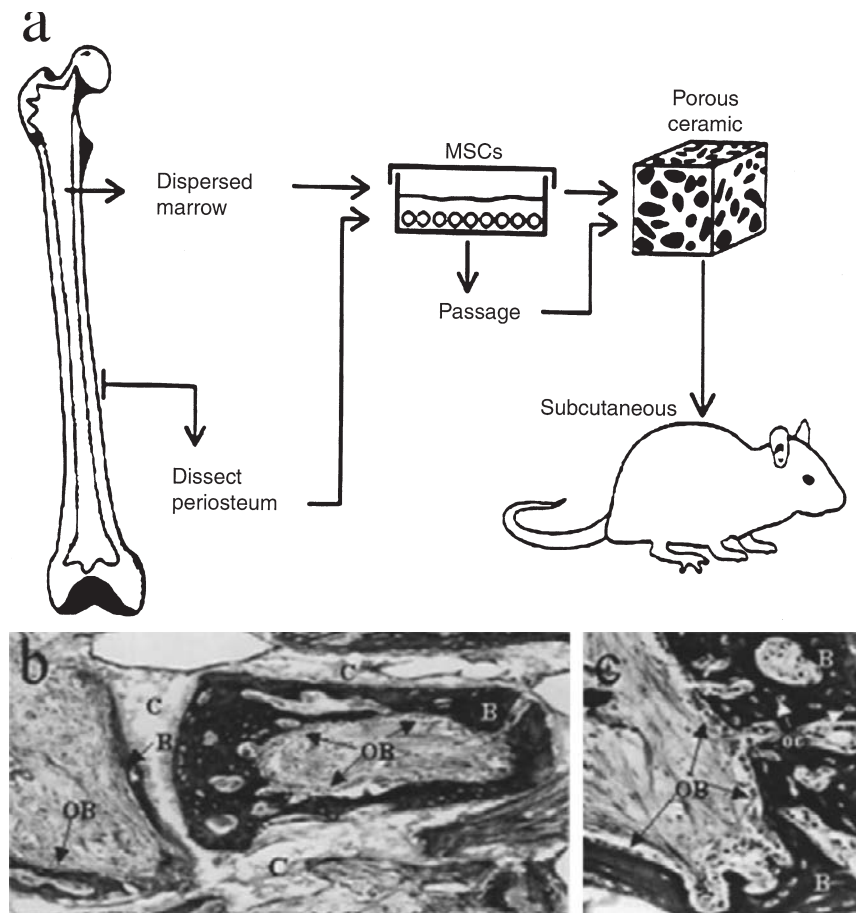

Fig. 48.5. The ceramic cube assay. (a) MSCs are isolated from bone marrow or periosteum and seeded into culture, where they adhere and mitotically expand. As the growing cells reach confluence, they are exposed to trypsin to liberate them from the dish and are either returned to new dishes (where they will continue to divide) or seeded into 3-mm porous calcium phosphate ceramic cubes. The cubes are then implanted into subcutaneous pouches in syngeneic or immunocompromised rodents. The cubes are harvested 3 to 6 weeks later and scored for the presence of bone and/or cartilage. (b) Histologic appearance of porous calcium phosphate ceramic loaded with MSCs and implanted subcutaneously in a syngeneic rat host. Six weeks after implantation bone is observed lining the surface of a pore. Vasculature is present at the center of the pore, and directs secretory osteoblasts (OB) to secrete bone matrix (B) onto the surface of the ceramic (C), which has been decalcified during histologic processing and thus appears as a grey granular material. Osteocytes are also present in regions of bone formation that are more advanced. (c) Illustration, at higher magnification, of active osteogenesis, with prominent palisades of osteoblasts (OB) laying down new bone matrix (B) with inclusion of osteocytes (oc). Mallory–Heidenhain staining.

our knowledge, has been successful in duplicating or mimicking the natural arrangement of sheets of secretory osteoblasts in a culture system. We suggest that this lack of success is due to our lack of detailed understanding about the key parameters involved in cell–cell, cell–matrix, and/or cell–vasculature relationships involved in osteogenic activity of secretory osteoblasts. Thus, it is important to construct a delivery system that has the potential to place sheets of osteoprogenitor cells in a configuration such that host vasculature can quickly position itself to provide the appropriate cueing. Likewise, the cell attachment face of the delivery vehicle should be a bonelike substance based on the view that such an environment could assist in the orientation of the osteoblasts' secretory products.

The success of such a cell-based approach for tissue engineering of bone is critically dependent on the development of an appropriate matrix scaffold for cell delivery. The ideal matrix formulation should possess several properties: (1) the material should foster uniform cell loading, cell

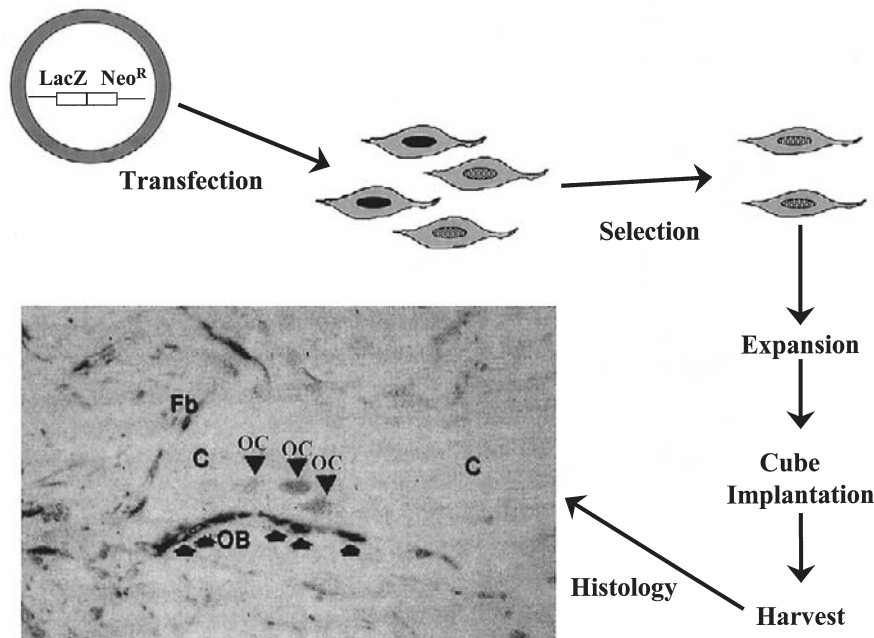

Fig. 48.6. LacZ expression and bone formation in vM5LacZ-transduced human MSCs. Human MSCs were transfected with a lacZ-containing retrovirus, selectively expanded in vitro, combined with ceramic cubes, and implanted in SCID mice. Mice were sacrificed and ceramic-cell composites were harvested 6 weeks later, X-Gal-stained for expression of LacZ, decalcified, embedded, sectioned, and counterstained with Mallory–Heidenhain. Osteoblasts (OB) are seen lining the surface of the ceramic (C), which also contains labeled osteocytes (OC) ( $\times 200$ ).

division, and retention; (2) the scaffold should support rapid vascular invasion; (3) the matrix should be designed to orient the formation of new bone in anatomically relevant shapes; (4) the composition of materials should be resorbed and replaced by new bone as it is formed; (5) the material should be radiolucent to allow the new bone to be distinguished radiographically from the original implant; (6) the formulation should encourage osteoconduction with host bone; and (7) it should possess desirable handling properties for the specific clinical indication.

This laboratory long ago explored the use of porous calcium phosphate ceramics together with whole marrow as a delivery vehicle for osteogenic cells at both heterotopic and orthotopic sites (Ohgushi *et al.*, 1989a,b). Based on this experience with whole marrow, we further refined the technology to allow us to efficiently situate culture-expanded MSCs onto the pore surfaces of such ceramic vehicles (Haynesworth *et al.*, 1992b; Dennis and Caplan, 1993; Dennis *et al.*, 1992). Figure 48.5a shows the outline of experiments wherein marrow or periosteal MSCs are obtained, culture expanded, and, with serial subculturing (passages), placed into a 3-mm porous ceramic cube, which is subsequently implanted into subcutaneous pockets in syngeneic or immunocompromised rodent hosts. We have used such ceramic cubes to assay the osteogenic potential of rodent, rabbit, goat, sheep, canine, and human MSCs (Lennon *et al.*, 1996; Kadiyala *et al.*, 1997b). Figure 48.5 shows the histologic appearance of newly forming bone in the pores of such a ceramic. The sheets are oriented, and secretory osteoblasts are clearly visible as new bone. Using cells that have been tagged by retroviral transfection with a reporter gene for  $\beta$ -galactosidase (*lacZ*), labeled osteoblasts and osteocytes derived from these MSCs can be observed in Fig. 48.6. Of importance is the fact that the stained cells were derived from labeled marrow-derived human MSCs, and that the characteristic cytoplasmic processes of mature osteocytes are observed in the newly fabricated bone within the pore of the ceramic vehicle. Notably, the osseous tissue that is formed in these implants is donor derived, and not dependent on the presence of host-derived osteoprogenitors (Allay *et al.*, 1997). This cube assay has now evolved into a semiquantitative assay to judge MSC number and/or osteochondrogenic potential (Dennis *et al.*, 1998; Cassiede *et al.*, 1996). To observe bone within the pores of the implant ceramic does not require an absolutely pure population of MSCs, because diluting the human MSCs by 50% with human dermal fibroblasts does not seem to affect the amount of bone in the ceramic cubes (Lennon *et al.*, 1999).

### BONE REGENERATION BY MSCs

To show clinical applicability of tissue regeneration therapies using MSCs, a series of pre-clinical studies was performed. These investigations, all aimed at achieving osseous regeneration

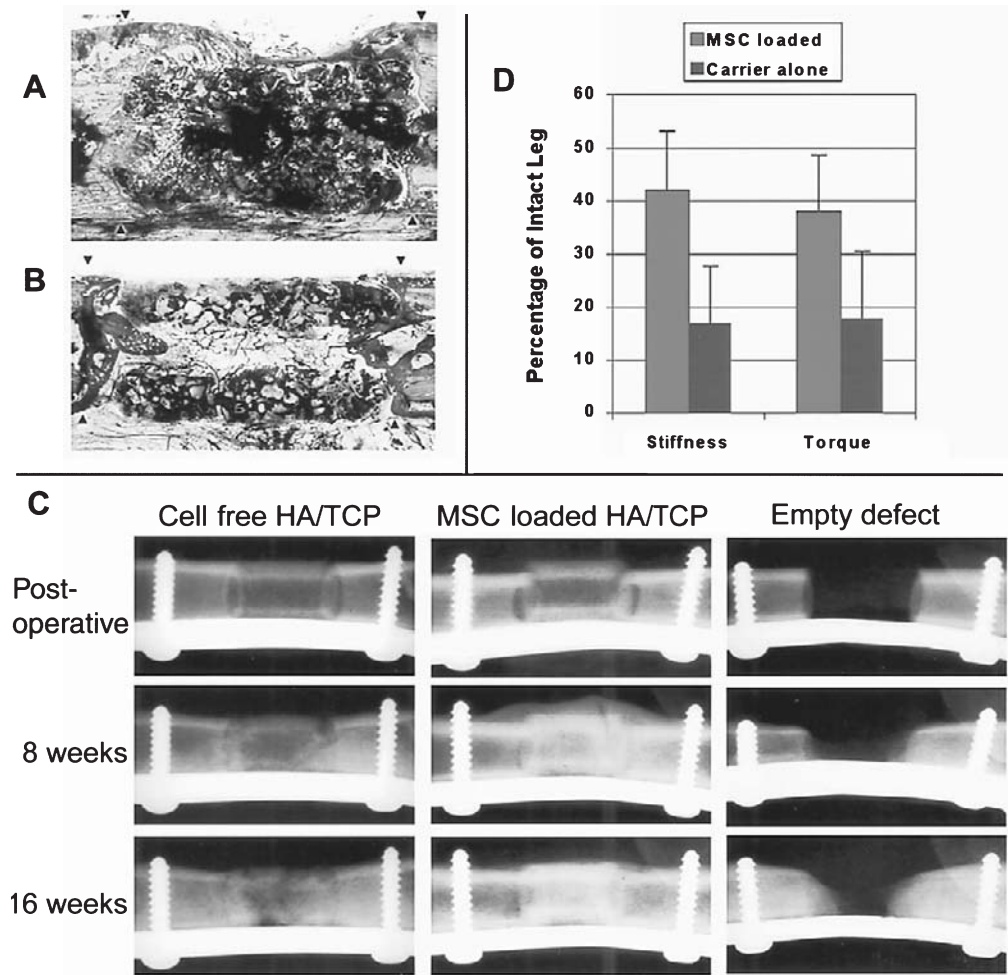

Fig. 48.7. MSC-mediated bone regeneration in preclinical animal studies of segmental defect repair. (A) Rat segmental defects fitted with a HA/TCP carrier loaded with syngeneic rat mesenchymal stem cells form a solid osseous union with the host, and contain substantial new bone throughout the pores by 8 weeks. (B) Defects fitted with a cell-free HA/TCP carrier do not contain bone within the pores of the implant, nor is there significant union at the interfaces, indicated by the arrowheads (stain, toluidine blue-O;  $\times 16$ ). (C) Radiographic appearance of bone healing in a 21-mm canine femoral gap defect 16 weeks after surgery. Animals that did not receive an implant had a fibrous nonunion. Animals that received a mesenchymal stem cell-loaded HA/TCP cylinder had a substantial amount of bone regeneration at the defect site, including a periimplant callus that remodeled to the size of the original bone by 16 weeks. Those animals receiving cell-free implants did not achieve healing of their defects, as is evident by the lack of new bone and the multiple fractures throughout the body of the implant material. (D) Results of biomechanical torsion testing performed on athymic rat femurs 12 weeks after implantation with human mesenchymal stem cell-loaded ceramics. Load to failure and overall stiffness was more than twice that of controls at the same time.

in a critical-sized defect of the femur, were designed to compare the efficacy and effective dosing when the cellular source was escalated from rodents to large animals, and eventually to humans. In the first study, culture-expanded, marrow-derived MSCs were used to repair a segmental defect in the femur of rats (Kadiyala *et al.*, 1997a). Syngeneic MSCs at a density of  $7.5 \times 10^6$  cells/ml were loaded onto a porous hydroxyapatite/ $\beta$ -tricalcium phosphate cylinder and implanted in an 8-mm-long diaphyseal defect. By 8 weeks, nearly every pore of the implants contained considerable new bone (Fig. 48.7A). In contrast, cell-free implants were well vascularized, but displayed little if any bone formation within the pores (Fig. 48.7B). In the defects treated with MSC-loaded implants, substantial new bone formation occurred at the interface between the host and the implant, leading to a continuous span of bone across the defect. Furthermore, a periosteal callus of

bone also was present in samples loaded with MSCs but not with cell-free implants. These studies established the proof of principle for MSC-based tissue regeneration therapy in bone.

The ability of MSC-loaded implants to repair defects in larger animals was examined in a canine femoral gap defect model (Bruder *et al.*, 1998b; Kraus *et al.*, 1999). The healing of a 21-mm osteoperiosteal defect was studied using ceramic implants made from porous hydroxyapatite/ $\beta$ -tricalcium phosphate that had been loaded with autologous culture-expanded MSCs at a density of  $7.5 \times 10^6$  cells/ml. At 16 weeks, atrophic nonunion occurred in all of the femurs that had untreated defects, and only a small amount of trabecular bone formed at the cut ends of the cortex of the host bone in this group (Fig. 48.7C). In contrast, radiographic union was established rapidly at the interface between the host bone and the implants in samples that had been loaded with MSCs. Numerous fractures, which became more pronounced with time, developed in the implants that had not been loaded with cells. Significantly more bone was found in the pores of the implants loaded with MSCs than in the cell-free implants. In addition, a large collar of bone formed around the implants that had been loaded with cells; this collar became integrated and contiguous with callus that formed in the region of the periosteum of the host bone. The collar of bone was remodeled during the study, ultimately resulting in a size and shape that were comparable with the segment of bone that had been resected. Osseous callus did not develop around the cortex of the host bone or around the implant in any of the specimens in the control groups.

Culture expanded *human* MSCs also have been shown to effect bone repair in a segmental gap defect model (Bruder *et al.* 1998c). Human MSCs were loaded onto ceramic cylinders similar to those described above, and used to repair an identical femoral defect created in athymic rats. Because these rats lack T lymphocytes, transplantation of xenogeneic material does not lead to graft rejection. Like the studies using syngeneic rat MSCs, substantially more bone was found in defects that received cylinders loaded with human MSCs than in those that received cell-free implants. With the MSC-loaded implants, complete union between bone and implant was achieved at 12 weeks. Before that time, there was an increasing amount of bone formed between the 4- and 8-week evaluation points. Biomechanical testing confirmed that femurs implanted with MSC-loaded ceramics were significantly stronger than those that received cell-free ceramics (Fig. 48.7D). Measurement of stiffness and torque showed increases of 245 and 212%, respectively, in the MSC-loaded samples compared with the cell-free carrier samples. These studies show that human and rat MSCs are capable of healing a clinically significant bone defect in a well-established model of bone repair.

The three studies described above show the success of using mesenchymal stem cells to regenerate bone in segmental defects. Using rat, canine, or human mesenchymal stem cells, bone fill ranged from 40 to 47% of available space, a value not likely to be exceeded given the nature of the scaffold and the requirement for vasculature and associated soft tissue (Kadiyala *et al.*, 1997a; Bruder *et al.*, 1998b,c). The cellular doses required to effect bone repair were constant across species, and the process of bone repair remained the same. The ability of the therapeutic approach to scale up in a predictable manner increases one's confidence that MSC-based therapies for bone repair will be effective in the treatment of human disease.

These studies indicate that culture-expanded MSCs can be presented in sufficient numbers in a supportive delivery vehicle to provide bony regeneration of a large, osteoperiosteal femoral defect in both small and large animals. Figure 48.8 depicts how this experience may potentially be used to construct an *autologous* cell-matrix composite for excision repair of femoral gaps and other osseous defects in humans. In the case pictured, we suggest that the use of an external fixator could allow load bearing by the patient shortly after implantation. If the fixator could be constructed to transfer partial load incrementally to the implant, the fixator could be sequentially off-loaded so that more and more load can be gradually transferred to the implant. As the MSCs differentiate into osteoblasts and fabricate bone onto the walls of the porous implant, the incremental loading would serve to orient the new bone and stimulate its acquisition of mechanical integrity. Eventually, the implant would carry 100% of the load and the external fixator could be removed so that no metal devices would remain. The delivery vehicle would be naturally replaced as osteoclasts resorb its matrix and osteoblasts replace it with new, host-derived bone as governed by the natural turnover sequence. The selection of appropriate biomaterials and configurations for each formulation will depend on the anatomic site for regeneration, the mechanical loads present at the site, and the desired rate of incorporation.

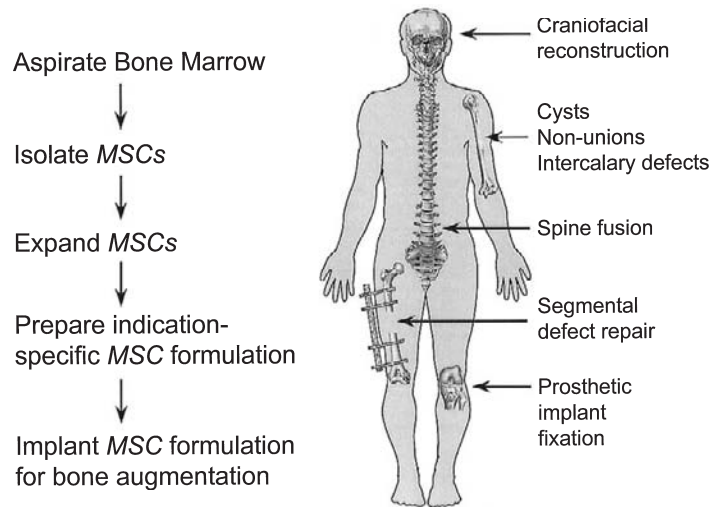

Fig. 48.8. Bone regeneration paradigm. MSCs are isolated from bone marrow and expanded in number in culture. When sufficient cells are available, they are loaded into an appropriate delivery vehicle and surgically inserted into the site requiring bone augmentation. In the case of segmental defect repair, an external fixator can be applied to initially carry all of the load by a device capable of the stepwise transfer of partial load to the implant. As bone forms in the implant, the load on the implant is sequentially increased to assist in orienting and stimulating bone formation. Eventually, 100% of the load is carried across the regenerated bone, at which time the external fixator is removed. In other clinical settings, fixation may not be necessary, or may take the form of simple casting.

It may also be possible to use allogeneic MSCs for these massive osseous repairs. In this case, the immunoreactive groups on the MSCs would need to be muted or inactive. The availability of allogeneic cell therapy, or universal donor cells, would provide easy access for trauma-related skeletal reconstruction or for gene therapy, as discussed below. In addition, we would propose that such allogeneic cells could be incubated in osteogenic supplement prior to implantation to cause them to all enter the osteogenic pathway. These osteogenic or jump-started cells could be loaded into the delivery vehicle, thereby accelerating the bone formation. In addition, the allo-MSCs would all become either osteocytes or would expire as osteoblasts. This accelerated bone formation would attract host-derived osteogenic cells to the repair site and the bulk of the repair bone would then become of host origin. Eventually, when the repair bone turned over, the allogeneic osteocyte-containing bone would be replaced by host bone, and immunosuppression therapy, if used, could be discontinued.

### MSCs AND GENE THERAPY

Figure 48.9 shows the hypothetical treatment of a patient with a genetic defect such as osteogenesis imperfecta. MSCs would be obtained from the patient, and, as they are mitotically expanded in culture, they could be transduced/transfected with a retrovirus containing the gene for normal type I collagen with its appropriate promoters. Such transfections have already been shown to allow the insertion of a selectable gene (*neo*) and a reporter gene (bacterial  $\beta$ -galactosidase) into human MSCs, without loss of the *in vivo* osteogenic potential of these transduced cells, as shown in Fig. 48.5 (Allay *et al.*, 1993, 1997). In order to effect efficient repopulation of the marrow by MSCs, the marrow must be injured. Hematopoietic progenitors could be obtained by current apheresis techniques (Brugger *et al.*, 1995) and the patient could then be given chemotherapy or radiation to compromise the bone marrow, followed by a transplantation of autologous hematopoietic progenitors to which the culture-expanded MSCs have been added. These cells would home to the bone marrow, reestablish themselves (Pereira *et al.*, 1995), and thus provide mesenchymal progenitors with the inserted normal type I collagen gene. As osteoblasts naturally and normally expire, the new osteoblasts would arise from transduced MSCs and would, hence, be "normal" relative to the synthesis of type I collagen and osteoid. This strategy depends on the

Fig. 48.9. Autologous gene therapy. MSCs are obtained from bone marrow and, as they proliferate in culture, a retrovirus or other vector is used to insert Gene A into the MSCs. The patient is exposed to radiation or chemotherapy to injure the marrow and to decrease the body pool of MSCs. Both autologous hematopoietic progenitors and MSCs are introduced intravenously, and they home to the bone marrow. Thereafter, as differentiated mesenchymal cells expire, they are replaced by newly differentiated mesenchymal cells, which originate from the MSC pool. These genetically altered MSCs will thus provide genetically altered progenies, which give rise to "normal" differentiated cells that express Gene A. Alternately, allogeneic MSCs with allogeneic hematopoietic progenitors, or allogeneic whole marrow, can be used to introduce genetically normal MSCs, as has been reported for OI patients (Horwitz *et al.*, 1999).

normal local *cueing* and the control of osteogenesis in the recovering and growing young patient. As long as the appropriate genetic control elements for type I collagen are present and the inserted gene does not interfere with other genes, this MSC transduction could, in principle, provide a molecularly engineered treatment for incurable bone diseases such as osteogenesis imperfecta. As previously stated, allogeneic bone marrow transplantation from normal donors could, likewise, accomplish this aim, as has already been reported (Horwitz *et al.*, 1999).

## PREVENTION OF AGE-RELATED BONE LOSS

Studies indicate that estrogen deficiency, which is involved in osteoporosis, leads to a diminution in the number of osteoprogenitors by virtue of their decreased proliferative potential (Tabuchi *et al.*, 1986). Similarly, the bone loss that occurs as a function of aging is likely due to the decrease in the number of resident MSCs. In view of this, early replenishment of the osteoprogenitor cell supply could serve to prevent, or even reverse, the bone loss associated with aging and osteoporosis. With this in mind, we have developed techniques and conditions for extensive subcultivation, without lineage progression, of human MSCs (Haynesworth *et al.*, 1992a,b; Lennon *et al.*, 1996). We have also shown that these cells can be cryopreserved and subsequently thawed for later use, with no loss in osteogenic potential (Bruder and Jaiswal, 1996; Bruder *et al.*, 1997b). Although it is advantageous to be able to increase dramatically the number of stemlike cells *ex vivo* for some clinical conditions, it may be desirable in other scenarios to stimulate osteogenic commitment and differentiation *in vitro* prior to reimplantation. This latter treatment could serve to hasten the *in vivo* lineage progression and thereby lead to more rapid and consistent bone formation. In the case of osteoporosis, however, providing culture-expanded autologous MSCs to the patient through an intravenous (Lazarus *et al.*, 1995) or intramedullary route should lead to a renewed source of endogenous MSCs. In this case, *in vitro* induction of osteogenesis would be undesirable, because the commitment of these cells would not allow their self-perpetuation as MSCs following reimplantation or infusion into the host. By repopulating the marrow reservoir with a "youthful" cache of undifferentiated mesenchymal progenitor cells, it should be possible for the body to recruit these cells into and maintain the normal bone remodeling cycle. Preliminary experiments from our laboratories, employing a standardized rat ovariectomy model, indicate that bone loss can be prevented via the systemic administration of syngeneic MSCs in rats (Fig. 48.10). Such a renewed

Fig. 48.10. Surgical removal of the ovaries from an adult causes the loss of circulating estrogen and subsequent bone loss. Culture-expanded MSCs can be introduced intravenously within a few weeks following ovariectomy to protect against such bone loss as measured by densitometric scanning or quantitative histomorphometry.

source of endogenous MSCs would also provide the cellular building blocks for the needs of other mesenchymal tissues. The utility of this self-cell therapy is that, because of our ability to manipulate these cells *ex vivo*, patients can indefinitely store their cryopreserved MSCs following a single harvest and then receive multiple bone-maintenance doses at appropriate intervals thereafter. Finally, we hope to engineer these same cell populations molecularly *in vivo* by providing the critical cues that instruct these cells first to divide, to travel to the proper sites, and to then form bone.

## CONCLUSION

The key to successful repair/regeneration of bone is to provide the repair site with sufficient osteogenic progenitor cells in a suitable delivery vehicle to ensure osteoblastic differentiation and optimal biosynthetic activity of bone matrix and growth and differentiation factors. Exclusion of interfering tissues, promotion of rapid vascular penetrance, and provision of appropriate mechanical and other instructional cues must be engineered. As we gain more information about the identity and reactivity of all of the cueing factors, it may be possible to orchestrate massive bone regeneration by clever combinations of delivery vehicles and such instructional agents. The management of MSCs, both *in situ* and *ex vivo*, will be crucial to the success of such tissue engineering. It may be that in older patients, whose MSC titers are decreasing with age, it will not be possible to accomplish these feats of local tissue engineering without first increasing the reservoir of available progenitor cells *in situ*. To this end, the *in vitro* expansion and manipulation of human MSCs for self-cell therapy are now being perfected and may become the therapy of choice in the future. The twenty-first century holds the promise of tissue regeneration protocols that we can now only dream about.

## ACKNOWLEDGMENTS

We thank our colleagues in the Skeletal Research Center and Osiris Therapeutics, Inc. for contributing to the studies described in this review. We extend special thanks to Victor M. Goldberg, Stephen E. Haynesworth, Neelam Jaiswal, Sudha Kadiyala, James E. Dennis, and Luis Solchaga. Studies reported here were funded in part by the National Institutes of Health and Osiris Therapeutics, Inc. Some of the technologies described herein have been transferred to Osiris Therapeutics, Inc., in which both authors hold an equity interest.

# ARTICULAR CARTILAGE INJURY

John M. McPherson and Ross Tubo

## INTRODUCTION

The fact that articular cartilage has little or no capacity for effective repair following traumatic injury has been recognized by clinicians for more than 250 years (Hunter, 1743). Even today the natural history of the progression of joint degeneration following injury is not completely understood, but it is clear that injury to articular cartilage often leads to symptomatic pain and eventually to osteoarthritis (Dandy, 1991; Johnson, 1986b; Johnson-Nurse and Dandy, 1985). It appears that degeneration of articular cartilage following injury may be a consequence of an imbalance in the normally slow remodeling and maintenance processes provided by chondrocytes, which are imbedded in the dense extracellular matrix of the articular surface. The mechanisms responsible for tilting the balance of remodeling in favor of degradation, versus synthesis, are not understood, but may in part reflect local changes in biomechanical loading of chondrocytes following injury that profoundly influence cell metabolism.

It has been postulated that articular cartilage has a limited capacity for repair due to a limited supply of cells in the vicinity of the wound to mediate the repair process (for review, see Gillingham *et al.*, 1998). Unlike skin, for example, in which both vasculature and adjacent tissues provide cells for mediating the wound healing process, articular cartilage contains no vascular supply. In addition, articular chondrocytes, which are normally involved in articular cartilage synthesis and maintenance, are encased in a dense extracellular matrix that limits their mobility and their ability to contribute to the wound healing process. Synovial cells are present in synovial fluid, but apparently their numbers are too few or their biological properties are too limited to mediate adequate repair of any but the most minute cartilage defects (Hunziker and Rosenberg, 1996).

Numerous surgical procedures have been developed during the past 30 years in an effort to deal with the problem of cartilage injury, particularly following the advent of arthroscopic surgery. The most conventional approach to cartilage injury is debridement and lavage (Baumgaertner *et al.*, 1990; Bert and Maschka, 1989; Dandy, 1991; Rand, 1991; Timoney *et al.*, 1990). The primary objective of this procedure is to improve the contour of the cartilage defect by shaving the edges of the lesion and removing the cartilage debris generated either by the original injury or the debridement procedure. In general, clinical reports in the literature suggest that debridement and lavage provide immediate short-term relief of the symptoms in the majority of patients with small cartilage defects. The efficacy provided by the procedure fades with time, particularly in defects of greater than 1 cm<sup>2</sup>, and many patients exhibit evidence of osteoarthritis, as judged by joint space narrowing.

Defects treated with debridement and lavage usually remain devoid of repair tissue unless the subchondral plate is penetrated during the debridement procedure. Based on this observation, surgeons developed several methods to penetrate the subchondral tissue (Fig. 49.1) with the objective of enabling mesenchymal cells from the bone marrow to migrate into the wound site and mediate the repair process. Abrasion arthroplasty involves the use of an arthroscopic burring device to remove tissue in the base of the wound to the level of subchondral bone (Bert and Maschka,

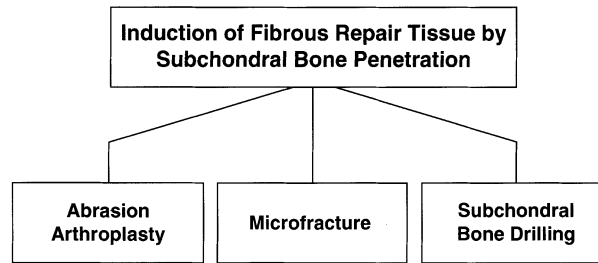

Fig. 49.1. Conventional surgical procedures utilized to treat damaged hyaline articular cartilage.

1989; Friedman *et al.*, 1984; Johnson, 1986a,b; Kim *et al.*, 1991). As with debridement and lavage, short-term results (i.e., less than 3 years) with this procedure appeared to provide satisfactory results in the majority of patients evaluated. Results were generally considered to be disappointing at time points in the time frame of 3 to 5 years, with only approximately 50% of the patients reporting satisfactory results. Alternative strategies for providing bone marrow-derived cells to the defect site have included microfracture and drilling (Buckwalter and Lohmander, 1994; Rodrigo *et al.*, 1994). Microfracture involves use of an awllike device to poke holes through the subchondral plate, and drilling involves arthroscopic drilling of holes through the subchondral plate. Both procedures provide access of blood and marrow-derived cells to the defect site. The clinical results using these procedures have reportedly been similar to those observed with abrasion arthroplasty, i.e., short-term efficacy but limited long-term utility (Gilligly *et al.*, 1998).

It is generally accepted that procedures that result in penetration of the subchondral plate lead to the formation of fibrocartilage. Fibrocartilage is composed primarily of type I collagen and proteoglycans such as versican, which are characteristic of mesenchymal tissues such as dermis. The extracellular matrix composition and organization of fibrocartilage provide significantly lower biomechanical compressive strength as compared to hyaline cartilage. The formation of fibrocartilage in articular defects following subchondral plate penetration is somewhat analogous to the formation of scar in skin following cutaneous injury. The main difference is that although the reduced biomechanical strength of scars in skin rarely leads to wound dehiscence, the reduced biomechanical properties of fibrocartilage in articular defects in most patients ultimately lead to failure of the repair tissue and degeneration of the surrounding tissue in the pathological process of osteoarthritis.

Articular cartilage, on the other hand, is normally composed of hyaline cartilage. Hyaline cartilage is composed of a complex organization of type II collagen and other minor collagens in combination with hyaluronic acid and a cartilage-specific proteoglycan termed aggrecan. Some of the differences in extracellular matrix composition between hyaline cartilage and fibrocartilage are summarized in Table 49.1. The hyaline cartilage-specific extracellular matrix molecules convey the capacity to withstand significant compressive forces without displaying significant deformation.

**Table 49.1. Biochemical comparison of hyaline cartilage and fibrocartilage<sup>a</sup>**

Hyaline cartilage	Fibrocartilage
Type II collagen	Type I collagen
Type VI collagen	Proteoglycans
Type IX collagen	Hyaluronic acid
Aggrecan	Link protein
Hyaluronic acid	
Link protein	
COMP protein	

<sup>a</sup>Key biochemical components that are useful for distinguishing hyaline articular cartilage from fibrocartilage. The specific biochemistry and organization of extracellular matrix molecules in these two types of cartilage dictate the capacity of the tissues to resist stress.

Hyaline cartilage also provides a very low frictional surface to accommodate joint movement. The physical properties of hyaline cartilage are a direct result of its extracellular matrix composition and organization.

Surgeons have developed alternative strategies to subchondral plate penetration in an effort to deliver a more appropriate “hyaline” cell type to articular cartilage defects, and thus to achieve more durable results. For example, autologous perichondrial grafts from the rib have been used to treat full-thickness articular defects in the knee (Homminga *et al.*, 1990). Perichondrial grafts were cut to fit the defects and were immobilized with fibrin glue in the defect site. By 1 year following transplantation, 18 of 25 patients exhibited excellent functional recovery, and arthroscopic assessment indicated that the defects were completely filled with cartilage-like tissue in 90% of the defects. Unfortunately, long-term follow-up (up to 8 years) with these and other patients revealed that approximately 60% of the patients experienced treatment failure, which in many cases was a consequence of endochondral ossification and graft delamination (Gilligly *et al.*, 1998).

O’Driscoll has utilized autologous periosteal tissue in full-thickness articular defects in an effort to achieve a more durable repair tissue (O’Driscoll *et al.*, 1986). This procedure involved debridement of the defect to a bleeding bed followed by suturing the periosteum to the base of the defect, with the cambium layer facing toward the joint space. Follow-up analysis of 15 patients reportedly treated with this procedure revealed that 9 patients experienced satisfactory results and 6 experienced graft failure within a few years. Other investigators that have utilized periosteal grafts have reported similar results in that their clinical case studies (Angermann, 1994; Hoikka *et al.*, 1990; Rubak *et al.*, 1982). These results have indicated lack of durability of the repair tissue in most patients and the available biopsy data have indicated that the repair tissue in the defect sites was not hyaline-like cartilage.

Another surgical approach to cartilage injury is osteochondral grafting. This approach involves the replacement of the entire bone and cartilage structure of the femoral condyle with size-matched human cadaver tissue (McDermott *et al.*, 1984). The reported clinical success observed using this procedure for repairing osteochondral defects, coupled with the lack of adequate donor tissue, has led to the development of an alternative approach for repair of small cartilage defects involving the use of autologous cylindrical plugs of hyaline cartilage and underlying bone. These plugs are harvested from a minor weight-bearing area of the intercondylar notch or the anterior superior lateral femoral condyle and are press-fitted into matching holes that have been introduced in defects in the femoral condyle (Bobic, 1996; Matsusue *et al.*, 1993). Preliminary results from patients treated with this procedure suggest that it may be useful for the treatment of small articular defects of less than 2 cm<sup>2</sup>. However, no long term data are available from patients that have been treated using this procedure, and concern has been expressed regarding the durability of the repair tissue as well as the ultimate fate of the harvest sites.

## AUTOLOGOUS CHONDROCYTE TRANSPLANTATION

Given the generally disappointing intermediate to long-term results obtained with the various surgical procedures outlined above for the treatment of full-thickness articular defects, investigators explored alternative strategies to mediate a more durable repair. Because recruitment of cells from bone marrow was observed to induce formation of fibrocartilage, and transplantation of tissues such as perichondrium or periosteum to cartilaginous defects often led to ossification, it was concluded that perhaps a more productive strategy was to isolate and utilize autologous articular chondrocytes to mediate the repair process. This strategy was particularly appealing because articular chondrocytes were the cell type normally involved in the production and maintenance of hyaline cartilage on the articular surface.

Pioneering work by Benya and Shaffer (1982) had demonstrated that it was feasible to isolate rabbit chondrocytes from articular cartilage and propagate them *in vitro*. The work of these investigators had demonstrated that once articular chondrocytes were enzymatically released from hyaline cartilage and cultured on tissue culture plastic, they exhibited a profound change in their phenotype, exhibited by development of a fibroblastic morphology and a switch in production from type II collagen to type I collagen. Importantly, it was demonstrated that once the propagated chondrocytes were released from the tissue culture plastic surface and placed in suspension culture, they went through a process of “redifferentiation” as judged by reexpression of type II collagen and chondroitin sulfate proteoglycans.

Based on these observations it seemed feasible that isolation of chondrocytes from a small biopsy sample of articular cartilage, followed by enzymatic isolation, propagation of the cells, and ultimate reintroduction of the propagated cells into an articular defect, may provide a means to repair the defect with "hyaline-like" cartilage, rather than the fibrocartilage that was observed when cells recruited from bone marrow had been used to mediate the repair process. It seemed likely that if it were possible to produce hyaline-like cartilage in an articular defect, then the quality and durability of the repair tissue would be superior to that provided by fibrocartilage.

It is worth noting that the concept of autologous cell-based therapy for treatment of serious tissue injury was initially developed and reduced to practice by Rheinwald and Green (1975; Compton *et al.*, 1993; Green *et al.*, 1979). These investigators developed methods to isolate keratinocytes from small skin biopsies, propagate the cells to form epidermal grafts, and then use these grafts to provide permanent skin replacement for severe burn victims. This technology was commercialized in 1989 and has been successfully utilized by many surgeons for treatment of catastrophic burn victims.

Armed with this information investigators initiated experiments to test the possibility of using propagated articular chondrocytes for treatment of articular defects in animal models of articular cartilage injury. Grande *et al.* (1989) evaluated the utility of autologous chondrocyte transplantation in a rabbit model of articular cartilage injury. A 3-mm-diameter chondral defect was introduced in the right and left patellas of the animals, chondrocytes were isolated from the cylindrical plugs of cartilage removed from the defect site, and cells were enzymatically released from the harvested tissue and propagated in tissue culture. Between 2 and 3 weeks following the first surgery, a second surgery was performed to introduce the propagated chondrocytes into the defect site of the right knee. The patella of the left knee served as the control in these experiments. A periosteal patch (cambium layer side toward the defect) was sutured in place over the defects in both knees and approximately  $1 \times 10^6$  cells were introduced underneath the patch of the right knee. Six weeks following implantation, the animals were sacrificed and their joints and defect sites were evaluated grossly and histologically. The results of this study revealed that grafted sites had markedly less synovitis and other degenerative changes as compared to control sites. Histologic evaluation of control sites indicated that there was an average of 18% fill of the control defects with repair tissue as compared to an average of 82% fill of the defects in cell-grafted sites. It was concluded, based on histologic evaluation, that the repair tissue in the cell-grafted defects was very similar to the hyaline cartilage present in surrounding nonwounded articular cartilage. Results of other experiments using propagated chondrocytes that had been radiolabeled with tritiated thymidine provided evidence that the implanted cells were incorporated into the repair tissue and were contributing to the repair process.

During the same period of time that Grande *et al.* were studying autologous chondrocyte implantation in rabbits, Wakitani *et al.* (1989) evaluated the use of allogeneic articular chondrocyte transplantation for treatment of articular cartilage defects in the patellar groove of the right femur of rabbits. These studies were different from those of Grande *et al.* not only in the use of allogeneic versus autologous cells but also by the fact that the allogeneic cells were not propagated and were delivered in a collagen gel versus a cell suspension underneath a periosteal patch. Despite these differences, the results of these studies indicated that defect sites implanted with cells exhibited dramatically improved healing as compared to untreated defects or defects treated with the collagen gel alone. Histologic evaluation of cell implant sites indicated that the repair tissue was composed of hyaline cartilage.

Based on these promising results Brittberg *et al.* initiated clinical evaluation of autologous chondrocyte implantation in human patients using the basic procedure described by Grande *et al.* (Fig. 49.2). The results of the first 16 patients treated with this therapy in femoral condyle defects and followed for 16–66 months are summarized in Table 49.2 (Brittberg *et al.*, 1994). The data indicated that two years after treatment, 14 of 16 patients of these patients experienced good to excellent clinical results. Clinical results for patients with patellar transplants were less impressive, with only 2 of 7 patients experiencing excellent results. Biopsy specimens were obtained for 15 of the 16 patients with femoral condyle transplants. Histologic evaluation of these biopsy specimens indicated that the majority (11 of 15) contained hyaline-like cartilage (Fig. 49.3). Immunohistochemical analysis of 5 biopsy specimens with hyaline-like cartilage provided evidence of type II collagen staining.

## COMMERCIALIZATION OF AUTOLOGOUS CHONDROCYTE IMPLANTATION

The preclinical and clinical results outlined above for autologous chondrocyte implantation, along with clear evidence of an unmet medical need in the area of clinical management of articular cartilage injury, stimulated interest in providing this treatment on a commercial basis, as had been done previously for autologous keratinocyte transplantation for severe burn victims. Conversion of the methods initially utilized by Brittberg *et al.* to a commercially feasible process presented many technical and quality control challenges. As noted above, autologous chondrocyte implantation relies on the use of cultured cells, initially isolated from a minor weight-bearing surface of the femoral condyle; the cells are expanded *in vitro*, and finally administered to the clinically relevant site for action. Because the biosynthetic profile of cultured animal chondrocytes was shown to be altered during proliferative expansion *in vitro* (Benya and Shaffer, 1982), an evaluation of the ability of propagated human chondrocytes subsequently to reexpress the appropriate cellular phenotype consistent with differentiated articular cartilage, as had been demonstrated for rabbit chondrocytes, was required to ensure the delivery of a functional and reproducible product.

Transcriptional analyses of human chondrocytes propagated on tissue culture plastic revealed that they underwent the reversible “dedifferentiation” process, as had been observed for other mammalian species, with reduction in expression of type II collagen and aggrecan and an up-regulation of type I collagen (Binette *et al.*, 1998). Release of the human chondrocytes from tissue culture plastic and subsequent culture in suspension culture resulted in a reexpression of type II collagen and aggrecan, but importantly showed no evidence of expression of type X collagen, a marker of chondrocyte hypertrophy and ossification (Fig. 49.4). The results of these experiments provided evidence that human chondrocytes, like the chondrocytes of other animal species, possessed the inherent capability to reexpress an articular cartilage phenotype following cellular propagation. This type of assay provided a useful means to assess the effects of various process changes on the capacity of cells to redifferentiate. For example, cultured autologous human articular chon-

drocytes for clinical use were first propagated in culture medium composed of Ham's F-12 medium supplemented with 15% (v/v) autologous serum (Brittberg *et al.*, 1994). Cells from each patient were cultured in medium supplemented with their own serum. The use of autologous human serum for propagation of chondrocytes was judged to be technically and economically infeasible. Therefore, the redifferentiation potential of adult articular chondrocytes cultured in donor-matched autologous human serum (Brittberg *et al.*, 1994) or a single lot of commercially

Fig. 49.4. Collagen types I, II, IX, and X gene expression during adult articular chondrocyte redifferentiation in long-term suspension culture. RNA isolated from human articular chondrocytes growing in a proliferative monolayer or in an alginate suspension was subjected to RNase protection assay using antisense RNA probes for types I, II, IX, and X collagen. From Binette *et al.* (1998).

available bovine serum [Dulbecco's modified eagle's medium (DMEM) supplemented with 10% (v/v) bovine serum] (Aulthouse *et al.*, 1989; Binette *et al.*, 1998; Bonaventure *et al.*, 1994) was compared. The study revealed that redifferentiation potential, or chondrocyte function, was more consistent in medium supplemented with the single lot of fetal bovine serum (FBS) (Fig. 49.5). The inconsistent maintenance of articular chondrocyte redifferentiation potential using matched donor sera was the likely consequence of varying levels of growth and differentiation factors observed in different lots of serum (Freshney, 1994; Yaeger *et al.*, 1997).

Subsequent studies using numerous strains of human chondrocytes propagated with media supplemented with 10% bovine serum revealed that the age of the individual from which the chondrocytes were isolated had a very modest effect on their potential to redifferentiate (Fig. 49.6). Likewise, it was observed that the number of population doublings expended prior to implantation was unaffected by age (Fig. 49.7). Because chondrocytes for implantation are routinely passaged an average of 8 population doublings prior to clinical use, it is worth noting that chondrocytes retain their ability to redifferentiate until just before cell senescence, at about 35–50 population doublings.

Prior to commercialization of autologous chondrocyte implantation, additional animal studies were performed in an effort to better understand and document the process of articular cartilage repair that was mediated by this cell-based therapy. Experiments in dogs revealed that redifferentiation of autologous articular chondrocytes was observed within 6 weeks of implantation into 4-mm cartilage defects created in the femoral condyle or trochlear groove in the stifle joint of the animals (Shortkroff *et al.*, 1996). A chondrocyte nesting phenomenon was observed, where

Fig. 49.5. Comparison of chondrocyte culture in autologous human serum vs. bovine serum. Effect of serum source on the ability of human articular chondrocytes to redifferentiate following proliferative expansion in monolayer. Human articular chondrocytes were cultured in culture medium supplemented with fetal bovine serum or donor-matched autologous human serum. Redifferentiation of chondrocytes was assessed by counting colonies in agarose suspension culture, as described by Benya and Shaffer (1982).

Fig. 49.6. Impact of patient age on the ability of human articular chondrocytes to redifferentiate in suspension culture following proliferative expansion in monolayer. The colony-forming ability of human articular chondrocytes derived from the articular cartilage of 22 donors ranging in age from 5 to 65 years was assessed following monolayer culture into the third passage (approximately 7–10 population doublings).

clusters of implanted chondrocytes in lacunae were located within type II collagen-positive matrix (Fig. 49.8). Chondrocytes having a fibroblastic morphology were observed in type I collagen-positive matrix. A transitional morphology was identified within the cartilage defect, whereby chondrocytic morphology was apparent in the depths of the defect and fibroblastic morphology was present toward the articular surface. Untreated defects without periosteum or cells, and defects treated with periosteum alone, exhibited cellular fill that was consistent with fibrocartilage.

At 6 months in the canine cartilage repair model, the tissue filling the cartilage defects was hyaline-like, with articular chondrocytes in lacunae (Shortkroff *et al.*, 1996). Columnar organization of chondrocytes was observed in some histologic sections (Fig. 49.9). Although a general trend toward more cartilage repair was observed at 6 months in the chondrocyte-implanted defects, the results were complicated by variable levels of spontaneous cartilage repair in the absence of chondrocyte implantation. The positive trend, in terms of improved cartilage repair in cell grafted sites as compared to controls, which was observed at 6 months, was no longer apparent at 12–18 months postimplantation (Breinan *et al.*, 1998). This was a consequence of both spontaneous healing in some of the control sites (no periosteum or cells) and development of degenerative joint disease in both control and treatment sites in many of the animals at these latter time points. Despite these limitations of the animal model, results of the study provided additional evidence for the safety of the procedure and provided insights into the mechanisms of chondrocyte-mediated repair in articular cartilage defects.

Autologous chondrocyte implantation was approved for treatment of articular cartilage defects by the Center for Biologics Evaluation and Research of the Food and Drug Administration in August, 1997, under provisions of accelerated approval guidelines. These regulations provide for approval of biological products for serious or life-threatening illnesses based on surrogate end-points that are likely to predict clinical benefit. Approval of products under these regulations generally requires additional postapproval clinical studies to confirm that the surrogate end points utilized to provide the basis for approval of the product do indeed correlate with clinical outcomes. Such studies are currently in progress with autologous chondrocyte implantation.

Fig. 49.7. The number of population doublings expended by human articular chondrocytes prior to clinical use. The number of population doublings was calculated as  $\log_2$  (number of cells at subculture/number of cells seeded).

Fig. 49.8. Histologic section of an articular cartilage defect treated with cultured autologous chondrocytes at 6 weeks, stained for type II collagen. Autologous articular chondrocytes were implanted into 4-mm focal defects in the articular cartilage of adult dogs. Animals were sacrificed at 6 weeks and analyzed by histology. Note the type II collagen staining around the nests of chondroid cells (arrow pointing left) and in the calcified cartilage layer (arrow pointing down). Reprinted from *Biomaterials*, Vol. 17, No. 2. S. Shortkroff, L. Barone, H. P. Hsu, C. Wrenn, T. Gagne, T. Chi, H. Breinan, T. Minas, C. B. Sledge, R. Tubo, and M. Spector, pp. 147–154. Copyright 1996, with permission from Elsevier Science.

In addition to these studies, a patient registry program was voluntarily initiated by Genzyme Tissue Repair, the company responsible for commercializing autologous chondrocyte implantation (ACI). The registry consists of data collected at the cartilage harvest, cell implantation, and periodic follow-up visits to the physician at 6, 12, and 24 months. All patients treated with ACI have been included in the registry. When defects on the femoral condyles have been treated with ACI, significant improvements in joint function and patient symptoms compared to base line have been observed (>2 years of follow-up), with 86% of the patients recorded by themselves and their clinician as improved (Browne *et al.*, 1998; LaPrade and Swiontkowski, 1999).

In addition to these data, the initial positive results reported for femoral condyle defects by

Fig. 49.9. Hyaline articular cartilage observed in a cartilage defect treated with cultured autologous chondrocyte implantation at 6 months. Animals were sacrificed at 6 months and histologic sections were stained with hematoxylin and eosin. Chondrocytes were observed in lacunae structures with columnar organization. This is characteristic of hyaline articular cartilage.

Brittberg *et al.* (1994) were further substantiated by a report on 219 patients at a 2- to 10-year follow-up visit (Peterson, 1998). Functional improvement was observed in 89% of cases with isolated femoral lesions. Moreover, histologic analysis of biopsies removed during second-look arthroscopy revealed that 74% of patients had hyaline-like articular cartilage repair. Good clinical outcome was correlated with hyaline-like repair tissue, supporting the hypothesis that biochemistry equals function in articular cartilage. The longevity of the ACI repair was also demonstrated, in that, 30 of the 31 patients (96%) who initially had good or excellent results at 2 years of follow-up maintained their good or excellent results at an average of 7.4 years postoperatively (Peterson, 1998). Additional reports from orthopedic surgeons have provided independent evidence that the procedure can be useful in the treatment of single large defects of up to 15 cm<sup>2</sup>, or multiple defects of the femoral condyles (Gillooly *et al.*, 1998; Minas, 1998).

### ALTERNATIVE STRATEGIES FOR THE DELIVERY OF CELL-BASED THERAPIES FOR CARTILAGE REPAIR

Despite the excellent clinical results with autologous chondrocyte implantation, opportunities for further improvement of this technology clearly exist. Patients who have been treated with autologous chondrocyte implantation do not typically return to full physical activity until at least 1 year postsurgery. The invasive nature of the surgical procedure, an open arthrotomy, and the time interval between chondrocyte implantation and production of a functional repair tissue have been hypothesized to be responsible for the relatively long period of patient rehabilitation. As noted above, the open arthrotomy, commonly known as an open-knee procedure, is required for the surgeon to suture the thin periosteal membrane directly to the margins of the cartilage defect. Therefore, strategies that facilitate the arthroscopic administration of a cartilage repair construct and at the same time accelerate the chondrocyte-mediated repair process are being investigated. The next-generation cartilage repair construct will likely be either a preformed cartilage tissue or will be composed of articular chondrocytes embedded within a biocompatible extracellular matrix supplemented with factors that positively impact chondrocyte growth and differentiation.

Articular chondrocyte viability and redifferentiation has been evaluated with several potential carrier matrices, including agarose (Rahfoth *et al.*, 1998), varying configurations of type I collagen gels and sponges (Ben-Yishay *et al.*, 1992; Frenkel *et al.*, 1997; Grande *et al.*, 1989, 1997; Qi and Scully, 1997; Wakitani *et al.*, 1989), type II collagen sponges (Nehrer *et al.*, 1998), hyaluronic acid derivatives (Solchaga *et al.*, 1999), poly(lactic acid), and poly(glycolic acid) and their derivatives (Freed *et al.*, 1994; Grande *et al.*, 1997; Vacanti *et al.*, 1991), and fibrin (Itay *et al.*, 1987; Sims *et al.*, 1998). The use of these materials to deliver articular chondrocytes to articular cartilage defects has resulted in varying degrees of cartilage repair in small animal models (Ben-Yishay *et al.*, 1992; Grande *et al.*, 1989; Itay *et al.*, 1987; Wakitani *et al.*, 1989). The results obtained in these models were complicated by varying levels of spontaneous repair, presumably due to penetration of the subchondral bone and the subsequent fibrocartilaginous response. However, the importance of cells in the repair of cartilage defects was illustrated by the fact that defects treated with extracellular matrix constructs containing cultured cells typically exhibited enhanced cartilage repair over control matrices without cells.

In terms of accelerating cell-mediated tissue repair, articular chondrocytes respond to a number of growth factors that stimulate proliferation and differentiation, including insulin, insulin-like growth factor I and II (IGF-I and IGF-II), and members of the TGF- $\beta$  superfamily, including some of the bone morphogenetic proteins (BMP2 and BMP4), basic fibroblast growth factor (bFGF), and platelet-derived growth factor (PDGF) (Martin and Buckwalter, 1996). Moreover, a positive impact on articular cartilage repair *in vivo* has been observed for several of these factors when supplemented into an extracellular matrix delivery vehicle including insulin-like growth factor-I into fibrin matrices (Fortier *et al.*, 1999), or members of the TGF- $\beta$  superfamily into type I collagen constructs (Hunziker and Rosenberg, 1996).

The paradigm for preformed cartilage tissue was set by osteochondral allografts. Osteochondral allografts have been used successfully for the resurfacing or reconstruction of joints missing large surface areas (Bentley, 1992; Nevo *et al.*, 1991). These bone and cartilage grafts have been shown to integrate very well with the existing bone and provide rapid clinical benefit. However, the supply of such tissue is extremely limited. Methods have been developed for the generation of a predifferentiated cartilage tissue *in vitro* (Kandel *et al.*, 1995; Peel *et al.*, 1998). The pre-differ-

Fig. 49.10. Histologic appearance of a cartilaginous composite graft composed of articular chondrocytes and small intestine submucosa following 8 weeks in culture. (A) Cartilaginous tissue (C) on small intestine submucosa (S) stained with toluidine blue. (B) A zone of mineralization (arrows) is apparent in the lower area of the cartilaginous tissue (C) when cultured under conditions favoring bone formation. This may be helpful for integration with the subchondral bone *in vivo*. From Peel et al. (1998).

entiated cartilaginous implant can be produced *in vitro* by culturing articular chondrocytes on a type II collagen-coated filter membrane, or on a thin membrane of small intestine submucosa (Kandel *et al.*, 1995, 1997; Peel *et al.*, 1998). After 4–6 weeks in culture a cartilage tissue construct characterized by the histologic hallmarks of hyaline articular cartilage is observed (Fig. 49.10). This hyaline-like cartilage persists when implanted into cartilage defects *in vivo*. Integration of the preformed cartilage implant with the cartilage surrounding of the defect is better than that observed to subchondral bone.

## CONCLUSIONS

Taken together, the preclinical and clinical data summarized above provide compelling evidence that chondrocyte implantation can provide superior clinical results in the treatment of articular cartilage defects as compared to alternative cell-based strategies that either generate fibrocartilage or ultimately lead to ossification at the repair site. Scientifically, the use of articular chondrocytes to mediate repair of articular cartilage seems logical, just as it seems logical to use keratinocytes to replace epidermis following massive cutaneous injury. Despite the promising results with autologous chondrocyte implantation, it is clear that significant opportunities for improvement of this procedure exist. As noted above, the current procedure is technically challenging and results in a lengthy rehabilitation process. Thus, it is likely that the next-generation cell-based product to treat articular cartilage damage will be performed using minimally invasive

procedures and will be configured in a manner that will significantly reduce the time to generate functionally active tissue in the defect site. It is also clear that the ultimate product to treat articular cartilage injury will be characterized by its ability to be used in large-scale joint resurfacing and will have the added ability to mediate the wound repair process in a manner to reverse the degenerative processes of osteoarthritis. Although such a product seems a distant fantasy, given the scientific progress that has been made in our understanding of cartilage maintenance and repair during the past 20 years, such a dream may be closer than we think.

# TENDONS AND LIGAMENTS

Francine Goulet, Denis Rancourt, Réjean Cloutier, Lucie Germain,  
A. Robin Poole, and François A. Auger

## INTRODUCTION

The need for human tissues and organs has increased over the past few years, mostly because of population growth. The risks for transmission of contagious diseases have also imposed serious restrictions to the availability of human transplants. Recent advances in tissue and organ engineering have generated much interest among clinicians and patients in various fields of medicine. This modern approach has already shown successful results with human skin substitutes all over the world.

This chapter is dedicated to ligament and tendon bioengineering. The technical approach developed to produce a human anterior cruciate ligament (ACL) substitute is described. This methodology may eventually be adapted to produce other ligaments or tendons in culture. A bioengineered ACL (bACL) was developed by seeding human ligament fibroblasts in a hydrated collagen matrix. Our bACL is anchored with two bones, because bone-to-bone insertion is reported as the most secure method for ligament fixation. The ACL substitute is a good tool to study connective tissue repair and the environmental and cellular factors that can affect collagen alignment and cross-linking *in vitro*. It may also become a therapeutic alternative for torn ACL replacement.

The effects of cyclic stretching on the histologic features of the bACL are also described. Mechanical stimuli represent one of several concepts to explore in order to optimize bioengineered tissues. Our findings may also be useful to readers involved in the fields of orthopedics and physical therapy. Histologic analyses of bACL cultured under cyclic traction revealed that fibroblasts are surrounded by bundles of collagen fibers organized in a wavy pattern, comparable to histologic features of native ACL. These results suggest that mechanical stimuli have an important impact on the evolution of bioengineered tissue *in vitro*.

## THE NEED FOR BIOENGINEERED TENDON AND LIGAMENT SUBSTITUTES

In the United States, at least 120,000 patients per year undergo tendon or ligament repairs (Langer and Vacanti, 1993). So far, the therapeutic options to repair torn ligaments are tissue reconstruction using autograft or allograft, reparation alone or with augmentation, or replacement using a synthetic prosthesis. Unfortunately, none of these surgical alternatives provides a long-term adequate solution. Synthetic material implantation was a very popular surgical technique in the 1980s but it frequently led to implant degeneration and failure (Olson *et al.*, 1988; Woods *et al.*, 1991). Allogeneic grafting of ligaments is still at an experimental stage and may lead to immunologic reactions that prevent good healing of the wound (Jackson and Kurzweil, 1991; Sabiston *et al.*, 1990). For most of the approaches, particular attention has been given to the surgical procedure for ligament fixation to the bones. This step would constitute a critical achievement toward the permanent implantation of bioengineered ACL *in vivo*, as mentioned in the literature (Kurosaka *et al.*, 1987; Olson *et al.*, 1988). Little is known about physiologic and pathologic events that regulate the histologic organization of ACL *in vivo*.

The recent advances in the domain of tendon and ligament bioengineering are summarized below. Tissue bioengineering raises considerable interest in the fields of biology and medicine, notably in orthopedics. Ligaments and tendons are frequently targets of sport and aging trauma. Many clinical studies have strived to develop new therapeutic alternatives such as allografts (Andrews *et al.*, 1994; Arnoczky *et al.*, 1982) and synthetic prostheses (Bessette and Hunter, 1990). However, functional problems frequently arise, despite some progress, because ligaments and tendons support large mechanical stresses *in vivo*.

Over the past few years, attempts have been made to discover new biocompatible materials for ligament and tendon replacement. Collagen alone or with cells isolated from the tissue of origin has been used to produce bioengineered functional organs *in vitro*. The main ideas behind such attempts were to first produce *in vitro* models of ligaments or tendons by tissue engineering, in order to implant them permanently *in vivo*, where their histologic and functional properties could be improved by local and systemic stimuli. Data reported from animal experimentations showed that vascularization, cell migration, tissue remodeling, and extracellular matrix deposition occurred *in vivo* in an acellular composite collagen prosthesis 12 weeks postgrafting (Dunn *et al.*, 1994). Several research groups are presently involved in the development of human bioengineered tissues that would include living cells, to obtain models showing several histologic and functional properties acquired under particular culture conditions prior to transplantation. Such models could also be useful to study various aspects of tendons and ligaments, such as healing and tissue remodeling *in vitro*.

## HISTOLOGIC DESCRIPTION OF TENDONS AND LIGAMENTS

Tendons connect bones to muscles, and ligaments join one bone to another. The literature used to describe the histologic structures of fascia, tendons, and ligaments is similar. They are dense connective tissues consisting of fibroblasts surrounded by type I collagen bundles (Amiel *et al.*, 1984). This may explain why patellar tendon and tensor fascia have frequently been used to replace the torn anterior cruciate ligament of the knee joint (Arnoczky *et al.*, 1982). The central quadriceps tendon autograft is reported as one of the best alternatives for ACL reconstruction (Arnoczky *et al.*, 1982; Fulkerson and Langeland, 1995). However, some pain, loss of motion, knee instability, and other problems can be associated with this approach (Tanzer and Lenczner, 1990; Tria *et al.*, 1994; Vergis and Gillquist, 1995), according to each type of trauma and depending on variables that are unique for each individual (Harner *et al.*, 1994; Johnson *et al.*, 1992; Parker *et al.*, 1994). The success of such grafts depends on the revascularization of the transplanted tissues as they are progressively surrounded by a synovial membrane, rich in vessels (Arnoczky *et al.*, 1982). The tendon finally gains some ligament properties and the term "ligamentization" was used by Amiel *et al.* (1986) to describe this physiologic phenomenon studied in *in vivo* postgrafting.

Both ligaments and tendons consist mainly of closely packed and thick collagen fibers (predominantly type I with a small proportion of type II collagen) but also include small quantities of glycosaminoglycans (dermatan sulfate and hyaluronic acid) (Watanabe *et al.*, 1994). The composition of these biochemical constituents is modulated during tissue growth and development, changing also in response to functional requirements (Watanabe *et al.*, 1994).

Tendon collagen fibrillogenesis is initiated in early development by fibroblasts (Trelstad and Hayashi, 1979). Fibrils are embedded in an organized, hydrated, proteoglycan matrix and cross-linked through aldol or Schiff base adducts between aldehydes on one or more of the  $\alpha$  chains of the collagen molecules and aldehydes or amino groups on adjacent chains or molecules (Davison, 1989). Such cross-links contribute to the tensile strength of the fibrils (Davison, 1989) and thus to the tensile properties of the whole tendon. The aldehyde-derived cross-links are found in two forms; some are unstable in dilute acids and others are stable (Davison, 1989). The ratio of one form to the other varies in different tissues, generally increasing with aging.

Data reported by Amiel *et al.* (1984) suggested that ligaments are more metabolically active than tendons, having more plump cellular nuclei, higher DNA content, larger amounts of reducible cross-links, and more type III collagen, as compared with tendons. They also contain slightly less total collagen than do tendons and more glycosaminoglycans, particularly close to the joint (Amiel *et al.*, 1984). Extracellular matrix fibers in ligaments are also less regularly arranged

than in tendons (Puddu and Ippolito, 1983), although the fibers are oriented parallel to the longitudinal axis of both tissues (Amiel *et al.*, 1984). For example, the anterior cruciate ligament, one of the strongest tissues of the body, is composed of multiple fascicles, the basic unit of which is type I collagen (Besette and Hunter, 1990). The collagen fibrils are nonparallel, but are themselves arranged into fibers that are oriented roughly in the long axis of the ligament in a wavy, undulating pattern ("crimp"), which slowly straightens out as small loads are applied to the ligament (Besette and Hunter, 1990). To give an example of the forces applied on such tissues *in vivo*, the ACL usually supports loads of about 169 Newtons (38 lb), and ruptures around 1730 Newtons (about 390 lb) (Besette and Hunter, 1990). An elongation of only 6% (about 2 mm) of human ACL (about 32 mm long) is reported to be the limit beyond which damage must be expected (Amis and Dawkins, 1991). Thus, the main challenges associated with the production of bioengineered tendons and ligaments are to obtain strong and functional tissues.

## PRODUCTION OF BIOENGINEERED TENDONS AND LIGAMENTS

Several approaches are proposed to produce bioengineered tissues *in vitro*. However, the development of such technology always involves the use of biocompatible and, preferably, biodegradable materials that (1) can provide mechanical resistance and (2) can be colonized and reorganized by living cells *in situ* postgrafting. Some tendons and ligaments are at the top of the list in terms of injury frequency and problems to repair, replace, or heal. In contrast with the medial collateral ligament, anterior cruciate ligament regeneration is hampered *in vivo* (Lyon *et al.*, 1991; Ross *et al.*, 1990). Certain anatomic factors may predispose people to ACL injury (Harner *et al.*, 1994). In the young and active population, reconstruction is often the best therapeutic option. However, to overcome the drawbacks associated with ACL repair and healing, several efforts have been put into the production of a bioengineered ACL model over the past decade.

In a composite material, the orientation and density of fibers in the matrix significantly affect its mechanical properties. From a macroscopic point of view, the ACL can be considered as a composite material in which the fibroblasts secrete collagen and elastin, which are organized into fibers. Hence, it is not surprising to see that human ligaments have a very low degree of stiffness in traction, for small strains, because of the cross-linked organization of the fibers (Strocchi *et al.*, 1992).

Collagen remains the basic protein of interest in the field of connective tissue bioengineering. Dunn *et al.* (1992, 1993, 1994), a group actively involved in the production of ligament biocompatible prostheses, have reported successful replacement of the ACL by a cross-linked collagen prosthesis implanted in rabbits. A similar approach was previously reported for the regeneration of the Achilles tendon (Kato *et al.*, 1991). Such a biodegradable prosthesis, prepared by the alignment of 200 cross-linked collagen fibers and fixed by surgically created bone tunnels (2.8 mm diameter) *in situ*, is produced using glutaraldehyde, dehydrothermal-cyanamide (DHTC), or carbodiimide as collagen cross-linking agents (Dunn *et al.*, 1993, 1994; Kato *et al.*, 1991). These collagen fibers have high tensile strengths (30–60 MPa) and small diameters (20–60  $\mu$ m) (Dunn *et al.*, 1994), similar to fibers of the normal ACL (Danylchuk *et al.*, 1978). Rapid ingrowth (within 8 weeks) of fibrous tissue and bone was observed in the bone tunnels after implantation following degradation of the composite collagen prosthesis (Dunn *et al.*, 1994). Thus, Dunn's group ACL model seems to be one of the promising bioengineering alternatives for human ligament replacement.

## A NEW LIVING BIOENGINEERED LIGAMENT MODEL

A different approach for the production of a human ACL model *in vitro* was established in our laboratory through bioengineering. This approach combines skills and concepts associated with tissue culture and biomechanical principles. Such expertise has been successfully developed in our laboratory for other human tissues, such as skin (Auger, 1988; Auger *et al.*, 1993, 1995; Bouvard *et al.*, 1992; López Valle *et al.*, 1992a,b; Rompré *et al.*, 1990; Black *et al.*, 1998), bronchi (Goulet *et al.*, 1996; Paquette *et al.*, 1998), and blood vessels (L'Heureux *et al.*, 1998). Our research programs aim at producing bioengineered tissues that can serve both experimental and clinical interests.

A new bioengineered ACL model was developed. The main differences between our bACL and other ligament models (Bellows *et al.*, 1982; Dunn *et al.*, 1994) consist of the following ad-

vantages: (1) Our bACL contains living ACL fibroblasts, which contract, synthesize, and initiate remodeling and organization of the extracellular matrix in which they are initially seeded. (2) Our bACL can be a very useful tool to study connective tissue repair *in vitro* because the cells can maintain their activities for at least 2 months in culture. (3) Our bACL is produced without chemical cross-linking agents and synthetic materials. Such an approach eliminates risks of cytotoxicity and the production of foreign molecules due to mechanical friction, which can occur *in vivo* in the case of its eventual use as ligament prosthesis. (4) Our approach uses bones to anchor the bioengineered tissue; these bones are included with the bACL structure, right from the start of its production, to facilitate its eventual transplantation *in vivo*. Moreover, autologous bone fragments and ligament fibroblasts can be used to produce bACLs for eventual ligament replacement in humans. Such a possibility could greatly reduce the risks of immune reactions and infections, favoring permanent graft integration posttransplantation.

Various research groups have shown that fibroblasts seeded in collagen gels can degrade and reorganize the surrounding extracellular matrix and adopt a specific orientation in a contracted collagen lattice as a function of culture conditions and time (Auger, 1988; Auger *et al.*, 1993, 1995; López Valle *et al.*, 1992b; Rompré *et al.*, 1990; Bell *et al.*, 1979, 1981a,b; Delvoye *et al.*, 1983; Grinnell and Lamke, 1984; Guidry and Grinnell, 1985, 1986, 1987; Huang *et al.*, 1993; Kasugai *et al.*, 1990). Several studies have also shown that mechanical stimuli of biological tissues can produce ultrastructural and histologic content variations. For instance, it is well known that ligament remodeling depends on the mechanical stress to which the ligament is subjected *in vivo* (Amiel *et al.*, 1984). Our experiences also confirmed such behavior with anchored dermal equivalents *in vitro* (Grinnell and Lamke, 1984). The addition of an anchorage to dermal equivalents resulted in cell and collagen alignment in the plane of geometric constraints induced by the anchoring device. In addition, bACLs have collagen and cells aligned in a direction parallel to the stress exerted. Finally, Huang *et al.* (1993) reported that the mechanical properties along with the ultrastructure of ligament equivalents change in response to mechanical strengthening *in vitro*. Similar observations were made following *in vitro* elongation studies on rabbit ACL (Matyas *et al.*, 1994).

Thus, a cyclic stretching machine (Fig. 50.1) was designed and produced to study the effect of cyclic stretching on the mechanical and histologic properties of our bACL *in vitro* (Langelier *et al.*, 1999). The results described in this chapter strongly suggest that it is possible to modulate tissue organization by dynamic mechanical stimuli *in vitro*. Such observations are promising for the production of bioengineered tissues, the ACL in particular.

The first aim of our work was to establish methods for the isolation and culture of ACL fibroblasts to reconstruct *in vitro* a three-dimensional bACL, reproducing the elongated shape of the tissue *in vivo*. Using this biotechnical approach to produce a cultured ligament, we have compared the effects of continuous static and cyclic stretchings on the tissue organization. The technical steps leading to the production and analyses of bACLs are described below. This approach could likely be adapted for the production of bioengineered tendons *in vitro*. Autologous bACLs could eventually be used as ACL replacement prostheses in humans.

## TECHNICAL STEPS TO PRODUCE AND ANALYZE OUR bACL

### STEP 1: HUMAN ACL FIBROBLAST ISOLATION AND CULTURE

Human ACL biopsies are collected from patients (28–65 years old) during total knee surgery. The biopsies were kept at 4°C for no longer than 3 hr before cell isolation. The human ACLs are weighed and cut into small pieces after removal of the periligamentous tissue. The fragments are digested with 0.125% collagenase, containing 2 mM CaCl<sub>2</sub> (1 ml of enzymatic solution/mg of tissue) for 20 hr under gentle agitation, at 37°C. A 0.1% trypsin solution (1 ml/mg of hydrated tissue) is then added to the cellular suspension for 1 hr. The enzymes are dissolved in Dulbecco's modified Eagle's medium (DMEM), pH 7.4, containing antibiotics. The human ligament fibroblasts (HLFs) isolated from the ACL are cultured in DMEM supplemented with 10% fetal calf serum (FCS), 100 IU/ml penicillin G, and 25 mg/ml gentamicin. When HLF primary cultures reach 85% confluence, the cells are detached from their culture flasks using 0.05% trypsin–0.01% ethylenediaminetetraacetic acid (EDTA) solution (pH 7.8), for about 30 min at 37°C. HLF suspensions are centrifuged twice at 200 *g* for 10 min. The cell pellets are resuspended in complete culture medium and the cells are counted with a Coulter counter and a Multisizer analyzer. The cellular viability is determined using the trypan blue exclusion method.

Several populations of HLFs were isolated and cultured from more than 20 patent biopsies. HLFs appear morphologically slightly bigger and present a less fusiform shape than do dermal fibroblasts in culture. All cells maintain their morphology for more than seven passages in culture. For bACL production, HLFs from passages 3 to 5 are used. Immunofluorescent labeling analysis reveals that HLFs extracted from ACL biopsies express vimentin, fibronectin, types I and III collagens, and elastin (Goulet *et al.*, 1997a).

### STEP 2: CULTURE OF bACL

#### Preparation of the bACL human bone anchors

Partially demineralized human bone pieces are cut into a cylindrical shape (average size, 1 cm in diameter and 2 cm long). A transverse hole (0.125 inch in diameter) is made in each of them. Two anchors are transferred in one sterile 15-ml plastic tube and kept in position by passing a hot metal pin across the tube and through the holes previously made. A bone is fixed at the bottom and another at the top of the tube. Then all the tubes containing the anchors are rinsed with 100% ethanol, dried, and sterilized with ethylene oxide.

#### Production of the human bACL *in vitro*

A solution of DMEM, 2.7×, containing antibiotics is mixed with a second solution containing heat-inactivated (30 min at 56°C) fetal calf serum (FCS), solubilized bovine type I collagen, and living HLFs (passages 3 to 5). The cells are added at a final concentration of 1 × 10<sup>6</sup> cells/ml. This mixture is quickly poured into a sterile plastic tube containing the two bone anchors. According to our latest protocol, the final concentration of bovine type I collagen is always 1.5 mg/ml in the bACL. All of the bACLs are cultured in DMEM supplemented with 10% FCS, 50 mg/ml ascorbic acid, 100 IU/ml penicillin G, and 25 mg/ml gentamicin. They are maintained in a static vertical position during the first 24 hr of culture.

### STEP 3: CULTURE CONDITIONS OF VARIOUS GROUPS OF bACLs

#### Static tension

Half of the bACLs (total of at least six) are transferred into sterile culture chambers containing two fixed pins, which are passed through the holes made in the osseous anchors. The initial static tension applied in the longitudinal axis of these bACLs is adjusted to the minimal level required to keep each tissue elongated to its full length for several weeks. Figure 50.2A shows a bACL after 10 days. The culture medium is changed every other day.

#### Cyclic stretching

The other group of bACLs (total of at least six) is cultured in a sterile chamber of the cyclic stretching device (Fig. 50.2B). The device is placed in a standard cell culture incubator, the stretch-

Fig. 50.2. A bACL installed into the sterile culture chamber of (A) the cyclic traction device [from Langelier et al. (1999), with permission] and (B) the static stretching device.

ing chamber allowing sterile exchanges with the surrounding 8% CO<sub>2</sub> atmosphere at 37°C. The bACL is maintained in place in the sterile chamber by inserting the bone anchors in metal pins, one rigidly fixed to a load cell and the other attached to a motion-controlled cursor. By controlling the position of the cursor, the bACL can be subjected to cyclic stretching with amplitudes from 0 to 30 mm at a frequency of up to 1 Hz for any extended period of time. The whole system is controlled via LABview VI software. The experimenter can easily change the experimental conditions and supervise the ongoing tests to make sure that everything is running smoothly. The device was designed to control parameters such as stretching amplitude and frequency. The bACL can be subjected to continuous cyclic stretching for several weeks.

Six experiments have been conducted under similar culture conditions to evaluate the effects of cyclic stretching on the evolution of our bACL model. The cycling frequency was fixed at 1 Hz. During the first 5 days, the bACLs are subjected to a 1-mm stretch per cycle, always returning to their initial length (about 4 cm) to complete each cycle. The amplitude is increased to 2 mm from day 5 to day 10. These conditions were established arbitrarily. We compared two groups of bACLs casted on the same day, seeded with the same ACL cell populations, suspended in the same collagen solution, in order to control as much as possible the cellular parameters involved. This approach allowed us to evaluate the effects of cyclic stretching on the histologic and ultrastructural properties of bACLs.

#### STEP 4: ACL HISTOLOGIC ANALYSES

Histologic studies were performed after 10 days on bACLs cultured under horizontal static tension compared to bACLs subjected to cyclic stretching. The bACL biopsies were fixed in Bouin's solution, paraffin embedded, and 6-mm-thick tissue sections were stained using the standard Masson's trichrome method, which allows excellent visualization of the matricial collagen fibers. The histologic features of both groups of bACLs were compared.

Culture under cyclic stretching did not induce any detectable change in the macroscopic aspect of the bACL. The alignment of matrix fibers in a direction parallel to the tension applied to a cell-populated collagen lattice has been reported. As expected, Masson's trichrome staining of tissue sections showed that matricial alignment in the control bACL was maintained under static horizontal elongation (Fig. 50.3A). Interestingly, bACLs subjected to cyclic stretching (Fig. 50.3B) contained thick bundles of extracellular matrix fibers, highly organized in a wavy pattern, typical of native ACL histologic features (Fig. 50.3C). Thus, cyclic stretching can induce complex structural organization of the extracellular matrix in bioengineered ligaments *in vitro*. The crimps were not observed in control bACLs. Results were repeatedly similar from one experiment to another.

#### STEP 5: bACL INDIRECT IMMUNOFLUORESCENCE ANALYSES

To determine the organization of the extracellular matrix, immunohistologic studies were performed on frozen sections of bACLs. The histologic immunostaining was performed on frozen tis-

Fig. 50.3. Photomicrographs of bACL histologic sections stained using Masson's trichrome methods. (A) A bACL cultured under static conditions, (B) a bACL submitted to cyclic traction, and (C) native human ACL ( $\times 40$ ). Note the wavy pattern of highly organized bundles of collagen fibers induced by cyclic traction.

sue sections (6 mm thick) fixed for 10 min with acetone at  $-20^{\circ}\text{C}$ , as described previously (Auger *et al.*, 1995). A monoclonal antichondroitin sulfate antibody, antihuman type I collagen, type III collagen, and elastin antibodies were used to analyze the organization of these extracellular matrix constituents in the cultured bACLs.

The network of matrix fibers is better organized in bACLs subjected to cyclic stretching than in those cultured under static tension. Type I collagen is the major constituent of the bundles of fibers induced by cyclic stretching (Fig. 50.4A), as observed in the native human ACL (Fig. 50.4B). Moreover, the bACLs cultured under cyclic stretching contain more chondroitin sulfate (Fig. 50.4D) than do the bioengineered tissues maintained under static tension (Fig. 50.4F). However, all bACLs contain less chondroitin sulfate than does native ACL (Fig. 50.4E).

#### STEP 6: bACL ULTRASTRUCTURAL ANALYSES

Biopsies can be processed and mounted for electron microscope analyses, as described previously (Auger *et al.*, 1993, 1995). Electron microscope analyses of bACLs subjected to cyclic traction revealed that the HLFs are surrounded by bundles of collagen fibers (Fig. 50.5A) aligned with the cells in the direction parallel to the long axis of all bACLs (Fig. 50.5B). The typical 67-nm periodicity of the collagen (Fig. 50.5C) is observed in the collagen fibers.

Fig. 50.4. Immunofluorescence labeling of human type I collagen fibers (A, B, and C) and chondroitin sulfate (D, E, and F) in frozen sections of native ACL (B and E) and bACL cultured for 10 days under cyclic (A and D) and static (C and F) elongation ( $\times 40$ ). Note the stronger signals of human type I collagen and chondroitin sulfate within the matricial network of bACL submitted to cyclic traction compared to static tension.

Fig. 50.5. Electron microscopy analyses of ultrathin sections of bACL cultured under cyclic traction. (A) Collagen fibers (arrowheads) surrounding a living HLF (bar: 8.3  $\mu\text{m}$  = 500 nm). (B) Bundles of collagen fibers oriented in a direction parallel to the long axis of the bACL (bar: 9.25  $\mu\text{m}$  = 500 nm). (C) A collagen fiber with the typical 67-nm periodicity.

## CONCLUSIONS

Recent advances in bioengineering and cellular biology have led to revolutionary new therapeutic applications in many medical fields. The use of autologous tissue-engineered epidermis and living skin substitutes for the treatment of human burns is an example of such progress (Auger *et al.*, 1993, 1995; Green *et al.*, 1979; Boyce *et al.*, 1991; Contard *et al.*, 1993; Fernyhough *et al.*, 1987; Germain *et al.*, 1993; Hansbrough *et al.*, 1989; López Valle *et al.*, 1992b). The bioengineered ligament model described in this chapter presents features that can be adapted to other culture conditions *in vitro* (our bACL) and very likely to *in vivo* postgrafting in animals (see, for example, Dunn's ligament substitute) (Dunn *et al.*, 1994).

Collagen fibers organized in wavy bundles can be obtained *in vitro* in a human bioengineered living tissue. Our data strongly suggest that living ACL cells seeded into bACL analogs can respond to mechanical stimuli *in vitro*. The stimulation of collagen secretion and the acute matrix remodeling observed in bACLs subjected to cyclic traction are very promising observations. Indeed, such bACLs could be cultured under these conditions for longer periods of time, to promote further development of histologic characteristics. We previously reported that HLFs isolated from human ACL biopsies and seeded into a collagen matrix can secrete and reorganize matricial fibers in response to static tension (Goulet *et al.*, 1997a,b). Our data strongly suggest that cyclic traction can induce the cells to organize thick bundles of collagen fibers into a wavy structural pattern.

Such matricial reorganization might improve the mechanical properties of the bACLs. Matrix strengthening of ligament equivalents (hydrated collagen gels seeded with human dermal fibroblasts) was reported after 12 weeks of mechanical stress *in vitro* (induced by maintaining the slowly contracting equivalent at a fixed length), with the maintenance of cell viability (Huang *et al.*, 1993). These results showed that it is possible to reinforce a bioengineered tissue using static mechanical stimuli. We expect to see comparable or better effects induced by dynamic stimuli, notably cyclic traction, on bACL strength. Cyclic traction may also contribute to maintaining the biomechanical response of the human ACL fibroblasts used to populate our bACL, on culture time.

This work was performed for a given cyclic frequency and stretching amplitude. Extensive studies have to be done to determine the optimal frequency and amplitude that would best reorganize the matrix. These studies raise hope for successful production of functional autologous ACL

analogs in culture through new bioengineering approaches. Presently, the strength of our bACL does not compare with the strength of native ACL. However, a bioengineered blood vessel developed in our laboratory, using human endothelial cells, smooth muscle cells, and fibroblasts organized in layers supported by a collagen matrix, can withstand a pressure of at least 2000 mmHg (L'Heureux *et al.*, 1998). The production of this blood vessel equivalent demonstrates that it is possible to obtain strong bioengineered tissues cultured *in vitro*.

A comparable level of strength may be obtained for our bACL in culture and the tissue could be further reinforced *in vivo*, during the animal implantation phase of the project. For instance, only a part of the patellar tendon is grafted when used as an autologous ACL analog. Orthopedic surgeons who practice the bone–patellar ligament–bone autograft for ACL reconstruction have described graft weakening at about 6 weeks posttransplantation. Despite this decrease in functionality, when these grafts are successful the implants are slowly revascularized after about 6 weeks and present most ACL histologic and functional properties after 30 weeks in humans. The graft becomes stronger and is revascularized as the patient slowly returns to normal activities, suggesting that a significant remodeling of our bACL could occur *in vivo*. Such remodeling could bring the bACL mechanical properties to a functional level. We are presently testing this hypothesis using autologous bACLs in goats. Preliminary observations made on the animal's legs only 1 month postimplantation are very encouraging.

Nevertheless, the main advantages of our bACL over other ligament models stem from its histologic organization which is progressively modulated by the living ACL fibroblasts included in its structure. Because fibroblasts seeded in the bACL secrete and reorganize extracellular matrix constituents in culture, it makes it a promising tool to study the role of various cellular elements involved in the maintenance or the induction of ligament organization *in vitro*.

## PERSPECTIVES IN TENDON AND LIGAMENT BIOENGINEERING

Combined techniques of cell biology and tissue engineering produce tendons and ligaments in culture. These different bioengineered tissues will indeed have to be optimized prior to human transplantation. However, investigators involved in this area of research have not yet started to exploit all the possibilities offered by this new biotechnological concept. For instance, gene therapy might find some interesting applications by introducing living transfected cells within various types of bioengineered tissues.

Despite the challenges that lie ahead for those hoping to reproduce tissues and organs *in vitro*, there is every reason to feel optimistic, based on the advances already made in various medical fields through tissue bioengineering (Langer and Vacanti, 1993). It is quite probable that in the near future, people will benefit from bioengineered tendon and ligament substitutes. Production may start in a laboratory and reach its final completion in a human body. Currently, a delay of 6 weeks after injury is required before ACL surgery is performed, and studies have shown that it is better to perform surgical intervention of the ACL when the nearly normal range of motion of the knee has returned and inflammation has been mostly eliminated (Johnson *et al.*, 1992). This time frame allows for the production of a bACL *in vitro*. Engineering of an autologous ACL would avoid the need for detrimental harvesting of the patients's tissues. This approach may limit the need for knee surgery, because it may be possible to graft a bACL anchored with bones simply by arthroscopy. In addition, bioengineered tissues cannot be rejected postgrafting when produced with autologous cells. That is the common ultimate goal shared by all researchers and clinicians. Realization of this goal would certainly revolutionize the present therapeutic approach to tendon and ligament implantation.

## ACKNOWLEDGMENTS

Dr. Albert Normand died early after the initiation of our work on human ligament bioengineering. Our research team expresses sincere gratitude to this devoted orthopedic surgeon, who was the first to propose cyclic stretching for the development of our bioengineered ACL *in vitro*. The authors are grateful to Jean Lamontagne and Marc Bouchard, for their helpful contribution as residents in orthopedic surgery on the human ACL bioengineering project. The authors thank Louis-Mathieu Stevens and Geneviève Bordeleau, two students who have actively contributed to the latest advances in this work; Julie Tremblay and Julie Bergeron for precious research assistance; Eve Langelier and Christine Lord for the design of the cyclic stretching device; Dominique Ro-

bitaille, Gilbert Castilloux, Stéphane Bouchard, François Berthod, and Pierre-Philippe Stevens for computer programming and functional setup for mechanical analyses; Michel Bordeleau and Roland Martineau for designing and producing the static culture device; Réjean Desbiens for helpful discussions as a consultant in mechanical engineering; Aristide Pusteria for sample preparation for electron microscopy analyses; and Claude Marin for photographic assistance. This work was supported by the Medical Research Council of Canada. The Canadian Orthopaedic Association, The Renaud-Lemieux Foundation of CHA, Pavillion Saint-Sacrement, and The Club Richelieu of Limoilou, Quebec.

# MECHANOSENSORY MECHANISMS IN BONE

Stephen C. Cowin and Melvin L. Moss

## INTRODUCTION

The mechanosensory mechanisms in bone include (1) the cell system that is stimulated by external mechanical loading applied to the bone, (2) the system that transduces that mechanical loading to a communicable signal, and (3) the systems that transmit that signal to the effector cells for the maintenance of bone homeostasis and for strain adaptation of the bone structure. The effector cells are the osteoblasts and the osteoclasts. These systems and the mechanisms that they employ have not yet been unambiguously identified. We review here candidate systems. In particular, we summarize the current theoretical and experimental evidence that suggests that osteocytes are the principal mechanosensory cells of bone, that they are activated by shear stress from fluid flowing through the osteocyte canaliculi, and that the electrically coupled three-dimensional network of osteocytes and lining cells is a communications system for the control of bone homeostasis and structural strain adaptation.

It has long been known that living adult mammalian bone tissue adapts its material properties, and that whole bones adapt their shape, in response to altered mechanical loading (Wolff, 1870, 1892, 1986; Frost, 1964, 1969; Uthoff and Jaworski, 1978; Jaworski *et al.*, 1980; Lanyon *et al.*, 1982). Progress is being made in understanding the cellular mechanisms that accomplish the absorption and deposition of bone tissue. The physiologic mechanism by which the mechanical loading applied to bone is sensed by the tissue, and the mechanism by which the sensed signal is transmitted to the cells that accomplish the surface deposition, removal, and maintenance, have not been identified. The purpose of this chapter is to review some of the background research on these mechanosensory mechanisms and to outline candidates for the mechanosensory system [see Burger *et al.* (1998) for an earlier review of similar literature].

All vital cells are “irritable,” i.e., capable of perturbation by, and response to, alterations in their external environment (Jacobs, 1998; Junge, 1998). The mechanosensing process(es) of a cell enable it to sense the presence of, and to respond to, extrinsic physical loadings. This property is widespread in uni- and multicellular animals (French, 1992; Kernan *et al.*, 1994; Fraser and MacDonald, 1994; Hamill and McBride, 1995; Hackney and Furness, 1995; Cui *et al.*, 1995), plants (Wildron *et al.*, 1992; Goldsmith, 1994), and bacteria (Olsson and Hanson, 1995). Tissue sensibility is a property of a connected set of cells and it is accomplished by the intracellular processes of mechanoreception and mechanotransduction. “Mechanoreception” is the term used to describe the process that transmits the informational content of an extracellular mechanical stimulus to a receptor cell. “Mechanotransduction” is the term used to describe the process that transforms the content of a mechanical stimulus into an intracellular signal. We employ the term “mechanosensory” to mean both mechanoreception and mechanotransduction. Additional processes of intercellular transmission of transduced signals are required at tissue, organ, and organismal structural levels.

Fig. 51.1. A scanning electron micrograph showing the replicas of lacunae and canaliculi *in situ* in mandibular bone from a young subject aged 22 years. The inset shows enlarged lacunae identified by a rectangle. This micrograph illustrates the interconnectivity of the CCN. From Atkinson and Hallsworth (1983), with permission.

## THE CONNECTED CELLULAR NETWORK

The bone cells that lie on all bony surfaces are osteoblasts, either active or inactive. Inactive osteoblasts are called bone-lining cells; they have the potential of becoming active osteoblasts. The bone cells that are buried in the extracellular bone matrix are the osteocytes. Each osteocyte, enclosed within its mineralized lacuna, has many (perhaps as many as 80) cytoplasmic processes. These processes are approximately 15  $\mu\text{m}$  long and are arrayed three-dimensionally in a manner that permits them to interconnect with similar processes of up to as many as 12 neighboring cells. These processes lie within mineralized bone matrix channels called canaliculi. The small space between the cell process plasma membrane and the canalicular wall is filled with bone fluid and macromolecular complexes of unknown composition. All bone cells except osteoclasts are extensively interconnected by the cell processes of the osteocytes, forming a connected cellular network (CCN) (Cowin *et al.*, 1991; Moss, 1991a,b). The interconnectivity of the CCN is graphically illustrated in Fig. 51.1, which is a scanning electron micrograph showing the replicas of lacunae and canaliculi *in situ* in mandibular bone from a young subject aged 22 years. The inset shows enlarged lacunae (outlined by a rectangle).

The touching cell processes of two neighboring bone cells contain gap junctions (Bennett and Goodenough, 1978; Doty, 1981, 1989; Jones and Bingmann, 1991; Schirmacher *et al.*, 1992; Jones *et al.*, 1993; Gourdie and Green, 1993; Civitelli, 1995). A gap junction is a channel connecting two cells. The walls of the channel consist of matching rings of proteins piercing the membrane of each cell, and when the rings associated with two cells connect with each other, the cell-to-cell junction is formed. This junction allows ions and compounds of low molecular weight to pass between the two cells without passing into the extracellular space. The proteins making up a

gap junction are called connexins; in bone the protein is either connexin 43 or 45, with 43 predominating (the number refers to the size of the proteins calculated in kilodaltons) (Minkoff *et al.*, 1994, 1999; Lecanda *et al.*, 1998). A ring of connexins in one cell membrane is generally called a connexon or hemichannel. Both mechanical strain and fluid shear stress cause increased expression of connexin 43 in vascular tissues (Cowan *et al.*, 1998). In cardiac tissue the turnover rate of connexin 43 is very rapid (Beardslee *et al.*, 1998). The rapid dynamics of gap junction turnover and the plasticity of gap junction expression in response to various stimuli offer the possibility for remodeling of the intercellular circuits, both within and between communication compartments in the cardiovascular system (Spray, 1998). In bone, gap junctions connect superficial osteocytes to periosteal and endosteal osteoblasts. All osteoblasts are similarly interconnected laterally on a bony surface; perpendicular to the bony surface, gap junctions connect periosteal osteoblasts with preosteoblastic cells, and these, in turn, are similarly interconnected. Effectively, each CCN is a true syncytium (Doty, 1989; Schirrmacher *et al.*, 1992; Rodan, 1992; Jones *et al.*, 1993). Gap junctions are found where the plasma membranes of a pair of markedly lapping canalicular processes meet (Rodan, 1992). In compact bone, canaliculi cross the cement lines that form the outer boundary of osteons. Thus extensive communication exists between osteons and interstitial regions (Curtis *et al.*, 1985).

Bone cells are electrically active (Bingmann *et al.*, 1988a,b; Chesnoy-Marchais and Fritsch, 1988; Massass *et al.*, 1990; Rubinacci *et al.*, 1998). In addition to permitting the intercellular transmission of ions and small molecules, gap junctions exhibit both electrical and fluorescent dye transmission (Jeansonne *et al.*, 1979; Schirrmacher *et al.*, 1993; Spray, 1994; Moreno *et al.*, 1994). Gap junctions are electrical synapses, in contradistinction to interneuronal, chemical synapses, and, significantly, they permit bidirectional signal traffic (e.g., biochemical, ionic, electrical). In a physical sense, the CCN represents the hard wiring (Cowin *et al.*, 1991; Moss, 1991a,b; Nowak, 1992) of bone tissue.

## MECHANOSENSATION ON THE CCN

### STIMULI

The *stimulus* for bone remodeling is defined as that particular aspect of the bone's stress or strain history that is employed by the bone to sense its mechanical load environment and to signal for the deposition, maintenance, or resorption of bone tissue. The bone tissue domain or region over which the stimulus is felt is called the *sensor* domain. When an appropriate stimulus parameter exceeds threshold values, loaded tissues respond by the triad of bone adaptation processes: deposition, resorption, and maintenance. The CCN is the site of intracellular stimulus reception, signal transduction, and intercellular signal transmission. It is thought that stimulus reception occurs in the osteocyte (Cowin *et al.*, 1991), and that the CCN transduces and transmits the signal to the surface lining or osteoblast. The osteoblasts alone directly regulate bone deposition and maintenance, and indirectly regulate osteoclastic resorption (Martin and Ng, 1994). The possible role of the osteoblast as a stimulus receptor has not yet been thoroughly investigated (Owan *et al.*, 1997). Although it is reasonably presumed that initial mechanosensory events occur at the plasma membrane of the osteocytic soma and/or canalicular processes, the initial receptive, and subsequent transductive, processes are not well understood.

It follows that the true biologic stimulus, although much discussed, is not precisely known. A variety of mechanical loading stimuli associated with ambulation (at a frequency of 1 to 2 Hz) have been considered for bone remodeling. The majority have followed Wolff (1892, 1986) in suggesting that some aspect of the mechanical loading of bone is the stimulus. The mechanical stimuli suggested include strain (Cowin and Hegedus, 1976), stress (Wolff, 1892, 1986), strain energy (Fyhrie and Carter, 1986; Huiskes *et al.*, 1987), strain rate (Hert *et al.*, 1969, 1971, 1972; O'Connor *et al.*, 1982; Lanyon, 1984; Goldstein *et al.*, 1991; Fritton *et al.*, 1999), and fatigue microdamage (Carter and Hayes, 1976; Martin and Burr, 1982). In some cases the time-averaged values of these quantities are suggested as the mechanical stimulus, and in others the amplitudes of the oscillatory components and/or peak values of these quantities are the candidates for the mechanical stimulus. Two dozen possible stimuli were compared in a combined experimental and analytic approach (Brown *et al.*, 1990). The data supported strain energy density, longitudinal shear stress, and tensile principal stress or strain as stimuli; no stimulus that could be described as rate

dependent was among the two dozen possible stimuli considered in the study [for a consideration of the stimulus in microgravity see Cowin (1998)].

The case for strain rate as a remodeling stimulus has been building over the past quarter century. The animal studies of Hert and co-workers [Hert *et al.*, 1969, 1971, 1972] suggested the importance of strain rate. Experiments (Lanyon, 1984; Goldstein *et al.*, 1991; Fritton *et al.*, 1999) have quantified the importance of strain rate over strain as a remodeling stimulus. The studies (Weinbaum *et al.*, 1991, 1994; Cowin *et al.*, 1995) directed at the understanding of the cellular mechanism for bone remodeling have suggested that the prime mover is the bone strain rate-driven motion of the bone fluid, the signal of which is transduced by osteocytes. In the model of Weinbaum *et al.* (1991, 1994) the shear stress from the bone fluid flow over the osteocytic processes in the canaliculi is a cellular mechanism-based model suggesting strain rate as a stimulus. The study of Gross *et al.* (1997) that showed bone deposition to be related to strain gradients actually, by the model of Weinbaum *et al.* (1991, 1994), also demonstrated a dependence on strain rate.

In experiments with cultured cells it has been shown that osteocytes, but not periosteal fibroblasts, are extremely sensitive to fluid flow, resulting in increased prostaglandin as well as nitric oxide (NO) production (Klein-Nulend *et al.*, 1995a,b). Three different cell populations, namely, osteocytes, osteoblasts, and periosteal fibroblasts, were subjected to two stress regimes, pulsatile fluid flow (PFF) and intermittent hydrostatic compression (IHC) (Klein-Nulend *et al.*, 1995a). IHC was applied at 0.3 Hz with 13-kPa peak pressure. PFF was a fluid flow with a mean shear stress of 0.5 Pa with cyclic variations of 0.02 Pa at 5 Hz. The maximal hydrostatic pressure rate was 130 kPa/sec and the maximal fluid shear stress rate was 12 Pa/sec. Under both stress regimes, osteocytes appeared more sensitive than osteoblasts, and osteoblasts more sensitive than periosteal fibroblasts. However, despite the large difference in peak stress and peak stress rate, PFF was more effective than IHC. Osteocytes, but not the other cell types, responded to 1 hr of PFF treatment with a sustained prostaglandin  $E_2$  up-regulation lasting at least 1 hr after PFF was terminated. By comparison, IHC needed 6 hr of treatment before a response was found. These results suggested that osteocytes are more sensitive to mechanical stress than are osteoblasts, which are again more sensitive than periosteal fibroblasts. Furthermore, osteocytes appeared particularly sensitive to fluid shear stress, more so than to hydrostatic stress. These conclusions are in agreement with the theory that osteocytes are the main mechanosensory cells of bone, and that they detect mechanical loading events by the canalicular flow of interstitial fluid, which results from that loading event. Weinbaum *et al.* (1994) used Biot's porous media theory to relate loads applied to a whole bone to the flow of canalicular interstitial fluid past the osteocytic processes. Their calculations predict fluid-induced shear stresses of 0.8–3 Pa, as a result of peak physiologic loading regimes. The findings that bone cells *in vitro* actually respond to fluid shear stress of 0.2–6 Pa (Reich *et al.*, 1990; Williams *et al.*, 1994; Hung *et al.*, 1995; Klein-Nulend *et al.*, 1995a,b) lend experimental support to the theory.

Osteocytes also rapidly release NO in response to stress (Pitsillides *et al.*, 1995; Klein-Nulend *et al.*, 1995b), and this NO response seems to be required for the stress-related prostaglandin release (Klein-Nulend *et al.*, 1995b). Therefore, the behavior of osteocytes compares to that of endothelial cells, which regulate the flow of blood through the vascular system, and also respond to fluid flow of 0.5 Pa with increased prostaglandin and NO production (Hecker *et al.*, 1993). The response of endothelial cells to shear stress is likely related to their role in mediating an adaptive remodeling of the vasculature, so as to maintain constant endothelial fluid shear stress throughout the arterial site of the circulation (Kamiya *et al.*, 1984).

Skeletal muscle contraction is a typical bone loading event and has been suggested (Moss, 1968, 1969, 1978) as a stimulus. Frequency is one of the critical parameters of the muscle stimulus and it serves to differentiate this stimulus from the direct mechanical loads of ambulation that occur at a frequency of 1 to 2 Hz. The frequency of contracting muscle in tetanus is from 15 Hz to a maximum of 50–60 Hz in mammalian muscle (McMahon, 1984). It has been observed (McLeod and Rubin, 1992; Rodriquez *et al.*, 1993) that these higher order frequencies, significantly related to bone adaptational responses, are (Rubin *et al.*, 1993) “present within the [muscle contraction] strain energy spectra regardless of animal or activity and implicate the dynamics of muscle contraction as the source of this energy band.” The close similarity of muscle stimulus frequencies to bone tissue response frequencies is noted below.

## RECEPTION AND TRANSDUCTION

The osteocyte has been suggested as the stimulus sensor, the receptor of the stimulus signal (Cowin *et al.*, 1991); histologic and physiologic data are consistent with this suggestion (Aarden *et al.*, 1994; Aarden, 1996). The placement and distribution of osteocytes in the CCN three-dimensional array are architecturally well suited to sense deformation of the mineralized tissue encasing them (Lanyon, 1993). Because only a population of cells, and not an individual receptor (Edin and Trulsson, 1992), can code unambiguously, the osteocytes in the CCN are potential mechanoreceptors by virtue of their network organization.

Osteocytic mechanotransduction may involve a number of different processes or cellular systems. These processes include stretch- and voltage-activated ion channels, cytomatrix sensation–transduction processes, cytosensation by fluid shear stresses, cytosensation by streaming potentials, and exogenous electric field strength. Each of these processes or cellular systems is discussed below.

### Stretch- and voltage-activated ion channels

The osteocytic plasma membrane contains stretch-activated ion channels (Guggino *et al.*, 1989; Duncan and Mislner, 1989; Keynes, 1994; Hamill and McBride, 1996), which are also found in many other cell types (Morris, 1990; French, 1992; Ghazi *et al.*, 1998). When activated in strained osteocytes, they permit passage of certain ions (Sachs, 1986, 1988; Sackin, 1995), including  $K^+$ ,  $Ca^{2+}$ ,  $Na^+$ , and  $Cs^+$ . Such ionic flow may, in turn, initiate cellular electrical events; for example, bone cell stretch-activated channels may modulate membrane potential as well as  $Ca^{2+}$  ion flux (French, 1992; Harter *et al.*, 1995). Rough estimates of osteocytic mechanoreceptor strain sensitivity have been made (Cowin *et al.*, 1991), and the calculated values cover the morphogenetically significant strain range of 0.1 to 0.3% in the literature (Lanyon, 1984; Rubin and Lanyon, 1984, 1987). This appears to be too low a strain to open a stretch-activated ion channel. A model involving bone fluid flow has been suggested for the amplification of the 0.1 to 0.3% strain applied to a whole bone to a value an order of magnitude larger at the osteocytic cytoplasmic process membrane (Cowin and Weinbaum, 1998). Stretch-activated ion channels also occur in osteoblastic cells (Davidson *et al.*, 1990).

As in most cells, the osteocytic plasma membrane contains voltage-activated ion channels, and transmembrane ion flow may be a significant osseous mechanotransductive process (Chesnoy-Marchais and Fritsch, 1988; Ravelsloot *et al.*, 1991; Ferrier *et al.*, 1991; Jan and Jan, 1992). It is also possible that such ionic flow generates osteocytic action potentials, capable of transmission through gap junctions (Schirrmacher *et al.*, 1993).

### Cytomatrix sensation–transduction processes

The mineralized matrix of bone tissue is strained when loaded. Macromolecular mechanical connections between the extracellular matrix and the osteocytic cell membrane exist, and these connections may be capable of transmitting information from the strained extracellular matrix to the bone cell nuclear membrane. The basis of this mechanism is the physical continuity of the transmembrane integrin molecule, which is connected extracellularly with the macromolecular collagen of the organic matrix and intracellularly with the cytoskeletal actin. The latter, in turn, is connected to the nuclear membrane (Hughes *et al.*, 1993; Watanabe *et al.*, 1993; Green, 1994; Richardson and Parsons, 1995; Clark and Brugge, 1995; Forgacs, 1995; Shapiro *et al.*, 1995; Dolce *et al.*, 1996; Shyy and Chien, 1997; Salter *et al.*, 1997; Meazzini *et al.*, 1998; Carvalho *et al.*, 1998; Ingber, 1998; Janmey, 1998). It is suggested that such a cytoskeletal lever chain, connecting to the nuclear membrane, can provide a physical stimulus able to activate the osteocytic genome (Jones and Bingmann, 1991), possibly by first stimulating the activity of components such as the *c-fos* genes (Uitto, 1991; Jones and Bingmann, 1991; Dayhoff *et al.*, 1992; Sadoshima *et al.*, 1992; Watanabe *et al.*, 1993; Yanagishita, 1993; Wang *et al.*, 1993; Haskin and Cameron, 1993; Petrov and Usherwood, 1994; Machwate *et al.*, 1995; Salter *et al.*, 1997).

### Cytosensation by fluid shear stresses

A hypothesis concerning the mechanism by which the osteocytes housed in the lacunae of mechanically loaded bone sense the load applied to the bone by the detection of dynamic strains was suggested by Weinbaum *et al.* (1991, 1994). It was proposed that the osteocytes are stimulat-

ed by relatively small fluid shear stresses acting on the membranes of their osteocytic processes. A hierarchical model of bone tissue structure that related the cyclic mechanical loading applied to the whole bone to the fluid shear stress at the surface of the osteocytic cell process was presented (Weinbaum *et al.*, 1994). In this model the sensitivity of strain detection is a function of frequency; in the physiologic frequency range (1–20 Hz), associated with either locomotion (1–2 Hz) or the maintenance of posture (15–30 Hz), the fluid shear stress is nearly proportional to the product of frequency and strain. Thus if bone cells respond to strains on the order of 0.1% at frequencies of 1 or 2 Hz, they will also respond to strains on the order of 0.01% at frequencies of 20 Hz. The fluid shear stresses would also strain the macromolecular mechanical connections between the cell and the extracellular bone matrix (mentioned in the previous section); thus fluid shear stress is also potentially capable of transmitting information from the strained matrix to the bone cell nuclear membrane, where it can effectively regulate its genomic functions.

Several investigators (Piekarski and Munro, 1977; Johnson *et al.*, 1982; Kufahl and Saha, 1990) have examined other aspects of the lacunar–canalicular porosity using simple circular pore models and have attempted to analyze its possible physiologic importance. These studies have primarily emphasized the importance of the convective flow in the canaliculi between the lacunae as a way of enhancing the supply of nutrients between neighboring osteocytes. Previous studies on the relaxation of the excess pore pressure have been closely tied to the strain-generated potentials (SGPs) associated with bone fluid motion. The SGP studies are briefly reviewed below.

### Cytosensation by streaming potentials

The fact that the extracellular bone matrix is negatively charged due to its proteins means that a fluid electrolyte bounded by the extracellular matrix will have a diffuse double layer of positive charges. When the fluid moves, the excess positive charge is convected, thereby developing streaming currents and streaming potentials. The cause of the fluid motion is the deformation of the extracellular matrix due to whole-bone mechanical loading. Pollack and co-workers (Pollack *et al.*, 1984; Salzstein *et al.*, 1987; Salzstein and Pollack, 1987) have laid an important foundation for explaining the origin of strain-generated potentials. However, there is disagreement on the anatomical site in bone tissue that is the source of the experimentally observed SGPs. Salzstein and Pollack (1987) concluded that this site was the collagen–hydroxyapatite porosity of the bone mineral, because small pores of approximately 16 nm radius were consistent with their experimental data if a poroelastic–electrokinetic model with unobstructed and connected circular pores was assumed (Salzstein *et al.*, 1987). Cowin *et al.* (1995), using the model of Weinbaum *et al.* (1994), have shown that the data of Salzstein and Pollack (1987), Scott and Korostoff (1990), and Otter *et al.* (1992) are also consistent with the larger pore space (100 nm) of the lacunar–canalicular porosity being the anatomical source site of the SGPs, if the hydraulic drag and electrokinetic contribution associated with the passage of bone fluid through the surface matrix (glycocalyx) of the osteocytic process are accounted for. The mathematical models of Salzstein *et al.* (1987) and Weinbaum *et al.* (1994) are similar in that they combine poroelastic and electrokinetic theory to describe the phase and magnitude of the SGP. The two theories differ in the description of the interstitial fluid flow and streaming currents at the microstructural level and in the anatomic structures that determine the flow. In Weinbaum *et al.* (1994) this resistance resides in the fluid annulus that surrounds the osteocytic processes, i.e., the cell membrane of the osteocytic process, the walls of the canaliculi, and the glycocalyx (also called the surface matrix or capsule) that exists in this annular region. In Cowin *et al.* (1995) the presence of the glycocalyx increases the SGPs and the hydraulic resistance to the strain-driven flow. The increased SGP matches the phase and amplitude of the measured SGPs. In the Salzstein *et al.* (1987) model this fluid resistance and SGP are achieved by assuming that an open, continuous small pore structure ( $\approx 16$  nm radius) exists in the mineralized matrix. The poroelastic model of Weinbaum *et al.* (1994) for bone fluid flow has been developed further (Zhang *et al.*, 1997, 1998a,b,c; Wang *et al.*, 1999) and a review of the related poroelastic literature has appeared (Cowin, 1999).

Experimental evidence indicating that the collagen–hydroxyapatite porosity of the bone mineral is unlikely to serve as the primary source of the SGP is obtained from several sources, including the estimates of the pore size in the collagen–hydroxyapatite porosity and permeability studies with different size-labeled tracers in both mineralized and unmineralized bone. Such permeability studies clearly show time-dependent changes in the interstitial pathways as bone ma-

tures. At the earliest times, the unmineralized collagen–proteoglycan bone matrix is porous to large solutes. The studies with ferritin (10 nm in diameter) in 2-day-old chick embryos (Dillaman, 1984) show a continuous halo around primary osteons 5 min after the injection of this tracer. The halo passes right through the lacunar–canalicular system, suggesting that, before mineralization, pores of the size predicted in Salzstein and Pollack (1987) (radii  $\approx$  16 nm) can exist throughout the bone matrix. In contrast, Montgomery *et al.* (1988), using this same tracer in adult dogs, also found a fluorescent halo surrounding the Haversian canals; however, this halo was not continuous but was formed by discrete lines, suggesting that the pathways were limited to discrete pores whose spacing was similar to that observed for canaliculi. This conclusion is supported by the studies of Tanaka and Sakano (1985) in the alveolar bone of 5-day-old rats using the much smaller tracer, microperoxidase (MP) (2 nm). These studies clearly showed that the MP penetrated only the unmineralized matrix surrounding the lacunae and the borders of the canaliculi and was absent from the mineralized matrix. Using more mature rats, the study of Ayasaka *et al.* (1992) confirmed the failure of the small (2 nm) MP tracer to penetrate the mineralized matrix tissue from the bone fluid compartments.

### Exogenous electric field strength

Bone responds to exogenous electrical fields (Otter *et al.*, 1998). Although the extrinsic electrical parameters are unclear, field strength may play an important role (Brighton *et al.*, 1992; Otter *et al.*, 1998). A significant parallelism exists between the parameters of exogenous electrical fields and the endogenous fields produced by muscle activity. Bone responds to exogenous fields in an effective range of 1–10  $\mu\text{V}/\text{cm}$ , strengths that are on the order of those endogenously produced in bone tissue during normal (muscle) activity (McLeod *et al.*, 1993; 1998).

### The uniqueness of osseous mechanosensation

The difference between mechanosensation in bone tissue and mechanosensation in nonosseous processes is revealing and thought to be significant. First, most mechanosensory cells are cytologically specialized (e.g., rods and cones in the retina); bone cells are not. Second, one bone loading stimulus can evoke three adaptational responses (deposition, maintenance, or resorption) whereas nonosseous process stimuli evoke one response (e.g., vision). Third, osseous signal transmission is aneural, whereas all other organismal mechanosensational signals (Moss-Salentijn, 1992) utilize afferent neural pathways (e.g., the visual pathway) (Hackney and Furness, 1995). Fourth, the evoked bone adaptational responses are confined within each “bone” independently (e.g., within a femur); there is no organismal involvement (e.g., touch is a generalized somatic sensation). However, all afferent transductive processes, osseous and nonosseous, share many common mechanisms and processes (Gilbertson, 1998; Wilson and Sullivan, 1998).

### SIGNAL TRANSMISSION

From a communications viewpoint the CCN is multiply noded (each osteocyte is a node) and multiply connected. Each osteocytic process is a connection between two osteocytes, and each osteocyte is multiply connected to a number of osteocytes that are near neighbors (see Fig. 51.1). Cell-to-cell communication is considered first below, then we speculate on the ability of the CCN to compute as well as signal. It is useful to note the possibility that bone cells, like neurons, may communicate intercellular information by volume transmission, a process that does not require direct cytological contact, but rather utilizes charges in the environment (Fuxe and Agnati, 1991; Marotti, 1996; Schaul, 1998).

### Cell-to-cell communication

In order to transmit a signal over the CCN, one osteocyte must be able to signal a neighboring osteocyte that will then pass the signal on until it reaches an osteoblast on the bone surface. There are a variety of chemical and electrical cell-to-cell communication methods (De Mello, 1987). The passage of chemical signals, such as  $\text{Ca}^{2+}$ , from cell to cell appears to occur at a rate that would be too slow to respond to the approximately 30-Hz signal associated with muscle firing. We focus here on electrical cell-to-cell communication. Zhang *et al.* (1997, 1998a) have formulated a cable model for cell-to-cell communication in an osteon. The spatial distribution of intracellular electric potential and current from the cement line to the lumen of an osteon was

estimated as the frequency of the loading and conductance of the gap junction were altered. In this model the intracellular potential and current are driven by the mechanically induced strain-generated streaming potentials produced by the cyclic mechanical loading of bone. The model differs from earlier studies (Harrigan and Hamilton, 1993) in that it pursues a more physiologic approach in which the microanatomical dimensions of the connexon pores, osteocytic processes, and the distribution of cellular membrane area and capacitance are used to estimate quantitatively the leakage of current through the osteoblast membrane, the time delay in signal transmission along the cable, and the relative resistance of the osteocytic processes and the connexons in their open and closed states. The model predicts that the cable demonstrates a strong resonant response when the cable coupling length approaches the osteonal radius. The theory also predicts that the pore pressure relaxation time for the draining of the bone fluid into the osteonal canal is of the same order as the characteristic diffusion time for the spread of current along the membrane of the osteocytic processes. This coincidence of characteristic times produced a spectral resonance in the cable at 30 Hz. These two resonances lead to a large amplification of the intracellular potential and current in the surface osteoblasts, which could serve as the initiating signal for osteoblasts to conduct remodeling.

### Signal processing and integration

When a physical representation of a CCN, such as Fig. 53.1, is viewed by someone familiar with communications, there is often an intuitive response that the CCN may function as a neural network for processing the mechanical loading stimulus signals being felt over the network. That idea is explored here with no justification other than shared intuition. A CCN is operationally analogous to an artificial neural network in which massively parallel, or parallel distributed, signal processing occurs (Edin and Trullsson, 1992; Denning, 1990; Martino *et al.*, 1994). Fortunately, the bases of connectionist theory are sufficiently secure to permit a biologically realistic CCN model (Dayhoff, 1990; Grossberg, 1988; Hinton and Anderson, 1989; McClelland and Rumelhart, 1987; Zorntzer *et al.*, 1990).

A CCN consists of a number of relatively simple, densely interconnected, processing elements (bone cells), with many more interconnections than cells. Operationally these cells are organized into layers: an initial input, a final output, and one or more intermediate or hidden layers. However, such networks need not be numerically complex to be operationally complex (Kupfermann, 1992).

The operational processes are identical, in principle, for all bone cells in all layers. Each cell in any layer may simultaneously receive several weighted (i.e., some quantitative measure) inputs. In the initial layer these are the loading stimuli (mechanoreception). Within each cell independently, "all the weighted inputs are then summed" (Wasserman, 1989). This net sum is then compared, within the cell, against some threshold value. If this liminal value is exceeded, a signal is generated (mechanotransduction in input layer cells) that is then transmitted identically to all the hidden layer cells (adjacent osteocytes) to which each initial layer cell is connected. Similar processes of weighted signal summation, comparison, and transmission occur in these layers until final layer cells (osteoblasts) are reached. The outputs of these surface-situated cells regulate the specific adaptation process of each group of osteoblasts (Parfitt, 1994). All neighboring osteoblasts that carry out an identical bone adaptational process form a communication compartment, a cohort of structurally and operationally similar cells, because all these cells are interconnected by open, functional gap junctions. At the boundary between such compartments that are carrying out different adaptational processes, the intervening gap junctions are closed and are incapable of transmitting information. These boundaries are probably changing continuously, because some of the cells have some down time (Jeansonne *et al.*, 1979; Spray, 1998).

Information is not stored discretely in a CCN, as is the case in conventional computers. Rather it is distributed across all or part of the network, and several types of information may be stored simultaneously. The instantaneous state of a CCN is a property of all of its cells and of their connections. Accordingly, its informational representation is redundant, assuring that the network is fault, or error, tolerant; i.e., one or several inoperative cells cause little or no noticeable loss in network operations (Wasserman, 1989).

CCNs exhibit oscillation; i.e., iterative reciprocal (feedback) signaling between layers enables them to adjustively self-organize. This is related to the fact that CCNs are not preprogrammed, rather they learn by unsupervised training (Fritzke, 1994), a process involving the adaptation of

the CCNs to the responses of the cytoskeleton to physical activity (Dayhoff *et al.*, 1992). In this way the CCN adjusts to the customary mechanical loading of the whole bone (Lanyon, 1984). In a CCN, structurally more complex attributes and behavior gradually self-organize and emerge during operation. These are not reducible; they are neither apparent nor predictable from a prior knowledge of the behavior of individual cells.

As noted above, gap junctions as electrical synapses permit bidirectional flow of information. This is the cytologic basis for the oscillatory behavior of a CCN. The presence of sharp discontinuities between groups of phenotypically different osteoblasts is related also to an associated property of gap junctions, i.e., their ability to close and so prevent the flow of information (Kam and Hodgins, 1992; Kodoma and Eguchi, 1994). Significantly, informational networks can also transmit inhibitory signals, a matter beyond our present scope (Marotti *et al.*, 1992).

It is suggested that a CCN displays the following attributes: developmentally it is self-organized and self-adapting and, in the sense that it is epigenetically regulated, it is untrained; operationally it is a stable, dynamic system, whose oscillatory behavior permits feedback—in this regard, it is noted that a CCN operates in a noisy, nonstationary environment, and that it also employs useful and necessary inhibitory inputs.

The CCN permits a triad of histologic responses to a (seemingly) unitary loading event. Although in this chapter, as in almost all the related literature, the organization of bone cells is treated as if it existed only in two dimensions, and as if bone tissue loadings occurred only at certain discrete loci, and that without consideration of loading gradients, the biologic situation is otherwise. Given such a loading event, a three-dimensional bone volume, gradients of deformation must exist, and each osteocyte may sense correspondingly different strain properties. Moreover, it is probable that each osteocyte potentially is able to transmit three different signals in three different directions, some stimulatory and some inhibitory: such states have not yet been modeled (Moss, 1997a,b).

### **A tentative mechanotransduction synthesis**

The molecular lever mechanisms that permit muscle function to regulate directly the genomic activity of strained bone cells, including their phenotypic expression, when combined together with electric field effects and contraction frequency energetics, provide a biophysical basis for an earlier hypothesis of epigenetic regulation of skeletal tissue adaptation (Moss and Young, 1960; Moss, 1962, 1968, 1969; Moss and Salentijn, 1969a,b).

It is probable (Moss, 1997c,d) that electrical and mechanical transductive processes are neither exhaustive nor mutually exclusive. While utilizing differing intermediate membrane mechanisms and/or processes, they share a common final pathway (Bhalla and Iyengar, 1999); i.e., both mechanical and electrical transductions result in transplasma membrane ionic flow(s), creating a signal(s) capable of intercellular transmission to neighboring bone cells via gap junctions (Weinbaum *et al.*, 1994; Zeng *et al.*, 1994; Cowin *et al.*, 1995; Zhang *et al.*, 1997, 1998a). These signals are inputs to a CCN, whose outputs regulate the bone adaptational processes.

The primacy of electrical signals is suggested here, because although bone cell transduction may also produce small biochemical molecules that can pass through gap junctions, the time course of mechanosensory processes is believed to be too rapid for the involvement of secondary messengers (French, 1992; Wildron *et al.*, 1992; Carvalho *et al.*, 1994). As was noted previously, the passage of chemical signals, such as  $\text{Ca}^{2+}$ , from cell to cell appears to occur at a rate that would be too slow to respond to the approximately 30-Hz signal associated with muscle firing.

### **QUESTIONS FOR FUTURE RESEARCH; SOCRATIC QUESTIONS**

1. Given that several alternative plausible osseous mechanosensory modalities are postulated in the literature, is it reasonable to consider that a possible “common pathway” exists, capable of subsuming them all (cf. Bhalla and Iyengar, 1999; Zuker and Ranganathan, 1999)?
2. Is it useful to consider osseous mechanosensation at the quantum level (cf. Ghazi *et al.*, 1998; Green and Triffitt, 1997)?
3. Does NO play a significant role in osseous mechanosensation (cf. Lee *et al.*, 1998; Pitsillides *et al.*, 1995; Klein-Nulend *et al.*, 1995b)?
4. Does the osteocytic syncytium share similar response characteristics with other cellular syncytia; i.e., are they also periodic, chaotic, and functioning at the edge of a state of chaos (cf. Kashimori *et al.*, 1998)?

5. Is bone a “smart material,” organized as a “smart structure” (cf. Wang and Kang, 1998; Culshaw, 1996)? Further, in this regard, is bone an “intelligent material” in the sense that this is reflected in the proposed relationship to “strain history”?

6. Is sufficient attention given to the inherent difference between *in vivo* and *in vitro* experimentation (cf. Brown *et al.*, 1998)?

7. Given the rapidly evolving conceptual bases for the complexity sciences, is it appropriate to consider the extent to which bone tissue and cellular responses to mechanical loadings are evidence of a self-adapting and self-organizing biological system (cf. Heylighen, 1997; Wriggers *et al.*, 1998; Cammarota and Onaral, 1998)?

8. Given that a single osteocyte, existing in a syncytial cellular network capable of signaling back-propagation, has three-dimensional connectivity, is it possible that in response to a unitary loading event, a unitary osteocyte is capable of simultaneously transmitting three different “signals,” one in each direction; i.e., one signal for deposition, one for resorption and one for stasis? If so, how is this accomplished? And if not, why not?

9. What factor(s) regulate the “size” (area) of a “packet” (communication compartment, cohort) of osteoblasts, all engaging simultaneously in the same activity (i.e., deposition, resorption, stasis) on a bone surface, at any one period of time?

10. What is the relationship between the electromagnetic frequencies to which bone responds and those frequencies to which other, nonosseous cells and tissues respond (cf. Shafik, 1998)?

11. Is it possible to develop a comprehensive explication of all aspects of bone tissue response to extrinsic “loadings” that is equally valid at all organizational levels—molecular, microscopic, cellular, tissue, and organismal (cf. Sasaki and Odajima, 1996)?

12. What are the rules of the self-assembly process that governs the formation of structure in bone? How does this process differ in morphogenesis, growth, strain adaptation, fracture healing, and the development of secondary osteons?

# MYOBLAST THERAPY

Joanne C. Cousins, Jennifer E. Morgan, and Terence A. Partridge

## INTRODUCTION

Interest in grafting muscle precursor cells (MPCs) initially arose from the desire to discover a treatment for genetic diseases of skeletal muscle, such as Duchenne muscular dystrophy (Partridge *et al.*, 1978). Duchenne muscular dystrophy (DMD), the most common inherited myopathy, is characterized by the lack of the subsarcolemmal protein dystrophin (Hoffman *et al.*, 1987). Muscle fibers that lack dystrophin undergo repeated cycles of necrosis and regeneration, resulting in progressive replacement of muscle fibers by fibrotic tissue and adipose tissue (Dubowitz, 1985). This is reflected in gradual loss of effective muscle function and eventual premature death (Partridge, 1993). Similar but less severe symptoms of muscle weakness and wasting are seen in the rarer Becker muscular dystrophy (BMD), a more phenotypically variable allelic form of muscular dystrophy. A truncated form of the dystrophin protein is present and disease onset is usually later with less severe muscle wasting, allowing some patients to remain ambulant throughout their lives (Dubowitz, 1985). The rationale behind myoblast transplantation therapy (MTT), is that normal myogenic MPCs would participate in the repair and remodeling of the degenerating muscle, making use of the regeneration pathway of normal adult skeletal muscle after injury (Partridge, 1991a; Partridge and Davies, 1995). Normal adult skeletal muscle consists of long, multinucleate postmitotic fibers and quiescent mononuclear MPCs, termed “satellite” cells, situated beneath the basal lamina of each fiber. Following damage to a fiber, satellite cells are activated to proliferate and fuse with the surviving portion of the syncytium to repair the damaged area of the fiber (Bischoff, 1994). MTT would therefore lead to repair of the degenerated region of the muscle fiber; the normal myoblasts and gene products produced by the myonuclei derived from these transplanted cells could compensate for deficient or abnormal host proteins, even if the missing gene or gene product causing the disease were unknown (Partridge and Davies, 1995). Myoblasts are also potentially effective vehicles for transfer of exogenous genes because they are able to divide extensively, migrate, and differentiate. Furthermore, long-term expression of exogenous genes is possible due to the longevity of the postmitotic nuclei derived from the implanted cells. This rationale would also make myoblast transplantation into skeletal muscle an attractive prospect for the synthesis of systemically active peptides and proteins for the treatment of nonmuscle diseases (Barr and Leiden, 1991). Myoblast transplantation has also provided useful insights into how postnatal muscle regenerates and is repaired, which is of vital importance when considering transplantation as a treatment for myopathies.

## MYOBLAST-MEDIATED GENE TRANSFER

Myoblast-mediated gene transfer has been investigated as a means to construct a recombinant protein factory within skeletal muscle to synthesize a range of systemically active peptides (Barr and Leiden, 1991). As a target tissue for cell therapy, skeletal muscle has several attractive properties. It is richly vascularized, which would allow efficient systemic delivery of transgene products. Moreover, transplanted myoblasts terminally differentiate on incorporation into the myofiber by

fusion with each other or with the existing fiber, thus providing a stable tissue for protein production.

C2C12 myoblasts have been used in myoblast transplantation (MT) to express human growth hormone (Barr and Leiden, 1991; Dhawan *et al.*, 1991). Myoblasts engineered in culture to produce recombinant human (Yao and Kurachi, 1992) and canine (Dai *et al.*, 1992) factor IX have given sustained expression of biologically active protein in the serum of transplanted mice. To optimize the procedure, myoblasts were first retrovirally infected with a *lacZ* reporter gene; this also confirmed that the C2C12 cell line used would form muscle on transplantation (Yao and Kurachi, 1992). Persistent factor IX mRNA expression and long-term protein expression were seen following transplantation of engineered primary cells (Yao *et al.*, 1994), and therapeutic levels of human protein were achieved by repeated transplantation (Wang *et al.*, 1997). Stable expression was seen in both studies, and the participation of donor cells in muscle fiber formation was again confirmed by  $\beta$ -galactosidase expression from the *lacZ* reporter gene.

Sufficient and sustained levels of functionally active human erythropoietin have been achieved by transplanting C2C12 myoblasts coexpressing erythropoietin and  $\beta$ -galactosidase; transplanted cells were seen to participate in muscle formation, although tumors were also frequently observed (Hamamori *et al.*, 1995). It should be noted that even though a number of these studies used the C2C12 myogenic cell line (Barr and Leiden, 1991; Dhawan *et al.*, 1991; Yao and Kurachi, 1992; Hamamori *et al.*, 1995), previous work has shown that C2C12 myoblasts generate tumors on transplantation into mouse muscle (Morgan *et al.*, 1992; Wernig *et al.*, 1991). Consequently, the exogenous protein detected could have been secreted by the tumor cells or by mature muscle. This has been addressed in work by Bou-Gharios *et al.* (1999), which demonstrated that mature fibers of donor origin expressed the recombinant protein. Direct intramuscular injection of plasmid DNA was compared to transplantation of *H-2K<sup>b</sup>-tsA58* myoblasts (Jat *et al.*, 1991) engineered *ex vivo* to secrete human  $\alpha$ -1-antitrypsin ( $\alpha$ 1-AT). Immunohistochemistry on the *mdx* nude muscles injected with myoblasts showed that mature donor fibers expressing dystrophin as a marker of donor origin also expressed human  $\alpha$ 1-AT. Detectable levels of human  $\alpha$ 1-AT were also observed in serum, although it is unclear whether the  $\alpha$ 1-AT seen in muscle fibers is directly related to the serum levels of  $\alpha$ 1-AT.

The problems associated with producing a protein factory within an existing muscle, such as reducing or terminating protein expression, can be overcome by transplanting engineered myoblasts (Irintchev *et al.*, 1998) or bioartificial muscles (organoids); developed in culture from myoblasts (Vandenburg *et al.*, 1996) these products can be surgically introduced into accessible subcutaneous sites. Irintchev *et al.* (1998) showed that as early as 1 week after subcutaneous implantation of myoblasts, muscle of mature morphology and phenotype was formed. These ectopic muscles were vascularized and often connected to underlying skeletal muscle and/or innervated. These are interesting findings in terms of producing recombinant proteins from engineered myoblasts; the subcutaneous space could be exploited for the development of these cells and for delivery of their protein product to the circulation.

## THERAPEUTIC MYOBLAST TRANSPLANTATION FOR MYOPATHIES

### ANIMAL STUDIES

*In vivo* MT was first used in the late 1970s to elucidate the basic cell biology of muscle lineages (Lipton and Schultz, 1979; Jones, 1979). To investigate the possibility that donor muscle cells might repair host muscles damaged by myopathy or injury, minced muscle grafts were transplanted between two strains of inbred mice and fusion was observed between donor and host myoblasts (Partridge *et al.*, 1978). Subsequently it has shown that single muscle precursor cells prepared from disaggregated donor muscle can be incorporated into an area of regeneration within the host mouse, forming hybrid fibers from the fusion of donor nuclei with host fibers (Watt *et al.*, 1982). It was postulated that transplantation of myoblasts could provide a possible therapy even without identification of the defective protein or gene responsible for the myopathy (Law *et al.*, 1988; Partridge *et al.*, 1989; Karpati *et al.*, 1989). The first evidence that implanted MPCs could ameliorate a biochemical deficiency was provided in phosphorylase kinase-deficient mice (Morgan *et al.*, 1988). This was followed by the formation of dystrophin-positive fibers in MPC-

injected muscular dystrophy (mdx) muscles (Partridge *et al.*, 1989). The mdx mouse (Bulfield *et al.*, 1984) is a biochemical homolog of DMD, lacking the protein dystrophin (Hoffman *et al.*, 1987) due to a point mutation in the dystrophin gene (Sicinski *et al.*, 1989). Characterized by early-onset muscle degeneration and regeneration and mild clinical phenotype, few deleterious effects are present until 20–24 months of age, when many pathological changes similar to DMD are seen (Pastoret and Sebillé, 1995a,b). The mdx mice have an almost normal life-span and efficient muscle regeneration, and cannot therefore be considered an ideal disease model (Partridge, 1991b, 1997). The initial experiments showed that dystrophin-positive fibers were produced after transplantation of normal myoblasts into regenerating mdx muscle (Partridge *et al.*, 1989; Karpati *et al.*, 1989), although with current knowledge, some of these fibers (Karpati *et al.*, 1989) were probably due to a reversion from a dystrophin-negative to a dystrophin-positive phenotype (Hoffman *et al.*, 1990) (see later). Blocking the regenerative capacity of the mdx muscle by local high doses of X-irradiation (Wakeford *et al.*, 1991; Quinlan *et al.*, 1995, 1997) and  $\gamma$ -irradiation (Weller *et al.*, 1991) provides a convenient model of the fiber atrophy and connective tissue replacement seen in DMD. Normal myoblasts transplanted into X-irradiated mdx muscles produced large numbers of dystrophin-positive fibers, fiber loss was counteracted, and there was restoration of an almost normal histologic appearance in the muscle (Morgan *et al.*, 1990). MPCs implanted into preirradiated mdx muscles gave rise to long-lived dystrophin-positive fibers and showed better migration when compared with nonirradiated controls (Morgan *et al.*, 1993). Results from a study involving implanting myoblasts overexpressing dystrophin into mdx mice gave an insight into the amount of dystrophin required to repair a fiber (Kinoshita *et al.*, 1998). Although there was a 50-fold overexpression of dystrophin, the membrane area covered by this expression was only increased by 3-fold, and the percentage of normal mRNA by only 4-fold. This can probably be explained by the limited diffusion of dystrophin protein along a fiber from the transgenic nucleus that produced it; however, as there are also mdx nuclei in a mosaic fiber, it does not have to be entirely composed of transplanted normal nuclei.

It has been suggested that lack of dystrophin in the mdx mouse may be compensated by up-regulation of a structurally related protein, utrophin (Deconinck *et al.*, 1997a). Mice lacking both utrophin and dystrophin have a severely myopathic phenotype with ultrastructural, neuromuscular, and myotendinous junction abnormalities (Deconinck *et al.*, 1997a). Mice lacking utrophin alone have subtle neuromuscular defects, and it has been speculated that the relatively mild phenotypes of the dystrophin and utrophin single-mutant mice, compared to the double mutant, reflect the compensation between the two proteins (Grady *et al.*, 1997). In much the same vein it has been suggested that the milder phenotype of the mdx mice compared to DMD patients may be attributable to more successful utrophin compensation, because utrophin is detected around the sarcolemma of regenerating adult mdx skeletal muscle fibers (Deconinck *et al.*, 1997a). Furthermore, expression of a truncated utrophin protein in transgenic mdx mice led to a major functional improvement (Deconinck *et al.*, 1997b) similar to that previously seen following transgenic expression of a truncated dystrophin protein (Dunckley *et al.*, 1993; Deconinck *et al.*, 1996), and expression of a full-length transgenic utrophin protein at the sarcolemma of mdx mice prevented the development of muscular dystrophy (Tinsley *et al.*, 1998). However, because neither the dystrophin nor the utrophin single-mutant mice are phenotypically normal, the two proteins cannot have completely overlapping developmental roles.

Although myoblast transplantation in the mdx mouse has generated large numbers of dystrophin-positive fibers that can persist for long periods of time (Morgan *et al.*, 1993), and restored near-normal muscle histology (Morgan *et al.*, 1990), the conditions required to achieve this are idealized for the animal model and are not directly transferable to human clinical trials. However, numerous studies have determined the feasibility of myoblast transfer therapy in the treatment of primary myopathies, such as Duchenne muscular dystrophy (Partridge, 1991a).

## PATIENT CLINICAL TRIALS

Successful myoblast transplantation in mdx mice (Partridge *et al.*, 1989) led to four human MT clinical trials (Law *et al.*, 1990; Gussoni *et al.*, 1992; Huard *et al.*, 1992; Karpati *et al.*, 1993). In the first trial Law *et al.* (1990) injected one patient's extensor digitorum brevis muscle with cloned satellite cells derived from a biopsy taken from the patient's father. The contralateral muscle was not injected with cells and served as a negative control. Western blots and immunocyto-

chemistry detected dystrophin at the sarcolemma in the cell-injected leg muscle, but not in the control muscles. A second trial saw dystrophin mRNA transcripts detected by reverse transcription and polymerase chain reaction (RT-PCR) from three of eight patients injected with cells from a first-degree relative (Gussoni *et al.*, 1992). The success of the transplantation into these three patients with deletions in the dystrophin gene was perhaps a virtue of their relative lack of fibrosis compared to older patients. In a preliminary study, Huard *et al.* (1991) reported dystrophin-positive fibers in a 16-year-old DMD patient following MT. The nine-patient MT clinical trial that followed, between human leukocyte antigen (HLA) class I (A, B, and C) and class II DR-matched donors and hosts, saw dystrophin expression in most patients, but this expression decreased with time (Huard *et al.*, 1992). This may have been due to an immune response because a reaction was observed against muscle proteins, including dystrophin, and antibodies detected in the patient's serum reacted against donor myoblasts and myotubes. Karpati *et al.* (1993), however, saw no significant strength improvement or increase in dystrophin in eight cyclophosphamide-immunosuppressed patients following multiple injections of donor MPCs. There was poor overall therapeutic efficiency of MT, attributed in part to cryptic immunorejection and/or toxic effects of the immunosuppressive agent. Tremblay *et al.* (1993) also saw generation of a humoral immune response following MT in young DMD patients, which suggested that cell (or gene) therapy would require host immunosuppression, because the antigens causing the immune response probably included the dystrophin protein. In a trial in which patients were immunosuppressed with cyclosporine, a moderate strength increase was seen in both cell and placebo-injected muscles, indicating an effect of the cyclosporine on muscle strength (Miller *et al.*, 1997). Previous trials had failed to control adequately for the ameliorating effects of either the cyclosporine immunosuppression (Law *et al.*, 1990) or placebo injection (Law *et al.*, 1993). Furthermore, in a study of Becker MD patients controlled for the effect of the transplantation procedure and cyclosporine immunosuppression, no improvement in strength was seen in myoblast-injected muscles (Neumeyer *et al.*, 1998). After a lull caused by the lack of success of human trials of myoblast therapy for DMD, animal studies have increasingly been used to elucidate the problems seen, and to further our understanding of the principles underlying muscle regeneration following injury or due to myopathic disease.

#### FACTORS FOR SUCCESSFUL TRANSPLANTATION

A number of problems have been held accountable for the poor outcome of MTT clinical trials to date, ranging from the preparation of the cells prior to implantation, to their poor dispersal and survival once implanted, and to controlling the immune response. The immune reaction seen following MT is being increasingly studied in animal experiments; the availability of immunodeficient animal strains has provided a means of avoiding this immune response for experimental purposes. However, this issue does need to be further evaluated if clinical trials are to succeed. The results of Vilquin *et al.* (1995b) following transplantation of myoblasts transgenically expressing  $\beta$ -galactosidase into mdx mouse muscle under cyclophosphamide immunosuppression mirrored those seen in the Karpati *et al.* (1993) clinical trial. It was concluded that as an immunosuppressant, cyclophosphamide at high concentrations was toxic to injected myoblasts and at low concentrations was not sufficiently immunosuppressive. Human myoblasts transplanted into immunodeficient or immunosuppressed mice were able to fuse and produce dystrophin, although there was evidence of humoral or cellular immune reaction from rejection of some cells in inadequately suppressed mice (Huard *et al.*, 1994b). In a separate study, dystrophin-positive fibers were still present 9 months after MT with histocompatible mouse cells into mdx mice, even though antibodies to dystrophin and/or the muscle membrane were also present in many mice, indicating that dystrophin incompatibility alone does not necessarily induce rejection (Vilquin *et al.*, 1995a). The need for adequate immunosuppression for MT in DMD patients was further highlighted in the failure of MT in normal mice (Guerette *et al.*, 1995). FK-506 was shown to be an effective immunosuppressant in mdx and normal mice (Kinoshita *et al.*, 1994a,b) and was also effective in preventing short-term immune reactions following MT in monkeys (Kinoshita *et al.*, 1996a). The inflammatory reaction can be prevented by treating the host with FK-506 and a monoclonal antibody against a lymphocyte function-associated antigen (LFA-1) (Guerette *et al.*, 1997a), although cell death was not reduced by treatment with FK-506 alone, indicating the mortality was

not due to a specific acute reaction (Guerette *et al.*, 1997b). The antiinflammatory property of a transforming growth factor (TGF- $\beta$ 1) on myoblast survival was investigated. TGF- $\beta$ 1 expression from retrovirally infected transplanted myoblasts decreased the inflammatory reaction against the transplanted cells, thus prolonging their survival (Merly *et al.*, 1998). Two approaches, blocking the action of interleukin-1 (IL-1) by engineering transplanted myoblasts to express a cytokine inhibitor, or selection of specific muscle-derived cell populations, have also been suggested to improve transplanted cell survival (Qu *et al.*, 1998).

Although the inflammatory reaction has been proposed as the cause of the cell death seen during the first 3 days posttransplantation, it cannot explain the massive cell death seen immediately posttransplantation in both immunocompetent (Huard *et al.*, 1994a) and nude mice (Beauchamp *et al.*, 1994). Using [ $^{14}$ C]thymidine, a semiconserved marker, Beauchamp *et al.* (1997) found that 17% of donor cells survived 48 hr after transplantation, similar to the 20% survival reported by Huard *et al.* (1994a) following transplantation of adenovirally marked cells. In the same study, with an inherited marker (Y chromosome) only 35% of the original number of copies of host genome were present after 48 hr, again indicating a massive loss of donor cells (Beauchamp *et al.*, 1997). In a previous study we estimated the amount of muscle formed from transplantation of a known number of myogenic cells by multiplication of the weight of the muscle by the percentage of dystrophin-positive fibers. Even assuming that all transplanted cells survive, these cells must divide extensively to account for the calculated value of  $\sim 10$  mg of donor-derived muscle (Morgan *et al.*, 1996). When the actual number of cells surviving transplantation is considered, all muscle of donor origin is formed from a small proportion of the initial injected population, which must, therefore, undergo rapid proliferation (Beauchamp *et al.*, 1999). Whether donor myoblasts were unlabeled or labeled with [ $^{14}$ C]thymidine or [ $^3$ H]thymidine, the outcome was the same, despite [ $^3$ H]thymidine being toxic to dividing cells. This indicates that the cells that survived transplantation and went on to proliferate and form muscle fibers were not labeled by [ $^3$ H]thymidine, presumably because they divide slowly in culture and were therefore not dividing during labeling (Beauchamp *et al.*, 1999). This slow division is characteristic of some stem cells (Morrison *et al.*, 1997), which are considered by many to be the ideal cells for MT, giving rise to both fully differentiated muscle and to more precursor cells capable of muscle regeneration following further periods of degeneration. This idea has received a boost by the demonstration that bone marrow-derived cells contribute to the regeneration of mouse skeletal muscle following bone marrow transplantation and also by direct grafting into host muscle (Ferrari *et al.*, 1998) and by the extraction of stemlike cells from muscle (Qu *et al.*, 1998; Gross and Morgan, 1999).

Webster and Blau (1990) showed that neonatal muscle cells have a greater regenerative potential compared with cells from either a teenage or an adult donor. Neonates would therefore be the preferred donor source because 30–40 cell doublings *in vitro* would be required from a muscle biopsy to replace the entire satellite cell pool within an adult (estimated at between  $10^{11}$  and  $10^{12}$  cells), even assuming all of the transplanted cells survived (Partridge and Davies, 1995). Karpati *et al.* (1993) found a loss of myogenicity in normal adult myoblasts after 15–18 doublings *in vitro* prior to implantation; in addition, there was a decrease in proliferative potential with the age of the donor. In parallel with the loss of proliferative capacity, telomere length of satellite cells also decreased during the first two decades of life, whereas telomere length of myonuclei contained within muscle fibers remained constant (Decary *et al.*, 1997). Telomeres are simple repetitive non-coding DNA sequences found at the end of chromosomes, and a decrease in telomeric DNA is associated with somatic cell division. There appears to be an inverse relationship between telomere length and proliferative capacity, and it is therefore supposed that the use of MPCs derived from young donors would be best for MTT due to greater proliferative potential of satellite cells. However, even in young DMD patients the replicative capacity of satellite cells is further reduced by the repeated cycles of degeneration and regeneration that are characteristic of DMD, and this has implications for the idea of *ex vivo* gene therapy in which the patient's own myogenic cells are engineered to produce dystrophin before being expanded *in vitro*, prior to their reimplantation. For experimental MTT in the mouse, the problem of limited proliferative capacity of donor cells in culture has been overcome by utilizing conditionally immortal myoblasts from transgenic animals, such as the *H-2K<sup>b</sup>-tsA58* mouse (Jat *et al.*, 1991; Morgan *et al.*, 1994). The transgene allows these cells to be cultured for long periods of time while still retaining their myogenic properties, and fol-

lowing transplantation they behave as normal MPCs. Long-term culture of these cells enables them to be marked, for example, with a reporter gene, allowing the survival and migration of donor cells to be monitored and facilitating the assessment of success of the MT procedure.

One marker of donor cells following transplantation is the presence of donor-derived normal dystrophin in a dystrophic host. However, it has been reported that dystrophic muscles of both mdx mice and DMD patients contain rare dystrophin-positive fibers, termed "revertant" fibers (Hoffman *et al.*, 1990), such that identification of a dystrophin-positive fiber alone is insufficient to demonstrate successful transplantation. This source of dystrophin-positive fibers was not considered by Law *et al.* (1990), although the trial conducted by Huard *et al.* (1992) had taken it into account. Full-length dystrophin mRNA is a useful marker of donor myoblasts, although in clinical trials Karpati *et al.* (1993) and Morandi *et al.* (1995) failed to identify any full-length dystrophin mRNA, whereas Gussoni *et al.* (1992) identified low levels that had no particular association with dystrophin-positive fibers on biopsy. Mendell *et al.* (1995), using antibodies specific to particular exons, showed up to 10% dystrophin-positive fibers in one DMD patient following MT. A panel of epitope-specific monoclonal antibodies and a polyclonal antibody were used to show the failure of MT in muscle samples from a patient who had received MTT in a clinical trial performed by the Cell Therapy Research Foundation (Memphis, TN) (Partridge *et al.*, 1998). No difference in dystrophin-positive fibers was seen between myoblast- and sham-injected muscles, and moreover, the pattern of dystrophin epitope expression corresponded to the patient's genetic deletion, indicating that the dystrophin-positive fibers were due to a reversion of the patient's fibers from a dystrophin-negative phenotype rather than to expression from normal donor myonuclei. Markers of donor origin have also been used to look at migration of transplanted cells. Fluorescently labeling normal myoblasts prior to implantation into mdx muscle showed that most of the fibers formed from donor cells are near the injection site, implying limited dispersion of the donor cells (Sato *et al.*, 1993). Moens *et al.* (1996) showed by grafting whole extensor digitorum longus (EDL) muscles between C57 and mdx mice that very few MPCs that are active in these grafted muscles are able to migrate into adjacent muscles, this may have been because the grafted muscles were not injured to further activate satellite cells. This implies that to make MT efficient enough to be utilized as a therapy for myopathies, every affected muscle will need to be given closely spaced injections of myoblasts. It has previously been shown that rat myoblasts in the same muscle may migrate from one fiber to another (Hughes and Blau, 1990), but migration between muscles did not occur unless the connective tissue barriers were damaged (Schultz *et al.*, 1986; Morgan *et al.*, 1987; Watt *et al.*, 1987, 1993, 1994). Migration of myoblasts following grafting into FK-506-immunosuppressed BALB/c and mdx mice has been increased by prior culture in concanavalin A (Con A), a tetravalent plant lectin (Ito *et al.*, 1998). The mechanism is unclear, although up-regulation of collagenase synthesis has been noted in a variety of cell types. A study by Skuk *et al.* (1999) demonstrated that precise delivery of transplanted myoblasts in primates by multiple, closely spaced injections can compensate for their poor migration *in vivo*, and that the presence of a myotoxic phospholipase, such as notexin, also increased the success of the transplantation. (Notexin is a phospholipase known to induce degeneration in muscle by destroying the plasma membrane of mature fibers, but sparing MPCs (Harris and Johnson, 1978; Dixon and Harris, 1996)). These were the best results obtained from myoblast transplantation in primates, which, due to a close phylogenetic relationship, provide a better model than the mouse for accurate extrapolation to man. An increased participation in regeneration of donor mouse myoblasts was seen in both normal and mdx mice following irradiation and notexin treatment of host muscle (Kinoshita *et al.*, 1994b). When human myoblasts were transplanted into irradiated and notexin-damaged severe combined immunodeficient (SCID) mice, the majority of fibers formed were of donor origin, although the actual number of fibers present was, at best, one-third of the normal number due to incomplete regeneration (Huard *et al.*, 1994c). Kinoshita *et al.* (1996b) saw a high percentage of fibers of donor origin in mdx mice injected several times with mouse cells cultured in the presence of basic fibroblast growth factor (bFGF), without notexin treatment. The bFGF did not increase the percentage of myogenic cells present within the primary culture because a myogenic clone cultured in the lowest concentration of bFGF showed the same improvement of MT. Gross and Morgan (1999) treated irradiated and cell-injected mdx muscle with notexin to show that some transplanted cells, in addition to forming dystrophin-positive fibers, can persist as muscle precursor cells.

As discussed, studies have shown the importance of the choice of donor cell population (Beauchamp *et al.*, 1999; Gross and Morgan, 1999) as a consideration for the increased efficacy of clinical trials, in addition to methods to increase donor cell survival and migration on transplantation (Moens *et al.*, 1996; Ito *et al.*, 1998; Skuk *et al.*, 1999). The source of donor cells also has implications when myoblasts are used as gene therapy vehicles, and greater success of this technique may be attained with the use of myogenic cells early in the myogenic pathway, such as muscle stem cells (Brown and Miller, 1996). Donor cells with stem cell characteristics have been identified in injected muscles. Yao and Kurachi (1993) were able to extract myogenic cells of donor origin from injected muscles, and Morgan *et al.* (1994) showed that cells isolated from irradiated and injected muscles could be passaged through further rounds of irradiated mouse muscle. There has also been success in differentiating uncommitted cells from nonmuscle tissue into skeletal muscle under appropriate conditions, providing a possible source of material for MT (Young *et al.*, 1995; Gibson *et al.*, 1995). Ferrari *et al.* (1998) showed that transplanted bone marrow-derived cells (possibly originating from multipotent mesenchymal stromal stem cells) migrated into mouse muscle that had been forced to degenerate, and that these cells were able to undergo myogenic differentiation and participate in the regeneration of the damaged fibers.

The existence of populations of cells with the ability to form new muscle, both immediately after transplantation and following future periods of degeneration, may prove crucial to the development of methods to improve the success of human MTT.

# PROTECTION AND REPAIR OF HEARING

Richard A. Altschuler, Yehoash Raphael, Jochen Schacht,  
David J. Anderson, and Josef M. Miller

## INTRODUCTION

Deafness is the number one disability in the United States. Hearing loss affects more than 35 million individuals in all age groups. It increases with age, affecting one in three persons over the age of 65 and 50% of individuals over the age of 75. With the increased longevity of our population, this disability is also increasing. Approximately one-half of all hearing losses are thought to be of genetic etiology. Acquired deafness affects one in four to five individuals and can occur from a variety of causes, including noise, drugs, disease, and aging. It is obviously important to develop interventions to help to prevent hearing loss or to improve the chances to restore hearing after deafness. The means for inducing regeneration of the sensory hair cells, the loss of which results in profound deafness, currently remains an unrealized goal in mammals. However, recent advances in our understanding of molecular mechanisms as well as new developments in cochlear prostheses raise the promise for new and effective treatments for protection from acquired and genetic deafness and better restoration of hearing. This chapter discusses the basis for the interventions and the methods for achieving the interventions.

## BASIS FOR INTERVENTIONS

### ACQUIRED DEAFNESS: ENDOGENOUS PROTECTIVE MECHANISMS

Treatments for protection from acquired deafness can be based on enhancement of endogenous protective mechanisms in the inner ear. Three such endogenous mechanisms have been identified: (1) reactive oxygen metabolites, (2) stress shock proteins, and (3) neurotrophic factors.

#### Regulation of reactive oxygen metabolites

The overproduction of superoxide radicals—and the ensuing chain reaction of formation of other free radicals—now appears to be a common mechanism by which many forms of stress cause damage in the inner ear, including noise and ototoxic drugs (such as aminoglycoside antibiotics). The formation of superoxide radicals occurs early and throughout the traumatizing event. They appear to form in association with intense mitochondrial activity, in response to prolonged tissue hypoxia and a rebound hyperperfusion (e.g., Thorne *et al.*, 1987) and an enhanced release of excitatory amino acids (Puel *et al.*, 1994, 1996). Reactive oxygen metabolites (ROMs) may be generated by stress events hours following the trauma (Yamane *et al.*, 1995). The formation of these radicals, in turn, leads to the initiation of a cascade of intracellular events that lead to cell death. Interventions can be effective at different steps in the sequence of events: before the formation of radicals, by blocking their formation, before they produce downstream effects, by intervention; and during the sequence, so as to reduce or restrict the extent of damage or to enhance repair.

### *Prevention of aminoglycoside-induced hearing loss*

In the case of aminoglycoside antibiotics, Schacht and colleagues have established a molecular mechanism of action that involves free radical formation. Aminoglycoside antibiotics are capable of forming a chelation complex with iron, as demonstrated for gentamicin by nuclear magnetic resonance. The complex, with a 1:1 stoichiometry of gentamicin to iron, is a redox-active compound that will reduce oxygen to the superoxide radical at the expense of an electron donor (Priuska and Schacht, 1995; Priuska *et al.*, 1998; Sha and Schacht, 1999a). This property is apparently shared by all aminoglycoside antibiotics (Sha and Schacht, 1999b) and is responsible for the ototoxic properties of these drugs. The latter can be deduced from the fact that compounds that suppress free radical formation by aminoglycosides *in vitro* are also capable of attenuating the ototoxic effects *in vivo*. Such compounds include well-established antioxidants such as glutathione and iron chelators (Garetz *et al.*, 1994a,b; Song and Schacht, 1996). Indeed, an excellent protection against the ototoxicity of several aminoglycosides was achieved in guinea pigs with the well-established chelating compounds 2,3-dihydroxybenzoate and deferoxamine. Their coadministration attenuated a gentamicin-induced hearing loss of 60–80 db to a negligible loss of around 10 db (Song *et al.*, 1997). Similar protective effects were seen against the cochlear and vestibular toxicity of kanamycin and streptomycin (Song *et al.*, 1998). Independent studies subsequently confirmed antioxidants as protectants against neomycin and amikacin (Conlon and Smith, 1998; Conlon *et al.*, 1999).

This *in vivo* protection both supports the mechanism of free radical involvement and points toward antioxidant treatment as a potential clinical therapy. A clinically feasible prophylactic therapy requires drugs that, alone, are nontoxic and easily administered to the patient. In their search for a practicable application, Sha and Schacht (2000) tested 2-hydroxybenzoate, a precursor of 2,3-dihydroxybenzoate, and found it effective. This compound, commonly known as salicylate, is a weak iron chelator and radical scavenger and may be oxidized under oxidative stress to the more powerful prophylactic 2,3-dihydroxybenzoate. Salicylates have a long medical history as anti-inflammatory drugs, mostly in the commonly supplied oral form of aspirin. These animal experiments then imply that aspirin is a suitable medication to protect from aminoglycoside-induced hearing loss. Clinical trials are now underway to determine efficacy in humans.

### *Prevention of noise-induced hearing loss*

The prophylactic approach is currently less feasible for other stresses, for which mechanisms behind ROM formation have yet to be elucidated or when a proactive treatment is not possible. This reservation would apply to clinical cases of noise-induced hearing loss, and studies are therefore currently focusing on interventions at later times. In animal models, however, the potential of antioxidants to limit noise trauma has been demonstrated.

Good evidence supports the view that ROMs are formed in the inner ear following intense sounds; for example, superoxide radicals have been found in the stria vascularis (Yamane *et al.*, 1995). Consistent with such a free radical involvement, hearing loss can be attenuated by scavengers, including superoxide dismutase and allopurinol (Seidman *et al.*, 1993), and lazaroids and lazaroid-related compounds (Quirk *et al.*, 1994), or by the up-regulation of antioxidant enzymes (Hu *et al.*, 1997). These observations were extended by studies showing the involvement of one of the major endogenous antioxidant systems, glutathione, in the limitation of noise trauma. Glutathione (L- $\gamma$ -glutamyl-L-cysteinylglycine) serves as an important physiologic antioxidant and radical scavenger, because it reacts directly with a number of ROMs, including superoxide anion radicals, hydroxyl radicals, hydrogen peroxides, and other organic peroxides, to form glutathione disulfide. Glutathione attenuates cochlear damage induced by gentamicin (Lautermann *et al.*, 1995a), kanamycin plus ethacrynic acid (Hoffman *et al.*, 1987), amikacin (Nishida and Takumida, 1996), and cisplatin (Lautermann *et al.*, 1995b; Ravi *et al.*, 1995).

Yamasoba *et al.* (1998) manipulated glutathione using L-buthionine-[S,R]-sulfoximine (BSO), which depletes glutathione by inhibiting its synthesis. Following exposure to broadband noise (102 dB SPL\*) for 3 hr/day for 5 days, glutathione-depleted guinea pigs showed significantly greater threshold shifts than did control subjects, and outer hair cell damage was more pronounced.

---

\*SPL is a physical measure of atmospheric pressure equal to 0.0002 dynes/cm<sup>2</sup>.

Similarly, tissue levels of glutathione can be influenced by the dietary availability of one of its precursors for synthesis, the amino acid L-cysteine. Decreased intake decreases cysteine levels in the plasma and glutathione concentration in tissues. By this mechanism, administration of a low-protein diet leads to a reduction of glutathione levels in the cochlea, thereby increasing the susceptibility to drug-induced hearing loss (Lautermann *et al.*, 1995a,b). When guinea pigs were administered a low-protein diet and exposed to noise, they demonstrated significant elevations in auditory brainstem response (ABR) threshold shifts as compared to animals on a normal protein diet (Ohinata *et al.*, 1999). In such glutathione-depleted animals, dietary glutathione ethyl ester can efficiently increase tissue glutathione levels (Puri and Meister, 1983). In fact, oral administration of glutathione ester and vitamin C elevated glutathione levels in the cochlear sensory epithelium in animals on a low-protein diet (Lautermann *et al.*, 1995b). In noise-exposed animals, administration of glutathione ester provided significant ABR protection at all frequencies as compared to their saline-injected controls on a low-protein diet (Ohinata *et al.*, 1999).

Interventions in noise-induced hearing loss may therefore now be based on the accelerated removal of superoxide or derived free radicals, or on the strengthening or supplementation of general detoxification systems.

### Heat-shock proteins

Heat-shock proteins (HSPs) provide a natural protective mechanism for cells in numerous systems and species. HSPs achieve their protective role by influencing the stress-related denaturation of proteins (either reducing the denaturation or enhancing renaturation and regaining the correct tertiary structure), as chaperones, or through an influence on cell death cascades. Several families of HSPs (commonly grouped by their molecular weights) include HSP 25/27, HSP 70/72, and HSP 90. Expression of the inducible form of HSP 70 in the cochlea has been shown with heat (Dechesne *et al.*, 1992), with transient ischemia (Myers *et al.*, 1992), and with noise (Lim *et al.*, 1993). This expression is generally found in the sensory hair cells and is transient, peaking 4–6 hr following the stress. HSP 27, on the other hand, is found constitutively (without the need for induction by stress) and has a more widespread distribution, not only in sensory hair cells, but in supporting cells and the lateral wall tissues (Leonova *et al.*, 1998). Stress appears to modulate this expression. A protective role of HSPs in the inner ear has been suggested. In several studies HSP levels were up-regulated by an initial stress, either low-level noise (Mitchell *et al.*, 1997a; Altschuler *et al.*, 1999) or heat (Yoshida and Liberman, 1999), followed by a noise exposure that would normally cause a significant hearing loss. Either preexposure resulted in a significant (30 db) reduction in noise-induced hearing loss and hair cell loss.

### Neurotrophic factors

Neurotrophins were so named because during development they induce neuronal differentiation, proliferation, growth, and migration, as well as the growth and migration of neuronal processes (reviewed by Davies, 1994). Different neurotrophic factors act on different classes of neurons (Davies, 1994) and act at different receptors. NGF (nerve growth factor) acts at the tyrosine kinase a (trka) receptor, neurotrophin-4 (NT-4) and brain-derived neurotrophic factor (BDNF) act at the trkb receptor, and neurotrophin-3 (NT-3) acts at the trkc receptor (reviewed by Klein, 1994). Other trophic factors with similar effects, but acting at different receptors, include ciliary neurotrophic factor (CNTF) (Sendtner *et al.*, 1994), fibroblast growth factor (FGF) (Eckenstein, 1994), and glial line-derived neurotrophic factor (GDNF) (Lin *et al.*, 1993). Many neurotrophic factors and/or their receptors have been shown in the normal cochlea, including GDNF (Ylikoski *et al.*, 1998) and NT-3 and BDNF (Ylikoski *et al.*, 1993). Neurotrophic factors may have a protective action through an influence on ROMs or via intervention in the cascade of events induced by ROM formation to block cell death. The factors may reduce oxidative stress-driven increases in intracellular  $Ca^{2+}$  (Hegarty *et al.*, 1997; Mattson *et al.*, 1995; Mattson and Furakawa, 1996) through induced expression of calcium-binding proteins (Collazo *et al.*, 1992; Cheng and Mattson, 1992) or antioxidant enzymes (Mattson *et al.*, 1995; Mattson and Furakawa, 1996). The neurotrophic factors may also share a similar biochemical pathway in providing protection and interact with ROM scavengers. Several studies have examined if local infusion of neurotrophins into the inner ear fluids prior to stress will result in protection from hearing loss. When levels of glial line-derived neurotrophic factor or neurotrophin-3 are increased in the inner ear pri-

or to noise overstimulation or prior to the administration of ototoxic drugs there is significant protection, with decreased hearing loss and hair cell loss (Altschuler *et al.*, 1999; Keithley *et al.*, 1998; A. M. Miller *et al.*, 1999; Park *et al.*, 1998; Shoji *et al.*, 2000; Yagi *et al.*, 1999). Thus neurotrophic factors can provide protection. They are less effective if provided following the stress, suggesting a greater role in protection than in repair.

#### ACQUIRED DEAFNESS: DEAFNESS-RELATED CHANGES AND THEIR MODULATION

Many changes occur following deafness, both in the inner ear and in the central auditory pathways. In the inner ear, following loss of inner hair cells, a series of pathophysiological changes follow, including scar formation, loss of the peripheral processes of the auditory nerve, and, over time, substantial loss of the auditory nerve. The loss of auditory nerve is now believed to be related to a loss of survival factors, including neural activity, causing these neurons to enter into the cell death cycle. Centrally, neuronal death is minimal but changes occur that include decreased neuronal cell size in the auditory brain stem; synaptic changes; reorganization of connections; changes in neurotransmitters, receptors, and ion channels; and changes in glia, cytoskeletal elements, and regulatory mechanisms (Altschuler *et al.*, 1997; Bledsoe *et al.*, 1997; Miller *et al.*, 1991, 1996). Although some of these changes are related to a down-regulation concomitant with decreased activity, other changes may be a reaction within the pathways to compensate for decreased activity. There can be a large impact on these deafness-induced changes when activity is returned to the auditory system, currently through cochlear prostheses and perhaps in the future through hair cell regeneration. Studies have therefore been designed to develop interventions that can modulate the deafness-related changes.

#### Enhancement of auditory nerve survival following deafness

Cochlear prostheses depend on direct stimulation of the auditory nerve, so auditory nerve survival is of major importance. Neurotrophic factors not only play a role in protection from stress and trauma (see above), but also are very important for cell maintenance, and their absence can lead to cell death (Rich, 1992). Auditory nerve death following inner hair cell loss has been postulated to be the result of an associated loss of critical survival factors, and studies have therefore examined if replacement of survival factors would stop the death of auditory nerve neurons. Indeed, chronic delivery of neurotrophic factors into the fluids of the inner ear has now been shown to enhance auditory nerve survival significantly following noise- or drug-induced deafness (Altschuler *et al.*, 2000; Ernfors *et al.*, 1996; J. M. Miller *et al.*, 1997; A. M. Miller *et al.*, 1999; Staecker *et al.*, 1996; Ylikoski *et al.*, 1998). Effective neurotrophic factors include BDNF and GDNF.

Depolarization has long been recognized as a trophic treatment in cultured cells, increasing cell survival and modulating neural biochemistry to alter neurotransmitter, neuropeptide, and enzyme expression and density of (functional) voltage-gated calcium channels (Franklin and Johnson, 1992). If activity also serves as a survival factor for the auditory nerve, then electrical stimulation should enhance survival. Studies have shown that chronic electrical stimulation of the auditory nerve does significantly enhance its survival following deafness (Lousteau, 1987; Hartshorn *et al.*, 1991; Miller *et al.*, 1991; Miller and Altschuler, 1995; Mitchell *et al.*, 1997b; Leake *et al.*, 1991, 1992, 1995). The electrical stimulation may serve as a survival factor through activation of voltage-gated ion channels and/or through up-regulation of autocrine factors, including neurotrophic factors. *In vitro* results suggest that a combination of treatments may be most effective (Hegarty *et al.*, 1997) and studies to examine this are still ongoing.

#### Regrowth of auditory nerve processes following deafness

Studies have also examined if neurotrophic factors can induce regrowth of the peripheral processes of the auditory nerve that regress following inner hair cell loss. Some neurotrophic factors that enhance auditory nerve survival following deafness, such as BDNF (see above), will also induce regrowth of peripheral processes (Cho *et al.*, 1998). Other factors such as FGF are not effective in enhancing auditory nerve survival, but if provided along with a factor such as BDNF, which does enhance survival, will induce even greater regrowth than seen with BDNF alone (Cho

*et al.*, 1998). Thus neurotrophic factors can serve not only to enhance survival of the auditory nerve but also to restore its peripheral processes, although different factors may be necessary to accomplish the most effective treatment.

### GENETIC DEAFNESS

One in 1000 newborns suffers from hearing impairment. In developed countries, more than half of the afflicted babies are deaf due to genetic reasons. Genetic inner ear impairments can be nonsyndromic, affecting only hearing, or syndromic, with multiple defects occurring in several body systems. Many of the genes for deafness have now been identified, as well as their products. Affected proteins of the inner ear include cytoskeletal proteins such as myosin and a tectorial membrane protein (reviewed by Probst and Camper, 1999). Identification of the genes that are mutated in families with genetic inner ear impairments is important not only for diagnostic purposes, but also for the potential for prevention and cure. One exciting study has addressed interventions into genetic deafness, and has identified a mutation in *Myo-15* as the cause for deafness and balance impairments in the shaker 2 deafness mouse (Probst *et al.*, 1999). This mouse is a model for several families in which mutations in the very same gene cause genetic inner ear impairments (Wang *et al.*, 1998). Probst *et al.* (1998) demonstrated that in transgenic mice destined (genetically) to become deaf, insertion of the wild-type (correct) gene sequence into the fertilized egg corrected the genetic deficit, leading to normal inner ear structure and function in the adult mouse. This demonstrated that addition of the correct copy of the gene can rescue the inner ear from genetic deficits. To make such interventions viable for clinical applications, it is necessary to develop the means for delivering genes into the inner ear cells, which are the cells directly affected by the mutations. Gene therapy is one of the most promising technologies for gene delivery.

### METHODS OF INTERVENTION

With effective protective measures for treating acquired deafness and measures for treatment following deafness identified, the next challenge is to find methods to provide these interventions.

#### AUDITORY PROSTHESES

Auditory prostheses can provide direct stimulation of the auditory pathways to promote return of hearing following deafness. Stimulatory activity can also act as a survival factor to enhance auditory nerve survival.

##### Cochlear prostheses

In severe and profound sensorineural hearing loss the sensory cells of the cochlea are destroyed. Cochlear prostheses bypass the damaged receptor epithelium and directly electrically excite the auditory nerve fibers. The development of the cochlear prosthesis has been the success story of the field of neuroprostheses. It has provided a therapy for the profoundly deaf, where none previously existed. The first Food and Drug Administration-approved inner ear implants, approximately 25 years ago, were single-channel devices that provided crude input and were an aid to lip reading. Now, multichannel devices, combined with many advances in signal-processing strategies, routinely provide open-set speech discrimination and even use of the telephone in the majority of implant recipients. Multichannel prostheses use strategies that attempt to approximate the "normal" encoding. One strategy is to divide the speech frequency range into six bands, with each activating an electrode in an analog fashion. Another strategy divides the speech frequency range into functionally significant regions (formants), with each assigned to clusters of electrodes that are activated differently depending on the distribution of speech energy in the formant region. Electrode arrays can be activated in an analog or digital fashion, with some devices providing simultaneous activation of sites and others only one at a time, cycling among the sites at a high rate. At this time there are no clear data to indicate that one strategy or approach is inherently better than another, and different devices and strategies work better for some subjects than for others.

##### Central auditory prostheses

Central auditory prostheses can be advantageous when the cochlea is not suitable for implantation or when there is insufficient auditory nerve survival. The dorsal-to-ventral axis of the

cochlear nucleus, as with most auditory nuclei, is tonotopically organized and is therefore a candidate for prostheses placed either on its surface or penetrating into its depth (McCreery *et al.*, 1998; Mobley *et al.*, 1995). Such implants are still in the development stage, although success with surface prostheses on the cochlear nucleus (the first central synapse in the auditory pathways) has been reported (e.g., Laszig *et al.*, 1997; Portillo *et al.*, 1993, 1995). Penetrating prostheses, such as the two-dimensional arrays using multichannel, multishank silicon substrate technology of the Michigan type (Anderson *et al.*, 1989) or the Utah Intracortical Electrode Array (Nordhausen *et al.*, 1994, 1996), offer greater access to the spectral organization. Ultimately, three-dimensional arrays constructed from multiple planes of two-dimensional silicon devices being used in animal experiments may offer even greater access to the organization of brain stem structures (Hoogerwerf and Wise, 1994).

### MINIOSMOTIC PUMPS

The fluid spaces of the cochlea provide for a closed environment well suited to receive local delivery of chemicals. Local delivery provides improved access and avoids the side effects that systemic delivery could entail. A model miniosmotic pump with cannula into the inner ear fluid of scala tympani, or into the middle ear with access through the round window, has been developed in animal models (e.g., Brown *et al.*, 1993; Park *et al.*, 1998), this model has been effectively utilized for local application of chemicals that provide protection from acquired deafness or enhance survival of auditory nerves (see above sections). Devices have also been developed for human applications (e.g., IntraEar, Inc).

### GENE THERAPY

Gene therapy is used to manipulate levels of specific proteins in cells and tissues. It can be used to inactivate specific proteins or to overexpress them. In most cases, this is accomplished by introducing a foreign gene into the cells. Viral vectors are the most efficient vehicles for gene transfer, and adenovirus, herpes simplex virus, adeno-associated virus, and lentivirus can mediate gene transfer into cells of the inner ear (reviewed by Raphael and Yagi, 1998). When mature mammalian inner ears are inoculated with adenoviral vectors, fibroblasts and other cells of connective tissue origin are transduced with the highest efficiency (Raphael *et al.*, 1996; Yagi *et al.*, 1999). At present this limits the applicability of adenovirus-based gene therapy in the inner ear to genes encoding secreted and diffusible proteins, such as the neurotrophins. Overexpression of the human GDNF transgene with an adenovirus vector has been shown to protect hair cells from noise and ototoxic drug insults in guinea pigs (Yagi *et al.*, 1999). Similar treatment was also efficient in protecting spiral ganglion neurons from degeneration following hair cell loss.

The next major challenge for inner ear gene therapy is to infect hair cells and supporting cells with a vector for delivering genes to these cells. Once this obstacle is overcome, it will be possible to test the function of proteins intrinsic to hair cells, such as Myo15 and Myo7a, and to deliver genes that can cure genetic inner ear impairments.

### COMBINATIONS

With studies showing that both electrical stimulation and chemical delivery are important interventions, methods that can combine these can be particularly effective. Tissue engineering interventions are therefore being developed using University of Michigan silicon substrate neuroprobe prostheses that will not only stimulate but will provide chemical factors as well.

### Prostheses with microchannels

University of Michigan neuroprobes can now be fabricated with microchannels for local delivery of fluids (Chen *et al.*, 1997). This provides the potential for site-specific delivery of neuroactive factors into the brain or inner ear. Because the neuroprobes containing the microchannels are also capable of stimulation and recording, it will be possible to provide both electrical stimulation and drug delivery to highly specific regions and to assess the functional results. This type of device opens new approaches to understanding the role of brain chemistry in information processing in the nervous system. By artificially adjusting levels of neuroactive components, neural circuits will be modified and will therefore change their function. Longer term changes in circuits, such as the population of dendrites, can be prompted by chemical action.

### Prostheses with biopolymers

Biopolymers can be synthesized such that they contain both the protein sequence for silk, to provide strength and flexibility, and sequences of functional domains that naturally occur in the extracellular matrix protein, to confer specific biological properties (Cappello, 1990; Cappello *et al.*, 1990). These can be “spun” in microstructured thin films on the surface of prosthetic devices (Anderson *et al.*, 1993). Biopolymers can be produced that contain the sequence of fibronectin or laminin to provide a biologic “glue” (for neurons and epidermal cells, respectively), which can then be coated on implants. This can, in turn, be used to influence and stabilize the neuroprobe tissue interface, or to attach transformed cells for *ex vivo* gene transfer (see below). There is excellent tissue compatibility for these coated probes, with or without attached Schwann cells (O’Shea *et al.*, 1996). The biopolymer can also be used for timed release of specific factors. Thus a prosthesis could be providing electrical stimulation while releasing one or more chemical factors through microchannels (above) and other factors through diffusion out of the biopolymer. Specific placement of biopolymer and microchannels can also provide different factors to different regions.

### Prostheses with biopolymers and *ex vivo* gene transfer

With *ex vivo* gene transfer, cultured cells are transformed to produce a specific gene product and are placed into a specific area of the body for region-specific release. One problem has been that the transformed cells can migrate to a different region. With the use of biopolymers with fibronectin or laminin, transformed cells (e.g., fibroblasts and fibronectin; Schwann cells and laminin), can be securely attached by the biopolymer to a neuroprobe or prosthesis, which is then inserted into the region of interest. The cells will then remain in place and their action will be highly localized.

## CONCLUSIONS

The past decade has brought major advances in our understanding of the molecular mechanisms underlying deafness and of the factors that influence and modulate its expression and progression. We can expect, as progress in these areas continues, that this knowledge will form the basis for “molecular otology.” Novel tissue engineering-based therapeutic interventions may become a major part of the practice of otolaryngology in the twenty-first century.

# VISION ENHANCEMENT SYSTEMS

Gislin Dagnelie, Mark S. Humayun, and Robert W. Massof

## VISUAL SYSTEM: ARCHITECTURE AND (DYS)FUNCTION

Human vision is mediated by one of the most highly developed sensory systems found in nature. The capacity to combine high spatial resolution near the center of fixation with a wide peripheral field of view, accurate depth perception, color discrimination, and light–dark adaptation over 12 orders of magnitude is unparalleled; every stage in the visual system is organized to accomplish this. The photoreceptor layer in the retina provides the high signal amplification of the rods required for night vision, and the dense packing of three cone types provides for detailed central and color vision. The intricate local preprocessing performed by subsequent retinal cell layers augments these functions by performing brightness and color comparisons, and helps to reduce the information stream acquired by over 100 million photoreceptors, allowing transport across a mere 1 million fibers in the optic nerve to the visual centers in the brain, where further parsing and interpretation of the image take place.

From a functional point of view, the visual system can be understood as depicted in Fig. 54.1, with sensors, preamplifiers, preprocessors, transmission lines, and several central processor stages. The two most crucial stages in the visual process—the conversion of light into chemical and electrical signals, and the signal transmission from the eyes toward the brain—are also the most vulnerable ones. Light conversion and signal amplification in the photoreceptors require a highly complex interplay between the molecules inside these cells, undergoing interconnecting cycles of conversion and regeneration, and the surrounding cells—in particular, the retinal pigment epithelium (RPE) cells, which provide nutrients to, and digest cell membrane discarded from, the photoreceptors. This process can easily be disrupted by nutritional deficits, overexposure to short-wavelength light (presumably causing oxidative changes), attacks by pathogens, and especially a genetic miscoding of one or more participating molecules (Heckenlively, 1988). Not only does this directly cause impaired signal transduction, but the additional energy demand, the presence of abnormal molecules, and the excess shed cell membrane may exceed the RPE cells' support capacity, inexorably leading to degeneration of both photoreceptors and RPE cells. These diseases are jointly known as retinal degenerations (Fig. 54.2, A and B). In general, secondary retinal cells (horizontal, bipolar, amacrine, and ganglion cells) are not affected to the same extent, a notable exception to transsynaptic degeneration patterns commonly found in the central nervous system. Morphometric studies of retinal tissue such as that shown in Fig. 54.2B have found average cell survival to be 80 and 30% in the macula (Santos *et al.*, 1997), and 40 and 20% at eccentricities up to 25° (Humayun *et al.*, 1999b) for bipolar and ganglion cells, respectively, in retinas devoid of photoreceptor nuclei.

At the signal transmission stage retinal ganglion cells (RGCs) encode the chemical signals in the form of electrical spike trains that travel along RGC axons toward the thalamic relay nuclei and other brain areas; at this stage the system is vulnerable to insults. Damage can result from injury to the optic nerve (trauma), increased pressure inside the eye, crushing the fragile axon fibers at the optic nerve head (glaucoma), and inflammation (optic neuritis) or impaired blood supply

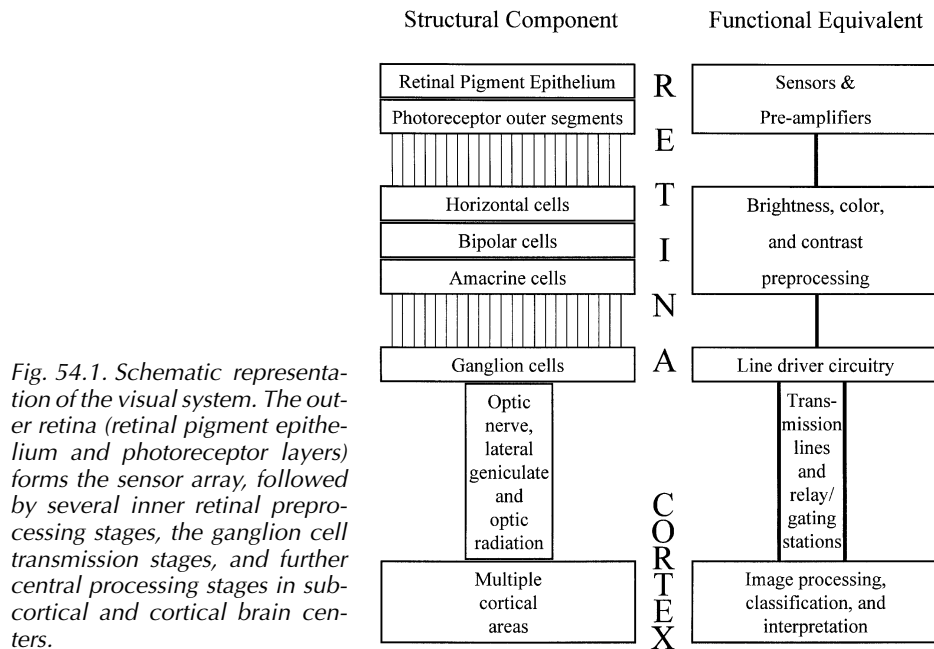

Fig. 54.1. Schematic representation of the visual system. The outer retina (retinal pigment epithelium and photoreceptor layers) forms the sensor array, followed by several inner retinal preprocessing stages, the ganglion cell transmission stages, and further central processing stages in sub-cortical and cortical brain centers.

Fig. 54.2. Representative samples of ocular morphology in healthy and diseased conditions. (A) Cross-section through the retina near its center (fovea), showing healthy photoreceptor outer segments (POS), multiple layers of photoreceptor cell nuclei in the outer nuclear layer (ONL), bipolar cell nuclei in the inner nuclear layer (INL), and ganglion cell bodies in the ganglion cell layer (GCL). (B) Retina of a patient with a long history of retinal degeneration, and bare light perception in the last years of life, showing lack of photoreceptor outer segments and cell bodies, in comparison with A. (C) Scanning electron microscope cross-section of the optic nerve head, showing healthy appearance of the support structure, the lamina cribrosa. (D) Optic nerve head from a patient with long history of glaucoma, showing compression of the lamina cribrosa and embedded nerve fibers (retinal ganglion cell axons). Micrographs C and D courtesy of Harry A. Quigley, the Johns Hopkins University (Baltimore, MD).

(ischemic neuropathy) of the optic nerve. Each of these insults can impair or interrupt the signal-carrying capacity of optic nerve fibers (Fig. 54.2, C and D).

In addition to damage occurring at these distinct stages, more generalized damage to the retina can occur. Common mechanisms for this are the leakage of capillaries in diabetic retinopathy and the interruption of the blood supply to the inner retina (retinal vascular occlusive disease). Each of these can lead to widespread cell death in the inner nuclear and ganglion cell layers throughout the affected area; vascular occlusive disease provokes angiogenesis; the new retinal vessels tend to leak and damage the retina's fragile structure. Diabetic retinopathy is a major cause of preventable blindness in the developed world.

## POSSIBLE APPROACHES TO VISION RESTORATION

As in all biomedical engineering, approaches to restore function can be based on reversal of the disease process and regeneration of autologous tissue, on tissue grafts, or on hybrid techniques involving tissue as well as synthetic materials and devices. To support the cells affected by disease or injury, neuroprotective substances, growth factors, and genetic modifications of cell function may be used, postponing or preventing further loss of function. In addition, as long as useful function remains, one can strengthen the stimulus and internal response signal, counteracting visual impairment as much as possible.

If little or no sensor function remains, one can seek to restore it through newly grown or transplanted photoreceptors and/or RPE cells, through a prosthetic device that will electrically stimulate remaining secondary retinal cells, or through man-made tissue(s) that mimic photoreceptor function. At the RGC level, substitution for lost signal transmission may be sought through protection of the cells and administration of factors promoting axon regeneration—this may require the use of synthetic tissues and factors enabling reconnection of axons with central structures—or through *in situ* growth of new cells, promoted to differentiate into RGCs and to send new axons through the optic nerve.

In preliminary form, some of these approaches exist in the laboratory, but others are merely ideas. In the two following sections, existing and prospective methods are presented.

## CURRENT APPROACHES

### OPTOELECTRONIC VISION ENHANCEMENT DEVICES

These devices are based on a combination of optical and electronic image enhancement techniques; their common principle of operation is to improve visibility of the image to the diseased eye, through magnification, contrast, and/or color enhancement, and filtering or feature extraction. Current implementations such as the Low Vision Enhancement System (LVES; Vision systems International; Minneapolis, MN) use optical magnification, zoom, automatic focus, and (in some cases) analog image enhancement (Fig. 54.3) (Massof, 1999). Digital feature enhancement, although possible in the laboratory, is not currently implemented in portable format; however, with the rapidly increasing power of chip-based image-processing circuitry such further improvements are not far off. The same is true for the product of field of view and resolution, i.e., the number of pixels across the screen, which is currently limited to that of standard video and the video graphics adapter (VGA), but which is likely to increase sharply with the introduction of high-resolution video camera and display formats (e.g., high-definition television). Similarly, compactness and color representation will be improved as smaller, lighter, and more luminous flat-panel displays become available.

A useful property of video cameras such as those employed in the LVES is their built-in automatic gain control (AGC), resulting in constant internal image brightness over a wide range of environmental illumination levels. Among other properties, this makes the image acquisition and processing stages of these systems highly suitable as sensors and preprocessors, respectively, for prosthetic and tissue-based image enhancement systems.

### VISION PROSTHESES BASED ON ELECTRICAL TISSUE STIMULATION

As was mentioned above, retinas with severe degeneration of the sensor layer retain high numbers of secondary cells. This opens the opportunity to convey pixelized images to the degenerated retina by a prosthetic device stimulating remaining secondary cells with a two-dimensional array

Fig. 54.3. The Low Vision Enhancement System (LVES), developed at the Lions Vision Center (Johns Hopkins University), with support from NASA and the Department of Veterans Affairs, is a characteristic example of optoelectronic vision enhancement systems. This system features binocular orientation cameras, a centrally placed 1.5–10× zoom camera with automatic focus, and a binocular projection path with built-in refractive correction and alignment for the wearer.

of microelectrodes,\* not unlike the rastered images provided by a stadium scoreboard (Dagnelie and Massof, 1996). From an engineering point of view this opens a range of possible approaches (to name a few, stimulation electrodes under vs. over the retina; fully integrated photosensor, image processor, and stimulator systems vs. external image capture and processing linked to an intraocular stimulating matrix) and a host of biocompatibility, signal processing, and power management questions.

The most pressing question, however, that of the feasibility to convey visual imagery to patients blind from retinal degeneration, has been answered affirmatively. In a series of experiments started at Duke University in 1992, and continued since 1993 at Johns Hopkins, more than a dozen volunteers with end-stage retinitis pigmentosa (RP)—whose remaining vision was limited to, at best, light perception—have participated in tests whereby, during a surgical procedure under local anesthesia, the inner surface of the retina was electrically stimulated with small and brief biphasic current pulses applied through single or multiple electrodes (Humayun *et al.*, 1996, 1999a). Among the most salient findings are the subjects' ability to see small punctate light flashes (phosphenes), whose perceived location corresponds exactly to that of the stimulation, and the ability to see simple patterns of multiple phosphenes when multiple electrodes are activated simultaneously. Stimulation at rates greater than 40–60 pulses/s is perceived as continuous stimulation, and perceived stimulus intensity increases with pulse duration and amplitude as well as repetition rate. Independent tests in human volunteers and in amphibian retina (Greenberg, 1998) have demonstrated that stimulus pulses 1 ms or longer in duration preferentially stimulate the (deeper) bipolar cells rather than the (more superficial) RGCs.

In a collaborative effort with the group at Johns Hopkins, researchers in the Department of Electrical Engineering at North Carolina State University (NCSU) have developed a modular system for retinal stimulation, with a video image acquisition system and a chipset (radiofrequency encoder/transmitter and decoder/demultiplexer/drivers) to control an intraocular electrode array (Fig. 54.4). These devices are currently being tested in experimental animals with naturally occurring retinal degenerations.

At the present time, several other groups are pursuing similar intraocular prosthetic devices, in two variants: integrated subretinal stimulating “photodiodes,” and epiretinal stimulator arrays with external image capture and preprocessing. In the first variant (Chow and Chow, 1997; Zrenner *et al.*, 1997) small units are placed at the level of the missing photoreceptor/RPE layer, and incoming light—which is focused by the optics of the eye at this original photoreceptor plane, thus

\* Note the similarity of such a device, in both principle and operation, to the cochlear prosthesis (Clark *et al.*, 1990).

Fig. 54.4. Photomicrograph of the Die3 chip, developed at North Carolina State University, for reception, decoding and driving of 100 intraocular multielectrode signals. A delay-locked loop (DLL) and filter are used to synchronize the amplitude-shift keyed (ASK) digital signal; the control logic extracts the pulse amplitude, sequencing, and duration settings. Each driver unit contains circuitry to drive five electrodes. For design considerations and other information, see Clements *et al.* (1999) and the web site at <http://www.ece.ncsu.edu/erl/erl—eye.html>. Photo courtesy of Wentai Liu (NCSU; Raleigh, NC).

providing a sharp image of the outside world—is used to generate electrical impulses that stimulate nearby (bipolar) cells in the overlying retina. The simplicity and elegance of such a system hinge on two important premises: that nutrients and oxygen from the underlying vasculature will still be able to reach the inner retina and that external energy can be provided to produce the necessary pulse generation and signal amplification, especially at low light levels. The developers of such systems are concentrating on finding solutions for these problems, as well as on the design of surgical methods to insert large arrays of such units under the retina.

The second prosthesis type, using an epiretinal stimulator array, is being pursued by two groups, Harvard/Massachusetts Institute of Technology (Wyatt and Rizzo, 1996; Rizzo and Wyatt, 1999) and a consortium of German universities (Eckmiller, 1997), in addition to work at Johns Hopkins/NCSSU (Humayun and de Juan, 1998). Each of these groups expects to have working prototypes of a prosthetic device for human implantation within a few years.<sup>†</sup>

In addition to retinal stimulation, two other approaches to electrical stimulation of the visual system are being studied. One of these, direct stimulation of the optic nerve (Veraart *et al.*, 1998), is less invasive surgically than implantation of devices inside the eye, but has the drawback that stimulation of individual optic nerve fibers will require microelectrode arrays much finer than those currently available, and a complex mapping system to establish the correspondence between visual field locations and individual electrodes (see below).

The oldest attempts at vision restoration involved stimulation of the visual cortex through intracranial electrodes, controlled by external image acquisition and signal-conditioning circuitry. Several decades ago, Brindley and Lewin (1968) took the first steps in this direction by implanting a set of electrodes over the visual cortex of a blind volunteer; the phosphenes described by this volunteer were similar to those elicited by intraocular stimulation. More recently, researchers at the National Institute for Neurological Disorders and Stroke (NINDS) have performed tests with over 30 electrodes penetrating the cortical surface (Schmidt *et al.*, 1996); the NINDS group as well as researchers at the University of Utah are preparing for implantation of denser intracortical electrode arrays (Fig. 54.5) (Normann *et al.*, 1996). The Utah researchers have also performed psychophysical studies to establish minimum requirements for prosthetic vision (Cha *et al.*, 1992a,b), and are testing device prototypes in primates.

The cortical prosthesis bypasses both retinal and optic nerve problems, and might therefore

<sup>†</sup> A significant complication in the design of a prosthesis with external image acquisition is the need for eye position monitoring, allowing adjustment of the camera angle as the prosthesis wearer shifts his/her gaze.

Fig. 54.5. Silicon multielectrode designed by Normann et al. (1996) for penetrating stimulation of the visual cortex or retina. Interelectrode distances between 200 and 400  $\mu\text{m}$  can be manufactured. The 1- to 2-mm-long electrode shafts are insulated, and the tips can be metalized with platinum black or other suitable metals.

be seen as a universal approach to vision restoration. However, cortical stimulation requires complex surgery of an otherwise healthy brain; moreover, the convoluted mapping of the visual cortex complicates mapping of objects and locations in the outside world into a pixelized image that can be understood by the prosthesis wearer. As with the epiretinal prosthesis, eye movement monitoring is required. Algorithms to establish this mapping have been tested through simulations in sighted volunteers (Dagnelie and Vogelstein, 1999), but thus far only for small (32) sets of simulated phosphenes.

### CELL TRANSPLANTATION

Cell transplantation in the neurosensory system can, in principle, restore function through two mechanisms: through rescue of threatened cells (e.g., through trophic factors produced by the transplanted cells) or through functional integration into the host tissue. Both mechanisms appear to be operational in retinal cell transplantation, and it is not always clear which mechanism is responsible for functional improvements observed.

Animal experiments performed in the past 15 years provide clear examples of this dilemma. RPE cell transplantation in RCS rats (Li and Turner, 1988; Lopez et al., 1989) can lead to photoreceptor rescue, and morphologic evidence of synapse formation suggests that transplanted photoreceptors in light-damaged rats (del Cerro et al., 1989) and rats with photoreceptor degenerations (Gouras et al., 1991) may be capable of assuming visual function. Yet, behavioral evidence of regained function in light-deprived rats following photoreceptor transplantation (DiLoreto et al., 1996) could be explained by either mechanism, and solid evidence that the observed synapses indeed provide useful vision is still lacking.

Fetal tissue has proved more successful than fully developed retina in forming synaptic connections and retinal morphology resembling that of intact retina (del Cerro et al., 1997a), and has become the tissue of choice in most transplantation attempts. This tissue also carries a lower risk of rejection by the host immune system, at least in photoreceptor grafts; indeed, rejection does not appear to occur in rat or mouse photoreceptor transplantation (del Cerro et al., 1997a). Admittedly, some caution is warranted, because immune reactions in rodents tend to be less severe than in humans. In rat RPE allografts, on the other hand, some inflammation has been observed (del Cerro et al., 1997a), suggesting that immune processes may play a more important role for this cell type.

Preliminary attempts at retinal cell transplantation in blind volunteers, performed primarily to demonstrate safety, have yielded results very similar to those in animals. Allografts of cultured RPE appear to provide protection to functional age-related macular degeneration (AMD) through trophic factors, but in exudative AMD the graft is quickly overwhelmed by an inflammatory re-

action (Gouras and Algere, 1996). Photoreceptor transplants appear to undergo a similar fate (del Cerro *et al.*, 2000), and also appear to convey an improvement in vision in some cases (del Cerro *et al.*, 1997b; Humayun *et al.*, 2000), but whether this is mediated by graft–host synapse formation or by trophic support to the few remaining photoreceptors cannot be distinguished.

Tissue preparation for these early attempts has varied—ranging from cell microaggregates (del Cerro *et al.*, 1997a) and patches of cultured RPE (Gouras and Algere, 1996) to agar-supported sheets of retinal tissue prepared by vibratome (Silverman and Hughes, 1989) or excimer laser (Liang *et al.*, 1994)—but to date no generally accepted methods have emerged.

### AXON REGENERATION

Retinal ganglion cells behave as central nervous system neurons in their inability to recover from severe injury: although the axons of peripheral (motor or sensory) neurons can regenerate (and even be reconnected), central nervous system neurons seem to lose that capacity following their original outgrowth during the organism's early development. An important factor preventing later regeneration is provided by Schwann cells or astroglia forming the protective myelin sheath around optic nerve axons. Cut rat optic nerve axons that will not form new neurites in their natural optic nerve environment can be made to regenerate into a peripheral nerve graft (Fukuda *et al.*, 1998; Thanos, 1997). This is a very active field of research, combining the drive to find favorable environments for axon regeneration with studies of nerve growth and neuroprotective factors. The long-term goals are therapies for glaucoma and optic nerve diseases; it undoubtedly offers great potential for tissue engineering approaches, and one may expect tissue engineering approaches to play a major role in achieving these goals.

### DRUG DELIVERY

Since 1995 the understanding of photoreceptor and RGC death has changed dramatically. It was previously thought that these cells die because a functional part—the photoreceptor outer segment and the axon, respectively—becomes dysfunctional, but both events are now widely understood to trigger cell death through apoptosis. Better understanding of these apoptotic mechanisms has given rise to the expectation that it may be possible to halt or even reverse this process.

The process of RGC degeneration following transection or crushing of the optic nerve can be halted, at least in animal models, with the use of neuroprotective agents such as neurotrophin-4/5 (NT-4/5) (Sawai *et al.*, 1996). It turns out, however, that this protection has only a limited duration: Most RGCs die within 2–4 weeks, even with sustained administration of NT-4/5 (Clarke *et al.*, 1998). It seems, therefore, that only axon regeneration may rescue the RGC.

In the case of photoreceptor degenerations, a variety of nerve growth factors and neuroprotective agents have been used, both *in vitro* and in rodent eyes, and several of these have shown promise (LaVail *et al.*, 1998). Clinical trials of some of these agents are planned for the near future, but the optimal route of administration is yet to be decided. Systemic administration is not an option, because these agents do not pass the blood–retina barrier very well, and unwanted side effects might occur elsewhere in the body. Administration as an eye drop is not effective, because the active substance would need to diffuse through the cornea or sclera, and most of it would be washed away in the tear film. Repeated injection into the vitreous is unattractive to the patient, and it is not clear how much of the active substance would reach the outer retina, rather than be washed out of the eye.

The most promising current ideas include slow-release implants and delivery by macromolecules. Slow-release implants could be inserted into the eye through a small incision and attached to its inside wall; this is the most direct approach for protection of the inner retina, i.e., retinal ganglion cells. Macromolecules, e.g., liposomes, to which an active substance is attached, are injected into the bloodstream; the active substance is released in the choroidal space under the retina by irradiation with a low-energy laser beam (Asrani *et al.*, 1997). At the present time this technique is experimentally used for the ablation of new vessel membranes growing into the retina in patients with exudative macular degeneration.

A different form of drug delivery is used in retinal ischemic disease. Just as in cerebral ischemia, if “clotbuster” drugs such as tissue plasminogen activator are used within hours after the ischemic event, much of the damage may be prevented; experimental therapy with these drugs has had promising results (Elman, 1996).

## GENETIC INTERVENTIONS

Delivery issues also play a role in the introduction of new genes into the degenerating retina. Most retinal degenerations are genetic in nature, either inherited from one or both parents, or are the consequence of a new mutation. The premise of gene therapy is that intervention at an early stage may restore normal function to the cell, and prevent the degeneration process that might otherwise ensue. Several strategies are needed to combat inherited retinal degenerations:

1. In recessively inherited diseases, both copies of a gene are defective, and introduction of a third copy may be sufficient to achieve adequate function of the molecule encoded by the defective gene. An inactivated (retro)virus is used to introduce a healthy copy of the gene. Small genes have been transfected successfully into photoreceptor and RPE cells using such viral vectors (Dunaief *et al.*, 1995; Sakamoto *et al.*, 1998); however, because the defective genes responsible for retinal degenerations are large, most vectors currently in use are not well suited for this task.

2. In X-linked disease, males carry only one copy of the X chromosome, including the defective gene; here, too, introduction of an additional healthy copy of the gene may suffice to achieve normal function.

3. In dominant disease, a single bad copy of the gene suffices to “poison” the delicate balance of the cellular machinery or, at the very least, prevent its proper function. To curb or prevent this, a therapeutic intervention has to block any step along the transcription pathway from the defective gene through (and including) its product molecule, but not along the path of the good copy of the gene; a gene for such a blocking agent could, in principle, permanently neutralize the defect. This technique has been used *in vitro* (Drenser *et al.*, 1998) and in a transgenic rat model (Lewin *et al.*, 1998), using ribozymes to destroy mRNA produced by the P23H mutant gene defect responsible for one form of autosomal dominant retinitis pigmentosa (RP). In the rat model, a gene for ribozyme production was successfully introduced into photoreceptors.

Gene therapy research is concentrated around RP and related diseases with a clear inheritance pattern. Macular degeneration and optic nerve diseases such as glaucoma and ischemia have no known genetic causes, though genetic predisposition for such diseases exists; other therapeutic approaches are more likely to be effective against these diseases.

## STEM CELL RESEARCH

As in other organ systems, use of stem cells, differentiating into various target cell lines depending on trophic factors *in vitro* or *in vivo*, is emerging as an exciting approach to replacement of lost retinal cells, but not much work has been done. Early reports suggest that adult rat hippocampal stem cells survive and differentiate in retina damaged by transient ischemia, but not in healthy control retina (Kurimoto *et al.*, 1999).

## APPLICATIONS OF ENGINEERED CELLS AND TISSUES: CHALLENGES AND TENTATIVE SOLUTIONS

Of the current approaches to vision enhancement considered above, only the use of stem cells can strictly be considered a form of tissue engineering. The complexity of ocular structures such as the retina and optic nerve poses daunting challenges to anyone seeking to recreate their function. Although this may explain the lag in progress compared to other organ systems, it should not keep researchers working to restore vision from drawing on the remarkable progress of tissue engineering approaches. We will briefly consider three application areas—corresponding to the aforementioned three sites in the early visual system where severe vision loss may occur.

## PHOTOSENSITIVE STRUCTURES

Current efforts in the areas of retinal cell transplantation and intraocular prosthesis design, although promising, are in no way guaranteed to lead to reliable—i.e., long-term stable and of high quality—restoration of useful vision. As was explained previously, each of the methods currently explored has inherent drawbacks.

Epiretinal electrode arrays require external image acquisition and preprocessing, including real-time eye movement compensation, and may well be limited in resolution to ambulatory vision or, at best, visual acuity near legal blindness. The principal cause for this is the distance of at

least 200  $\mu\text{m}$  separating the electrodes from the target cells; as a rule of thumb, resolution can be no better than the separation from the target cells, and higher electrode densities are ineffective. However, it may be possible to develop electrodes that make more intimate contact with the target cells, leading to much better resolution; a possible approach would be to use electrodes that penetrate superficial layers of the retina, making close contact with the bipolar cells and potentially improving visual acuity by an order of magnitude.

One can envisage such a penetrating array as the Normann microelectrode shown in Fig. 54.5, but the damage such an array might do to the delicate microphysiology of the retina is a distinct disadvantage. As an alternative one might envisage inserting or growing, *in situ*, an array of parallel “neurites,” penetrating the retina until they reach a specific target environment, e.g., the inner nuclear layer; these neurites would act as “tubes,” releasing either electrical charge or a neurotransmitter that would activate inner retinal (e.g., bipolar) cells. Such tubes will be much less rigid than silicon, finding their way between retinal cells rather than penetrating them.

Subretinal electrode arrays may overcome the resolution limitation of epiretinal arrays, but this advantage remains to be demonstrated, as does the long-term biocompatibility of these arrays under the primate retina. The most serious limitation, however, is the low yield of semiconductor photoelectric conversion, causing considerable heat production, and demand for high illumination levels or a separate energy source. Consequently, introduction of a high-yield photoelectric process would greatly benefit the development of these devices.

Such high-yield conversions are known to be performed by photosystem I (PSI), a macromolecule present in the membrane of thylakoids, which can be found inside the chloroplasts that give the green color to plant leaves and algae. Experiments with thylakoids (Lee *et al.*, 1996) have shown that it is possible to anchor them onto a metal surface and use them as miniature photovoltaic elements. Lee *et al.* (1997) have also demonstrated that it is possible to chemically modify thylakoid surface membranes to create charge displacement in a specific direction.

The engineering successes of thylakoids and PSI open the opportunity to create “cells” that assume a dipole charge distribution or, with the help of some form of “intracellular electronics,” produce a biphasic pulse between the cell’s “poles”; in a subsequent stage of development, automatic gain control could be incorporated, as a limited form of light/dark adaptation. If these cells can be made to attach to the outer retinal layers or to migrate into the inner nuclear layer, one could achieve microscopic local current sources with sufficient conversion efficiency to ensure vision at a broad range of (day)light levels: To achieve true night vision, an external device such as a night vision scope could be used.

Note that in this idealized situation the synthetic photoreceptors might be small and sensitive enough to provide good vision without external image preprocessing (e.g., magnification and contrast/edge enhancement). It is to be expected that preliminary forms of such light-sensing units will be neither small nor sensitive enough to provide the dynamic range and resolution required; at this intermediate solution level, external image processing with an advanced LVES-type headset would be a necessary complement to this intraocular light conversion array.

## OUTER RETINAL CELL TRANSPLANTATION

Transplantation of RPE and/or photoreceptor cells has not demonstrated full integration of the transplanted cells into the host retina. Also, even if the host immune response appears to be mild, its effects on graft survival—especially of transplanted RPE—cannot be ignored, and this host reaction will have to be effectively controlled, without long-term systemic immune suppression. Both areas can profit from tissue engineering approaches.

Finally, a problem that has not been addressed in any detail is the secondary degeneration of RPE cells in photoreceptor degenerative disease, and of photoreceptors in RPE degeneration. This problem may be addressed adequately only by performing a combined graft of RPE and photoreceptors, presumably prepared in a tissue culture environment and stimulated toward integration with a variety of nerve protection and neurotrophic factors.

Culturing stem cells or differentiated cell lines might allow transplant researchers to create heterogeneous structures such as RPE/photoreceptor double sheets, with multiple photoreceptors over each RPE cell. Culture conditions and growth stage of these sheets should be modulated to create optimal conditions for integration with the host retina. In order to provide sufficient structural support to these fragile sheets, a resorbable polymer layer could be used as a substrate.

### CELL MATRICES SUPPORTING AXONAL REGROWTH

As was noted previously, an RGC axon damaged by glaucoma, optic nerve disease, or injury can form new neurites only under the right environmental conditions, essentially mimicking those in a developing organism. At the same time, neuroprotective factors are required to sustain the RGC long enough for the axon to take over this support function. If the diagnosis of axon loss is made early enough, it may be possible to save most of the threatened axons, and thus spare most RGCs and the patient's vision.

The experimental conditions created thus far, using peripheral nerve sheaths to create a substrate for axonal regrowth, are less than ideal, because they do not provide an integrated environment in which regrowing axons combine with intact remaining axons, and in which protection of the threatened RGCs is built into the environment. Tissue engineering approaches may provide both the necessary synthetic materials and a better understanding of the necessary conditions to create such an integrated environment for axonal regrowth.

One approach to such an integrated solution might be that engineered cells could be grown *in situ*, as a loose skeleton of supporting tissue, to follow the course of the optic nerve to the chiasm and optic tract; these cells would be programmed to exude the necessary factors promoting axon growth and RGC protection. Alternatively, it might be possible to influence the normal environment of the optic nerve, prohibiting axonal outgrowth, to become one that (temporarily) allows or even stimulates this growth. Assuming that it would be possible to guide outgrowing axons toward the appropriate cerebral hemisphere, depending on their (hemi)retinal origin, RGCs may actually be capable of restoring their connections to the same midbrain visual centers where normal visual processing occurs.

### REPOPULATING ISCHEMIC OR DIABETIC RETINA

New capillaries, formed under the influence of an angiogenic tissue response, tend to be poorly organized and fragile, causing hemorrhaging and thus a great deal of damage to the already stressed retinal tissue. Therefore, the prospects of restoring vision in such retinal areas are, at the present time, poor.

This may change, however, if cell populations can be grown *in vitro* and introduced into the retina under physiologic conditions mimicking those in the embryonal retina. In that case the formation of new blood vessels would follow a much more orderly pattern, and the implanted cells would be in a much better condition to form functional connections. Whether and when it will be possible to recreate embryonal conditions and grow such integrated retinal tissue, from RPE to RGC axons, required to restore vision to the ischemic portion of the retina is difficult to predict; it is a challenge of a magnitude exceeding that of RPE/photoreceptor transplants, functional stimulation of inner retinal cells, and RGC protection/axonal regrowth combined.

### TOWARD "2020" VISION

The potential applications of tissue engineering sketched pose enormous challenges, well exceeding the competency of any single group or institution. Concerted research efforts by multidisciplinary groups may allow the implementation of the complex systems required to restore and enhance vision. With improvement of the fundamental understanding of processes such as photoconversion, graft integration, immune regulation, and axon regeneration on the one hand, and the engineering ability to control tissue properties and growth, both *in vitro* and *in situ*, on the other, implementation of partial vision restoration at the RPE/photoreceptor level and at the RGC level is likely to advance to the level of experimental or even clinical therapy. Integration of all these areas to recreate the full range of retinal processing is a much more distant goal.

To accomplish any of these forms of vision restoration, however, funding mechanisms for multidisciplinary research and interest from the corporate sector will have to increase well beyond their current levels. The number of severely visually impaired individuals and the economic impact of vision restoration may not justify that these approaches receive priority over treatment of life-threatening conditions, but the investment required is relatively modest and the improvement in quality of life for (nearly) blind patients can be very significant.

# BRAIN IMPLANTS

Lars U. Wahlberg

## INTRODUCTION

Tissue engineering applied to the central nervous system (CNS) is a relatively young but expanding field. Experimental data strongly support the use of tissue engineering concepts and promise new therapy for patients with poorly treated or untreatable neurological disorders. Parkinson's disease (PD) has been a major target for brain implantation because this disease lacks an optimal therapy and is relatively well studied and understood. The symptoms of PD are caused by the progressive destruction of dopamine-producing neurons, resulting in the hallmark clinical signs of rigidity, tremor, and bradykinesia. Although the detailed toxic mechanisms involved in the destruction of the dopaminergic neurons are not well known, many of the neuroanatomy, neurophysiology, and implant strategies have been elucidated. The discussion of brain implants will therefore focus on this disease.

Despite the success of many drugs for Parkinson's disease, such as L-dihydroxyphenylalanine (L-DOPA) therapy introduced in the late 1960s, most patients on chronic L-DOPA therapy develop progressive symptoms and drug-induced side effects with time. Therefore, surgical treatment strategies developed during the 1950s, such as the ventrolateral pallidotomy for Parkinsonian rigidity, have been rejuvenated. With improvements in imaging and surgical techniques, ablative procedures yield excellent results in select groups of PD patients (Laitinen, 1995; Speelman and Bosch, 1998). Building on the same principles, neural stimulators that inhibit neuronal transmission have been implanted with reports of good therapeutic results (Benabid *et al.*, 1998). Despite the successful resurrection and development of neurosurgical procedures for Parkinson's disease, these procedures are based on the inhibition or destruction of normal neurons within complementary areas of the motor system. They do not address the biology of the underlying disease and, albeit successfully applied in many patients, the destruction of normal tissue is not an optimal treatment for neurodegenerative disorders. There is therefore a need for new treatment strategies that can address the pathology more directly. Fortunately, the accumulated knowledge of the pathological processes, molecular and cell biology, biomaterials, imaging, and surgical procedures makes it now possible to implement tissue engineering concepts to the treatment of PD. This chapter reviews some of the approaches applied, beginning with a discussion of naked cell implants, followed by discussions of encapsulated cells, controlled delivery of biomolecules, axonal guidance, and other disease targets.

## NAKED CELL IMPLANTS

### PRIMARY TISSUE

Oral L-DOPA therapy is the main treatment for PD. L-DOPA, a precursor to dopamine that passes the blood-brain barrier, is taken up by the dopaminergic neurons that, in turn, convert L-DOPA to dopamine and increase their dopamine production. However, with the progressive loss of dopaminergic neurons, the L-DOPA therapy eventually becomes ineffective and severe fluctuations in the ability to initiate movements occur. Because of the finding that L-DOPA can increase

the striatal production of dopamine and alleviate the symptoms of PD, a reasonable therapeutic approach may be to implant dopamine-secreting cells in the striatum. Considering this idea, the first transplantation for Parkinson's disease was done at the Karolinska Hospital in Stockholm, Sweden in 1982 (Backlund *et al.*, 1985). In this experimental procedure, dopamine-secreting adrenal chromaffin cells were harvested from one of the adrenal glands from the patient and transplanted to the putamen (autograft). This type of procedure was adapted very quickly by the neurosurgical community and initial reports indicated good clinical results (Madrazo *et al.*, 1991). However with time, other studies showed poor survival of the cells and minimal positive clinical effects, resulting in the cessation of the procedure in many places (Kordower *et al.*, 1997).

During the late 1970s and early 1980s, a promising cell transplantation strategy for PD was developed by Björklund and co-workers at Lund University in southern Sweden (Björklund and Stenevi, 1979). They collected discarded aborted fetal tissue and dissected out the ventral mesencephalon to create cell suspensions containing developing dopaminergic neurons for transplantation experiments. After several years of extensive validation of the concept in animal models, cells were transplanted to the striatum of two patients in 1987 (Lindvall *et al.*, 1989). The first results were relatively unimpressive but prompted modifications to various parts of the experimental procedure, and a second pair of patients transplanted about 1 year later with the modified techniques fared much better. These patients showed positive clinical recovery starting about 4 months after the procedure. Positron emission tomography (PET) data indicated that the grafts were able to take up dopamine and survive (Lindvall *et al.*, 1990a,b). Greater than 10 years out from the procedure, one of the patients shows persistent graft viability on PET scanning and is functioning with minimal L-DOPA therapy (Björklund, personal communication). To date, more than 200 patients have been transplanted with fetal ventral mesencephalic tissue at different centers around the world. Although results have varied, there is consistent evidence of survival and efficacy (Freed *et al.*, 1992; Levivier *et al.*, 1997; Olanow *et al.*, 1997; Lindvall, 1998).

On an experimental level, the transplantation of primary cells from fetal dopaminergic tissue has shown good results, indicating that cell transplantation for Parkinson's disease may be an excellent treatment strategy. However, the paucity of suitable tissue, processing problems, and ethical issues prevent the use of primary fetal tissue on a scale needed to make a medical product beneficial to a large patient population. On the other hand, experimental fetal transplantation to the CNS has given us invaluable information for the development of alternative tissue engineering strategies. The fetal transplantation data show that allotransplantation to the CNS is feasible and that transplanted cells can survive and function for many years, even after the withdrawal of immunosuppressive therapy. Although successful, because of the inability to apply the fetal transplant technology to a larger group of patients, many alternatives to human fetal tissue are being explored. One of the simplest replacements is porcine fetal ventral mesencephalon. This tissue can be readily obtained under controlled circumstances but without major ethical concerns (Galpern *et al.*, 1996; Deacon *et al.*, 1997; Edge *et al.*, 1998). However, the recent awareness of the risks of zoonosis and possible immunologic rejection issues make porcine cell transplantation less desirable from both safety and efficacy aspects.

Another interesting primary tissue is the carotid body, which contains dopaminergic glomus cells that could potentially be transplanted in PD (Hansen *et al.*, 1988). In several studies, dopaminergic glomus cells were reported to alleviate Parkinson's disease symptoms in both the 6-hydroxydopamine (6-OHDA) rodent and the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) nonhuman primate models of Parkinson's disease (Espejo *et al.*, 1998; Luquin *et al.*, 1999). Behavioral recovery associated with the survival and sprouting of dopaminergic neurons was noted, indicating the possibility to use these cells to treat PD in humans as either auto- or allografts.

### PRIMARY CELL LINES

Two of the most important drawbacks to using primary tissue are its limited supply and the difficulty to cryopreserve and bank primary tissues. The fetal transplantation experiments for Parkinson's disease have therefore required fresh tissue from four to eight donors, resulting in procedural difficulties and poor quality control. As mentioned, porcine fetal grafting is not an optimal replacement. Fortunately, new techniques allow for the expansion of populations of human fetal cells. This takes advantage of the human fetal source but removes some of the ethical sensi-

tivity, because one fetal tissue could support the transplantation of thousands or perhaps millions of patients.

The ability to expand and cryopreserve cells in cell banks is paramount to create allogeneic cell replacements for primary fetal tissue. The expansion of normal, genetically unmodified cells that are potentially useful for brain implantation has been achieved using cell isolation and defined culture conditions. These cultures retain a limited number of cell cycles but the cell expansion may still provide enough cells to transplant thousands of patients from a single donor. Cultured cells can be expanded yet retain normal geno- and phenotypes and normal contact inhibition and differentiation behaviors. These cells are therefore relatively safe to use, and the formation of tumors or other abnormal behaviors is unlikely.

One example is mitogen-responsive human neural progenitor cell cultures that can be isolated from first-trimester aborted human tissue and expanded for greater than 1 year *in vitro* (Carpenter *et al.*, 1999). This was accomplished using defined media containing epidermal growth factor (EGF), fibroblast growth factor (FGF-2), and leukemia inhibitory factor (LIF). Similar to previously described EGF-expanded mouse neural progenitor cells (Reynolds *et al.*, 1992), these cells can form the three major phenotypes of the nervous system (neurons, astrocytes, and oligodendrocytes) *in vitro*. These human neural stem cell-containing cultures have been transplanted to various regions in the adult rat and have been shown to survive, integrate, migrate, differentiate, extend neurites, and arborize (Fricker *et al.*, 1999). Unlike mouse and rat stem cell cultures, the human cultures make large numbers of neurons *in vivo*, creating a potential source of cells for implantation in PD and Huntington's disease (HD). Both *in vitro* and *in vivo*, differentiated neurons containing  $\gamma$ -amino butyric acid (GABA) can be observed. Early data indicate that various factors can also induce dopaminergic differentiation of stem cell cultures. This may have great implications for the treatment of PD.

Another interesting source of a dopamine-producing primary cell line is the retinal pigmented epithelial cells found in the retina. Retinal pigmented epithelial (RPE) cells can be harvested from the eyes of organ donors and grown in culture to produce cell lines estimated to be capable of transplanting around 10,000 Parkinson patients per isolation. Attached to gelatin microcarriers to improve survival, these cells have been implanted in the striatum of a rhesus monkey model of MPTP-induced Parkinson's disease. The single injection of the cells resulted in significant improvement in Parkinsonian symptoms that lasted over the course of the 8-month-long study (Subramanian, 1999).

## IMMORTAL CELL LINES

Immortal cells are different from cultured primary cells in that they have a genetic change that renders them immortal. Often, tumor cells show aberrant chromosome numbers, lack contact inhibition, and display pleomorphism. However, not all tumor cell lines lose chromosomes and behave erratically. An intriguing tumor cell line has been isolated from a human testicular teratocarcinoma isolated from a metastasis in a patient (Andrews *et al.*, 1982). This immortal cell line is pluripotent and can be induced to stop dividing and to differentiate into a neuronal phenotype using retinoic acid (Andrews, 1984). This cell line is being investigated in the treatment of ischemic stroke, and animal data suggest that the postinjury transplantation of this cell line into an infarcted area can improve recovery (Saporta *et al.*, 1999). The mechanisms surrounding this effect are unclear. Nevertheless, this cell line is currently being transplanted in the United States into patients with lacunar stroke in a small safety trial (12 patients) at the University of Pittsburgh (P. Sanberg, personal communication). The transplantation of a cell line derived from a human cancer has obvious associated risks. However, the approval of this trial demonstrates that cell transplantation for severe neurological disorders is seen as a reasonable strategy by the regulatory agency, as long as safety and efficacy can be demonstrated in animal models.

Other groups are investigating the transplantation of immortal cell lines but are using genetic engineering to immortalize cells. Advances in genetic engineering have made it possible to extend the number of doublings a primary cell line can go through by inserting various oncogenes and cell cycle regulators. This allows for the selection, clonal expansion, and banking of a large number of cells. Besides the genetic modification, these cells retain otherwise normal genotypic characteristics.

One group in England has developed an undifferentiated neuroepithelial stem cell line im-

mortalized with the simian virus (SV40) large T oncogene under temperature-sensitive regulation (Sinden *et al.*, 1997). Using these cells, they have demonstrated positive effects on the sensory neglect and motor asymmetries in a rodent ischemic stroke model. Based on reports in the literature, various human neural cell lines have been created using the same immortalization strategy. Similar to the Pittsburgh study, the initial clinical target is stroke and clinical trials are anticipated to start in late 2000.

Other investigators have immortalized mouse and human neural stem cells using retroviral transduction of the *v-myc* oncogene (Snyder, 1995; Flax *et al.*, 1998). These cells have been transplanted to rodent models and are able to survive, migrate, integrate, and differentiate into neurons, astrocytes, and oligodendrocytes (Snyder *et al.*, 1997; Taylor and Snyder, 1997; Billingham *et al.*, 1998).

Engineered immortal cell lines could potentially be made and expanded to treat millions of patients. However, genetically engineered cells may also show a greater propensity to form tumors compared with unmodified cells. To ensure safety, cells may need to be engineered with genes that render the cells mitotically inactive or that commit "suicide" if exposed to particular drugs. Extensive safety studies will be required before these cells can be tested in humans.

### GENETICALLY ENGINEERED IMMORTAL CELL LINES

Genetic engineering has also been extended to manipulate cells to secrete specific neurotransmitters or proteins for local delivery in the brain. Again, Parkinson's disease has been one of the disease targets and two basic strategies have been investigated. The first involves replacing the function of lost dopaminergic neurons by implanting engineered L-DOPA or dopamine-producing cells in the striatum. A second strategy involves the protection of transplanted or endogenous dopamine neurons by the delivery of trophic factors, such as glial cell line-derived neurotrophic factor (GDNF), in proximity to the neurons.

It is well known that the rate-limiting enzyme for dopamine synthesis is tyrosine hydroxylase (TH), which converts tyrosine to L-DOPA. An additional enzyme called aromatic amino acid decarboxylase (AADC) is needed to convert L-DOPA to dopamine and is by necessity present in dopaminergic neurons. However, other cells in the striatum may also contain enough AADC to convert L-DOPA to dopamine. Therefore, a relatively simple strategy may be to create and transplant cell lines that secrete L-DOPA, not dopamine. In animal models, the transplantation of various cells secreting L-DOPA and dopamine has been described. Results have shown behavioral improvements with both types of cells (Chen *et al.*, 1991; Fisher *et al.*, 1991; Lundberg *et al.*, 1996; Kaddis *et al.*, 1997). No human trial using this type of approach has been described.

Because Parkinson's disease involves a slow and progressive degeneration of dopaminergic neurons, the ability to arrest or slow the degenerative process could form one therapeutic strategy. Many protein factors have been shown to protect fetal dopaminergic neurons both *in vitro* and *in vivo* and one of the most powerful factors is GDNF (Lin *et al.*, 1993). This factor promotes the survival (neurotrophic effect) and neurite extension (neurotropic effect) of dopaminergic neurons both *in vitro* and *in vivo* (Hoffer *et al.*, 1994; Clarkson *et al.*, 1995; Tomac *et al.*, 1995). Based on positive animal data (Gash *et al.*, 1998), GDNF has been tried in humans; intraventricular bolus injections of GDNF were performed monthly, but the trial was stopped, reportedly because of lack of efficacy (Amgen press-release, April, 1999). This is an unfortunate outcome for patients suffering from PD. However, this is consistent with the idea that potent protein factors such as GDNF may need to be delivered locally and at constant low doses to show efficacy and to avoid toxicity (Rosenblad *et al.*, 1999). The implantation of genetically engineered cells that secrete GDNF may therefore remain applicable to PD. This approach will most likely be tried in the future.

Another interesting application of protein factor-secreting cells is to support the survival and integration of transplanted dopaminergic cells. For example, it has been shown that chromaffin cells show improved survival and convert to a neuronal phenotype when exposed to nerve growth factor (NGF) (Strömberg *et al.*, 1985). Studies using cotransplants of chromaffin cells with engineered cells that secrete NGF (Nijijima *et al.* 1995) show enhanced survival. An improvement in the clinical outcome in a PD patient implanted with chromaffin cells perfused with NGF has also been reported (Olson *et al.*, 1991).

Fetal ventral mesencephalic grafts have shown superior survival compared to chromaffin cell

implants. However, even in the most optimal grafts, the total fraction of surviving dopaminergic neurons is only about 10–20% (Brundin and Björklund, 1987). This has required a large number of donors (four to eight) to assure enough surviving cells for a clinical effect. Experiments using trophic support of fetal cell transplants have shown excellent results in animal models, with increases in viability, integration, arborization, and functional outcome (Takayama *et al.*, 1995; Clarkson *et al.*, 1998). One relatively simple strategy to improve the outcome and reduce the requirement for primary tissue would thus be to cografth trophic factor-secreting cells with ventral mesencephalic tissue. This has not yet been attempted in the clinic. In this scenario, the application of polymeric or encapsulated delivery devices could also be possible, because the trophic support does not necessarily need to be chronic.

## ENCAPSULATED CELL IMPLANTS

The implantation of naked cells has the advantage of allowing for migration, integration, and the formation of neurites and synapses. These may be advantageous features for transplantation in PD, because dopamine needs to be distributed over a relatively large volume in the striatum. However, naked cells cannot be retrieved. Therefore, if a potent protein factor or potentially tumorigenic cells need to be removed, a retrievable encapsulated cell device may be a good option. Encapsulated cell implants are essentially drug delivery devices that provide chronic delivery of biological molecules. One of the most studied devices consists of a tubular polymeric membrane, approximately 1 mm in outer diameter, that surrounds a core of cells suspended in a polymer matrix (Fig. 55.1) (Aebischer *et al.*, 1991b). The polymeric membrane excludes larger molecules and cells but allows for the bidirectional passage of nutrients and secreted products. The encapsulated cells can thus be protected from immune rejection, making xenogeneic transplantation possible and immunosuppressive therapy unnecessary. The host is also protected and the risk of tumor formation or dissemination of cells can be significantly reduced. The macrocapsule can be attached to a polymeric tether making a device that can be easily handled and removed in the case of untoward effects (Fig. 57.1). These devices can be implanted intraparenchymally, intracerebroventricularly (ICV), or intrathecally, depending on the application. Cellular survival and continuous production of neurotransmitters and factors have been demonstrated for at least 6 months in the rodent and guinea pig (Aebischer *et al.*, 1991a) and several months in humans (Aebischer *et al.*, 1996). Encapsulated devices secreting GDNF have been studied in the rodent model (Tseng *et al.*, 1997; Sautter *et al.*, 1998). In these studies, both histologic and behavioral data show neuroprotective effects of encapsulated cell delivery of GDNF on transplanted and intrinsic dopaminergic neurons.

## CONTROLLED-RELEASE IMPLANTS

Acellular polymeric brain implants that are able to deliver protein factors to the CNS have also been developed (Tabata *et al.*, 1993; Langer, 1995; Kuo and Saltzman, 1996; Mahoney and Saltzman, 1996; am Ende and Mikos, 1997; Roskos and Maskiewicz, 1997; Yewey *et al.*, 1997). These systems release drugs by degradation- or diffusion-based mechanisms over an extended time (weeks), but cannot sustain release over a long time (months), which is possible with cellular-based systems. The advantage with polymeric release is that cells are not used, the dose can be controlled, and the duration can be set. On the negative side, the formulation and stability of the factor or drug may be problematic. In addition, biodegradable implants often cause a mild inflammatory reaction, which may immunologically sensitize a cellular coimplant.

Fig. 55.1. An encapsulated device is illustrated. A growth factor-engineered mouse immortal myoblast line (C2C12) is housed in an extracellular matrix-coated poly(vinylalcohol) (PVA) hydrogel foam contained within an immunoisolatory poly(ethersulfone) (PES) membrane. The foam scaffold promotes diffusion, adherence, differentiation, and survival. The tether allows for handling and removal of the device. Magnifications from left to right are  $\times 1$ ,  $\times 25$ , and  $\times 100$ . The sections are stained with hematoxylin and eosin.

Appropriately designed, polymeric controlled-release devices have several possible applications and could, for example, support the survival and integration of transplanted cells. Furthermore, a polymeric system can support the sequential release of growth factors that may be necessary to support fully the stepwise differentiation of immature cells. This concept can be applied to neural stem cells that may lack important embryonic signals in the adult brain (Wahlberg, 1997). Synthetic drugs that cannot be made in cellular-based systems can also be delivered by these implants. The local delivery of steroids (Christenson *et al.*, 1991) and cyclosporin A may be two applications that could be used in combination with cell implants to avoid early immunologic sensitization and rejection.

## AXONAL GUIDANCE IMPLANTS

The transplantation of fetal dopaminergic cells to the striatum is called heterotopic transplantation. This means that the dopaminergic cells are transplanted into an area different from their normal location, which is the substantia nigra (SN). The heterotopic implantation of dopaminergic neurons may result in the loss of important normal innervation and feedback loops. Many transplants for PD may thus only function as simple cellular “pumps” that increase the striatal dopamine levels. Although simplicity is desired, an ultimate strategy to treat PD could be to transplant the dopaminergic neurons to their anatomically correct position (homotopic), regenerate the nigrostriatal axonal pathway, and induce sprouting and innervation of the striatal target neurons. This would regenerate the appropriate connections and represent a more physiologic strategy (Fig. 55.2D).

Unfortunately, axonal outgrowth has been limited in the CNS and the ability to regenerate axonal pathways has been difficult. Fortunately, science has made progress in this area; what was thought impossible only a few years ago now appears more feasible. Several molecules are now known to both promote and guide axonal outgrowth. As mentioned, GDNF is a strong promoter of axonal outgrowth of dopaminergic neurons. In addition, extracellular matrix proteins, such as laminin, can guide axonal outgrowth. It has been demonstrated that the creation of laminin bridges promotes the growth of dopaminergic processes from the substantia nigra toward the striatum *in vivo* (Zhou and Azmitia, 1988). Unlike the CNS, the peripheral nervous system is readily able to regenerate axons. Using this fact, the brain implantation of peripheral nerve bridges (Aguayo *et al.*, 1984), and Schwann cell bridges secreting FGF-2 (Brecknell *et al.*, 1996), result in enhanced axonal regeneration. From a tissue engineering point of view, the creation of a degradable regeneration channel releasing survival- and neurite-promoting factors and coated with molecules that facilitate axonal outgrowth may be a future reality (Fig. 57.2D). These types of implants could have great potential use for regeneration in many areas of the CNS, including the spinal cord.

## DISEASE TARGETS

As mentioned, Parkinson’s disease has been the main target for tissue engineering approaches to treat neurologic disease. However, there are other neurologic indications that should be mentioned.

In Huntington’s disease (HD), several neuronal populations slowly degenerate and cause the clinical signs of choreiform movements and progressive dementia. HD is inherited as an autosomal dominant disease and the responsible mutation has been located to chromosome 4 [for a review, see Haque *et al.* (1997)]. Carriers of the disease can therefore be screened for and identified before the onset of symptoms. This makes a protective strategy for HD an attractive possibility, whereby the delivery of neurotrophic factors could prolong the symptom-free interval. One such factor is ciliary neurotrophic factor (CNTF), which protects striatal neurons in both rodent and nonhuman primate models of HD (Emerich *et al.*, 1997a,b). Considering these results, a small clinical trial using an intracerebroventricularly placed encapsulated cell device secreting CNTF is currently ongoing (fig. 57.2A) (M. Peschanski, personal communication).

Based on positive results in animal models [for a review, see Peschanski *et al.*, (1995)], primary fetal striatal tissue transplantation for HD is also being attempted at a handful of centers in the world (Fig. 57.2A). An initial report has described mild improvements in one of the implanted patients (Kopyov *et al.*, 1998). Because the number of implanted patients is few, it is currently difficult to draw any major conclusions regarding the clinical utility of transplantation for HD.

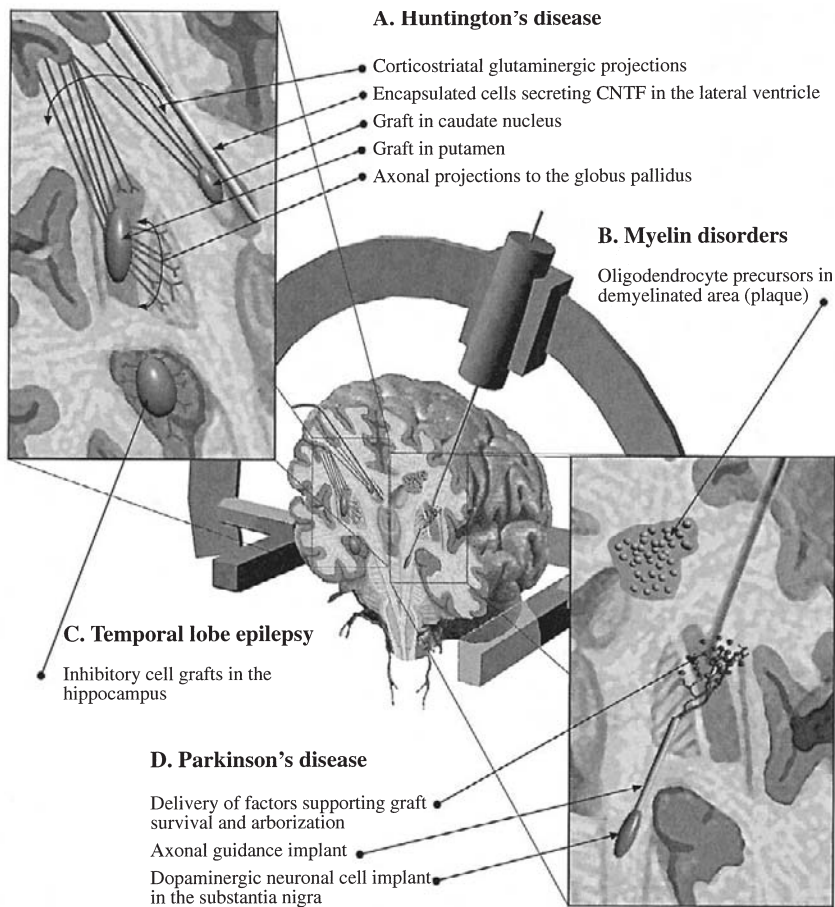

Fig. 55.2. Tissue engineering approaches. In the center, an oblique frontal view of a cut section of the human brain shows a stereotactic injection into the putamen, which is the standard method used for fetal transplantation in PD. (A) In HD, both endogenous (corticostriatal) and transplant axonal projections are important and may need extensive regeneration in late stages of the disease. Encapsulated cells delivering CNTF in proximity to the caudate nucleus may protect both endogenous neurons and transplanted cells. Implants may need to be placed in both the putamen and caudate nucleus to achieve the most optimal therapeutic effect. Not all axonal projections need to be extensive, because of the proximity of some of the efferent and afferent nuclei (globus pallidus). (B) Implantation of oligodendrocyte precursors or Schwann cells may remyelinate plaques in myelin disorders such as multiple sclerosis. (C) Temporal lobe epilepsy may be treated with the implantation of cells secreting inhibitory substances such as GABA in the area of the seizure focus. (D) A futuristic treatment strategy for PD is illustrated whereby the dopaminergic precursor cells are homotopically transplanted to the substantia nigra followed by deposit of an axonal guidance implant along the stereotactic tract. Additional local deposits of GDNF-releasing polymers or cells in the striatum may promote survival and arborization.

One possible advantage over PD is that the transplantation for HD involves homotopic implantation, which at least theoretically should allow for the differentiation of the fetal tissue using normal environmental cues. However, in HD, multiple sets of neuronal populations degenerate, including both cortical and striatal neurons. The homotopic transplantation for HD may thus require extensive regeneration of axonal pathways (Fig. 55.2A).

Other diseases that could be amenable to the implantation of cells within the brain are the myelin disorders (Fig. 55.2B). Animal experiments have shown the ability of neural tissue, purified oligodendrocytes, oligodendrocyte precursors, immortalized glial cells, and neural stem cells to remyelinate areas of demyelination [for a review, see Duncan and Milward (1995)]. Although oligodendrocyte precursor cultures can be established from rodent cells, equivalent human cells have not been easy to make.

One substitute may be to transplant growth factor-expanded Schwann cells. This is based on the fact that patients with CNS myelin disorders do not display demyelination of the peripheral nervous system (PNS). In fact, myelination of central axons may spontaneously occur by ingrowth of Schwann cells (the myelinating cell of the PNS) from the periphery (Duncan and Hoffman, 1997). An intriguing therapeutic possibility is therefore to grow Schwann cells from a nerve biopsy and expand these cells in culture. In turn, these cells could be transplanted into demyelinated areas in the same patient. Physiologically, this may not be the best strategy, because Schwann cells myelinate only single axons, whereas oligodendrocytes myelinate multiple axons. However, animal data indicate that, for a limited volume, Schwann cells can remyelinate (Blakemore and Crang, 1985) and restore functions (Felts and Smith, 1992) to central demyelinated areas. Preparation for clinical trials using this strategy are ongoing.

One of the most common neurologic disorders is epilepsy, which affects about 2% of the population. A subgroup of these patients has temporal lobe epilepsy that is generated by a loss of neurons and an imbalance of inhibitory and excitatory neurotransmitters in the hippocampal formation. In intractable cases, this disease is often treated surgically with the removal of the medial hippocampus and the abnormal area. This procedure eliminates or reduces the frequency of seizures in selected patients but involves a major surgical procedure and the ablation of normal tissue. Therefore, a less invasive procedure may be to implant in the seizure focus inhibitory cells that would raise the seizure threshold. This idea is supported by animal experimentation data that indicate that locus coeruleus grafts and the local delivery of inhibitory substances such as GABA can increase the seizure threshold (Benzon *et al.*, 1990; Kokaia *et al.*, 1994; Lindvall *et al.*, 1994). However, with the lack of suitable cells, such as GABA-producing cells, transplantation for focal epilepsy has not been as extensively studied as for some of the aforementioned disease targets.

Other disease indications that may benefit from brain implant strategies include stroke, brain injury from trauma, Alzheimer's disease, and rare disorders such as cerebellar degeneration and inherited metabolic disorders. These indications will be discussed elsewhere.

## SURGICAL CONSIDERATIONS

The surgical implantation of most brain implants involves the use of stereotactic techniques (Fig. 57.2). Stereotaxis in brain surgery was established in the beginning of this century and is now well established in neurosurgical practice (Speelman and Bosch, 1998). It involves attaching a rigid frame (stereotactic frame) to the skull followed by imaging such as magnetic resonance imaging. Attached markers (fiducials) create a three-dimensional coordinate system in which any point in the brain can be defined and related to the frame with high precision. In the operating room, the markers used during imaging are replaced with holders that guide the instruments. It is a relatively simple neurosurgical procedure done under local anesthesia and mild sedation. The procedure is therefore safe and relatively painless. Among the >200 patients transplanted with fetal grafts for Parkinson's disease, rare surgical complications have been reported. The patients are usually discharged from the hospital after an overnight observation.

## CONCLUSIONS

In this chapter, various brain implants have been described that may have potential to treat Parkinson's disease and other neurological disorders using tissue engineering strategies. Most of the current literature describes the transplantation of various primary cells, such as fetal tissue and chromaffin cells. Tissue engineering principles have only more recently been introduced. Applications using growth factor support, genetic engineering, scaffolds, extracellular matrices, and encapsulation have all been able to improve the survival and function of the brain implant. The ultimate implants are yet to be developed and may combine genetically modified cells, controlled delivery devices, axonal bridges, scaffolds, and encapsulated cells.

# NERVE REGENERATION

Eric G. Fine, Robert F. Valentini, and Patrick Aebischer

## NERVE REGENERATION AND NEURAL TISSUE ENGINEERING

In human adults, many tissues, including those of the peripheral nervous system (PNS), are capable of healing and regeneration. Neural tissue, due to its complex and numerous long-distance interconnections, must heal by true regeneration, because healing by scar will not reestablish electrical connectivity. In certain situations, underlying disease (such as diabetes or drug-induced neuropathy) or extensive damage (such as large nerve defects or avulsion injuries) leads to negligible recovery. In contrast, central nervous system (CNS) tissues, which include the brain and spinal cord, show limited healing under almost all circumstances. A major impediment to healing is the inability of adult neurons to proliferate *in vivo* and to be cultivated *in vitro*. Neural tissue engineering seeks to provide new strategies to optimize and enhance regeneration through the use of three-dimensional scaffolds, the delivery of growth-promoting molecules, and the use of neuronal support cells or genetically engineered cells. The objectives of this chapter are to provide an overview of the basic biology of neural regeneration (using the PNS as a model), to review biomaterial-based strategies for nerve repair, and to present more recent neural tissue engineering approaches (Table 56.1).

### PROBLEMS AND CHALLENGES

Every year, hundreds of thousands of patients are treated for degenerative disease or traumatic PNS and CNS damage, and the attendant social and economic costs are staggering. The adult PNS retains the capacity for regeneration following injury, and many of the molecular/neurotrophic factors are known. Nonetheless, the return of function in the clinical setting is quite variable and motor and sensory deficits invariably persist. Repair of the CNS, which includes the brain and spinal cord, represents an even greater challenge, because almost all injuries lead to an irreversible loss of function and because many victims are young. Refinements in microsurgical techniques and drug therapies have had some beneficial effects on neural repair, but seem to have reached an impasse, suggesting that biologic rather than technical factors are limiting. During World War II, the large caseload of nerve injuries led to the development of nerve repair techniques that involved end-to-end reconnection. Functional outcomes were further improved with advances in microsurgical techniques and instrumentation. In the 1970s and 1980s, advances in polymer science provided synthetic guidance channels for experimental nerve repair, although an ideal clinical material has not been identified. From the 1980s to the present, progress in biotechnology and molecular biology has uncovered some of the molecular and genetic bases of neural diseases, thus opening biological avenues for promoting regeneration. Neural tissue engineering seeks to promote neural repair by combining the potency and specificity of biologically based repair strategies (neurotrophic molecules, extracellular matrix equivalents, transplanted/genetically engineered cells, etc.) with the purity and definition of synthetic technologies (material design/modification, drug delivery systems, microelectronic fabrication, etc.). Neural tissue engineering may provide a means of reducing health care costs and improving the quality of life by accelerating healing, pro-

viding alternatives to current treatments, and enabling repair where it is not currently feasible. Neural tissue engineering also entails efforts to replace neuroactive molecules in the CNS, to recreate neural circuitry *in vitro*, and to design functional neural interfaces. This chapter concentrates mainly on issues of neural regeneration.

## OVERVIEW OF NEURAL REGENERATION

It has long been appreciated that the PNS is capable of regeneration following injury. The central dogma that the adult CNS is not capable of regeneration has been challenged subsequent to reports based on studies suggesting that there is a vigorous capacity for regrowth under optimal conditions. In both nervous systems, regeneration is limited by the fact that adult neurons are not capable of proliferating. In successful regeneration, sprouting axons from proximal nerve tissues traverse the injury site, enter the distal nerve tissue, and make new connections with target structures. For the purposes of this chapter, we will use the PNS as a model for nerve regeneration.

### PERIPHERAL NERVOUS SYSTEM

Peripheral nerves are responsible for the innervation of the skin and skeletal muscles and contain electrically conductive fibers, the axons, whose cell bodies reside in or near the spinal cord. Neurons are structurally unique in that axonal processes may extend for considerable distances (e.g., up to 1 m or longer). All axons are ensheathed by Schwann cells, which provide structural and chemical support for all PNS neurons. In fact, neuronal survival is contingent on the continuous, retrograde flow of neurotrophic molecules synthesized by Schwann cells or target tissues. Motor neurons originate in the anterior horn (inner gray matter) of the spinal cord and are responsible for directing voluntary movement. Sensory neurons are localized in dorsal root ganglia found adjacent to the spinal cord and function to sense the local environment through specialized sensors (stretch receptors, Pacinian corpuscles, etc.). Sympathetic neurons are located in sympathetic ganglia found along the length of the cord and are responsible for regulating involuntary functions (sweating, vascular tone, etc.). A single nerve may contain many hundreds of the three neuronal types. Together, nerve fibers, Schwann cells, blood vessels, and surrounding connective tissue constitute a nerve fascicle, which is the basic structural unit of a peripheral nerve. Most peripheral nerves contain one or more fascicles, each containing numerous myelinated and unmyelinated axons. The surgical repair of cut nerves is complicated by the fact that the fascicular tracts branch frequently and follow a tortuous pathway.

### PNS REGENERATION

Nerves (including the cell body and axons) react in a characteristic fashion to transection injury (Sunderland, 1991). Injuries occurring close to the spinal cord are more likely to result in neuronal death because a large axonal segment is lost. More peripheral lesions, such as those in the hand or fingers, show a greater degree of successful regeneration. If the neuronal cell body survive the initial injury, it swells and decreases neurotransmitter (i.e., the chemicals that control neuronal signaling) production and increases production of the substrates necessary for reconstituting axonal and membrane components. Immediately after injury, the tip of the proximal nerve stump

(i.e., the segment closest to the spinal cord) swells considerably and the severed axons retract several millimeters. After several days the proximal axons begin to sprout vigorously and growth cones emerge. Growth cones are mobile extrusions of the cut axons that flatten and spread when they encounter an adhesive terrain. Growth cones elicit numerous extensions (e.g., filipodia) that extend outward in all directions until the first sprout reaches an appropriate terrain. The lead sprout is the only one to survive and the others die back in a process of pruning.

In the distal nerve stump, a process termed “Wallerian degeneration” begins within hours after transection. Wallerian degeneration is characterized by the degradation of axons and the proliferation of Schwann cells, which organize into ordered columns, or bands of Bünger. Schwann cell columns provide an optimal environment for growth cone adhesion and axonal outgrowth. In successful regeneration, axons sprouting from the proximal stump bridge the injury gap and encounter an appropriate Schwann cell column (band of Bünger). In humans, axons elongate at an average rate of 1 mm per day. Some of the axons reaching the distal stump traverse the length of the nerve to form functional synapses, but changes in the pattern of muscular and sensory reinnervation invariably occur. The misrouting of growing fibers occurs primarily at the site of injury because once they reach Schwann cell columns their paths do not deviate further. Failures in regeneration may lead to the formation of a neuroma, a dense, irregular tangle of axons, which can cause painful sensations. It should be noted that peripheral nerve transection also leads to marked atrophy of the corresponding targets (e.g., muscle fibers). Accelerated axonal outgrowth and regeneration is an important clinical goal because it results in less muscle wasting and decreased loss of sensory units.

### **Surgical repair of peripheral nerves**

In the absence of reconnection, recovery of function following a nerve injury is negligible. This may be due to one or more factors, including (1) that neurons do not survive due to severe retrograde effects, particularly due to the loss of neurotrophic support, (2) that a gap separating the nerve stumps prevents sprouting axons from finding the distal stump, (3) that scar tissue ingrowth at the injury site acts as a physical barrier to axonal elongation, and (4) that the proximal and distal fascicular patterns differ so much that extending axons cannot find an appropriate distal pathway.

Early attempts to reconnect severed peripheral nerves utilized a crude assortment of materials, and anatomic repair rarely led to an appreciable return of function (Sunderland, 1991). Materials used include biologic materials such as catgut, silk, and cotton, and metal wires. Interventions were often doomed by the high rates of infection resulting from poor sterile techniques and inadequate sterilization of implanted materials. In the 1950s the concept of end-to-end repair, or coaptation, was refined by surgeons who directly reattached individual nerve fascicles or groups of fascicles. Further refinements occurred during the 1960s with the introduction of the surgical microscope and the availability of finer suture materials and instrumentation. In microsurgical nerve repair the ends of severed nerves are apposed and realigned by placing several strands of very fine suture material through the epineurial connective tissue without entering the underlying nerve fascicles. This process is termed epineural repair. In instances in which individual fascicles can be identified, they are often reattached individually in a process called fascicular or perineural repair. Interestingly, perineural repair does not result in significantly better functional recovery when compared to simpler epineural repair. Nerve grafting procedures are performed when nerve retraction or nerve tissue loss prevents direct end-to-end repair. Nerve grafts are also employed when nerve stump reapproximation would create tension along the suture line, a situation that is known to hinder the regeneration process by compromising blood flow. In grafting surgery, an autologous nerve graft from the patient, such as the sural nerve (or other sensory nerves, the removal of which results in acceptable functional deficit), is interposed between the ends of the damaged nerve. Presently, the most commonly used biomaterial in end-to-end repair or nerve grafting is fine monofilament nylon (polyamide) suture hooked to stainless steel needles.

### **Repair with fibrin glue or fusion with poly(ethylene glycol)**

There have also been efforts to develop “gluing” techniques for nerve repair, thus avoiding the disadvantages associated with suturing. Sutures at the injury site can cause tissue reaction and local scar tissue formation, impeding axonal outgrowth. Microsurgical repair techniques usually re-

quire expensive instrumentation, take relatively long to perform, and require training and specialized techniques. In addition, some neural tissues, including the CNS, are rather amorphous, making suturing difficult or impossible.

Fibrin glue or "plasma clot" materials have been used for many years in experimental nerve repair (Sunderland, 1991). Fibrin is derived from blood and is a major component of clots and scabs. Fibrin glue is a two-component system composed of concentrated fibrinogen, which is activated and polymerized into fibrin on the addition of thrombin. Some experimental studies show that fibrin glue repair of peripheral nerves is comparable to standard microsurgical repair. Practical advantages include straightforward application, rapid repair time, and easier use in poorly accessible locations. One limitation is in the case of nerve gaps, because the nerve ends cannot be readily approximated.

One unique experimental system uses poly(ethylene glycol) (PEG) to fuse axons of transected nerves in invertebrate animals (earthworms) (Krause and Bittner, 1990). The use of PEG immediately following nerve transection resulted in morphologic fusion of individual axons. The concentration and molecular weight of PEG appear important in determining the extent and quality of fusion. Major limitations of this approach include the need for immediate repair (so that Wallerian degeneration and axonal destruction do not occur) and the requirement that the nerve ends be reapproximated under minimal tension.

### Repair with nerve guidance channels

The frequent occurrence of nerve injuries during the World Wars of this century stimulated surgeons and scientists to seek simple, effective means of repairing damaged nerves. A variety of biologic and synthetic materials were shaped into cylinders and used to entubulate cut nerves. Bone, collagen membranes, arteries, and veins were used to repair nerves from the late 1800s through the 1950s. These materials did not enhance the rate of nerve regeneration when compared to standard techniques, and clinical applications were not widespread. Magnesium, rubber, and gelatin tubes were evaluated during World War I and cylinders of parchment paper and tantalum were used during World War II. The poor results achieved with these materials can be attributed to poor biocompatibility, because the channels elicited an intense tissue response that limited the ability of growing axons to reach the distal nerve stump. Following World War II, polymeric materials with more stable mechanical and chemical properties became available. Millipore (cellulose acetate), a microporous filter material, showed early favorable results in experimental models. After long-term implantation (several months) in humans, however, the Millipore material became calcified and eventually fragmented so that its use was discontinued. Silastic (silicone elastomer) tubing was first tested experimentally in the 1960s. Thin-walled Silastic channels were reported to support regeneration over large gaps in several mammalian species. Thick-walled tubing was associated with nerve necrosis and neuroma production. Thin-walled Silastic tubing and bioresorbable poly(glycolic acid) (PGA) tubes are the only synthetic materials currently used, on a very limited basis, in the clinical repair of severed nerves. The subsequent sections discuss results obtained with these and other synthetic materials in experimental nerve repair.

## EXPERIMENTAL USE OF GUIDANCE CHANNELS

The availability of a variety of new biomaterials (particularly polymers) led to a resurgence of entubulation studies in the 1980s. In repair procedures using nerve guidance channels, the free or mobilized ends of a severed nerve are positioned within the lumen of a tube and are anchored in place with sutures (Fig. 56.1). Tubulation repair provides several advantages, as listed in Table 56.2. The most important factors include prevention of scar tissue invasion into the regenerating environment, provision of directional guidance for elongating axons, and maintenance of endogenous trophic or growth factors.

Guidance channels are useful in experimental procedures evaluating the process of nerve regeneration because (1) the gap distance between the nerve stumps can be precisely controlled, (2) the fluid and tissue entering the channel can be tested and evaluated, (3) the properties of the channel can be varied, and (4) the channel can be filled with various drugs, gels, etc. Nerves of different sizes and with various dimensions from several mammalian species, including mice, rats, rabbits, hamsters, and nonhuman primates, have been studied. The regenerated tissue in the guidance channel can be evaluated morphologically to quantify the outcome of regeneration. Parameters

Fig. 56.1. Nerve guidance channel.

analyzed include the cross-sectional area of the regenerated nerve cable, the number of myelinated and unmyelinated axons, and the relative percentages of cellular constituents (e.g., epineurium, endoneurium, blood vessels). Electrophysiology and functional evaluation can also be performed in studies conducted for long time periods (several weeks or longer).

In the early 1980s the rat sciatic nerve model emerged as a useful system for studying nerve repair and for evaluating guidance channels. The spatial–temporal progress of nerve regeneration across a 10-mm rat sciatic nerve gap repaired with a silicone elastomer tube has been described in detail and provides a point of reference for evaluating other systems (Longo *et al.*, 1984; Williams *et al.*, 1983). During the first hours following repair the tube fills with a clear, protein-containing fluid exuded by the cut blood vessels in the nerve ends. The fluid contains the clot-forming protein, fibrin, as well as neurotrophic factors known to support nerve survival and outgrowth. By the end of the first week the lumen is filled with a longitudinally oriented fibrin matrix that coalesces and undergoes syneresis to form a continuous bridge between the nerve ends. The fibrin matrix is then invaded by cells migrating from the proximal and distal nerve stumps. This includes fibroblasts (which first organize along the periphery of the fibrin matrix), Schwann cells, macrophages, and endothelial cells (which form capillaries and larger vessels). At 2 weeks, axons advancing from the proximal stump are engulfed in the cytoplasm of Schwann cells. After 4 weeks some axons have reached the distal nerve stump and many have become myelinated. The number of axons reaching the distal stump is related to the distance the regenerating nerve has to traverse and the length of original nerve resected. Silicone guidance channels do not support regeneration if the nerve gap is greater than 10 mm and if the distal nerve stump is left out of the guidance channel (Lundborg *et al.*, 1982). In these experimental models, the morphology and structure of the regenerated nerve are far from normal. The size and number of axons and the thickness of myelin sheaths are less than normal. Electromyographic evaluation of nerves regenerated through silicone tubes reveals

that axons can make functional synapses with distal targets, although nerve conduction velocities and signal amplitudes are slower than normal, even after many months.

Attempts to improve the success rate and quality of nerve regeneration have led to the use of numerous biomaterials as guidance channels (Table 56.3). Biodurable materials such as acrylic copolymers (Aebischer *et al.*, 1989a; Uzman and Villegas, 1983), and polyethylene (Madison *et al.*, 1988), and bioresorbable materials such as polyglycolides (Molander *et al.*, 1989), polylactides (Nyilas *et al.*, 1983), polyesters (Henry *et al.*, 1985), and collagen (Archibald *et al.*, 1991) have been investigated. There is some concern that biodurable materials may cause long-term complications via compression injury to nerves or soft tissues. Biodegradable materials offer the advantage of disappearing once regeneration is complete, but success thus far has been limited by swelling, increased scar tissue induction, and difficulty in controlling degradation rates. In all cases, these materials have displayed variable degrees of success in bridging transected nerves and the newly formed nerves are morphologically quite different from normal peripheral nerves.

### BIOMATERIAL-BASED APPROACHES TO NERVE REPAIR

Studies using nerve guidance systems suggest that neural degeneration is influenced by the polymer system used and that it should not be considered a passive player. For example, manipulating the physical, chemical, and electrical properties of synthetic channels allows control over the regenerating environment and optimization of the regeneration process. The following features of synthetic nerve guidance channels have been studied and will be reviewed: (1) transmural permeability, (2) surface texture/microgeometry, (3) electrical charges, and (4) release of drugs.

### TRANSMURAL PERMEABILITY

The synthetic nerve guidance channel controls the regeneration process by influencing the cellular and metabolic aspects of the regenerating environment. Because transected nerves lose the integrity of their blood–nerve barrier and are in contact with the wound environment, the guidance channel's transmural mass transfer characteristics control solute exchange between the regenerating tissue and the surrounding fluids. Nerves regenerated through semipermeable tubes display more normal morphologic characteristics than do nerves regenerated in impermeable silicone elastomer (SE) and polyethylene (PE) tubes or freely permeable (microporous) expanded poly(tetrafluoroethylene) (e-PTFE) tubes. Nerves found in semipermeable tubes feature more myelinated axons and less connective tissue (Aebischer *et al.*, 1989a; Uzman and Villegas, 1983). The range of permselectivity is important and optimal regeneration is observed with a molecular weight (MW) cutoff range of 50,000–100,000. Permselective poly(acrylonitrile)/poly(vinyl chloride) (PAN/PVC) channels with a MW cutoff of 50,000 support regeneration even in the absence of a distal nerve stump (Aebischer *et al.*, 1988, 1989a).

These observations suggest that controlled solute exchange between the internal regenerative and external wound healing environments is essential in controlling regeneration. The early availability of oxygen and other nutrients in permselective tubes may minimize connective tissue formation in PAN/PVC and polysulfone (PS) tubes. Decreased oxygen levels and waste buildup due to impermeable wall structures may increase connective tissue formation in SE and PE tubes. Regeneration may also be modulated by excitatory and inhibitory factors released by the wound healing environment. Semipermeable channels may sequester locally generated growth factors while preventing the inward flux of molecules inhibitory to regeneration.

### SURFACE TEXTURE/MICROGEOMETRY

The microgeometry of the luminal surface of the guidance channel plays an important role in regulating tissue outgrowth. Expanded microfibrillar e-PTFE tubes exhibiting different internodal distances (1, 5, and 10  $\mu\text{m}$ ) were compared to smooth-walled, impermeable PTFE tubes. Larger internodal distances result in greater surface irregularity and increased transmural porosity. Highly porous, rough-walled tubes contained isolated fascicles of nerves dispersed within a loose connective tissue stroma. The greater the surface roughness, the greater the spread of fascicles (Valentini and Aebischer, 1993). In contrast, smooth-walled, impermeable PTFE tubes contained a discrete nerve cable delineated by an epineurium and located within the center of the guidance channel. Similar results were observed with semipermeable tubes with either smooth or rough inner walls that were fabricated with the same polymer (PAN/PVC) and exhibited similar mechanical properties and MW cutoffs (50,000) (Aebischer *et al.*, 1990). Nerve regenerated in tubes containing alternating sections of smooth and rough inner walls showed similar morphologies, with an immediate change from single-cable to numerous fascicle morphology at the interface of the smooth and rough segments.

These studies suggest that the microgeometry of the guidance channel lumen also modulates the nerve regeneration process. Wall structure changes may alter the protein and cellular constituents of the regenerating tissue bridge. For example, the orientation of the fibrin matrix is altered in the presence of a rough inner wall. Instead of forming a single, longitudinally oriented bridge connecting the nerve ends, the fibrin molecules remain dispersed throughout the lumen. As a result, cells migrating in from the nerve stumps fill the entire lumen in a loose pattern rather than forming a dense central structure.

### ELECTRICAL CHARGE CHARACTERISTICS

Applied electrical fields and direct current stimulation are known to influence nerve regeneration *in vitro* and *in vivo*. Silicone tubes fitted with electrical leads and used as cuffs to surround lesioned nerves have shown increased regeneration in rat models (Kerns *et al.*, 1991).

Certain dielectric polymers may be used to study the effect of electrical activity on nerve regeneration *in vivo* and *in vitro*. Electret materials are advantageous in that they provide electrical charges without the need for an external power supply, can be localized anatomically, are biocompatible, and can be formed into a variety of shapes including tubes and sheets. Electrets are a class of dielectric polymers that can be fabricated with stable bulk/surface charges because of their unique molecular structure. True electrets, such as PTFE, can be formed to exhibit a static surface

charge due to the presence of stable, monopolar charges located in the bulk of the polymer. The sign of the charge is dependent on the poling conditions. Positive, negative, or combined charge patterns may be achieved. Piezoelectric materials such as poly(vinylidene fluoride) (PVDF) display transient surface charges related to dynamic spatial reorientation of molecular dipoles located in the polymer bulk. The amplitude of charge generation is dependent on the degree of physical deformation (i.e., dipole displacement) of the polymer structure. The sign of the charge is dependent on the direction of deformation, and the materials show no net charge at rest.

Negatively and positively poled PVDF and PTFE tubes have been implanted as nerve guidance channels. Poled PVDF and PTFE channels contain significantly more myelinated axons than do unpoled, but otherwise identical, channels (Aebischer *et al.*, 1987; Valentini *et al.*, 1989). In general, positively poled channels contained larger neural cables with more myelinated axons, compared with negatively poled tubes. It is not clear how static or transient charge generation affects the regeneration process. The enhancement of regeneration may be due to electrical influences on ligand binding, ionic fluxes, receptor mobility, growth cone motility, cell migration, etc.

### DELIVERY OF NEUROTROPHIC FACTORS

Growth or neuronotrophic factors ensure the survival and general growth of neurons and are produced by support cells (e.g., Schwann cells) or by target organs (e.g., muscle fibers). Some factors support neuronal survival, others support nerve outgrowth, and some do both (Table 56.4) (Raivich and Kreutzberg, 1993). Numerous growth factors have been identified, purified, and synthesized through recombinant technologies (Table 56.4). *In vivo*, growth factors are found in solution in the serum or extracellular fluid or bound to extracellular matrix (ECM) molecules. The release of soluble agents, including growth factors and other substrates from synthetic guidance channels, may improve the degree and specificity of neural outgrowth. Using single or multiple injections of growth factors has disadvantages, including early burst release, poor control over local drug levels, and factor degradation in biologic environments. Guidance channels can be pre-filled with drugs or growth factors, but the aforementioned limitations persist. Advantages of using a local, controlled delivery system are that the rate and amount of factor release can be controlled and the delivery can be maintained for long periods of time (several weeks). Channels composed of an ethylene vinyl acetate (EVA) copolymer have been fabricated and are designed to release incorporated macromolecules in a predictable manner (Aebischer *et al.*, 1989b). The amount of drug loaded, size of the drug, and geometry of the drug-releasing structure affect the drug release kinetics (Langer and Folkman, 1976). It is possible to restrict drug release to the luminal side of the guidance channel by coating its outer wall with a film of pure polymer.

Nerve guidance channels fabricated from EVA and designed to slowly release basic fibroblast growth factor (bFGF) support regeneration over a 15-mm gap in a rat model (Aebischer *et al.*,

**Table 56.4. Growth factors in neural regeneration**

Growth factor	Possible function
Neural factors	
Nerve growth factor (NGF)	Neuronal survival, axon–Schwann cell interaction
Brain-derived neurotrophic factor (BDNF)	Neuronal survival
Ciliary neuronotrophic factor (CNTF)	Neuronal survival
Glia-derived neurotrophic factor (GDNF)	Neuronal survival
Glial growth factor (GGF)	Schwann cell mitogen
Neurotrophin-3 (NT-3)	Neuronal survival
Neurotrophin-4/5 (NT-4/5)	Neuronal survival
General factors	
Insulin-like growth factor 1 (IGF-1)	Axonal growth, Schwann cell migration
Insulin-like growth factor 2 (IGF-2)	Motoneurite, sprouting, muscle reinnervation
Platelet-derived growth factor (PDGF)	Cell proliferation, neuronal survival
Acidic fibroblast growth factor (aFGF)	Neurite regeneration, cell proliferation
Basic fibroblast growth factor (bFGF)	Neurite regeneration, neovascularization

1989b). Control EVA tubes supported regeneration over a maximum gap of only 10 mm, with no regeneration in 15-mm-long gaps. Another study using extruded EVA tubes designed to deliver nerve growth factor (NGF) also supported regeneration over a critical nerve gap (Valentini *et al.*, 1995). The concurrent release of growth factors that preferentially control the survival and outgrowth of motor and sensory neurons may further enhance regeneration, because the majority of peripheral nerves contain both populations. For example, NGF and bFGF control sensory neuronal survival and outgrowth, and brain-derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), and glial cell line-derived neurotrophic factor (GDNF) control motor neuronal survival and outgrowth. Other molecules, neurotrophins (NT-3 and NT-4/5), may do both. Factors that promote Schwann cell proliferation [e.g., glial growth factor (GGF)] may be useful in enhancing nerve growth or in culturing transplantable cells. The local release of other pharmacologic agents (e.g., antiinflammatory drugs) may also be useful in enhancing nerve growth. Growth factors released by guidance channels may allow regeneration over large nerve deficits and in sites where regeneration does not normally occur (e.g., brain and spinal cord).

## BENCHTOP FABRICATION METHODS OF NERVE GUIDANCE CHANNELS

### Trophic factor-releasing tubes

Different experimental methods have been used to tailor the attributes of the nerve guidance channels. These tubes have been made by dipping a mandrel in a polymer solution (Aebischer *et al.*, 1989b; Perego *et al.*, 1994). A volatile solvent allows the first layer of polymer to dry when it is removed from the solution before it is dipped again, forming the next layers. The mandrel is then removed and a hollow cylinder is formed. This technique was improved by coating a horizontally spinning mandrel (Borkenhagen *et al.*, 1998a). The thickness of the tube can easily be controlled and thus its rigidity, strength, toughness, and other mechanical properties are controlled.

If a solvent for the polymer can be chosen such that it does not destroy a protein's activity, different proteins/drugs and carrier molecules can be incorporated into the tube wall for eventual release into the lumen after implantation. Another method incorporates through the length of the tube, a thin polymer rod containing neurotrophic factors, allowing for their long-term sustained release (Bloch *et al.*, 1999).

Thermoplastic polymers can be formed into tubes by extruding them at elevated temperatures and pressures through a die and nozzle (Fine *et al.*, 1991). By mixing relevant proteins into the polymer dope, these tubes can be used as release systems (Valentini *et al.*, 1995).

### Semipermeable tubes

There may be some interest in controlling the transfer of moieties from the regenerating environment because optimization of the tube's molecular weight cutoff enhances nerve regeneration (Aebischer *et al.*, 1989a). In addition, it has been shown that a semipermeable channel will allow the regeneration of an axotomized peripheral nerve in the absence of a distal stump, whereas no growth occurs in impermeable Silastic tubes (Aebischer *et al.*, 1988). Semipermeable synthetic polymer fibers can be fabricated by a dry-jet wet-spinning techniques (Cabasso *et al.*, 1976; Michaels, 1971). A polymer dissolved in its solvent is pumped through the outer lumen of a double-bored nozzle and a nonsolvent flows through the inner lumen. As the two liquids come into contact at the exit, a phase inversion occurs. When the solvent and nonsolvent are chosen so that they have a greater affinity for each other than the solvent has for the polymer, the polymer comes rapidly out of solution, forming a semipermeable layer. The nonsolvent continues to move slowly outward past the initial interface, through the polymer solution, forming larger pores (with a trabecular structure). As the forming tube exits the nozzle, it heads towards a nonsolvent bath, which will solidify a dense (tight pored) exterior layer. Altering the parameters of flow, temperature, solvent/nonsolvent pairing, and distance from the nozzle to the nonsolvent bath will modify the resulting hollow fiber formed, and its permeability.

### Biodegradable tubes

In trying to produce a more ideal nerve guidance channel that is biodegradable, therefore eliminating the need for a second operation to remove the tubing, many techniques of fabrication are

being combined. The desired tube would slowly lose its mass, yet still be strong enough to maintain its shape and protect the regeneration environment during the period of cable reformation before totally resorbing. A balance is sought between degradation rate and the inflammation that degradation products incite. Fine soluble particles such as sugars and salts added to the exterior coatings of mandrel dip-coated tubes form pores when dissolved out, reducing the mass of the bulk polymer (Pennings *et al.*, 1990). Other experimental methods blend in a second filler polymer that is preferentially dissolved away after tube formation. Degradable polyester urethane tubes have been formed with a porous honeycomb structure by casting the polymer solution in a mold and freezing the mold. The frozen solvent crystals are then sublimated under vacuum conditions, leaving a porous structure (Jordan *et al.*, 1999). The pores allow for infiltration of phagocytic cells and create a greater surface area for them to degrade the polymer faster.

## TISSUE ENGINEERING APPROACHES TO NERVE REPAIR

Biomaterial-based approaches to nerve repair show promise for certain clinical applications, but may not provide sufficient support to bridge large gaps or to stimulate CNS repair. A higher level of intricacy takes place when using the hollow nerve guidance channel tube as a receptacle for hydrogel scaffolds, in an attempt to enhance regeneration by providing molecular constituents that are present during embryonic development, are found at elevated levels during nerve injury, or are actual components of the nerve tissue to be regenerated. Hydrogels are also used as matrices to seed neuronal support cells or trophic-factor producing genetically engineered cells within the nerve guides. Further advances in understanding the cellular and molecular aspects of neural repair may provide more potent strategies for stimulating regeneration.

### INCLUSION OF INSOLUBLE GELS

As noted earlier, a fibrin cable bridging the nerve stumps serves as a scaffold over which outgrowing cells and axons migrate. Prefilling SE tubes with a longitudinally oriented fibrin gel has been shown to accelerate regeneration across the gap and to increase the distance over which regeneration occurs (Williams *et al.*, 1987). Filling the tube with protein gels also influences the rate and quality of regeneration. Filling guidance channels with fairly viscous gels of laminin and collagen has been shown to improve and accelerate nerve repair in some models. Matrigel (a gel containing collagen type IV), laminin, and glycosaminoglycans (another ECM component), introduced in the guidance channel lumen, support some degree of regeneration over a long gap in adult rats (Madison *et al.*, 1988). SE channels preloaded with templates of collagen and glycosaminoglycans also increase the distance over which regrowth occurs (Yannas *et al.*, 1985). One study using semipermeable tubes filled with a range of collagen and Matrigel showed less regeneration in gel-filled tubes compared with tubes filled only with saline. This suggests that the viscosity and orientation of the gel may be as important as its chemical makeup (Valentini *et al.*, 1987).

### USE OF FUNCTIONALIZED GELS

The extracellular matrix consists of complex proteins known to control cell shape, position, and function. The availability of artificial ECM analogs will enable control of cell–substrate adhesion, cell–cell communication, and cell guidance. The glycoprotein laminin, an extracellular matrix component present in the basal lamina of Schwann cells, has been reported to promote nerve elongation *in vitro* and *in vivo*. Other ECM products, including the glycoprotein fibronectin and the proteoglycan heparin sulfate, have also been reported to promote nerve extension *in vitro*. Some subtypes of the ubiquitous protein, collagen, also support neural attachment. Inappropriate physicochemical properties of these gels may interfere with the regeneration process. In an alternate approach, the activity of these large, insoluble ECM molecules (up to  $10^6$  Da) can be mimicked by short peptide sequences of a few amino acids (e.g., GRGDS, YIGSR, SIKVAV) (Table 56.5) (Graf *et al.*, 1987; Iwamoto *et al.*, 1987; Kleinman *et al.*, 1988). The availability of small, soluble, bioactive agents allows more precise control over the chemistry, conformation, and presentation of neuron-specific substances. Additionally, their stability and linear structure facilitate their use compared with labile (and more expensive) proteins that require tertiary structure for activity. *In vitro* two-dimensional work demonstrated that immobilized peptides are indeed capable of promoting cell attachment and differentiation (Ranieri *et al.*, 1993, 1995). Three-di-

**Table 56.5. Neuronal attachment and neurite-promoting factors**

Laminin	SIKVAV, YIGSR, RGD
Neural cell adhesion molecule (NCAM)	—
N-Cadherin	—

mensional substrates containing peptide mimics have also been shown to promote neural attachment and regeneration *in vitro* (Bellamkonda *et al.*, 1995a,b) and *in vivo* (Borkenhagen *et al.*, 1998b). This research has centered on the functionalization of naturally occurring gels and polyelectrolytes (e.g., agarose, alginate) with various oligopeptides. Functionalized gels can be placed within guidance channels or implanted along injured neural tracts in the PNS and CNS. Agarose functionalized with laminin-derived peptides has been shown to support neurite elongation *in vitro* and peripheral nerve regeneration *in vivo*. In future studies, it will be important to evaluate the influence of gel viscosity and pore structure as well as the density and gradients of immobilized ligands.

#### SEEDING NEURONAL SUPPORT CELLS

All axons are ensheathed by support cells, the Schwann cells. Larger axons are surrounded by a multilamellar sheath of myelin, a phospholipid-containing substance that serves as an insulator and enhances nerve conduction. An individual Schwann cell may ensheath several unmyelinated axons, but only one myelinated axon, within its cytoplasm. Schwann cells are delineated by a fine basal lamina that contains laminin, collagen type IV, and other ECM molecules. The Schwann cell basal lamina is capable of promoting neural outgrowth.

Adding neural support cells to the lumen of guidance channels is another strategy being used to improve regeneration or to make regeneration possible over otherwise irreparable gaps (Table 56.6). Schwann cells can be expanded *in vitro* from small nerve biopsies (Morrisey *et al.*, 1991). For example, Schwann cells cultured in the lumen of semipermeable guidance channels have been shown to improve nerve repair in adult rodents (Guénard *et al.*, 1992; Xu *et al.*, 1997). Cells harvested from inbred rats were first cultured in PAN/PVC tubes using various ECM gels as stabilizers. The Schwann cells and gel formed a cable at the center of the tube after several days in culture. Once implanted, the cells were in direct contact with the nerve stumps. A dose-dependent relationship between the density of seeded cells and the extent of regeneration was noted. The culture and expansion of human Schwann cells have proved difficult and may benefit through the use of GGF and other Schwann cell mitogens. CNS glial cells, such as astrocytes, may also support neural regeneration, although astrocytes obtained from older animals are less supportive than are cells from young animals. The addition of Schwann cells to astrocytes seeded in guidance channels improved the outcome of regeneration (Guénard *et al.*, 1994).

Olfactory ensheathing cells have been harvested and used to help support regeneration of

**Table 56.6. Schwann cell support of neural regeneration**

Form organized columns following injury (bands of Bünger)
Secrete basal lamina with neurite-promoting properties (laminin, collagen type IV, etc.)
Secrete nerve growth factor and other neurotrophic molecules
Express NGF receptors (sequester NGF at injury site, juxtacrine stimulation of axons)
May be genetically engineered to secrete particular neurotrophins

axons in the central nervous system (Li *et al.*, 1997). These cells were used because the normally occurring support cells of the CNS in adults are inhibitory to regeneration. Contrary to this, olfactory receptor neurons continuously arise from the neuroepithelium and it is believed that they have this capacity, in part, due to the olfactory glia that ensheath their axons (Ramon-Cueto and Valverde, 1995). For the first time, nerve fibers have crossed a gap in the spinal column and have reentered distal tracks when harvested olfactory ensheathing cells were seeded into the lumen of a nerve guide tube and used as the conduit (Ramon-Cueto *et al.*, 1998).

### SEEDING WITH GENETICALLY ENGINEERED CELLS

Another approach toward nerve repair involves the use of cells (Schwann cells, fibroblasts, myoblasts, etc.) that are genetically engineered to secrete growth factors (Gage *et al.*, 1991). The use of support cells that release neuronotrophic and neurite-promoting molecules may enable regeneration over large gaps or in recalcitrant tissues such as the spinal cord. There is significant evidence that PNS elements, especially Schwann cells, are capable of supporting CNS regeneration. For example, Schwann cell-seeded semipermeable channels support regeneration of the optic nerve (R. F. Valentini, and P. Aebischer, unpublished observations) and of the fimbria–fornix pathway (Kromer and Cornbrooks, 1985), which are CNS structures. In addition, fibroblasts engineered to secrete NGF enhance neuronal survival after a lesion of the fimbria–fornix, a CNS structure implicated in Alzheimer's disease (Hoffman *et al.*, 1993). The development of transfection/transduction techniques for the sustained, *in vivo* expression of functional genes (encoding NGF, CNTF, GGF, etc.), is under intense investigation.

### SPECIFICITY OF NERVE RECONNECTIONS

Nerve entubulation techniques increase the number of axons and the distance that axons regenerate. Another limitation that must be confronted for nerve repair and regeneration is the mismatch of regenerating nerves to incorrect distal connections, thus limiting functional recovery. In reanastomosis of nerve cables with mixed populations, sensory neurons can haphazardly reinnervate the motor end organs, and the motor axons can reinnervate the sensory organs. Brushart and Seiler (1987) showed in rat experiments that if the proximal motor branch of the femoral nerve was placed in a silicone Y-tube, one-half of the axons made the wrong choice of growing into the end of the tube containing the distal sensory nerve stump, instead of the one containing the distal motor nerve stump, when the gap distance was 2 mm. Interestingly, two thirds of the motor axons grew into the correct branch of the silicone tube when the distance was increased to 5 mm. Despite this increase when lengthening the gap, there is no assurance that the neurons reconnect to their original end organs. Efforts have been initiated to fabricate a microelectronic switchboard that could be inserted into the regenerating environment (Rosen *et al.*, 1990; Zhao *et al.*, 1997). Placed in the nerve guidance channel perpendicular to the regenerating axons, holes in the “nerve chip” would allow neurites to pass through and reconnect to distal targets, and an electronic signal processor could be envisioned that would allow the nerve impulses to be sensed and rerouted to their proper destinations (Dario *et al.*, 1998; Kovacs *et al.*, 1992; Lundborg *et al.*, 1998). This system would have the drawbacks of a chronic long-term implant and the electronics would be subjected to the harsh destructive *in vivo* environment.

### SUMMARY

The permeability, textural, and electrical properties of nerve guidance channels can be optimized to impact favorably on regeneration. The release of growth factors, addition of growth substrates, and inclusion of neural support cells and genetically engineered cells also enhances regeneration through guidance channels. Current limitations in PNS repair, especially the problem of repairing long gaps, and in CNS repair, because brain and spinal cord trauma rarely result in appreciable functional return, may benefit from advances in engineering and biology. The ideal guidance system has not been identified, but will most likely be a composite device that contains novel synthetic or bioderived materials and that incorporates genetically engineered cells and new products from biotechnology.

# TRANSPLANTATION STRATEGIES FOR TREATMENT OF SPINAL CORD DYSFUNCTION AND INJURY

Jacqueline Sagen, Mary Bartlett Bunge, and Naomi Kleitman

## INTRODUCTION

The spinal cord occupies a unique position in the central nervous system (CNS) in that it provides our primary conduit for communication and interaction with the world around us. With the exception of the unique sensors in the head, virtually all environmental stimuli are processed by somatosensory systems via the spinal cord. In addition, our responses to and interactions with our environment are under the control of motor systems functioning via final common pathways in the spinal cord. Autonomic sensations and responses also involve the flow of information to and from the spinal cord. Thus the spinal cord plays a critical role in the normal daily functioning of the organism in its environment, and any disruption can have severe consequences in the motor, sensory, and autonomic realms. The use of cellular or tissue transplantation for restoration of function has found potential CNS application in several disease and injury models (Azmitia and Björklund, 1987; Dunnnett and Richards, 1990; Freeman and Widner, 1998; Gash and Sladek, 1988). For application to spinal cord dysfunction, several approaches may be envisioned: (1) the use of neural implants as axonal bridges for repair of damaged spinal circuitry, (2) provision of cells for replacement of lost or damaged neuronal or glial elements, and (3) provision of neurotransmitters and/or neurotrophic factors by implanted cellular “minipumps.” These approaches are the subject of this chapter. The reader is also referred to other reviews (e.g., Bregman, 1998; Bunge and Kleitman, 1999; Fawcett, 1998; Giménez y Ribotta and Privat, 1998; Plant *et al.*, 2000; Sagen, 1998; Schwab and Bartholdi, 1996; Steeves and Tetzlaff, 1998; Zhang *et al.*, 1999).

## SPINAL IMPLANTS AS AXON BRIDGES

The primary goal of implantation of cellular bridges into the spinal cord is to provide a permissive substrate for axonal growth across the injury site to enable repair of cord circuitry and restoration of function following traumatic injury. For this purpose, the most common animal models utilized include compression and contusion (leading to cavitation) injuries, which may closely resemble crush injuries found in the clinic. Hemisection and complete transection models, also much studied, provide information relevant to laceration lesions. The criterion for “success” using various transplantation approaches is a subject of debate. Clearly, the best indication of success would be nearly complete restoration of function. Whereas some indication of functional improvement has been reported using a variety of interventions and a variety of behavioral tests, this appears to be limited, at least for the adult spinal cord, given the presently available technology. Nevertheless, numerous studies have demonstrated that the capacity for regeneration in the adult spinal cord is greater than previously thought, and suggest that restoration of function may ulti-

mately be possible under the right circumstances (e.g., Bregman *et al.*, 1998; Cheng *et al.*, 1996; Feraboli-Lohnherr *et al.*, 1997; Grill *et al.*, 1998; Li *et al.*, 1997; Liu *et al.*, 1999).

Following traumatic spinal cord injury, in addition to obvious cellular destruction at the site of the injury, axons from several sources are damaged or severed. These include segmental axons (e.g., primary axons derived from dorsal root ganglion cells), intersegmental axons (propriospinal or interneuronal), and long axons (e.g., descending axons from the corticospinal tract, monoaminergic axons from the locus coeruleus and raphe nuclei). Approaches toward regeneration of these damaged axons include the use of artificial or biologic matrices and peripheral nerve, Schwann cell, and fetal CNS tissue grafting.

### ARTIFICIAL AND BIOLOGIC MATRICES

Materials that have been utilized in bridges in spinal cord injury models include collagen, Matrigel (a basement membrane preparation), Millipore filters, carbon filaments, and fibrin. Polyacrylonitrile/polyvinylchloride and polycarbonate tubes have been utilized to contain bridging cellular transplants [for additional review, see Plant *et al.* (2000)]. Using a cat spinal cord transection model, de la Torre (1982) found that a cell-free collagen matrix could integrate well with host spinal tissue and attract several host cell types, including Schwann cells, fibroblasts, and meningeal cells. Numerous tyrosine hydroxylase-positive fibers were found invading the graft and perhaps reentering the spinal cord, suggesting the possibility of axonal regeneration from brainstem catecholaminergic nuclei. Joosten and colleagues (1995), likewise observing axonal growth along with other cell types into collagen, found that the time of gelation was key for ingrowth of regenerating fibers; corticospinal fibers grew into collagen grafts injected initially as a fluid but not into collagen implanted as a self-assembled gel. Further refinements in this approach include the use of chemical cross-linking of collagen gels (Marchand *et al.*, 1993) and the addition of neurotrophic or growth-promoting substances such as laminin (Goldsmith and de la Torre, 1992). Neurotrophin-3 (NT-3) added to collagen grafts improves corticospinal axon ingrowth (Houweling *et al.*, 1998).

Substrate-bound neurotrophic factors have been added to nitrocellulose implants (Houlé and Johnson, 1989; Houlé and Ziegler, 1994). In spinal transection cavities of adult rats, nerve growth factor (NGF)-treated nitrocellulose strips coimplanted with fetal spinal cord tissue induced extensive ingrowth of axons expressing calcitonin gene-related peptide (CGRP), most probably derived from dorsal root axons. In addition, many fibers appeared to extend into the host spinal cord rostral to the lesion and graft site, suggesting the potential for regrowth of ascending sensory axons using such an approach. Improvement in sensory axon regrowth into the spinal cord has also been obtained using Millipore filters coated with embryonic astroglia (Kliot *et al.*, 1988, 1990).

The future application of artificial and biologic matrices in spinal cord injury is an important and promising area of research. A type of biocompatible and bioresorbable polymer to be further tested is poly(lactic-co-glycolic acid). This compound is well tolerated by Schwann cells and spinal cord tissue (Gautier *et al.*, 1998). Three-dimensional hydrogels are also being investigated in CNS repair. When combined with collagen, they support new tissue growth, thus enabling tissue reconstruction and regeneration (Plant *et al.*, 1995, 1998). Hydrogels can be prepared with added sequences such as the RGD sequence found in extracellular matrix molecules (Plant *et al.*, 1997). Following transplantation into the CNS, such a combination initiates axonal regeneration. Schwann cells may be added to hydrogels as well to improve neurite growth-promoting activity (Woerly *et al.*, 1996).

### PERIPHERAL NERVE GRAFTS

It is well established that regeneration of several axonal processes in the CNS is greatly limited in contrast to axonal regeneration in the peripheral nervous system (PNS). Several possible explanations for this have been put forward, including the induction of an astroglial scar barrier (cellular or molecular) in response to CNS injury, the lack of supportive trophic factors and/or matrices, and the presence of growth inhibitory factors produced by CNS oligodendrocytes and the myelin they form. In contrast, peripheral nerves, and particularly Schwann cells, are remarkably supportive for the regrowth of axonal processes, including those of CNS origin. Thus, a rationale for intraspinal implantation of peripheral nerve segments is the provision of a conducive matrix for axon bridging and reconnection in severed CNS pathways following traumatic injury.

Although attempts at using peripheral nerve segments for spinal repair have been reported since the early 1900s, interest in this approach gained momentum in the 1970s and 1980s (for review, see Aguayo, 1985; Vrbová *et al.*, 1994). Peripheral nerve grafts can serve as bridges across transection lesions of the adult spinal cord; fibers enter the PNS grafts from neurons in the host spinal cord rostral and caudal to the lesion (Richardson *et al.*, 1980). Long peripheral nerve bridges circumventing the cord carry CNS axonal processes for remarkable distances, e.g., from the lower medulla to the thoracic cord (as much as 30 mm) (David and Aguayo, 1981). Thus, reconnection of intersegmental and perhaps long axonal pathways may be possible using this approach. Unfortunately, most findings indicate that, once the regenerating axons reach the CNS parenchyma, their further elongation is limited to the immediate vicinity of the graft–host border. One possible impediment to axon regeneration may be the disruption of the astrocytic array that is caused by the transection; this organization may provide an important guidance pathway for axon growth in the stumps (Davies *et al.*, 1994; Li and Raisman, 1994; Reier, 1986). Another, of course, is the neurite growth inhibitory barrier that forms between the peripheral nerve graft and the host cord, such as at the dorsal root entry zone.

Another approach that has been utilized is the implantation of peripheral nerve segments into the lesioned dorsal columns, leaving the rest of the spinal cord intact (Pallini *et al.*, 1988; Wilson, 1984, 1991). Good graft–host junctions were obtained, and some retrograde tracing studies indicated that neurons in the spinal cord sent axonal projections into the graft (Pallini *et al.*, 1988). In addition, there seemed to be some transmission through the grafted peripheral nerve segments, as indicated by electrophysiological recordings, and some improvements in sensation and motor coordination (Waldrope and Wilson, 1986; Wilson, 1991). Neurons in the dorsal root ganglia also can send axonal processes into grafted peripheral nerve fragments, because retrogradely labeled cells were noted in dorsal root ganglia several segments caudal to the graft (Pallini *et al.*, 1988). Other studies have utilized predegenerated peripheral nerve segments as graft material in the dorsal columns (Oudega *et al.*, 1994), the rationale being that their support of regeneration will be improved due to the increased production of neurotrophic factors (Heumann *et al.*, 1987). When combined with lesioning to condition the dorsal root ganglion neurons, more sensory fibers penetrated the peripheral nerve graft (Oudega *et al.*, 1994). When both were combined with neurotrophin infusion beyond the graft, sensory fibers not only extended into grafts but also into the cord beyond (Oudega and Hagg, 1996, 1999). Another study utilizing peripheral nerve implants in spinal dorsal columns demonstrated the capacity of injured dorsal column axons to reinnervate grafted Pacinian corpuscles (Jirmanová *et al.*, 1994).

Peripheral nerve grafts can be utilized to restore segmental motor connectivity by providing axonal bridges from ventral horn motor neurons to skeletal muscle (Bertelli and Mira, 1994; Bertelli *et al.*, 1994; Cullheim *et al.*, 1989; Horvat *et al.*, 1989). In these studies, when peripheral nerve segments were inserted into the spinal cord and denervated skeletal muscle following nerve avulsion injuries, spinal motor neurons were capable of regenerating axonal input to skeletal muscle. As evidence for this, muscle twitch responses could be elicited by electrical stimulation of the implanted nerve segments (Cullheim *et al.*, 1989), functional cholinergic neuromuscular junctions and endplates could be demonstrated (Bertelli and Mira, 1994), and coordinated voluntary and automatic activities could be obtained (Bertelli and Mira, 1994). Carlstedt *et al.* (1995) reported a case study of brachial plexus injury in which avulsed ventral roots were reintroduced directly (C6) and via sural nerve grafts (C7) into the cord just below the surface so as not to interfere with tracts. Voluntary activity in arm muscles was detected electromyographically after 9 months and clinically after 1 year; there was voluntary activity after 3 years. A possible additional benefit of such an approach is the potential survival-promoting effects of peripheral nerve grafts due to their endogenous neurotrophic factors. This is supported by studies demonstrating enhanced motoneuron survival and inhibition of nitric oxide synthase in spinal motor neurons when peripheral nerve segments are implanted at the time of root avulsion; normally root avulsion leads to significant motoneuron loss (W. Wu *et al.*, 1994). In another type of study, taking advantage of survival-promoting factors in muscle, peripheral nerve was used to attach muscle to adult rat cord that received a graft of embryonic spinal cord containing motoneurons (Sieradzan and Vrbová, 1989). (Results of this study are described later, with a discussion of lower motor neurons.)

The above studies indicate the potential for peripheral nerve grafts to aid in the restoration of segmental innervation in the injured spinal cord. Long spinal axon regeneration, e.g., the corti-

cospinal tract, however, is more difficult to achieve using this approach. The work of Cheng *et al.* (1996) is an exception to this. These authors transplanted multiple intercostal nerve grafts with fibrin glue containing a fibroblast growth factor (FGF-1), positioning of the graft endings toward gray matter, and stabilization of the spinal column. The authors reported brainstem and corticospinal growth through and beyond the grafts, and partial recovery of locomotor functions. Corticospinal growth was indicated by both retrograde and anterograde tracing. Combining neurotrophic factors with peripheral nerve transplants improves the regenerative response of subchronically and chronically injured supraspinal nerve cells (Ye and Houle, 1997).

### SCHWANN CELL GRAFTS

The Schwann cells of peripheral nerves possess many attributes that predict their capability of fostering CNS axonal regeneration (reviewed in Guénard *et al.*, 1993). There is also the possibility of autotransplanting Schwann cells obtained from a spinal cord-injured person; Schwann cells can be obtained from a piece of their peripheral nerve and expanded in number in culture (see Bunge and Kleitman, 1999). Also, while in culture, they may be genetically modified to generate neurotrophic factors. When cultured Schwann cells are microinjected in small volumes directly into long axon tracts such as the corticospinal tract or dorsal columns, both ascending and descending tracts extend for considerable distances along the tracts and branch into the grafts (Li and Raisman, 1994). Cultured Schwann cell suspensions have also been utilized in bridges in the spinal cord lesioned by various means, including photochemically (Paino and Bunge, 1991; Paino *et al.*, 1994), by inflatable microballoon compression (Martin *et al.*, 1991, 1993), by transection (Wrathall *et al.*, 1984; Xu *et al.*, 1995a; Guest *et al.*, 1997), and by suction (Kuhlengel *et al.*, 1990).

Matrices or guidance channels are often combined with Schwann cells (Paino and Bunge, 1991; Paino *et al.*, 1994; Xu *et al.*, 1995a, 1997). Using semipermeable polymer channels filled with Schwann cells suspended in Matrigel in complete transection lesions, Xu *et al.* (1997) demonstrated in the grafts numerous axons from dorsal root ganglion cells and spinal interneurons as far away as the C3 and S4 levels. The transplanted Schwann cells either myelinated or ensheathed the axons that regenerated into the graft. There was limited regrowth of serotonergic and noradrenergic fibers, whose parent somata are in the brainstem. As in the case of most peripheral nerve transplantation studies, Schwann cell bridges do not engender corticospinal fiber regeneration into the graft and fibers do not leave the graft. The use of a similar type of channel enclosing Schwann cells, but only half the size (i.e., filling a lateral hemisection rather than a complete transection), leads to improved regeneration in that fibers reenter the host cord (Xu *et al.*, 1999). Possibly the restoration of cerebrospinal fluid circulation and more stable cord-graft interfaces (due to a more limited laminectomy) are important factors in the improvement.

Channels containing the Schwann cell grafts that fill complete transection gaps are more effective in a combination strategy. When a neuroprotective compound, methylprednisolone, is administered at the time of Schwann cell transplantation, the Schwann cell bridge contains three times as many myelinated axons, and twice as many spinal neurons respond by extending axons into the graft (Chen *et al.*, 1996). Also, brainstem neurons respond, even though the transplant is in the thoracic region, far from the brainstem nuclei. Moreover, a modest growth of fibers from the graft into the distal cord is observed. When neurotrophins, NT-3, and brain-derived neurotrophic factor (BDNF) are infused into the space around the Schwann cell graft, more myelinated axons are present in the graft and more spinal neurons extend axons into the graft (Xu *et al.*, 1995b). Brainstem neurons also respond to the neurotrophin-containing Schwann cell graft. Genetically modifying the Schwann cells to produce human BDNF leads to an improved regenerative response as well (Menei *et al.*, 1998). Schwann cells genetically modified to secrete high levels of another neurotrophin, nerve growth factor, engender dopaminergic and adrenergic axonal regeneration (Tuszynski *et al.*, 1998). Thus, genetically manipulating Schwann cells to increase their production of neurotrophins improves their ability to support CNS axonal regeneration.

### GRAFTS OF OTHER CELL TYPES

Tuszynski *et al.* (1994) have pioneered the use of genetically modified fibroblasts to secrete a variety of neurotrophic factors to improve regeneration in the cord. They have found, for example, that the administration of NT-3 from fibroblasts to a hemisectioned spinal cord leads to growth of corticospinal tract fibers, not through the fibroblast graft but in the gray matter around the graft

in adult rat cord (Grill *et al.*, 1998). An improved locomotor outcome was documented in this work as well. Schnell *et al.* (1994) had initially shown that corticospinal fibers are responsive to NT-3, both during development and after axotomy. Also, transplanted NT-3-producing tissue can rescue axotomized Clarke's nucleus neurons (Tessler *et al.*, 1992). A new paper demonstrates that regeneration of rubrospinal fibers occurs in the wake of transplantation of fibroblasts engineered to secrete BDNF into a cervical hemisection cavity in adult rat cord (Liu *et al.*, 1999). The axons regenerate through and around the transplants, grow for long distances in the white matter below the transplant, and terminate in gray matter regions. These results are accompanied by significant recovery of forelimb usage.

Another cell type that appears to be highly promising in spinal cord regeneration without genetic modification is the ensheathing glial cell. A unique cell in the olfactory system, these cells have been found to support corticospinal tract regeneration in a very localized lesion (Li *et al.*, 1997, 1998) and to enable lengthy axon regeneration and also growth from Schwann cell grafts into the distal cord (Ramón-Cueto *et al.*, 1998). It is not yet known in what ways ensheathing glia affect CNS regeneration: Do they shelter the axon? Do they provide a permissive growth substrate? Or, do they secrete molecules that modify the lesion milieu?

Cells that may make the lesion milieu more favorable for neurite growth are macrophages, which secrete a variety of cytokines and growth factors. Macrophages have been activated *in vitro* by pieces of peripheral nerve and then injected into transected spinal cord (Rapalino *et al.*, 1998). This strategy leads to nerve fiber growth across the transected site, partial recovery of motor function, and evoked muscle responses. Retranssection of the cord above the initial lesion site leads to loss of recovery, indicating the involvement of fiber growth across the lesion.

Additional cell types used to bridge lesions, replace lost cells, serve as relay stations, or act as "minipumps" (with added genes) are stem cells. Because they are now known to be present in normal adult CNS tissue, an important area of research will be to determine in what ways they may be influenced to proliferate and populate lesion areas. Or, alternatively, they may be isolated to be used in transplantation. An example showing the potential of neural stem cell transplantation is the intracerebroventricular injection at birth to correct the widespread dysmyelination in the shiverer (*shi*) mouse due to the lack of myelin basic protein (Yandava *et al.*, 1999). The injected cells differentiate into myelin basic protein-expressing oligodendrocytes throughout the *shi* brain, promoting improved widespread myelination with amelioration of behavioral symptoms. An intriguing aspect is that neural stem cells may possess a mechanism whereby their differentiation is directed to replenish deficient cell types. (See further discussion on myelin-forming cells, with discussion of lower motor neurons.)

## FETAL CNS GRAFTS

It has been hypothesized that the fetal CNS, the environment in which CNS neurons grow during development, may be most conducive to encouraging axonal regrowth (Stokes and Reier, 1991). Potential advantages of fetal CNS tissue for grafting in spinal cord include not only the possibility to bridge an injury site with a growth-promoting environment but also the possibility of cellular replacement. In particular, the use of homotypic fetal spinal cord tissue implants may provide a relay via synaptic connections to and from the implant. This approach has been primarily successful when used in neonatal animals (Bregman and Kunkel-Bagden, 1994; Bregman *et al.*, 1993; Kunkel-Bagden and Bregman, 1990; Iwashita *et al.*, 1994; Diener and Bregman, 1998a,b). When spinal hemisections are performed in rats at birth, corticospinal tract axons are spared, because they have not yet grown past the site of injury (Schreyer and Jones, 1983). These developing axons are capable of elongating through fetal spinal cord implants and making appropriate connections with host spinal neurons caudal to the lesion. In addition to corticospinal axons, immunocytochemical and tracing studies revealed that descending serotonergic and noradrenergic axons extend throughout the transplant. CGRP fibers, presumably from dorsal root axons, also grow into and project through the transplant (Bregman and Kunkel-Bagden, 1994; Bregman *et al.*, 1993; Bregman, 1987; Bregman and Bernstein-Goral, 1991; Houle and Reier, 1989). Of particular interest is the apparent restorative capacity of fetal spinal cord transplants in neonates, which improved the maturation of locomotor patterns and shifted the time course of sensorimotor development toward that of normal intact animal (Bregman and Kunkel-Bagden, 1994; Bregman *et al.*, 1993). This includes enhanced recovery evidenced by frequency of contact-placing re-

sponses, improved performance on a grid runway, and increased base of support. Iwashita *et al.* (1994) reported long-lasting functional recovery when embryonic spinal cord segments were implanted in the proper orientation in neonatal rats with complete spinal resection. Histologically, in successful cases, the grafts showed remarkable survival and “seamless” integration with the host (14 of 22 cases); the others showed complete degeneration and resorption. Tracing studies indicated bidirectional long axonal projections across successful grafts. In addition, animals with successful replacement exhibited good motor performance with hindlimb/forelimb coordination. Surprisingly, this was not seen when embryonic spinal cord tissue was implanted in the incorrect orientation.

Grafting of embryonic day 14 (ED14) fetal cervical cord tissue after cervical hemisection yielded similar results in neonatal rats (Diener and Bregman, 1998a,b). Improved reflex responses and skilled forelimb activity were associated with growth of raphespinal, corticospinal, brainstem, and dorsal root projections. Raphe projections were seen apposed to propriospinal neurons, suggesting reestablishment of supraspinal input to spinal circuitry below the lesion.

In contrast to neonates, fetal spinal cord implantation in adult injured rat spinal cord has generally yielded less successful outcomes in restoring supraspinal input (Bregman and Kunkel-Bagden, 1994; Bregman *et al.*, 1993; Houle and Reier, 1988, 1989; Bernstein and Goldberg, 1989; Itoh and Tessler, 1990; Jakeman and Reier, 1991; Nothias and Peschanski, 1990; Pallini *et al.*, 1989; Patel and Bernstein, 1983; Reier *et al.*, 1986). Although CGRP-positive dorsal root axons are apparently capable of penetrating the grafted tissue throughout its extent, ingrowth of descending fibers is limited to the immediate host–graft interface. Some functional recovery has been reported, such as improved recovery in stride length and grid runway performance (Bregman and Kunkel-Bagden, 1994; Bregman *et al.*, 1993), although permanent deficits remain and motor behavior does not return to control levels. Slightly better results were reported in adult cats with spinal compression injuries (Wirth *et al.*, 1992), which showed some recovery in walking, gait, and stair climbing. This may be due to later maturation of cat spinal cord, or to the use of a compression, rather than a transection, injury model, which may spare host long axon pathways to some extent. Using a contusion injury model in adult rats, and transplants of fetal spinal tissue in cell suspension rather than solid segments, long-lasting improvements in some motor tasks have been reported, particularly in motivated fine motor behaviors, base of support, stride length, and more normalized inhibitory control of reflex excitability (Stokes and Reier, 1992; Thompson *et al.*, 1993). Suggested mechanisms for these beneficial effects include enhanced anatomic sparing, improved function of remaining systems, or the facilitation of alternative pathways.

Restoration of segmental innervation, particularly from dorsal root axons, is a consistent observation in adult animals with spinal cord injuries (Bernstein and Goldberg, 1989; Bregman *et al.*, 1993; Itoh *et al.*, 1993a,b; Jakeman *et al.*, 1989; Kikuchi *et al.*, 1993; Rhrich-Haddout *et al.*, 1994). Cut central axons of dorsal root ganglion cells readily regenerate into embryonic spinal tissue grafts placed in hemisection cavities, and form synaptic contacts. Numerous fibers immunoreactive for CGRP, which is present in small-diameter primary afferents derived from dorsal root ganglion cells, are found in transplanted tissue for at least 1 year following fetal spinal cord implantation (Itoh *et al.*, 1993b). Further, electrophysiological responses could be evoked in the fetal grafts by regenerated dorsal root axons, indicating the potential for functional segmental recovery using this approach. In addition, embryonic spinal grafts can apparently undergo normal differentiation to some extent, particularly the dorsal horn, because they demonstrate characteristics similar to the adult substantia gelatinosa, including the presence of met- and leu-enkephalin, neurotensin, substance P, and somatostatin immunoreactivity (Jakeman *et al.*, 1989). Thus, such grafts may possess the capacity for neuronal replacement if appropriate intraspinal circuitries can be restored.

The absence of regeneration in descending fiber tracts may not be an intrinsic limitation of adult CNS neurons, but an insufficiency of trophic support provided by the fetal CNS grafts. When members of the neurotrophin family were administered concurrently with transplantation, increased serotonergic, noradrenergic and corticospinal ingrowths of axons into fetal spinal cord grafts were observed in adult rats (Bregman *et al.*, 1997). The effect was at least somewhat selective, in that ciliary neurotrophic factor (CNTF) had no effect on growth of supraspinal axons. This finding is similar to that of Xu *et al.* (1995b), who showed improved supraspinal axonal re-

generation into Schwann cell grafts when the neurotrophins BDNF and NT-3 were infused into the graft environment (see above).

Fetal CNS grafts, however, do provide some trophic substances. The observation of some degree of functional recovery, even in the absence of host reinnervation by the graft, has suggested that the recovery may be due to neurotrophic support provided by graft-derived astrocytes or other cellular components (Bernstein and Goldberg, 1989). Support for this comes from studies using heterotopic fetal CNS tissue as graft material. Fetal neocortical transplants in the adult spinal cord can rescue axotomized Clarke's nucleus neurons (Himes *et al.*, 1994), provide graft-derived astrocytes (Bernstein and Goldberg, 1989), and differentiate to produce defined neuronal and glial cell populations (Connor and Bernstein, 1987). Furthermore, studies of fetal spinal transplantation in neonates and adults have suggested a neurotrophic component to observed enhancements in recovery. Following complete midthoracic spinal transection in neonatal rats, Miya *et al.* (1997) observed incomplete integration of the grafts, although some descending serotonergic fibers grew through and beyond the graft. Although anatomic repair was incomplete, some rats were able to demonstrate sufficient coordinated adaptable locomotion to suggest that the effect of the limited supraspinal input was augmented by nonspecific trophic effects of the transplant on the distal cord. Bregman *et al.* (1998) observed that either fetal spinal grafts or neurotrophic factor application reversed atrophy of mature rubrospinal neurons. Both interventions together were more effective than either alone, suggesting the enhancement of graft efficacy may be associated with indirect effects of the trophic factors on the grafts themselves as well as direct effects on the regenerating axons. A report by Broude *et al.* (1999) confirms that both fetal spinal grafts and trophic factors activate neuronal responses, such as c-Jun expression, that may be associated with axonal growth. Thus, it will also be important to consider strategies to activate neuronal expression of regeneration-associated genes (reviewed in Richardson and Lu, 1994; Steeves and Tetzlaff, 1998).

When other fetal CNS tissues, such as cerebellum, neocortex (Himes *et al.*, 1994), and hippocampus (Li and Raisman, 1993), have been grafted, target specificity has been reported in the response of host neurons. Interestingly, "nontarget" CNS grafts (embryonic hippocampus or cortex) did not elicit entry of cut brainstem fibers in a full transection model (Bernstein-Goral *et al.*, 1997). In their hemisectioned cord model, sprouting of uninjured contralateral axons appeared to account for at least some of the observed ingrowth, leading these authors to suggest that sprouting and regenerating axons may differ in growth responsiveness after injury. The implantation of human fetal spinal cord allografts has undergone initial clinical testing in the United States and Sweden (Falcı *et al.*, 1997; Wirth *et al.*, 1998, 1999). This approach has been used in clinical trials in spinal cord-injured patients with recurring syringomyelia (cystic lesions of the cord causing progressive loss of function and increased symptoms such as pain, spasticity, and autonomic dysreflexia). Graft survival and recurrence of cyst expansion are being studied using magnetic resonance imaging and physiologic assessment is underway.

## SPINAL IMPLANTS FOR REPLACEMENT OF SPECIFIC CELL POPULATIONS

### LOWER MOTOR NEURONS

As discussed above, in addition to providing a supportive growth environment, homotypic grafts of fetal spinal cord could potentially provide for the replacement of lost neuronal populations and restore spinal circuitry via reciprocal host-graft connections. To some extent, the dorsal horn of transplanted embryonic spinal cord appears to differentiate and take on characteristics typical of the adult substantia gelatinosa (Jakeman *et al.*, 1989). However, in general, ventral horn motor neurons do not appear to survive or differentiate well after transplantation. Instead, this region is characterized by small and medium neurons, with a paucity of large neurons, suggesting that the larger motoneurons, which are the earliest born, either selectively die or fail to mature to the adult form. Nevertheless, the conditions necessary to enhance motoneuron replacement and integration in host circuitry could be important in the treatment of neurologic diseases such as amyotrophic lateral sclerosis (ALS) and poliomyelitis. This topic has been the subject of intense investigation by Vrbová and colleagues (1994). This group has identified several factors, both host and graft, that influence the survival of transplanted embryonic motoneurons. First, optimal donor

gestational age appears to be after the onset of motoneuron pool proliferation but before axonal extension into the periphery commences. Second, the availability of an appropriate target (i.e., denervated muscle) is essential. Third, the implanted motoneurons must be able to reach the target via a conduit, such as peripheral nerve implanted in the vicinity of the graft. In addition, the authors have found that depletion of the host's own motoneuron pool, similar to the cerebellum of Purkinje cell-deficient mice receiving Purkinje cell transplants (Sotelo and Alvarado-Mallart, 1987), may create necessary "empty niches" for occupation of embryonic motor neurons migrating from the grafts.

Using this approach, Vrbová's group transplanted small fragments of embryonic rat ventral spinal cord (ED11–ED12) into the lumbar segment of hosts whose spinal cord motor neurons had been selectively depleted several weeks earlier by sciatic nerve crush at birth (Sieradzan and Vrbová, 1989). In addition, a host muscle with a length of attached nerve was implanted to create a conduit and target muscle. Donor embryos were prelabeled *in utero* with 5-bromo-2'-deoxyuridine (BrdU) to aid in identification of donor-derived cells following transplantation. Results indicated numerous BrdU-labeled nuclei in the graft as well as host spinal cord, with some labeled cells attaining a larger size than embryonic motoneurons. Retrograde tracing studies indicated that some of these motoneurons, and the expression of choline acetyltransferase (ChAT) and CGRP, which are useful markers for motoneurons, was quite low, again suggesting either selective motoneuron death or the failure to reach full maturity (Sieradzan and Vrbová, 1993). In addition, axons of these grafted neurons were not able to enter vacated endoneurial sheaths of spinal ventral roots to reinnervate muscles deprived of their innervation, and thus recovery of lost motor function was not achieved. In a subsequent study, attempts were made to guide axons from grafted embryonic motoneurons to their target via a reimplanted ventral root (Nógrádi and Vrbová, 1996). Retrograde labeling 3–6 months later revealed axons of graft origin in the ventral ramus and some reversal of the losses in muscle force.

In other studies, fetal spinal neurons have been grafted as a suspension, using cell populations specifically enriched in motoneurons by density-gradient purification or fractionation using the low-affinity NGF receptor as a ligand (Demierre *et al.*, 1990; Peschanski, 1993; Peschanski *et al.*, 1992). These motoneurons survived, received host innervation, and in some cases migrated into host parenchyma. However, as in solid grafts, ChAT expression was generally poor. The neurotoxic lectin, volkensin, has been used to deplete selectively adult motoneurons as a better model of human degenerative motoneuron disease (Nógrádi and Vrbová, 1994). Again, transplanted fetal neurons migrated into host tissue, but few CGRP-positive neurons were found.

Erb *et al.* (1993) implanted dissociated ED14 ventral spinal cord cells into the distal stump of axotomized tibial nerves of adult rats. Large multipolar neurons were observed at the implantation site, with some myelinated axons. Axons were traced to the experimentally denervated gastrocnemius muscle and were seen to form neuromuscular junctions. Completely denervated adult rat gastrocnemius muscles shortened repeatedly, for hours, without electromyographic failure, after reinnervation by ED14–ED15 ventral spinal cord cells and exogenous electrical stimulation (Thomas *et al.*, 1998). Some reinnervated motor units also contract spontaneously, demonstrating some intrinsic excitability of the grafted motoneurons (Sesodia *et al.*, 1999). Using a similar paradigm, Fleetwood *et al.* (1998) reported that stem cells isolated from embryonic mouse spinal cord cultured in FGF-2 and epidermal growth factor (EGF), and prelabeled with 3,3'-dioctadecyloxycarbocyanine perchlorate (DiO), were able to grow axons into denervated sciatic nerve segments. The resultant neuronal cells were immunoreactive for a microtubule-associated protein (MAP-2) and ChAT.

In addition to motoneuron replacement, the provision of appropriate neurotrophic factors by cellular implants may aid in the treatment of neurodegenerative diseases such as ALS by retarding additional motor neuron loss or protecting transplanted embryonic motor neurons. As an example, in animal models of chronic motoneuron degeneration, CNTF can prevent motor neuron loss (Sendtner *et al.*, 1992). Taking advantage of these findings, encapsulated baby hamster kidney (BHK) cells that were genetically engineered to produce CNTF reduced motoneuron death after facial nerve axotomy and prolonged the life-span of mutant mice with progressive mononeuropathy (Sagot *et al.*, 1995). An open-label safety study using encapsulated BHK–hCNTF cells implanted intrathecally in ALS patients revealed detectable levels of CNTF in the cerebrospinal fluid of these patients, with no significant adverse effects noted (Aebischer *et al.*, 1996). However,

evaluation of Norris scale slopes before and after implantation indicated that the disease continued to progress. Nevertheless, these findings indicate that it is possible to achieve sustained delivery of a neurotrophic factor intrathecally using cellular implantation.

### MYELIN-PRODUCING CELLS

The efforts of several laboratories have been focused on the potential for grafts of myelin-producing cells to remyelinate axonal pathways, because demyelinating and dysmyelinating disorders such as multiple sclerosis and the leukodystrophies continue to debilitate patients. For many of these studies, mutant animals such as the myelin-deficient (*md*) rat and the shaking pup (*sh*) have been used. Both the *md* rat and *sh* pup have a point mutation in the proteolipid protein gene that results in severe dysmyelination of the CNS and is the molecular basis of dysmyelination in patients suffering from Pelizaeus–Merzbacher disease. Remyelination could theoretically be derived from two distinct cell types: Schwann cells, which myelinate peripheral nerves, and oligodendrocytes, which myelinate CNS axons. Both of these sources have been utilized in attempts to achieve remyelination in the spinal cord. Schwann cells are particularly aggressive in their ability to proliferate and remyelinate axons in the CNS and compete successfully with oligodendrocytes for positions on axonal surfaces, especially in the absence of type 1 astrocytes (Blakemore and Crang, 1989; Blight and Young, 1989). In a sense, this competition for space on axonal surfaces may be detrimental in the long run, because the Schwann cells may displace host oligodendrocytes and astrocytes (Vrbová *et al.*, 1994). Nevertheless, Schwann cell grafts have been shown to be capable of remyelinating spinal cord axons in myelin-deficient mutants (e.g., the quaking mouse, *sh* mouse, and *md* rat), as well as in adult rats experimentally demyelinated using ethidium bromide (Baron-Van Evercooren *et al.*, 1993; Blakemore, 1977, 1980, 1983, 1984; Blakemore *et al.*, 1987; Duncan *et al.*, 1981, 1988). Remyelination by Schwann cells can arise from either peripheral nerve segments placed alongside or inserted into the dorsal columns, or by cultured Schwann cell suspensions. The latter are capable of migrating quite some distance toward the demyelinated regions (Baron-Van Evercooren *et al.*, 1991; Langford and Owens, 1990).

Imaizumi *et al.* (1998) have reported that olfactory ensheathing cells, which have properties resembling both astrocytes and Schwann cells, can remyelinate dorsal column axons following demyelination by X-ray irradiation and ethidium bromide injection. Suspensions of cells from neonatal rat olfactory bulbs were injected. Three weeks later, remyelinated axons showed improved conduction velocity and frequency-response properties associated with PNS-like myelination of axons. Olfactory ensheathing cells are highly migratory, and show evidence of having myelinated areas remote from the injection site. Li *et al.* (1998) reported that suspensions of cells from olfactory bulb injected into small electrolytic lesions of the corticospinal tract at C1–C2 supported regeneration along the tract's original CNS pathway. Regenerating corticospinal axons were associated with myelin sheaths immunopositive for protein-zero (typical of peripheral myelin segments) and exhibiting typical peripheral nerverlike morphologies. Peripheral and central myelin segments were observed to be adjacent on some axons at the transition zone between damaged and undamaged host cord (Li *et al.*, 1998).

As mentioned, the invasive nature of Schwann cells, and possibly olfactory ensheathing glia grafts, may limit their usefulness in human application if they cannot be adequately controlled. In contrast, oligodendrocytes may be a better choice, because, together with astrocytes, they are potentially capable of forming a more normal and well-balanced glial environment (Vrbová *et al.*, 1994). As with Schwann cells, oligodendrocyte transplants have been derived either from intact tissue (in this case embryonic spinal cord) or from defined glial cell cultures (Blakemore and Crang, 1988, 1989; Duncan *et al.*, 1988, 1992; Gout *et al.*, 1988; Rosenbluth *et al.*, 1989, 1993; Utzschneider *et al.*, 1994). For example, embryonic spinal cord grafted into the spinal cord of *sh* mice or *md* rats resulted in the formation of normal myelin sheaths with regular periodicity around axons (Rosenbluth *et al.*, 1989). Further, the implantation of spinal glial cell suspensions in *md* rats resulted in a threefold increase in axon conduction velocity and normalized frequency-response properties (Utzschneider *et al.*, 1994). The potential usefulness of oligodendrocytes in spinal transplantation is enhanced by the ability to utilize xenogeneic sources (Rosenbluth *et al.*, 1993; Archer *et al.*, 1994) and cryopreservation techniques (Archer *et al.*, 1994). In addition, transplanted oligodendrocytes can apparently migrate rostrocaudally, particularly toward lesion sites (Duncan *et al.*, 1988; Duncan and Milward, 1995; Gumpel *et al.*, 1989). However, the extent of remyelination

has been limited to patches of dysmyelination. A study in canine myelin mutants has indicated that donor tissue derived from fetal sources is most efficacious in myelinating large areas of the CNS (Archer *et al.*, 1997). Using mixed glial cell populations from the brain of an embryonic day (ED) 45 normal canine, injected into the dorsal columns of *sh* pups, extensive remyelination near the implant sites and up to 2 cm rostrally and caudally was observed.

Thus, more recent approaches have utilized progenitor cells as donor sources for remyelination (for review, see Billingham *et al.*, 1998; Dubois-Dalcq, 1995; Rogister *et al.*, 1999; Zhang *et al.*, 1999). For example, conditionally immortalized glial precursor cell lines (using the temperature-sensitive SV40 T antigen) were generated from ED14 mouse brain and transplanted in the dorsal columns of rats with ethidium bromide demyelinating lesions (Trotter *et al.*, 1993). Myelin formation with regular periodicity could be observed around demyelinated axons following injections of early passages, although myelin sheaths were thin and showed breaks. The success of remyelination and behavioral recovery after experimental demyelination paradigms is dependent on remaining axonal integrity (Jeffery *et al.*, 1999); however, these models have established the potential for functional remyelination by precursor cell transplants. In another laboratory, a growth factor-dependent cell line of rat oligodendrocyte precursors (CG4) could migrate extensively along axonal tracts from the injection site in *md* rats and myelinate dorsal column axons (Tontsch *et al.*, 1994). Results of grafting CG4 cells into neonatal *md* rats indicated that highly motile, proliferative oligodendrocyte precursors yield the best survival and functional myelination (Espinoza de los Monteros *et al.*, 1997).

A particularly promising approach is the use of epidermal growth factor-responsive neural stem cells, which can be generated from embryonic and adult brain and propagated continuously as spheres (neurospheres) in an undifferentiated state in the presence of EGF (Hammang *et al.*, 1994; McKay, 1997; Reynolds and Weiss, 1992). Under appropriate culture conditions, these cells can be induced to differentiate into oligodendrocytes, astrocytes, or neurons. When transplanted in the undifferentiated stem cell state into the spinal cords of *md* rats, the cells can differentiate into myelinating oligodendrocytes and produce densely packed, normal-appearing myelin (Hammang *et al.*, 1997). Interestingly, although clonal neural stem cells preferentially differentiate into astrocytes *in vitro*, a majority of these multipotential cells may shift toward oligodendroglial lineage in response to environmental cues in myelin-deficient states (Hammang *et al.*, 1997; Yandava *et al.*, 1999). Similar findings have been observed in *sh* pup mutants receiving transplants of EGF-responsive neurospheres derived from the normal canine brain (Milward *et al.*, 1997). Although most studies have utilized progenitor cells derived from embryonic or neonatal animals, multipotent stem cells are also present in the adult brain ependyma and can generate myelin-producing oligodendrocyte progenitors (Zhang *et al.*, 1999). In addition, allogeneic donor sources may be feasible with appropriate immunosuppression (Li and Duncan, 1998), and myelinating oligodendrocyte progenitors may be derived from ectopic sites, such as the optic nerve (Fanarraga *et al.*, 1998).

The first *in vivo* evidence that neurotrophic influences may promote the expansion of oligodendrocyte lineage cells in the spinal cord was attained by McTigue *et al.* (1998). In this study, fibroblasts producing NT-3, BDNF, CNTF, NGF, FGF-2, or  $\beta$ -galactosidase were transplanted subacutely into adult spinal cord injured by contusion. The NT-3 and BDNF groups showed increased numbers of axons and enhanced myelination associated with increased numbers of BrdU-positive oligodendrocytes, suggesting the trophic factors had initiated proliferation and differentiation of endogenous oligodendrocyte precursor cells. Because multipotent neural stem cells could potentially be engineered to produce neurotrophic factors, they may be ideally suited for combination strategies requiring both cell replacement and delivery of therapeutic molecules (Billinghurst *et al.*, 1998).

## SPINAL IMPLANTS FOR PROVISION OF NEUROTRANSMITTERS

### MONOAMINERGIC CELLS FOR RESTORATION OF MOTOR FUNCTIONS

Several laboratories have utilized serotonergic or noradrenergic cells as graft sources in spinal-injured or -denervated animals. Serotonergic cells have typically been obtained from embryonic mesencephalic or medullary raphe regions (Foster *et al.*, 1985, 1989; Privat *et al.*, 1988, 1989; Reier *et al.*, 1992a,b). In spinal cords of adult rats denervated of serotonergic input by 5,7-dihydroxytryptamine, serotonergic cell suspensions implanted 7 days after the lesion were found to sur-

vive for up to 12 months after grafting, with dense fiber outgrowth rostral and caudal to the grafts (Foster *et al.*, 1985, 1989). In general, it appears that better survival of serotonergic neurons is obtained with medullary raphe grafts, possibly because this region is the normal source of serotonergic innervation of the spinal cord. With medullary raphe grafts, many motoneurons could be found surrounded by serotonergic fibers. Serotonin (5-HT) levels in the denervated cord after transplantation were restored to 40% of that in unlesioned animals. In addition, electrical stimulation of the grafts could excite motoneurons, suggesting that functional connections had been formed. Using complete spinal transection, which depletes spinal cord 5-HT, similar survival and integration was reported with embryonic raphe cell suspensions implanted 1 week following the lesion (Privat *et al.*, 1988, 1989). In the early postgrafting period, synaptic afferents to serotonergic neurons were frequently seen. Later, serotonergic innervation was found in normal 5-HT-innervated sites such as the ventral horn near motoneurons, intermediolateral cell column, and superficial dorsal horn. In addition, sexual reflexes, which are under the control of 5-HT and absent in paraplegic rats, were restored in transplanted animals. The window between spinal transection and grafting was opened by Reier *et al.* (1992a,b), who found that fetal serotonergic grafting delayed from 1 to 3 months posttransection could still project their axons into gray matter regions normally innervated by bulbospinal 5-HT neurons.

Noradrenergic neurons from embryonic brainstem containing the locus coeruleus have also been utilized as intraspinal grafts to restore function in spinal transected or 6-hydroxydopamine (6-OHDA)-denervated animals (Buchanan and Nornes, 1986; Commissiong and Sauv , 1989; Moorman *et al.*, 1990; Nornes *et al.*, 1988; Nygren *et al.*, 1977; Yakovlev *et al.*, 1989). Bulbospinal noradrenergic systems are involved in a number of functions, including motor activities, autonomic reflexes, and modulation of nociception. Good survival of noradrenergic neurons in locus coeruleus transplants has been reported by inserting grafts directly into spinal cord parenchyma or following placement in subpial cavities. The transplanted cells were found to grow processes and reinnervate the spinal gray matter to nearly normal levels. In particular, immunoreactive noradrenergic processes with terminals were found around motoneurons. In addition, improvements in motor performance tasks involving noradrenergic input were reported, including increased force of hindlimb flexion reflexes (Buchanan and Nornes, 1986; Nornes *et al.*, 1988; Yakovlev *et al.*, 1989), rhythmic locomotion and step frequency (Yakovlev *et al.*, 1989), and motor coordination (Commissiong and Sauv , 1989).

Studies show that embryonic transplants of either raphe or locus coeruleus regions yield dense monoaminergic reinnervation of host lumbar interneurons after a T8–T9 spinal transection, and motoneurons in lumbar segments after grafting at T12–T13 (Yakovlev *et al.*, 1995). Effects on two fictive motor patterns, stepping and hindpaw shaking, could be discriminated 1 to 3 months later: both types of grafts increased the excitability of the spinal stepping generator compared to surgical controls, but neither significantly affected hindpaw shaking. More direct evidence of influence of fetal grafts on spinal stepping generators has been described (Feraboli-Lohnherr *et al.*, 1997). Spinal cord locomotor circuits display plasticity independent of supraspinal input (Gim nez y Ribotta and Privat, 1998). This plasticity can be modulated pharmacologically or by transplantation of embryonic monoaminergic neurons. By injecting 6-OHDA to eliminate noradrenergic inputs after transplantation of fetal raphe or coeruleus cells, Feraboli-Lohnherr *et al.* (1997) showed for the first time that transplanted serotonergic neurons can activate the spinal pattern generator for locomotion independent of adrenergic influence. Electromyographic studies showed that this locomotor-like activity was facilitated by the 5-HT reuptake blocker, zimelidine.

Adrenal chromaffin cells have also been used as intraspinal grafts to restore deficits after spinal catecholamine depletion by 6-OHDA (Pulford *et al.*, 1994). Neonatal rat adrenal medullary cells cultured in the presence of NGF were implanted in the lumbar region of the spinal cord 2 weeks after denervation. These grafts survived for at least 3 months postimplantation. In addition, the long latency component of the hindlimb withdrawal reflex, which is catecholamine modulated, was significantly more forceful than control implanted or unimplanted animals, and equally as effective as fetal noradrenergic implants.

### SPINAL CORD GRAFTS FOR PAIN MODULATION

Adrenal medullary chromaffin cells have also been utilized for transplantation in the spinal subarachnoid space to alleviate pain. The choice of chromaffin cells was based on their ability to produce neuroactive substances with known antinociceptive properties, including the cate-

cholamines epinephrine and norepinephrine and opioid peptides met-enkephalin and leu-enkephalin. In addition, chromaffin cells produce other agents that could potentially modulate pain, including neurotrophic factors and other neuropeptides. The catecholamines and opioid peptides released from the implanted cells can interact with local host spinal opioid and  $\alpha$ -adrenergic receptors. Furthermore, it is thought that decreased pain sensitivity results from the synergistic actions of opioid peptides and catecholamines, because subeffective levels of agents acting at both receptors produce potent analgesia, possibly with reduced tolerance development (Yaksh and Reddy, 1981; Wilcox *et al.*, 1987; Drasner and Fields, 1988; Sherman *et al.*, 1988). Early studies in the Sagen laboratory utilized standard analgesiometric assays—the tail flick, paw pinch, and hot plate tests—to assess whether released neuroactive substances from adrenal medullary allografts could exert behavioral changes (Sagen *et al.*, 1986a). Following nicotinic stimulation to increase release of neuroactive substances from transplanted cells, the level of acute pain tolerance in animals with adrenal medullary transplants was much greater than in control animals. This antinociceptive response was most likely due to the corelease of opioid peptides and catecholamines from transplanted cells, because it could be attenuated by opiate antagonist naloxone or  $\alpha$ -adrenergic antagonist phentolamine. Similarly, isolated chromaffin cells obtained from xenogeneic bovine adrenal glands could reduce acute pain sensitivity using these tests (Sagen *et al.*, 1986b). Neurochemical studies of CSF samples collected via push-pull superfusion revealed increased levels of both opioid peptides and catecholamines in the CSF of animals with adrenal medullary implants (Sagen and Kemmler, 1989; Sagen *et al.*, 1991). In addition, good viability of transplanted chromaffin cells, either in solid tissue allografts or isolated suspensions of xenografts, has been consistently demonstrated using immunocytochemistry and electron microscopy.

Behavioral findings using adrenal medullary or chromaffin cell transplants have been extended to chronic pain models, including inflammatory pain (Ortega-Alvaro *et al.*, 1997; Sagen *et al.*, 1990; Siegan and Sagen, 1997; Vaquero *et al.*, 1991; Wang and Sagen, 1995), neuropathic pain (Décosterd *et al.*, 1998; Ginzburg and Seltzer, 1990; Hama and Sagen, 1993, 1994), and central pain models (Brewer and Yezierski, 1998; Hains *et al.*, 1998; Yu *et al.*, 1998a,b). In particular, adrenal medullary transplants have been shown to markedly reduce persistent pain resulting from peripheral or central nervous system injury in rodent models. These pain syndromes, which are difficult to manage clinically using conventional therapies, may be uniquely sensitive to the therapeutic cocktail produced by chromaffin cell transplants, which likely includes neurotrophic factors (Unsicker, 1993) and *N*-methyl-D-aspartate (NMDA) antagonist neuropeptides (Lemaire *et al.*, 1993; Siegan *et al.*, 1997), in addition to catecholamines and opioid peptides. In support for this, recent findings suggest that adrenal medullary transplants may also provide a degree of neuroprotection as a result of either reducing hyperexcitability or secretion of neurotrophic factors. A long-term consequence of persistent noxious activation, such as that resulting from injury to the peripheral or central nervous system, may be a loss of vulnerable inhibitory interneurons, which would otherwise serve to limit pain. For example, peripheral nerve injury results in the appearance of hyperchromatic “dark neurons” indicative of transsynaptic degeneration and a loss of inhibitory GABAergic neurons in the superficial spinal dorsal horn (Sugimoto *et al.*, 1990). Both the appearance of dark neurons and the loss of GABAergic neurons are reduced by adrenal medullary transplants (Hama *et al.*, 1996; Ibuki *et al.*, 1997).

Using three distinct models of spinal cord injury pain, chromaffin cell allografts or xenografts have been shown to reduce hypersensitivity to mechanical and thermal stimuli (Brewer and Yezierski, 1998; Hains *et al.*, 1998; Yu *et al.*, 1998a,b). As an example, an excitotoxic spinal cord injury that results in pathologic changes comparable to ischemic and traumatic clinical spinal cord injury can be produced by intraspinal injections of the mixed (+/-) $\alpha$ -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)/metabotropic receptor agonist quisqualic acid (Yezierski *et al.*, 1998). This results in a behavioral syndrome of mechanical and thermal allodynia and excessive grooming at approximately 10–14 days following quisqualic acid injections. The excessive grooming continued to increase in severity in animals receiving control skeletal muscle transplants (Brewer and Yezierski, 1998). In contrast, in animals with adrenal medullary transplants, the progressive increase in grooming was blocked, and skin areas were completely recovered to normal in a few cases. Both mechanical allodynia and thermal allodynia were also attenuated by adrenal medullary transplants compared to control transplants.

A chronic pain model used in our laboratory is the chronic constriction nerve injury model

described by Bennett and Xie (1988). Chronic constriction of the sciatic nerve results in abnormal pain behaviors closely paralleling clinical neuropathic pain syndromes such as causalgia, including allodynia (perception of innocuous stimulus as painful) and hyperalgesia (increased sensitivity to a painful stimulus). Two weeks following induction of peripheral nerve injury, rats were implanted with either adrenal medullary or control tissues. In rats with adrenal medullary allografts, exaggerated responses to noxious thermal and mechanical stimuli induced by nerve constriction can be reversed within 1 week postimplantation. In addition, heightened sensitivity to innocuous cold stimuli and tactile stimuli (von Frey hairs) was reduced in animals with adrenal medullary, but not control, transplants.

Similar reductions in neuropathic pain symptoms were obtained in animals implanted with bovine chromaffin cell xenografts (Hama and Sagen, 1994). These findings suggest that xenogenic donors are a potential resource for cell transplantation in the therapy of chronic pain. However, the survival of xenogenic cells in the rodent CNS has required at least short-term immunosuppression with cyclosporin A treatment (Ortega *et al.*, 1992). One approach toward overcoming the problem of immunologic mismatch is the use of encapsulation technology. Polymer capsules made of permselective membranes can allow two-way diffusion of neuroactive substances from encapsulated cells and nutrient/trophic support from the host, while providing a barrier to immunoregulatory cells, antibodies, and complement proteins (Aebischer *et al.*, 1988). Using this approach, isolated bovine chromaffin cells were loaded into capsules and transplanted to the subarachnoid space of the lumbar enlargement (Sagen *et al.*, 1993). Rats were tested using tail flick, paw pinch, and hot plate tests. Results demonstrated that antinociceptive effects of encapsulated bovine chromaffin cells were similar to previous studies with unencapsulated cells, were reproducible throughout the 8-week course of the study, and, like results from either rat adrenal medullary allografts or bovine chromaffin cell xenografts, the antinociception could be attenuated by opioid and  $\alpha$ -adrenergic antagonists. Good survival of chromaffin cells in the capsules was confirmed by both neurochemical assays and immunocytochemistry in capsules retrieved from the spinal subarachnoid space at the end of behavioral analysis.

Studies have also suggested that encapsulated bovine chromaffin cells can also alleviate symptoms of chronic spinal cord injury pain in rats (Yu *et al.*, 1998b). A chronic allodynic state was produced using a tunable argon ion laser aimed at the T13 vertebral segment of rats injected with erythrosin B. Animals were implanted with either encapsulated bovine chromaffin cells or control capsules containing alginate matrix only. Using calibrated von Frey hairs to test vocalization thresholds to mechanical pressure and ethyl chloride spray to assess cold allodynia, chromaffin cell-containing capsules were found to totally reverse mechanical allodynia and attenuate cold allodynia, in contrast to control capsules. These effects were stable for at least 2 months postimplantation, suggesting that the encapsulated bovine chromaffin cells survive longer in the rat subarachnoid space than do unencapsulated bovine chromaffin cell suspensions in nonimmunosuppressed animals (Yu *et al.*, 1998a).

Based on the promising results obtained from animal models, clinical studies using adrenal medullary allografts were initiated in limited clinical trials. Initial clinical trials using human adrenal medullary allografts were conducted at the University of Illinois at Chicago in five patients suffering from severe pain secondary to inoperable cancer. Adrenal medullary tissue was obtained from adult adrenal glands via the Regional Organ Bank of Illinois following pathogen screening, and adrenal medullary tissue was dissected, cultured for 5–10 days, and verified for catecholamine synthesis. Tissue from approximately two adrenal glands was implanted in the subarachnoid space of patients via lumbar puncture using a 14-gauge Touhy needle. In follow-up, four of the patients had marked reductions in visual analog scale (VAS) scores and analgesic consumption within 2–8 weeks following adrenal medullary transplantation. Three of these patients remained free of pain throughout the remainder of their lives, two for approximately 1 year [detailed case histories of the patients can be found in Winnie *et al.* (1993)]. Using a similar protocol, Lazorthes *et al.* (1995) performed adrenal medullary allogeneic implants in seven patients suffering from intractable pain due to cancer. A multidisciplinary pain evaluation demonstrated progressively decreased pain scores in six of the patients and opioid analgesic intake was decreased in three of the patients, stabilized in two other patients, and increased in two patients. This study is ongoing and currently includes 15 patients with similar promising results (Y. Lazorthes, personal communication).

Phase I clinical trials have also been conducted at several centers using encapsulated bovine

chromaffin cell implants (Aebischer *et al.*, 1994; Buchser *et al.*, 1996; Burgess *et al.*, 1996, 1999). Phase I clinical trials were conducted to assess safety and preliminary efficacy at the University of Lausanne, Switzerland, in seven patients with severe pain, using capsules containing approximately 2 million bovine chromaffin cells. Capsules were implanted under local anesthesia via lumbar puncture, with the active portion of the capsule containing the chromaffin cells in the lumbar cistern, and held in place via a silicone tether sutured to the lumbodorsal fascia. Except for occasional reports of postdural puncture headaches, no adverse effects from the procedure were noted. Of the seven patients, four who were receiving epidural morphine at the time of the implant were reported to have decreased opioid use following the implant, with either a modest improvement or no worsening in pain ratings. Three patients who were not receiving oral or epidural morphine treatment at the time of the implant reported improvement in pain ratings. Histologic examination of the spinal cords, when possible, revealed no remarkable pathology, and chromaffin cell viability was confirmed in retrieved capsules by catecholamine release and immunostaining.

A similar phase I clinical trial has been conducted in the United States (Burgess *et al.*, 1996, 1999). This study was conducted under a commercially sponsored (CytoTherapeutics, Inc.) investigational new drug (IND) application reviewed by the United States Food and Drug Administration and included 19 patients with intractable pain secondary to incurable malignancies and life expectancy less than 5 months. Initially, 15 patients received capsules containing  $1 \times 10^6$  cells (5.0 cm in length), and an additional 4 patients received capsules containing  $3 \times 10^6$  cells (7.0 cm in length). Participants selected for the study were advanced cancer patients with chronic pain inadequately relieved by conventional therapies. No serious complications directly attributable to the implant were noted and routine clinical pathology showed no evidence of adverse reactions. The few mild adverse experiences attributable to lumbar puncture, including postlumbar puncture headaches, subcutaneous fluid collections at the implant site, and subarachnoid–cutaneous fistula were easily resolved. Evidence of analgesic efficacy was suggested by reductions in pain scores in 9 patients, and opiate reduction in 8 of the original 15 patients (Burgess *et al.*, 1996). Mean VAS scores showed a gradual decline over time, with an approximate decline of 39% at 4 weeks postimplant. Of the patients exhibiting improved pain control, the majority had pain complaints that were localized to body regions innervated by lumbar and sacral nerves, suggesting that diffusion of pain-reducing neuroactive agents to higher levels may be limited.

Given the initial safety and potential efficacy findings using encapsulated bovine chromaffin cells, a large multicenter, placebo-controlled study in patients with cancer pain was initiated in Switzerland, the Czech Republic, and Poland. The initial evaluation of findings from this trial indicated no difference in pain reduction between encapsulated bovine chromaffin cell implants and placebo control capsules containing matrix only. Although the evaluation has not yet been completed sufficiently to distinguish pain localization (e.g., lumbosacral versus cervicothoracic) or quality (e.g., neuropathic vs. nociceptive), findings of this study suggest that pain therapies using this approach may be limited by achievable doses provided by limited numbers of encapsulated cells and/or production of natural analgesic agents.

Another possible approach is the utilization of cell lines engineered to produce higher levels of natural or novel analgesic agents. Earlier studies have been reported using cell lines to produce opioid peptides or catecholamines. To provide opioid peptides, the AtT-20 cell line, derived from the mouse anterior pituitary, was implanted intrathecally around rat and mouse spinal cord (H. Wu *et al.*, 1993, 1994b). This cell line releases high levels of opioid peptide,  $\beta$ -endorphin. In addition, a genetically modified version of this cell line, AtT-20/hEnk, which has been transfected with the human proenkephalin gene), was implanted in some animals. This cell line secretes enkephalin in addition to  $\beta$ -endorphin. Neither of these cellular implants altered base-line responses to acute noxious thermal stimuli, but antinociception was rapidly induced by intrathecal injections of the  $\beta$ -adrenergic agonist isoproterenol, presumably via activation of AtT-20 cell surface  $\beta$  receptors. In another study, this group implanted catecholamine-secreting cell lines, derived from the B16 melanoma (H. Wu *et al.*, 1994a). Implantation of the F1C29 clone, which apparently releases higher levels of catecholamines, around the mouse spinal cord enhanced the antinociceptive effect of exogenously administered morphine to a noxious thermal stimulus. This effect could be blocked by  $\alpha_2$ -adrenergic antagonists, suggesting mediation via release of catecholamines from implanted cells.

Encapsulated  $\beta$ -endorphin-secreting tumor cell lines implanted in the CSF of rats at the lev-

el of the atlanto–occipital junction has also been reported to reduce pain sensitivity as assessed by tail pinch, hot plate, and neuromuscular electrical stimulation (Saitoh *et al.*, 1995). Both the mouse neuroblastoma Neuro2A and the mouse pituitary AtT-20 cell lines transfected with the proopiomelanocortin (POMC) gene were effective, and the antinociception was attenuated by the opiate antagonist naloxone. Encapsulated cells actively secreted peptides and survived for at least 1 month following transplantation.

Another approach, which may address potential limitations of tumor cell lines such as risk of continuous unrestricted cell division, is the use of conditional immortalization strategies. Conditional immortalization is a means to generate an immortalized cell line that can later be disimmortalized to stop cell division. Using the temperature-sensitive mutant of the SV40 large T antigen (tsTag), transfected cells undergo continual cell division at low temperature conditions (e.g., 32–34°C), but differentiate and become postmitotic when the temperature is raised (37–39°C). Conditional immortalization with tsTag has been used to create rodent neuronal cell lines bioengineered with novel genes to deliver potentially antinociceptive molecules following grafting into the subarachnoid space (Eaton *et al.*, 1997, 1999). The transfected genes tested thus far include the synthetic enzymes for the neurotransmitters 5-HT and GABA, the preproenkephalin gene for met-enkephalin synthesis, and the preprogalanin gene for the peptide galanin synthesis. Using the chronic constriction injury model of neuropathic pain, 1 million cells expressing bioengineered GABA or 5-HT were transplanted in the rat subarachnoid space at L4–L5 levels. The presence of grafted cells secreting antinociceptive molecules reversed the behavioral hypersensitivity within 1 week of grafting, and these effects lasted at least throughout the 8-week time course of the study. In contrast, the control vector-only cell lines, which do not express the novel genes but survive and differentiate under similar conditions, had no effect on the peripheral neuropathic pain.

In summary, during the past few years, the field of neural transplantation and development of potential strategies for the treatment of spinal cord dysfunction and injury have witnessed rapid growth. Only a short while ago, complications of spinal cord trauma and disease were thought to be irreparable, but recent breakthroughs have demonstrated the regenerative capacity in the adult spinal cord, and suggested that restoration of function may ultimately be attainable under the right circumstances. Numerous promising approaches have been described in this chapter, including the use of artificial and cellular bridges, provision of neurotrophic factors, and replacement of specific cell populations. It is likely that the ultimately successful strategy will incorporate a combination of these approaches in the treatment of these debilitating disorders.

# NEURAL STEM CELLS

Martin P. Vacanti

## INTRODUCTION

The general medical doctrine has been that damage to the central nervous system, including the brain and spinal cord, is irreversible. As stated by Valentini and Aebischer (1997), “a major impediment to healing is the inability of adult neurons to proliferate *in vivo* and to be cultivated *in vitro*.” The emergence of neural stem cell biology in the adult mammal has broken this barrier. The combination of neural stem cell biology with the applied principles of tissue engineering will revolutionize the medical approach to the treatment of damaged central nervous system tissue, including injuries or diseases of both the brain and the spinal cord. Additionally, current strategies using gene insertion techniques to replace a missing neural product may be enhanced when these corrected cells are delivered using tissue engineering techniques.

## BACKGROUND

Neural stem cells qualify as an ideal cell for use in repair strategies of the central nervous system, including the spinal cord. Many of the characteristics that these unique cells possess make them ideal candidates for the creation of functional central nervous system constructs. In the adult mammal these stem cells lay dormant in a quiescent state, but have the capacity to proliferate, producing mature cells with the properties of the damaged or injured tissue (Hines, 1997). As defined by McKay (1997), a neural stem cell must have the capacity to differentiate into the three major cell types of the central nervous system, neurons, astrocytes, and oligodendrocytes. Additionally, the term “progenitor cell,” compared with a stem cell, is defined as a cell that has a more restricted potential. A cell isolated from the spinal cord may be restricted to lineage in that it may have the capacity to differentiate only into an oligodendrocyte. In many cases it is impossible to determine if one is dealing with a stem cell or a progenitor cell. To add confusion to the issue, the ultimate fate of a cell may depend on the cell's environment, whether it be *in vivo* or *in vitro*, and the presence or absence of particular cytokines, or combination of cytokines, or even the particular time that the cell is exposed to cytokines. For simplicity's sake, undifferentiated neural cells with the capacity to differentiate into neurons, astrocytes, and oligodendrocytes will be referred to as stem cells. In reality, these cells may actually be a continuum of cell types, from the pure stem cell to the committed progenitor cell.

Reynolds and Weiss (1992) isolated cells from the striatum of the adult mouse. They demonstrated that these cells could be stimulated to proliferate *in vitro* by use of epidermal growth factor (EGF). Before differentiating, these cells expressed nestin, a marker for neuroepithelial stem cells (Lendahl *et al.*, 1990). As the cells divided, they formed clusters of circular cells described as neurospheres. If these cells were allowed to attach to poly(L-ornithine)-coated glass cover slips, they would differentiate into various cells, some with the morphologic characteristics of astrocytes and some with the characteristics of neurons. Immunocytochemistry demonstrated cells with glial fibrillary acidic protein (GFAP) and cells with neuron-specific enolase (NSE), markers of astrocytes and neurons, respectively. If these neurospheres were disassociated and regrown in culture media

containing EGF, they would continue to divide and would test positive for the intermediate filament nestin, indicating an undifferentiated state. Additionally, these secondarily derived cells would again differentiate into both astrocytes and neurons if attachment was allowed.

Additional work by Reynolds and Weiss (1996) established stem cell characteristics in cells that were derived from striatum removed from embryonic day 14 mice. Specifically, these cells were EGF responsive and they were able to differentiate into neurons, astrocytes, and oligodendrocytes. When cultured with EGF these cells were passaged 10 times with a billionfold increase in their cell number and still retained their proliferative and multilineage potential. Markers such as  $\beta$ -tubulin, microtubule-associated protein-2 (MAP-2), and neurofilament (NF) indicated neuronal differentiation. Finally, the marker O4 demonstrated the capacity of these stem cells to differentiate into oligodendrocytes.

Gage *et al.* (1995b) isolated fibroblast growth factor-2 (FGF-2)-responsive cells from the hippocampus of the adult rat. In culture these cells were positive for both glia and neuronal cell markers. It was noted on implantation into the adult rat hippocampus that the cells migrated and differentiated both into neurons and into glia. It was also observed that some of these implanted cells were ensheathed by several layers of myelin, indicating maturation. Gage suggested that these hippocampal-derived cells responded to endogenous cues that regulate neurogenesis. This concept is critical in regard to application of tissue engineering practices in the context of implantation of stem cells suspended on a biodegradable scaffolding material: growth, development, and differentiation occur in response to the particular environmental cues at the site of implantation.

Additional work of Weiss *et al.* (1996) demonstrated the presence and responsiveness of adult thoracic spinal cord neural stem cells that were induced to proliferate, self-renew, and expand in the presence of EGF and basic fibroblast growth factor (bFGF). These cells were isolated in all regions of the spinal cord, including the thoracic and lumbosacral areas. They demonstrated stem cell properties in regard to their proliferation and conversion to neurospheres, retaining the capacity to differentiate into all three neural cell lines. Attachment as previously described drove these stem cells toward maturation.

Shihabuddin *et al.* (1997) isolated what appeared to be the same cell type but in the adult rat spinal cord. Essentially, cells were isolated from all regions of the spinal cord and differentiated into neuronal, astroglial, and oligodendrocytic cell lines. Additionally, some large neuronlike cells expressed markers for p75NGFr, possibly implicating them as motor neurons. Neural stem cells seem to be ubiquitous in the central nervous system, including the spinal cord, striatum, and even the cortex.

Davis and Temple (1994) demonstrated neuroectodermal cells in the cortical ventricular zone that had the capacity to generate into the three major cell types of the central nervous system. In the embryonic rat they found that these cells maintained the ventricular zone and were responsible for creation of the subventricular zone that persists into adulthood. They felt that multipotential neural stem cells could be the ancestors of other cortical progenitor cells. Morshead *et al.* (1994) isolated adult mouse neural stem cells that resided in the subependymal area of the lateral ventricle. Undifferentiated, these cells expressed nestin but had the capacity to differentiate into both neurons and glia. The work of Craig *et al.* (1996) demonstrated an endogenous subependymal neural cell population in the adult mouse brain. They demonstrated that EGF stimulated proliferation, and with its withdrawal, these cells were found to differentiate into neurons, astrocytes, and oligodendrocytes. Johansson *et al.* (1999) presented evidence that ependymal cells are neural stem cells, capable of giving rise to a rapidly proliferative cell type that differentiates into neurons and migrates to the olfactory bulb. They also note that after spinal cord injury these same cells proliferate and differentiate into astrocytes. Bjornson *et al.* (1999) demonstrated the versatility of neural stem cells when they are engrafted into irradiated BALB/c mice. With genetic markers these cells differentiated into a variety of blood cell types, including myeloid, lymphoid, and early hematopoietic cells.

Taylor and Snyder (1997) demonstrated successful engraftment into most areas of the brain of what they described as neural progenitor cells, introduced by injection into the lateral ventricle. These cells were derived from the external germinal zone of neonatal mouse cerebellum and were immortalized with the *v-myc* oncogene. They also discuss the potential of those cells for gene product delivery. Shihabuddin *et al.* (1995), using an immortalized cell line, demonstrated differ-

entiation into cells similar to both hippocampus and cerebral cortex cells following transplantation of the cell line into these respective areas in the adult Lewis rat. They discuss the plasticity of the cells in response to local microenvironmental signals. A key concept of this study is that the adult mammalian brain has the capacity to guide differentiation of neuronal cells such that they are similar to neurons endogenous to the area of implantation.

Knowledge derived from studies of neural stem cells is increasing rapidly. Included in such studies are immortalized cell lines that are generally isolated from embryonic central nervous system (CNS) using nontransforming oncogenes such as *v-myc* or the temperature-sensitive T antigen of SV40 (Lundberg *et al.*, 1996). Although much information regarding the basic behavior of neural stem cells will be obtained from these studies, at present we are reluctant to use these cell lines in neural tissue engineering applications because of obvious concerns about conversion to malignancy.

In terms of basic cell biology studies delineating characteristics of mammalian neural stem cells, most of the work has been done on rodent embryos. The study of stem cell biology from cells derived from the adult mammal is an emergent field. This is ideal when considering the applications of tissue engineering, with its focus on the use of autologous cells to generate tissue constructs. Although a generalization, it may be that the behavior of stem cells, whether they are derived from the adult or fetal mammal, is essentially the same, with similar responses to trophic and microenvironmental cues.

Gage *et al.* (1995a) discusses both multipotent cells and lineage-restrictive cells that reside in the mature central nervous system. He emphasizes that they can be maintained, cultured, and stimulated to multiply and differentiate with many of the same factors that stimulate their embryonic counterparts. Realizing that *in vitro* culture systems will not contain all the necessary ingredients to guide the growth and development of the cells, he discusses implantation studies utilizing these precursor cells in specific areas of the developing or adult central nervous system. Both the importance of the microenvironment of the implantation site with respect to cellular differentiation and the adherent plasticity of these cells are emphasized. The therapeutic implications of using these cells, with the understanding of what factors and conditions will result in a desired phenotype, reside in their potential to repair portions of the damaged or diseased brain.

Brustle and McKay (1996) recognized the persistence of neural stem cells in the adult mammalian brain and mentioned the ability of these stem cells to migrate and differentiate into neurons. They feel that the guidance and recruitment of these transplanted cells will be determined by external signals. They see the future of neuronal replacement depending on the development of strategies of using these cells in a reconstructive context.

We feel that combining the use of neural stem cells with the principles of tissue engineering will provide a powerful reconstructive context in regard to neuronal replacement. More precisely, we believe this approach will result in the creation of functioning neural tissue constructs. We foresee applications to effect repair of a damaged or diseased central nervous system. Each particular aspect will have to be developed according to its own unique demands, regarding cell type and specific environmental cues and conditions. For instance, Jankovski *et al.* (1996) found that cerebellum postnatal precursor cells grafted into the cerebellum of adult mice generated only two adult phenotypes, granule cells and molecular layer interneurons. They concluded that these progenitors were strictly specified at the time of grafting. Frantz and McConnell (1996) found that late cortical progenitor cells are not able to generate deep-layer neurons, but are restricted to the upper layers. Alternatively, Snyder *et al.* (1997) suggest that microenvironmental alterations created by using targeted photolytic cell death induced multipotent neural precursors to differentiate into layers 2–3 of neocortical pyramidal neurons. It was noted that this neuronal differentiation usually occurs only during embryonic corticogenesis.

This emphasizes the potential of devising strategies that alter status quo conditions in effecting the development of new neural tissue. Feldman *et al.* (1996) demonstrated that CNS progenitor cells can have their morphologic and electrophysiologic properties modified by culture conditions, including growth factors and attachment substratum. Hammang *et al.* (1997) demonstrated that nestin-positive undifferentiated neural stem cells injected into myelin-deficient rat spinal cord differentiated into oligodendrocytes that produced myelin. These same cells *in vitro* developed into astrocytes. Zigova *et al.* (1998) took subventricular zonal progenitor cells from postnatal rats, and implanted them into the striatum of adult rats. The majority of the surviving cells

were found to have a neuronal phenotype. These cells integrated into the striatal area of the rat brain.

Cheng *et al.* (1996) discuss multipotent stem cells serving as progenitors for the development of cortical neurons and glia. They talk of stereotyped division patterns within lineage trees. Both intrinsic cell factors and environmental signals are described as likely to have a key role in a stem cell's behavior. More importantly, they suggest evidence is accumulating that cortical stem cells under the influence of both environmental cues and intrinsic factors change with development. Galiano and Fishell (1998) described the existence of both pluripotent and unipotent neural progenitors. They also suggest that both intrinsic cell factors and extrinsic cues guide neural cell fate.

Although environmental and intrinsic cell cues appear to guide the fate of these neural stem cells, the role of natural factors also appear to play a major role. Cameron *et al.* (1998) discussed the role of peptide growth factors, neurotransmitters, and neuroactive peptides in regard to the generation of neurons and glia in the developing nervous system. They provide evidence from both *in vivo* and *in vitro* studies. They find that basic fibroblastic growth factor, transforming growth factor  $\alpha$  (TGF- $\alpha$ ), insulin-like growth factor-1, and the monoamine neurotransmitters stimulate the proliferation of neural precursors. Additionally, they find that glutamate,  $\gamma$ -aminobutyric acid, and opioid peptides play a role in down-regulation. Other factors such as vasoactive intestinal peptide, pituitary adenylate cyclase-activating peptide, platelet-derived growth factor, ciliary neurotrophic factor, and members of the TGF- $\beta$  family have differential effects on these systems.

The variables involved in the actions of these trophic factors are very complex. Cameron *et al.* (1998) showed that cells grown in 0.1 ng/ml of basic fibroblastic growth factor generated exclusively neurons, whereas a concentration of 10 ng/ml of basic fibroblastic growth factor generated a combination of neurons and glia. Therefore, just varying the concentration of one particular growth factor changes the outcome. A combination of factors may have an effect different in terms of outcome from that when using the factors alone or in sequence. For instance, a population of neural stem cells may be more responsive to the effects of basic fibroblastic growth factor after pretreatment with epidermal growth factor.

For more detailed information concerning the role of growth factors, neural transmitters, and cytokines in the regulation of stem cell development, the reviews by Cameron *et al.* (1998) and Mehler *et al.* (1995) are very informative. If it is possible to make a generalization, it would be that epidermal growth factor stimulates the proliferation of neural stem cells, keeping them in an undifferentiated state. It appears that combining epidermal growth factor and basophilic growth factor has the same effect on mammalian spinal cord stem cells.

To identify the stage of development of neural stem cells, immunocytochemical markers are very useful. The marker nestin, an intermediate filament, is used to identify undifferentiated or neural stem cells. The markers neurofilament, neuron-specific enolase, and microtubule-associated protein identify neurons. O4, a sulfatide, is a good marker of oligodendrocytes. GFAP, an intermediate filament, identifies astrocytes. Gage *et al.* (1995a) provide a complete review of neural markers.

Investigators are recognizing the potential of neural stem cells for gene therapy and neural degenerative conditions. Snyder *et al.* (1995) reports restoring  $\beta$ -glucuronidase along the entire neuroaxis of treated mice with transplanted neural progenitors containing the missing enzyme. They reported widespread correction of this lysosomal storage disease in affected mice by use of this method. Pinkus *et al.* (1998) feel that "progenitors are ideal for genetic manipulation and may be engineered to express exogenous genes for neural transmitters, neurotrophic factors, and metabolic enzymes." They recognize that neural precursors do exist in the adult mammalian brain and that they may be used to develop strategies for central nervous system repair. Tissue engineering may offer an advantage in the quantity and duration of expression of these necessary neural products by creating tissue constructs of genetically corrected neural stem cells.

## NEURAL STEM CELL APPLICATIONS IN TISSUE ENGINEERING

Our laboratory is developing functional CNS tissue constructs derived from seeding biodegradable polymer scaffolding materials with neural stem cells suspended in hydrogel, with the goal of implantation into the appropriate site and correction of lost or absent neural function. The biodegradable scaffolding will serve to hold the neural stem cells in the appropriate three-dimensional configuration and also provides an attachment site for differentiation. The local microen-

vironment should provide the endogenous cues and cytokines needed to orchestrate growth, development, and differentiation of these neural stem cells into functioning neural constructs. The hydrogel suspension allows the infusion of nutrients and oxygen into, and exit of waste products and CO<sub>2</sub> out of, the cells. Conceptually, there are no restrictions placed on these cells in terms of their ability to grow, organize, and differentiate. The ideal scaffolding material should be biologically inert and should disappear over time.

Our model required the isolation of neural stem cells from the adult mammal, with the idea of an autologous application. An autologous source of neural stem cells negates concerns of rejection and immunosuppression. Although others have described the central nervous system as immunoprivileged, CNS autoimmune diseases do exist and the potential for subtle but chronic rejection of allogenic cells cannot be excluded.

Our laboratory has successfully isolated neural stem/progenitor cells from the rodent cortex, striatum, and spinal cord (Fig. 58.1). The stem cells are stimulated to divide and are kept in an undifferentiated state using EGF and bFGF. When these cells are driven to maturation with the addition of serum and/or attachment to the bottom of flask, they take on the morphologic characteristics of neurons, astrocytes, and oligodendrocytes (Fig. 58.2). Immunohistochemistry done on these cells shows differentiation toward neurons, astrocytes, and oligodendrocytes, as indicated by positive marking for neurofilament, GFAP, and O4 respectively. Additionally, we have shown that neural stem cells suspended in the hydrogel Pluronics F-127 at 23% survive and proliferate *in vitro* (Fig. 58.3) (Vacanti *et al.*, 1998). Under these same conditions the phenotypic expression of these stem cells is controlled by growth factors in a fashion similar to stem cells cultured in media alone (Lachyankar *et al.*, 1997).

Our goal was to develop a model in the rodent of neural injury, the correction of which by the use of tissue engineering techniques would be readily demonstrable by gross, microscopic, imaging, and neurologic criteria. Cheng *et al.* (1996) demonstrated partial restoration of hindlimb function in adult rats that sustained complete spinal cord resections that were bridged with multiple intercostal nerve grafts. We adopted this model of injury in the adult rat with the idea of combining spinal cord neural stem cells with tissue engineering techniques to effect repair by the creation of spinal cord tissue constructs.

We first developed a simple technique of isolating spinal cord stem–progenitor cells from the adult Fisher rat, modifying a technique used by Lachyankar *et al.* (1997). *In vitro* these isolated cells started as simple rounded structures from 2 to 4 μm in diameter, with the capacity to differentiate into cells with morphologic characteristics of oligodendrocytes, astrocytes, and mature neurons. Additionally, when these cells were suspended in the hydrogel Pluronics F-127 and were used

to saturate small segments of poly(glycolic acid) (PGA), the stem cells were found to survive and attach to the PGA scaffolding material when placed in an incubator at 37°C.

The hydrogel Pluronic F-127 is a copolymer of ethylene and propylene oxide with unique gelation properties. Between 15° and 50°C it is a gel (body temperature is 37°C); it is a liquid above and below this range (Cao *et al.*, 1998). PGA fibers are 15 μm in diameter, with inner spaces averaging 75 to 100 μm (Vacanti *et al.*, 1993). We felt this combination of polymers to be the ideal candidate to serve as our scaffolding material for implantation of the spinal cord neural stem cell constructs. The hydrogel characteristics would allow easy diffusion of oxygen, nutrients, CO<sub>2</sub>, and waste products, and the polymer scaffolding material would serve as a site of attachment of the neural stem cells, consequently providing anchorage to drive differentiation, and the large inner spaces would not restrict the growth and development of the neuronal construct.

We hypothesized that spinal cord neural stem cells would grow, develop, and organize, driven by their own intrinsic cell properties and communicating with each other as they orchestrated their development, with guidance by local endogenous cues found in their unique environment,

i.e., recent surgical injury (a segment of resected spinal cord). Our experimental group consisted of adult Fisher rats, which, under surgical conditions, had 4-mm sections of their spinal cord removed at the T8–T9 segments, creating a clinical condition of paralysis. These animals received implants of adult syngeneic spinal cord progenitor/stem cells suspended in scaffolding as previously described (M. P. Vacanti, J. L. Leonard, B. Dore, L. J. Bonassar, Y. Cao, S. J. Stachelek, J. P. Vacanti, F. O’Connell, C. S. Yu, A. P. Farwell, and C. A. Vacanti, unpublished study).

We realized that the original synaptic connections of the injured spinal cord are extremely complex and extremely difficult, if not impossible, to reduplicate. We felt that any reestablishment of viable neurons and supporting glia would have potential therapeutic benefits because of the inherent plasticity of the central nervous system, which may allow new connections and restoration of function. One unanswered question concerned how these cells would form connections or synapses with what was left of the intact neural tissue after the resection procedure. We felt it was theoretically possible because transected neurons *in vivo* will generate or sprout new dendritic processes. We felt it was logical to assume that these forming processes would synapse with the forming processes of the implanted neural stem cells. If these synapses or connections did occur, we thought functional recovery would result because of the ability of the brain to learn these new connections. Over time this learning process would be reflected in functional neurological recovery.

We used a simple scale to monitor both motor and sensory function of the experimental group as opposed to the control groups. Over an 8-week time period the experimental group had a significant increase in neurological recovery of both sensory and motor function as opposed to the control groups. Gross dissection (Fig. 58.4), magnetic resonance imaging, and histologic evaluation (Fig. 58.5) demonstrated the creation of tissue-engineered spinal cord constructs in the experimental group as opposed to the control group. This model needs much work in its refinement concerning ideal cell numbers, cytokines, and implantation materials. We do feel that it does powerfully demonstrate the potential therapeutic benefit of this approach.

Other future applications may be the creation of models that would demonstrate possible repair of cortical injuries such as stroke or trauma. Additionally, the use of neural stem cells in combination with tissue engineering techniques might be applied to neurodegenerative processes, e.g., Parkinson’s disease, or neurogenetic degenerative processes, e.g., Tay Sach’s disease, combined with gene insertion technology. Other applications may include repair or replacement of damaged or diseased peripheral nerves, autonomic dysfunction (Hirschsprung’s disease), and atonic bladder.

(B) A transverse section of the same construct highlighting myelin production with luxol fast blue staining.

Neural stem cells may be used to augment the creation of other tissue-engineered constructs, e.g., the innervation of tissue-engineered constructs such as bowel or liver. Finally, these cells may have the ability to guide and orchestrate the growth and development of other cell types used in the creation of tissue-engineered organs.

### SUMMARY

Neural stem cell biology and tissue engineering are both emergent fields with great medical potential. We feel that the combination of these disciplines will have a powerful beneficial effect on future treatments of diseased or damaged CNS.

# PERIODONTAL APPLICATIONS

Neal A. Miller, Marie C. Béné, Jacques Penaud, Pascal Ambrosini,  
and Gilbert C. Faure

## INTRODUCTION

Periodontitis is a disease that results in the destruction of supporting tissues of the teeth, subsequent gingival pocket formation, and ultimately tooth loss. The main etiology is bacterial infection, but occlusal and systemic disorders are considered aggravating factors. Although periodontitis is not life threatening, it is one of the most widespread disorders found among human populations. Most surveys in Europe state that more than 40% of persons in the age group 35–45 years old present periodontal pocketing (Miyazaki *et al.*, 1991). The periodontal status deteriorates as the subjects grow older: in France the percentage of people with periodontitis exceeds 60% in the age group 45–64 years old (Miller *et al.*, 1987). In the United States 36% of the population 19 years and older presents periodontitis; this increases to 52.5% of persons 45–64 years old (Brown *et al.*, 1989). Health costs for this disease have been estimated at \$5–6 billion involving 120–133 million hours of treatment (Oliver *et al.*, 1989), even though most patients do not seek treatment.

Initial concern was in arresting the evolution of the disease after restoring lost periodontal material. For several decades, periodontists have been striving to regenerate destroyed periodontium (Hancock, 1989). Among earlier attempts, curettage, open-flap debridement, and diverse bone grafting procedures can be cited. These therapeutic modalities most often result only in partial repair and in residual pockets, primarily because progenitor cells of highly specialized tissues are not easily secured but also because of the particularly difficult wound closing conditions pertaining to periodontal surgery. As in any type of wound, a blood clot is formed very rapidly. In dermal wounds, fibrin bridging is sufficient to close the wound, and epithelial proliferation, which starts within 24 hr, is limited to the epidermal lesion (Clark, 1988). In periodontal lesions, the gingiva can bind only to the vascular surface of the teeth, and very often the adherence is too frail, or the blood clot is resorbed too rapidly. In this case, a long junctional epithelium may develop, between the tooth and the flap, resulting in the formation of a pocket (Polson and Proye, 1983). An additional complication is the accumulation of plaque. Oral microorganisms adhere to the portion of the tooth surface that is next to the marginal gingiva. Because of these wound closure hindrances, complete submersion of the teeth under gingival flaps has been advocated (Klinge *et al.*, 1981) but is seldom feasible in human clinical situations.

New advances in periodontal therapy include the use of membrane barriers to guide the regenerative tissue, and implantation of bone substitutes. These techniques apply to vertical bone lesions and are becoming quite efficacious and predictable. Promoting regeneration at a distance from a potential source of osseous cells remains difficult, but better knowledge of chemoattractants, growth factors, and osteoinduction proteins is likely to help develop clinical applications that enhance healing and facilitate the selection of proper cell populations for bone or gingiva reconstruction. These approaches are detailed in this chapter.

## GUIDED TISSUE REGENERATION

Nyman *et al.* (1982), as others, observed that the presence of gingiva is detrimental to the regeneration of the attachment apparatus. However, Nyman and co-workers were the first to find an effective way of excluding gingival epithelial and connective tissue cells from reconstruction sites. Their initial attempt to regenerate periodontium in the human succeeded in forming 5 mm of new attachment with collagen fibers embedded in cementum. They used a Millipore filter, which served as a barrier to keep connective tissue cells out of the resorbed site and avoid downward growth of the gingival epithelium along the root surface. Little bone was produced, perhaps because the filter collapsed against the tooth. Soon after, another material was adopted: expanded poly(tetrafluoroethylene) (e-PTFE), or Teflon. The advantages of e-PTFE are its stiffness, that it allows more room for bone formation, is biocompatible, and the ease with which it can be removed. Numerous studies have proved the ability of e-PTFE membranes to promote repair of intrabony and furcation defects (Becker *et al.*, 1987; Pontoriero *et al.*, 1987). Histologic confirmation of the repair, evidencing neoformation of cementum, periodontal ligament, and alveolar bone, was obtained in both humans (Nyman *et al.*, 1982) and animals (Caffesse *et al.*, 1988b). The material has, however, two major drawbacks: it causes severe gingival recession and, once exposed, accumulates large amounts of bacterial plaque (Becker *et al.*, 1987; Selvig *et al.*, 1990; Grevstad and Leknes, 1993). Vascularization of the marginal gingiva is provided solely by terminal capillaries. The placement of a cell-tight barrier disturbs the blood supply and avoids endothelial anastomosis with blood vessels originating from the underlying tissues. Bacteria actively proliferating in the crevicular part of the tooth will then colonize the e-PTFE membrane. Because of the subsequent inflammation, the Teflon membrane must be removed between 4 and 6 weeks after placement (Becker *et al.*, 1987). To avoid the requirement for second-stage membrane retrieval and to minimize bacterial infection, resorbable membranes (Minabe, 1991) have been developed using collagen or polysaccharide polymers. Collagen membranes used experimentally can be made from rat tail, bovine dermis, or other sources. Industrially produced collagen membranes include collagen from calf endocardium and are in use in human clinics (Penaud *et al.*, 1992). Different types of poly(lactic acid) or poly(galactic acid) have been used to form polymer membranes. A novel product dissolves lactic acid in *N*-methyl-2-pyrrolidone. The paste hardens in contact with water. It can be directly applied *in situ* and thus conforms particularly well with the root forms (Bogle *et al.*, 1997; Rosen *et al.*, 1998). When exposed, resorbable membranes accumulate small amounts of bacterial plaque because bacterial and salivary enzymes accelerate their resorption. Thus permeabilized, the membrane is partially protected by the tissue exudate. Many polymer barriers feature pores that allow fluid circulation or even a limited amount of tissue ingrowth (Gottlow *et al.*, 1994). The resorption rate of resorbable barriers can be modulated and thus their effect prolonged if needed (Robert and Frank, 1994). How long a membrane should stay in place has not been determined, but Miller *et al.* (1996) have shown that resorption rates of some products are too fast to assure sufficient cell differentiation. Because of the infections mentioned above, e-PTFE membranes have been removed between 4 and 6 weeks after placement. This is widely considered as being sufficient for specific cells to occupy the defect and avoid ingrowth of the gingival chorion. However, Florès de Jacoby *et al.* (1994) have reported that on removal of e-PTFE membranes, an average 65% of root surface was covered by a neoformed tissue failing to mineralize completely. At 9 to 12 months after placement of the barrier, only 31% of the same root surfaces were still covered. This demonstrates that more than half of the soft red tissue found under an e-PTFE membrane after removal does not mineralize to form either cementum or bone. The neoformed tissue was shown in Taiwan monkeys to be particularly labile when exposed to bacterial plaque (Ling *et al.*, 1994). Advancement of the histologic process is not well known. Amplifying divisions of periodontal ligament cells may have completed by postoperative day 21 (Iglhaut *et al.*, 1988), but these cells must be protected much longer. Sigurdsson *et al.* (1994), using e-PTFE membranes on dogs, demonstrated that no regeneration occurs if the membranes are removed at 3 weeks, whereas at 8 weeks 75% of the bone and 40% of the cementum are repaired. When collagen barriers are used, a period of 10 days is sufficient to avoid epithelial downgrowth (Kodama *et al.*, 1989). When complete resorption occurs before 30 days, neocementum is present, but not new bone (Pitaru *et al.*, 1989). Although membranes exclude gingival tissue they do not enable the selection of periodontal ligament cells or bone cells. It was first postulated that periodontal ligament cells were the slowest to migrate. This was supported by experiments showing that after injury the proliferation of periodontal ligament cells peaked at 2 or 3 days (Aukhil and Iglhaut, 1988). It was suspected

that this apparently limited proliferation was caused by a weak angiogenesis and that premature differentiation delayed migration (Aukhil *et al.*, 1986). However, Nyman *et al.* (1987) found no alkylosis on 11 teeth from 10 patients. In their opinion this was proof that periodontal ligament cells reach the root surfaces before bone cells do. Buser *et al.* (1990) placed an implant in contact with a retained root in a dog. Periodontal ligament cells migrated several millimeters along the implant, producing cementum and a periodontal-like ligament. The cells were able to colonize a fairly large surface much faster than the osseous cells crossed the minute space left by the drill. It seems then that these two types of cells do not compete, but primarily restore their intended functions. Whether resorbable or made of e-PTFE, membranes should be positioned under the flap margin. It is recommended to extend their limits at least 2 mm beyond the edges of the osseous defect in order to seal it completely from the gingiva. Gingival covering of the membrane is considered to be of great importance (Tonetti *et al.*, 1993). When second-stage surgery is needed (removal of nonresorbable membrane), care must be taken to cover the neoformed tissue with gingiva, and it is wise to consider the amount and quality of gingiva available before implantation of a membrane (Anderegg *et al.*, 1995). Reported results vary. Pontoriero *et al.* (1987) closed interradicular bony lesions (furcation defects) in 90% of their cases, whereas Demolon *et al.* (1994) closed none. However, Lekovic *et al.* (1989) demonstrated that furcation defects receiving membranes respond much better than those treated by flap surgery and curettage alone. Interdental vertical defects respond quite well, as can be seen in Fig. 59.1. Laurell *et al.* (1994) obtained a mean 4.9-mm gain in pe-

A

B

Fig. 59.1. (A) An angular defect has nearly reached the apex of the mandibular bicuspid. (B) Placement of a resorbable membrane promoted bone formation to the alveolar crest.

riodontal attachment using poly(lactic acid) barriers for 47 intrabony defects. In a study limited to mandibular three-walled intraosseous lesions, Becker and Becker (1993) evaluated an average gain in bone filling of 4.3 mm for 24 patients treated with e-PTFE membranes. The appropriate use of barrier membranes promotes predictable osseous repair and histologically verifiable new attachment with neof ormation of cementum and periodontal ligament fibers.

## BONE SUBSTITUTES

Intraoral autologous bone grafts are, of course, choice material when osseous defects need to be repaired (Becker *et al.*, 1994). However, intraoral autologous bone is not always available in sufficient quantities, particularly when patients present a deficiency of alveolar bone resulting from severe periodontitis. Bone substitutes include synthetic materials such as hydroxyapatite and methyl methacrylate, and modified mineralized biologic substances such as coralline or bovine trabecular bone and lyophilized human bone. These products provide surgical ease and patient comfort, and their various resorption rates are interesting. Opponents of bone grafting techniques affirm that regeneration of the periodontal attachment apparatus is not achievable by, or at least has not been evidenced for, procedures other than membrane implantation (Egelberg, 1987). These assertions overlook the very thorough work of Dragoo (1981), who produced histologic evaluation of human material for every type of regenerative surgery that was known at the time and demonstrated that bone grafts can produce new attachment with neocementum. In an articulate study, Bowers *et al.* (1989a,b) produced histologic evidence of attachment regeneration after implantation of demineralized freeze-dried bone allografts (DFDBAs). The best results were obtained when teeth were submerged under flaps (Bowers *et al.*, 1989a), or when the sites were protected from epithelial downward growth by gingival grafts (Bowers *et al.*, 1989b). Bone substitutes have been suspected to impair the regeneration of connective tissue attachment. Takata *et al.* (1993) have shown that periodontal ligament cells are capable of covering blocks of hydroxyapatite embedded in root surfaces and of subsequently secreting cementum on synthetic material. Production of this newly formed connective attachment with inserted collagen fibers is slightly delayed compared to regeneration on natural dentine surfaces. It is sometimes postulated that new attachment occurs preferentially where new bone is present (Caffesse *et al.*, 1994). All techniques that enhance bone formation would then be beneficial to connective attachment regeneration. Research by Lowenguth *et al.* (1993) exposed a factor that may be important in this view. They implanted surface-demineralized dentine cylinders in rat skin and observed that appropriate approximation of dentine surfaces enhanced the orientation of fibroblasts and collagen fibers perpendicular to the walls of the cylinders. The customary use of bone substitutes has been in intrabony pockets (Yukna, 1994a) and alveolar ridge preservation (Greenstein *et al.*, 1985), but this presents some limitations. If resorbable, the substances can be resorbed by the gingiva. The material can also cause necrosis of the papillar and gingival tissue covering the defects. In such cases the bone substitute is lost and the defect is even harder to treat. Therefore, in spite of the fact that bone substitutes may induce great amounts of bone repair, as can be seen in Fig. 59.2, they are more often associated with resorbable (Penaud *et al.*, 1992) or nonresorbable (Caffesse *et al.*, 1994) membranes. Proponents of the membrane technique often admit that barriers alone do not induce the formation of much alveolar bone, or at least not above the existing crestal level. Only bone grafting techniques with bone or substitute materials promote the formation of new bone, cementum, and periodontal ligament coronal to the ridge (Yukna, 1994b). Another reason to use synthetic materials is as spacers. It is thought that osseous formation under membranes is often limited by the barrier collapsing against tooth structures because of the pressure exerted by the overlaying soft tissues. Bone grafting materials are thus used both as spacers and as bone-conducting substances (Caffesse *et al.*, 1994; Plotzke *et al.*, 1993), sometimes associated with membranes. Dragoo (1981) showed that techniques used in the late 1970s caused epithelial downward growth and residual pockets. The material that blocked apical migration was mostly iliac vital bone, which quickly occupied the root surface and induced ankylosis. Later, blocking epithelial downward growth with a barrier was shown to be a sure and innocuous process. The combined use of grafting material and membranes alone (Lekovic *et al.*, 1989). The choice of a bone substitute will depend on the final goal. Poly(methyl methacrylate) is highly biocompatible, but promotes no bone formation and usually ends up encapsulated in fibrous connective tissue with no increased connective attachment apparatus (Plotzke *et al.*, 1993). The new interest in dental implants now encourages

*Fig. 59.2. (A) A deep angular bony defect is visible on the mesial aspect of the mandibular molar. (B) The defect has been filled with a bone substitute of bovine origin. (C) Reentry 1 year later: total bone fill has been obtained.*

surgeons to use materials that will subsequently allow osteointegration (Seibert and Nyman, 1990; Nevins and Mellonig, 1992), i.e., resorbable bone substitutes ultimately replaceable by new bone. For two- or three-walled defects, rapidly resorbed substances such as demineralized freeze-dried bone allograft can be used. Where rapid osseous repair seems less likely, slowly resorbing materials are preferred, such as freeze-dried bone, use of which appears to result in more bone repair than does DFDBA. In a report by Rummelhart *et al.* (1989), FDBA-treated sites gained 2.4 mm of new bone vs. 1.7 mm in sites treated with DFDBA, even though bone matrix protein was directly available in the demineralized allograft. Slow resorption might also avoid rapid replacement of the material by gingival connective tissue and macrophages. This might be why such materials as coralline calcium carbonate promoted a mean fill of 2.3 mm in the patients treated by Yukna (1994b). The concern that implanted materials of bovine or human origin might contain viruses or prions has implemented the search for new totally synthetic materials. Bioactive glass seems quite promising in its ability to promote bone fill (Lovelace *et al.*, 1998; Price *et al.*, 1997). It also presents antimicrobial properties (Stoor *et al.*, 1998), which could be interesting in treating infected defects in combination with other materials.

## DENTAL IMPLANTS

Dental implants replace the dental root, not the periodontium. They are made of inert material, usually titanium, and their placement cannot be considered a tissue engineering technique. Nevertheless, their use often involves an increase of the existing osseous volume. Until 1969, efforts aimed at producing a ligament-like tissue around dental implants, but such fibrous tissue lacked perpendicular collagen fibers embedded in cementum. It rather contained parallel collagen sheets on the surface of the implant, encapsulating it as a foreign substance. In 1969, Bränemark *et al.* introduced the notion of osteointegration. It was then thought that the bone grew in direct contact with the titanium. Later, Albrektsson *et al.* (1985) demonstrated that the interface between implants and bone is a 20- to 40-nm-wide area containing proteoglycans and nonmineralized collagen (Sennerby *et al.*, 1991). Soft tissues around teeth and implants present similarities (Berglundh *et al.*, 1991) but also differences (Buser *et al.*, 1990). A long junctional epithelium connects the implant to the oral epithelium. Apical to the epithelial junction, there is no true connective tissue attachment. The fibers are at first perpendicular to the implant, then take a vertical course as they near its surface, and surround it.

Alveolar bone exists to support the teeth, and this supportive bone begins to resorb if a tooth is extracted. Alveolar atrophy can be severe in edentulous patients, but in many cases, dental implants are difficult to place. Among the most common anatomical obstacles are the sinuses and the mandibular dental nerve. But the height of the crest is not the only problem, because sufficient width is also necessary (Fig. 59.3). Different forms of tissue engineering can be applied in such cases. The most common, guided bone regeneration using a membrane, can be performed before, after, or at the time of implantation, depending on the anatomic situation. The aim of guided bone regeneration in dental implantology is different from guided tissue regeneration in periodontology. When treating infrabony pockets, the periodontist wants to enhance the migration of periodontal ligament cells. When a deficit in osseous volume is the problem, the surgeon merely tries to avoid competition between the bone and the gingiva. Linde *et al.* (1993) and Misch and Dietsch (1993) have shown that gingival fibroblasts cultured in the presence of osseous cells inhibit the production of the latter. Schenk *et al.* (1994) demonstrated that if the membranes were occlusive, they could promote woven bone within 2 months, and distinct cortical and trabecular structures by 4 months. A membrane rigid enough to protect the underlying blood clot can be used alone (Hardwick *et al.*, 1995). However, membranes tend to collapse and must often receive extra support. This can be provided by screws or pins made of titanium or absorbable polymers (Nevins and Mellonig, 1994). These devices are used as tent poles, lifting up the center of the membrane. When made of titanium, they must be removed after ridge augmentation is achieved. Most studies so far have used e-PFTE barriers for guided bone regeneration with less drawbacks than when it is used for periodontal lesions. Flap closure avoids eventual exposure and bacterial colonization, and this nonresorbable material can remain in place as long as necessary, even several years (Dahlin *et al.*, 1991). Barriers can also be used with bone substitutes to achieve ridge augmentation (Nevins and Mellonig, 1992). The materials must at first support the membrane, then be resorbed and replaced by bone. The delay before implantation possibly depends on the nature

of the substance applied, and can be quite long. As the material is resorbed the barriers tend to collapse. Reinforced barriers have been designed to avoid this problem. Resorbable membranes disappear long before the material has been transformed into bone. A solution for both concerns is the use of titanium membranes. If bone or bone substitutes are used, the thick titanium mesh allows the passage of blood vessels while maintaining the desired volume (von Arx and Kurt, 1999). When no material is placed, thin nonperforated titanium membranes will provide enough support to keep the gingiva out of the defect and will enable new bone formation. Thus bone is formed much faster than biomaterials can be resorbed and replaced by osseous tissue (Lundgren *et al.*, 1995).

Placement of dental implants in the maxillary premolar and molar regions is often impeded by sinuses. Surgical techniques have been developed to push back the sinus mucous membrane and increase the height of the alveolar bone by autogenous grafting (Springfield, 1992) or by use of other materials such as hydroxyapatite (Misch and Dietsch, 1993).

## GROWTH FACTORS AND PLASMA PROTEINS

For many periodontologists, protection of the blood clot that forms after a surgical procedure is the key to periodontium regeneration (Egelberg, 1987), and this can be achieved, among other ways, by membrane barriers. A different type of research is focused on enhancing rapid reorganization of the blood clot. Polson and Proye (1983) have suggested that fibrin linkage between collagen fibers of demineralized dentine matrix and the gingival chorion could enhance and accelerate the formation of a new connective attachment. However, fibrinogen is present in all sites of injury, and studies demonstrating that a supplement of fibrinogen could improve new attachment are lacking. Chemoattraction and cell orientation have also been intensively studied. Fibronectin has been considered a promising promoter of fibroblastic activity. Wikesjo *et al.* (1988) demonstrated that topical application of fibronectin on demineralized roots could be beneficial to healing. Terranova *et al.* (1987) have shown that fibroblast growth factor (FGF) has a potent chemotactic effect on fibroblasts derived from periodontal ligament tissues. FGF is 10,000 times more powerful than fibronectin in inducing fibroblast growth. Platelet-derived growth factor (PDGF) is another chemoattractant with great potential, and no amount of fibronectin can stimulate the proliferation of periodontal ligament fibroblasts to the extent achieved by nanograms of PDGF (Terranova *et al.*, 1987). The usefulness of fibronectin can also be questioned, because it has been shown that it enhances the migration of basal keratinocytes (Woodley *et al.*, 1990). Where epithelial cells colonize the root before connective tissue is formed, there will be no attachment apparatus. Therefore, although fibronectin attracts and orients fibroblasts properly, some of its effects might not be desirable. Plasmatic protein sealants containing large quantities of fibrinogen, but also fibronectin and coagulation factors, have been used with success to avoid suturing, but Caffesse *et al.* (1988a) demonstrated very moderate gains in attachment levels when fibronectin was applied on demineralized root surfaces. Biologic glues have also been proposed as spacers to keep membrane barriers at a distance from the roots (Pini Prato *et al.*, 1988), but the usefulness of fibrinogen and/or fibronectin in periodontal surgery is still inconclusive.

Growth factors nevertheless seem worthy of investigation and clinical trials, for if the membrane technique allows tissue selection and thus favors periodontal attachment, it does not accelerate the healing process. FGF and PDGF both have powerful effects on periodontal ligament fibroblasts. Periodontists have also shown interest in transforming growth factor  $\beta$  (TGF- $\beta$ ), which appears to promote more significant deposition of fibroblast collagen than any of the other growth factors, although it is not a fibroblast chemoattractant (Lynch *et al.*, 1989). The combination of FGF and insulin-like growth factor (IGF-1) seems promising as well, promoting the same collagen deposition as TGF- $\beta$  and a greater proliferation of ligament fibroblasts than PDGF alone (Lynch, 1994). The PDGF-IGF-1 combination is chemotactic and mitogenic for periodontal fibroblasts; PDGF is chemotactic for osteoblasts, and promotes the synthesis of noncollagenous proteins in bone cultures, and IGF-1 promotes the synthesis of collagen proteins. The PDGF-IGF-1 combination results in greater bone matrix formation than any individual growth factor, and interacts synergistically to yield significant collagen formation and healing in soft tissue wounds (Lynch, 1994). Animal experiments have demonstrated that a gel containing this mixture produces more and faster regeneration in the same procedures performed without these growth factors (Giannobile *et al.*, 1994). The delivery of growth factors through a gel allows the presence

Fig. 59.3. (A) The width of the crestal part of the alveolar ridge is insufficient to house the cervical part of this dental implant. (B) Holes have been drilled into the cortical plate and a bone substitute has been placed as a spacer. (C) A resorbable membrane excludes the gingival chorion from the healing site. (D) Six months later, guided bone regeneration has occurred, completely embedding the implant in osseous tissue.

D

Fig. 59.3. (continued).

of a great amount of PDGF and IGF-1 during a short period of time, and even better results could perhaps be obtained with a slow-release system. Lynch *et al.* (1991) showed that the PDGF-IGF-1 mixture in a methyl cellulose gel had a half-life clearance of 3 to 4.2 hr, with more than 96% of the factors cleared by day 4. Repair requires several weeks and it will be interesting to develop slow-release devices. Other reports have suggested that the type of PDGF used might be important with regard to matrix or cell surface attachment (Kelly *et al.*, 1993), and consequently to the ability of activated fibroblasts to produce new collagen (Cho and Garant, 1981). Additional studies in animal models have supported interest in these compounds and their association to regenerative therapy (Cho *et al.*, 1995; Park *et al.*, 1995). Another group of promising molecules is that of bone morphogenic proteins (BMPs), a mixture of peptides initially identified as a bone growth factor and later shown to comprise at least 13 individual proteins (Wozney, 1995). BMPs can promote new bone formation at the site of implantation, instead of changing the bone growth rate of existing bone. In the early 1970s BMPs were shown to be factors from the extractable protein of bone matrix capable of autoinduction (Urist and Iwata, 1973) and of inducing bone formation in nonosseous environments (Sampath and Reddi, 1981). BMPs induce mesenchymal precursor cells to differentiate in cartilage (Chen *et al.*, 1991) and in bone-forming cells (Yamaguchi *et al.*, 1991). Thus, with recombinant human bone morphogenic protein 2 (rhBMP2), the proximity of residual bone is less important for osseous formation. According to Sigurdsson *et al.* (1995a), rhBMP in a carrier enhances periodontal regeneration. When healing is compared with regeneration following membrane implantation, rhBMP produces more bone, but it is primary woven bone. The membrane promotes a thicker cellular cementum. The use of rhBMP significantly reduced post-surgical resorption. The membrane favors migration and proliferation of already differentiated cells, whereas rhBMP promotes the grouping of mesenchymal stem cells in clusters, later developing in appropriate tissues. Sigurdsson *et al.* (1995b), using rhBMP, managed to promote vertical bone formation in horizontal osseous defects generated in dogs. The abundant bone produced not only covered the denuded half-root but in some cases even grew over portions of the crowns of the teeth. A small 12.5-kDa peptide discovered by Terranova *et al.* (1994), PDL-CTX, also seems to be a potent chemoattractant for periodontal ligament cells, with mitogenic properties.

A totally new approach to reconstructing resorbed periodontal tissues is the use of amelogenin. This growth factor, found in the epithelial cells forming the enamel organ, has been extracted from pigs and results in neoformation of acellular cementum (Hammarström, 1997). *In vitro* experiments show that amelogenin increases proliferation of ligament fibroblasts but not of epithelial cells (Gestrelus *et al.*, 1997). Clinical trials in animals (Zetterström *et al.*, 1997; Araujo and Lindhe, 1998) and humans (Hammarström *et al.*, 1997) have demonstrated significant gains of bone, periodontal ligament, and cementum.

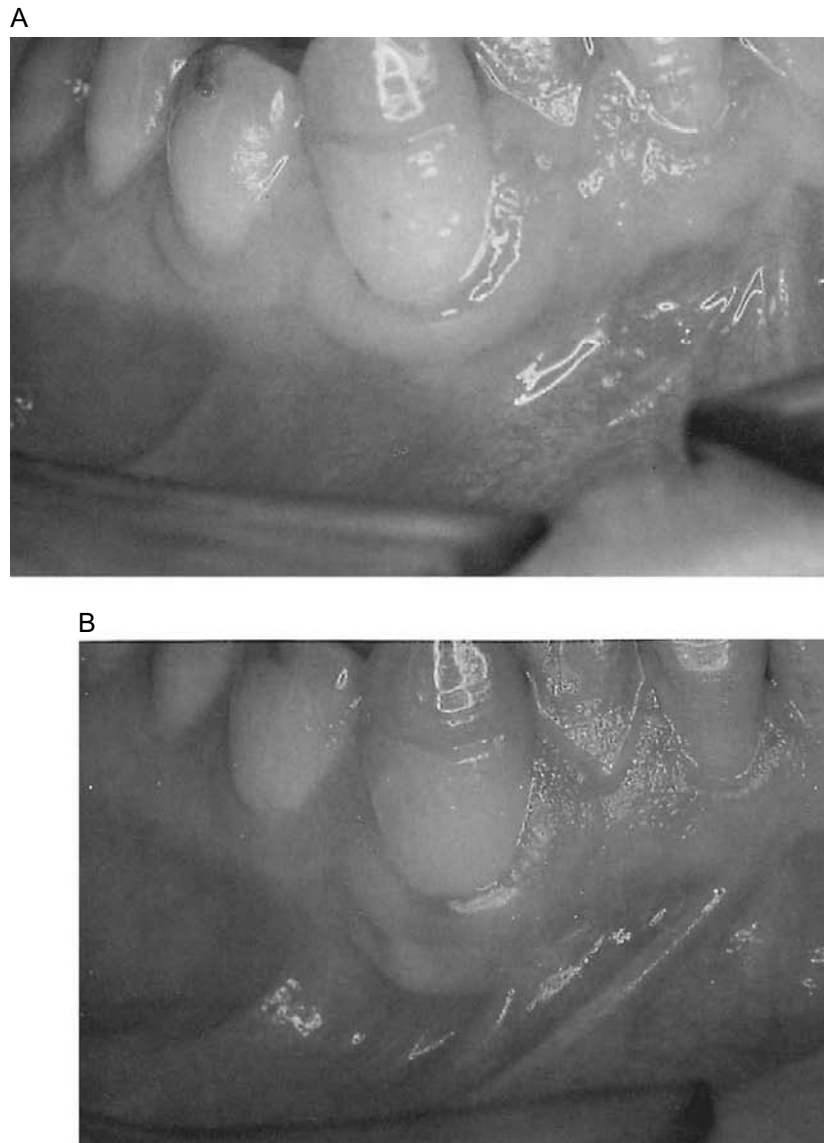

Fig. 59.4. (A) Insufficiently attached gingiva on a mandibular cuspid. (B) Two months after grafting a lattice containing cultured gingival fibroblasts (gingival chorion equivalent), a large band of attached gingiva is now present. (C) A biopsy of the healing gingiva was performed at 3 months. A sharp difference in the height of the epithelium is visible at the junction between neoformed gingiva and recipient bed tissue. The two gingival tissues, however, have a similar appearance, although the new gingiva (to the left) harbors more capillaries and less fibrous tissue than the residual gingiva (to the right).

## CELL CULTURE TECHNIQUES

Cell culture techniques have seldom been used to treat periodontal disease. Hanachowicz *et al.* (1989) cultured epithelial cells to treat gingival recession by grafting the cultured epithelial equivalent. The procedure was successful in reinforcing the remaining gingiva, but there was little gain in root coverage. P. Ambrosini and N. A. Miller (unpublished data) applied the method developed by Bell *et al.* (1979) to the culture of human gingiva fibroblasts, and grafted the gingival chorion equivalent they had obtained at the margin of a gingival recession (Fig. 59.4A). Twenty-one days later, a biopsy was performed at the healed wound edge. Histologic examination showed that the gingival chorion equivalent grafted had reconstituted an apparently normal gingival tissue with dense collagen fibers and was covered by keratinized epithelium (Fig. 59.4B). This technique appears to offer interesting advantages. The patient does not experience great discomfort, because an initial biopsy of 8 mm<sup>2</sup> is sufficient to induce the culture. The culture can produce great quantities of chorion, which can be used for the reconstruction of several gingival recession sites. Drawbacks are the time and money needed to sustain such cultures; the use of palate donor sites allows a more rapid reconstruction (Martin *et al.*, 1995). Such techniques, using autologous cultured tissues, could, however, be considered when extensive reconstruction is needed.

Because osseous cells are not as easily harvested as gingival fibroblasts, some researchers have sought to differentiate other cells into osteoblasts. Lecoer and Ouhayoun (1997) have cultured adipous cells in media containing rhBMP2 and dexamethasone. Thus treated, the adipocytes produced a high output of alkaline phosphatase, suggesting that these cells could undergo an osteogenic differentiation. This has brought hope that such cells could afterward be transplanted into periodontal defects.

## CONCLUSION

A certain number of factors impeding spontaneous regeneration of the periodontium have begun to be adequately understood and addressed. For example, the problems of tissue competition between epithelium and connective tissue at the root surface and between gingival chorion and osseous cells in bony defects are rather satisfactorily solved with the use of membranes. Spacing and some degree of osseous conduction can be provided by bone substitutes, and use of these products, associated or alone, is now widespread and partial regeneration of periodontal defects is predictable. The best results are obtained in angular alveolysis. The number of bony walls at the lesion is important: two- or three-walled defects will have better prognosis than one-wall defects. The quality of the bone forming the lesion walls should also be considered: thick walls with cancellous bone will produce more osseous cells compared with cortical bone. The source of bone cells and the distance they must travel are crucial to assess the chances of success of treatment modalities currently in use. Research is opening new horizons. Growth factors seem promising tools to attract the appropriate cells to healing sites and in promoting angiogenesis, an especially interesting feature considering the avascular nature of the dental root. The use of BMPs, amelogenine, or other inductor proteins might even enable induction of stem cells to differentiate into bone or periodontal ligament cells. The biologic effects of cytokines and their carriers still have to be studied. Substances that will not hinder healing but will release biological agents at a suitable rate need to be developed. Animal models demonstrate that horizontal alveolysis can be repaired, and clinical applications will surely emerge with time.

Considering the progress achieved since the early attempts at repairing dental defects with biomaterials, it seems that we are getting closer to the possibility of totally regenerating periodontium destroyed by disease, if not preventing such events.

# REGENERATION OF DENTIN

R. Bruce Rutherford

## INTRODUCTION

The goal of engineering the formation of new dentin is primarily motivated by the clinical need to restore or thicken this mineralized tissue. Dentin surrounds and protects the vital tissues of the tooth that reside in the dental pulp. Dentin is approximately 80% mineralized and provides, in combination with enamel, the major structural mass of the tooth. Like enamel, dentin is a non-vascular tissue; however, unlike enamel, the cells that synthesize dentin (odontoblasts) may remain vital throughout adult life and may synthesize additional dentin. Recent experimental evidence has suggested that, even if the odontoblast cells (which line the dentin pulp interface) are lost, it may be possible to induce the differentiation of odontoblasts from pulp tissue using certain bone morphogenetic proteins and thereby induce the synthesis of new dentin. Successful development of a process to engineer successfully the regeneration of dentin could have commercial applications as an enhanced pulp capping agent, as an alternative to root canal therapy under certain circumstances, and as a potential means of reducing tooth sensitivity often associated with the placement of tooth fillings.

## DENTIN

There are several different forms of dentin. Primary and secondary dentins are terms generally applied to dentins that form during the development of teeth. Tertiary dentins are those forming in response to a specific stimulus, such as partial removal of the dentin layer. Tertiary dentin matrices are categorized as reparative or reactionary. Reparative dentin is a tertiary dentin matrix formed by new odontoblast-like cells in response to a specific stimulus after loss of those odontoblasts responsible for synthesis of primary and secondary dentin. Reactionary dentin is formed by original odontoblasts (Smith *et al.*, 1995). We use the terms “reparative” and “reactionary” dentin when referring to tertiary dentin matrices of mammalian teeth. The induction of differentiation of new odontoblasts from undifferentiated tissues may require different strategies than the stimulation of extant odontoblasts. It is likely that mature adult pulps contain stromal cells capable of producing reparative dentin if given the appropriate stimulus, in that most data indicate that connective tissue repair is mediated by resident stromal cells near the site of wounding (Prokop, 1997).

## BONE MORPHOGENETIC PROTEINS

Bone morphogenetic proteins (BMPs) are a group of signaling molecules that were originally isolated and described for their capacity to induce endochondral bone formation in subcutaneous, intramuscular, or intrabony sites in mammals (Sampath *et al.*, 1990; Wang *et al.*, 1990). There are now more than 30 BMP-like proteins that have been identified, though only a small subset, at this time, have been demonstrated to be osteogenic (Wozney and Rosen, 1998).

Structurally all BMPs are members of the transforming growth factor  $\beta$  (TGF- $\beta$ ) superfamily and several have been implicated in key stages of embryonic tissue morphogenesis (Hogan, 1996). As such, the early implications for this class of proteins were that their potential role in tis-

sue formation could be possibly broader than a more limited role in cartilage and bone induction. The first nonbone, noncartilage tissue that has been demonstrated to be induced by a bone morphogenetic protein is dentin. The experimental evolution of the use of BMPs to engineer dentin regeneration is described below.

## INDUCTION POTENTIAL OF DENTIN

Several investigators have demonstrated that demineralized dentin powder, like demineralized bone powder (Urist, 1965), induces ectopic bone formation (Bang, 1972; Butler *et al.*, 1977; Inoue *et al.*, 1986). However, unlike demineralized bovine bone powder, for which the specific proteins for bone induction have been identified (Sampath *et al.*, 1990), demineralized dentin powders have not been further characterized and the molecular basis for dentin BMP activity has not been established. It is likely that several of the BMPs are involved.

Dentin is also dentinogenic. Mineralized tissue superficially resembling dentin forms in association with dentin fragments introduced into pulp during mechanical exposure (Seltzer and Bender, 1981), and demineralized dentin implanted into dental pulp induces mineralized tissue formation (Tziafas and Kolokuris, 1990; Tziafas *et al.*, 1992). The dentin-associated dentinogenic activity, like the bone-associated osteogenic activity (Sampath *et al.*, 1990), is at least partially soluble in 4 M guanidine hydrochloride, implicating molecules similar to the BMPs (Nakashima, 1990). In addition, crude dentin fractions prepared by ethylenediaminetetraacetic acid (EDTA) extraction and collagenase digestion stimulate reparative dentinogenesis in small pulp exposures in ferrets (Smith *et al.*, 1990) or reactive dentinogenesis when applied to freshly cut dentin surfaces (Smith *et al.*, 1994). In addition, dog dental pulps respond to crude allogenic, bone-derived BMP by forming reparative dentin (Nakashima, 1990; Lianjia *et al.*, 1993).

## RECOMBINANT HUMAN BMPs INDUCE DENTIN FORMATION

Experiments linking BMPs to reparative dentinogenesis utilized recombinant human BMP2, BMP4, BMP7, TGF- $\beta$ , and platelet-derived growth factor (PDGF). In a follow-up study to her previous work, Nakashima reported that recombinant human BMP2 and BMP4, but not TGF- $\beta$ , induce reparative dentinogenesis in dogs when placed on partially amputated dental pulps (Nakashima, 1994). In this study, addition of BMP2 or BMP4 doubled (82 to 42%) the amount of reparative dentin formed in partially amputated dog dental pulps when compared to teeth treated with the collagen-based carrier material after 60 days. The TGF- $\beta$  was inactive in these experiments. The carrier was allogenic dentin collagen prepared in a manner similar to that described above and mixed with chondroitin 6-sulfate and acid-soluble rat tail tendon collagen.

Qualitatively similar data were obtained from nonhuman primate studies using recombinant human BMP7 (Rutherford *et al.*, 1993, 1994). These studies demonstrated that recombinant human BMP7 complexed with an insoluble type I collagen matrix (CM) delivery vehicle predictably and reliably induced reparative dentinogenesis when placed on freshly cut healthy pulp tissues (Fig. 60.1) in nonhuman primates. The initial experiments in this series tested the hypothesis that recombinant human BMP7-induced tissue formation occurs in the place of and replaces the inductive material. This suggests that the size and shape of the mass of inductive material control the size and shape of the reparative dentin. Placing variable amounts of the BMP7/CM combination in a surgically induced model of pulp exposure resulted in the formation of variable amounts of reparative dentin, demonstrating that the mass of reparative dentin formed is, indeed, proportional to the mass of BMP7/CM placed (Fig. 60.2).

This hypothesis also predicts that the reparative dentin should form largely superficial to, and hence preserve the volume of, the remaining pulp tissue. Initial experiments tested this hypothesis by layering osteogenic protein-1 (OP-1)/CM on the cut surface of the partially amputated pulp and extending it laterally onto the adjacent cut dentin surface. We observed that the reparative dentin formed largely superficial to the existing pulp tissue and extended laterally onto the existing dentin, also superficial to the level of the amputated pulp (Rutherford *et al.*, 1993).

This dentinogenic response appears to be independent of the amount of the pulp tissue removed. We have created variably sized lesions in coronal pulps, ranging from small and superficial (1 mm in diameter and 0.5 mm deep) (R. B. Rutherford, unpublished observations) to large lesions (approximately  $1-1.5 \times 2-2.5 \times 2-3$  mm deep), which effectively removed all the dentin covering the pulp chamber (Rutherford *et al.*, 1993), to complete removal of the coronal pulp

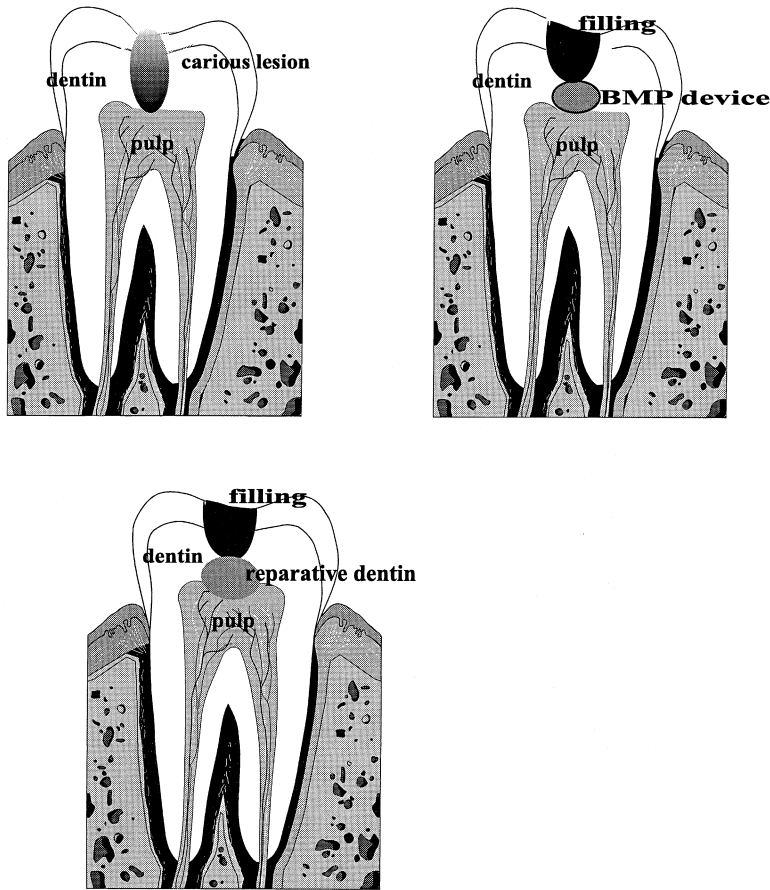

Fig. 60.1. Depiction of the application of the BMP7 device (recombinant human BMP7 with a bovine-derived, type I collagen matrix) to a freshly cut pulpal surface in a surgically induced model of pulp exposure.

(Rutherford *et al.*, 1994). In addition, we have removed approximately 75% of the root pulp from healthy ferret teeth and layered BMP7/CM over the remaining pulp (R. B. Rutherford, unpublished observations). In most cases there was robust formation of reparative dentin. The formation process is described below.

Initially the BMP7/CM is converted to a minimally inflamed, highly vascular granulation tissue that matures to a loose, fibrous connective tissue resembling dental pulp. This new tissue begins an apparently random pattern of mineralization, trapping cells and vascular channels in lacunae. BMP7/CM-induced reparative dentin in monkeys and ferrets is, at first, predominantly

Fig. 60.2. Cross-sectional area of reparative dentin formed in response to varying quantities of the BMP7 device placed in surgically induced primate models of pulp exposure, as determined by histomorphometric analysis (Rutherford *et al.*, 1993).

atubular, with contiguous zones of tubular dentin adjacent to the dental pulp appearing after a few weeks. Odontoblast-like cells are associated with areas of tubular-like dentin with cellular processes apparently extending into the dentinal tubules (Rutherford *et al.*, 1994). Approximately 95% of the original mass of tissue is mineralized by 6 months, yet only about 20% of the surface was composed of tubular dentin and associated columnar odontoblasts, whereas 50% of the pulpal surface is lined with very flat cells that appear metabolically quiescent (Rutherford *et al.*, 1994). The remaining cells appear more cuboidal and are associated with dentin that appears to be atubular.

## DELIVERY SYSTEMS

With regard to the choice of delivery systems for application of a dentinogenic substance, the experiments that have been performed to date have utilized naturally sourced, bioresorbable collagen matrices for several important reasons. First and foremost, collagen matrices provide a highly desirable environment for the chemoattraction and retention of local cell types at the site of tissue damage or deficit. Second, collagen matrices provide a temporary scaffold for initiation of the tissue repair/regeneration process. Last and not insignificantly, collagen matrices provide for hemostasis, which is often an important advantage in a site that is likely to exhibit substantial bleeding.

The use of naturally-sourced delivery materials is, of course, not optimal from the standpoint of pharmaceutical development. Inevitably, variations in source material as well as the inherent risk of infectious disease make naturally sourced products or delivery systems less than ideal. However, to date, these naturally sourced delivery materials have provided the most compatible systems for the promotion of tissue regeneration, particularly for the bone- and dentin-promoting activities associated with the BMP subclass of the TGF- $\beta$  subclass of proteins. Careful selection of source materials and rigorous manufacturing processes can eliminate the potential problems associated with naturally sourced delivery systems. Ultimately, better characterized, biocompatible, bioresorbable, synthetic materials may provide a more desirable alternative.

## CLINICAL CONSIDERATIONS

The experiments described above (Nakashima, 1990, 1994; Rutherford *et al.*, 1993, 1994) utilized clinically healthy teeth. No attempt was made to induce inflammation (pulpitis) specifically or to test the capacity of the recombinant proteins to induce reparative dentinogenesis in previously diseased tissues. To determine the effect of a preexisting pulpitis on the response to BMP7/CM, we have developed an animal model of experimental pulpitis by injecting bacterial lipopolysaccharide (LPS; *Salomonella typhimurium*, 5  $\mu\text{g}/\mu\text{l}$ ) into small surgical exposures of adult ferret teeth. The teeth were sealed with standard dental materials. After 3 days, most coronal pulps displayed foci of chronic inflammation with variable tissue necrosis in the center of the lesion. All lesions observed ( $n = 10$ ) were limited to the coronal tissues with the subjacent root pulp free of inflammatory cells (R. B. Rutherford, unpublished observations). After 3 days, the teeth were surgically reexposed, the pulp removed to the level of the root canal, and BMP7/CM layered on the freshly amputated pulp tissue. Four concentrations of BMP7 (0, 2.5, 7.5, and 25  $\mu\text{g}/\text{mg}$  CM;  $n = 20$  teeth per group) were tested. In all cases, no reparative dentin formed in teeth pretreated with LPS, whereas all three BMP preparations induced reparative dentinogenesis in healthy or sham-infected pulps. Most pulps were necrotic after 2 weeks. These data suggest that a single application of recombinant BMP fails to induce reparative dentinogenesis in freshly debrided tissues deep to a focus of inflamed pulp tissue. The reasons for this failure are not clear. It is possible that too few responsive cells are present in the noninflamed pulp deep to the experimental inflammatory lesions. However, this explanation seems unlikely given earlier data suggesting that responsive tissue is present nearly the entire length of the root (see above). More likely, perhaps, is that the effectiveness of BMP7 is attenuated in inflamed tissues to the extent that a single application of up to 25  $\mu\text{g}$  BMP7 is insufficient to induce a reparative response.

It is possible that other clinical conditions exist wherein a single local application of a recombinant protein will prove insufficient to induce tissue regeneration. Therefore, in collaboration with Renny Franceschi, we have developed and are testing a recombinant replication-defective adenovirus that contains a mouse BMP7 gene driven by a cytomegalovirus promoter. Preliminary experiments reveal that the virus transduces dental pulp cells *in vitro* and *in vivo* and induces reparative dentinogenesis in a manner similar to exogenous recombinant protein. Further

experiments testing the efficacy of this vector in experimentally inflamed teeth are in progress (R. B. Rutherford, unpublished observations).

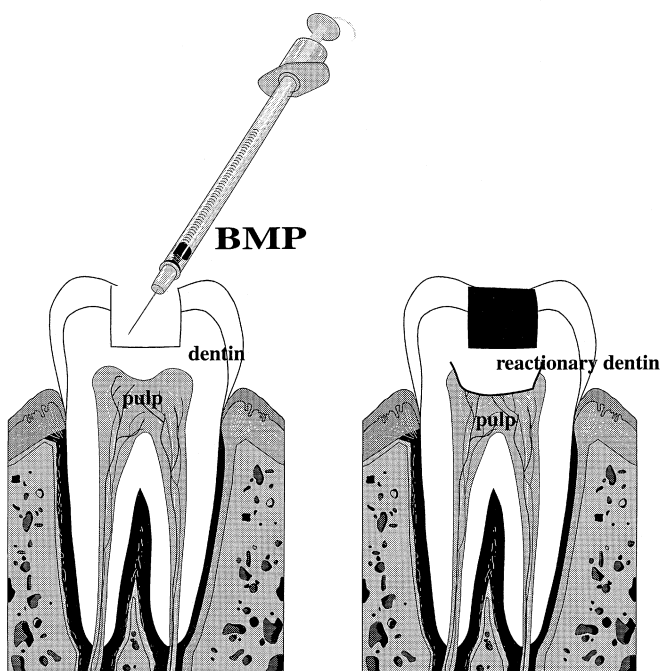

### ADDITIONAL CONSIDERATIONS

Qualitatively the pattern of reparative dentin formation in response to the crude preparations or to highly purified recombinant proteins described above is similar. The tissue initially appears atubular with cellular and soft tissue inclusions. Subsequently a more tubular form of matrix with associated odontoblast-like cells appears attached to the mass of atubular matrix. This observation supports the idea that some extracellular matrix component is a prerequisite to odontoblast differentiation and tubular dentin formation (Veis, 1985). A detailed study of the structure of the surface of the atubular dentin and the dynamics of the associated odontoblast differentiation may reveal the critical factors involved in this process. Such knowledge may provide the opportunity to regulate odontoblast differentiation and hence the architecture of the tissue. Regulation of dentin architecture may be important. The function of dentinal tubules is not known. The long-term viability of atubular dentin, its caries susceptibility, permeability, and the magnitude of the bond strength with existing dentin bonding agents are not known. Optimally engineered reparative dentin may comprise a combination of atubular and tubular dentin. For example, if a layer of tubular-like dentin adjacent the pulp is required for long-term tissue viability, yet atubular dentin is less susceptible to caries, an optimal layer of reparative dentin may be composed of a layer of tubular dentin deep to a layer of atubular dentin.

### POTENTIAL APPLICATIONS OF BMP-INDUCED DENTINOGENESIS

Surgical debridement to expose vital pulp and the application of a recombinant BMP (or other dentinogenic molecule) protein or a recombinant viral vector capable of transducing cells to produce a BMP7-based product could lead to several new therapeutic modalities for the preservation of vital and functional teeth. The development of such procedures could provide for improved pulp capping agents with enhanced biological responsiveness as well as potential alternatives to conventional root canal therapy in certain instances.

Another application for the dentinogenic properties of BMPs is the potential reduction of tooth sensitivity via the transdentinal stimulation of reactionary dentin. In this approach BMP7 was applied to freshly cut dentin surfaces in a liquid formulation with the hope that BMP7 might diffuse through the dentinal tubules and stimulate the formation of reactionary dentin within the

*Fig. 60.3. Depiction of the application of recombinant human BMP7 in a liquid formulation to freshly cut dentinal tubules in a deep cavity preparation intended to stimulate the formation of new reactionary dentin.*

Fig. 60.4. Dose-dependent response of reactionary dentin formation to recombinant human BMP7 under residual dentin in a primate model of deep cavity preparation. (Rutherford *et al.*, 1995).

pulp chamber (Fig. 60.3). Initial experiments appear to indicate that this is possible (Rutherford *et al.*, 1995). Stimulation of reactionary dentin by an ethanol-containing solution of BMP7 revealed a dose-dependent response of the pulpal tissue to the dentinogenic properties of BMP7 (Fig. 60.4). Unfortunately, it is not possible to measure adequately parameters of tooth sensitivity in animal models. As such, the rigorous establishment of a correlation between the capacity of BMP7 to induce a thickening of the residual dentin layer separating a dental filling from the pulp, and thereby, potentially diminish the sensitivity of teeth to newly placed dental fillings, must await clinical investigation in human subjects.

## PART XIX: SKIN

This Page Intentionally Left Blank

# WOUND REPAIR: BASIC BIOLOGY TO TISSUE ENGINEERING

Richard A. F. Clark and Adam J. Singer

## INTRODUCTION

The skin is the largest organ in the body and its primary function is to serve as a protective barrier against the environment. Other important functions of the skin include fluid homeostasis, thermoregulation, immune surveillance, sensory detection, and self-healing (Holbrook and Wolff, 1993). Loss of the integrity of large portions of the skin due to injury or illness may result in significant disability or even death. The most common cause of significant skin loss is thermal injury, with an estimated 2.5 million burns each year in the United States alone (Centers for Disease Control, 1982). Other causes of skin loss include chronic ulcerations (secondary to pressure, venous stasis, or diabetes mellitus), trauma, excision of skin tumors, or other dermatology conditions such as pemphigus or toxic epidermal necrolysis. It is estimated that the prevalence of leg ulcers alone is between 0.5 and 1.5%, with an annual cost of nearly \$1 billion (Phillips and Dover, 1991). Some experts have estimated that the total number of chronic wounds exceeds 2 million annually in the United States (Medical Data International, 1998). The social and financial tolls of chronic wounds are extremely high.

Principal goals in wound management are to achieve rapid wound closure and a functional and aesthetic scar. Over the past two decades extraordinary advances in cellular and molecular biology have greatly expanded our comprehension of the basic biological processes involved in wound repair and tissue regeneration (Clark, 1996a). Ultimately these strides in basic knowledge will lead to advancements in wound care resulting in accelerated rates of ulcer and normal wound repair, scars of greater strength, and prevention of keloids and fibrosis. Already one growth factor and several skin substitutes have reached the marketplace for second-line therapy of recalcitrant ulcers (Singer and Clark, 1999). Furthermore, because tumor stroma generation is similar to wound healing (Dvorak, 1986), the increased knowledge in wound repair may lead to unexpected advances in tumor therapy. Clearly scientific breakthroughs today in the processes of wound healing and tissue regeneration will lead to future therapeutic successes in wound care and tissue engineering. In this chapter the use of cultured keratinocytes, tissue-engineered skin substitutes, and recombinant growth factors for wound care are discussed in the context of wound healing biology.

Wound repair is not a simple linear process in which growth factors released by phylogistic events activate parenchymal cell proliferation and migration, but is rather an integration of dynamic interactive processes involving soluble mediators, formed blood elements, extracellular matrix, and parenchymal cells. Unencumbered, these wound repair processes follow a specific time sequence and can be temporally categorized into three major groups: inflammation, tissue formation, and tissue remodeling. The three phases of wound repair, however, are not mutually exclusive but rather overlapping in time. In this overview, current ideas about wound repair are presented in a sequence that roughly follows the chronology of wound repair. The reader is referred

to "The Molecular and Cellular Biology of Wound Repair" (Clark, 1996a) for a more detailed discussion of the many processes involved in wound healing.

## INFLAMMATION

Severe tissue injury causes blood vessel disruption with concomitant extravasation of blood constituents. Blood coagulation and platelet aggregation generate a fibrin-rich clot that plugs severed vessels and fills any discontinuity in the wounded tissue. While the blood clot within vessel lumen reestablishes hemostasis, the clot within the wound space provides a provisional matrix for cell migration.

## PLATELETS

Successful hemostasis is dependent on platelet adhesion and aggregation. Platelets first adhere to interstitial connective tissue, then aggregate. In the process of aggregation, platelets release many mediators, including ADP, and express several clotting factors on their membrane surface. Together these platelet products facilitate coagulation and further platelet activation.

When activated platelets discharge their  $\alpha$  granules, several adhesive proteins, including fibrinogen, fibronectin, thrombospondin, and von Willebrand factor VIII, are released. The first three act as ligands for platelet aggregation whereas von Willebrand factor VIII mediates platelet adhesion to fibrillar collagens and their subsequent activation (Ruggeri, 1993). Platelet adhesion to all four adhesive proteins is mediated through the platelet glycoprotein (GPIIb/IIIa; integrin  $\alpha$ IIb $\beta$ 3) surface receptor (Ginsberg *et al.*, 1992). Platelet fibrinogen, once converted to fibrin by thrombin, adds to the fibrin clot. In addition, platelets release chemotactic factors for blood leukocytes (Weksler, 1992), and growth factors such as platelet-derived growth factor (PDGF) (Heldin, 1992), transforming growth factor  $\alpha$  (TGF- $\alpha$ ) (Nanney and King, 1996), and TGF- $\beta$  (Roberts and Sporn, 1996), which promote new tissue generation.

## NEUTROPHILS

The coagulation pathways activate complement pathways and injured parenchymal cells generate numerous vasoactive mediators and chemotactic factors, which together recruit inflammatory leukocytes to the wound site. Infiltrating neutrophils cleanse the wounded area of foreign particles, including bacteria. If excessive microorganisms or indigestible particles have lodged in the wound site, neutrophils will probably cause further tissue damage as they attempt to clear these contaminants through the release of enzymes and toxic oxygen products. When particle clearance has been completed, generation of granulocyte chemoattractants ceases and the remaining neutrophils become effete.

## TRANSITION BETWEEN INFLAMMATION AND REPAIR

Whether neutrophil infiltrates resolve or persist, monocyte accumulation continues, stimulated by selective monocyte chemoattractants (Clark, 1996b). Besides promoting phagocytosis and debridement, adherence to extracellular matrix also stimulates monocytes to undergo metamorphosis into inflammatory or reparative macrophages. Wound macrophages, in fact, express TGF- $\beta$  and PDGF mRNA as well as TGF- $\alpha$  and insulin-like growth factor-1 (IGF-1) mRNA (Rappolee *et al.*, 1988). Because cultured macrophages produce and secrete the peptide growth factors interleukin-1 (IL-1), PDGF, TGF- $\beta$ , TGF- $\alpha$ , and fibroblast growth factor (FGF), presumably wound macrophages also synthesize these protein products (Clark, 1996b). Such macrophage-derived growth factors may support the initiation and propagation of new tissue formation in wounds. Thus, macrophages appear to play a pivotal role in the transition between inflammation and repair (Riches, 1996).

## EPITHELIALIZATION

Reepithelialization of a wound begins within hours after injury. It is clear that rapid reestablishment of any epithelial barrier decreases victim morbidity and mortality. Epithelial cells from residual epithelial structures move quickly to dissect the clot and the damaged stroma from the wound space and to repave the surface of viable tissue.

Migrating wound epidermal cells do not terminally differentiate as do keratinocytes of normal epidermis. These migrating cells do not contain keratin proteins normally found in mature

stratified epidermis nor do they contain filaggrin, a matrix protein in which these keratins are embedded. In contrast, cells in all layers of the migrating epidermis contain keratins normally found only in the basal cells of stratified epidermis (Mansbridge and Knapp, 1987). Nevertheless, the phenotype of migrating epidermal cells is not identical to basal cells, in that the migrating cells also contain involucrin, a component of differentiated keratinocyte cell walls, and transglutaminase, an enzyme that cross-links cell wall proteins.

If the basement membrane is destroyed by injury, epidermal cells migrate over a provisional matrix of fibrin(ogen), fibronectin, tenascin, and vitronectin as well as stromal type I collagen (Clark, 1996b). Fibrinogen is interspersed with stromal type I collagen at the wound margin and interwoven with the fibrin clot in the wound space (Clark *et al.*, 1999). Wound keratinocytes express cell surface receptors for fibronectin, tenascin, and vitronectin (Clark, 1990; Juhasz *et al.*, 1993; Larjava *et al.*, 1993; Clark *et al.*, 1996a). These specialized cell membrane receptors are of the integrin superfamily (Table 61.1) (Hynes, 1992; Yamada *et al.*, 1996). In addition, the integrin  $\alpha 2\beta 1$  collagen receptors, which are normally disposed along the lateral sides of basal keratinocytes, redistribute to the basal membrane of wound keratinocytes as they come in contact with type I collagen fibers of the dermis.

The migrating wound epidermis does not simply transit over a wound coated with provisional matrix but rather dissects through the wound, separating desiccated or otherwise nonviable tissue from viable tissue. The path of dissection appears to be determined by the array of integrins that the migrating epidermal cells express on their cell membranes, as described above. In addition,  $\alpha v\beta 3$ , the receptor for fibrinogen/fibrin (Cheresh *et al.*, 1989) and denatured collagen (Davis, 1992), is not expressed on keratinocytes *in vitro* (Adams and Watt, 1991) or *in vivo* (Gailit *et al.*, 1994). Therefore, keratinocytes do not have the capacity to interact with these matrix proteins (Kubo *et al.*, 1999). Furthermore, in the presence of fibrinogen or fibrin, epidermal cells fail to bind fibronectin (Kubo *et al.*, 1999), yet can bind type I collagen. Hence migrating wound epidermis avoids the fibrin-, fibronectin-rich clot while migrating over a bed of fibrinogen, fibronectin, and type I collagen (Fig. 61.1).

Extracellular matrix degradation is clearly required for the dissection of migrating wound epidermis between the collagenous dermis, the fibrin eschar (Bugge *et al.*, 1996), and probably depends on epidermal cell production of both collagenase (Woodley *et al.*, 1986) and plasminogen activator (Grondahl-Hansen *et al.*, 1988) and perhaps stromelysin (Saarialho-Kere *et al.*, 1994). Plasminogen activator activates collagenase as well as plasminogen (Mignatti *et al.*, 1996) and

**Table 61.1. Integrin superfamily**

Integrins	Ligand	Integrin	Ligand
<b><math>\beta 1</math> Integrins</b>		<b><math>\alpha v</math> Integrins</b>	
$\alpha 1\beta 1$	Fibrillar collagen, laminin-1	$\alpha v\beta 1$	Fibronectin (RGD), vitronectin
$\alpha 2\beta 1$	Fibrillar collagen, laminin-1	$\alpha v\beta 3$	Vitronectin (RGD), fibronectin, fibrinogen, von Willebrand factor, thrombospondin, denatured collagen
$\alpha 3\beta 1$	Fibronectin (RGD), laminin-5, entactin, denatured collagens	$\alpha v\beta 5$	Fibronectin (RGD), vitronectin
$\alpha 4\beta 1$	Fibronectin (LEDV), VCAM-1	$\alpha v\beta 6$	Fibronectin, tenascin
$\alpha 5\beta 1$	Fibronectin (RGD)

Fig. 61.1. Integrins in early (three-dimensional) reepithelialization. The migrating epidermis in contact with type I dermal collagen expresses a gene set including the collagen receptor  $\alpha 2\beta 1$ , urokinase plasminogen activator (uPA), and interstitial collagenase (MMP-1). With this armamentarium the epidermis can dissect a path between viable dermis and nonviable clot and denature stroma, ultimately leading to slough of the eschar.

therefore facilitates the degradation of interstitial collagen as well as provisional matrix proteins. Interestingly, keratinocytes in direct contact with collagen greatly increase the amount of interstitial collagenase [matrix metalloproteinase-1 (MMP-1)] they produce compared to that produced when they reside on laminin-rich basement membrane or purified laminin (Petersen *et al.*, 1990). The migrating epidermis of superficial skin ulcers and burn wounds, in fact, expresses high levels of MMP-1 mRNA in areas where it presumably comes in direct contact with dermal collagen (Saarialho-Kere *et al.*, 1992; Stricklin and Nanney, 1994).

At 1 to 2 days after injury, epithelial cells at the wound margin begin to proliferate (Krawczyk, 1971). The stimuli for epithelial proliferation during reepithelialization have not been delineated, but several possibilities exist. Perhaps the absence of neighbor cells at the wound margin signals both epithelial migration and proliferation. The “free edge effect” has been thought to stimulate reendothelialization of large blood vessels after intimal damage (Heimark and Schwartz, 1988) and may relate to dissolution of cadherin junctions on the free edge (Dejana, 1996). Other possibilities, not exclusive of the former, are release of autocrine or paracrine growth factors that induce epidermal migration and proliferation and/or increased expression of growth factor receptors. Leading contenders include the epidermal growth factor (EGF) family (Nanney and King, 1996), especially TGF- $\alpha$  (Barrandon and Green, 1987) and heparin-binding epidermal growth factor (HB-EGF) Higashiyama *et al.*, 1991); the FGF family (Abraham and Klagsbrun, 1996), especially keratinocyte growth factor (KGF) (Werner, 1998); insulin-like growth factor (Galiano *et al.*, 1996); and TGF- $\beta$  (Zambruno *et al.*, 1995). Although some growth factors, such as IGF, may derive from the circulation and thereby act as a hormone, other growth factors, such as HB-EGF and KGF, derive from macrophages and dermal parenchymal cells, respectively, and act on epidermal cells through a paracrine pathway (Werner, 1998). In contrast, TGF- $\alpha$  and TGF- $\beta$ , originate from keratinocytes and act directly on the producer cell or adjacent epidermal cells in an autocrine or juxtacrine fashion (Coffey *et al.*, 1987; Brachmann *et al.*, 1989). Many of these growth factors have been shown to stimulate reepithelialization in animal models (Brown *et al.*, 1989; Lynch *et al.*, 1989; Hebda *et al.*, 1990; Staino-Coico *et al.*, 1993) or to lack receptors in models of deficient reepithelialization (Werner *et al.*, 1994), supporting the hypothesis that they are active during normal wound repair.

As reepithelialization ensues, basement membrane proteins reappear in a very ordered sequence from the margin of the wound inward in a zipperlike fashion (Clark, 1996b). Epidermal cells revert to their normal phenotype, once again firmly attaching to reestablished basement membrane through two hemidesmosomal proteins,  $\alpha 6\beta 4$  integrin and 180-kDa bullous pemphigoid antigen (Gipson *et al.*, 1993), and to the underlying neodermis through type VII collagen fibrils (Gipson *et al.*, 1988).

#### EPIDERMAL AUTOGRAFTS AND ALLOGRAFTS

Immediate wound coverage, whether permanent or temporary, is one of the cornerstones of wound management. When the epidermis fails to heal normally or when a large surface area has

been destroyed, supplemental epidermal coverage can be beneficial. Ideally, wound coverage would be achieved using autologous skin or material having qualities similar to those of autologous skin. Use of skin grafts, however, often requires extensive, invasive harvesting and is of limited quantity.

Autologous cultured keratinocyte grafts were first used in humans by O'Conner *et al.* (1981). Subsequently there has been extensive experience with cultured epidermal grafts for the treatment of burns as well as other acute and chronic wounds (Gallico *et al.*, 1984; Odessey, 1992; Munster, 1996). The major advantage of this technique is the ability to provide autologous grafts capable of covering large areas with reasonable cosmetic results. Another significant advantage of autologous grafts is their ability to serve as permanent wound coverage, because the host does not reject them. Disadvantages include the time interval of 2–3 weeks required before sufficient quantities of keratinocytes are available, the need for an invasive and painful procedure to obtain autologous donor cells, and the large costs, estimated at \$13,000 per 1% total body surface area covered (Rue *et al.*, 1993). Furthermore, graft take is widely variable based on wound status, general host status, and operator experience.

Cultured keratinocyte allografts were developed to help overcome the need for a biopsy and a separate cultivation for each patient to produce autologous grafts and to ameliorate the long lag period between epidermal harvest and graft product. Successful keratinocyte allografting was first reported in burns using keratinocytes obtained from cadaver skin (Hefton *et al.*, 1983). Since then, cultured epidermal cells from both cadavers and unrelated adult donors have been used for the treatment of burns (Madden *et al.*, 1986), for skin grafts (Thiovet *et al.*, 1986), and for treating chronic leg ulcers (Leigh *et al.*, 1987). Importantly, these allografts can result in accelerated and sustained wound healing without any evidence of rejection. This tolerance is probably secondary to the inability of cultured keratinocytes to express major histocompatibility complex class II human leukocyte (HLA-DR) antigens (Hefton *et al.*, 1983), and the absence of Langerhan's cells, the major antigen-presenting cells (APCs) of the epidermis (Thiovet *et al.*, 1986). Nevertheless, these keratinocyte allografts are eventually replaced by recipient cells.

Current allografts utilize neonatal foreskin keratinocytes, which are more responsive than adult cells to mitogens. In addition, they release more growth factors that stimulate adjacent keratinocytes (Gilchrest *et al.*, 1983). Cultured neonatal foreskin allografts promoted accelerated healing and prompt pain relief in a variety of acute and chronic skin ulcers (Phillips *et al.*, 1989). Another major advance was the development of cryopreserved allografts that gave results comparable to those with fresh allografts (Teepe *et al.*, 1990; De Luca *et al.*, 1992). Cryopreserved allografts have been used to cover large wounds with exposed bone and cartilage after Mohs micrographic surgery at a cost of \$150 per application (Kolenik and Leffell, 1995). It is hoped that cryopreservation will allow mass allograft production and wide availability.

## RECOMBINANT GROWTH FACTORS FOR EPIDERMAL WOUNDS

Epithelial-targeted growth factors, such as EGF and more recently KGF, have been investigated as potential treatment for nonhealing epidermal wounds and/or acute large-defect epidermal wounds. EGF was studied in patients with thermal burns and it was shown to accelerate the healing of donor graft sites by 1.5 days (Brown *et al.*, 1989). Although initial clinical investigations of EGF appeared significant (G. L. Brown *et al.*, 1989; G. Brown *et al.*, 1991), later large clinical trials sponsored by the biotechnology and pharmaceutical industries did not confirm therapeutic benefit. Keratinocyte growth factors are the newest members of the FGF family (Werner, 1998). KGF-1 and -2 are secreted by fibroblasts in response to injury and have both mitogenic and motogenic paracrine effects on keratinocytes, particularly those in hair follicles and sebaceous and sweat glands (Pierce *et al.*, 1994; Igarashi *et al.*, 1998). Although exogenous administration of KGF-1 has been shown to stimulate keratinocyte proliferation and reepithelialization in partial-thickness porcine burns, it had no effect on reepithelialization of full-thickness burns (Danilenko *et al.*, 1995). Likewise, KGF-1 stimulated reepithelialization of partial-thickness, but not full-thickness, excisional porcine wounds; however, the thickness of the neoepidermis in both partial- and full-thickness wounds was significantly increased (Staino-Coico *et al.*, 1993). Animal studies with KGF-2 are promising (Jimenez and Rampy, 1999) and clinical investigations with this factor are now in progress. Clinical investigations with recombinant growth factors that target dermal components of the skin, as well as epidermis, will be discussed at the conclusion of the following section on granulation tissue.

## GRANULATION TISSUE

New stroma, often called granulation tissue, begins to form approximately 4 days after injury. The name derives from the granular appearance of newly forming tissue when it is incised and visually examined. Numerous new capillaries endow the neostroma with its granular appearance. Macrophages, fibroblasts, and blood vessels move into the wound space as a unit (Hunt, 1989), which correlates well with the proposed biologic interdependence of these cells during tissue repair. Macrophages provide a continuing source of cytokines necessary to stimulate fibroplasia and angiogenesis, fibroblasts construct new extracellular matrix necessary to support cell ingrowth, and blood vessels carry oxygen and nutrients necessary to sustain cell metabolism. The quantity and quality of granulation tissue depend on biologic modifiers present, the activity level of target cells, and the extracellular matrix environment (Sporn and Roberts, 1986; Juliano and Haskill, 1992). As mentioned previously in the discussion on inflammation, the arrival of peripheral blood monocytes and their activation to macrophages establish conditions for continual synthesis and release of growth factors. In addition, injured and activated parenchymal cells can synthesize and secrete growth factors. The provisional extracellular matrix also promotes granulation tissue formation. Once fibroblasts and endothelial cells express the proper integrin receptors, they invade the fibrin/fibronectin-rich wound space (Fig. 61.2).

## FIBROPLASIA

Components of granulation tissue derived from fibroblasts, including the fibroblast cells and the extracellular matrix, are collectively known as fibroplasia. Cytokines, especially PDGF and TGF- $\beta$  (Heldin and Westermark, 1996; Roberts and Sporn, 1996), in concert with the provisional matrix molecules (Brown *et al.*, 1993; Gray *et al.*, 1993; Xu and Clark, 1996), presumably stimulate fibroblasts of the periwound tissue to proliferate, express appropriate integrin receptors, and

### Integrins in 3 day Cutaneous Wound Repair

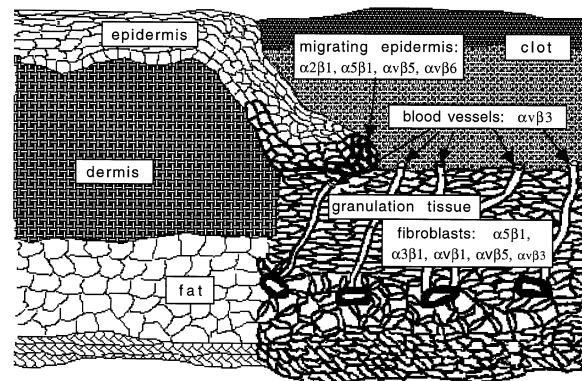

Fig. 61.2. Provisional matrix integrin expression is the rate-limiting step in granulation tissue induction. Once the appropriate integrins are expressed on periwound endothelial cells and fibroblasts on day 3, the cells invade the wound space shortly thereafter (on days 4 and 5). Fibroblasts and endothelial cells express the fibrinogen/fibrin receptor  $\alpha v \beta 3$  and therefore are able to invade the fibrin clot; the epidermis, however, does not express  $\alpha v \beta 3$  and therefore dissects under the clot. Ultimately the clot that has not been transformed into granulation tissue by invading fibroblasts and endothelial cells is dissected free of the wound and sloughed as eschar.

### Integrins in 5 day Cutaneous Wound Repair

migrate into the wound space. Many of these growth factors are released from platelets and macrophages; however, fibroblasts can produce growth factors, to which they respond in an autocrine fashion (Leof *et al.*, 1986; Raines *et al.*, 1989). Multiple complex, interactive biologic phenomena occur within fibroblasts as they respond to wound cytokines, including the induction of additional cytokines (Leof *et al.*, 1986; Raines *et al.*, 1989) and modulation of cytokine receptor number or affinity (Oppenheimer *et al.*, 1983; Assoian *et al.*, 1984). *In vivo* studies support the hypothesis that growth factors are active in wound repair fibroplasia. Several studies have demonstrated that PDGF, PDGF-like peptides, TGF- $\beta$ , TGF- $\alpha$ , HB-EGF, and FGF family members are present at sites of tissue repair (Matsuoka and Grotendorst, 1989; Pierce *et al.*, 1992; Werner *et al.*, 1992; Ansel *et al.*, 1993; Levine *et al.*, 1993; Marikovsky *et al.*, 1993; Frank *et al.*, 1996). Furthermore, purified and recombinant-derived growth factors have been shown to stimulate wound granulation tissue in normal and compromised animals (Sporn *et al.*, 1983; Lynch *et al.*, 1989; Greenhalgh *et al.*, 1990; Mustoe *et al.*, 1991; Steed *et al.*, 1992; Shah *et al.*, 1995), and a single growth factor may work both directly and indirectly by inducing the production of other growth factors *in situ* (Mustoe *et al.*, 1991).

Structural molecules of the early extracellular matrix, termed the "provisional matrix" (Clark *et al.*, 1982), contribute to tissue formation by providing a scaffold or conduit for cell migration (fibronectin) (Greiling and Clark, 1997), low impedance for cell mobility (hyaluronic acid) (Toole, 1991), a reservoir for cytokines (Nathan and Sporn, 1991), and direct signals to the cells through integrin receptors (Damsky and Werb, 1992). Fibronectin appearance in the periwound environment as well as the expression of fibronectin receptors appear to be critical rate-limiting steps in granulation tissue formation (Clark *et al.*, 1996b; Gailit *et al.*, 1996; McClain *et al.*, 1996; Xu and Clark, 1996; Greiling and Clark, 1997). In addition, a dynamic reciprocity between fibroblasts and their surrounding extracellular matrix creates further complexity. That is, fibroblasts affect the extracellular matrix through new synthesis, deposition, and remodeling of the extracellular matrix (Kurkinen *et al.*, 1980; Welch *et al.*, 1990), whereas the extracellular matrix affects fibroblasts by regulating their function, including their ability to synthesize, deposit, remodel, and generally interact with the extracellular matrix (Mauch *et al.*, 1988; Grinnell, 1994; Clark *et al.*, 1995; Xu and Clark, 1996). Thus the interactions between extracellular matrix and fibroblasts dynamically evolve during granulation tissue development.

As fibroblasts migrate into the wound space, they initially penetrate the blood clot composed of fibrin and lesser amounts of fibronectin and vitronectin. Fibroblasts presumably require fibronectin *in vivo* for movement from the periwound collagenous matrix into the fibrin/fibronectin-laden wound space, as they do *in vitro* for migration from a three-dimensional collagen gel into a fibrin gel (Greiling and Clark, 1997). Fibroblasts bind to fibronectin through receptors of the integrin superfamily (Table 61.1) (Hynes, 1992; Yamada *et al.*, 1996). The Arg-Gly-Asp-Ser (RGDS) tetrapeptide within the cell-binding domain of these proteins is critical for binding to the integrin receptors  $\alpha 3\beta 1$ ,  $\alpha 5\beta 1$ ,  $\alpha v\beta 1$ ,  $\alpha v\beta 3$ , and  $\alpha v\beta 5$ . In addition, the CSIII domain of fibronectin provides a second binding site for human dermal fibroblasts via the  $\alpha 4\beta 1$  integrin receptor (Gailit *et al.*, 1993). *In vivo* studies have shown that the RGD-dependent, fibronectin receptors  $\alpha 3\beta 1$  and  $\alpha 5\beta 1$  are up-regulated on periwound fibroblasts the day prior to granulation tissue formation and on early granulation tissue fibroblasts as they infiltrate the provisional matrix-laden wound (Xu and Clark, 1996). In contrast, the non-RGD-binding  $\alpha 1\beta 1$  and  $\alpha 2\beta 1$  collagen receptors on these fibroblasts were either suppressed or did not appear to change appreciably (Gailit *et al.*, 1996; Xu and Clark, 1996).

Both PDGF and TGF- $\beta$  can stimulate fibroblasts to migrate (Seppa *et al.*, 1982; Senior *et al.*, 1985; Postlethwaite *et al.*, 1987) and can up-regulate integrin receptors (Heino *et al.*, 1989; Ahlen and Rubin, 1994; Gailit *et al.*, 1996). Therefore these growth factors may be partially responsible for inducing a migrating-fibroblast phenotype. Interestingly, PDGF increases  $\alpha 3\beta 1$  and  $\alpha 5\beta 1$  while decreasing  $\alpha 1\beta 1$  in cultured human dermal fibroblasts (Gailit *et al.*, 1996). Furthermore, fibronectin- or fibrin-rich environments promote the ability of PDGF to increase  $\alpha 3\beta 1$  and  $\alpha 5\beta 1$ , but not  $\alpha 2\beta 1$ , mRNA steady-state levels by increasing the stability of these mRNA moieties (Xu and Clark, 1996). This suggests a positive feedback loop between the extracellular matrix and extracellular matrix receptors. *In vitro* fibroblast migration has also been observed in response to a variety of chemoattractants, including fragments of the fifth component of complement (Senior *et al.*, 1988); types I, II, and III collagen-derived peptides (Postlethwaite and Kang, 1976); a fi-

bronectin fragment (Postlethwaite *et al.*, 1981); elastin-derived peptides (Senior *et al.*, 1980); and interleukin-4 (Postlethwaite and Seyer, 1991).

Movement into a cross-linked fibrin blood clot or any tightly woven extracellular matrix may also necessitate an active proteolytic system that can cleave a path for migration. A variety of fibroblast-derived enzymes in conjunction with serum-derived plasmin are potential candidates for this task, including plasminogen activator, interstitial collagenase-1 and -3 (MMP-1 and MMP-13, respectively), the 72-kDa gelatinase A (MMP-2), and stromelysin (MMP-3) (Mignatti *et al.*, 1996; Vaalamo *et al.*, 1997). In fact, high levels of immunoreactive MMP-1 have been localized to fibroblasts at the interface of granulation tissue with eschar in burn wounds (Stricklin and Nanney, 1994) and many stromal cells stain for MMP-1 and MMP-13 in chronic ulcers (Vaalamo *et al.*, 1997). Although TGF- $\beta$  down-regulates proteinase activity (Laiho *et al.*, 1987; Overall *et al.*, 1989), PDGF stimulates the production and secretion of these proteinases (Circolo *et al.*, 1991).

Once the fibroblasts have migrated into the wound they gradually switch their major function to protein synthesis (Welch *et al.*, 1990). Ultimately the migratory phenotype is completely supplanted by a profibrotic phenotype characterized by decreased  $\alpha 3\beta 1$  and  $\alpha 5\beta 1$  provisional matrix receptor expression, increased  $\alpha 2\beta 1$  collagen receptor expression, abundant rough endoplasmic reticulum, and Golgi apparatus filled with new collagen protein (Welch *et al.*, 1990; Xu and Clark, 1996). The fibronectin-rich provisional matrix is gradually supplanted with a collagenous matrix (Welch *et al.*, 1990; Clark *et al.*, 1995). Under these conditions, PDGF, which is still abundant in these wounds (Pierce *et al.*, 1995), stimulates extremely high levels of  $\alpha 2\beta 1$  collagen receptor, but not  $\alpha 3\beta 1$  or  $\alpha 5\beta 1$  provisional matrix receptors, supporting the contention that the extracellular matrix provides a positive feedback for integrin expression (Xu and Clark, 1996). TGF- $\beta$ , which is observed in wound fibroblasts at this time (Clark *et al.*, 1995), can induce fibroblasts to produce great quantities of collagen (Ignatz and Massague, 1986; Roberts *et al.*, 1986). IL-4 also can induce a modest increase in types I and III collagen production (Postlethwaite *et al.*, 1992). Because IL-4-producing mast cells are present in healing wounds, as well as fibrotic tissue, they may contribute to collagenous matrix accumulation in these sites.

Once an abundant collagen matrix is deposited in the wound, fibroblasts cease collagen production despite the continuing presence of TGF- $\beta$  (Clark *et al.*, 1995). The stimuli responsible for fibroblast proliferation and matrix synthesis during wound repair were originally extrapolated from many *in vitro* investigations over the past two decades and then confirmed by *in vivo* manipulation of wounds within the past 10 years (Sprugel *et al.*, 1987; Pierce *et al.*, 1991; Schultz *et al.*, 1991). Less attention had been directed toward elucidating the signals responsible for down-regulating fibroblast proliferation and matrix synthesis. Both *in vitro* and *in vivo* studies suggest that  $\gamma$ -interferon may be one such factor (Duncan and Berman, 1985; Granstein *et al.*, 1987). In addition, collagen matrix can suppress both fibroblast proliferation and fibroblast collagen synthesis (Grinnell, 1994; Clark *et al.*, 1995). In contrast, a fibrin or fibronectin matrix has little or no suppressive effect on the mitogenic or synthetic potential of fibroblasts (Clark *et al.*, 1995; Tuan *et al.*, 1996).

Although the attenuated fibroblast activity in collagen gels is not associated with cell death, many fibroblasts in day 10 healing wounds develop pyknotic nuclei (Desmouliere *et al.*, 1995), a cytological marker for apoptosis or programmed cell death (Williams, 1991), as well as other signs of apoptosis. These results in studies of cutaneous wounds and other results in studies of lungs and kidney suggest that apoptosis is the mechanism responsible for the transition from a fibroblast-rich granulation tissue to a relatively acellular scar (Desmouliere *et al.*, 1997). The signal(s) for wound fibroblast apoptosis have not been elucidated. Thus fibroplasia in wound repair is tightly regulated, whereas, in fibrotic diseases such as keloid formation, morphea, and scleroderma, these processes become dysregulated.

## NEOVASCULARIZATION

Fibroplasia would halt if neovascularization failed to accompany the newly forming complex of fibroblasts and extracellular matrix. The process of new blood vessel formation is called angiogenesis (Madri *et al.*, 1996), and has been extensively studied in the chick chorioallantoic membrane and the cornea (Folkman and Shing, 1992). The soluble factors that can stimulate angiogenesis in wound repair are gradually being elucidated (Roesel and Nanney, 1995), but the factors that do stimulate wound angiogenesis are less clear. Angiogenic activity can be recovered from ac-

tivated macrophages as well as various tissues, including the epidermis, soft tissue wounds, and solid tumors. Some years ago acidic or basic fibroblast growth factor (aFGF and bFGF) appeared to be responsible for most of these activities (Folkman and Klagsbrun, 1987), but other molecules have now also been shown to have angiogenic activity. These include vascular endothelial growth factor (VEGF) (Keck *et al.*, 1989), TGF- $\beta$  (Yang and Moses, 1990), TGF- $\alpha$  (Schreiber *et al.*, 1986), tumor necrosis factor  $\alpha$  (TNF- $\alpha$  (Leibovich *et al.*, 1987), platelet factor 4 (PF4) (Montrucchio *et al.*, 1994), angiogenin (Vallee and Riordan, 1997), angiotropin (Hockel *et al.*, 1988), angiopoietin (Suri *et al.*, 1996), interleukin-8 (Koch *et al.*, 1992), PDGF (Battagay *et al.*, 1994), thrombospondin (Nicosia and Tuszynski, 1994), low-molecular-weight substances, including the peptide KGHK (Lane *et al.*, 1994), low oxygen tension, biogenic amines, and lactic acid (Folkman and Shing, 1992), and nitric oxide (NO) (Montrucchio *et al.*, 1997). Some of these factors, however, are intermediaries in a single angiogenesis pathway, for example TNF- $\alpha$  induces PF4, which stimulates angiogenesis through NO (Montrucchio *et al.*, 1997).

Angiogenesis cannot be directly related to proliferation of cultured endothelial cells. In fact, Folkman (Folkman and Shing, 1992) has postulated that endothelial cell migration can induce proliferation. If this is true, endothelial cell chemotactic factors may be critical for angiogenesis. Some factors, of course, may have both mitogenic and chemotactic activities. For example, PDGF (Senior *et al.*, 1985) and EGF (Chen *et al.*, 1994) can be either chemotactic factors or mitogenic factors for dermal fibroblasts.

Besides growth factors and chemotactic factors, an appropriate extracellular matrix is also necessary for angiogenesis. Three-dimensional gels of extracellular matrix proteins have more pronounced effects on cultured endothelial cells than do monolayer protein coats (Feng *et al.*, 1999a), as has been observed with smooth muscle cells (Koyama *et al.*, 1996). Rat epididymal microvascular cells cultured in type I collagen gels with TGF- $\beta$  produce capillary-like structures within 1 week (Madri *et al.*, 1988). Omission of TGF- $\beta$  markedly reduces the effect. In contrast, laminin-containing gels in the absence of growth factors induce human umbilical vein and dermal microvascular cells to produce capillary-like structures within 24 hr of plating (Kubota *et al.*, 1988). Matrix-bound thrombospondin also promotes angiogenesis (Nicosia and Tuszynski, 1994), possibly through its ability to activate TGF- $\beta$  (Schultz-Cherry and Murphy-Ullrich, 1993). We have developed a sprouting angiogenesis assay using neonatal human dermal microvascular endothelial cells (HDMECs) and have shown that fibrin, but not collagen, gels support sprouting angiogenesis (Feng *et al.*, 1999b). These studies support the hypothesis that the extracellular matrix plays an important role in angiogenesis. Consonant with this hypothesis, angiogenesis in the chick chorioallantoic membrane is dependent on the expression of  $\alpha v \beta 3$ , an integrin that recognizes fibrin and fibronectin, as well as vitronectin (Brooks *et al.*, 1994a). Furthermore, in porcine cutaneous wounds  $\alpha v \beta 3$  is expressed only on capillary sprouts as they invade the fibrin clot (Clark *et al.*, 1996b). *In vitro* studies in fact demonstrate that  $\alpha v \beta 3$  can promote endothelial cell migration on provisional matrix proteins (Leavesley *et al.*, 1993).

Given the information outlined above, a series of events leading to angiogenesis can be hypothesized. Substantial injury causes tissue cell destruction and hypoxia. Potent angiogenesis factors such as FGF-1 and FGF-2 are released secondary to cell disruption whereas VEGF is induced by hypoxia. Proteolytic enzymes released into the connective tissue degrade extracellular matrix proteins. Specific fragments from collagen, fibronectin, and elastin, as well as many phylogistic agents, recruit peripheral blood monocytes to the injured site, where these cells become activated macrophages that release more angiogenesis factors. Certain angiogenic factors, such as FGF-2, stimulate endothelial cells to release plasminogen activator and procollagenase. Plasminogen activator converts plasminogen to plasmin and procollagenase to active collagenase and in concert these two proteases digest basement membrane constituents.

The fragmentation of the basement membrane allows endothelial cells to migrate into the injured site in response to FGF, fibronectin fragments, heparin released from disrupted mast cells, and other endothelial cell chemoattractants. To migrate into the fibrin/fibronectin-rich wound, endothelial cells express  $\alpha v \beta 3$  integrin. The newly forming blood vessels first deposit a provisional matrix containing fibronectin and proteoglycans, but ultimately form basement membrane. TGF- $\beta$  may induce endothelial cells to produce the fibronectin and proteoglycan provisional matrix as well as assume the correct phenotype for capillary tube formation. FGF and other mitogens such as VEGF stimulate endothelial cell proliferation, resulting in a continual supply of endothe-

lial cells for capillary extension. Capillary sprouts eventually branch at their tips and join to form capillary loops through which blood flow begins. New sprouts then extend from these loops to form a capillary plexus.

Within a day or two after removal of angiogenic stimuli, capillaries undergo regression as characterized by mitochondria swelling in the endothelial cells at the distal tips of the capillaries, platelet adherence to degenerating endothelial cells, vascular stasis, endothelial cell necrosis, and ingestion of the effete capillaries by macrophages. Although  $\alpha v\beta 3$  has been shown to regulate apoptosis of endothelial cells in culture and in tumors (Brooks *et al.*, 1994b),  $\alpha v\beta 3$  is not present on wound endothelial cells as they undergo programmed cell death, indicating another pathway of apoptosis in healing wound blood vessels (X. Feng, R.A.F. Clark, and M. G. Tonnesen, unpublished observations). Thrombospondin appears to be a good candidate for this phenomenon (DiPietro *et al.*, 1996).

### RECOMBINANT GROWTH FACTORS FOR WOUND HEALING

With the development of recombinant DNA technology the production of large quantities of growth factors is now possible, leading to an increased interest in their potential therapeutic role in wound healing. The four families of growth factors that have shown the greatest potential for enhancing wound repair include the EGF family, the FGF family, the PDGF family, and the TGF- $\beta$  family.

The EGF family of growth factors includes EGF, TGF- $\alpha$ , and HB-EGF. As mentioned in the previous discussion of epithelialization, these growth factors are potent keratinocyte mitogens and motogens (promote cellular motility) that are released at the site of injury (Feliciani *et al.*, 1996). Attempts to enhance healing of burns by application of EGF or TGF- $\alpha$  in animals have led to conflicting results. Although some have noted enhancement (Brown *et al.*, 1989), other studies have failed to demonstrate consistent and significant biologic effects when EGF was applied to either partial- or full-thickness burns in pigs (Danilenko *et al.*, 1995). Limited acceleration of healing of chronic venous stasis ulcers has similarly been demonstrated in humans with EGF (Brown *et al.*, 1991; Falanga *et al.*, 1992).

The family of FGF includes multiple polypeptides that stimulate proliferation of both keratinocytes and fibroblasts. In excisional wound animal models, basic FGF (FGF-2) significantly increases both granulation tissue formation and reepithelialization (Pierce *et al.*, 1992). FGF has been shown to enhance the healing of chronic pressure sores in a limited number of paraplegics (Robson *et al.*, 1992a). Larger studies sponsored by the pharmaceutical industry, however, failed to show clinical benefit.

The superfamily of PDGF includes PDGF and VEGF. PDGF occurs in three isoforms PDGF-AA, -AB, and -BB (Heldin, 1992). The latter two isoforms are the most potent and are secreted by platelets (PDGF-AB), macrophages (PDGF-BB), and epidermal cells (PDGF-BB) in response to injury or other perturbations and cause substantial proliferation of fibroblasts (Heldin and Westermarck, 1996). Application of PDGF to incisional wounds has resulted in more rapid healing. PDGF has also stimulated reepithelialization and granulation tissue formation in animal excisional wound models and burns (Pierce *et al.*, 1992; Danilenko *et al.*, 1995). Clinical trials using PDGF for the treatment of pressure sores and diabetic ulcers have been encouraging, demonstrating more rapid and complete healing in wounds treated with PDGF (Robson *et al.*, 1992b; Steed, 1995). Recombinant PDGF-BB, in fact, is the first recombinant growth factor to gain approval by the Food and Drug Administration (FDA) with an indication to enhance healing of diabetic foot ulcers. This factor has been placed on the market as Regranex by Ortho-McNeil Pharmaceuticals.

VEGF is secreted by keratinocytes and macrophages and induces vascular permeability as well as angiogenesis (Iruela-Arispe and Dvorak, 1997). It has been shown to enhance healing of gastric and duodenal ulcers (Folkman, 1995) and is currently under investigation for use in the treatment of ischemic tissues (Isner, 1997). Other isoforms of VEGF have been described (Veikkola and Alitalo, 1999), but no animal or clinical data are available at this time.

Within another large family, TGF- $\beta$  has three isoforms that are chemotactic for macrophages and are potent stimulators of procollagen type I and fibronectin (Roberts and Sporn, 1996). Multiple animal studies have demonstrated the ability of TGF- $\beta 1$  and TGF- $\beta 2$  to enhance wound healing (Davidson *et al.*, 1985; Mustoe *et al.*, 1987; Ksander *et al.*, 1990). Preliminary human

studies suggest that TGF- $\beta$ 2 may be of benefit in the treatment of venous stasis ulcers (Robson *et al.*, 1995). Both TGF- $\beta$ 1 and TGF- $\beta$ 2 have been shown to increase scar formation in wound models (Border and Noble, 1994), whereas application of neutralizing antibodies has been shown to reduce scarring (Shah *et al.*, 1994). Interestingly, TGF- $\beta$ 3 has also been shown to reduce scar formation in rat incisions (Shah *et al.*, 1995), but this finding is under debate.

### OTHER CYTOKINES

Growth hormone has been studied and found to be of benefit in the treatment of donor sites in both children and adults with extensive burns (Herndon *et al.*, 1990, 1995). Granulocyte-macrophage colony-stimulating factor (GM-CSF) and monocyte colony-stimulating factor (M-CSF) are potent stimulators of monocyte activation and chemotaxis and have been shown to accelerate healing of wounds in rats (Middleton and Aukerman, 1991; Jyung *et al.*, 1994). In contrast, granulocyte colony-stimulating factor (G-CSF) has not had any beneficial effects on wound healing. Interleukin-1 $\beta$ , which is chemotactic for neutrophils and macrophages, has been evaluated in the management of pressure sores (Robson *et al.*, 1994).

Although clinical experience with growth factors and other mediators is limited, overall results have been discouraging. This is not surprising when one considers that wound repair is the result of a complex set of interactions between soluble cytokines, formed blood elements, extracellular matrix, and cells. It is possible that combinations of various mediators given at precisely timed intervals will be more efficacious at promoting wound healing. Indeed, synergistic effects on wound healing have been demonstrated for the following combinations: IGF-1 and PDGF (Lynch *et al.*, 1989; Greenhalgh *et al.*, 1993), TGF- $\alpha$  and PDGF (Brown *et al.*, 1994), and KGF and PDGF (Danilenko *et al.*, 1995).

### DERMAL SUBSTITUTES

The use of cultured keratinocytes to enhance wound healing has met with success, but it lacks a dermal component that would help prevent wound contraction and provide greater mechanical stability. Allografts of cadaver skin containing dermis have been used for many years yet provide only temporary coverage due their rejection by the host. However, this skin can be chemically treated to remove the antigenic epidermal cellular elements (Alloderm; Life Cell Corporation; Woodlands, TX) and has been used alone or in combination with cultured autologous keratinocytes for closure of various wounds and burns (Cuono *et al.*, 1986; Kraut *et al.*, 1995).

In 1981 Burke *et al.* developed a composite skin graft made of a collagen-based dermal lattice (containing bovine collagen and chondroitin 6-sulfate) with an outer silicone covering. After placement on the wound, the dermal component is slowly degraded. Several weeks later the silastic sheet is removed and covered with an autograft. This composite graft has been used successfully to treat burns (Heimbach *et al.*, 1988) and has received FDA approval for this indication (Integra; Integra Life Sciences Corporation; Plainsboro, NJ). A similar product, in which the silastic outer covering is replaced with human keratinocytes and the dermal component includes viable fibroblasts, has also been used successfully in burns and chronic wounds (Boyce *et al.*, 1995).

Another rendition of a dermal substitute is Trancyte (Dermagraft-TC) (Advanced Tissue Sciences Inc.; La Jolla, CA). This consists of an inner nylon mesh in which human fibroblasts are embedded together with an outer silastic layer to limit evaporation. The fibroblasts are lysed in the final product by freeze-thawing. Prior to lysis, the fibroblasts had manufactured collagen, matrix proteins, and cytokines, all of which promote wound healing by the host. Trancyte has been used successfully as a temporary wound coverage after excision of burn wounds (Purdue, 1996), and has been approved by the FDA for this indication. Dermagraft is a modification of this product in which a biodegradable polygalactin mesh is used instead of a silastic layer and the fibroblasts remain viable. Use of this dermal substitute has had limited success in the treatment of diabetic foot ulcers (Genzkow *et al.*, 1996).

### COMBINED DERMAL AND EPIDERMAL SUBSTITUTES

Bell was the first to describe a bilayered model of skin consisting of a collagen lattice with dermal fibroblasts that was covered with epidermal cells (Bell *et al.*, 1981). Modification of this human skin equivalent (HSE) composite consisting of type I bovine collagen and live allogeneic human skin fibroblasts and keratinocytes has been developed (Apligraf; Organogenesis; Canton,

MA). It has been used successfully in surgical wounds (Eaglstein *et al.*, 1995) and venous ulcers (Sabolinski *et al.*, 1996). In a large multicenter trial this product resulted in accelerated healing of chronic nonhealing venous stasis ulcers when compared to standard compressive therapy (Falanga *et al.*, 1998). Both Apligraf (for venous stasis ulcers) and Dermagraft (for diabetic neurotrophic ulcerations) have been available in Canada since 1997. Apligraf has become available in the United States as well, although Dermagraft is still awaiting approval by the FDA.

Several other composite skin substitutes combining dermal and epidermal elements have been developed. Composite cultured skin (CCS; Ortec International Inc.; New York, NY) is composed of both neonatal keratinocytes and fibroblasts embedded in distinct layers of bovine type I collagen. This product is being evaluated in clinical trials for the treatment of burns and in patients with epidermolysis bullosa. More extensive comparative data of the various biologic dressings have been published (Phillips, 1998).

### “SMART” MATRIX FOR WOUND HEALING

Our laboratory has taken an indirect approach to dermal repair, by creating “smart” (a trademark name) matrix constructs that will provide a reparative dressing or packing material for acute and chronic wounds and in addition facilitate granulation tissue formation (patent issued). The first construct will be a recombinant fibronectin mutant composed of the three cell-binding domains (described below) conjugated to a matrix backbone of hyaluronan. Using a testing system (patent issued) wherein fibroblasts move from a collagen gel onto a surface coated with protein, various combinations of recombinant fibronectin fragments (Barkalow and Schwarzbauer, 1994), as well as the enzymatically derived 120-kDa fibronectin fragment, have been tested for their ability to permit fibroblast movement.

The 120-kDa enzymatically derived fragment, which contains cell-binding peptides limited to the classic RGD domain (Pierschbacher and Ruoslahti, 1984) and the PHSRN synergy site (Obara *et al.*, 1988), does not permit fibroblast movement. Furthermore, recombinant proteins containing the Hep II domain (Heparin II domain; HV0) have little, if any activity. However, combinations of the 120-kDa fragment with the Hep II domain do permit fibroblast motility. A recombinant protein containing both the classic cell-binding domain and the Hep II domain also allows movement, but no better than the combination of the 120-kDa fragment and the Hep II domain. These studies demonstrate that the classic cell-binding domain plus the Hep II domain are necessary and sufficient to permit fibroblast movement, but the movement is submaximal compared to intact fibronectin. Maximum movement, however, is attained when the IIIICS domain is present along with the 120-kDa fragment and Hep II domain. A recombinant protein containing the classic cell-binding domain, the Hep II domain, and the IIIICS domain also promotes maximal migration. Thus, the classic cell-binding domain plus the Hep II domain plus the IIIICS domain are necessary and sufficient to allow maximal fibroblast movement compared to intact fibronectin.

In experiments in which synthetic CS1, CS5, and HI through HV fibronectin peptides were added to the fibrin gel, we found that CS1 and CS5, when added separately to the assay, enhanced PDGF-stimulated fibroblast movement from collagen gels into the fibrin gel, whereas HI, HII, HIV, and HV, but not HIII, inhibited this movement. In contrast, when CS1 and CS5 were added to the *in vitro* assay together, they inhibited fibroblast migration. Thus, HI, HII, HIV, HV, and either CS1 or CS5, together with RGDS and possibly PHSRN, are necessary for mesenchymal cell migration.

Composites will be tested for their ability to permit or promote fibroblast transmigration from a collagen organotypic construct into the interstices of the composites. All composites that have the capacity to permit or promote fibroblast migration *in vitro* will be tested for their capacity to promote cutaneous wound repair *in vivo* (McClain *et al.*, 1996). The matrix will be biocompatible and absorbable over a several-week period.

### WOUND CONTRACTION AND EXTRACELLULAR MATRIX REORGANIZATION

During the second and third week of healing, fibroblasts begin to assume a myofibroblast phenotype characterized by large bundles of actin-containing microfilaments disposed along the cytoplasmic face of the plasma membrane and the establishment of cell–cell and cell–matrix link-

ages (Welch *et al.*, 1990). In some (Darby and Gabbiani, 1990), but not all (Welch *et al.*, 1990), wound situations myofibroblasts express smooth muscle actin. Interestingly, TGF- $\beta$  can induce cultured human fibroblasts to express smooth muscle actin (Desmouliere *et al.*, 1993) and may also be responsible for its expression *in vivo*.

The appearance of the myofibroblasts corresponds to the commencement of connective tissue compaction and the contraction of the wound. Fibroblasts link to the extracellular fibronectin matrix through  $\alpha 5\beta 1$  (Welch *et al.*, 1990), to collagen matrix through  $\alpha 1\beta 1$  and  $\alpha 2\beta 1$  collagen receptors (Ignatius *et al.*, 1990), and to each other through direct adherens junctions (Welch *et al.*, 1990). Fibroblast  $\alpha 2\beta 1$  receptors are markedly up-regulated in 7-day-old wounds (Xu and Clark, 1996), a time when new collagenous matrix is accumulating and fibroblasts are beginning to align with collagenous fibrils through cell–matrix connections (Welch *et al.*, 1990). New collagen bundles in turn have the capacity to join end to end with collagen bundles at the wound edge and ultimately to form covalent cross-links among themselves and with the collagen bundles of the adjacent dermis (Yamauchi *et al.*, 1987; Birk *et al.*, 1989). These cell–cell, cell–matrix, and matrix–matrix links provide a network across the wound whereby the traction of fibroblasts on their pericellular matrix can be transmitted across the wound (Singer *et al.*, 1984).

Cultured fibroblasts dispersed within a hydrated collagen gel provide a functional *in vitro* model of tissue contraction (Bell *et al.*, 1979). When serum is added to the admixture, contraction of the collagen matrix occurs over the course of a few days. When observed with time-lapse microphotography, collagen condensation appears to result from a “collection of collagen bundles” executed by fibroblasts as they extend and retract pseudopodia attached to collagen fibers (Bell *et al.*, 1983). The transmission of these traction forces across the *in vitro* collagen matrix depends on two linkage events: fibroblast attachment to the collagen matrix through the  $\alpha 2\beta 1$  integrin receptors (Schiro *et al.*, 1991) and cross-links between the individual collagen bundles (Woodley *et al.*, 1991). This linkage system probably plays a significant role in the *in vivo* situation of wound contraction as well. In addition, cell–cell adhesions and cell–fibronectin linkages appear to provide an additional means by which the traction forces of the myofibroblast may be transmitted across the wound matrix.

F-Actin bundle arrays, cell–cell and cell–matrix linkages, and collagen cross-links are all facets of the biomechanics of extracellular matrix contraction. The contraction process, however, needs a cytokine signal. In fact, cultured fibroblasts mixed in a collagen gel contract the collagen matrix only if serum is added to the medium (Bell *et al.*, 1979). PDGF, the major fibroblast mitogen serum, in fact, stimulates fibroblast contraction of the collagen matrix (Clark *et al.*, 1989). PDGF is abundant in wounds (Ansel *et al.*, 1993), thus it may also provide the signal for wound contraction. TGF- $\beta$  has also been shown to stimulate fibroblast-driven collagen gel contraction (Reed *et al.*, 1994). Because this factor persists in wound fibroblasts during the time of tissue contraction (Clark *et al.*, 1995), it is an additional candidate for the stimulus of contraction. Perhaps both PDGF and TGF- $\beta$  signal wound contraction—one more example of the many redundancies observed in the critical processes of wound healing. In summary, wound contraction represents a complex and masterfully orchestrated interaction of cells, extracellular matrix, and cytokines.

Collagen remodeling during the transition from granulation tissue to scar is dependent on continued collagen synthesis and collagen catabolism. The degradation of wound collagen is controlled by a variety of collagenase enzymes from macrophages, epidermal cells, and fibroblasts. These collagenases are specific for particular types of collagens but most cells probably contain two or more different types of these enzymes (Hasty *et al.*, 1986). Three matrix metalloproteinases have been described that have the ability to cleave native collagen: MMP-1, or classic interstitial collagenase, which cleaves types I, II, III, XIII, and X collagens (Grant *et al.*, 1987); neutrophil collagenase (Hasty *et al.*, 1990); and a novel collagenase produced by breast carcinomas and prominent in chronic wounds (Vaalamo *et al.*, 1997). It is not known whether interstitial collagenases, other than MMP-1, are active in the remodeling stage of human wound repair (Saarialho-Kere *et al.*, 1993; Stricklin and Nanney, 1994).

Other MMPs potentially important in wound repair include two gelatinases, 72-kDa gelatinase A (MMP-2) and 92-kDa gelatinase B (MMP-9), with identical substrate specificity to degrade denatured collagens of all types as well as native types V and XI collagens (Hibbs *et al.*, 1987; Stetler-Stevenson *et al.*, 1989); and stromelysin-1, -2, and -3, which degrade a wide variety of substrates, including types III, IV, V, VII, and IX collagens as well as proteoglycans and glycoproteins

(Saus *et al.*, 1988; Murphy *et al.*, 1991). Although gelatinase A and B are expressed in early wounds (Salo *et al.*, 1994), they may play a lesser role in later tissue remodeling. Gelatinase A is produced constitutively by many cells and is up-regulated only by TGF- $\beta$  (Overall *et al.*, 1991), whereas gelatinase B is subject to regulation by a variety of physiologic signals, because its promoter contains two AP-1 regulatory elements (Huhtala *et al.*, 1991). Two other metalloproteinases that do not belong to the above subgroups are macrophage metalloelastase (Shapiro *et al.*, 1993) and a novel transmembrane metalloproteinase that can activate secreted progelatinase A (Sato *et al.*, 1994). MMP enzymatic activities are controlled by various inhibitor counterparts called tissue inhibitors of metalloproteinases (TIMPs), which are finely regulated during wound repair (Madlener *et al.*, 1998).

Cytokines such as TGF- $\beta$ , PDGF, and IL-1 plus the extracellular matrix clearly play an important role in the modulation of collagenase and TIMP expression *in vivo* (Circolo *et al.*, 1991; Sporn and Roberts, 1992; Huhtala *et al.*, 1995). Interestingly, type I collagen induces MMP-1 expression through the  $\alpha 2\beta 1$  collagen receptor while suppressing collagen synthesis through the  $\alpha 1\beta 1$  collagen receptor (Langholz *et al.*, 1996). Type I collagen also induces expression of  $\alpha 2\beta 1$  receptors (Klein *et al.*, 1991; Xu and Clark, 1996), thus collagen can induce the receptor that signals a collagen degradation–remodeling phenotype. Such dynamic, reciprocal cell–matrix interactions probably occur generally during tissue formation and remodeling processes such as morphogenesis, tumor growth, and wound healing, to name a few.

Wounds gain only about 20% of their final strength by the third week, during which time fibrillar collagen has accumulated relatively rapidly and has been remodeled by myofibroblast contraction of the wound. Thereafter the rate at which wounds gain tensile strength is slow, reflecting a much slower rate of collagen accumulation. In fact, the gradual gain in tensile strength has less to do with new collagen deposition than with further collagen remodeling, with formation of larger collagen bundles and an accumulation of intermolecular cross-links (Bailey *et al.*, 1975). Nevertheless, wounds fail to attain the same breaking strength as uninjured skin. At maximum strength, a scar is only 70% as strong as intact skin (Levenson *et al.*, 1965).

### THERAPIES DESIGNED TO REDUCE SCARRING

Fetal healing is characterized by lack of scarring. The relative lack of TGF- $\beta 1$ , a profibrotic cytokine, in fetal skin may help explain why the fetus heals without scarring (Adzick and Lorenz, 1994). Studies using neutralizing antibodies to TGF- $\beta 1$  and TGF- $\beta 2$ , as well as using TGF- $\beta 3$ , which down-regulates the other TGF- $\beta$  isoforms, have resulted in reduced scarring, supporting the central role of TGF- $\beta 1$  in scar formation (Shah *et al.*, 1995). Several strategies are being used to block TGF- $\beta 1$  and TGF- $\beta 2$  in wounds in an attempt to attenuate scar formation.

# SKIN

Nancy L. Parenteau, Janet Hardin-Young, and Robert N. Ross

## INTRODUCTION

The engineering of skin tissue has been at the forefront of tissue engineering for many years and has now yielded some of the first medical products to emerge from this field of work. This is the result of work over the past 25 years in the areas of keratinocyte cell biology, extracellular matrix biology, collagen scaffolds, polymer scaffolds, and tissue equivalents. The repair of skin using tissue engineering has taken on many forms—from simple to complex. In this chapter the various strategies are discussed, with an emphasis on the biologic relevance of each to normal skin structure and function and the healing of wounds.

Skin wounds normally heal by formation of epithelialized scar tissue rather than by regeneration of full-thickness skin. Consequently, strategies for the clinical management of wound healing have depended historically on providing a passive cover to the site of the wound during the period required for the reparative mechanisms of wound healing: reepithelialization, remodeling of granulation tissue, and formation of scar tissue. Therapy could do little more than facilitate these little understood processes. But recent advances in our understanding of fetal wound healing, the concerted action of several growth factors, the role of the extracellular matrix in regulating the healing process, and the demonstrated ability of epidermal sheet grafts to close severe wounds not raise the possibility of intervening therapeutically in tissue repair by providing lost epithelium, stimulating dermal regeneration, and reconstituting full-thickness skin.

Tissue-engineered skin substitutes composed of autologous epidermal cell sheets (Epicel, Genzyme Tissue Repair, Cambridge, MA), dermal substrates (Integra Artificial Skin, Integra Life Sciences, Plainsboro, NJ; Alloderm, Lifecell Corporation, Woodlands, TX; Dermagraft, Advanced Tissue Sciences, La Jolla, CA), or temporary coverings (Transcyte, Advanced Tissue Sciences and Smith and Nephew) and a human skin equivalent (HSE) composed of both living dermal and epidermal components [Apligraf\* (Graftskin) HSE, Organogenesis Inc., Canton, MA] are now available, or nearly so, for the treatment of acute and chronic wounds. These products represent the first of their kind and are the result of basic research in the biology of skin and wound healing and clinical experience with skin grafts, cultured keratinocyte grafts, acellular collagen matrices, cellular matrices, and cultured composite grafts (Eaglstein and Falanga, 1997; Mian *et al.*, 1992; Palmieri, 1992; Zacchi, *et al.*, 1998).

The dynamics of a chronic wound may be quite different from those of an acute wound. It is not clear in venous ulcers, for instance, what pathologic mechanisms prevent the normal migration of the epidermis over the wound bed. It is hoped, however, that introducing the appropriate factors and living cells into the engineered skin products will provide needed tissue and/or correct the balance of elements, to promote the healing and repair of deep wounds (e.g., burns), large acute wounds, and long-term chronic wounds (e.g., venous ulcers, diabetic ulcers and pressure ulcers).

## SKIN STRUCTURE AND FUNCTION

The passive and active functions of skin are carried out by specialized cells and structures located in the two main layers of skin, the epidermis and the dermis (Fig. 62.1A). Complex functional relationships between these two anatomic structures of skin maintain the normal properties of skin. Tissue engineering applications in skin depend on an understanding of the structural components of skin, their spatial organization, and their functional relationships.

### THE EPIDERMIS

The skin is a physical barrier between the body and the external environment. The outermost layer of skin, the epidermis, must therefore be tough and impermeable to toxic substances or harmful organisms. It must also control the loss of water from the body to the relatively drier external environment. The epidermis is composed primarily of keratinocytes, which form a stratified squamous epithelium (Fig. 62.1). Proliferating cells in the basal layer of the epidermis anchor the epidermis to the dermis and replenish the terminally differentiated epithelial cells lost through normal sloughing from the surface of the skin. These basal cells stop proliferating and terminally differentiate as they move from the basal layer through the suprabasal layers to the surface of the epidermis. Keratin filaments and desmosomes contribute physical strength in the living layers and maintain the integrity of the epidermis.

The most superficial keratinocytes in the epidermis form the stratum corneum, the dead outermost structure that provides the physical barrier of the skin. In the last stages of differentiation, epithelial cells extrude lipids into the intercellular space to form the permeability barrier. The cells break down their nuclei and other organelles and form a highly cross-linked protein envelope immediately beneath their cell membranes. The physically and chemically resilient protein envelope connects to a dense network of intracellular keratin filaments to provide further physical strength to the epidermis. The cornified envelopes serve as the bricks and the lipids as mortar of the stratum corneum.

Additional cells and structures in the epidermis perform specialized functions (Fig. 62.1A). Skin plays a major role in alerting the immune system to potential environmental dangers. The interacting cells in skin comprise a dynamic network capable of sensing a variety of perturbations (trauma, ultraviolet irradiation, toxic chemicals, and pathogenic organisms) in the cutaneous environment and rapidly sending appropriate signals that alert and recruit other branches of the immune system (Streilein, 1983; Bos and Kapsenberg, 1993). To restore homeostasis in the skin immune system, the multiple proinflammatory signals generated by skin cells must eventually be counterbalanced by mechanisms capable of promoting resolution of a cutaneous inflammatory response. Dendritic cells of the immune system (Langerhans cells) reside in the epidermis and form

a network of dendrites through which they interact with adjacent keratinocytes and nerves (Streilein and Bergstresser, 1984). Melanocytes distribute melanin to keratinocytes in the form of melanosomes. Melanin protects the epidermis and underlying dermis from ultraviolet radiation. Sweat glands help to regulate body temperature through evaporation of sweat secreted onto the skin surface. Sebaceous glands associated with hair follicles secrete sebum, an oily substance that lubricates and moisturizes hair and epidermis. Hair keeps the body warm in many mammals, although maintaining body temperature is not an important role for hair in humans. Hair follicles, however, are an important source of proliferating keratinocytes during reepithelialization after severe wounds.

## THE DERMIS

The dermis underlies the epidermis. The dermis is divided into two regions: the papillary dermis, which lies immediately beneath the epidermis, and the deeper reticular dermis. The reticular dermis is more acellular and has a denser meshwork of thicker collagen and elastic fibers compared with the papillary dermis. The reticular dermis provides skin with most of its strength, flexibility, and elasticity. Loss of reticular dermis can often lead to excessive scarring and wound contraction.

The dermis provides physical strength and flexibility to skin as well as the connective tissue scaffolding that supports the extensive vasculature, lymphatic system, and nerve bundles. The dermis is relatively acellular, being composed predominantly of an extracellular matrix of interwoven collagen fibrils. Interspersed among the collagen fibrils are elastic fibers, proteoglycans, and glycoproteins.

Fibroblasts, the major cell type of the dermis, produce and maintain most of the extracellular matrix. Endothelial cells line the blood vessels and play a critical role in the skin immune system by controlling the extravasation of leukocytes. Cells of hematopoietic origin in the dermis (e.g., macrophages, lymphocytes) contribute to surveillance function. A network of nerve fibers extends throughout the dermis, which serves a sensory role in the skin (and, to a more limited extent, a motor function). These nerve fibers also secrete neuropeptides that influence immune and inflammatory responses in skin through their effects on endothelial cells, leukocytes, and keratinocytes (Williams and Kupper, 1996).

## IMMUNOLOGY AND THE SKIN

The first stage in the induction of a primary immune response in skin is the processing of antigen by dendritic cells (Langerhans cells with dermal dendritic cells), the antigen-presenting cells in skin. These cells process antigen and migrate out of the skin to the draining lymph node, where they can recruit and activate T cells. The interaction of keratinocytes and fibroblasts with T cells has important implications for the use of allogeneic cells in tissue engineering. Under normal conditions, keratinocytes and fibroblasts do not express major histocompatibility complex (MHC) class II antigens; they can be induced, however, by interferon- $\gamma$  to express MHC-class II molecules and thereby acquire the ability to present antigen to T cells. Because the keratinocytes and fibroblasts are deficient in the necessary costimulatory molecules (Nickoloff and Turka, 1994; Phipps *et al.*, 1989), antigen presentation by keratinocytes and fibroblasts does not result in T cell activation. Instead, this antigen presentation can result in T cell nonresponsiveness (Gaspari and Katz, 1988; Bal *et al.*, 1990) or T cell anergy (Gaspari and Katz, 1991). Therefore, the primary mode of skin rejection is likely mediated via an attack on the vasculature present in a normal skin graft (Poher *et al.*, 1986; Moulon *et al.*, 1999).

Autologous skin grafts avoid issues of immunogenicity, of course, but autologous grafts have significant limitations. Growing graft tissues from biopsy takes several weeks, the donor site creates another wound, and in some patients (e.g., severe burn patients) there may be no appropriate donor site. Reproducibly making complex HSE constructs to order from autologous cells would be technically difficult, time consuming, and very costly. Therefore, our ability to effectively use allogeneic human cells is a key element in the success of engineered skin replacements.

## THE PROCESS OF WOUND HEALING

The immediate tissue response to wounding is clot formation to stop bleeding. Simultaneously, there is a release of inflammatory cytokines that regulate blood flow to the area, recruit lymphocytes and macrophages to fight infection, and later stimulate angiogenesis and collagen depo-

sition (Williams and Kupper, 1996). These latter processes result in the formation of granulation tissue, a highly vascularized and cellular wound connective tissue. Fibroblasts rich in actin, called myofibroblasts (Desmouliere and Gabbiani, 1996), are recruited through the action of factors such as platelet-derived growth factor (PDGF) and transforming growth factor  $\beta$  (TGF- $\beta$ ). Granulation tissue forms in the wound bed, stimulated by factors such as PDGF. This tissue is gradually replaced by scar tissue through the action of the myofibroblasts and factors such as TGF- $\beta$ . Keratinocytes are stimulated to proliferate and to migrate into the wound bed to restore epidermal coverage. From our preclinical observations using both full-thickness HSE and dermal matrices, coverage by the epidermis appears to play a key role in the regulation of the underlying inflammatory response. Providing a noninflammatory living connective tissue implant in the wound defect also appears to be beneficial in directing the granulation response.

As this brief description shows, wound healing involves the interaction of many tissue factors and elements. The poor healing response in chronic wounds has been attributed to an imbalance of factors rather than to an insufficiency of any particular factor (Parenteau *et al.*, 1997). However, most, if not all, factor-based approaches have had marginal success. Identification of putative wound healing factors has led to several attempts to speed wound healing by local application of one or more factors that promote cell attachment and migration. Transforming growth factor- $\beta$ , epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), and platelet-derived growth factor have been candidates for this purpose (McKay and Leigh, 1991; Martin *et al.*, 1992; Abraham and Klagsbrun, 1996; Nanney and King, 1996; Roberts and Sporn, 1996). Of these, only PDGF has shown efficacy in clinical trials and is approved for clinical use (Regranex, Ortho McNeil, Inc., Raritan, NJ). The arginine-glycine-aspartic acid (RGD) matrix peptide sequence has been found to promote the migration of connective tissue cells, and thus stimulate production of a dermal scaffold within the wound bed. This approach has been shown to accelerate healing of sickle cell leg ulcers (Wethers *et al.*, 1994) and diabetic ulcers (Steed *et al.*, 1995), compared with placebo, but not when compared with standard care. In addition, complex cell extracts have been used in hopes of providing the appropriate mixture of elements. These include the use of platelet extract to provide primarily platelet-derived growth factor (Knighton *et al.*, 1989), and the use of keratinocyte extracts to provide a complex mixture of elements of rapidly growing keratinocytes (Duinslaiger *et al.*, 1994); again, effects have been marginal, in part due to the complex nature of the wound healing response (Nathan and Sporn, 1991). In addition, the use of factors is not a sufficient approach, in and of itself, in situations where there is severe or massive loss of skin tissue.

Why should living tissue be different in its response? The epidermal and dermal responses are regulated by inflammatory cytokines and by autocrine and paracrine factors produced by the dermal fibroblasts and epidermal keratinocytes (Ansel *et al.*, 1990; McKay and Leigh, 1991). These factors regulate growth and differentiation of keratinocytes, proinflammatory reaction, angiogenesis, and deposition of extracellular matrix. Living tissue created through tissue engineering can provide complex temporal control of factor delivery and effect and can be used to provide the needed combination of chemical, structural, and, last but not least, normal cellular elements (Marks *et al.*, 1991; Sabolinski *et al.*, 1996).

### CELL COMMUNICATION AND REGULATION IN THE SKIN

Regulation of its own function is an essential requirement of skin. Epidermis, for example produces parathyroid hormone-related protein (PTHrP), and plays a role in the regulation of keratinocyte growth and differentiation (Blomme *et al.*, 1998). Keratinocytes produce a large variety of polypeptide growth factors and cytokines; these act as signals between cells, regulate keratinocyte migration and proliferation, and stimulate dermal cells in various ways (e.g., to promote matrix deposition and neovascularization) (McKay and Leigh, 1991; Parenteau *et al.*, 1997). Cytokines produced by keratinocytes are thought to regulate Langerhans cell migration and differentiation (Lappin *et al.*, 1996). Keratinocytes also translate a variety of stimuli into cytokine signals, which are transmitted to the other cells of the skin immune system. Dermal cells produce and respond to cytokines and growth factors to regulate numerous processes critical to skin function (Williams and Kupper, 1996).

Approaches to dermal repair and regeneration center around control of fibroblast repopulation and collagen biosynthesis to limit scar tissue formation. One of the keys to improving dermal

repair is control, or redirection, of the wound healing response so that scar tissue does not form. One promising observation is that fetal wounds heal without scarring (Mast *et al.*, 1992). TGF- $\beta$ 1, which is not expressed in the fetus, is a potent stimulator of collagen biosynthesis by fibroblasts in the adult and is thought to be an important inducer of scar formation. The matrix composition of the fetal dermis is also significantly different than that of adult dermis or granulation tissue, therefore providing a better matrix environment for dermal cell repopulation, which may also be key in controlling scar formation.

An engineered skin graft should incorporate as many of these factors as possible: (1) the extracellular matrix, (2) dermal fibroblasts, (3) the epidermis, and (4) a naturally occurring semi-permeable membrane, the stratum corneum. These components may act alone, but more importantly they should act synergistically as part of a fully integrated tissue to protect the underlying tissues of a wound bed and to direct healing of the wound (Sabolinski *et al.*, 1996). Dermis containing fibroblasts may be necessary for the maintenance of the epidermal cell population (Lazarus *et al.*, 1994). In turn, the epidermis is necessary for the formation of the so-called neoderms, in the absence of a dermal layer (Compton *et al.*, 1989), and can dramatically influence underlying connective tissue response. The formation of the epidermal barrier also likely influences these processes through control of water loss and its influence on epidermal physiology (Parenteau *et al.*, 1996).

## ENGINEERING SKIN TISSUE

Although the epidermis has an enormous capacity to heal, there are situations in which it is necessary to replace large areas of epidermis or in which normal regeneration is deficient. The dermis has very little capacity to regenerate. The scar tissue that forms in the absence of dermis lacks the elasticity, flexibility, and strength of normal dermis. Consequently, scar tissue limits movement, causes pain, and is cosmetically undesirable. Engineered tissues that not only close wounds but also stimulate the regeneration of dermis would provide a significant benefit in human wound healing.

## DESIGN CONSIDERATIONS

Tissue engineering has not focused on regenerating certain skin structures, such as hair follicles or sebaceous glands, the loss of which is clinically less significant than the loss of dermis and epidermis, which are needed to cover and protect the underlying tissues. There is some preliminary evidence that sebaceous glands may be possible in the HSE (Wilkins *et al.*, 1994), although the development of functioning adnexal structures is likely to be years away. There has also been little need to stimulate extraneously the regeneration of other dermal components (e.g., blood vessels and cells of the immune system) through tissue engineering methods because these components have the ability to repopulate quickly and to normalize the area of a wound. Langerhans cells, for example, have been shown to migrate and repopulate effectively within months (Desmouliere and Gabbiani, 1996). Control of vascularization is dependent on the makeup of the extracellular matrix and the degree of inflammation present in the wound. Whether modification of vascularization through the use of exogenous factors will be of additional benefit for certain wounds remains to be determined. Although it is technically possible to add melanocytes to HSE for pigmentation (L. Wilkins, personal communication), clinical studies using Apligraf HSE, which essentially lacks melanocytes, have shown repigmentation of the grafted areas through repopulation of the area with host melanocytes, resulting in normal skin color for each individual. Therefore, tissue engineering approaches have primarily focused on providing or imitating structural and biologic characteristics of dermis, epidermis, or both. Some technologies, such as the HSE, have sought to reproduce living, full-thickness tissue for transplantation.

The key features to be replicated in an engineered skin construct are as follows:

1. A dermal or mesenchymal element capable of aiding appropriate dermal repair and epidermal support.
2. An epidermis capable of easily achieving biologic wound closure.
3. An epidermis capable of rapid reestablishment of barrier properties.
4. A permissive milieu for the components of the immune system, nervous system, and vasculature.

5. A tissue capable of achieving normalization of structure and additional function such as reduction of long-term scarring and reestablishment of pigmentation.

## EPIDERMAL REGENERATION

Reepithelialization of the wound is a paramount concern. Without epithelial coverage, no defense exists against contamination of the exposed underlying tissue or loss of fluid. The approaches to reestablishing epidermis are numerous, ranging from the use of cell suspensions to full-thickness skin equivalents possessing a differentiated epidermis. Silicone membranes have been used as temporary coverings in conjunction with dermal templates (Heimbach *et al.*, 1988), but living epidermal keratinocytes are necessary to achieve permanent, biologic wound closure.

Green *et al.* (1979; Phillips *et al.*, 1989) developed techniques for growing human epidermal keratinocytes from small patient biopsy samples using coculture methods (Rheinwald and Green, 1975). The mouse 3T3 fibroblast feeder cell system allows substantial expansion of epidermal keratinocytes and can be used to generate enough thin, multilayered epidermal sheets to resurface the body of a severely burned patient (Gallico *et al.*, 1984). Once transplanted, the epidermal sheets quickly form epidermis and reestablish epidermal coverage (Compton, 1993). With time, the cultured epithelial autograft (CEA) stimulates formation of new connective tissue ("neodermis") immediately beneath the epidermis (Compton *et al.*, 1989), but scarring and wound contraction remain significant problems (Sheridan and Tompkins, 1995). Studies have shown that grafting of CEA onto pregrafted cadaver dermis greatly improves graft take (Odessey, 1992). Cultured epithelial autografts (Epicel) have been available since the late 1980s.

## DERMAL REPLACEMENT

Human cadaver allograft skin has been used when autologous skin grafts are not possible. Problems associated with human cadaver allografts include the possibility of an immune rejection reaction, potential for infection, and problems of supply and variability in the quality of the material. Decellularized dermal tissue has also been used in an attempt to recapitulate as much of the normal architecture as possible while providing a natural scaffold for reepithelialization (Middelkoop *et al.*, 1995; Langdon *et al.*, 1988; Livesey *et al.*, 1995; Cuono *et al.*, 1986). Cadaver allograft dermis can be processed to make an immunologically inert, acellular dermal matrix with an intact basement membrane to aid the "take" and healing of ultrathin autografts (AlloDerm) (Lattari *et al.*, 1997). Currently, only the upper papillary layer of dermis is used clinically (AlloDerm). One limitation to this approach is that deep dermis and the more superficial papillary layer differ in architecture. The deep reticular dermis is needed to prevent wound contraction. Work is being done to develop a similar type of implant derived from deeper reticular dermis. Providing an appropriate scaffold for deep dermal repair remains a challenge for groups investigating native as well as synthetic matrices.

Tissue engineering has investigated the possibility of redirecting granulation tissue formation through the use of scaffolds and living cells. In one of the earliest tissue engineering approaches to improving dermal healing, Yannas *et al.* (1982) designed a collagen-glycosaminoglycan sponge to serve as a scaffold or template for dermal extracellular matrix. The goal was to promote fibroblast repopulation in a controlled way that would decrease scarring and wound contraction. A commercial version of this material composed of bovine collagen and chondroitin sulfate, with a silicone membrane covering (Integra, Integra Life Sciences, Plainsboro, NJ) is currently approved for use in burns (Burke *et al.*, 1981; Heimbach *et al.*, 1988). The dermal layer is slowly resorbed, and the silicone membrane is eventually removed, to be replaced by a thin autograft (Lorenz *et al.*, 1997).

Several variations on the collagen sponge have been studied. Efforts have been made to improve fibroblast infiltration and collagen persistence by collagen cross-linking (Middelkoop *et al.*, 1995; vanLuyn *et al.*, 1995; Cooper *et al.*, 1996), by inclusion of other matrix proteins (Hansbrough *et al.*, 1989; Ansel *et al.*, 1990; de Vries *et al.*, 1993; Murashita *et al.*, 1996), with hyaluronic acid (Cooper *et al.*, 1996), and by modifying porosity of the scaffold (Hansbrough *et al.*, 1989; Yannas *et al.*, 1989).

Although matrix scaffolds have shown some improvement in scar morphology, no acellular matrix has yet been shown to lead to true dermal regeneration. This may be due in part to limits

in cell repopulation, the type of fibroblast repopulating the graft (J. Gross, personal communication), and control of the inflammatory and remodeling processes (i.e., the ability of the cells to degrade old matrix while synthesizing new matrix). The inflammatory response must be controlled in dermal repair in order to avoid the formation of scar tissue. Therefore, dermal scaffolds must not be inflammatory and must not stimulate a foreign-body reaction. This has been a problem in the past for some glutaraldehyde cross-linked collagen substrates, for example (de Vries *et al.*, 1993). The ability of the matrix to persist long enough to redirect tissue formation must be balanced with effects of the matrix on inflammatory processes. One way to achieve this is to form a biologic tissue that is recognized as living tissue, not a foreign substance.

There have been advances in the design of artificially grown dermal tissues using human neonatal fibroblasts grown on rectangular sheets of biodegradable mesh (Dermagraft). The fibroblasts propagate among the degrading fibers, producing extracellular matrix in the interstices of the mesh (Hansbrough *et al.*, 1992). Clinical trials of this material are ongoing and the material is commercially available in some European countries and Canada. A related product is a nonviable temporary covering for burns. In this case a nylon mesh, coated with porcine collagen, layered with a nonpermeable silicone membrane (Biobrane, Dow Hickam, Sugarland, TX), serves as a platform for deposition of human matrix proteins and associated factors by the human dermal fibroblast (Transcyte, Dermagraft-TC) (Hansbrough *et al.*, 1997). The material is then frozen to preserve the matrix and factors produced by the fibroblasts. The temporary covering must be removed prior to autografting. It is commercially available for the treatment of second- and third-degree burns (Hansbrough, 1997).

## COMPOSITE SKIN GRAFTS

Human skin autograft has been the gold standard for resurfacing the body and closing wounds that are difficult to heal. Cultured epidermal grafts are more likely to take when the dermal bed is relatively intact, probably because dermal factors influence epithelial migration, differentiation, attachment, and growth (Cuono *et al.*, 1987; Phillips *et al.*, 1990; Clark, 1993; Greiling and Clark, 1997). The epidermis and dermis act synergistically to maintain homeostasis (Leary *et al.*, 1992; Parenteau *et al.*, 1997).

Boyce *et al.* have modified the approach first proposed by Yannas *et al.* to form a bilayered composite skin made using a modified collagen–glycosaminoglycan substrate seeded with fibroblasts and overlaid with epidermal keratinocytes (Boyce and Hansbrough, 1988). An autologous form of this composite skin construct has been used to treat severe burns with some success (Hansbrough *et al.*, 1989). An allogeneic form of the construct showed improved healing in a pilot study in chronic wounds (Boyce *et al.*, 1995). A similar technology has been studied in the treatment of patients with genetic blistering diseases (Eisenberg and Llewelyn, 1998).

One of the first attempts to replicate a full-thickness skin graft was by Bell *et al.* (1981), who described a bilayered skin equivalent. The dermal component consisted of a lattice of type I collagen contracted by tractional forces of rat dermal fibroblasts trapped within the gelled collagen. This contracted lattice was then used alone or as a substrate for rat epidermal keratinocytes. Bell's group demonstrated the ability of these primitive skin equivalents to take as a skin graft in rats. This technology has now advanced to enable the production of large amounts of human Apligraf HSE from a single donor (Wilkins *et al.*, 1994). Using methods of organotypic culture, which provides a three-dimensional culture environment that is permissive for proper tissue differentiation, the resulting HSE develops many of the structural, biochemical, and functional properties of human skin (Parenteau *et al.*, 1992; Bilbo *et al.*, 1993; Nolte *et al.*, 1993).

The process for formation of the HSE has been covered in detail many times (Parenteau, 1994; Wilkins *et al.*, 1994) and will not be detailed here. However, there are points to be made about the approach to these procedures. The culture of the HSE proceeds best with minimal intervention. Normal cell populations seem to have an intrinsic ability to reexpress their differentiated program *in vitro* to an extent that is now only beginning to be appreciated (Parenteau, 1999). A medium that supplies adequate amounts of nutrients, lipid precursors, vitamins, and minerals may be all that is required (Wilkins *et al.*, 1994). Another element is the environmental stimulus provided by culture at the air–liquid interface, which promotes differentiation and formation of the epidermal barrier (Nolte *et al.*, 1993).

The immunology of allogeneic tissue-engineered skin grafts is poorly understood. Inconsistencies in the literature are due, in part, to the complexity of biologic and immunologic factors, which determine the ability of a graft to take and to persist over time. Among the properties that determine the immunogenicity of an engineered allogeneic graft are purity of cell populations, antigen-presenting capabilities of graft cells, and the vascularity of the graft.

Purity of cell populations is critical. Differences in cell purity between laboratories may contribute to the conflicting results found in murine and human studies (Hefton *et al.*, 1983; Thivolet *et al.*, 1986; Geilen *et al.*, 1987; Aubock *et al.*, 1988; Cairns *et al.*, 1993). Both culture condition and passage number will affect the purity of cell populations. Very early passages of keratinocyte and fibroblast cultures might be expected to contain contaminating cell populations. The antigen-presenting capabilities of keratinocytes and fibroblasts are also critical to determining the immunogenicity of the HSE grafts. Fibroblasts and keratinocytes are not professional antigen-presenting cells and fail to stimulate the proliferation of allogeneic T cells (Nickoloff *et al.*, 1986; Niederwieser *et al.*, 1988; Gaspari and Katz, 1991; Theobald *et al.*, 1993). Both of these cell populations inherently do not express HLA class II molecules (Nickoloff *et al.*, 1985) or costimulatory molecules such as B7-1 (Nickoloff *et al.*, 1993). The inability of keratinocytes and fibroblasts to induce proliferation of allogeneic T cells is primarily due to the lack of expression of costimulatory molecules, even though aberrant antigen processing and invariant chain expression may also contribute (Nickoloff and Turka, 1994).

The ability to utilize allogeneic cells rather than autologous cells, as in CEA therapy, enables the reproducible manufacture of consistent Apligraf HSE (Wilkins *et al.*, 1994). The inability of epidermal keratinocytes and dermal fibroblasts to stimulate a T cell response, discussed above, permits their use in allogeneic applications. Studies in athymic mice also indicate that the use of a differentiated tissue such as the Apligraf HSE also beneficially affects its ability to engraft successfully (Nolte *et al.*, 1994; Parenteau *et al.*, 1996). Severe combined immunodeficient (SCID) mice lack a functioning immune system and can be successfully transplanted with a functioning human immune system without risk of rejection. SCID mice transplanted with human leukocytes were used as an *in vivo* model to assess the immunogenicity of allogeneic skin grafts (Moulon *et al.*, 1999). In these studies, human skin was rejected but allogeneic tissue-engineered skin graft survival was 100%.

Falanga *et al.* (1998) tested the safety, efficacy, and immunologic impact of Apligraf HSE (Graftskin) in the treatment of venous leg ulcers. There were no signs of rejection or bovine collagen-specific immune responses or response to alloantigens expressed on keratinocytes or fibroblasts. Apligraf HSE (Graftskin) has now been studied clinically in a number of applications, including chronic wounds (Sabolinski *et al.*, 1996), dermatologic excisions, and burns. Its effectiveness in the treatment of venous leg ulcers has been attributed to its ability to interact with the wound in multiple ways (Sabolinski *et al.*, 1996). The integrated tissue architecture of Apligraf HSE provides a robustness needed for clinical manipulation. The pivotal study by Falanga *et al.* (1998) of Apligraf HSE for the treatment of venous leg ulcers showed Apligraf HSE to be safe and effective, healing more ulcers in shorter time when compared to conventional therapy. Data from this study served as the basis for approval by the United States Food and Drug Administration for commercial use. A study of Apligraf HSE (Graftskin) in surgical patients showed take in 12 of 15 patients and also showed no evidence of rejection (Eaglstein *et al.*, 1995). In addition, Apligraf HSE has been studied in burns (Waymack *et al.*, 2000) and diabetic foot ulcers, and most recently, in the treatment of genetic blistering diseases (Falabella *et al.*, 1999).

The living epidermal keratinocytes and the dermal fibroblasts produce cytokines, which serve to regulate themselves, each other, and the cells of the patient. The living dermal extracellular matrix contains collagen and glucosaminoglycans, which serve as noninflammatory living tissue implants and scaffolds for tissue remodeling. The stratum corneum provides physical protection and maintains the proper physical and biologic environment for wound closure. Application of Apligraf HSE (Graftskin) can trigger a cascade of events that lead to normal healing even in the absence of graft take. In this regard, the HSE serves as a "smart material," providing the appropriate factors as needed, responding to the dynamics of the wound healing process, and beneficially changing the condition of the wound, even though the HSE may not always persist as a graft. Our clinical observations and results lead us to believe that all factors are important contributors to the wound healing process (Sabolinski *et al.*, 1996).

## CONCLUSION

The routine treatment of skin wounds using engineered skin grafts has become a reality thanks to a firm scientific foundation established over the past 25 years, a readily available cell source (infant foreskin tissue), and the hard work and dedication of many individuals. Perhaps more importantly, our experience with the development of Apligraf HSE demonstrates that making a broadly available, effective medical device through tissue engineering is possible. It also illustrates the important immune tolerance of certain allogeneic cells. In addition, Apligraf HSE demonstrates the flexibility and broad utility of living tissue therapy.

# DERMAL EQUIVALENTS

Gail K. Naughton

## INTRODUCTION

Tissue engineering, the science of growing living tissues for transplantation, promises to revolutionize a number of aspects of medical care. This science integrates the principles of cell biology, polymer development, biochemistry, bioengineering, and transplantation science to create human physiologic tissues to replace damaged and diseased areas. Tissue engineering offers the ability to create highly tested physiologic human tissues and organs for transplantation. The most advanced area in tissue engineering is the manufacture of skin for the treatment of patients with burns or chronic wounds, with initial products having already received regulatory approval in the United States and other global markets. A number of approaches have been utilized to tissue-engineered skin substitutes. Such approaches have included cellular bovine-based (Yannas and Burke, 1980) human cadaveric materials (Sheridan *et al.*, 1998) and animal collagens containing human cells (Bell *et al.*, 1984; Hansbrough *et al.*, 1989; Eisenberg and Llewelyn, 1998). This chapter describes the development, manufacturing, and clinical development of a human dermal equivalent manufactured by growing newborn allogeneic human dermal fibroblasts on a biodegradable three-dimensional scaffold to produce a human cell and human tissue implant for a variety of wounds (Naughton and Tolbert, 1996).

## CELL TESTING AND ESTABLISHMENT OF MANUFACTURING CELL BANKS

Tissue-engineered products offer advantages over cadaveric materials in that the cells utilized, as well as the final manufactured product, are highly tested for a variety of viruses, contaminants, and pathogens. The human fibroblast cell strains used to produce the human dermal equivalent, Dermagraft (Dg) (Advanced Tissue Sciences, Inc., La Jolla, CA), are established from neonatal foreskin (discarded after surgical circumcision) (Kruse and Patterson, 1973; Jakoby and Pastan, 1979) and cultured by standard methods. Maternal blood samples are tested for exposure to infectious diseases, including human immunodeficiency virus (HIV), human T cell lymphotropic virus (HTLV), herpes simplex virus (HSV), cytomegalovirus (CMV), and hepatitis virus. An initial screen is made of the cultured cells for sterility, mycoplasma, and for the eight human viruses: adeno-associated virus, HSV-1 and -2, CMV, HIV-1 and -2, and HTLV-I and -II. Master cell banks (MCBs) and manufacturer's working cell banks (MWCBs) are created and tested according to applicable sections of the U.S. Food and Drug Administration (FDA) points to consider (1993) and the guidelines from the European Union Committee for Proprietary Medicinal Products (CPMP) (1989). This testing provides a more uniform and highly tested product than is available from cadaveric donors (tissue banks) (Blood *et al.*, 1979; White *et al.*, 1991).

## MANUFACTURING A DERMAL REPLACEMENT

Dermagraft is manufactured through the three-dimensional cultivation of human diploid fibroblast cells on a polymer scaffold. The fibroblasts secrete a mixture of growth factors and matrix

proteins to create a living dermal structure that, following cryopreservation, remains metabolically active after being implanted into the patient's wound bed (Cooper *et al.*, 1991; Landeen *et al.*, 1992). This dermal product was designed to be shipped and stored at  $-70^{\circ}\text{C}$ . Cryopreservation of a tissue-engineered product offers the advantage of extensive sterility and cell and matrix testing, ensuring the release of only sterile, uniform, and reproducible products.

### CLOSED MANUFACTURING SYSTEMS

A closed bioreactor system is utilized for the manufacture of Dermagraft. This closed system offers major advantages, including the maintenance of sterility during manufacture, the ability to utilize in-process testing to maintain cell growth and matrix deposition, and the use of automated processes for tissue growth. The rate of deposition of matrix proteins during growth in the bioreactor system is shown in Fig. 63.1, showing that matrix is deposited in both growth-associated (glycosaminoglycans) and non-growth-associated patterns (human collagens).

A series of Dermagraft products is created by seeding the polymer scaffolds at passage 8. This is a population doubling level of approximately 30 (which is about half the life-span for this cell type). Utilization of fibroblasts from neonatal foreskins offers a number of advantages, including the fact that these young cells actively proliferate under routine cell culture conditions and are from a uniform source (same sex, age, and anatomical location), helping reduce variability of starting material as well as final manufactured product. Fibroblasts are seeded into multicavity EVA bags containing a  $5 \times 7.5$  cm piece of knitted lactic acid/glycolic acid copolymer, mesh which is welded into the bag to prevent movement during the growth process or loss of the implant during rinse of the product prior to implantation. Seeded bags are rotated to enhance uniform cell seeding and are cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with bovine calf serum, glutamine, ascorbate and nonessential amino acids (growth medium), with periodic changes of medium. Tissue is grown under static conditions with medium, changes being made by peristaltic pumping within the closed system. Samples of medium are routinely taken to test for pH and glucose utilization and to predict the precise time for tissue harvest. At harvest, the medium is drained and replaced by a 10% dimethyl sulfoxide-based cryopreservative solution.

Manufacturing, cryopreservation, storage, shipping, and thawing protocols were all established to maintain integrity and metabolic activity of this tissue-engineered implant. The final product is a 2-inch by 3-inch tissue in a laser-welded EVA bioreactor (Fig. 63.2). This bioreactor design allows for use of an EVA container for sterilization, seeding, tissue growth, freezing, shipping, and product storage and prevents any need for product repackaging. The up-scaled bioreactor systems are designed to manufacture over 1000 units of Dermagraft per lot. A cross-section of the dermal implant clearly shows the physiologic characteristics of this product, with human fibroblasts arranged in parallel and surrounded by naturally secreted human matrix proteins.

The bioreactor containing the engineered dermal implant is translucent to allow tracing of the wound and precise trimming of the implant with sterile scissors. Dermagraft is cut to wound size, removed from the ethylvinylacetate (EVA) package, and placed into the wound bed. No su-

tures are required. Dressings are utilized to ensure that the dermal implant remains in place, is kept moist during integration into the patient's wound bed, and functions as a replacement dermis.

### PRODUCT CHARACTERIZATION

Dermagraft has been designed to replace the dermal layer of the skin and provide the stimulus for the normal wound healing process. Characterization studies have shown that Dermagraft is potentially a good model to study *in vitro* epithelialization (Contard *et al.*, 1993) and the interactions between the extracellular matrix, fibroblasts, and migrating epithelial cells (Landeem *et al.*, 1992).

Histological characterization of Dermagraft has shown that it has the structure of the papillary dermis of newborn skin. This dermal implant contains normal matrix proteins (Table 63.1), which play an integral role in providing structure as well as enhancing cell growth. A transmission electron micrograph of the tissue shows deposition of parallel collagen fibers (Fig. 63.3). These fibers have normal periodicity and normal ratios of collagens type III and type I. In addition, all of the glycosaminoglycans (GAGs) found in young healthy dermis are present in Dermagraft (Table 63.2). These matrix components, vital for cell migration and for the binding of growth factors, are secreted by the newborn fibroblasts during the manufacturing process to yield a dermal implant with an appropriate complement of human GAGs. The fibroblasts, evenly dispersed throughout the tissue, remain metabolically active after implantation and delivery: a variety of growth factors that are key to neovascularization, epithelial migration and differentiation, and integration of the implant into the patient's wound bed. Detection and quantification of specific messenger RNA as well as expression of growth factors have been previously described (Jiang and Harding, 1998; Mansbridge *et al.*, 1998; Naughton *et al.*, 1997). The final product is extensively tested after manufacture for sterility as well as for specific levels of collagens and other matrix proteins. Because Dermagraft was designed to be a living tissue, remaining viable and delivering growth factors and matrix proteins into the wound bed after implantation, testing is performed pre- and postcryopreservation to assess its metabolic activity. A routine 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay is utilized for this assessment both at time of manufacture and for testing of product stability over time.

#### IMPORTANCE OF GROWTH FACTORS IN A DERMAL REPLACEMENT

Wound healing is a complicated process that involves a number of dynamic cellular and molecular events. Factors regulating wound healing are many and originate from different sources. Key parameters, including cell migration, proliferation, angiogenesis, matrix deposition and degradation, and immune modulation, are essential for this process (Arbiser, 1996; Bennett and Schultz, 1993; Folkman and Klagsbrun, 1987; Marks *et al.*, 1991; Moulin, 1995; Pettet *et al.*, 1996; Raghov, 1994; Schaffer and Nanney, 1996). Improvement of cell motility (e.g., dermal fibroblasts, keratinocytes, melanocytes), angiogenesis (formation of vessels; migration and motility of endothelial cells), and modification of matrix turnover all have impact on wound healing.

A tissue-engineered human dermal replacement can exploit the fact that the skin fibroblast is one of the most important and predominant cell types in the tissue repair process. This cell type appears at an early stage after injury, increasing in number as healing progresses (Arbiser, 1996; Bennett and Schultz, 1993; Folkman and Klagsbrun, 1987; Marks *et al.*, 1991; Moulin, 1995; Pettet *et al.*, 1996; Raghov, 1994). The cell is known to play a central role in the regulation of matrix deposition and degradation in the wound. Fibroblasts, however, also synthesize a rich array of cytokines, regulators of tissue repair in wounds, including interleukins, growth factors, and angiogenic factors.

#### TISSUE EXPANSION PROPERTIES OF DERMAGRAFT

Jiang and Harding (1998) evaluated the ability of Dermagraft to stimulate tissue growth in an *ex vivo* tissue expansion assay. Extracellular matrix gel was used as a support of tissue in order to test the effect of factors on the tissue expansion from patients with chronic and acute wounds. Briefly, Matrigel was dissolved in culture medium at 500  $\mu\text{g}/\text{ml}$ . This was added to a 24-well tissue culture plate. Materials and the complete system were kept ice cold at any given time until the

Betaglycan	TGF- $\beta$ type III receptor
Syndecan	Binds growth factors, enhances activity

next step. Wound tissue was washed vigorously in culture medium and finely minced with a dissecting scalpel and scissors (approximately 0.5 mm in diameter), then further washed and transferred to cool Matrigel solution in a culture well. The temperature for the system was then quickly raised to 37°C to form an irreversible gel, thus allowing the wound tissue to be embedded in the Matrigel. Coculture inserts with Dermagraft were then placed on top of the well for coculturing. The system was monitored over a 4-week period using a Panasonic charge-coupled device (CCD) camera and the distance between the wound edge and the leading front of the expansion was calculated using image analysis software (Optimas; Optimas Ltd., UK).

In Matrigel, wound tissue was able to expand in a three-dimensional manner. Viable tissue obtained from patients with acute and chronic wounds revealed various patterns of cell migration. Briefly, after embedding, polymorphonuclear cells began to migrate out of the wound tissue. However, a large-scale migration of other cells (fibroblasts and endothelial cells) were seen from day 3 onward. The distance between the leading front of the area and the edge of the wound became quantifiable from day 7. Images from these cocultured tissues were then taken with a digital camera (UltraBix; Cambridge Scientific Instrument; Cambridge, UK). The relative distance between this leading edge and wound tissue, termed the “expansion index” in this report, was then quantified from these images with image analysis software (Optimas). When Dermagraft was included, there was a marked expansion of the wound tissue when compared with tissue without the Dermagraft ( $p = 0.0015$ ). At a higher magnification, the expansion areas represents a mixture of cells and structures. Most cells are fibroblast-like cells and endothelial cells. After a prolonged culture (over 2 weeks), a vessel-like structure was clearly seen (Jiang and Harding, 1998).

A number of studies have been performed to correlate growth factor expression and secretion with *in vitro* and *in vivo* wound healing characteristics of Dermagraft (Jiang and Harding, 1998; Mansbridge *et al.*, 1998; Naughton *et al.*, 1997; Newton *et al.*, 1999). The angiogenic-promoting properties of this human dermal replacement have been well characterized and provide a unique tool for wound bed vascularization and promotion of healing.

### ANGIOGENIC PROPERTIES OF DERMAGRAFT

Tissue-engineered fibroblast-based tissues are capable of inducing rapid endothelialization and vascularization. Providing such biologically active natural materials has been clinically shown to induce new capillary formation and reduce inflammation in the wound bed of patients with diabetic foot ulcers (Jiang and Harding, 1998; Newton *et al.*, 1999). The tissue-engineered implants secrete a variety of growth factors known to be critical to tissue regeneration and angiogenesis (Table 63.3).

The angiogenic properties of our fibroblast-based engineered tissue have been investigated using a range of techniques, including the chick chorioallantoic membrane assay, the rat aortic ring assay, stimulation of endothelial cell proliferation, chemokinesis, chemotaxis, and the inhibition of apoptosis. These assays cover a wide range of the important individual steps in angiogenesis as well as the overall process.

Analysis of our tissue-engineered human matrix has shown it to contain several components

**Table 63.3. Growth factors**

Growth factors	Function
PDGF-A	Mitogen for fibroblasts, granulation tissue, chemotactic
IGF	Mitogen for fibroblasts
KGF	Mitogen for keratinocytes
HBEGF	Mitogen for keratinocytes, fibroblasts
TGF- $\alpha$	Mitogen for keratinocytes, fibroblasts
TGF- $\beta$ 1	Stimulates matrix deposition
TGF- $\beta$ 3	Stimulates matrix deposition, antiscarring
VEGF	Angiogenesis
SPARC	Both anti- and proangiogenic

that may be beneficial in neovascularization. Fibronectin present in the matrix has been shown to stimulate the proliferation of endothelial cells, and the denatured collagen has been proved to be a favorable substrate for human endothelial cell attachment. Bound growth factors in the matrix include transforming growth factor  $\beta$  (TGF- $\beta$ ) and hepatocyte growth factor (HGF), which are important in stimulating new capillary formation and endothelialization. Finally, the matrix contains laminin-1, which can serve to inhibit initial hyperplasia via the YIGSR peptide. The combination of these matrix proteins along with naturally secreted growth factors offers a physiologic solution to promoting the *in vivo* induction of angiogenesis.

#### Stimulation of angiogenesis in the chick chorioallantoic membrane

Ten-day-old chicken embryos were obtained from McIntyre Farms (Lakeside, CA) and incubated at 37°C. Eggs were candled to locate and mark a target area void of large vessels. Two small

Fig. 63.4. Dermagraft-stimulated angiogenesis in the chorioallantoic membrane assay. Top two panels show the macroscopic view, bottom two panels show histology. Left panels are of scaffold alone (top) or nonviable Dermagraft (bottom); the panels to the right are treated with Dermagraft.

Fig. 63.5. Effect of Dermagraft (Dg) on capillary blood vessel formation in the CAM. Bars represent 95% confidence intervals.

holes were made in the shell with a needle, directly over the air sac and over the target area. Suction was applied to the first hole, causing the chorioallantoic membrane (CAM) to drop away from the marked area. Using a Dremel Moto-Tool, the eggshell was removed from the target area to create a “window.” A 4-mm-diameter circular sample (fibroblast-based engineered tissue or control) was then placed on the membrane near, but not on top of, a large blood vessel. The hole was covered with a piece of clear adhesive tape and the eggs were incubated for 72 hr at 37°C to allow blood vessel growth. The treated section of the membrane was then removed, photographed, and fixed in methanol. The number of fine blood vessel branch points in the region of the sample was counted. Biopsy samples were fixed in methanol and sections stained with Masson’s Trichrome.

The three-dimensional fibroblast-based tissues induced vessel development in the CAM to a greater extent than control (Fig. 63.4), including both fine capillary development and evidence for increased permeability. The development of capillary blood vessels in CAMs treated with three-dimensional fibroblast cultures was also clearly visible by histology. This type of capillary development is characteristic of vascular endothelial growth factor (VEGF)-induced angiogenesis. It differs from that observed using basic fibroblast growth factor (FGF) stimulation, whereby the vessels show a larger diameter with little or no increase in permeability. When the number of vessels per sample in the CAM was counted, there was a statistically significant difference between the scaffold and the three-dimensional cultures (Fig. 63.5). VEGF stimulated angiogenesis in a dose-dependent manner. The angiogenic activity of the three-dimensional culture was reduced by >90% by preincubation with anti-VEGF’s neutralizing antibody prior to placement on the CAM.

### Angiogenesis in the rat aortic ring assay

In the aortic ring assay, the ability of the endothelial cells isolated from rat aorta to generate microvessels was used to demonstrate angiogenesis (Jiang and Harding, 1998). Thoracic aortas, removed from 1- to 2-month-old Sprague–Dawley male rats, were transferred to serum-free MCDB131. The periaortic fibroadipose tissue was carefully removed, and the aortas were washed 8 to 10 times and cut into 1-mm lengths. Wells were punched in a 1.5% agarose gel and filled with clotting fibrinogen solution (20  $\mu$ l of 50 NIH units/ml bovine thrombin in 1 ml fibrinogen). The aortic rings were placed into the centers of the wells. After clotting, the dishes were flooded with serum-free MCDB131. The cultures were incubated at 37°C with 5% CO<sub>2</sub>, with medium changes every 3 days. Newly formed microvessels were counted on days 3, 7, and 14. When aortic rings were cocultured with living fibroblast-based engineered tissue, there was a significant increase in the number of microvessels formed (Fig. 63.6).

Fig. 63.6. Stimulation of blood vessel formation by Dermagraft (Dg) in the aortic ring assay.

Fig. 63.7. Stimulation of endothelial cell proliferation by Derma-graft (Dg).

### Stimulation of endothelial cell proliferation

Endothelial cell proliferation is a critical component of angiogenesis. The ability of fibroblast-based engineered tissue to stimulate this activity was determined by [<sup>3</sup>H]thymidine incorporation. Various growth factors and concentrated conditioned medium samples were assessed for their influence on the proliferation of human vascular endothelial cells (HUVECs). Confluent cultures were detached and resuspended in HUVEC growth medium to a final concentration of  $2.5 \times 10^4$  cells/ml. Attachment Factor Solution (Cell Applications, Inc.) was used to pretreat 24-well plates and cells were added, 1 ml of cell suspension per well. Cells were allowed to settle and attach and then were switched to Endothelial Serum Free medium (Cell Applications, Inc.), supplemented with fibroblast culture medium or medium conditioned by monolayer or three-dimensional fibroblast cultures. On day 2, the cells received fresh serum-free medium supplemented as appropriate with 1  $\mu$ Curie/ml [<sup>3</sup>H]thymidine. On day 3, medium was removed, cells were washed three times with phosphate-buffered saline (PBS), and 250  $\mu$ l of 2.3% sodium dodecyl sulfate (SDS) solution was added to solubilize the cells. After 30 min, the SDS extract and 1 ml of a PBS wash were transferred to a scintillation vial. Then 5 ml of ScintiVerse (Fair Lawn, NJ) was added to vials and radioactivity was determined using a Beckman LS6500 Scintillation Counter (Fullerton, CA).

Medium conditioned by incubation with three-dimensional fibroblast cultures stimulated [<sup>3</sup>H]thymidine incorporation in cultures of endothelial cells (Fig. 63.7). The proliferative effect is dose dependent.

### Stimulation of endothelial cell chemokinesis

The ability of our fibroblast-based engineered tissue to stimulate endothelial cell migration was tested in two assays. The first was a chemokinesis assay that determines the stimulation of cell movement without any directional definition. The second measured cell migration toward a stimulation source. The chemokinesis assay was performed and reported by Martin and colleagues (1998). Endothelial cells were grown on Cytodex-2 beads. The assay estimates the dissociation of cells from the beads and reassociation with a culture plate. The cells on the plate were stained and

Fig. 63.8. Stimulation of endothelial cell motility by Derma-graft (Dg).

Fig. 63.9. Stimulation of endothelial cell chemotaxis by Derma-graft.

counted. As shown in Fig. 63.8, coculture of the cells with the fibroblast-based engineered tissue gave a marked increase in transfer of cells from bead to plate ( $p = 0.0003$ ). The activity of the three-dimensional fibroblast cultures was inhibited about 60% using anti-HGF neutralizing antibody.

### Stimulation of endothelial cell chemotaxis

Cell migration was analyzed with an endothelial cell chemotaxis assay utilizing a Neuro Probe 48-well Boyden chemotaxis chamber (Neuro Probe, Inc.). Polycarbonate membrane filters (Poretics Corporation;  $25 \times 80$  mm) were soaked in 0.5 M acetic acid overnight, washed three times for 1 hr with water, incubated in a solution of 0.01% calf skin gelatin type III (Sigma; St. Louis, MO) for 12–16 hr, and air dried. HUVECs were detached and resuspended in HUVEC growth medium at a final concentration of  $1.0 \times 10^5$  cells/ml. The Boyden chamber was assembled as follows: 30  $\mu$ l/well of sample or standard was added to the bottom wells, the gelatin-coated membrane was placed on top, and 50  $\mu$ l of cell suspension was added to the upper wells. The chamber was incubated at 37°C for 3 hr. Membranes were then carefully removed from the chamber and the cell side was rinsed in PBS and drawn across a wiper blade to remove nonmigrated cells. The membranes were stained with Wright's Geimsa stain and either the number of cells counted or the density of staining was reported against a standard curve generated with 20, 10, 5.0, and 0 ng/ml purified VEGF.

Medium conditioned by the fibroblast-based engineered tissue greatly stimulated cell migration in a dose-dependent manner (Fig. 63.9). The three-dimensional fibroblast-conditioned medium stimulated HUVEC migration to a greater extent than the positive control using VEGF, even at 50 ng/ml. Anti-VEGF antibody inhibited migration stimulated by three-dimensional fibroblast-culture-conditioned medium by 50%.

### Induction of integrin $\alpha v \beta 3$

The  $\alpha v \beta 3$  integrin has been shown to play an important role in angiogenesis, and neutralizing antibodies directed at it are capable of blocking capillary blood vessel formation. Its expression is induced by VEGF and it is thought to play a critical role in endothelial cell migration.

The presence of integrins and cell surface receptors was determined by flow cytometry on a FACStar (Cytometry Research Services; San Diego, CA). Cells were prepared for analysis as follows: HUVECs were trypsinized and the cells resuspended at  $1 \times 10^6$  cells/ml. Volumes of 250–500  $\mu$ l of the cell suspensions were washed three times with Hank's Balanced Salt Solution (HBSS; GibcoBRL; Grand Island, NY) and finally resuspended in 10% FBS in HBSS. The cells were incubated for 30 min with primary antibodies diluted to 1  $\mu$ g/ml in 10% FBS in HBSS, washed three times with HBSS, incubated for 30 min with secondary antibodies diluted to 1  $\mu$ g/ml in 10% FBS in HBSS, washed three times with HBSS, and fixed in 200  $\mu$ l of 10% formalin (Baxter; Deerfield, IL) at a density of  $10^6$  cells/ml.

The presence of  $\alpha v \beta 3$  integrin on the surface of endothelial cells was analyzed by flow cytometry after treatment with medium conditioned by fibroblast-based engineered tissue. Cultured HUVECs display substantial surface expression of  $\alpha v \beta 3$  integrin under normal culture conditions. Nonetheless, medium conditioned by the fibroblast-based engineered tissue stimulated a significant increase in expression of this integrin.

### Expression of angiogenic growth factors

Several of the angiogenic properties of fibroblast-based engineered tissue described above were demonstrated to be sensitive to neutralizing antibodies against specific growth factors, notably vascular endothelial growth factor and hepatocyte growth factor/scatter factor. Accordingly, experiments were performed to examine the expression of these and other angiogenic factors by the fibroblast-based tissue. Growth factor expression was examined both by estimation of mRNA levels by polymerase chain reaction methods and estimation of the free protein by enzyme-linked immunosorption assay.

Specific messenger RNAs were estimated by quantitative reverse transcriptase and polymerase chain reaction (RT-PCR) using the ABI TaqMan method (Perkin-Elmer; Foster City, CA). Total RNA was extracted from the cells using a Rapid RNA Purification Kit (Amresco; Solon, OH). The RNA was reverse transcribed using Superscript II (Life Technologies; Grand Island, NY) with random hexamer primers (Sigma; St. Louis MO). Amplification of samples of cDNA containing 200 ng of total RNA was detected in real time and compared with the amplification of plasmid-derived standards for specific mRNA sequences using a copy number over a range of five orders of magnitude within 40–4,000,000/reaction. In purification and the efficiency of reverse transcription, mRNA sequences for platelet-derived growth factor (PDGF) B chain, VEGF, or TGF- $\beta_1$  were added to RNA isolations, and their yield measured by the TaqMan procedure. The control mRNA sequences were obtained by T7 RNA polymerase transcription of plasmids containing the corresponding sequence. The values were normalized using glyceraldehyde-3-phosphate dehydrogenase as a control.

## CLINICAL RESULTS OF WOUND HEALING

### CRITICAL PRODUCT SPECIFICATION

Any device designed to act as a replacement tissue must provide critical therapeutic benefits to the patient and function as a physiologic replacement. To conduct such physiological interactions with both the wound bed and the migrating epidermis, it is essential that the dermal implant have a sufficient number of viable, metabolically active fibroblasts remaining after the cryopreservation/storage/thaw process. The pivotal study was performed to examine the use of cryopreserved tissue-engineered living human dermal tissue for the treatment of diabetic foot ulcers. Results from this study elucidated the specific product parameters necessary for a tissue-engineered implant to function physiologically as a dermal replacement (Mansbridge *et al.*, 1998; Naughton *et al.*, 1997; Pollak *et al.*, 1997). A complete analysis of all *in vitro* and clinical data at the conclusion of the study confirmed that the metabolic activity of Dermagraft must lie within an optimal therapeutic range (TR) to ensure that the tissue will be sufficiently active after implantation to affect wound healing by regaining its ability to synthesize and secrete normal dermal proteins, including growth factors. Statistically significant improved healing was observed in patients receiving therapeutically active product at their first two implants and in at least half of their implants (DG-TR group,

Fig. 63.10. Histologic evaluations of wound site biopsies of patients before and after implantation with Dermagraft show a marked reduction in inflammatory cell infiltration and an increase in blood vessels. Similar results were not evident in the tissue of placebo-treated patients. Magnification, 40 $\times$ .

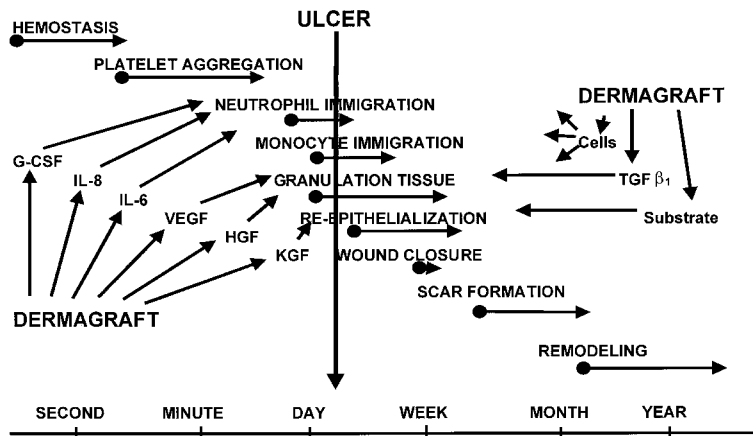

Fig. 63.11. Dermagraft secretes a variety of growth factors and proteins that have been shown to be important in reducing inflammation and enhancing wound bed regeneration and reepithelialization.

$n = 61$ ). A total of 50.8% of this patient population experienced complete wound closure within 12 weeks ( $p = 0.006$ ). Patients who received every dose of Dermagraft with the correct metabolic activity ( $n = 37$ ) had the highest percentage of complete wound closure (54.1%) by week 12 and were by themselves statistically significantly better than the control group ( $p = 0.007$ ).

In addition to patients being followed through week 12, data were collected for week 32 healing, a full 6 months after the last application of Dermagraft. Because the dosage of Dermagraft was complete at the end of the first 8 weeks, it was expected that the difference between Dermagraft and control healing would narrow considerably at week 32, a full 6 months after the last dose. Despite the long time since the last implantation, however, the Dermagraft-treated patients continued to do much better than the controls. The DG-TR group still had significantly more patients healed than the control group ( $p = 0.039$ ), and the median time to complete healing was twice as fast with Dermagraft (13 weeks for Dermagraft vs. 28 weeks for control). Previous studies have shown that fibroblasts implanted clinically in the Dermagraft product persist for at least 6 months *in vivo* after implantation. The persistence of these cells clearly shows the uniqueness of a tissue-engineered product in wound healing: persistent cells are capable of secreting growth factors and normal matrix proteins long term into the wound bed, thus promoting an on-going physiological healing environment.

## SUMMARY

Clinical use of our fibroblast-based tissue-engineered implants has shown rapid vascularization of the wound bed, remodeling of the tissue, and reduction in inflammation (Fig. 63.10). The mechanism of action of this healing has been well studied (Jiang and Harding, 1998; Mansbridge *et al.*, 1998, 1999; Naughton *et al.*, 1999) (Fig. 63.11) and has led clinicians to look for new applications associated with problem wounds whereby this action would be beneficial. This approach offers obvious benefits over a single growth factor approach, such as the local application of exogenous VEGF, because multiple angiogenic factors are naturally secreted by the fibroblast-based tissue-engineered constructs at physiologically relevant ratios. These cells can respond to biological signaling *in vivo* and induce a more physiologic healing process. In addition, the matrix components have been shown to induce endothelial migration and may serve as a source of natural undamaged proteins that can enhance *in vivo* remodeling.

The strong clinical safety profile of this product, along with the physiologic properties that promote rapid healing, make it an excellent candidate for use in the study of revascularization and regeneration of damaged tissue in a variety of chronic and acute wounds.

## PART XX: WOMB

This Page Intentionally Left Blank

# ARTIFICIAL WOMB

Christopher S. Muratore and Jay M. Wilson

A SQUAT grey building of only thirty-four stories. Over the main entrance the words, CENTRAL LONDON HATCHERY AND CONDITIONING CENTRE, and, in a shield, the World State's motto, COMMUNITY, IDENTITY, STABILITY. . . .

In the Bottling Room all was harmonious bustle and ordered activity. Flaps of fresh sow's peritoneum ready cut to the proper size came shooting up in little lifts from the Organ Store in the sub-basement. Whizz and then, click! The lift-hatches flew open; the bottle-liner had only to reach out a hand, take the flap, insert, smooth-down, and before the lined bottle had had time to travel out of reach along the endless band, whizz, click! another flap of peritoneum had shot up from the depths, ready to be slipped into yet another bottle, the next of that slow interminable procession on the band.

Next to the Liners stood the Matriculators. The procession advanced; one by one the eggs were transferred from their test-tubes to the larger containers; deftly the peritoneal lining was slit, the morula dropped into place, the saline solution poured in . . . and already the bottle had passed. . . .

Each bottle could be placed on one of fifteen racks, each rack, though you couldn't see it, was a conveyor traveling at the rate of thirty-three and a third centimetres an hour. Two hundred and sixty-seven days at eight metres a day. Two thousand one hundred and thirty-six metres in all. One circuit of the cellar at ground level, one on the first gallery, half on the second, and on the two hundred and sixty-seventh morning, daylight in the Decanting Room. Independent existence—so called.

"But in the interval," Mr. Foster concluded, "we've managed to do a lot to them. Oh, a very great deal." His laugh was knowing and triumphant.

"That's the spirit I like," said the Director once more. "Let's walk around. You tell them everything, Mr. Foster."

Mr. Foster duly told them.

Told them of the growing embryo on its bed of peritoneum. Made them taste the rich blood surrogate on which it fed. Explained why it had to be stimulated with placentin and thyroxin. Told them of the *corpus luteum* extract. Showed them the jets through which at every twelfth metre from zero to 2040 it was automatically injected. Spoke of those gradually increasing doses of pituitary administered during the final ninety-six metres of their course. Described the artificial maternal circulation installed in every bottle at Metre 112; showed them the reservoir of blood-surrogate, the centrifugal pump that kept the liquid moving over the placenta and drove it through the synthetic lung and waste product filter. Referred to the embryo's troublesome tendency to anaemia, to the massive doses of hog's stomach extract and foetal foal's liver with which, in consequence, it had to be supplied. [Aldous L. Huxley, "Brave New World" (932)]

Although Huxley's "Brave New World" describing a futuristic science was written many decades ago, the principles of constructing an artificial womb were remarkably accurate. The womb would require a vessel, biologic tissue for implant (sow's peritoneum), nutrition (blood surrogate),

hormones (placental, thyroxin, pituitary), unknown growth factors (corpus luteum extract, hog stomach extract, fetal foal liver), oxygen, a centrifugal pump, a synthetic lung, a waste product filter, and temperature and light controls. Today, long after Huxley conjured his new world, this list has changed little. Although the “ideal” artificial womb would be a total tissue construct, practically speaking, the CYBORG (cybernetic and organic) approach outlined by Huxley will undoubtedly yield the first practical womb substitute. But, before one begins the task of developing an artificial womb, it is useful to first understand why such a construct might be useful in the first place.

## WHAT DOES THE FIELD OF TISSUE ENGINEERING HAVE TO OFFER THE PREMATURE INFANT?

Prematurity is the leading cause of neonatal death and morbidity worldwide, accounting for 60–80% of deaths of infants without congenital abnormalities. The overall neonatal mortality rate in the United States is approximately 7 per 1000, a rate that ranks nineteenth in the world and well below many industrialized and Third World countries. This mortality rate has steadily decreased largely because of improvements in neonatal intensive care, leading to infant survival rates of approximately 50, 80, and 97% for infants born at 24, 28, and 32 weeks of gestation, respectively (normal gestation is 40 weeks (Kipikasa and Bolognese, 1997)). However, survival rates alone do not tell the whole story. Many premature survivors have significant morbidity. In one study, children who weighed less than 705 g at birth demonstrated substantially higher rates of mental retardation, cerebral palsy, and visual disabilities as well as neurobehavioral dysfunction and poor school performance. Other complications, including respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, bronchopulmonary dysplasia, sepsis, patent ductus arteriosus, and retinopathy of prematurity, increase with decreasing gestational age (Kipikasa and Bolognese, 1997; Dawson *et al.*, 1997).

Currently, the preterm viable infant (>24 weeks of gestation) is cared for in a neonatal intensive care unit (ICU), where it must survive the transition from the protective liquid fetal environments to the harsh invasive realm of the New World. During this transition, rapid and profound physiologic changes enable the infant to make the successful passage from intrauterine to extrauterine life. These changes are developmental tasks that all babies must complete. To accomplish them successfully, the fetus must have relatively mature organ systems, including renal, skin, pulmonary, and cardiovascular. The earlier in gestation the infant is born, the greater the number and magnitude of fetal tasks that are unfinished and the more vulnerable the infant (Rowe, 1998).

Invariably, lung underdevelopment is the most formidable challenge faced by the preterm infant, although significant underdevelopment of the skin, cardiovascular, and immune systems compounds the problem. Although lifesaving, the invasive environment of the modern newborn ICU inflicts an iatrogenic toll that might be avoided if the preterm infant could complete the developmental process while being maintained in a liquid incubation system simulating the protective *in utero* environment.

## PREMATURITY—THE CONSEQUENCES

### INTRAVENTRICULAR HEMMORRHAGE

The most common form of brain injury in premature infants is intraventricular or periventricular hemorrhage. Risk of intracranial hemorrhage is directly associated with the degree of prematurity. Overall, 46–58% of infants with extremely low birth weight sustain some form of intraventricular hemorrhage; 50% of intraventricular hemorrhages occur on the first day of life and 90% occur by age 1 week. Intraventricular hemorrhage (IVH) is graded on a scale of one to four based on the extent of hemorrhage and the involvement of the surrounding structure. Prognosis is directly related to the severity of the hemorrhage, with mortality rates ranging from 16 to 50% and the incidence of major neurodevelopmental handicaps from 45 to 86%. Extensive hydrocephalus and significant periventricular injuries are associated with more than a 90% risk of major long-term neurodevelopmental sequelae (Rowe, 1998; Dawson *et al.*, 1997). The cause of IVH is thought to be immature development of the brain compounded by the stress of the fetus trying to survive in a postnatal environment for which it is poorly equipped.

### HYALINE MEMBRANE DISEASE

Hyaline membrane disease (HMD) contributes significantly to morbidity and mortality among premature infants. The primary biochemical abnormality in HMD is deficiency of pulmonary surfactant, which leads to increased atelectasis, worsening of pulmonary compliance, and progressive respiratory failure. Long-term follow up of survivors of HMD has demonstrated persistent abnormalities in pulmonary function testing, increased susceptibility to pulmonary infections, and development of bronchopulmonary dysplasia, in the most severely affected infants (Dawson *et al.*, 1997).

### BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD), or chronic lung disease, in infants is the most common pulmonary sequela of mechanical ventilation of both premature and full-term infants. The incidence of BPD among premature infants is inversely proportional to gestational age and birth weight. Up to 70% of infants with birth weights less than 1000 g will develop BPD. Many factors play a role in the development of BPD, but the most significant are the degree of pulmonary structural and functional immaturity at birth and the degree and length of mechanical ventilation and oxygen support (Dawson *et al.*, 1997). Prevention of HMD and BPD is challenging in the current neonatal ICU setting, but may be achieved utilizing an extrapulmonary source for gas exchange to allow the lungs to mature without injury.

### SKIN MATURATION AND TRANSEPIHELIAL AND INSENSIBLE WATER LOSS

Insensible water loss is the invisible loss of water from the lungs and skin. The major component of insensible water loss during the newborn period is transepithelial water loss (TEWL). In the low-birth-weight infant, TEWL can have profound effect on fluid balance and thermoregulation, and it can ultimately effect mortality. TEWL results from water molecules diffusing across the superficial capillaries of the skin. For the extremely low-birth-weight infant with almost no keratinization, water loss can be enormous. As water is lost, so is heat. For every milliliter that evaporates, 0.58 kcal of heat are dissipated. TEWL is inversely related to gestational age and birth weight (Rowe, 1998). Prevention of TEWL is impossible in the current newborn ICU, but might be possible if the preterm infant is cared for in a liquid-based environment.

### NECROTIZING ENTERCOLITIS

Since the introduction of neonatal intensive care medicine in the 1960s, and with increasing neonatal survival, necrotizing enterocolitis (NEC) has become the most common gastrointestinal tract disease of the newborn (Albanese and Rowe, 1998). The incidence of NEC is approximately 1 to 3 in 1000 live births, but the true incidence is difficult to ascertain. NEC is predominantly a disease of low-birth-weight premature infants. It is believed that the susceptibility of the immunologically immature gut makes it vulnerable to an inciting agent such as endogenous bacteria or hypoxic injury. Enteral feedings also stress the immature gut and provide a substrate for bacterial proliferation, resulting in mucosal injury. The breakdown of the gut barrier initiates an inflammatory cascade, ultimately resulting in intestinal necrosis (Albanese and Rowe, 1998). Prevention may require providing nutrition by a source other than enteral.

### LONG-TERM COSTS OF PREMATURITY

Long-term costs of perinatal disabilities secondary to prematurity are dramatic. There are direct cost issues such as hospital bills, physician fees, office visits, laboratory tests, rehabilitation services, and medical expenses, in addition to parental out-of-pocket costs. Indirect costs also reflect foregone opportunities of family members, such as wages lost while seeking medical treatment or while the infant is convalescing (McCormick and Richardson, 1998). The additional costs to society of caring for the complications of prematurity are currently unknown, but are undoubtedly enormous.

### THE IDEAL ARTIFICIAL WOMB

Because none of the complications of prematurity occur in a fetus that remains in the womb, one novel method of addressing the problem would be to maintain profoundly premature infants

in the fetal environment. No apparatus to achieve this exists, thus we will endeavor to describe the “ideal” artificial womb and then to review the data on preliminary attempts to create it. The ideal artificial womb would have to reproduce many of the functions of the maternal/placental unit, such as gas exchange and nutrition, as well as provide a protective environment for continued development in an environment free of bacterial and viral contamination. The time frame during which such support might be necessary could range from 5 to 15 weeks.

The relatively new field of tissue engineering owes its existence to the understanding of cellular physiology, growth, proliferation, communication, and interaction with biodegradable polymer constructs. On a more global scale, successful maintenance of a fetus mandates that near-perfect fetal physiology is maintained. The goal therefore, for an artificial womb, either completely or partially tissue engineered, would be to mimic as closely as possible the *in utero* environment, maintain fetoplacental circulation, and reproduce the contributions and physiology of the placenta.

### RECREATING THE *in Utero* ENVIRONMENT

As depicted in Fig. 64.1, conceptually, the fetus, still in continuity with the umbilical cord and placenta, would be placed in a flexible incubator that permits fetal movement. The incubator is filled with a warm electrolyte solution, closely mimicking amniotic fluid, which is circulated, filtered, and returned to the incubator. Reproduction of a liquid-based protective environment would prevent insensible water loss from the lungs and skin, making fluid balance and thermoregulation easier (Rowe, 1998). Moreover, this liquid-based environment would apply pressure to the outside of the fetal chest, equilibrating and counterbalancing an equal pressure transmitted via an open airway to the lungs (Adzick and Harrison, 1991). This fluid pressure contributes the resultant intrapulmonary distending pressure, which is essential to proper lung development (Adzick and Harrison, 1991). Amniotic fluid is also swallowed and plays an active role in the maintenance and development of the gastrointestinal tract. In order to completely support the fetus, a myriad of growth factors would have to be added to this fluid.

### MAINTENANCE OF FETOPLACENTAL CIRCULATION

Normal fetal growth and development are dependent on umbilical blood flow to meet the growing demand of fetoplacental exchange of oxygen, carbon dioxide, nutrients, metabolic wastes, and hormones. Umbilical blood flow increases in direct proportion to the increase in fetal body weight, so that flow remains approximately constant at 110 to 125 ml/min/kg during the third trimester. Furthermore, fetal biventricular cardiac output is near maximal under basal conditions in near-term fetal sheep and the umbilical–placental circulation is near maximally dilated (Adams *et al.*, 1998). This umbilical blood flow represents about 30% of the fetal biventricular cardiac output. At birth, however, umbilical–placental circulation begins to close. Flow rapidly decreases

Fig. 64.1. Authors' conception of the ideal artificial womb, based on modifications of current experimental extrauterine fetal support systems. TPN, Total parenteral nutrition.

after delivery to less than 20% of the normal fetal value. This is accompanied by significant decreases in umbilical artery and vein diameters (Adamson *et al.*, 1998). Maintenance of umbilical blood flow and near-maximal placental vascular dilatation will be essential to extrauterine fetal survival. Consequently, understanding the factors that regulate umbilical blood flow is critical to maintaining umbilical–placental vascular patency. The exogenous use of vasoactive factors would be an important adjunct to ensure umbilical–placental blood flow in the extrauterine fetus.

Interestingly, there are no detectable adrenergic or cholinergic nerve fibers in the human placenta or in the human umbilical cord vessels. Thus the absence of the innervation of the extrafetal umbilical cord vessels and the placenta indicates that these vessels are not under neural control (Adamson *et al.*, 1998). Therefore, pharmacologic manipulation directed at adrenergic or cholinergic receptors would not be necessary to maintain umbilical–placental blood flow for the extrauterine fetus. However, there are a number of systemic and placental-derived vasoconstrictors that contribute to umbilical–placental blood flow regulation, including angiotensin II, bradykinin, catecholamines, thromboxane, prostaglandins, endothelin-1, histamine, peptides, and serotonin. In humans, thromboxane and endothelin-1 are potent vasoconstrictors of the placental vessels. Endothelin-1 in particular may increase the sensitivity to other vasoconstrictors and thus modify the vasoactive response of the umbilical–placental circulation to other agents (Adamson *et al.*, 1998). Likewise, a number of hormones have vasodilatory actions on the placenta. Important factors considered to have a vasodilatory role on the umbilical–placental circulation include adenosine, corticotropin-releasing hormone (CRH), endothelial-derived relaxing factor (EDRF), natriuretic peptides, and prostacyclin. In particular, CRH at physiologic concentrations and EDRF appear to play an important role in the maintenance of low vascular resistance in this vascular bed (Adamson *et al.*, 1998).

## PLACENTAL PHYSIOLOGY

The importance of the native placenta to the artificial incubator cannot be neglected. Many vasoactive factors are produced and act locally in the placenta; this provides additional justification for including the placenta in the artificial incubation system. The placental membrane surface area is responsible for diffusion of oxygen, carbon dioxide, nutrients, and many systemic and locally produced hormones. Contemporary extracorporeal membrane oxygenator (ECMO) units, whether utilizing a roller pump or centrifugal pump, currently provide adequate gas exchange. The membrane oxygenator can oxygenate and remove CO<sub>2</sub> from either whole blood or a blood substitute such as liquid perfluorocarbon. Nutrition provided in the form of total parenteral nutrition (TPN) can be infused either directly into the placental blood or diffused across the engineered placental–ECMO interface. Likewise, antibiotics and other medications may be given similarly, provided they can cross the interface barrier.

Finally, the development of an autologous placenta–ECMO interface, derived and engineered from human tissue, as a conduit would be far superior to the currently used silastic tubing. To enhance the autologous nature of the ECMO interface membrane, the membrane might be constructed of umbilical vein-derived endothelial cells, seeded on a biodegradable polymer. A tissue-engineered membrane would further obviate the need for anticoagulation or routine circuit changes, both of which are necessary with the conventional ECMO, because the risk of mural thrombi would be less. Moreover, fewer circuit changes translate into a lower risk of infection, and less fetal disturbance or manipulation.

## STATE-OF-THE-ART ARTIFICIAL PLACENTA DESIGN

The first efforts to develop long-term extrauterine extracorporeal maintenance of a premature fetus were initiated in the late 1950s and were continued by many groups into the 1960s. The early studies used a pump oxygenator to sustain life or to provide adequate perfusion in pre-viable fetuses. In 1958, Westin *et al.* reported that seven pre-viable human fetuses had been kept alive 5–12 hr by extracorporeal perfusion of the umbilical vein and induction of hypothermia (Callaghan *et al.*, 1956; Westin *et al.*, 1958). In 1961, Lawn and McCance described an incubation system designed to support the isolated fetus and called it an artificial uterus or artificial placenta. The authors used both open and closed tanks filled with isotonic glucose to contain the fetus. In this design the fetal heart pumped the blood through the oxygenator via the umbilical arteries to maintain the circulation. The authors were interested in studying the effects of pressure and flow in the

umbilical vessels, and oxygen consumption in the fetus. In 1969, Zapol *et al.* developed an artificial placenta consisting of an extracorporeal circuit and one silicone membrane blood oxygenator. This circuit was connected to the fetus via the umbilical vessels. Arteriovenous perfusion was achieved. Blood from the umbilical artery was collected in a reservoir bag pumped through the membrane lung and returned to the fetal umbilical vein while the fetus was maintained submerged in a warm saline bath. With this apparatus, they were able to maintain exteriorized premature fetuses for up to 55 hr.

In 1987, Kuwabara *et al.* reported the development of an extrauterine fetal incubation system also using an extracorporeal membrane oxygenator. This group exteriorized a preterm fetal goat and cannulated the umbilical vessels with polyvinyl catheters. Following systemic heparinization, the catheters were connected to the ECMO circuit and the fetus was placed into the incubator filled with artificial amniotic fluid consisting of a balanced electrolyte solution, which was warmed to 39.5°C. The fluid was circulated and cleaned by an in-line filter. The ECMO circuit consisted of polyvinyl chloride tubing, a roller pump, and a microporous membrane oxygenator and a heat exchanger. The blood was drained from the umbilical arteries, oxygenated, and returned to the umbilical vein. This system required anticoagulation, which was maintained with a continuous infusion of heparin that was titrated to keep the activated clotting time to approximately 250 sec. Fetal electrocardiogram heart rate, arterial blood pressure, central venous pressure, and electroencephalogram, tracheal pressure, gross movements, and flow rates of perfusate were continuously recorded. Blood samples were sequentially obtained from the circuit for hematologic, biochemical, and blood gas analyses. A catheter was transabdominally implanted in the urinary bladder for the measurement of urine volume, osmotic pressure, and electrolytes.

With this system, fetuses were kept under fairly stable physiologic conditions for periods up to 165 hr. The most common causes of death were circulatory failure and blood clotting. Massive intraperitoneal hemorrhage was noted in some of the cases due to administration of excessive heparin, whereas other cases reported clotting in the oxygenator due to insufficient heparinization. Nevertheless, utilizing this system, reasonable fetal circulation and fetal blood gas profiles were maintained for up to 7 days.

In later studies, Kuwabara *et al.* (1989) reported an improvement in the extrauterine system that allowed for maintenance of the fetus for as long as of 236 hr, with a mean duration of 146.5 hr of extrauterine survival. These improved results were attributed to several improvements in the experimental methods. The flow rate of the extracorporeal circulation was maintained at approximately 100 ml/min/kg.  $PaO_2$  and  $PaCO_2$  were kept between 25–35 and 35–45 mmHg, respectively, which was achieved by changing the flow rate of oxygen, nitrogen, and  $CO_2$  gases. Anticoagulation was maintained with continuous infusion of heparin to achieve a lower activated clotting time of approximately 200 sec. All fetuses received a physiologic electrolyte solution intravenously containing 7.5–10% glucose at a rate of 10 ml/hr. An improvement in catheter design, allowing the tips of the catheters to be positioned in the lower part of the abdominal aorta, made it possible to maintain more consistent flow throughout the extracorporeal circuit.

In the previous studies, marked water retention resulting in massive ascites, plural effusions, and subcutaneous edema had appeared as early as the second or third day of the incubation period (Zapol *et al.*, 1969). The etiology for this phenomenon remains unclear but, excess fluid intake by infusion and fetal swallowing and immature renal function together with endocrinologic and/or metabolic disturbances while on the ECMO circuit were thought to contribute. To prevent fluid retention on extracorporeal dialysis ultrafiltration method was utilized. This improved the fluid balance, as shown by the fact that no severe water retention was observed at autopsy of any fetus, and the electrolyte balance of the fetus was maintained within the physiologic ranges throughout the study, in contrast to earlier studies. Causes of death, again, in all cases of long-term incubation not associated with mechanical failure, were due to circulatory failure. Circulatory failure was noted to progress slowly throughout the duration of incubation.

In 1990, Unno *et al.* utilized the extrauterine fetal incubation system to study extrauterine fetal physiology compared to *in utero* fetal physiology. Many studies had shown that mammals under physiologic conditions had the ability to maintain a normal oxygen consumption level by increasing the oxygen extraction ratio when oxygen delivery fell to a certain extent. Using extrauterine fetal incubation, Unno *et al.* revealed that the same phenomenon occurred. They determined that the oxygen consumption decreased when the oxygen delivery was less than 10 ml/min/kg and it remained almost constant when the oxygen delivery exceeded 10 ml/min/kg. The

relation suggested that this level of oxygen consumption was a basic requirement for the extrauterine goat fetus on ECMO and that the critical oxygen delivery value was approximately 10 ml/min/kg. This study indicated that the oxygen consumption of an isolated goat fetus incubated in an isothermic environment with umbilical arteriovenous extracorporeal membrane oxygenation was almost equal to a fetus *in utero*.

The incubation periods for this experiment were between 58 and 236 hr, a significant improvement from prior attempts. Although these data provided significant information on oxygen delivery and utilization by an extrauterine fetus, the exteriorized animal did not survive for more than 10 days. During these studies excessive fetal gross movements and water imbalance due to swallowing of artificial amniotic fluid during the extrauterine fetal incubation were strongly suspected of being the causes of circulatory deterioration and failure during long-term incubation (Unno *et al.*, 1990). To suppress fetal movement and swallowing, pancuronium bromide was administered in subsequent studies (Unno *et al.*, 1993). This was provided either as a continuous infusion or as an intermittent bolus, with the doses adjusted according to fetal activity. The extracorporeal circuit was maintained as previously mentioned. With the administration of muscle relaxant, the externalized goat fetus on ECMO could be supported for approximately 3 weeks. Fetal parameters, including fetal blood gas, O<sub>2</sub> saturation, and PaO<sub>2</sub>, PaCO<sub>2</sub>, and measurements of oxygen consumption all remained stable during long-term extrauterine fetal incubation, demonstrating that the fetus was able to adapt better to extrauterine fetal circulation when fetal activity was suppressed.

Although these physiologic parameters demonstrated that the fetal cardiovascular system was able to adapt to the extracorporeal environment for a lengthy period of time, long-term immobilization is not at all physiologic. When attempts were made to initiate spontaneous lung respiration after 3 weeks of paralysis, spontaneous breathing did not occur. The long-term administration of pancuronium bromide in the preterm state may have caused fetal neuromuscular disturbances that prevented spontaneous breathing, or inadequate muscle development occurred secondary to muscular weakness due to the long-term immobilization.

## ORGAN MATURATION DURING MAINTENANCE WITH ARTIFICIAL WOMB

Although the prior studies have shown that long-term paralysis prevented subsequent spontaneous respiration, in 1998, Yasufuku *et al.* demonstrated that the use of an extrauterine support system nevertheless did permit continued lung growth and maturation. Using twin goat fetuses as controls, they compared production of surfactant, maintenance of pulmonary epithelial ion transport, and lung maturation by histologic criteria. To prevent net efflux of lung liquid they ligated the tracheas of their extrauterine fetus. The ductus arteriosus was maintained open with high flow and low oxygen saturation, thereby maintaining fetal circulation. Their results demonstrated normal production of surfactant, maintenance of ion transport of the pulmonary epithelium, increase in lung weight, and increase in mature alveolar type II cells in the ligated animal lungs. This report provided preliminary evidence that the use of an extrauterine fetal incubation system could support the preterm fetus while allowing continued growth and maturation of immature fetal organs such as the fetal lung.

## VARIATIONS OF ARTIFICIAL WOMB TECHNOLOGY

All of the above experiments were performed using a fetus without the placenta. An alternative approach, hybrid respiratory support, includes the placenta with extracorporeal membrane placental oxygenation (Akagi *et al.*, 1991). In this conceptual design, a preterm fetus could potentially be connected to a placenta instead of an oxygenator. The placenta would be interfaced with an artificial uterus, namely, the ECMO circuit. The ECMO circuit in this case uses an artificial blood substitute (Perfluorocarbon) to deliver oxygen to the placenta. In *in vitro* experiments, gas exchange took place between the fetal blood and the ECMO circuit across the placental membrane. This hybrid system relied on flow rates of the artificial blood through the placental-ECMO circuit at a fixed rate of 3 liters/min. In these *in vitro* experiments the gas transfer rate increased consistently with the blood flow rates of 60 ml/min per oxygen at 40 ml/min per CO<sub>2</sub> at a blood flow rate of 1 liter/min. These results are comparable to that of clinically available membrane oxygenators for infants today and could represent an alternative method for extrauterine maintenance of a preterm fetus in the future (Akagi *et al.*, 1991).

## CONCLUSION

Despite the revolutionary advances that have occurred in modern medicine, premature labor remains an unsolved problem. Consequently, preterm infants are unique patients who require a unique branch of medicine devoted to their care and management. For infants >24 weeks old, the modern newborn ICU is sufficiently equipped to provide care. However, a combination of infant underdevelopment and iatrogenic injury place the premature infant at unique risk. Furthermore, for those infants born <24 weeks of gestation, there is currently no technology that will sustain them. Twenty-four weeks represents a milestone in fetal development because it is approximately the transition period from the pseudoglandular stage of pulmonary development to the terminal saccular stage. The terminal saccular stage represents the earliest histologic and physiologic stages of lung development capable of adequate gas exchange. It is generally accepted that there is no capacity for gas exchange prior to this stage of lung development. As such, attempts to ventilate mechanically an infant <24 weeks of gestation are generally unsuccessful. The development of an artificial womb that could sustain the preterm fetus in a liquid-based environment could potentially salvage the fetus born <24 weeks of gestation.

The invasive environment of the modern newborn ICU inflicts an unintentional iatrogenic toll that might be avoided if the preterm infant could complete the developmental process while being maintained in a protective liquid incubation system. Complications of prematurity, including respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, bronchopulmonary dysplasia, sepsis, patent ductus arteriosus, and retinopathy, may be avoided with the development of an artificial womb, thereby making Huxley's vision a reality.

# REGULATORY CONSIDERATIONS

Kiki B. Hellman, Ruth R. Solomon, Claudia Gaffey,  
Charles N. Durfor, and John G. Bishop III

## INTRODUCTION

The United States Food and Drug Administration (FDA) is a science-based regulatory agency in the United States Public Health Service (PHS) whose mission is to promote and protect the public health through regulation of a wide range of products, by assuring the safety of foods, cosmetics, and radiation-emitting electronic products, as well as the safety and effectiveness of human and veterinary pharmaceuticals, biologicals, and medical devices. The FDA recognizes that an important segment of the products that it regulates arises from applications of new technology, such as tissue engineering. Tissue engineering, which applies life sciences and engineering principles to the maintenance, modification, improvement, restoration, or replacement of human tissue or organ function, has led to a broad range of products based on their common source materials, i.e., human tissues or organs (e.g., autologous or allogeneic tissues); animal tissues or organs (e.g., transgenic animals or xenotransplants); and processed, selected, or expanded human or other mammalian cells (e.g., stem/progenitor cells, genetic and somatic cellular therapies), with or without biomaterials and totally synthetic materials of biomimetic design. Representatives of these product classes are in different stages of development. To date, some have been approved for use by the FDA and many are under either preclinical investigation or regulatory evaluation. This chapter provides background on and an overview of the regulatory considerations related to the FDA review and approval of tissue-engineered medical products (TEMPs). It discusses the FDA's legislative authority and product regulatory process together with updates of proposed regulatory approaches, development of standards/guidance, and communications with industry. The review of products is conducted on a case-by-case basis and the product's safety and effectiveness are assessed with respect to its manufacture and clinical performance, as applicable, as well as the manufacturer's claim of intended use. The FDA is divided into six centers, each staffed with the scientific and regulatory expertise appropriate for evaluating the products in its jurisdiction. In addition, each center can apply any of the FDA's statutory authorities to regulate its products. The agency has adopted a cooperative approach across the appropriate FDA centers in developing the regulatory approaches for TEMPs. These approaches have simplified and facilitated the administrative process for evaluating TEMPs, the resolution of product regulatory jurisdiction questions, and the evaluation of product specific safety and effectiveness issues. As tissue engineering technology continues to evolve, leading to new and different products, new and different product-specific issues will also be expected. The FDA will continue to build on current initiatives, apply lessons learned from previous products as applicable, and look to the best scientific minds and methods to achieve innovative, flexible, and appropriate resolutions. A productive dialogue among the FDA, industry, and consumers is the key in this endeavor in order to establish the proper place for TEMPs in clinical medicine.

## TISSUE-ENGINEERED MEDICAL PRODUCTS

### Range of products

Tissue engineering has been defined as the application of the principles of life sciences and engineering in developing biologic substitutes for the maintenance, modification, improvement, restoration, or replacement of tissue or organ function (Skalak and Fox, 1988; Langer and Vacanti, 1993; Hellman *et al.*, 1998). Products developed through this technology, or tissue-engineered medical products (TEMPs), may be thought of as a broad range of products based on their common source materials—human tissues or organs (e.g., autologous or allogeneic tissues); animal tissues or organs (e.g., transgenic animals or xenotransplants); and processed, selected, or expanded human or other mammalian cells (e.g., stem/progenitor cells, genetic and somatic cellular therapies), in combination with or without biomaterials. Totally synthetic materials of biomimetic design may also be considered tissue engineered.

### Product examples

Since its inception, the multidisciplinary technology of tissue engineering, which encompasses advances in cell and molecular biology, materials science, surgical techniques, and engineering, has given rise to a diverse array of potential therapeutic products for many different medical conditions, affecting virtually every organ and system in the body. These products provide either a structural/mechanical function or a metabolic function. Examples, among others published in the scientific literature, include artificial skin constructs, expanded cells for cartilage regeneration, engineered ligament and tendon, bone graft substitutes, products intended for nerve regeneration, cells for spinal cord repair, engineered cornea and lens, products for periodontal tissue repair, engineered products for cardiovascular repair/regeneration, blood substitutes, and encapsulated cells for restoration of tissue or organ function, used either as implants (encapsulated pancreatic islet cells), or *ex vivo* as metabolic support systems (liver-assist devices) (Hellman *et al.*, 1998; Hellman, 1995; Bonassar and Vacanti, 1998). To date, some of these products have been approved for use by the FDA and many are under either preclinical investigation or regulatory evaluation.

## LEGISLATIVE AUTHORITY/OVERSIGHT

### LAWS

Because TEMPs and their source materials span a broad spectrum of potential clinical applications, the responsibility for overseeing their development and commercialization within the United States federal government has been divided among different regulatory agencies, centers, and programs. The Health Resources Services Administration (HRSA) oversees the National Organ Transplant Program and the National Marrow Donor Program. The remaining tissue-engineered products are regulated by FDA.

The FDA is a science-based regulatory agency in the PHS. The agency's legislative authority for product oversight, premarket approval, and postmarket surveillance and enforcement is derived principally from the Federal Food, Drug, and Cosmetic (FD&C) Act and the Public Health Service Act. Under these authorities, the FDA evaluates and approves medical products for the marketplace, inspects manufacturing facilities sometimes before and routinely during commercial distribution, and takes corrective action to remove products from commerce when they are unsafe, misbranded, or adulterated.

### FDA ORGANIZATION

The FDA's mission is to promote and protect the public health through regulation of a wide range of products by assuring the safety of foods, cosmetics, and radiation-emitting electronic products, as well as assuring the safety and effectiveness of human and veterinary pharmaceuticals, biologicals, and medical devices. The FDA's six centers are each staffed with personnel having the scientific and regulatory expertise appropriate to a center's mission. The Center for Biologics Evaluation and Research (CBER) regulates biologics; the Center for Drug Evaluation and Research (CDER) regulates drugs; the Center for Devices and Radiological Health (CDRH) regulates medical devices and radiation-emitting electronic products; the Center for Food Safety and Applied

Nutrition (CFSAN) regulates foods and cosmetics; the Center for Veterinary Medicine regulates animal drugs, devices, and feed; and the National Center for Toxicological Research (NCTR) conducts product-related toxicology research. However, each center can apply any of the statutory authorities to regulate its products. For example, many products reviewed by CBER are regulated under the medical device authority. In addition to the centers, a number of other FDA offices, for example, the Office of Regulatory Affairs (ORA) and the Office of Orphan Products (OOP), provide assistance to the centers on regulatory procedures and facility inspections, as necessary.

## PRODUCT EVALUATION AND THE REGULATORY PROCESS

### CATEGORIES OF PRODUCTS

Regulations applicable to human medical products depend on whether the product is designated a biologic, drug, medical device, or combination product. Products are reviewed generally by the FDA center with the lead responsibility and jurisdiction for the particular product category. The term “biological product” is defined as a virus, therapeutic serum, toxin, antitoxin, vaccine, blood, blood component or derivative, allergenic product or analogous product, or arsphenamine or its derivatives (or any other trivalent organic arsenic compound), applicable to the prevention, treatment, or cure of diseases or injuries of man [42 U.S.C. 262(a)]. The phrase “analogous product” has been applied to a broad range of products (21 U.S.C. 600.3). A drug is an article intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in humans or other animals, and an article (other than food) and other articles intended to affect the structure or any function of the body of humans or other animals [21 U.S.C. 321(g)]. A device is an instrument, apparatus, implement, machine, contrivance, implant, *in vitro* reagent, or other similar or related article, including any component, part, or accessory, which is intended for use in the diagnosis of disease or other conditions, or in the cure, mitigation, treatment, or prevention of disease, in humans or other animals, or intended to affect the structure or any function of the body of humans or other animals, and which does not achieve any of its principal intended purposes through chemical action within or on the body of humans or other animals, and which is not dependent on being metabolized for the achievement of any of its principal intended purposes [21 U.S.C. 201(h)]. When biologics, drugs, and/or devices are combined, such products are designated combination products. Tissue-engineered medical products do not comprise a specific product category under the FDA regulations.

### TYPES OF PRODUCT PREMARKET SUBMISSIONS

The Federal FD&C Act requires demonstration of safety and efficacy for new drugs and devices prior to introduction into interstate commerce. The PHS Act requires demonstration of safety, purity, and potency for biological products before introduction into interstate commerce. Consequently, premarket clinical studies with new drugs and devices must be carried out under exemptions from these laws. For drugs and biologics, which are considered drugs under the FD&C Act, the application for the exemption is called an Investigational New Drug (IND) application. For a device, the application is called an Investigational Device Exemption (IDE). The FDA regulations describing the IND application are found in Title 21 of the Code of Federal Regulations (CFR), section 312 (21 CFR 312); the regulations for an IDE are in 21 CFR 812.

The contents of IND and IDE applications are similar. Applications will include a description of (1) the product and manufacturing processes and methods sufficient to allow an evaluation of product safety and (2) preclinical studies that were appropriately designed to assess risks and potential benefits of the product. The IND and IDE applications contain a proposal for a clinical protocol, which describes the indication being treated, proposed patient population, patient inclusion and exclusion criteria, treatment regimen, study end points, patient follow-up methods, and clinical trial stopping rules. Both IND and IDE investigations require Institutional Review Board (IRB) approval before they may commence. Although IND and IDE requirements are somewhat different (e.g., in cost recovery and device risk assessment areas), it is important to note that FDA will apply comparable standards of safety and efficacy for either type of application. When the FDA determines that there is sufficient information to allow clinical investigations to proceed, the IND or IDE exemptions are approved.

The first clinical trials conducted under the IND or IDE applications are often clinical trials

involving a small number of individuals (e.g., phase 1/feasibility studies) designed primarily to assess product safety. If these earlier studies indicate reasonable safety, phase 2 studies may be developed to investigate proper and safe dosing and potential efficacy. Phase 3/pivotal studies utilize well-controlled clinical trial designs that support a determination regarding safety and efficacy and lead to an application to FDA for premarket approval of the product.

It should be noted that there can be circumstances in which the first study under an IND or IDE will not be a phase 1/feasibility study. This may occur, for example, when sufficient clinical experience exists to establish the safety of a product after use overseas or in a different patient population. The FDA may review data from clinical studies performed outside the United States in the IND/IDE process and/or in an application for marketing approval. The agency strongly encourages a sponsor to meet with the FDA staff to discuss the clinical protocol, study results, statistical analyses, and applicability of the data to a United States population before submitting the Premarket Approval (PMA) or Biologics License (BLA) applications.

According to the laws and regulations governing commercial distribution of medical products, there are several different types of product premarket submissions. As a general rule, the type of submission for a specific product will depend on the type of product (biologic or device). Tissue-engineered medical products regulated as biologics will require review and approval of a BLA that demonstrates the safety and effectiveness of the product before it may be marketed commercially. If the TEMP is regulated as a device, a PMA demonstrating safety and effectiveness must be approved, or a Premarket Notification [510(k)] must receive clearance. In order to obtain a 510(k) premarket clearance for a product, the sponsor would need to demonstrate substantial equivalence to a legally marketed predicate device. A humanitarian use device (HUD) is a product that may be marketed under an exemption for treatment or diagnosis of a disease or condition that affects fewer than 4000 patients per year in the United States. A Humanitarian Device Exemption (HDE) exempts a HUD from the effectiveness requirements for devices if certain criteria are met as described in Section 529(m)(1) of the FD&C Act, as amended February, 1998.

Postmarket surveillance for TEMPs is an important area of consideration. Manufacturers, user facilities such as hospitals and nursing homes, and health care professionals need to report adverse events through the FDA MedWatch process. Record keeping should be instituted by manufacturers of cellular and tissue therapies to allow tracking, when applicable, of donor tissues or cells and of patients who receive the final product. Postmarketing studies may be necessary when (1) a sponsor seeks a change in labeling, (2) such studies are a condition of the FDA approval, or (3) such studies are necessary to protect the public health or to provide safety or effectiveness data. In addition, postmarket surveillance of a medical device introduced into interstate commerce after January 1, 1991, may be required if it is (1) intended for use in supporting or sustaining human life, (2) presents a potential serious risk to human health, or (3) is a permanent implant, whose failure may cause serious, adverse health consequences or death (see Section 522 of the FD&C Act).

## REVIEW OF PRODUCT PREMARKET SUBMISSIONS

The intended use of the product, the claims that the sponsor wants to make for the product, and safety concerns specific to the product will determine the types of data to be developed and submitted for the FDA review. Regulatory evaluation of medical products is conducted on a case-by-case basis. The assessments of safety and effectiveness are the basic elements of premarket review. The manufacturer is responsible for providing evidence of the product's safety and effectiveness.

Product safety and effectiveness are evaluated with respect to product manufacture and the product's clinical performance, as applicable, as well as the manufacturer's claim of intended use (i.e., the patient population to be treated and the role of the product in the diagnosis, prevention, monitoring, treatment, or cure of a disease or condition). For TEMPs, issues of product manufacture can include cell/tissue and biomaterials sourcing, processing and characterization, detection and avoidance of adventitious agents, and product consistency and stability, as well as quality control procedures. Other important considerations include evaluation of the preclinical data, e.g., toxicity testing, biomaterials compatibility, and *in vitro*/animal models for product effectiveness. Collecting data on product performance in humans requires insight into clinical trial design (e.g., patient entry criteria and study end points), study conduct, and subsequent data analyses.

At the request of the sponsor of a new drug, the FDA will facilitate the development and ex-

pedite the review of such drug if it is intended for the treatment of a serious or life-threatening condition and it demonstrates the potential to address unmet medical needs for such a condition. The development program for such a drug or biologic may be designated a fast-track development program. The FDA works closely with sponsors of products in fast-track development programs and may apply special procedures such as accelerated approval based on surrogate end points, submission and review of portions of an application, and priority review to facilitate its development and expedite its review, as published in the November 18, 1998, Guidance for Industry: Fast Track Development Programs (see web site at <http://www.fda.gov/cber/guidelines.htm>).

With regard to the expedited review of medical devices, the FDA published on March 20, 1998, the guidelines entitled “PMA/510(k) Expedited Review Guidance for Industry and CDRH Staff” (<http://www.fda.gov/cdrh/modact/expedite.pdf>). This guidance document describes the criteria for and procedures under which Premarket Approval Applications (PMAs), PMA Supplements, and Premarket Notification [510(k)] applications undergo expedited review. In general, applications dealing with the treatment or diagnosis of life-threatening or irreversibly debilitating diseases or conditions may be candidates for expedited review if (1) the device represents a clear, clinically meaningful advantage over existing technology, (2) the device is a diagnostic or therapeutic modality for which no approval alternative exists, (3) the device offers a significant advantage over existing approved alternatives, or (4) availability of the device is in the best interest of patients. Granted expedited review status means that the marketing application will receive priority review before other applications. When multiple applications for the same type of medical device (which offer a comparable advantage over existing approved alternatives) have also been granted expedited review, the applications will be reviewed with the priority according to their respective submission due dates.

## PRODUCT JURISDICTIONAL DECISIONS

A product jurisdictional decision consists of the determination as to whether a product should be regulated as a biologic, drug, device, or combination product. Jurisdictional decisions for a combination product are based on the product’s primary mode of action. In addition, as part of a jurisdictional determination are the decisions as to which center will take the lead for product premarket review and which type of submission is the most appropriate. These determinations may be made on a routine basis when product premarket submissions are filed and reviewed by the individual center’s divisions. However, there are times when it is not clear what the product’s regulatory path should be. This may often occur with TEMPs because of their novel composition and combination of biologic, drug, and/or device components. In this case, the jurisdictional decision is delegated to the center’s management and/or to the FDA Office of Chief Mediator and Ombudsman (OCMO) within the FDA’s Office of the Commissioner (e-mail address: [ombudsman@oc.fda.gov](mailto:ombudsman@oc.fda.gov)).

### How are combination products regulated?

Section 16 of the Safe Medical Devices Act (SMDA) of 1990 [21 U.S.C. 353(g)] describes how the FDA will determine which center within the agency will have the primary jurisdiction for the premarket review and regulation of any combination product. Designation of the lead FDA center for product review is based on the primary mode of action of the combination product. Designations also frequently will indicate whether a center other than the lead center will be asked to assist the review in a consulting or collaborative capacity.

The regulation on combination products, 21 CFR Part 3, was adopted in November, 1991, and implements Section 16. It defines combination products and discusses the appropriate regulatory approaches. To enhance the efficiency of agency operations, the scope of the regulation was extended to apply to any product for which the jurisdiction is unclear or in dispute. The regulation specifies how a sponsor can obtain an agency determination early in the process before any required filing and which FDA center will have primary jurisdiction for the premarket review and regulation of the product.

## FDA InterCenter Agreements

The FDA InterCenter Agreements between CBER, CDER, and CDRH were established in the early 1990s to clarify product jurisdictional issues. The three documents describe the allocation of responsibility for certain products and product categories.

The sponsor seeking a jurisdictional decision may contact the designated center identified in the InterCenter Agreement before submitting an application for product premarket review or to confirm jurisdiction and to discuss the application process. For a combination product not covered by a guidance document or for a product for which the center with primary jurisdiction is unclear or in dispute, the sponsor of an application for premarket review should follow outlined procedures to request a designation of the lead center through a Request for Designation (RFD) to the OCMO, as per CFR Part 3, before submitting applications.

These legislative and regulatory initiatives have simplified and facilitated the resolution of administrative questions such as product regulatory jurisdiction for TEMP's within the FDA. Currently, TEMP's are regulated by both CBER and CDRH. Both centers are involved in the evaluation of these products, with the lead center for product review identified by the product's primary mode of action and the other center acting as a consultant (Hellman *et al.*, 1998; Hellman, 1995). For example, (1) human tissue products (e.g., musculoskeletal tissue, skin, cornea) that are manufactured by methods that do not change tissue function or characteristics are the regulatory responsibility of the Human Tissue Program, Office of Blood Research and Review, CBER; (2) CDRH performs the premarket review of certain cellular wound healing products incorporating a supportive matrix; and (3) xenotransplant, somatic cell, and encapsulated cell and gene therapies are regulated by the Office of Therapeutic Research and Review, CBER. Certain cellular therapies (e.g., *ex vivo* liver-assist devices) are evaluated jointly by CBER and CDRH as combination products, with CBER designated as the lead center.

### **Tissue Reference Group**

The Tissue Reference Group (TRG) was established in 1997 to assist the FDA Ombudsman in determining product jurisdiction for human cellular and tissue-based products ([www.fda.gov/cber/tissue/trg.htm](http://www.fda.gov/cber/tissue/trg.htm)). The TRG is an intercenter standing committee composed of six voting members, three representatives from CBER and three from CDRH, and a liaison from OCMO. This committee was established to assist in making jurisdictional decisions and applying consistent policy to the regulation of cellular and tissue-based products. Typically, when an inquiry is directed to the TRG, the sponsor is asked to provide written information about the product in question. At a regularly scheduled meeting, the TRG members discuss this product and render a consensus recommendation, which is then forwarded to the centers for sign off, and relayed to the sponsor in writing. A sponsor may request a meeting with the TRG, either before or after a TRG decision is reached. The sponsor who chooses to address a product jurisdiction inquiry to the TRG has the option of submitting an RFD to the OCMO at any time during this process. In addition to working on specific product jurisdiction, the TRG members discuss general regulatory and scientific issues related to human cellular and tissue-based products and facilitate exchange of information between CBER and CDRH reviewers for these types of products.

### **ADDITIONAL ONGOING FDA INTERCENTER ACTIVITIES**

The FDA, recognizing the complex nature of TEMP's, has taken a cooperative approach across its centers in developing the necessary oversight for these products. These include rulemaking, guidance documents, and long-standing cross-cutting working groups, such as the Wound Healing Clinical Focus Group (WHCFG) and the FDA InterCenter Tissue Engineering Working Group (TEWG). The initiatives of the FDA working groups contribute substantially to this cooperative approach in addressing the scientific issues of TEMP's and providing input/recommendations on regulatory oversight for these products. These groups do not work in isolation, but rather work in a cooperative, complementary way.

### **Wound Healing Clinical Focus Group**

The Wound Healing Clinical Focus Group (WHCFG) was formed in the early 1990s and is composed of approximately 20 members representing CBER, CDER, and CDRH. Its members are, in general, the reviewers of applications to the FDA regarding wound healing products. The mission of the WHCFG is to facilitate the development and assessment of products for wound healing. The group serves to enhance consistency of reviews across centers, share information from all parts of the agency, provide a forum for problem solving, and act as a direct liaison from the FDA to academic and industry organizations. The group has also been charged with preparing a

guidance document for industry on wound healing agents. To this end, the WHCFG organized Advisory Committee Meetings to discuss issues associated with clinical trials of patients with chronic (July 15, 1997) and burn (November 14, 1997) wounds.

### **FDA InterCenter Tissue Engineering Working Group**

The FDA InterCenter Tissue Engineering Working Group (TEWG) is composed of scientific research and review staff from five participating FDA centers, CBER, CDER, CDRH, CFSAN, and CVM and certain FDA offices. It was established in July, 1994, to identify and address the emerging scientific and science-based regulatory issues of TEMP. The group, focusing the agency on TEMP, facilitates intercenter communication and cooperation among the FDA research, review, and administrative staff in review and regulation of TEMP, and explores international perspectives on TEMP (Hellman, 1997; Durfor, 1997). Its goal is to support and strengthen product review, and it works to promote regulatory consistency for TEMP across the FDA through networking mechanisms on science and review issues.

Communication and education are important functions for the TEWG. Different approaches are being used to disseminate information on TEMP both within and outside the agency. These include an education/training program in the agency and TEWG-initiated symposia, workshops, short courses, and other projects. The group works in cooperation with other federal agencies such as the National Institutes of Health (NIH), National Science Foundation (NSF), and National Institute of Standards and Technology (NIST), as well as societies, institutes, and academe, to review the scientific and regulatory issues concerning TEMP (Durfor, 1997).

Recognizing that TEMP are being developed for a potential worldwide marketplace, the TEWG develops initiatives to gather and assess information on how entities other than the FDA are regulating these products in order to acquire a global perspective for the evaluation of these products. Among others, the TEWG organized a meeting, the Workshop on Tissue Engineering: A Global Regulatory Perspective for Tissue-Engineered Products at the 5th World Congress on Biomaterials, in May, 1996, in order to understand the regulatory approaches for TEMP by different national regulatory bodies. It was learned that, although there are certain differences in procedures, there are also similarities in requirements for manufacture and performance of TEMP (Durfor, 1997).

As a result of outreach initiatives, the TEWG and its members are participating in the development of voluntary consensus standards for various aspects of TEMP through the American Society for Testing and Materials (ASTM), a U.S.-based standard-setting organization, which communicates with the International Standards Organization (ISO). It is believed that standards that meet FDA requirements will be helpful for both the FDA in its regulatory review of TEMP and for the industry in guiding product development.

### **FDA Transmissible Spongiform Encephalopathies Working Group**

Processing issues related to cell/tissue sourcing and the detection and elimination of adventitious agents are important issues for any medical product, including TEMP, that incorporates animal or human tissue(s). Following reports of a variant form of Creutzfeldt–Jakob disease (vCJD) in humans in Great Britain in 1996, attention immediately focused on a possible link between human transmissible spongiform encephalopathy (TSE) disease and bovine spongiform encephalopathy (BSE), of high incidence in the cattle of Great Britain, and on the many products using bovine-derived materials.

The InterCenter FDA TSE Working Group, formed in the late 1980s following the report of BSE in the cattle of Great Britain, had been monitoring the disease and developing initiatives for safeguarding the FDA-regulated products containing or manufactured from bovine-, ovine-, and caprine-derived materials. These initiatives have included recommendations, in the form of letters and guidance to the industry, on the safe sourcing and processing of these animal materials used in the FDA-regulated products. In view of the reports of vCJD, the Group, which is now composed of approximately 30 members for all FDA centers and offices, was charged in March, 1996, with assessing the impact of TSE agents on FDA-regulated products and recommending actions that could be taken to protect animal and human health and to alert industry to appropriate safeguard measures.

Recognizing the importance of the concerns associated with the TSE agents, i.e., resistance to

conventional means of inactivation and the lack of a presymptomatic diagnostic test for identification of animal and human cell/tissue donors, the agency sponsored a meeting, the International Workshop on TSE Risks in Relation to Source Materials, Processing, and End-Product Use, in June, 1998. The FDA TSE Working Group has marshaled efforts with international groups, as well as across the FDA, to provide prudent, rational, practical, and timely decisions and actions to safeguard the FDA-regulated products and animal and human health. The Working Group was instrumental in the development of this workshop. The primary objective of the workshop, held under the auspices of the Joint Institute for Food Safety and Applied Nutrition (JIFSAN), a partnership between the University of Maryland and the FDA, was to identify practical guiding principles for evaluating risks posed by animal and human TSE agents in FDA-regulated products, including TEMPs. An outline of critical elements to consider in addressing TSE risk evaluation was developed at the workshop and is available via e-mail ([tse@life.umd.edu](mailto:tse@life.umd.edu)). This outline is a first step in the development of a generic framework of practical guiding principles for evaluating TSE risks in three interrelated areas: sourcing (selection of raw material), material processing, and the use of final products made from these materials. In parallel, a set of information tools has been developed to facilitate risk evaluation and access to TSE information. This paradigm for decision making may provide a useful model for assessing the impact of other emerging infectious disease agents on medical products.

For sourcing of human cells and tissues, the emergence of vCJD, a human TSE, provides new challenges for the evaluation of risks of possible iatrogenic transmission via human tissues and fluids following tissue transplants or transfusion. Evaluating the risks of vCJD transmission is complicated by several factors: (1) it is not known if vCJD has transmission characteristics similar to CJD, (2) the pathogenesis of vCJD is not yet known, and (3) the number of individuals with subclinical vCJD cannot be determined with certainty. The absence of a definitive diagnostic test for human TSE agents, including the agent of vCJD, means that safe sourcing for human tissues, fluids, and organs must be based on exclusion criteria, which are periodically reviewed and revised (Workshop, 1999).

## RECENT DEVELOPMENTS IN PRODUCT EVALUATION

### INTERIM RULE AND FINAL RULE: HUMAN TISSUE INTENDED FOR TRANSPLANTATION

The FDA published an Interim Rule (58 FR 65514, December 14, 1993) that required all facilities engaged in procurement, processing, storage, or distribution of human tissues intended for transplantation to ensure that certain infectious disease testing and screening of the donors of these tissues for human immunodeficiency virus (HIV), hepatitis B, and hepatitis C were performed and that records documenting such testing and screening be available for the FDA inspection. Such tissues are derived from a human body, are intended for administration to another human for the diagnosis, cure, mitigation, treatment, or prevention of any condition or disease, and are recovered, processed, stored, or distributed by methods not intended to change tissue function or characteristics. These tissues included musculoskeletal tissue (e.g., bone, ligaments, tendon, fascia, cartilage), ocular tissue (e.g., cornea), and skin. The rule did not apply to organs, semen, reproductive tissue, human milk, and bone marrow, and did not cover tissue that was currently regulated as a drug, biological product, or medical device. In response to comments received, the FDA clarified and modified many of the provisions in the Interim Rule when it published the Final Rule (62 FR 40429, July 29, 1997). At the same time, the agency issued a Guidance for Screening and Testing of Donors of Human Tissue Intended for Transplantation.

### SOMATIC CELL AND GENE THERAPY

In 1993, the FDA published a somatic and gene therapy statement (Application of Current Statutory Authorities to Human Somatic Cell Therapy Products and Gene Therapy Products, Notice 58 FR 53248) outlining how the FDA's statutory authorities governing therapeutic products would apply to somatic cell therapy and gene therapy products. The statement defines somatic cell therapy products as autologous, allogeneic, or xenogeneic cells that have been propagated, expanded, selected, pharmacologically treated, or otherwise altered in biological characteristics *ex vivo* to be administered to humans and applicable to the prevention, treatment, cure, diagnosis,

or mitigation of disease or injuries. Gene therapy products are defined as products containing genetic material administered to modify or manipulate the expression of genetic material or to alter the biological properties of living cells. Some gene therapy products (e.g., those containing viral vectors) to be administered to humans fall within the definition of biological products and are subject to the licensing provisions of the PHS Act, as well as to the drug provisions of the FD&C Act. Other gene therapy products, such as chemically synthesized products, meet the definition for a drug and are regulated only under the relevant portions of the FD&C Act. Cellular products intended for use as somatic cell therapy are biological products subject to regulation pursuant to the PHS Act (42 U.S.C. 262) and also fall within the definition of drugs in the FD&C Act [21 U.S.C. 321(g)]. As biologicals, somatic cell therapy products are subject to licensure to ensure product safety, purity, and potency. At the investigational stage, these products must be in compliance with 21 CFR part 312, which stipulates that clinical trials are to be conducted under the code for INDs. The statement also discusses the combination of biological products with drugs or devices.

### PROPOSED APPROACH TO REGULATION OF CELLULAR AND TISSUE-BASED PRODUCTS

In the 1990s, the FDA devoted considerable resources to the regulation of human cellular and tissue-based products. In analyzing its regulatory approach to these products, the FDA came to realize that the existing patchwork of regulatory policies did not fully address many issues raised in this rapidly evolving area of product development.

On February 28, 1997, the FDA announced a document entitled, "A Proposed Approach to the Regulation of Cellular and Tissue-Based Products," in conjunction with "Reinventing the Regulation of Human Tissue," the sixth "Reinventing Government" report, produced in conjunction with the Vice President's National Performance Review. A notice of availability was published on March 4, 1997 (62 FR 9721) (see web site, [www.fda.gov/cber/tissue/docs.htm](http://www.fda.gov/cber/tissue/docs.htm)). The regulatory framework was designed to provide a comprehensive approach to the regulation of a broad spectrum of human cellular and tissue-based products, both traditional and new. This approach would consist of a tiered, risk-based regulatory program that would protect the public health without either imposing unnecessary government oversight or inhibiting innovation and product development in this rapidly growing field.

Under the proposed approach a human cellular and tissue-based product is defined as a product containing or consisting of human cells or tissues that are intended for implantation, transplantation, infusion, or transfer into a human recipient, e.g., musculoskeletal, ocular, and skin tissue; hematopoietic stem cells; reproductive cells and tissues; human dura mater; human heart valve allografts; somatic cell therapy products; and combination products. The term would not include vascularized human organs for transplantation; whole blood, blood components, or blood derivative products; secreted or excreted human products; minimally manipulated bone marrow; ancillary products used in the manufacture of cellular or tissue-based products, cells, tissues, and organs derived from animals other than humans; and *in vitro* diagnostic products.

The agency identified the principal public health and regulatory concerns for the cellular and tissue-based products, included in the proposed approach, as (1) transmission of communicable disease, (2) processing controls to prevent contamination and preserve product integrity and function, (3) clinical safety and efficacy, (4) promotional claims and labeling, and (5) monitoring and communicating with the industry. The agency also recognized that certain characteristics were major determinants of the degree of risk associated with the use of these products, i.e., (1) source of cells or tissue—autologous or allogeneic, (2) cell and tissue viability, (3) homologous or nonhomologous function, (4) degree of manipulation—minimal or more than minimal, (5) systemic or local effect, (6) storage—in a bank or not stored (unbanked), and (7) combination of cells or tissue with a drug or device.

In analyzing the above concerns and product characteristics, the agency concluded that a cellular or tissue-based product with all of the following characteristics would have the least amount of risk, and thus could be regulated without an actual premarket submission to the FDA—minimal manipulation, homologous function, not combined with a drug or device component, and having a local effect. If a product had any one of the following characteristics, it would present a greater risk and, thus, would be regulated as a biological drug or device requiring a premarket submission to the FDA for evaluation of clinical safety and efficacy—more than minimal manipula-

tion, promoted or labeled for a nonhomologous function, combined with a drug or device component, or having a systemic effect (except in certain specified situations). Certain general requirements would apply to all establishments and products, i.e., registration of the establishment and listing of products, with periodic updates as necessary; determination of donor suitability through donor testing and screening; and current good tissue practices, such as proper handling and processing controls.

As indicated, transmission of communicable disease has been identified as a principal public health and regulatory concern for cellular and tissue-based TEMPs. For a TEMP containing allogeneic cells or tissues, most risks of transmission can be controlled through adequate donor screening and product manufacturing procedures. A lower level of transmission risk would be expected with the use of autologous cells or tissues. However, cell manipulation or processing of autologous tissue may activate latent virus expression, which may present an increased risk when reintroduced to the donor, and inadvertent use of allogeneic tissue may occur if manufacturing and storage procedures do not prevent it. In addition, although certain processing methods may reduce or eliminate the presence of most viruses and, thus, decrease the risk of exposure, no process is currently known to be effective for complete inactivation of all agents without concomitant destruction of the cellular or tissue component.

#### **IMPLEMENTATION OF PROPOSED APPROACH—RULES**

As part of the implementation of the proposed approach to the regulation of cellular and tissue-based products, the agency has stated that it will promulgate three proposed rules, which will expand on the existing regulations for human cell and tissue products, both in scope and in content. [See “Human Tissue Intended for Transplantation,” Final Rule, 62 FR 40429, July 29, 1997 ([www.fda.gov/cber/tissue/docs.htm](http://www.fda.gov/cber/tissue/docs.htm)).]

The first of these proposed rules, “Establishment Registration and Listing for Manufacturers of Human Cellular and Tissue-Based Products,” was published on May 14, 1998 (63 FR 26744) (see [www.fda.gov/cber/tissue/docs.htm](http://www.fda.gov/cber/tissue/docs.htm)). The FDA proposed a consolidated registration and listing system for establishments engaged in the recovery, screening, testing, processing, storage, labeling, packaging, or distribution of human cellular and tissue-based products. This registration and listing system would establish a database for future communication with this industry. The proposal stated the criteria for determining (1) whether a product would be subject to registration, product listing, and the other proposed regulations, and (2) whether a human cellular or tissue-based product would be subject only to the regulations being promulgated under Section 361 of the PHS Act, or would be regulated as a biological drug or medical device under Section 351 of the PHS Act and/or the FD&C Act. All cell and tissue establishments would use the same registration and listing procedures (as well as the same FDA form) to maintain a unified database. This proposed regulation also specified the details of when, how, and where a manufacturer would register and list, and how a registration number would be assigned.

Two proposed rules are being developed and are expected to be published at a later date: one addressing suitability determination for donors of human cellular and tissue-based products, and the other describing proposed current good tissue practices (GTPs). The agency anticipates that it will also develop Guidance for Industry documents, which would provide information on practices that the FDA would find acceptable in complying with the regulations.

#### **TISSUE ACTION PLAN**

In order to develop the regulations and guidance documents needed to implement the proposed approach in a timely manner, the FDA, under CBER leadership, has outlined a tissue action plan that created a core team and several task groups (see [www.fda.gov/cber/tissue/tissue.htm](http://www.fda.gov/cber/tissue/tissue.htm)). The core team consists of individuals from CBER, CDRH, ORA, and the Office of the Commissioner who meet monthly to oversee progress, make decisions on significant policy issues, and provide final review and sign-off. Although ancillary products were excluded from the proposed approach, the agency has formed a task group to develop guidance for industry in this area.

#### **XENOTRANSPLANTATION ACTION PLAN**

The current working PHS definition of xenotransplantation is a procedure that involves the use of live cells, tissue, or organs from a nonhuman animal source (a xenograft), transplanted or

implanted into a human or used for *ex vivo* contact with human body fluids, cells, tissues, or organs that are subsequently given to a human recipient. Although many believe that xenotransplantation offers a potentially promising source of therapeutic materials, the use of live animal grafts raises concerns regarding the potential infection of recipients with both known and unknown infectious agents and possible subsequent transmission to their close contacts and into the general human population.

To coordinate activities related to the regulation of xenotransplantation (through the IND and licensing mechanisms), the FDA has established a Xenotransplantation Action Plan and a Xenotransplantation Core Team, which oversees the work of several task groups charged with writing proposed regulations and guidance documents. In addition, the FDA participates with other federal agencies and the Office of Policy within the Office of the Assistant Secretary of Planning and Evaluation in the Department of Health and Human Services (DHHS) in developing policies and guidelines with respect to xenotransplantation. Priorities of this collaborative effort include revision of The Draft Guideline on Infectious Disease Issues in Xenotransplantation (1996) and other initiatives.

## INTERACTION BETWEEN FDA HEADQUARTERS AND FIELD OFFICES

### TEAM BIOLOGICS

Team Biologics is a plan, implemented in 1997, for reinventing the FDA's ability to optimize compliance of regulated biologics industries, including blood and plasma establishments, plasma fractionators, vaccine manufacturers, licensed *in vitro* diagnostics manufacturers, and the biotechnology industry. The approach involves three elements—a core team of certified ORA investigators, CBER certified inspectors, and specially trained compliance officers, who will actually perform the inspections, with the ORA team member taking the lead role; a steering committee, which will quality control this effort; and an operations group, which will be responsible for actual implementation and daily oversight. Inspectional guidance documents, such as a Compliance Program and an Inspection Guide, are being developed and will be updated periodically.

### REGIONAL TRAINING

Because the inspection of tissue establishments is a relatively new area for field investigators, the FDA has made efforts to share the technical expertise at the FDA headquarters with the field. Regional training of field investigators from several districts took place in Baltimore, Maryland in February, 1999, at a 3-day workshop developed by the Central Regional Training Center of the FDA. The workshop included presentations by CBER, CDRH, ORA, the State of Maryland, the American Association of Tissue Banks (AATB), and the Eye Bank Association of America (EBAA).

Future training programs are being planned to enable field investigators to better evaluate the regulatory compliance of tissue establishments in the areas of recovery, screening, testing, processing, storage, and distribution of human tissue. New teaching methodologies, such as interactive video conferences and self-paced learning via electronic mail, are being considered.

## DEVELOPMENT OF STANDARDS

### HEMATOPOIETIC STEM CELL MODEL

The development of standards intended to ensure the safety and effectiveness of biological products has traditionally occurred in parallel by industry, standard-setting bodies, and the FDA. Such efforts have been labor intensive for all involved. In an attempt to ease the regulatory burden on industry and on the agency, while providing protection to the public, the agency is considering an approach whereby industry would be requested to develop product standards. These standards would be reviewed by the agency and, if found acceptable, would be adopted by the FDA. The agency would develop a process that would include reliance on standards as a basis for licensure.

On January 20, 1998, the FDA published a Request for Proposed Standards for Unrelated Allogeneic Peripheral and Placental/Umbilical Cord Blood Hematopoietic Stem/Progenitor Cell Products; Request for Comments (63 FR 2985) (see [www.fda.gov/cber/tissue/docs.htm](http://www.fda.gov/cber/tissue/docs.htm)). This

notice requested submission of comments, accompanied by supporting clinical and nonclinical laboratory data and other relevant information, proposing manufacturing standards and product specifications for minimally manipulated hematopoietic stem cells obtained from peripheral blood and cord blood for unrelated allogeneic use (in a recipient unrelated to the donor).

The notice stated that industry and the public would have 2 years to develop and submit data, followed by approximately 1 year for the FDA to review the data. If the FDA determines that the submissions support the development of standards, the FDA intends to issue such standards following the agency's procedures (good guidance practices). If the FDA determines that adequate information for standards development is not available, the agency intends to enforce the traditional IND and license application requirements at the close of the 3-year period.

#### **AMERICAN SOCIETY FOR TESTING AND MATERIALS—FDA PARTICIPATION**

As indicated above, the development of standards is envisioned increasingly as an effective vehicle for the FDA to use in its product review process and for the industry to use in its product development. This is consistent with the Food and Drug Administration Modernization Act (FDAMA) of 1997 that contains provisions for standards development for products under the FDA's jurisdiction in order to streamline the product approval process. This legislation allows the FDA to recognize formally appropriate voluntary consensus standards for medical devices developed by nationally and internationally recognized standards development organizations, without making them federal requirements subject to notice, comment, and rulemaking. Under FDAMA, the FDA will continue to select and adopt standards that meet the FDA's regulatory requirements for use in the review process, because it believes that the formal recognition of standards and the manufacturer's ability to conform to such standards will benefit the industry, consumers, and the FDA (Marlowe and Phillips, 1998). Further information on the recognition of consensus standards and declaration of conformity to standards is available in the guidance document entitled "FDA Modernization Act of 1997: Guidance for the Recognition and Use of Consensus Standards; Availability" (63 FR February 25, 1998) (see [www.fda.gov/cdrh/modact/k982.html](http://www.fda.gov/cdrh/modact/k982.html)).

Recognizing the importance of standards as well as guidance documents in product development and regulatory review, FDA scientific research and review staffs are active participants/representatives in the recently established American Society for Testing and Materials (ASTM) initiative on TEMPs. For example, the scope of the ASTM effort, in Committee F04, Medical and Surgical Materials and Devices, Division IV: Tissue-Engineered Medical Products, is the development of standards for TEMPs focusing on the components of these products, such as the biological component (cell, tissue, cellular product, and/or biomolecule) and the biomaterial component (biological, biomimetic, and/or synthetic) (see [www.astm.org](http://www.astm.org)). This division is working with other ASTM committees and other organizations with mutual interests. The division currently includes 10 subcommittees, each working in a different standard area related to TEMPs. Through its voluntary consensus process that encourages input from expert groups and all interested parties, the ASTM procedures aim to ensure that the standards are technically sound and rest on a solid scientific foundation. The standards may include test methods, specifications, practices, guides, classifications, or terminology.

#### **COMMUNICATIONS WITH INDUSTRY**

Commensurate with its public health mission in assuring the safety and effectiveness of medical products for human use, the FDA is establishing effective vehicles of communication with the industry on topics ranging from basic research to product development and commercialization. These include FDA-sponsored workshops in emerging research areas such as the annual FDA Science Forums—a session on tissue engineering was a highlight of the December, 1998, FDA Science Forum on Biotechnology—and workshops focused on areas of potential product-related public health concern such as the June, 1998, Workshop on TSE Risks. In addition, the FDA Staff Colleges of the different centers develop courses on generic and specific science and/or product-related areas to provide continuing education of the FDA research, review, and administrative staff. For example, the FDA Staff College course on tissue engineering is currently in its fifth year and has dealt with topics ranging from new technological approaches and product applications to issues important for designing appropriate preclinical and clinical studies for TEMPs. The FDA also

develops and participates in a number of national and international meetings focused on TEMP-related scientific and regulatory issues. The FDA considers this participation to be an important vehicle for maintaining an effective dialogue with the industry. In addition, representatives of industry and research and development consortia have been invited to present their research and to discuss both generic and specific product-related regulatory concerns with the FDA staff. Individual meetings with product sponsors are encouraged from the very early stages of product concept through the later stages of product development and approval. Industry representatives are also encouraged to attend the public meetings of the FDA advisory committees on topics of product-related concern, such as the FDA TSE Advisory Committee's deliberations on the safe procurement and processing of animal- and human-derived material used in FDA-regulated products. The industry is also encouraged to comment on proposed regulations and guidance documents that are made publicly available through the Federal Register and the FDA web sites.

## THE FDA AND FUTURE PERSPECTIVES FOR TISSUE-ENGINEERED MEDICAL PRODUCTS

As exemplified by some of the initiatives described in this chapter, the FDA will continue to develop science-based rationales with regard to its regulatory oversight of TEMPs that will provide a road map for the FDA reviewers as well as industry. Such an approach will seek to enhance product review and to address questions for manufacturers early on in product development. The initiatives described seek to promote innovation, at the same time ensuring that the proper and appropriate levels of control for safety and effectiveness are maintained during the development of all medical products, including TEMPs. In support of these initiatives, the FDA centers and cross-cutting working groups will continue their programs in research, technology monitoring, guidance/standards, training/education for the FDA staff and industry, and cooperation with public and private groups.

An important part of the FDA assessment for medical products, including TEMPs, will continue to be premarket review, based on product-by-product review. Pivotal in the regulatory review for all products are the manufacturer's claim of intended use, product quality control procedures, and product performance. As tissue engineering technology evolves, leading to new and different products, new and different product-specific issues will also be expected. As a result, the FDA will continue to build on current initiatives in order to resolve such issues through its continuing research, review, and assessment of TEMPs. The lessons learned from previous product categories, such as lessons involving recombinant DNA technology and propagation of cell lines, may be applicable to new products and technologies in some cases. In other cases, the agency will look to the best scientific minds and methods to achieve innovative, flexible, and appropriate resolutions. A productive dialogue among the FDA, industry, and consumers is the key element in this endeavor in order to establish the proper place for TEMPs in the armamentarium of clinical medicine.

## ACKNOWLEDGMENTS

The authors gratefully acknowledge the expert assistance of Colleen Catron in preparation of this manuscript and the following FDA colleagues for constructive critical review of the manuscript: Jill Warner, Steve Unger, Donald Marlowe, Christine Nelson, Elizabeth Jacobson, Jay Siegel, Susan Alpert, Jay Epstein, Philip Noguchi, and Celia Witten.

## EPILOGUE

---

---

This volume represents a comprehensive compilation of the field of tissue engineering. It captures a moment in time in an area of science and medicine that is continuously growing, gaining new knowledge, and inventing new technologies. Its composition reflects the interdisciplinary nature of the field. There are contributions from clinical surgeons and physicians; biologists expert in cell biology, developmental biology, and molecular biology; and engineers from broad areas of that discipline. The breadth of tissues and organs covered spans the entire mammalian organism. The nature of the science ranges from the chemistry of living systems and biomaterials to the physiology of the whole organism. It includes the understanding of cellular machinery, a hierarchical organization of cells in their local environment, and their association over great distances relative to the entire organism. The organization of the book is intended to provide an in-depth understanding for these diverse areas that is easily accessible. The hope is that it is a compendium for those who are knowledgeable in the field, but can also provide inspiration and instruction to those students who are either interested in or just entering the field.

The amount of new information and the number of experimental systems that are now entering human clinical trials is substantially greater than in the first edition. Because of the exponential rise in interest in the field, this trend is expected to continue. It is not possible to predict the changes that will occur in the next few years, which likely will radically alter the next edition of this text. One of the greatest gifts of Western thought to mankind is that at any given instant in time, humanity has never known so much about the physical world and will never again know so little.

---

- A**
- ACL, *see* Anterior cruciate ligament
- ADA, *see* Adenosine deaminase
- Adenosine deaminase (ADA), gene therapy for  
deficiency, 620, 638
- Adrenal chromaffin cell  
pain modulation, overview, 325  
spinal implants for pain modulation  
animal models, 810–812  
clinical trials, 811–812  
encapsulated cells, 811–813  
rationale, 809–810
- Agarose gel, cell interactions, 230
- Alginate  
breast reconstruction application, 415  
liver tissue engineering, 577  
parathyroid cell encapsulation, 517–518  
periosteal cell growth, 675–676
- Alginate/poly(L-lysine), islet cell encapsulation,  
501
- ALS, *see* Amyotrophic lateral sclerosis
- Amelogenin, periodontitis therapy, 841
- Amyotrophic lateral sclerosis (ALS), encapsulation  
therapy with ciliary neurotrophic factor re-  
combinant cells, 325–326
- Angiogenesis  
basic fibroblast growth factor role, 136  
breast reconstruction tissue promotion, 419–  
420  
cell–extracellular matrix interactions, 37–38,  
40
- Dermagraft assays  
chick chorioallantoic membrane, 896–897  
endothelial cells  
chemokinesis, 898–899  
chemotaxis, 899  
proliferation, 898  
growth factor expression, 900  
integrin  $\alpha v\beta 3$  induction, 899  
rat aortic ring assay, 897  
microgravity effects, 159  
thrombospondin effects, 119–121  
vascular grafts, 431–434, 437–441  
wound repair, 864–866
- Angiostatin, tumor therapy, 392
- Animal cell culture  
adrenal cortical cells, 112  
amino acid supplements, 112  
anchorage of cells, 102  
extracellular matrix components and functions,  
571–572  
factors affecting lineage position and phenotype,  
570–571  
feeder cells, 573  
growth factor discoveries, 113–114  
historical perspective, 111–112  
hormonally defined medium, 571  
neural stem cells, 115–116  
oncogene isolation, 116  
relevance to *in vivo* studies, 112–116  
senescence, 115  
serum-supplemented medium, 571  
soluble signals, 571  
vitamin supplements, 112
- Anterior cruciate ligament (ACL), replacement  
anchoring, 714–715  
collagen cross-linking, 713  
culture, 715  
cyclic stretching effects, 714–716, 718  
fibroblasts  
isolation and culture, 715  
seeding, 714  
histologic analysis, 716  
immunostaining, 716–717  
load support of native ligament, 713  
overview, 711  
static tension effects, 715, 718  
strength, 719  
timing of implantation, 719  
ultrastructure, 717
- Antigen-presenting cell (APC), allograft rejection  
mechanisms, 287–288
- Aortic valve, *see* Cardiac valve
- APC, *see* Antigen-presenting cell
- Apligraf  
allogeneic cells, 286, 288  
clinical trials, 867–868, 886  
construct design, 12  
development of Apligraf HSE, 885–887  
overview, 10  
shelf life, 13
- Apoptosis  
encapsulated islet cells, 336  
extracellular matrix interaction  
development, 39, 103–104  
signal transduction, 45–46  
wound healing, 42  
lymphopoiesis, 616, 626  
osteopontin inhibition, 123
- Aqueous humor, chemical composition, 476
- Articular cartilage, *see* Cartilage
- Aspirin, protection against aminoglycoside-in-  
duced hearing loss, 752
- B**
- B cell  
lymphopoiesis, *see* Hematopoietic stem cell
- memory B cells  
culture  
germinal center stimulation, 624–625  
lipopolysaccharide plus anti- $\mu$  stimulation  
in suspension culture, 625  
markers, 624  
transcription factors in development, 625–  
626
- precursor cell  
clinical applications, 620  
culture  
human cells, 624  
mouse cells, 623–624  
overview, 621  
embryonic stem cell differentiation in cul-  
ture, 618  
markers, 620, 622–623  
self-renewal, 619–620  
properties, 612  
receptors and differentiation, 611
- BDNF, *see* Brain-derived neurotrophic factor
- Bioartificial hemofilter, *see* Kidney
- Bioartificial liver, *see* Hepatocyte
- Bioartificial tubule, *see* Kidney
- Biocompatibility, overview, 14
- Bioreactor  
applications, 143, 154  
cell–polymer constructs, 143–144  
cell seeding, 144–145, 153  
definition, 13  
Dermagraft manufacture, 892  
functional tissue cultivation  
cardiac tissue, 151–152  
cartilage, 151  
functions, 143, 154  
geometries of rotating bioreactors, 145, 147  
hydrodynamic conditions, 147  
liver assist devices  
design  
compartmentalization, 585  
overview, 583–584  
scale-up, 584–585  
tissue mimicry, 584  
HepatAssist, 553–557  
hollow-fiber bioreactor, 548–550  
packed-bed bioreactor, 548  
performance analysis  
flow dynamics, 586  
glucose uptake rate, 586–587  
metabolism, 587  
quality assurance, 587  
mass transport and perfusion, 153  
mechanical force application, 153–154  
microgravity studies, *see* Microgravity

- Bioreactor (*continued*)  
 mixed versus static dishes, 153  
 modulation of tissue formation, 147, 149–151  
 tissue cultivation, 145, 147
- Bladder  
 fetal reconstruction, 357–358  
 fetal tissue engineering, 357–358, 661–662  
 function and malfunction, 659  
 injectable therapies for incontinence, 663–664  
 reconstruction, 659  
 small intestinal submucosa in engineering, 659  
 substitute with cell culture on scaffolds, 659–660
- Blimp-1, B cell development role, 625–626
- Blindness, *see* Vision
- Blood vessel  
 artificial graft, historical background, 427, 448  
 coronary bypass  
 graft sources, 447–448  
 history, 447  
 vein suitability, 447  
 graft engineering  
 bioresorbable grafts, 434–437, 449–453  
 endothelial cell seeding, 437–439  
 manipulation of healing process, 433–434  
 stent grafts, 440–441  
 surface modifications, 432–433  
 totally tissue-engineered grafts, 439–440  
 graft failure  
 infection, 430–431  
 patency rates, 430  
 healing of grafts  
 angiogenesis, 431–432  
 endothelial and smooth muscle cell ingrowth, 429–430  
 graft characteristics, effects on healing  
 compliance, 431  
 flow surface characteristics, 431  
 porosity, 431  
 neutrophil and monocyte infiltration, 429  
 platelet deposition, 428  
 protein adsorption, 428  
 small-diameter graft tissue engineering  
 substrates for bioresorbable grafts  
 collagen, 450  
 intestinal collagen layer, 451–453  
 small intestine submucosa, 450–451  
*in vitro*, 448–449  
*in vivo*, 449–453
- BMPs, *see* Bone morphogenetic proteins
- Bone  
 applications of engineering, 683  
 assays for formation, 82–83  
 biomechanics, 679–680  
 cell sources for engineering  
 chondrocyte seeding, 675  
 periosteal cells, 675–676  
 cell types, 724  
 connected cellular network structure, 724, 730  
 developmental sequence of formation, 82  
 electric field response, 729  
 extracellular matrix interactions, 674  
 gap junctions, 724–725  
 historical background of engineering, 671–672  
 mechanosensory mechanisms  
 cytomatrix sensation–transduction processes, 727  
 fluid flow stimuli, 726  
 fluid shear stress cytosensation, 727–728  
 ion channels, 727  
 mechanical stimuli, 725–726  
 mechanoreception and mechanotransduction, 723  
 muscle contraction as stimuli, 726  
 nitric oxide production by osteocytes, 726  
 overview, 723  
 prospects for research, 731–732  
 signal transmission  
 cell-to-cell communication, 729–730  
 modeling, 731  
 signal processing and integration, 730–731  
 strain-generated potentials, 728–729  
 uniqueness of osseous mechanosensation, 729  
 osteochondral allografts, 707–708  
 periodontitis substitutes, 836, 838  
 progenitor cells, *see* Mesenchymal stem cell  
 prospects for engineering, 88–89  
 stem cell precursors, 86–87  
 support matrices for engineering, 675–676
- Bone marrow  
 artificial bone marrow  
 historical background, 636–637  
 long-term cultures, 636  
 organoids, 637  
 perfused hematopoietic culture systems, 637–638  
 supporting matrices, 636–637  
 bioreactors, 143–144
- Bone morphogenetic proteins (BMPs)  
 actions beyond bone, 85  
 chondrogenesis induction, 84  
 concentration-dependent thresholds, 85  
 delivery systems, 87–88  
 dentin regeneration  
 animal studies with human recombinant proteins, 850–852  
 applications, 851–852  
 clinical considerations, 850–851  
 delivery systems, 850  
 overview, 847–848  
 extracellular matrix binding, 85  
 functional overview, 81  
 gene therapy application, 87  
 identification and isolation, 81, 83  
 periodontitis therapy, 841  
 pleiotropic regulation, 85  
 receptors, 85–86  
 structures, 83–84  
 types, 83–84, 847
- Brain implants  
 epilepsy, 780  
 Huntington's disease, 778–779  
 myelin disorders, 779–780  
 Parkinson's disease  
 axonal guidance implants, 778  
 controlled-release implants, 777–778  
 encapsulated cells, 777  
 naked cells  
 fetal cells and tissue, 774–775  
 genetically engineered cells, 776–777  
 immortal cell lines, 775–776  
 primary cell lines, 774–775  
 primary tissue, 773–774  
 retinal pigment epithelial cells, 775  
 survival, 777  
 surgical considerations, 780
- Brain-derived neurotrophic factor (BDNF)  
 nerve guidance channel delivery, 793  
 protection against deafness, 753–755
- Breast reconstruction  
 animal models for tissue engineering studies, 417–419  
 approaches, 409–410  
 cell types, 409, 411–412  
 expansion of cells, 411  
 goals, 410–411  
 incidence of breast cancer, 409  
 mastectomy versus other surgeries, 409  
 materials for cell scaffolding  
 implantable materials, 412–413  
 injectable materials, 415–417  
 tissue engineering rationale, 410  
 vascularization promotion of engineered tissue, 419–420
- C**
- Cadherins  
 catenin binding and functional modulation, 21  
 E-cadherin loss in metastatic carcinoma, 21  
 epithelial–mesenchymal transformation role  
 epithelial organization stabilization, 20–21  
 loss in transformation, 20–21  
 mesenchymal cadherin upregulation, 21  
 mesenchymal–epithelial transformation role, 21  
 organogenesis role, 238
- Cardiac muscle bioreactors  
 cell–polymer constructs, 143–144  
 cell seeding, 144–145  
 functional tissue cultivation, 151–152  
 hydrodynamic conditions, 147  
 modulation of tissue formation, 151  
 tissue cultivation, 145, 147
- Cardiac valve  
 animal valve prosthesis  
 Carpentier valve, 457–458  
 endothelial cell seeding, 465  
 glutaraldehyde tanning, 457, 459  
 Hancock valve, 457–458  
 Ionescu valve, 457–458  
 autograft valves, 459–461, 464–465  
 calcific degeneration, 459  
 catheter technology for nonsurgical treatment, 464  
 culture *in vitro*, 464–465  
 disease transmission, 458, 463–464  
 durability of tissue prosthesis, 455, 465  
 fascia lata valves, 456–457, 464  
 history of surgery, 455  
 homograft valves, 458–459  
 ideal repair or replacement, 465–466  
 pericardial patches, 460, 463–464  
 repair versus replacement, 463, 466  
 sheep model for prosthesis, 459–460  
 stenting, 461–462
- Cartilage, *see also* Chondrocyte  
 applications of engineering, 676, 678  
 arthroscopic surgery, 697–699  
 biomechanics, 679–680  
 bioreactors

- cell-polymer constructs, 143–144  
 cell seeding, 144–145, 153  
 functional tissue cultivation, 151  
 hydrodynamic conditions, 147  
 mass transport and perfusion, 153  
 microgravity studies, 145, 147, 150  
 modulation of tissue formation, 147, 149–151  
 tissue cultivation, 145, 147  
 growth factors in repair, 678  
 historical background of engineering, 671–672  
 hyaline cartilage versus fibrocartilage biochemistry, 698–699  
 mechanical properties, measurement, 204–205  
 osteochondral grafts in repair, 699, 707–708  
 perichondral grafts in repair, 699  
 prospects for engineering, 708  
 repair capacity, 697
- Cartilage-derived morphogenetic proteins (CDMPs)  
 functional overview, 85  
 gene therapy application, 87  
 identification and isolation, 81, 84
- Cartilage oligomeric matrix protein (COMP), functions, 66
- cCAF, *see* Chicken chemotactic and angiogenic factor
- CCN, functions, 124
- CD36, cell-extracellular matrix interaction role, 36
- CD44, cell-extracellular matrix interaction role, 36, 68
- CDMPs, *see* Cartilage-derived morphogenetic proteins
- Cell adhesion, assays for polymer interactions, 221–224
- Cell adhesion molecules, overview, 238
- Cell aggregation, assays for polymer interactions, 223–224
- Cell culture, *see* Animal cell culture
- Cell lifeline number, calculation, 170
- Cell migration  
 assays for polymer interactions, 223  
 ligand density effects, 245  
 modeling in tissue, 200–201  
 substrata material effects, 201
- Cell sourcing, *see also specific cells*  
 allogeneic cells, 10, 286  
 autologous cells, 10, 285–286  
 immortalized cell lines, 286–287  
 recruitment of autologous cells, 286  
 tumor-derived cells, 569  
 xenogeneic cells, 10, 287, 569
- Cell spreading  
 assays for polymer interactions, 221–224  
 polymer type effects, 225
- Central nervous system, *see* Spinal cord
- Chemokines, *see specific chemokines*
- Chicken chemotactic and angiogenic factor (cCAF)  
 extracellular matrix interaction, 34  
 processing, 34  
 wound healing role, 41
- Chitosan  
 biopolymer scaffolds, 265–266  
 breast reconstruction application, 416
- liver tissue engineering, 577–578  
 structure, 265
- Chondrocyte, *see also* Cartilage  
 autologous transplantation for cartilage repair  
 clinical studies, 701–702, 706  
 commercialization, 701–706  
 difficulty, 708  
 dog models, 704–705  
 historic background, 700  
 overview, 285–286  
 patent registry, 706  
 rabbit models, 700–701  
 rationale, 699–700  
 carrier matrices, 706–707  
 collagen expression in culture, 703  
 differentiation and dedifferentiation, 678, 702–704  
 growth factors, 707  
 isolation and culture, 700, 702–704  
 microgravity effects, 160  
 substrates for seeding, 676, 678
- Chromaffin cell, *see* Adrenal chromaffin cell
- Ciliary neurotrophic factor (CNTF)  
 amyotrophic lateral sclerosis encapsulation therapy with recombinant cells, 325–326  
 Huntington's disease prevention, 778, 806–807  
 nerve guidance channel delivery, 793
- CJD, *see* Creutzfeldt–Jakob disease
- CNTF, *see* Ciliary neurotrophic factor
- Cochlear implant, *see* Deafness
- Collagen  
 abundance of types, 264  
 barrier applications, 273  
 basement membrane collagens and associated collagens  
 endostatin, 62–63  
 multiplexins, 62  
 types and functions, 62  
 vascular physiology and pathology, 62  
 chondrocyte expression in culture, 703  
 fibril-associated collagens with interrupted triple helices

 Viscoelasticity  
 measurement in tissues, 205  
 tissue properties, 203–204  
 Vision  
 diseases, 761, 763  
 overview of system, 761–762  
 restoration approaches  
 axon regeneration and supporting matrices, 767, 770  
 drug delivery, 767  
 electrical tissue stimulation, 763–766, 768–769  
 gene therapy, 768  
 intervention sites, 763, 770  
 microelectrode arrays, 768–769  
 optoelectronic vision enhancement, 763  
 repopulating ischemic or diabetic retina, 770  
 retinal pigment epithelium transplantation, 766–767, 769  
 stem cells, 768  
 sensitivity, 761  
 Vitronectin, overview, 238–239
- W**  
 WAP, *see* Whey acidic protein  
 Whey acidic protein (WAP), extracellular matrix role in expression, 39  
 WNT-4, epithelial–mesenchymal transformation role, 25  
 Wnts  
 muscle development role, 95  
 receptors, 190  
 Womb, artificial  
 extracorporeal membrane oxygenator units, 909–911  
 fetoplacental circulation maintenance, 908–909  
 history of development, 909–911  
 hybrid respiratory support, 911  
 need, *see* Premature infant  
 organ maturation during maintenance, 911  
 placental physiology considerations, 909  
 recreating *in utero* environment, 908  
 requirements, 905–908  
 Wound contraction  
 overview, 868–870  
 regeneration inhibition, 173–174  
 Wound healing  
 acute versus chronic wounds, 879  
 animal models, 134–135  
 cell–extracellular matrix interaction roles  
 adhesion and migration, 40–41  
 apoptosis, 42  
 differentiation, 42  
 proliferation, 41–42  
 epithelialization  
 extracellular matrix degradation, 859–860  
 growth factors, 860  
 integrin expression, 859  
 migrating epidermal cells, 858–859  
 extracellular matrix reorganization and wound contraction, 868–870  
 granulation tissue formation  
 degradative enzymes, 864  
 fibroplasia, 862–864  
 integrin expression, 862–863, 866  
 neovascularization, 864–866  
 growth factors  
 recombinant proteins in repair, 861, 866–867  
 roles, 129–137, 860, 862–865, 882, 894  
 inflammation  
 neutrophils, 858  
 platelets, 858  
 transition between inflammation and repair, 858  
 keratinocyte autografts and allografts, 860–861  
 scarring prevention, 870, 883  
 skin equivalent modeling, 184  
 smart matrix development, 868  
 stages, 130, 136, 857–858, 881–882  
 tissue engineering, *see* Skin  
 vascular grafts, *see* Blood vessel  
 Wound Healing Clinical Focus Group, 920–921
- Y**  
 YIGSR motif, adhesion promotion, 240, 794–795  
 Young's modulus, *see* Elasticity
